Treatment. Treatment is symptomatic. The more disfiguring lesions can be excised if not too diffuse [63]. Carbon dioxide laser surgery is a treatment modality for cutaneous neurofibromas, but hypertrophic and atrophic scars can result and a preliminary test treatment is recommended [64]. Surgery is also indicated when an increase in size and pain suggests possible malignant change. Epilepsy should be thoroughly investigated, as neurosurgical relief is sometimes practicable. Prolonged follow-up with routine checks every 6–12 months is advisable.

NF1 has a significant impact on quality of life through alteration of health and appearance [65]. Adolescence is a particularly difficult time when neurofibromas may grow in response to hormonal changes.

Genetic counselling is important. Informing families about the varied complications of NF1 is a difficult counselling task, and there is a fine balance between providing adequate information and causing unnecessary alarm. It should be made clear to patients that 50% of their children are likely to be affected and the disease may be severe. First-degree relatives (e.g. siblings and offspring) who have no stigmata of the disease are unlikely to carry the gene and the risk for their offspring is small but not absent, as gonadal mosaicism has been observed.

Neurofibromatosis 2 (MIM 101000)

SYN. BILATERAL ACOUSTIC NEUROFIBROMATOSIS

This condition was originally considered to be part of the spectrum of von Recklinghausen's disease but is now recognized as a separate entity, because of its distinct genetic basis and natural history [1,2]. Genetic studies have confirmed that the gene for NF2 is located on chromosome 22 [3]. The *NF2* gene, localized on chromosome 22q11.21, encodes a protein known as s*chwannomin*, which appears to be important in the linking of cytoskeletal proteins to membranes. Mutations distributed throughout the 17 exons of the *NF2* gene have been reported in different families. Loss of the normal (wild-type) allele is characteristically found when examining tumour tissue. Such events arise as somatic mutations and conform to the tumour suppressor 'two-hit' hypothesis originally proposed by Knudson [4,5].

NF2 is characterized by bilateral vestibular schwannomas (acoustic neuromas), as well as other central nervous system tumours of meningeal and glial origin. Café-au-lait spots and cutaneous neurofibromas may be seen, but are usually few in number and much less common than in NF1. The mean age of first symptoms in a UK study was 22.6 years (range 2–52 years) and the mean age of diagnosis 27.6 years (range 5–66 years); 10% presented before the age of 10 years [6]. Cataracts were present in 81% of patients in the series of Parry *et al*. [7], of which most were posterior subcapsular cataracts.

Diagnostic criteria for NF2 [6,8] are as follows.

1 Bilateral vestibular schwannomas, either proven histologically or seen by MRI with gadolinium enhancement.
2 A parent, sibling or child with NF2 and either:
(a) unilateral vestibular schwannoma; or
(b) one of the following—meningioma, glioma, schwannoma, posterior subcapsular lenticular opacities, cerebral calcification.
3 Unilateral vestibular schwannoma and one of the following: meningioma, glioma, schwannoma, posterior subcapsular lenticular opacities, cerebral calcification.
4 Multiple meningiomas (two or more) and one of the following: glioma, neurofibroma, schwannoma, posterior subcapsular lenticular opacities, cerebral calcification.

It is recommended that annual clinical screening of at-risk individuals is performed from early childhood and should include skin and ophthalmological examinations. Annual 'acoustic screen' MRI should be performed from the age of 15 years unless symptoms necessitate earlier scanning [8]. When a mutation is identified in an affected individual, it can be used as a presymptomatic test within the family [9]. The first application of preimplantation genetic diagnosis for NF2 has been reported [10].

NF1, juvenile xanthogranulomas and juvenile chronic myeloid leukaemia

The association of juvenile xanthogranulomas with NF1

has been noted in many patients [1]. It is now recognized that children with NF1 and juvenile xanthogranulomas have a 20–32-fold higher risk for juvenile chronic myeloid leukaemia than do patients with NF1 who do not have juvenile xanthogranulomas [2]. Juvenile chronic myeloid leukaemia is a rare type of leukaemia and accounts for about 1–2% of childhood leukaemias. There is some debate as to the validity of this association.

Segmental neurofibromatosis [1–7]

This condition is characterized by café-au-lait spots, cutaneous neurofibromas and sometimes visceral neurofibromas, limited to a circumscribed body segment. The condition probably represents a somatic mosaicism of the *NF1* gene. Rubenstein *et al.* [8] reported two patients with segmental NF in which signs of generalized NF appeared in a single member of the next generation. It is difficult, in the the light of these and other anecdotal examples, to reassure patients with apparent segmental NF that there is no risk of NF1 occurring in their offspring, although the risk is small.

Café-au-lait spots and pulmonary stenosis (MIM 193520) [1,2]

SYN. WATSON'S SYNDROME

In three families, café-au-lait macules were associated with pulmonary stenosis and low intelligence. Some affected individuals also had freckling in the axillae, perineum and elsewhere. There was no other evidence of NF [2]. Café-au-lait spots are present in about 60% of patients with this syndrome [1]. Allanson *et al.* [3] demonstrated linkage with markers for the *NF1* gene, and Tassabehji *et al.* [4] identified an *NF1* mutation in a family with features of Watson's syndrome and NS. The pathogenesis of this distinct phenotype is as yet unclear.

Neurofibromatosis–Noonan syndrome (MIM 601321)

Patients with features of both NF1 and NS have been described, although considerable variability of phenotypic expression exists. Whether a specific NF–NS phenotype exists is unclear at present. In a survey of the Noonan phenotype in a series of NF1 patients, it was concluded that this was not a distinct syndrome [1]. In a case report and review of the literature, Buehning and Currey [2] document two studies of NS families with no proven linkage to the *NF1* gene [3,4] and two studies of patients with NF1 and some features of NS that showed molecular abnormalities at the *NF1* locus [5,6]. Their own patient with NF–NS did not have any demonstrable mutation or deletion at the *NF1* site [2].

Diffuse neurofibroma [1]

Diffuse neurofibroma is a newly recognized distinct clinical entity. A report of four adult cases [1] described 3–8-cm, hard, sclerotic plaques with an irregular surface but without protruding nodules, present for 1–12 years. Histologically, the tumours consisted of spindle cells with wavy fibrillar cytoplasm and elongated nuclei. Electron

microscopy and special stains confirmed their neural origin. Excision revealed infiltration well beyond the clinical margins, and malignant transformation in one. Early diagnosis is important, as prompt surgical treatment is recommended.

Tuberous sclerosis complex (MIM 191100)

SYN. EPILOIA; BOURNEVILLE'S DISEASE

Definition, history and aetiology. Tuberous sclerosis complex (TSC) is now the preferred name for the condition previously known as tuberous sclerosis and represents a genetic disorder of hamartoma formation in many organs, particularly the skin, brain, eye, kidney and heart. The characteristic skin lesions are angiofibromas, the shagreen patch, periungual fibromas and 'ash-leaf' white macules, classically, although not invariably, seen in association with epilepsy and mental retardation. The term 'complex' emphasizes the multisystem involvement and variable expression of the disease.

TSC was first recognized in the 19th century [1]. Rayer [2] gave the first description of the fibrovascular papules, and Bourneville [3] reported the case of a mentally retarded girl who also suffered from hemiplegia and epilepsy. He did not recognize her facial eruption or kidney tumour as being part of the disease. Sherlock [4] coined the now outmoded term 'epiloia', indicating the diagnostic clinical triad of *epi*lepsy, *l*ow *i*ntelligence and *a*denoma sebaceum.

Early population studies greatly underestimated the prevalence of TSC. More recent studies have shown the incidence to be 1 in 10 000 in the Oxford region [5] and 1 in 27 000 in the west of Scotland [6]. Osborne *et al*. [7] have estimated that the birth incidence may be in the region of 1 in 5800, which makes TSC one of the more common single-gene disorders.

The inheritance of TSC is determined by a single autosomal dominant gene, showing variability of expression, even within a single family. Genetic linkage studies first mapped the *TSC* gene to chromosome 9 [8,9]. It is now recognized that about half the TSC families are linked to 9q34 (*TSC1*) and the other half to 16p13 (*TSC2*) [10,11]. The proportion of families who do not link to either chromosome 9 or 16 is small. The *TSC1* gene has not yet been cloned. The *TSC2* gene encodes a protein named tuberin. Tuberin shows one area of homology to the catalytic domain of the GTPase-activating protein Rap1. Rap1 is a member of the same group of GTPases as *ras* and is involved in the regulation of cell proliferation and differentiation. This suggests that some of the biological functions of tuberin and neurofibromin are similar. Loss of tuberin activity is thought to lead to activation of Rap1 in tumours of patients with TSC [12]. Further support for a tumour-suppressor role comes from the study of loss of heterozygosity for the *TSC1* and *TSC2* gene regions in various hamartomas from TSC patients [13–15]. No obvious phenotypic differences have been found between families linked to *TSC1* and *TSC2* [16]. Analysis of deletions of the *TSC2* locus has identified one specific correlation, namely severe polycystic kidney disease [17].

Approximately 60–70% of TSC cases are thought to be the result of new mutations, but before genetic counselling of the normal parents of an affected child, both parents should be fully investigated, including Wood's lamp examination, computed tomography (CT) [18], renal ultrasound or intravenous pyelography, and expert ophthalmological examination. A study using these tests showed that about 30% of 'normal' parents had TSC [19].

Pathology [20]. The defect in organogenesis may affect almost any tissue. Most of the lesions are hamartomas, and in many organs the cells resemble embryonic cells, suggesting that the defect occurs at an early stage in life. In many lesions, for example angiomyolipoma of the kidney, there is malformation of vascular and mesenchymal tissue. In other lesions, the aberrant cells are uniform. The lesions are slow-growing and tend to produce symptoms by pressure effects, although sometimes there is haemorrhage from a vascular lesion.

Most of the cutaneous lesions show an excess of collagen. The shagreen patches show no other change and cannot be identified on the histological findings alone. The angiofibroma (formerly misnamed adenoma sebaceum) consists of hyperplastic blood vessels and sebaceous glands of immature hair follicles. Collagen synthesis is increased in the angiofibroma, although total collagen content is decreased, suggesting that there may be an increased turnover of collagen [21]. Histopathology of the periungual fibromas shows a distal part with loose collagen and many blood vessels and a larger proximal part composed of dense collagen bundles and fewer capillaries [22]. The white ash-leaf-shaped macules contain abnormal melanocytes with reduced tyrosinase activity [23] and electron microscopy shows defective melanization of melanosomes [24,25].

The characteristic tuberosclerotic nodules of glial proliferation may occur anywhere in the cerebral cortex, basal ganglia and ventricular walls, but are rare in the cerebellum, medulla or cord [20]. Gliomas are not uncommon and almost always develop in the striothalamic region. Renal tumours of embryonic type, usually multiple, subcapsular and benign, are found in about 80% of cases at post-mortem but are frequently asymptomatic. The angiomyolipoma is the characteristic lesion but cystic renal disease also occurs [26]. The so-called congenital

Table 12.3 Clinical features of tuberous sclerosis complex (TSC).

Major features
Facial angiofibromas or forehead plaque
Non-traumatic ungular or periungual fibroma
Shagreen patch (connective tissue naevus)
Multiple retinal nodular hamartomas
Cortical tuber*
Subependymal nodule
Subependymal giant cell astrocytoma
Cardiac rhabdomyoma, single or multiple†
Lymphangioleiomyomatosis and/or renal angiomyolipoma‡
Hypomelanotic macules (more than three)
Suggestive features requiring further investigation
Multiple randomly distributed pits in dental enamel
Hamartomatous rectal polyps§
Bone cysts§
Cerebral white matter radial migration lines*¶
Gingival fibromas
Non-renal hamartoma§
Retinal achromic patch
'Confetti' skin lesions
Multiple renal cysts§
Skin tags
Positive family history in first-degree relative

* When cerebral cortical dysplasia and cerebral white matter migration tracts occur together, they should be counted as one rather than two features of TSC.
† On echocardiogram.
‡ When both lymphangioleiomyomatosis and renal angiomyolipomas are present, other features of TSC should be present before a definitive diagnosis is assigned.
§ Histological confirmation is suggested.
¶ Radiographic confirmation is sufficient.

rhabdomyoma of the heart is an abnormal and premature differentiation of embryonic myocardium into atypical Purkinje cells. The lungs may show interstitial fibrosis or fibroleiomyomatosis with cystic changes [27–29]. Lymphoblastoid cell lines and fibroblasts from patients with TSC are abnormally sensitive to radiation and radiomimetic chemicals [30].

Clinical features [31–36]. The characteristic features of the syndrome are skin lesions, mental retardation and epilepsy, but these show very wide variation in age of onset and severity. Onset before the age of 5 years with cutaneous changes or with epilepsy is usual, although the disease may remain latent until adolescence or adult life. Diagnostic criteria determined by a committee of the US National Tuberous Sclerosis Association [37,38] have since been modified [39]. A definitive diagnosis of TSC requires two major features (Table 12.3). Brain MRI or non-enhanced CT, renal ultrasound or echocardiogram may be necessary.

Skin lesions are found in 60–70% of cases. Lesions of four types are pathognomonic.

Fig. 12.11 Tuberous sclerosis: angiofibromas.

1 Angiofibromas (Fig. 12.11) may rarely be present at birth or develop in infancy, but usually appear between the ages of 3 and 10 years, and sometimes later. They often become more extensive at puberty and then remain unchanged. Firm, discrete, red-brown, telangiectatic papules, 1–10 mm in diameter, extend from the nasolabial furrows to the cheeks and chin, and are occasionally found in the ears. They may be numerous and conspicuous, and very rarely may form large cauliflower-like masses. In many cases they are easily overlooked, being confined to a small area on each side of the nose or the chin.
2 Periungual fibromas (Koenen's tumours) appear at or after puberty as smooth, firm, flesh-coloured excrescences emerging from the nail folds. They are usually 5–10 mm in length, but may be very large. This can be the only clinically evident abnormality.
3 The shagreen patch is an irregularly thickened, slightly elevated, soft, skin-coloured plaque, usually in the lumbosacral region.
4 White ovoid or ash-leaf-shaped macules [23,40–42] 1–3 cm in length, most easily detectable by examination under Wood's light, are frequently present on the trunk or limbs. They are a valuable physical sign, as they may be found at birth or in early infancy, some years before other signs of the disease develop, and may suggest the correct diagnosis in infants with convulsions. However, it is important to appreciate that hypopigmented macules are seen in 2–3 per 1000 of apparently normal newborn babies and therefore alone their presence is not indicative of TSC [43].

Other cutaneous manifestations include firm fibromatous plaques, especially on the forehead [44] and scalp (Fig. 12.12), soft pedunculated fibromas around the neck and axillae, and poliosis [45].

Fig. 12.12 Tuberous sclerosis: fibromatous nodule on the forehead.

Fibromatous tumours are occasionally present on the gums and palate and rarely are found on the tongue, larynx and pharynx [46]. Small pits commonly occur in the tooth enamel in adult patients; although less obvious in the deciduous teeth, these pits have been used as an early diagnostic sign in children with TSC [47].

Mental deficiency is present in 60–70% of cases and may be progressive, but if mental development has been normal throughout childhood subsequent deterioration is uncommon [34]. Some cases have presented gross behaviour disorders, although they have been of normal intelligence. Psychotic symptoms, including schizophrenia, sometimes develop [48], and we have known patients in mental hospitals with depression or schizophrenia to be correctly diagnosed after the discovery of TSC in a near relative.

Epilepsy [49] is seen in almost all mentally retarded patients and in some 70% of those with average intelligence. It usually begins in infancy or early childhood, thus often preceding the skin lesions by many years. Less frequently, the onset of epilepsy is delayed until puberty or adult life. The attacks may be focal and often become progressively more frequent and severe, but there may be long remissions. Intracranial malignant change occurs in a few patients. Symptoms and signs of raised intracranial pressure usually result from obstruction by a tumour at the foramen of Monro. Very rarely, cord lesions produce focal neurological signs.

Ocular signs [50,51] occur in 50% of cases but may be hard to detect. Retinal phacomas are seen as white streaks along the vessels or as small rounded tumours near the disc. Pigmentary and other retinal abnormalities can occur. Symptoms are rare but there may be scotomas or amaurosis. Hypopigmented spots in the iris also occur and these may be analogous to the ash-leaf macule in the skin [52].

Cardiac and renal tumours are often asymptomatic unless by reason of their size or site. Cardiac rhabdomyomas, detected by echocardiography, occur in over 50% of infants [53–55]. These tumours may result in early death; however, recent evidence suggests that in the majority these tumours regress in early infancy and again in adolescence [55]. Prenatal detection of these tumours is now possible by fetal echocardiography [56,57]. Renal involvement includes angiomyolipoma [58], a benign tumour of the renal parenchyma and, less commmonly, renal cysts [59,60]. Rarely, the presenting symptoms may be of renal origin, usually haematuria [61].

Pulmonary changes [28] are rare and seldom cause symptoms, but if extensive can result in increasing dyspnoea and recurrent spontaneous pneumothorax. They occur much more frequently in females and tend to become clinically manifest in the second decade [27,29]. They may result in death from tension pneumothorax or cor pulmonale. The rare association of TSC with chylothorax resulting from lymphangiomyoma appears to be significant [62].

Gastrointestinal tumours may occur [63]. These are usually hamartomatous colonic polyps. Colonoscopy should be considered in the investigation of patients with TSC.

Endocrine and other metabolic disturbances may be present [64]. Most frequently reported are pituitary–adrenal dysfunction, thyroid disorders and premature puberty.

Associated abnormalities. These include primary localized gigantism [65,66] and diffuse cutaneous reticulohistiocytosis [67].

Partial forms. In some cases, only one component of the syndrome is clinically evident, although post-mortem findings in such cases often show involvement of other organs. Unilateral, multiple, facial angiofibromas have been reported in two patients and the authors hypothesized that this represented a mosaic form of TSC [68].

Radiological findings [69] may be as follows.

Skull. Calcification is seen on plain skull X-ray in about 50% of patients, although it is not usually apparent until later childhood or adult life. Investigation should now include CT and MRI [70]. The characteristic CT findings include periventricular (subependymal) nodules, parenchymal hamartomas (cortical tubers), ventriculomegaly and, rarely, subependymal giant cell astrocytomas. The typical CT appearance of TSC consists of calcified periventricular nodules that project into the lateral ventricles and hypoattenuated parenchymal lesions. MRI is more sensitive in the detection of parenchymal lesions. The periventricular lesions may not be seen initially and can progress to calcified lesions with time. This is also true of the parenchymal lesions.

Hands and feet [71]. Cyst-like lesions of the phalanges and irregular thickening of the cortex of metatarsals and metacarpals have been reported, and similar lesions localized in vertebrae, pelvis or long bones are not uncommon.

Lungs. There may be irregular reticulation of the lung fields, not radiologically distinguishable from other types of interstitial fibrosis.

Kidneys. Investigation includes ultrasound and CT [72]. Angiography is helpful in differentiating renal hamartomas from other lesions [73].

Electroencephalographic findings. The proportion of cases showing abnormal findings is high and increases with age, but there is no diagnostic pattern.

Course and prognosis. The expectation of life for a severely affected infant is poor: 3% die in the first year, 28% under 10 years and 75% before age 25 years. Death is usually due to epilepsy or intercurrent infection, but occasionally it is due to a tumour, cardiac failure or pulmonary fibrosis. The prognosis for the older child or young adult with the cutaneous stigmata and epilepsy is unpredictable. Each case must be investigated in detail and individually assessed.

Diagnosis [36]. The telangiectasia and the lack of comedones and pustules distinguish angiofibromas from acne vulgaris. The firm, skin-coloured papules of epithelioma adenoides cysticum must also be differentiated. The full syndrome presents few problems. Difficulties arise in infancy when the classical triad is not evident. The identification of white ash-leaf-shaped macules under Wood's light, in the presence of unexplained epilepsy, retinal phacomas, or radiological or electroencephalographic findings, or a positive family history will help establish the diagnosis. The partial forms are often unsuspected until post-mortem. Any child of a person diagnosed as having TSC has a 50% chance of inheriting the disease. Family screening and genetic counselling should be carried out by referral to a clinical genetics service. DNA testing is available in 85% of cases and should be discussed. Gonadal mosaicism is possible in around 3% of families where parents are not known to have overt TSC. Prenatal diagnosis is not an option for the 60–70% of cases who represent new mutations.

Treatment. The cosmetic appearance may be improved by removing angiofibromas with the pulsed dye vascular laser (wavelength 585 nm). The more papular/nodular lesions are best treated with the carbon dioxide laser in the first instance [74]. The treatment of lesions in other organs is unsatisfactory, and surgical procedures may be required for relief of symptoms. Neurosurgery should be considered when epilepsy is uncontrolled by drugs and there is a fixed, circumscribed, electroencephalographic focus [75].

Gardner's syndrome (MIM 175100)

Aetiology. The syndrome comprises multiple epidermoid cysts, fibrous tissue tumours, osteomas and polyposis of the colon; its inheritance is determined by an autosomal dominant gene of variable expressivity [1–4]. Gardner's syndrome is located on chromosome 5q, near bands 5q21–q22 [5,6]. It is now thought that Gardner's syndrome and familial polyposis coli are allelic disorders, caused by mutation in the *APC* (adenomatous polyposis coli) gene.

Congenital hypertrophy of the retinal pigment epithelium is a frequent finding in Gardner's syndrome and is a valuable clue to the presence of the gene in persons who have not yet developed other manifestations [7,8].

Turcot's syndrome, in which polyposis of the colon is associated with malignant tumours of the central nervous system [9], was present in the uncle of a patient with gastric polyposis and multiple epidermoid cysts [10]. It has been suggested that Turcot's syndrome represents a variant of Gardner's syndrome.

Pathology. The pathology and natural history of the polyposis are essentially similar to familial polyposis coli. The syndrome in which polyposis of the colon is associated with perifollicular fibrosis is probably distinct [11]. Several groups have reported the association of hepatoblastoma with polyposis coli [12,13].

Histology and immunohistochemistry of cutaneous cysts suggest that these are derived from follicular stem cells [14].

Clinical features [3,11,15–17]. Polyposis of the colon or rectum usually arises during the second decade, but may occur in early childhood. It is present in about 50% of cases by the age of 20 years. There are few symptoms and intussusception is not a feature. Malignant change develops some 15–20 years later in over 40% of reported cases.

The variable expressivity of the gene must be remembered when a family is investigated [18]. Cutaneous and skeletal changes may be present without polyposis, and polyposis may be present when one or more of the other features of the syndrome is lacking [19].

Epidermoid cysts, which may be numerous, are usually irregularly distributed on the face, scalp and extremities, and are less frequent on the trunk. They may first appear between the ages of 4 and 10 years, but often considerably later, and are ultimately present in almost all cases.

Osteomas develop mainly in the maxilla, mandible and sphenoid bones, but also in other bones of the skull and, less frequently, in the long bones. They are usually small, multiple and present in some 50% of cases. The age of onset is often not accurately known, but they may be present at puberty.

Fibromas or desmoid tumours are less frequently present. They are usually poorly localized tumours in incisional scars of the abdomen, but may occur at other sites. Fibrosarcomas have also been associated with the syndrome. Fibromatous growths of the mesentery may be discovered at operation, and severe peritoneal scarring may follow surgery. A very large desmoid tumour extensively involving the chest wall and the left anterior abdominal wall has been described in a patient with a family history of Gardner's syndrome. The desmoid arose at the site of a thoracotomy scar following the removal of a large aneurysm of the left atrial appendage 5 years before [20].

Lipomas in the subcutaneous tissues, and in other organs, have frequently been noted.

Leiomyomas of the stomach or ileum, or retroperitoneal tissue, are sometimes present.

Diagnosis. Because multiple epidermoid or sebaceous cysts may be inherited as an isolated abnormality and may thus have no sinister significance, their discovery is an indication for a detailed family history and a careful examination for osteomas, including radiological examination of the skull, and for other dermal tumours. The cutaneous lesions are an important indicator of possible asymptomatic polyposis.

Cowden's syndrome (MIM 158350)

SYN. MULTIPLE HAMARTOMA SYNDROME

Definition. In this rare disorder, multiple hamartomatous lesions of ectodermal, endodermal and mesodermal origins are associated with a predisposition to malignant tumours, particularly of the breast. Cowden was the name of the family in whom the disease was first described [1].

The condition is characterized by mucosal and cutaneous papillomatosis and fibromatosis, with fibrocystic breast disease in the female and thyroid goitre or adenoma.

Aetiology. Inheritance of the disease is determined by an autosomal dominant gene of variable expressivity. Germline mutations of the *PTEN1* gene located on chromosome 10 have been identified in a proportion of kindreds.

However, Cowden's syndrome, like so many other inherited disorders, shows locus heterogeneity, with some families developing the disease due to heterozygous mutation of the transforming growth factor (TGF)-β type 1 receptor, known as bone morphogenetic receptor type 1 (*BMPR1A*). Both genes encode proteins required in regulation of cell proliferation, and loss of the wild-type allele has been detected in tumour tissue, in accord with the Knudson 'two-hit' hypothesis [2]. About 100 cases have been reported [3].

Pathology [4,5]. The skin lesions around the mouth, eyes and chin are trichilemmomas [6]. The breast lesions are fibroadenomas, which are liable to undergo malignant degeneration. A unique fibroma on the face and other sites has been described [5,7], composed of broad acellular collagen bundles in a lamellar or whorl-like pattern with occasional giant cells. This has been referred to by Barax *et al.* [3] as 'Cowden's fibroma'. An immunohistochemical study of the sclerotic fibroma has shown strong staining with an antibody directed at human type I procollagen [8]. There is a report of amyloid in association with multiple hamartoma syndrome [3].

Clinical features [9–14]. Mucocutaneous lesions have been present in all reported cases of this disease, but they have varied in their distribution, extent and age of onset. Skin-coloured lichenoid papules up to 4 mm in diameter, tending to coalesce to give a cobblestone appearance, are distributed on and around the eyes and mouth. On the dorsa of hands and wrists are lesions like those of acrokeratosis verruciformis. On palms and soles and on palmar and plantar aspects of fingers and toes are small translucent keratoses. Multiple angiomas and lipomas have been found in several cases. Malignant melanoma has occurred [15].

Verrucous and papillomatous lesions are seen in some patients on the labial and buccal mucosa, fauces and oropharynx, and may extend to the larynx.

In a series of 21 patients [14], craniomegaly was noted to be the most frequent extracutaneous finding, affecting 70% of patients.

Of the many other abnormalities that have been reported in this syndrome, the most frequent involve the thyroid and breasts. Approximately 30% of reported female cases developed breast cancer [14]. Fibrocystic disease of the breast sometimes leads to massive hyperplasia. Goitre or thyroid adenoma is present in many cases and thyroid carcinoma has been reported [7,9]. Adenocarcinoma of the uterus has been reported in 6% of women with multiple hamartoma syndrome [14]. Less frequent associations include adenoid facies, high-arched palate, vitiligo, café-au-lait spots, skeletal abnormalities, retinal glioma, pseudotumour cerebri, gastrointestinal polyposis and various gynaecological disorders (menstrual irregularity, uterine fibroids). An association with renal cell adenocarcinoma and primary neuroendocrine carcinoma of the skin (Merkel cell carcinoma) in one patient has been documented [16].

Ruschak *et al.* [17] described a patient with this syndrome who had a deficiency of T-lymphocyte function, with recurrent cellulitis and abscess formation, and the eventual development of acute myeloid leukaemia.

Differential diagnosis. The combination of clinical and histological findings is pathognomonic. It seems possible that the skin lesions have in the past been confused with Darier's disease, and some cases may have been reported as TSC with mucosal involvement [7]. The relationship between Cowden's syndrome and gingival fibromatosis with hypertrichosis [18] is uncertain, but they are probably separate conditions.

Treatment. Cosmetic surgery may be helpful. The possibility of carcinoma of breast or thyroid must be borne in mind. Female patients with this syndrome should avoid oestrogen therapy and should have frequent breast investigations, including mammography, or even prophylactic mastectomy [19].

Ectodermal dysplasias

Nomenclature. The ectodermal dysplasias are a heterogeneous group of disorders, the classification of which has been substantially reviewed as a consequence of molecular genetic studies. Weech [1] used the term to describe certain heritable developmental disorders of tissue derived from the ectoderm but, with time, many new syndromes were described in which the term was loosely used. Freire-Maia [2,3] suggested limiting the term 'ectodermal dysplasia' to those disorders with a primary defect in hair, teeth, nails or sweat gland function. Solomon and Keueur [4] discussed the problem of classification, and suggested limiting the term to disorders that are congenital, nonprogressive and diffuse. The number of distinctive syndromes in which there is a defect in one or more epidermal appendages is now so large (more than 150) that Freire-Maia and Pinheiro [5–7] proposed a provisional classification based on which ectodermal derivatives are affected. According to their classification, '1' indicates hair dysplasia, '2' dental dysplasia, '3' nail dysplasia and '4' sweat gland dysplasia. The different subgroups are referred to either by the combination of these numbers or by their Greek names, for example 1-2-3-4 is tricho-odonto-onychodyshidrosis. Although this classification is unsatisfactory in many respects, it has helped in imposing some order on a heterogeneous and complex group of disorders. The principal syndromes and some of the rarer disorders are detailed in this section (Table 12.4).

Hypohidrotic ectodermal dysplasia, X-linked (MIM 305100) [1–4]

SYN. CHRIST–SIEMENS–TOURAINE SYNDROME; ANHIDROTIC ECTODERMAL DYSPLASIA

Definition. Hypohidrotic ectodermal dysplasia is characterized by partial or complete absence of sweat glands, hypotrichosis and hypodontia.

Aetiology. Hypohidrotic ectodermal dysplasia was first described in 1848 by Thurnam [5] and later in the 19th century by Darwin [6]. It was assigned to the X chromosome in 1921 by Thadani [7], who later reported that carrier females could manifest signs of the condition. The inheritance of this syndrome is determined by an X-linked recessive gene [8,9]. Linkage studies have mapped this disorder to Xq12–q13.1 [10,11], and it is caused by mutation in a novel transmembrane protein with a suggested role in epithelial–mesenchymal signalling [12]. It has been proposed that decreased expression of the epidermal growth factor receptor plays a causal role in the hypohidrotic ectodermal dysplasia phenotype [13]. The incidence of hypohidrotic ectodermal dysplasia was estimated by Stevenson and Kerr [14], based on prevalence in Oxfordshire, to be 1 per 100 000 births. Several hundred cases, of which over 90% are males, have been reported in many different races. The complete syndrome does not occur in females, but female carriers may show dental defects, sparse hair, reduced sweating and dermatoglyphic abnormalities [2,15].

Pathology [16,17]. The epidermis is thin and flattened and eccrine sweat glands are absent or rudimentary, or few and poorly developed. The reduction in the number of sweat glands, hair follicles and sebaceous glands is variable. Large and clinically visible sebaceous glands were, however, present on the faces of two affected twins [18]. Dermal connective tissue usually appears grossly normal, but collagen and elastic fibres may be fragmented or sparse. In some cases, mucous glands are absent in the upper respiratory tract and in the bronchi [3]. Salivary glands show inflammatory changes and ectasia of ducts [19]. An interesting finding was sparsity of amniotic fluid at birth [20]. The cell-mediated immune response may be depressed and the serum IgE level elevated as in the atopic state [21].

Clinical features. The essential features of the syndrome are absent or reduced sweating, hypotrichosis and total or partial anodontia. In the more complete forms the appearance of the patient is distinctive, with prominent frontal ridges and chin, saddle nose, sunken cheeks, thick everted lips, large ears and sparse hair. The skin is smooth, soft, dry, finely wrinkled (especially around the eyes) and appears prematurely aged.

Absent or reduced sweating causes heat intolerance, and affected individuals may present with unexplained fever in infancy or childhood [22]. Extreme discomfort can follow exertion or eating hot foods. Thyroid medication may also induce hyperpyrexia [8]. Happle and Frosch [23] demonstrated that sweat testing of the back reveals a pattern consistent with Blaschko's lines and explained this phenomenon on the basis of lyonization.

The temporary and permanent teeth may be entirely absent, or there may be a few teeth present. The incisors and/or canines are characteristically conical and pointed (Fig. 12.13). The jaws develop normally even in complete anodontia, but the gums may be atrophic [17]. The mouth may be dry from hypoplasia of the salivary glands and the lacrimal glands may also be deficient. Otorhinolaryngological features include atrophic rhinitis, persistent foul-smelling nasal discharge and crust formation, chronic respiratory infections and hearing problems [24,25]. Poor development of mucous glands in the gastrointestinal tract may result in dysphagia and, more rarely, stomatitis and diarrhoea. Aplasia or hypoplasia of the breasts is occasionally noted.

Fig. 12.13 Conical teeth in X-linked hypohidrotic ectodermal dysplasia.

Alopecia is often the first feature to attract attention, but it is seldom total. The scalp hair is sparse, dry, fine and usually remains short. The structure of the shaft may be abnormal. The eyebrows are sparse or absent, but the lashes are usually normal. The beard, pubic and axillary hair are often sparse and other terminal hairs on trunk and limbs may be absent.

The nails are abnormal in about half the cases and may be brittle, thin or ridged, but are seldom grossly deformed.

Ocular abnormalities are unusual, although corneal and lenticular opacities have occurred [8,26]. Atopic eczema and asthma are often present [3,24].

General physical development may be somewhat stunted, but sexual development is usually normal; primary hypogonadism is occasionally associated [27]. Mental development is retarded in 30–50% of cases but usually not greatly. The expectation of life is normal or only slightly reduced.

Partial forms should be sought among the relatives of known cases and are found mainly among carrier females. The conical pointed teeth are the key feature of the syndrome and may be the only obvious abnormality. In other cases, they may be associated with congenital alopecia, and defective sweating, if present, may be detectable only on appropriate testing [28].

Associated abnormalities. In one family, the typical syndrome was associated with Friedreich's ataxia in four brothers [29]. In another, Horner's syndrome of central type with nystagmus was evidence of a developmental defect of the brainstem [30].

Diagnosis. The diagnosis is rarely made until the child is old enough for deficiencies of hair and teeth to arouse parental anxiety, but should be suspected in unexplained hyperthermia. The characteristic facies is pathognomonic but may not be recognized in infancy. Assessment of the dental status of the child and siblings may establish the diagnosis. In the older child with the full syndrome, the diagnosis is unmistakable. In partial forms, the pointed conical teeth provide the most reliable indication and should suggest the need for sweat testing and a skin biopsy.

Treatment. Little can be offered except advice concerning restriction of physical exertion, choice of suitable occupation and avoidance, if practicable, of warm climates. Special schooling and psychological support may be needed. Regular dental supervision is essential and dentures may be required at an early age [19]. The use of DNA-based mutational analysis now offers the opportunity for prenatal diagnosis [31].

Hypohidrotic ectodermal dysplasia, autosomal dominant and recessive types (MIM 129490 and MIM 224900)

A number of cases of hypohidrotic ectodermal dysplasia have been reported in which autosomal recessive inheritance of the syndrome seems probable [1–3]. Phenotypically, the features are indistinguishable from those of the X-linked form, except that the complete syndrome occurs in both sexes. It has been claimed that the sweating deficiency is less severe in the autosomal recessive form. Sweat glands are reduced in number but are not absent [1]. Dominant and recessive inheritance patterns are due to different types of mutation of the same gene, located at 2q11–q13. The *ED3* gene encodes a protein with a single transmembrane domain, shows many features in keeping with the TNF receptor family of genes, and shows strong homology to the *downless* mouse mutant [4].

Hidrotic ectodermal dysplasia (MIM 129500)

SYN. CLOUSTON'S SYNDROME

Definition. Hidrotic ectodermal dysplasia is characterized by nail dystrophy, associated with defects of the hair and keratoderma of palms and soles.

Aetiology. Several reports have described an extensive kindred of French extraction, which migrated to Canada, Scotland and the USA [1–6]. The inheritance of the syndrome is determined by an autosomal dominant gene; the homozygous state may be lethal. A molecular defect of keratin was proposed but linkage to known keratin genes has been excluded [7]. The gene responsible for hidrotic ectodermal dysplasia maps to the pericentromeric region of chromosome 13q and the *ED2* gene has been shown to be a member of the gap junction family known as connexin 30 (*GJB6*) [8]. These proteins mediate the direct diffusion of ions and metabolites between the cytoplasm of connecting cells. It is of interest that mutations in the connexin proteins have also been associated with inherited forms of hearing loss, and a number of families with both deafness and hidrotic ectodermal dysplasia have been reported.

Pathology. Hyperkeratosis resulting from reduced desquamation is most evident on palms and soles. Biophysical and biochemical studies of the hair give findings consistent with the hypothesis that there is depletion of matrix protein and disruption of, or a failure to form, disulphide bonds in the remaining keratin. Ultrastructural studies of hair [9,10] have shown disorganization of hair fibrils with loss of the cuticular cortex.

Clinical features [1,4,11–13]. Dystrophy of the nails is the key feature of the syndrome and in some 30% of those affected there may be no other obvious defect. The nails are thickened, striated, often discoloured and grow slowly. Less often they are short, thin and brittle. Persistent paronychial infections are frequent and may partially or completely destroy the matrix. The skin is thickened beneath the free edges of the nails, over the finger joints and knuckles, and sometimes over the knees and elbows. Diffuse hyperkeratosis of the palms and soles, extending in varying degree to the sides of the dorsal aspects, is frequent and may be severe; fissuring is sometimes troublesome.

In the complete forms, scalp hair is very sparse, fine, pale and brittle or completely lacking. It may be more or less normal in infancy, but seldom remains after puberty. The eyebrows are thinned or absent, especially in their outer two-thirds, and lashes are few and small. Vellus and pubic and axillary hair are sparse or absent. One affected woman developed numerous eccrine poromas [14].

The teeth are often normal [15]; they show no characteristic defect but may be poor, with early caries. The skull is sometimes thickened and there may be tufting of the terminal phalanges of fingers and toes [6].

General physical development is normal but affected individuals may be shorter than unaffected siblings. Genital maturation and expectation of life are unaffected. Mental development may be retarded but is often normal.

In one family, five members with this condition developed bilateral premature cataracts [16].

Diagnosis. The presenting manifestation may be alopecia, palmoplantar keratoderma or the unsightly and often painful nail changes. The diagnosis is established by the nail dystrophy in a patient with normal facies, no specific dental defect and normal sweating.

Rapp–Hodgkin syndrome (MIM 129400) [1–3]

In this autosomal dominant syndrome, hypohidrosis is severe enough to result in intolerance of heat. Hair is sparse, light in colour and of 'steel-wool' texture, and may

show pili torti [4] or pili canaliculi [5]. The nails are narrow and dystrophic. Other abnormalities include small stature, cleft lip or palate, and hypospadias. A high forehead, narrow nose, small mouth and maxillary hyperplasia give a distinctive facies. The dentition is poor, with conical teeth and hypodontia. The lacrimal puncta may be aplastic. One case associated with palmar keratoderma has been described [6]. Rapp–Hodgkin syndrome seems to overlap with both the ectrodactyly–ectodermal dysplasia–clefting (EEC) syndrome [7] and the ankyloblepharon–ectodermal dysplasia–clefting (AEC) syndrome [8,9].

EEC syndrome (EEC1, MIM 129900; EEC2, MIM 602077; EEC3, MIM 604292) [1–3]

The association of ectrodactyly (lobster-claw deformity of the hand) (Fig. 12.14) with cleft lip and palate, transmitted as an autosomal dominant trait, was originally described by Cockayne in 1936 [4]. The EEC syndromes are characterized by locus heterogeneity, with families displaying autosomal dominant inheritance and the genes mapping to 7q11.2–q21.3 (*EEC1*), chromosome 19 (*EEC2*) and 3q27 (*EEC3*). Of these, the only gene so far characterized is that for *EEC3*. Mutations in *p63*, which shows strong homology to *p53*, a well-known tumour-suppressor gene, have been identified. The majority of the *EEC3*-causing mutations are amino-acid substitutions that lead to the production of a protein that is defective in its ability to bind to DNA and thereby regulate the expression of other genes [2]. As a clear example of the correlation between the functional impact of a mutation and the observed clinical phenotype, other missense mutations of the *p63* gene affect the sterile alphamotif (SAM) domain and are predicted to impinge on *p63*-mediated protein–protein interactions. These mutations have recently been reported in a range of congenital ectodermal dysplasias (see below).

Fig. 12.14 EEC syndrome: typical lobster-claw deformity of the hand.

The main clinical features of the EEC syndromes are ectrodactyly, sparse wiry hypopigmented hair, peg-shaped teeth with defective enamel, cleft lip and palate, and lacrimal duct stenosis. The normal mucosal covering of the laryngeal folds is absent, and the voice tends to have a breathy quality, as it does in anhidrotic ectodermal dysplasia [5]. Conductive deafness is associated with clefting. Although ectodermal dysplasia is a feature, there are numerous sweat glands on the skin biopsy, and sweating may be normal in some patients [6]. In a study of 25 Brazilian patients, 13 had genito-urinary anomalies [7]. Corneal scarring and blindness are serious complications [8,9]. Absence of meibomian glands has been noted [10]. Hamartoma of the tongue in an infant was documented by Hanna *et al*. [11]. The EEC syndrome can be associated with hypothalamic–pituitary dysfunction [12].

Not all the defects are present in every patient. Anodontia was the sole clinical feature in a mother who had two children with ectrodactyly, one of whom had a cleft lip and palate [13].

Multidisciplinary management is essential, with the early involvement of a clinical geneticist. Cleft lip and palate can be detected by ultrasound examination prenatally, which may be of value in the genetic counselling of affected families [14]. At present, molecular genetic analysis is confined to those harbouring *p63* mutations.

ADULT (*a*cro-*d*ermato-*u*ngual–*l*acrimal–*t*ooth) syndrome (MIM 103285) [1]

A family of seven affected individuals has been reported with an autosomal dominant syndrome that closely resembles EEC syndrome. Linkage studies suggest that the related ADULT syndrome is also caused by mutations in the *p63* gene. The main manifestations are hypodontia and/or early loss of permanent teeth, ectrodactyly, obstruction of lacrimal ducts, onychodysplasia and excessive freckling.

AEC syndrome (MIM 106260) [1–3]

SYN. HAY–WELLS SYNDROME

The inheritance of this syndrome is determined by an autosomal dominant gene of variable expressivity. The syndrome is due to mutation in the SAM domain of the *p63* gene product [4]. The essential features are ankyloblepharon (fused lid margins), ectodermal defects and cleft lip and palate. Hair may be absent, but if present is sparse and coarse with electron microscopic appearances resembling those of Marie–Unna hypotrichosis. The nails are absent or dystrophic and the widely spaced, pointed teeth are soon shed. Sweating is diminished. The nasal bridge tends to be broad and the maxilla sunken. Denuded skin at birth and chronic scalp erosions complicated by infection are common features of this syndrome [5].

Some cases have other defects, including lacrimal duct stenosis, ptosis, microphthalmia, supernumerary nipples, syndactyly, deformities of the auricle, interventricular septal defect and Waardenburg's syndrome.

Rosselli–Gulienetti (cleft lip/palate) syndrome (MIM 225000) [1]

The inheritance of this syndrome is probably determined by an autosomal recessive gene. Hypohidrosis accompanies slight frontal bossing and some depression of the nasal bridge. The scalp hair is often fine, dry, sparse and light in colour; the nails are dystrophic and teeth are few and small. Other features are cleft lip and palate, syndactyly and defects of the external genitalia. There may also be popliteal web formation. The disorder includes both Zlotogora–Ogur syndrome and Margarita Island ectodermal dysplasia, and was assigned to chromosome 11q23 by linkage mapping [2]. This was followed by a positional cloning approach to identify the gene as *PVRL1*, encoding nectin-1, an immunoglobulin-related transmembrane cell–cell adhesion molecule that is part of the NAP cell adhesion system. Nectin-1 is also the principal cell surface receptor for α-herpesviruses. Suzuki *et al*. [2] speculated that the high frequency of this syndrome on Margarita Island in the Caribbean Sea might have resulted from resistance of heterozygotes to infection by these viruses.

Alopecia–onychodysplasia–hypohidrosis–deafness [1]

This is a distinct syndrome of autosomal recessive inheritance. An affected child may be born bald and remain so, apart from the few thin yellow hairs on the scalp. Teeth are small, the fingernails are normal, but the toenails are thick and dystrophic. There is hypohidrosis and also hyperkeratosis of the palms and soles, knees and elbows and, to some extent, on the skin generally, except on the

head and neck. There may be severe sensorineural deafness, and also defects of other organs.

Basan's syndrome (MIM 129200) [1]

This autosomal dominant syndrome is characterized by hypohidrosis and dryness of the skin and the mucous membranes of the mouth and vulva. Severe dental caries develops early. Body hair, eyebrows and eyelashes remain sparse throughout life. There may at first be a normal quantity of scalp hair but of coarse texture: it is shed during the second decade. The nails are thick and short. The dermatoglyphic pattern is unusual or absent and there are single palmar flexion creases. The family described by Jorgenson [2] had a similar, if not the same, condition.

Greither-type ectodermal dysplasia [1]

Hypohidrosis is accompanied by almost total alopecia, with loss of teeth, corneal and lenticular opacities, dystrophic nails and the transgredient form of palmoplantar keratoderma.

Greither's syndrome is a separate entity (see p. 12.65).

Xeroderma–talipes–enamel defect [1]

SYN. MOYNAHAN'S SYNDROME

Two siblings born to consanguineous parents were reported with congenital hypohidrosis, nail dystrophy, cleft palate, bilateral talipes and mild mental deficiency with electroencephalographic abnormalities. The teeth were yellow and malformed due to an enamel defect. At least six other members of the family had defective tooth enamel without the other features of the syndrome.

Anonychia with bizarre flexural pigmentation (MIM 106750) [1]

In this autosomal dominant syndrome, fingernails and toenails are absent from birth and the palmar and plantar skin is dry, thin and peeling. Sweating is diminished. The hair is coarse and sparse in the frontovertical region. There is early dental caries. The diagnostic feature is the presence of mottled hyperpigmentation and hypopigmentation in the axillae, groins and natal cleft.

REFERENCE

1 Verbov J. Anonychia with bizarre flexural pigmentation: an autosomal dominant dermatosis. *Br J Dermatol* 1975; **92**: 469–74.

Tricho-onychodental dysplasia [1]

Tricho-onychodental dysplasia is a rare syndrome characterized by taurodontic molars, defective enamel and dentine dysplasia. There are few teeth, widely spaced, and deciduous teeth tend to persist. Nails, particularly toenails, are thin with longitudinal striations and cracks. There is hypohidrosis with a risk of hyperthermia.

Tricho-dento-osseous syndrome (MIM 190320)

Definition and aetiology. The inheritance of tricho-dento-osseous (TDO) syndrome, first described in 1966 [1], is determined by an autosomal dominant gene. There is enamel hypoplasia, with enlarged pulp chambers of all teeth, tight curly hair, and bone and nail defects. Three distinct clinical variants are recognized (TDO-I, TDO-II, TDO-III). The gene maps to the chromosomal region 17q12.3–q22 and is a member of the distal-less homeobox gene family known as *DLX3* [2]. This family of genes is involved in transcriptional regulation of gene expression, which may help explain the pleiotropic manifestations of the clinical disorders.

Pathology [3]. Hair from one case showed no abnormality on light microscopy, and its stress–strain characteristics were normal. The serum acid phosphatase level is increased [2]. In TDO-II dentin is dysplastic, whereas it is normal in TDO-I.

Clinical features [3,4]. TDO-I [3] is characterized by kinky or curly hair, dolichocephaly (due to premature fusion of cranial sutures, especially the sagittal), enamel hypoplasia, increased dental caries, radiodense bones and occasionally brittle nails.

Individuals with TDO-II [5] show sparse as well as curly hair, more striking nail changes, and thickening and sclerosis of the calvarium [6]. The nails may show splitting of their superficial layers. Dental eruption is delayed in TDO-I and precocious in TDO-II.

Shapiro *et al.* [7] described a family that differed from both of these (TDO-III); affected persons showed macrocephaly and obliterated diploë and no long-bone sclerosis. Physical and mental development were normal.

Trichorhinophalangeal syndrome I (MIM 190350)

Aetiology. The first description of trichorhinophalangeal syndrome (TRPS)-I was in 1966 [1]. The disorder is determined by an autosomal dominant gene of variable expressivity. Women are affected more frequently than men. Sanchez *et al.* [2] described a complex chromosome rearrangement in a boy with TRPS-I. Fryns and Van den Berghe [3] reported a patient with TRPS-I and a small interstitial deletion of 8q24.12. Buhler *et al.* [4] described a case of TRPS-I with a mosaic deletion of that band. Detailed analysis of both microdeletion families and the use of linkage studies led to the isolation of the *TRPI* gene, with a range of mutations predicted to result in premature truncation of the protein product. *TRP1* encodes a zinc-finger protein, which functions as a transcription factor. Mutations of the *TRP1* gene have also been reported in additional families with features like TRPS-I but characterized by significant brachydactyly (known as TRPS-III and designated MIM 190351) [5].

Clinical features [1,6–10]. A large, pear-shaped nose is conspicuous above a high philtrum, with slight maxillary prognathism and mandibular hypoplasia. A peculiar tubercle of normal skin below the lower lip is a reliable indicator of the syndrome when seen in a person with a pear-shaped nose. Brachyphalangeal dysostosis gives rise to fusiform swelling of the proximal interphalangeal joints and angulation of the fingers [11].

The hair is fine, brittle and sparse, but the degree of alopecia varies considerably. The eyebrows are dense at their medial ends but sparse laterally. In some patients, the nails are thin and brittle. The stature is short, although growth hormone production is normal [12].

Trichorhinophalangeal syndrome II (MIM 150230) [1–3]

SYN. LANGER–GIEDION SYNDROME

This syndrome has similarities to TRPS-I, particularly with regard to facies, bulbous nose and sparse hair. Distinguishing features are multiple exostoses, microcephaly and loose/redundant skin. Less consistent features include hyperextensible joints, mental retardation and delayed speech. TRPS-II represents a typical contiguous gene defect, with visible cytogenetic deletions, associated with the loss of a number of genes including the *TRP1* gene. Cytogenetic evaluation of a child presenting with significant mental retardation and the clinical appearance of TRPS-I is mandatory. Analysis of some parents will reveal a balanced parental translocation. All reported cases are sporadic [1].

Schöpf–Schulz–Passarge syndrome (MIM 224750) [1–3]

Cystic eyelids, palmoplantar keratoderma and hypotrichosis are associated with marked reduction in the number of teeth and with brittle and furrowed nails. The inheritance is autosomal recessive, although one report was consistent with segregation of an autosomal dominant trait, suggesting that this is a heterogeneous disorder [2]. The frequent occurrence of benign and malignant tumours of the palms and soles has been noted [2]. Lipid biochemical investigation of stratum corneum has shown a decrease in the ceramide fraction and an increase in free fatty acids [2].

Chondro-ectodermal dysplasia (MIM 225500)

SYN. ELLIS–VAN CREVELD SYNDROME

Aetiology. This rare syndrome is determined by an autosomal recessive gene [1,2]. Ossification is delayed in the primary centres but occurs prematurely in the secondary centres in the carpals and phalanges, with consequent progressive distal shortening of the extremities. The largest kindred was investigated by McKusick *et al.* [3] in an inbred religious isolate, the Old Order Amish, in Pennsylvania. The gene maps to chromosome 4p16 and encodes a protein with 992 amino acids. Mutations that predict premature truncation of the putative protein do not manifest in the heterozygous carrier. In contrast, several missense mutations have been reported in the milder condition, Weyers' syndrome (acrodental dysostosis, MIM 193530), which appears as an autosomal dominant condition.

Pathology. Skeletal histopathology in fetuses with chondro-ectodermal dysplasia shows chondrocytic disorganization of the physeal growth zone [4].

Clinical features [3,5–8]. The principal features of the syndrome are chondrodysplasia and polydactyly, ectodermal dysplasia and congenital defects of the heart. Short arms or legs on a normally proportioned trunk with lumbar lordosis, genu valgum and an extra digit on the ulnar side of the hand are the most obvious of the multiple skeletal abnormalities.

The teeth are small and defective and may be peg-shaped, and the sulcus between the upper lip and the gum may be obliterated. The upper lip is short and bound down by multiple frenula [9]. The nails are small, thin, short and ridged. The hair is usually normal, but may be sparse and brittle. Sweating and sebaceous activity are normal.

Occasionally, there may be abnormalities in the liver, kidneys [7], urinary tract and central nervous system [10].

Over one-third of cases die in the first 2 weeks of life. If infancy is survived, the expectation of life is not greatly reduced, except in those cases with severe cardiac defects [11].

Christian *et al.* [1] reported the unusual case of an infant with both Ellis–Van Creveld and Dandy–Walker syndromes and with homozygosity for an unusually long segment of the long arm of chromosome 9. McKusick [12] observed hydrocephalus and the Dandy–Walker anomaly in two Amish cases of Ellis–Van Creveld syndrome.

Mahoney and Hobbins [13] proposed fetoscopy and ultrasound as methods of prenatal diagnosis. In a study of three pregnancies terminated at 22–23 weeks because of ultrasound confirmation of short limbs and growth retardation, radiology showed that each fetus had acromelic and mesomelic shortness of long bones with smooth round metaphyses, vertically short iliac bones, short ribs and normal vertebrae. Other findings noted at post-mortem were polydactyly in all three cases, congenital heart defect in two and an abnormal frenulum in one [4].

Diagnosis. Defective teeth and nails, and extra digits in an achondroplastic dwarf are not easily confused with any other syndrome. Mutations of the gene may be investigated using molecular genetic analysis [14].

Polydactyly and congenital heart defects also occur in trisomy 13 (Patau's syndrome).

Tricho-odonto-onychial dysplasia

The inheritance of this syndrome is autosomal recessive. The hair is dry, brittle and sparse, with alopecia of the crown of the scalp. Enamel hypoplasia affects deciduous and permanent teeth and there is a variable degree of nail dystrophy. Other defects include supernumerary nipples, palmoplantar hyperkeratosis, pigmented naevi and a mixed hearing defect [1].

A different syndrome with aplasia cutis of the scalp and poikiloderma has been described in one patient as the tricho-odonto-onycho-dermal syndrome [2].

Schinzel–Giedion syndrome (MIM 269150) [1,2]

The cutaneous features of this autosomal recessive syndrome include generalized hypertrichosis, delayed tooth eruption, narrow deep-set triangular nails, and telangiectases over the nose and cheeks, with simian creases and dermatoglyphic changes. Other features include mental and physical growth retardation, epilepsy, spasticity, recurrent bouts of apnoea, bone anomalies, high-arched palate, atrial septal defect, abnormal pinnae, anteverted nostrils, hypertelorism and hypoplastic nipples.

Fried's tooth and nail syndrome [1]

In this autosomal recessive syndrome, the hair is fine and short, the teeth are few and peg-shaped and the nails are thin and dystrophic.

REFERENCE

1 Fried K. Autosomal recessive hydrotic ectodermal dysplasia. *J Med Genet* 1977; **14**: 137–9.

Odonto-onychodysplasia with alopecia [1]

In this rare syndrome there is almost total alopecia, small widely spaced teeth, brittle fingernails with a tendency to infection and thick spoon-shaped toenails. Other features include myopia, bilateral webbed toes, supernumerary nipples, irregular areolae, hypertrophied Montgomery glands, palmoplantar hyperkeratosis and simian creases.

Hypodontia and nail dysgenesis [1–4]

The condition is inherited as autosomal dominant with variable expressivity. There are few teeth and these are conical and widely spaced. There are small, dystrophic or spoon-shaped nails, which grow slowly. The hair is fine and brittle, and the lips are everted.

Odontomicronychial ectodermal dysplasia

Described by Pinheiro *et al*. [1], this condition is characterized by precocious eruption and shedding of deciduous dentition, precocious eruption of secondary dentition with short rhomboid roots, and short, thin, slow-growing nails. It probably results from an autosomal recessive gene.

REFERENCE

Odonto-onycho-dermal dysplasia

Originally described by Fadhil *et al.* in 1983 [1], odonto-onycho-dermal dysplasia was described in two unrelated inbred Lebanese families, who showed telangiectatic atrophic patches on the face, sparse hair, conical or widely spaced teeth, hyperkeratosis of the palms and soles, and dystrophic nails. Zirbel *et al.* [2] reported a boy who was similarly affected with persistent atrophic malar plaques [2].

Dermo-odontodysplasia [1,2]

This syndrome was originally reported in a white family, affecting 11 subjects over four generations, presumably by autosomal dominant inheritance. The skin is dry and thin, with simian creases, and the teeth are small and poorly developed with persistence of the deciduous teeth. The nails are dysplastic and brittle, and the hair is thin, dry and slow growing, with areas of alopecia on the crown.

Odontotrichomelic syndrome [1–4]

This probably autosomal recessive syndrome is characterized by severe hypotrichosis, few and small conical teeth, and hypoplastic or absent areolae. There is cleft lip and extensive tetramelic dysplasia. Growth is retarded.

Salamon's syndrome (MIM 278200) [1,2]

This syndrome, probably of autosomal recessive inheritance, is characterized by sparse brittle hair, which is readily shed. Pili torti and other hair-shaft defects are present, the teeth are few and small, the nails are dystrophic, and numerous ophthalmic defects can occur. The facies has features of classical hypohidrotic ectodermal dysplasia but sweating is normal.

Coffin–Siris syndrome (MIM 135900) [1–5]

The syndrome is characterized by mental retardation; coarse facial features with sparse scalp hair; bushy eyebrows; low nasal bridge, anteverted nostrils and thick lips; absent fifth fingernails and toenails; short distal phalanges; lax joints; delayed eruption of the teeth, which are small; microcephaly; retarded growth; and multiple skeletal abnormalities. The inheritance is autosomal dominant with variable expression [2]. McGhee *et al.* described an 11-year-old girl with Coffin–Siris syndrome and a *de novo*, apparently balanced reciprocal translocation t(7;22)(q32;q11.2). The 7q break-point in this patient was very similar to a previous report with a balanced translocation t(1;7)(q21.3;q34) [4,5]. Together, these patients provided evidence that the 7q32–q34 region contains the gene responsible for Coffin–Siris syndrome. The condition should be distinguished from Coffin–Lowry syndrome (see p. 12.56), which is a completely unrelated syndrome due to a defect in the *RSK2* gene on the X chromosome.

Dwarfism–alopecia–pseudoanodontia–cutis laxa [1]

The cutaneous features of this rare autosomal recessive syndrome include generalized atrichia, unerupted teeth of both dentitions, hyperconvex nails and cutis laxa with fragile skin, which is slow to heal. Other features include dwarfism, deafness, glaucoma, keratoconus, micrognathia, protruding lips, prominent supraorbital ridges, depressed nasal bridge, delayed bone maturation, skeletal abnormalities, hepatosplenomegaly, choanal atresia and hypoplastic mammary glands.

Oral–facial–digital syndromes

Four distinct clinical variants of oral–facial–digital (OFD) syndrome are recognized: OFD-I, OFD-II, OFD-III and OFD-IV.

Oral–facial–digital syndrome type I (MIM 300170)

SYN. PAPILLON–LÉAGE SYNDROME

Aetiology. This syndrome is present in about 1.5% of children with cleft lip or palate [1]. The familial incidence suggests X-linked dominant inheritance, lethal in the male [2–4], so that all affected patients seen are female. Wahrman *et al.* [5] described the condition in an XXY male. To identify the gene responsible for OFD-I, Ferrante *et al*. [6] analysed several transcripts that mapped to Xp22 and found mutations in the *CXORF5* gene. They investigated three familial and four sporadic cases of OFD-I. In the sporadic cases, they found a missense (*de novo*), a nonsense, a splice site and a frameshift mutation. RNA *in situ* studies on mouse embryo tissue sections showed that the Ofd1 protein is developmentally regulated and is expressed in all tissues affected in OFD-I syndrome.

Clinical features [3,7–9]. The profile is usually distinctive, with a short upper lip and hypoplastic alae nasi on a hooked pug nose. The frenula of upper and lower lips and tongue are hypertrophied. The tongue is bifid or multilobed and often shows small tumours, which lie within the clefts and are shown histologically to contain aberrant mucous glands and nests of smooth muscle [10]. Clefts of the hard and soft palates are frequent. The teeth may be widely separated and misplaced, and may develop early and atypical caries.

Deformities of the hands are regularly present, either a trident hand or varying combinations of brachydactyly, syndactyly and polydactyly.

The hair is often dry, coarse, lustreless and brittle. There is a variable degree of alopecia. Fine scales may be conspicuous on the scalp and the upper part of the face. Numerous milia may be seen on the face, ears and dorsa of the hands; some may erupt to leave scars.

Polycystic disease of the kidneys and liver has been present in some cases [4,10–12].

About half the patients are mentally retarded. Towfighi *et al.* [13] reported a variety of central nervous system malformations in OFD-I.

Extreme variability of expression of this syndrome has been observed [12]. Some affected individuals may show only minor oral or digital malformations. Dermatoglyphic studies are then of value in diagnosis [12,14]. Anneren *et al.* [15] suggested that irregular mineralization of the bones of the hands and feet is an important feature of OFD-I that distinguishes it from OFD-II.

Oral–facial–digital syndrome type II (MIM 252100)

SYN. MOHR'S SYNDROME

This genetically distinct syndrome is inherited as an autosomal recessive trait. First described by Mohr [1], features include polydactyly, syndactyly and brachydactyly, a lobate tongue, cleft palate, a normal or flaring alveolar ridge, and a broad bifid nasal tip. Rimoin and Edgerton [2] reported three affected siblings (two male and one female), and suggested that this syndrome should be called OFD-II. In addition to the different mode of inheritance, Mohr's syndrome shows none of the skin and hair changes seen in X-linked OFD-I, but does show conductive hearing loss and bilateral polysyndactyly of the halluces, not present in OFD-I. Gustavson *et al*. [3] reported two affected sisters. Balci *et al*. [4] reported two sisters with Mohr's syndrome from a consanguineous family. At post-mortem, in addition to the typical physical abnormalities of Mohr's syndrome, the fetus showed natal teeth and absence of the olfactory nerves, two features not previously reported in this syndrome. The authors stressed the role of early ultrasonographic examination as a means of prenatal diagnosis.

Oral–facial–digital syndrome type III (MIM 258850)

Sugarman *et al*. [1] reported a new form of OFD syndrome in two sisters. Features are mental retardation, eye abnormalities, lobulated hamartomatous tongue, dental abnormalities, bifid uvula, postaxial hexadactyly of hands and feet, pectus excavatum, short sternum and kyphosis. One of the sibs showed 'see-saw winking'. Inheritance is presumed autosomal recessive.

REFERENCE

1 Sugarman GI, Katakia M, Menkes JH. See-saw winking in a familial oral–facial–digital syndrome. *Clin Genet* 1971; **2**: 248–54.

Oral–facial–digital syndrome type IV (MIM 258860)

Baraitser [1] suggested the existence of a fourth type of OFD but recognized that considerable overlap of the features of the various forms gives rise to difficulties in precise clinical differentiation. The autosomal recessive mode of inheritance and severe tibial dysplasia differentiate type IV from type I.

REFERENCE

1 Baraitser M. The orofaciodigital (OFD) syndromes. *J Med Genet* 1986; **23**: 116–9.

Oculodentodigital dysplasia (MIM 164200)

SYN. OCULO-DENTO-OSSEOUS DYSPLASIA

This rare syndrome is determined by an autosomal dominant gene of variable expressivity [1–4].

The characteristic features of the syndrome are small eyes with microcornea, enamel hypoplasia and camptodactyly. The small, closely set, sunken eyes, small mouth with overlapping upper lip and the thin nose without alar flare produce a distinctive facies. There may also be malformations of the iris, hypertelorism, etc. Syndactyly of toes and fingers is associated with camptodactyly of the radially deviated fifth fingers. The teeth are yellowish.

In some cases, the scalp hair is sparse, dry and lustreless and fails to grow to its normal length. Eyebrows and eyelashes may be sparse or absent.

Paznekas *et al*. [5] analysed the connexin-43 gene (*GJA1*) located on chromosome 6q21–q23 as a candidate for oculodentodigital dysplasia and identified mutations in all 17 families studied; 16 different missense mutations and one codon duplication were detected. These mutations may cause misassembly of channels or alter channel conduction properties.

Berlin's syndrome [1]

This syndrome was described in two brothers and two sisters with stunted growth, 'bird-like' legs and severe mental retardation. The fine, thin, dry skin showed mottled pigmentation and leukoderma ('leopard skin'). The facies, with a flat saddle-shaped nose, thick lips and fine wrinkling around the eyes and mouth, recalled that of the Christ–Siemens type of ectodermal dysplasia. The dentition was delayed and incomplete. There were no vellus hairs.

Johanson–Blizzard syndrome (MIM 243800)

In this distinctive syndrome [1–4], which is probably due to autosomal recessive inheritance, there is congenital aplasia cutis of the scalp, sparse hair, deafness, absence of the permanent teeth buds and hypoplasia of the alae nasi. Other features include short stature, microcephaly, mental retardation, hypotonia, malabsorption due to pancreatic insufficiency, primary hypothyroidism and abnormalities of the genitalia and rectum. An association with diabetes has been reported [5].

Tricho-oculo-dermo-vertebral syndrome (MIM 601701) [1]

In this syndrome, the hair is sparse, dry and brittle, the nails are dystrophic and there is plantar keratoderma. There is kyphoscoliosis with short stature, cataract and other ocular defects.

REFERENCE

1 Alves AFP, dos Santos PAB, Castelo-Branco-Neto E *et al*. An autosomal recessive ectodermal dysplasia syndrome of hypotrichosis, onychodysplasia, hyperkeratosis, dwarfism, kyphoscoliosis, cataract and other manifestations. *Am J Med Genet* 1981; **10**: 213–8.

Curly hair–ankyloblepharon–nail dysplasia syndrome (CHANDS) (MIM 214350) [1]

This syndrome, believed to be of autosomal recessive inheritance, includes curly hair and the presence at birth of fused eyelids. The nails are hypoplastic, but sweating and teeth are normal.

REFERENCE

1 Baughman FA. CHANDS: the curly hair–ankyloblepharon–nail dysplasia syndrome. *Birth Defects* 1971; **VII**: 100–2.

Kirman's syndrome [1]

The original description was of a female with anhidrosis, almost total alopecia and severe mental retardation. Nails, teeth and breasts were normal.

REFERENCE

1 Kirman BH. Idiocy and ectodermal dysplasia. *Br J Dermatol* 1953; **67**: 303–7.

Hypoplastic enamel–onycholysis–hypohidrosis (MIM 189500) [1]

SYN. WITKOP–BREARLEY–GENTRY SYNDROME

The original description of this autosomal dominant syndrome included 10 members of a family.

There are defects of the teeth, nails and scalp. The skin is generally dry, with keratosis pilaris on the limbs. Hair is normal, but there is patchy scaling and crusting of the scalp. There is onycholysis and subungual hyperkeratosis. The teeth show a hypoplastic type of enamel defect with multiple unerupted teeth, which undergo absorption within the alveolus. There is a marked degree of facial hypohidrosis.

Jumlongras *et al*. [2] found linkage between this tooth-and-nail syndrome and polymorphic markers in the region harbouring the *MSX1* gene on chromosome 4p16 in a three-generation family [2]. Direct sequencing and restriction enzyme analysis demonstrated a heterozygous stop mutation in the homeodomain of *MSX1*. The precise function of this gene is as yet unknown but these findings clearly demonstrate its importance in ectodermal development.

Nail dystrophy–deafness syndrome [1]

SYN. ROBINSON'S SYNDROME

This syndrome, probably of autosomal dominant inheritance, combines widely spaced coniform teeth and small dystrophic nails with sensorineural deafness. Some affected individuals also have polysyndactyly and increased sweat chloride levels. The hair is normal.

In another family with congenital deafness and onychodystrophy, the inheritance appeared to be autosomal recessive [2].

Dento-oculo-cutaneous syndrome [1]

There may be taurodontia, pyramidal or fused molar roots. The fingernails are dystrophic, with longitudinal ridges and distal splitting. There are pigmented and indurated areas over the interphalangeal joints of the fingers. The philtrum is thick and wide, and there is ectropion of the lower lids.

Sandmann–Andra syndrome [1]

This type of ectodermal dysplasia was present in three generations of a family. Inheritance was of autosomal dominant type. The patients were hypohidrotic and the number of teeth was considerably reduced.

Ectodermal dysplasia with cataracts and hearing defects (MIM 154780) [1]

SYN. MARSHALL'S SYNDROME

This rare syndrome comprises mild defects of the teeth and sweating, with cataracts and deafness. Some patients also have other ocular defects. The facies is abnormal, with a short depressed nose and underdeveloped maxilla. This disorder has clinical overlap with Stickler's syndrome and mutation analysis of the *COL11A1* and *COL2A1* genes has confirmed that some cases of these disorders are allelic [2].

Oto-onycho-peroneal syndrome (MIM 259780) [1]

SYN. PFEIFFER'S SYNDROME

Two brothers have been reported in whom abnormal 'crumpled' pinnae were associated with partial or complete aplasia of the nails and fibulae.

REFERENCE

Deafness, onycho-osteodystrophy and mental retardation (MIM 220500)

SYN. DOOR SYNDROME; TRIPHALANGEAL THUMBS WITH ONYCHODYSTROPHY

At least three families have been reported in which sensorineural deafness was associated with absent or hypoplastic fingernails and toenails, triphalangeal thumbs and great toes, mental retardation and epilepsy. The inheritance appears to be autosomal recessive [1], although Goodman *et al.* [2] described a family with dominant inheritance.

Hypohidrosis with neurolabyrinthitis [1,2]

SYN. HELWIG-LARSEN–LUDWIGSEN SYNDROME

Sweat glands are absent or reduced in number in this autosomal dominant syndrome. There are no dental or hair anomalies. Neurolabyrinthitis develops between the ages of 35 and 45 years.

REFERENCES

Other ectodermal syndromes

The following syndromes are not strictly speaking ectodermal dysplasias, but they may be conveniently considered in this section.

Simple anhidrosis [1]

Very rarely, the complete absence of sweat glands may be inherited as an isolated defect, the epidermis being otherwise normal.

Knuckle pads, leukonychia and deafness (MIM 149200) [2]

SYN. BART–PUMPHREY SYNDROME

This rare syndrome is characterized by the association of knuckle pads, sensory deafness and leukonychia, all of which are present from early childhood. In some patients, palmoplantar keratoderma may develop later.

Deafness, with vitiligo and muscle wasting [3]

Two patients in one family have been described with early sensory deafness, vitiligo and marked muscle wasting of the hands, feet and legs.

Amelo-cerebro-hypohidrotic syndrome [4]

SYN. KOHLSCHÜTTER'S SYNDROME

This rare condition has been reported mainly from Germany and Switzerland. There may be X-linked or autosomal recessive inheritance. The syndrome is characterized by thin, yellow, hypoplastic tooth enamel and severe epilepsy in childhood, with progressive spasticity and mental retardation. The sweat and sebaceous glands are decreased in number. Most, if not all, patients have been male and most died in the first decade.

Hyperhidrosis, premature canities and premolar aplasia [5]

SYN. BÖÖK'S SYNDROME

In 18 patients in one family, aplasia of the premolar teeth was associated with premature greying of the hair and, in most patients, hyperhidrosis of the palms and soles. Inheritance was via an autosomal dominant gene.

Keratitis, ichthyosis and deafness (MIM 148210) [6–8]

SYN. KID SYNDROME

In 1915, Burns [9] described a patient with generalized keratoderma, keratitis and deafness. Skinner *et al.* [8] proposed the term 'KID syndrome'. Ichthyosis is usually present at birth, and erythematous and verrucous plaques may develop. These are well marginated with a serpiginous outline. There is also severe diffuse hyperkeratosis of the palms and soles with a characteristic reticulate surface pattern. Perioral furrows may also be seen, and leukoplakia has occurred in some patients.

Severe sensory deafness develops at birth or within the first 2 years of life. Photophobia and diminished visual acuity is reported in about 75% of patients, and this is due to a vascularizing keratitis. The condition may progress to blindness.

About half the patients have an increased susceptibility to cutaneous infections, but laboratory tests have failed to show any immunological defects [8].

In 50% of cases, there is hypotrichosis affecting the scalp, eyebrows and eyelashes. Dystrophic nails and diminished sweating have also been reported, and the condition is easily confused with hypohidrotic ectodermal dysplasia. It is thought to be inherited as an autosomal recessive trait. Richard *et al.* [10] have provided compelling evidence that KID syndrome is caused by heterozygous missense mutations in the gap junction connexin-26 gene, *GJB2*. In each of 10 patients with this syndrome, they identified a point mutation leading to substitution of conserved residues in the cytoplasmic amino terminus or first extracellular domain of connexin 26. One of these mutations was detected in six unrelated sporadic cases and also segregated in one family with vertical transmission of KID syndrome. These findings indicated the presence of a common recurrent mutation and established KID syndrome as an autosomal dominant disorder. Detailed functional analysis revealed that the mutant connexin 26 was incapable of inducing intercellular coupling *in vitro*. Decreased host defence and increased carcinogenic potential in KID syndrome illustrates that gap junction communication plays a crucial role not only in epithelial homeostasis and differentiation but also in immune response and epidermal carcinogenesis.

Growth retardation, alopecia, pseudoanodontia and optic atrophy (MIM 230740)

SYN. GAPO SYNDROME

A girl born to related parents was normal at birth but then developed hydrocephalus, almost complete hair loss, papilloedema and secondary optic atrophy [11]. Growth was retarded, and by the age of 9 years her facies was abnormal, with low-set ears, high-arched palate and pseudoanodontia (teeth were present but unerupted). A similar patient has been reported by Anderson and Pindborg [12]. To date, 15 cases have been documented [13].

Craniofacial dysostosis with hypertrichosis and hypodontia [14]

Two sisters who complained of ulcerated feet were found to have craniofacial dysostosis, hypertrichosis, hypodontia,

and ocular and cardiac defects. The condition had some similarities to the Treacher Collins type of mandibulofacial dysostosis.

Coffin–Lowry syndrome (MIM 303600) [15,16]

This condition shows dominant inheritance, but males are more severely affected. The facies is distinctive, with sunken eyes, a thin nose, sparse hair and thick prominent lips. There is severe mental retardation, short stature and hand anomalies, and the skin is loose and easily stretched. Skin biopsy shows intracytoplasmic inclusions suggestive of a lysosomal storage disorder. Molecular genetic studies have shown that Coffin–Lowry syndrome is caused by mutations in the *RSK2* gene, which is located on the X chromosome and encodes a ribosomal protein kinase [16].

Palmoplantar and perioroficial keratoderma with corneal epithelial dysplasia [17]

A boy has been reported with palmoplantar keratoderma, nail dystrophy, perioral keratoderma and bilateral corneal epithelial dysplasia leading to severe corneal scarring and impaired vision.

Polycystic brain associated with ectodermal dysplasia [18]

This is a neurocutaneous syndrome comprising brain cysts, irregular retinal pigment epithelium, thin hair, dystrophic nails and dental abnormalities.

Scalp–ear–nipple syndrome (MIM 181270) [19]

Scalp–ear–nipple syndrome is a rare autosomal dominant condition that causes aplasia cutis congenita of the scalp, alteration of the shape of the external ear, and hypoplasia of the nipple. Dental changes include widely spaced or missing secondary teeth; some patients have partial syndactyly of fingers and toes.

Syndromes associated with DNA instability

Xeroderma pigmentosum (MIM 278730 and 278700)

Definition [1]. Xeroderma pigmentosum (XP) is a rare autosomal recessive disease characterized by photosensitivity, pigmentary changes, premature skin ageing, neoplasia and abnormal DNA repair. Some patients with XP also have neurological complications.

Aetiology. The initial report of this disorder was made by Hebra and Kaposi in 1874 [2] and the term 'xeroderma pigmentosum', meaning pigmented dry skin, was introduced in 1882 [3].

XP is found worldwide in all races with an equal sex incidence. It occurs with a frequency of approximately 1 in 250 000 in Europe and the USA [4]. In Japan, the frequency has been reported to be higher (1 in 40 000) [5].

Inheritance is autosomal recessive; parents of affected individuals, who are thus obligate heterozygotes, are clinically normal. The genetic heterogeneity of the syndrome, suspected on clinical grounds, has been confirmed by experimental studies. There are at least eight different subtypes that are recognized, designated complementation groups A–G and XP variant (Table 12.5).

Cleaver first reported in 1968 [6], and in subsequent studies [7–9], that fibroblasts from most patients with typical XP lack the normal capacity to repair UV radiation damage to DNA. In 1970, Epstein *et al.* [10] showed that

Table 12.5 Nucleotide excision repair disorders. (Data compiled from published literature by A.R. Lehmann, Genome Damage and Stability Centre, University of Sussex, UK.)

Complementation group	Gene	Chromosome localization	Size of gene product (amino acids)	Activity	Comments
Xeroderma pigmentosum (XP)					
XP-A	*XPA*	9q22	273 (31 kDa)	Binds damaged DNA	Common; severe skin and neurological abnormalities
XP-B	*XPB*	2q21	782 (89 kDa)	Helicase. Part of TFIIH	Rare; only three kindreds, two with XP/CS, one with TTD
XP-C	*XPC*	3p25	940 (106 kDa)	Damage recognition	Common; severe skin abnormalities
XP-D	*XPD*	19q13	760 (87 kDa)	Helicase. Part of TFIIH	Common; severe + neurological abnormalities; also includes two cases of XP/CS and most cases of TTD
XP-E	*XPE*	11p12	427 (48 kDa)	Damaged DNA binding	Rare; mild features
XP-F	*XPF*	16p13	905 (103 kDa)	Nuclease subunit with ERCC1	Rare; fairly mild
XP-G	*XPG*	13q33	1196 (133 kDa)	Nuclease	Rare; severe + neurological abnormalities; half of cases have XP/CS
*Cockayne's syndrome (CS)**					
CS-A	*CSA*	5q12–q31	396 (44 kDa)	Transcription-coupled repair	Rare
CS-B	*CSB*	10q11	1493 (168 kDa)	Transcription-coupled repair	Common
Trichothiodystrophy (TTD)					
Most TTD patients are in XP-D group, one family in XP-B group, and one unique family in a separate TTD-A group. Gene not yet identified. Note that some TTDs have no repair defect. They cannot therefore be assigned to a complementation group					

* CS also found rarely in combination with XP in XP-B, XP-D and XP-G groups.

DNA repair was defective *in vivo*. Approximately 80% of patients with XP show a defect in the initiation of DNA excision repair of UV photoproducts [11–13]. In these patients, it has since been shown that repair replication is reduced in all cell types examined: epidermal cells, dermal fibroblasts, lymphocytes, conjunctival cells, corneal cells, liver cells and basal cell carcinoma cells [14]. It has also been demonstrated in amniotic fluid cells and used successfully for prenatal diagnosis of XP [15].

The unscheduled DNA synthesis assay (following UV irradiation of the cells in culture) is the standard laboratory method for diagnosis of XP [16].

In 1972, De Weerd-Kastelein *et al*. [17], by using cell fusion techniques, demonstrated genetic heterogeneity in the XP repair defect. Cultured fibroblasts from two different patients with XP are fused so that their nuclei coexist in the same cytoplasm (forming a heterokaryon). If both nuclei have the same defect, then the heterokaryon shows defective DNA repair after UV irradiation and the patients are in the same complementation group. If the nuclei have different defects, then each will supply what the other is lacking and DNA repair within the heterokaryon will be normal. The two patients are then said to be in different complementation groups. Within this group of patients, seven distinct complementation groups are recognized (A–G).

Nucleotide excision repair [18–20]. This process, whereby damaged DNA is removed and replaced with new DNA using the intact strand as a template, involves the products of some 30 genes [21]. The genes involved in nucleotide excision repair (NER) have now been cloned (Table 12.5). The excision repair cross-complementing (ERCC) genes are so called because of their ability to complement DNA repair in mutant rodent cells. The names of the XP genes have superseded those of the corresponding ERCC genes. The complete process of NER has now been reconstructed [22] (Fig. 12.15). The initial step in the process involves recognition of the damaged DNA by the XP-C protein together with its partner HR23B [23]. This results in the recruitment of the dual function transcription factor TFIIH, composed of at least six subunits including XP-B and XP-D proteins, which both have helicase activity. These helicases open out the structure at the damaged site. The exact function of the crucial XP-A protein is not clear, but it seems to have a role in verifying the positions of the other proteins on the damaged structure. This enables the structure-specific nucleases to incise the DNA. ERCC1-XP-F and XP-G are both structure-specific nucleases, which cut the DNA on either side of the damage. The repair-synthesis step requires DNA polymerase ε (polε), the replication accessory factor proliferating-cell nuclear antigen (PCNA) and replication factor C (RFC); the new DNA is then joined to the old by DNA ligase. As well as these proteins, the incision reaction is stimulated by the product of the *XPE* gene, which is the smaller subunit of a dimeric protein that binds specifically to UV-irradiated DNA and is thought to assist in the early recognition of cyclobutane pyrimidine dimers.

Subsequent studies have shown that a deficiency of NER is also associated with Cockayne's syndrome (CS) and trichothiodystrophy.

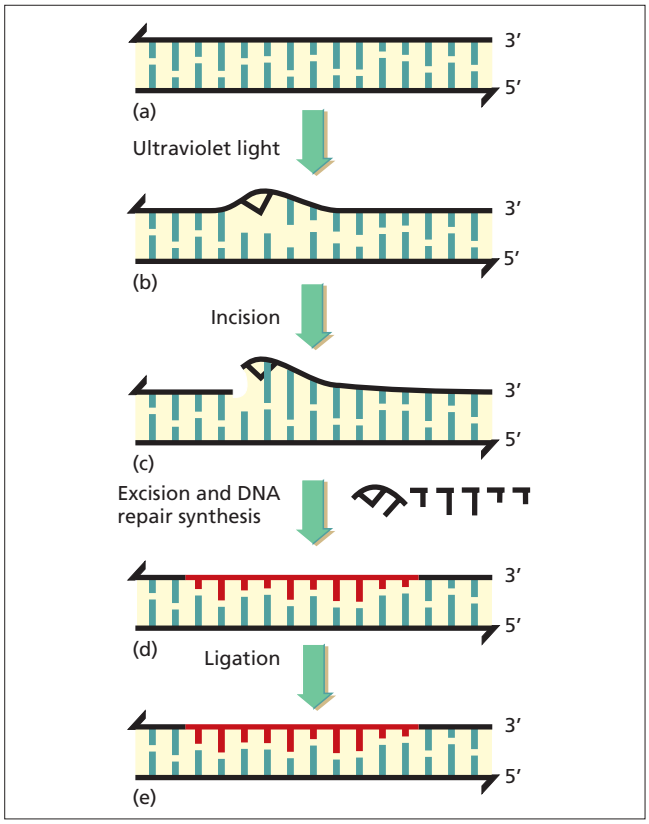

Fig. 12.15 Excision repair of pyrimidine dimers. Distortion in DNA double helix by pyrimidine dimer is located (b), the damaged strand excised (c), the dimer removed together with neighbouring nucleotides and the gap filled with new DNA (d); ligation (e) completes repair. (From Pawsey *et al.* [1].)

XP variant [24]. The other 20% of patients, called XP variants, have normal NER [25] but have a defect in an alternative repair process, known as post-replication or daughter-strand repair. XP variants have a defect that manifests as a reduced molecular weight of newly synthesized DNA in UV-irradiated cells and a delay in the production of intact high-molecular-weight DNA strands following UV irradiation [26]. Further, XP-variant fibroblasts are uniquely sensitive to caffeine inhibition of increase of molecular weight of newly replicated DNA after UV treatment [27]. The protein missing in XP variants is a novel DNA polymerase, designated polη, which is able to replicate DNA past UV-induced cyclobutane thymine dimers and some other types of DNA damage, in most cases inserting the 'correct' nucleotides opposite the damaged bases [28]. This property of polη contrasts with that of the DNA polymerases that carry out normal DNA replication. The latter are extremely accurate, but are blocked by most types of DNA damage.

Despite the substantial increase in our understanding of the genetics, it is still far from clear how these defects relate to the clinical diversity. The various subtypes of XP show clinical and epidemiological differences. The majority of patients in group C, which is most common in Europe and the USA, show no neurological defects. Patients in group A tend to develop neurological disease before the age of 7 years, whereas those in group D tend to develop neurological damage after this age [29].

Skin photosensitivity. XP is very variable in expression of sun sensitivity. The inconsistency noted in tests for light sensitivity no doubt reflects the heterogeneity of the syndrome. Some cases of the typical form show a papular and vesicular reaction, mainly to light in the 290–320 nm range [30]. The minimal erythema dose is lower than normal at most wavelengths [31].

XP and neoplasia. Cultured dermal fibroblasts from XP patients exhibit increased UV-induced mutagenesis. The neoplasms in XP patients, which occur predominantly on sun-exposed surfaces, are thought to be the result of UV-induced mutations [16]. Indeed, skin tumours from XP patients carry mutations bearing a 'UV signature' in the *p53* and *PTCH* genes [32,33]. UV exposure also triggers a complex series of signal transduction pathways that result in immunosuppression of the skin, which may well be an important factor [34,35].

Pathology. The histological changes in the fully developed case in the atrophic stage closely resemble those of senile skin. The epidermis is thin and flattened, and the dermal collagen shows basophilic degeneration. Irregular proliferation of rete pegs, heavily laden with pigment, is a distinctive feature. The keratoses and the various types of malignant tumour that ultimately complicate all but the mildest cases show no special histological characteristics.

Electron microscopic studies [36,37] show shrinkage of keratinocytes and their nuclei, and abnormalities of nuclear morphology. Melanocytes are also abnormal, with polymorphic melanosomes, and there may be giant pigment granules in melanocytes or keratinocytes. There are also abnormalities of desmosomes, the endoplasmic reticulum and mitochondria. The dermal fibroblasts appear to behave like macrophages and engulf melanosomes within vacuoles [37].

In hypopigmented macules the melanocytes are scanty, but Langerhans' cells are numerous [38].

Clinical features [4,39] (Fig. 12.16). The skin is normal at birth; the first symptoms are noticed between the sixth month and the third year in over 75% of cases, but may appear in very early infancy or in later childhood. Although the disease advances relentlessly and in orderly fashion through its successive stages, the rate of progression is unpredictable and bears no constant relationship to the age of onset. Most cases beginning in early childhood have reached the tumour stage before the age of 20 years,

Fig. 12.16 Xeroderma pigmentosum. (From Harper J. *Handbook of Paediatric Dermatology*, 2nd edn. Oxford: Butterworth-Heinemann, 1990.)

although a few run a more benign course and some cases of later onset may develop multiple tumours within a few years.

Freckling and increasing dryness on light-exposed surfaces are usually the earliest manifestations; they may follow an acute sunburn or more persistent erythema. The freckles appear first on the face and hands and later on other exposed parts, the neck and the lower legs, the lips and the conjunctiva; in severe cases the trunk is affected. Varying in colour from light to dark brown and in size from a pinpoint to a centimetre or more, they may fuse to form irregular patches of pigmentation. Fading at first in the winter months, they soon become permanent. As they increase progressively in number, telangiectases and small angiomas appear interspersed among them. Telangiectases and angiomas on unexposed skin and on the lingual and buccal mucous membrane have been reported. Small, round or irregular, white, atrophic spots are soon added to the picture. Some follow crusted vesiculobullous lesions; others arise independently. Superficial ulcers, healing with difficulty, leave disfiguring scars, and contractures may produce ectropion and obliterate the outline of the eyelids. Keratoacanthomas may form, even in the mildest cases, and resolve spontaneously in a few months. Actinic keratoses are frequent; they may separate spontaneously or may undergo malignant change.

The first malignant tumours may develop as early as the third or fourth year. Basal cell carcinoma is common and large numbers, sometimes pigmented, may appear over the course of years. Squamous cell carcinoma is also common. Squamous cell carcinoma of the anterior tongue, the portion that may be exposed to UV radiation, has been reported [40]. Melanomas arise and may be multiple; they may lead to early death from widespread metastases or may run a benign course, even in adults, although histologically malignant. Other malignant tumours, such as angiosarcoma and fibrosarcoma, may rarely occur.

The disease is often fatal before the age of 10 years, and worldwide two-thirds die before 20 years of age. These statistics have improved in those countries where children are adequately protected from the sun. Multiple metastases of squamous cell carcinoma or melanoma are one cause of death. However, many patients die from infection, to which they are abnormally susceptible, or from neurological complications [41]. Survival beyond middle age is sometimes possible in mild cases or with adequate treatment. Striking interfamily variation in expectation of life has been reported.

Ocular lesions [4,39]. The eyes are affected in some 80% of cases. Photophobia and conjunctivitis are common early symptoms. Ectropion and destruction of the lower lids expose the bulbar conjunctiva, and symblepharon and ulceration may occur. Pigmented macules on the conjunctiva are common. Vascular pterygium, corneal opacities and epitheliomas of the lids, conjunctiva or cornea may develop.

Neurological complications. Neurological abnormalities occur in approximately 20% of XP patients [39], with one or more of the following: mental retardation, areflexia or hyporeflexia [42], spasticity, ataxia, sensorineural deafness, dysphasia and abnormal electroencephalographic findings. Patients with neurological abnormalities usually have group A and D disease, although a few have been reported with group C and XP variant disease [39]. There is a positive correlation between the severity of neurological involvement and the sensitivity of XP fibroblasts to killing by UV radiation [4]. It is possible that DNA repair mechanisms are essential for maintaining the normal function of neurones, and progressive damage, perhaps caused by ingested or endogenous chemicals, might cause premature death of susceptible neurones.

De Sanctis–Cacchione syndrome [43–45]. This term has been applied to the association of XP with microcephaly, severe mental deficiency, dwarfism, hypogonadism, deafness, choreoathetosis and ataxia. Post-mortem findings show cerebral and olivopontocerebellar atrophy from neurone loss, without primary damage to white matter, or gliosis.

Associated abnormalities. XP patients are often of small stature and poor physical development.

XP with CS. Rarely, CS can be found in combination with XP in XP-B [46], XP-D [47], XP-G [48,49] and CS-B [50].

XP and SLE. An 18-year-old woman with the typical cutaneous and ocular changes of XP-C developed arthritis, anaemia and a high antinuclear antibody titre [51].

Dominant form of XP. An autosomal dominant form of XP was described in a Scottish kindred by Anderson and Begg [52]. These patients had a mild clinical course.

Diagnosis. In the fully developed case, the diagnosis is unmistakable. The mild or early case must be differentiated from ordinary freckling. Other forms of photosensitivity and premature ageing must be excluded. These include progeria, acrogeria, Rothmund–Thomson syndrome, Bloom's syndrome, CS, Hartnup's syndrome and hydroa vacciniforme.

Prenatal diagnosis by amniocentesis is possible [53], but for some families molecular genetic techniques are now available and allow for an earlier and more reliable result. DNA-based prenatal carrier detection for XP-A in a chorionic villous sample has been successfully performed [54].

Treatment. As soon as the diagnosis is established, patients must be protected from sunlight by every possible means. They must not go outdoors during daylight hours, except in the early morning or evening, and even then they should wear two layers of clothing and a broad-brimmed hat. All uncovered skin surfaces must be protected by a total sun-block cream, and sunglasses with side shields should be worn. UV radiation is harmful up to at least 320 nm, and some fluorescent lights can emit radiation below this wavelength. Chemical light screens can combine a cosmetic and protective function.

Early and adequate excision of all tumours is essential, and is to be preferred to radiotherapy because of the atrophic and degenerate state of the skin. Topical 5-fluorouracil may be useful for early or premalignant lesions. Chemical peeling and dermabrasion can also be helpful [55]. Plastic surgery and grafting of large areas of facial skin may sometimes be required [56].

There is now substantial evidence to suggest that oral retinoids reduce the occurrence of skin cancer in XP [57–59]. A trial of prophylactic therapy should therefore be considered.

The eyes may need to be treated with artificial tears, soft contact lenses or even corneal transplant. The relatives of known cases should be carefully examined and tested [30] so that mildly affected individuals may be detected at the earliest possible stage.

A recent clinical trial used the microbial enzyme T4 endonuclease V applied regularly as a topical liposome lotion. This enzyme is able to bypass the defect in XP cells. Employed over a period of 1 year, it significantly reduced the onset of both new basal cell carcinomas and actinic keratoses [60].

Cockayne's syndrome (MIM 216400)

Definition. An inherited syndrome characterized by short stature, mental deficiency, photosensitivity, disproportionately large hands, feet and ears, ocular defects and extensive demyelination.

Aetiology [1]. This rare syndrome affects the sexes equally; inheritance is determined by an autosomal recessive gene. Skin fibroblasts are abnormally sensitive to UV irradiation [2–4]. Unlike XP, the global NER process occurs normally in CS cells *in vivo* and *in vitro*. However, CS cells are defective in an important subpathway of NER. Following DNA damage, it is of prime importance for the cell to remove damage from actively transcribed regions of DNA, and in human cells repair is more rapid in transcribed than in untranscribed regions. This preferential repair is referred to as transcription-coupled repair, and it is this rapid preferential repair that is specifically defective in CS cells [5]. The associated failure of cells to restore normal levels of RNA synthesis after UV irradiation [6] has provided a means for carrying out complementation tests on CS cells and two complementation groups have been identified, CS-A and CS-B [7] (Table 12.5). The products of the two known CS genes, *CSA* (chromosome 5) and *CSB* (chromosome 10q11–q21) are envisaged to fulfil a transcription-coupled repair function [8]. CS can rarely be found in combination with XP (see p. 12.60).

Clinical features [9–11]. Although very early onset has been reported in a significant minority of cases, the child usually appears normal for the first year, when facial erythema in the butterfly distribution develops after exposure to sunlight. This provokes repeated exacerbations, which may be febrile. The sensitivity to light is eventually lost, but not before mottled pigmentation and atrophic scars have given the patient a prematurely senile appearance, which is enhanced by the progressive loss of subcutaneous fat on the face and the sunken eyes. The skin

elsewhere shows little change, although the long limbs and disproportionately large hands and feet are often blue and cold. The association of these striking features with large protruding ears has suggested a fanciful resemblance to Mickey Mouse. The hair is usually normal but may be sparse and has sometimes been prematurely grey.

Physical and mental development are greatly retarded and the child remains dwarfed, although sexual maturation occurs in some cases [12]. Optic atrophy, retinal degeneration and cataracts [13] lead to loss of vision, and progressive deafness is usual but variable in degree. Skeletal deformities [14] and limited joint movement increase the child's disabilities. There is extensive diffuse demyelination of the peripheral nerves and the central nervous system [10]. Survival beyond the second decade is unusual, although two affected brothers, aged 42 and 55 years, have been reported [15].

Diagnosis. Progeria has frequently caused confusion, since dwarfism and a prematurely senile appearance are characteristic of both syndromes, and in both the child appears normal in its first year. The light sensitivity, ocular defects, normal hair and disproportionately large extremities are typical of CS. In Rothmund–Thomson syndrome, the cutaneous changes begin in early infancy and affect the buttocks and extremities as well as the face. In Bloom's syndrome, the erythema of face and hands is associated with growth retardation, but mental development is normal. The condition is distinguished from XP by the unusual facies, the demyelination with delayed nerve conduction velocity, the lack of cutaneous malignancy [10] and the normal level of global NER. Prenatal diagnosis is possible by amniocentesis [16,17] or from chorionic villous samples, using the RNA synthesis recovery test.

Bloom's syndrome (MIM 210900) [1]

SYN. CONGENITAL TELANGIECTATIC ERYTHEMA AND STUNTED GROWTH

Definition. The syndrome is characterized by telangiectatic facial erythema, short stature, a distinctive facies, abnormal immune response and predisposition to malignancy.

Aetiology [2,3]. Bloom's syndrome is determined by an autosomal recessive gene. Males are affected more frequently than females and the majority have been Jewish. Cultured lymphocytes and fibroblasts from patients show a high incidence of chromosomal aberrations; cultures from parents have sometimes shown similar changes [4]. Cells with abnormally high rates of sister-chromatid exchange are uniquely characteristic of Bloom's syndrome [2,5]. The gene for Bloom's syndrome (*BLM*) has been mapped to chromosome 15q26.1 [6,7] and has been identified as a DNA helicase [8,9]. This helicase is thought to be involved in resolving abnormal structures that can arise during DNA replication.

Clinical features [2,10–14]. Bloom's syndrome patients bear a striking resemblance to each other. They have a narrow, slender, delicate facies with a relatively prominent nose. The essential features are erythema of the face and stunted growth (both prenatal and postnatal). The telangiectatic erythema develops during infancy or early childhood as red macules or plaques, which may simulate lupus erythematosus. They are most numerous on the 'butterfly' area of the nose and cheeks, but may involve the margins of the eyelids, the forehead and the ears, and sometimes the dorsa of hands and forearms. There may be slight scaling. Exacerbation after exposure to sunlight is usual but not invariable, and light may also provoke bullae, bleeding and crusting of the lips.

Birth weight is low, and growth disturbance is proportionate and of moderate degree. The build is slender and the skull dolichocephalic (head circumference disproportionately smaller compared with height).

Other associated abnormalities include [13,15] café-au-lait patches, clinodactyly, syndactyly, congenital heart disease, annular pancreas and a high-pitched voice, possibly due to the craniofacial anatomy and high-arched palate. Many associated developmental defects have been reported.

Testicular atrophy is common and adult male patients appear to be infertile. Although the tubular elements of the testes function poorly, the androgen-secreting portions are spared, thus permitting normal puberty [16]. Fertility in female patients remains unknown, although one female patient had a full-term pregnancy [17].

There are no impairments of neurological development; however, most under-perform at school [18]. Some develop unusual personality features and behavioural patterns secondary to their unusual appearance and small size [12].

The mortality from neoplastic disease, particularly acute leukaemia, during the second or third decade is significantly increased [3–5,19]. Cancers of the types and sites seen in the general population arise frequently and unusually early. They are predominantly internal rather than cutaneous malignancies [14]. Reported associations include B-cell lymphoma [20] and Wilms' tumour [21].

Poikilodermatous syndromes

Dyskeratosis congenita (MIM 305000)

SYN. ZINSSER–COLE–ENGMANN SYNDROME

Definition. Dyskeratosis congenita (DKC) is a rare inherited disorder characterized by atrophy and pigmentation of the skin, nail dystrophy, leukoplakia, bone marrow failure and a predisposition to malignancy.

Aetiology. The syndrome is rare, but widely distributed. It was first described in 1906 by Zinsser [1], and later by Cole *et al.* [2] and Engmann [3]. Most reported cases have been in males, although the full syndrome [4] and partial forms with only pigmentary changes [5,6] have occurred in females. The available pedigrees suggest that it is usually determined by an X-linked recessive gene, localized to Xq28 [7]. Using a positional cloning strategy, the gene was subsequently identified with five different missense mutations in five unrelated patients. *DKC1* is highly conserved across species barriers and is the ortholog of rat *NAP57* and *Saccharomyces cerevisiae CBF5*. The peptide, referred to as dyskerin, contains several motifs and multiple phosphorylation sites. By analogy to the function of the known dyskerin genes in other species, involvement in the cell cycle and nucleolar function has been predicted for the protein [8]. Autosomal dominant inheritance has also occurred [9–11].

Pathology [9]. The cutaneous changes are not pathognomonic and are unimpressive. The epidermis is flattened; the dermis is vascular and contains pigment-laden macrophages and an inconstant lymphocytic infiltrate. The connective tissue is usually normal.

Clinical features [9,11–17]. The essential features of the syndrome are atrophy and pigmentation of the skin, nail dystrophy and oral leukoplakia. The nail changes are usually the first to appear. Between the ages of 5 and 13 years, the nails become dystrophic and are shed: they may be reduced to horny plugs or be completely destroyed. There may be recurrent episodes of suppurative paronychia.

The pigmentary changes may appear simultaneously or 2 or 3 years later, and reach their full development in 3–5 years. Fine, reticulate, grey–brown pigmentation is most conspicuous on the neck (Fig. 12.17) and thighs, but involves the greater part of the trunk. The skin is atrophic, and telangiectases may be sufficiently numerous to give a

Fig. 12.17 Dyskeratosis congenita: reticulate pigmentation on the neck.

Fig. 12.18 Dyskeratosis congenita: the development of leukoplakia.

poikilodermatous appearance. The skin of the face is red and atrophic, with irregular macular pigmentation, while that of the dorsa of the hands and feet is diffusely atrophic, transparent and shining. The palms and soles may be thickened and hyperhidrotic, and may form bullae with trauma.

A 9-year-old girl with DKC was reported who had, in addition to the known manifestations of the disease, tufts of hairs on the limbs and an early onset of keratinized basal cell papillomas on her trunk [18].

The onset of the mucous membrane lesions may coincide with, or follow, the nail and skin changes. Small blisters and erosions of the lingual and buccal mucous membranes are succeeded by irregular patches of leukoplakia (Fig. 12.18). Similar changes on the tarsal conjunctiva may obliterate the lacrimal puncta, resulting in excessive lacrimation and soreness and scarring of the lids, and anorectal or urethral leukoplakia may produce stenosis. Similar changes may occur throughout the gastrointestinal tract and on the urogenital mucous membranes. Gastrointestinal complications include oesophageal stricture and portal hypertension [19]. Another recognized complication is interstitial pneumonia [20].

General physical and mental growth is sometimes retarded. Intracranial calcification may occur [21]. The teeth tend to be defective and irregularly implanted, and periodontal disease and early caries are usual. The hair may be normal but is sometimes sparse and dry. Premature canities and cicatricial alopecia [15] have occasionally been noted. Various immunological defects have been reported [10,22].

Malignancy. The incidence of carcinoma in the areas of leukoplakia appears to be high; it may prove fatal between the ages of 30 and 50 years. Carcinoma has also developed on other mucosal surfaces and in atrophic skin. Other neoplasms reported include pancreatic carcinoma and Hodgkin's disease. In a review of 104 cases [14], 12% had developed one or more tumours at the time of reporting (mean age of patients at reporting was 21 years).

Haematological abnormalities [6]. Many cases have shown blood dyscrasias, myeloid aplasia, refractory anaemia or pancytopenia. Haematological manifestations are usually added to the clinical picture from the age of 10 years. The resulting infection or haemorrhage is an important cause of death [22]. Rarely, neutropenia can be an early finding [23].

Prognosis. The prognosis is usually poor, for either the blood dyscrasia or carcinoma may prove fatal. However, in some patients only nail dystrophy and pigmentation are present [21], and in such cases the expectation of life is normal.

Diagnosis. Because of the relatively late onset of the characteristic features of this syndrome, their relationship is often overlooked for some years [16]. Rothmund–Thomson syndrome has often been confused. Here, erythema of the face, buttocks and limbs in infancy is progressively succeeded by poikiloderma. Nail changes are unusual and leukoplakia does not occur. In anhidrotic ectodermal dysplasia the dental changes, distinctive facies, sparse or absent hair and normal nails provide points of differentiation.

Treatment. The aplastic anaemia associated with DKC can be successfully treated by allogeneic bone marrow transplantation; however, this approach does not reverse the other systemic manifestations of the syndrome [24,25]. Granulocyte colony-stimulating factor has been used successfully to improve haematological parameters in the short term [23,26].

Retinoids have been reported to cause regression of lesions in leukoplakia [27] and so may reduce the incidence of malignancy.

Greither's syndrome [1]

This syndrome, reported in two brothers, has many features in common with DKC but appears to be distinct. Warty keratoses are irregularly distributed over the dorsa of the hands and feet and on the legs. The soles show large islands of keratoderma. Poikiloderma, with a prominent pigmentary component, is conspicuous on the face, hands, arms, feet and legs. The nails and hair are normal.

Rothmund–Thomson syndrome (MIM 268400)

SYN. POIKILODERMA CONGENITALE

Aetiology. Rothmund–Thomson syndrome is a rare hereditary disorder, occurring predominantly in females (1.4 : 1) and determined by an autosomal recessive gene [1–3]. The initial description by Rothmund [4] referred to children with cataracts and a peculiar degeneration of the skin. Thomson [5] described sisters with similar skin changes and subsequently [6] labelled the disorder as 'poikiloderma congenitale'. Cataracts were not a feature of his cases. Taylor [7] reviewed the literature and proposed the eponym of Rothmund–Thomson syndrome. The spectrum of clinical features suggests some degree of genetic heterogeneity. There have been several reports of various karyotypic abnormalities, including trisomy 8 mosaicism [8,9]. Reduced DNA-repair capacity and increased sensitivity to UVC have been reported in individual patients [10,11]. Genes responsible for Werner's syndrome and Bloom's syndrome have been identified as homologues of *Escherichia coli RecQ*, which encodes a DNA helicase that unwinds double-stranded DNA into single-stranded DNA. Kitao *et al*. [12] have reported three patients with Rothmund–Thomson syndrome who carried two types of compound heterozygous mutations in a further member of this family, known as *RECQL4*. The fact that the mutated alleles were inherited from the parents in one affected family and were not found in ethnically matched controls suggest that mutation of *RECQL4* at 8q24.3 is responsible for at least some cases of Rothmund–Thomson syndrome.

Pathology [13]. In childhood, the histological changes are flattening and atrophy of the epidermis, with oedema of the dermal–epidermal junction. There may be some vasodilatation and perivascular lymphocytic infiltration in the dermis. In the adult, the exposed skin shows the combination of fragmentation of elastic tissue in the dermis with patchy Bowenoid dyskeratosis of the epidermis.

Clinical features [2,7,14–20]. The skin appears normal at birth. The earliest lesions usually develop between the third and sixth month, but sometimes as late as the second year. Plaques of erythema and oedema, or more transitory

diffuse erythema, are succeeded by varying combinations of atrophy, telangiectasia, pigmentation and depigmentation. The pigmentation, dull brown in colour, irregularly macular or reticulate, develops later than the atrophy and telangiectasia on which it is superimposed, although it may extend much beyond these areas, especially on the neck and trunk, where it may be the only change. On the face and hands telangiectasia predominates. Ultimately the lesions closely resemble chronic radiodermatitis.

The cheeks are first and most severely involved, but the forehead, chin and ears seldom escape. The hands, forearms and lower legs are next affected, and the buttocks and thighs are frequently involved. Light sensitivity is a feature of many cases, and exposure to sunlight may extend the distribution of the eruption on the upper trunk; however, it is not limited to light-exposed skin, and the poikiloderma may develop without preceding erythema. Light sensitivity may be so severe that a bullous response is elicited, and although this tends to diminish after early childhood, it may persist into adult life [13,18].

Once they have reached their full development in early life, the skin lesions tend to remain unchanged, but in many cases keratoses develop on exposed skin from adolescence onwards, and large warty keratoses of hands, wrists, feet, ankles and elsewhere may restrict the patient's activities [21]. Squamous carcinoma may develop in the keratoses or in the surrounding atrophic skin [2].

Scalp hair is often sparse and fine, and may be absent. Eyebrows and eyelashes and pubic and axillary hair are often sparse or absent. Nails are normal or small and dystrophic. Teeth are often normal, but microdontia and early caries have been reported.

Bilateral cataracts have developed, usually between the fourth and seventh year, in about 40% of reported cases, and are more frequent in some families than in others.

Physical development is frequently retarded; most patients are of small stature and some are dwarfs. The dwarfism is proportionate, with slender delicate limbs, small hands and feet, and short stubby fingers. The skull may be small and the features bird-like, sometimes with a saddle nose. Hypogonadism of slight or severe degree is frequent and the incidence of hyperparathyroidism appears also to be increased [22]. The association of Rothmund–Thomson syndrome and Addison's disease has also been reported [23].

Skeletal abnormalities include radial ray defect [24], which may present as thumb hypoplasia with an abnormal radial head, or complete absence of the radius. There is a recognized risk of osteosarcoma, especially in the bones of the lower leg, which can present in childhood [19,25–27].

Other associations reported include myelodysplastic syndrome [28], malignant eccrine poroma [29], malignant fibrous histiocytoma [30] and annular pancreas with duodenal stenosis [31].

Individuals with Rothmund–Thomson syndrome are usually of normal intelligence. Life expectancy depends on the development of an associated malignancy; otherwise it appears to be normal.

Associated features. Amino-aciduria has occasionally been reported, but has been of no consistent type. One patient had osteogenesis imperfecta [32].

Diagnosis. The essential features in differential diagnosis are the age of onset, the distribution of the lesions and the combination of atrophy, telangiectasia and mottled pigmentation, most intense on light-exposed skin but not necessarily confined to it.

In Werner's syndrome, the skin changes are essentially sclerodermatous, and both skin and ocular lesions develop later than in Rothmund–Thomson syndrome. In DKC, reticulate pigmentation develops between the ages of 5 and 13 years, and is most marked on the neck, trunk and thighs. Atrophy and telangiectasia may appear later. The nail changes are constant and severe. In progeria, the child is often small but otherwise normal during the first year; thereafter development is retarded. The scalp hair, eyebrows and eyelashes are lost and the skin assumes an increasingly senile appearance. In CS, light sensitivity is a conspicuous feature after the first year, but there is no poikiloderma. Hypohidrotic ectodermal dysplasia should be identified by the association, in variable combinations, of conical teeth, hypotrichosis and partial or complete anhidrosis. The skin is atrophic but not poikilodermatous. XP should not cause confusion. In mild forms, only freckle-like macules are present; in mild forms of Rothmund–Thomson syndrome telangiectasia is the conspicuous feature. Telangiectasia, often irregular, linear and present at birth, is a feature of focal dermal hypoplasia. In Bloom's syndrome, erythema, and not poikiloderma, is the essential change. Congenital poikiloderma is a feature of other hereditary syndromes (see below).

Treatment. Protection against sunlight is important. Careful supervision is essential to ensure detection of carcinoma. Low blood concentrations of vitamin A have been found in patients with dyskeratoses [1], and in one case the lesions improved with retinoids [33]. Telangiectasia, especially on the face, can be improved significantly by treatment with the vascular pulsed dye laser [34].

Acrokeratotic poikiloderma of Weary [1]

This syndrome, probably determined by an autosomal dominant gene, appears to be a distinct entity. Ten members of a family were affected. The main clinical features were (i) a vesiculopustular eruption of hands and feet in infancy and childhood; (ii) extensive eczema from around 4 months to 5 years; (iii) persistent poikiloderma, sparing only the face, scalp and ears; and (iv) warty papules on hands, feet, elbows and knees.

REFERENCE

1 Weary PE, Manley WF, Graham GF. Hereditary acrokeratotic poikiloderma. *Arch Dermatol* 1971; **103**: 409–22.

Kindler's syndrome [1,2]

Kindler's syndrome is an autosomal recessive disorder characterized by neonatal blistering, sun sensitivity, atrophy, abnormal pigmentation and fragility of the skin. It has been considered to be a variant of acrokeratotic poikiloderma of Weary. Linkage and homozygosity analysis in an isolated Panamanian cohort and in additional inbred families mapped the gene to 20p12.3. Loss-of-function mutations were identified in the *KIND1* gene encoding kindlin-1. Kindlin-1 is a human homologue of the *Caenorhabditis elegans* protein UNC-112, a membrane-associated structural/signalling protein that has been implicated in linking the actin cytoskeleton to the extracellular matrix.

Other poikilodermatous syndromes

These include the diffuse and atrophic macular dermatosis of Stevanovic and hereditary sclerosing poikiloderma of Weary (see Chapter 46).

Miscellaneous syndromes

Bazex–Dupré–Christol syndrome (MIM 301845)

SYN. BDC SYNDROME; BAZEX SYNDROME; FOLLICULAR ATROPHODERMA AND BASAL CELL CARCINOMAS

First described by Bazex *et al*. in 1964 [1,2], the mode of inheritance is now known to be X-linked dominant with evidence of linkage to Xq24–q27 [3]. This represents the

identification of a gene presumed to be involved in hair follicle development and skin tumour formation. Several large family pedigrees have been studied [4–7]. The essential features are follicular atrophoderma, present from birth, and the development of multiple basal cell carcinomas of the face from adolescence onwards. In infancy and childhood, milia are often present. The follicular atrophoderma affects the dorsa of the hands and feet, and sometimes large areas on the extensor surfaces or lower back are affected. The exaggerated follicular funnels ('ice-pick' marks) are caused by deep and lax follicular ostia rather than a true atrophy. The basal cell carcinomas present as lightly pigmented papules, which resemble melanocytic naevi.

Inconstant features include facial hypohidrosis with or without generalized hypohidrosis [8]; hypotrichosis, which in males is diffuse and affects all scalp hairs, whereas females tend to have normal hairs intermingled with abnormal hairs; and hair-shaft abnormalities, like pili torti and trichorrhexis nodosa [6,9]. The condition is easily distinguished from Gorlin's syndrome (see Chapter 36). It must not be confused with a completely different disorder, acrokeratosis paraneoplastica, a cutaneous marker of malignancy that has also been labelled as Bazex syndrome [10].

Focal facial dermal dysplasia (MIM 136500)

The focal facial dermal dysplasias are a genetically heterogeneous group of disorders characterized by congenital, bitemporal, round, scar-like lesions with or without associated facial anomalies. Kowalski and Fenske [1] proposed a classification for this group of disorders: type 1, autosomal dominant; type 2, autosomal recessive; and type 3 with other facial features (Setleis' syndrome).

Brauer [2] originally reported a large kindred in which the inheritance was autosomal dominant. The facial lesions were described as scar-like and varied in size. Hair was absent in the lesions and no sweating could be demonstrated. Apart from the temporal defects, no other abnormalities were noted.

Setleis *et al.* [3] subsequently described five children from three apparently unrelated Puerto Rican families with scar-like defects on each temple and other features: (i) an aged, leonine appearance; (ii) eyelashes that were either absent from both eyelids, or in multiple rows on the upper eyelids and absent on the lower; (iii) eyebrows that slanted sharply upwards and outwards; (iv) puckered skin around the eyes; (v) a scar-like median furrow on the chin; and (vi) a nose and chin that felt rubbery. Histology revealed a thin epidermis and dermis with little elastic tissue and absence or scarcity of adnexae. Inheritance was assumed to be an autosomal recessive trait.

Jensen [4] described two northern English families with temporal scars and eyelash abnormalities, one with autosomal dominant inheritance and the other autosomal recessive.

McGeoch and Reed [5] documented 31 affected persons in six generations of an Australian family with pigmented atrophic lesions on the temples and linear radiating depressions on the forehead. In addition, clefting and hairless depressions on the chin were described. Autosomal dominant inheritance was clearly demonstrated.

The genetic basis for this group of disorders is unclear. Ward and Moss [6] reported an affected 14-month-old boy, his sister and mother. They all had similar facial features, with sparse lateral eyebows, a prominent upper lip and down-turned mouth. Additional features in the baby included medial epicanthal folds and skin dimpling on one side of the chin. Inheritance was presumed to be autosomal dominant and they proposed that focal facial dermal dysplasia and Setleis' syndrome are a single disorder.

Focal dermal hypoplasia (MIM 305600)

SYN. GOLTZ SYNDROME

Definition and aetiology. Focal dermal hypoplasia is a rare multisystem condition in which developmental defects of the skin are associated with ocular, dental and skeletal abnormalities. Approximately 200 cases have been reported, although the incidence is likely to be underestimated, as mildly affected subjects may go unrecognized. Most affected individuals have been female, and X-linked dominant inheritance with lethality in males has been proposed as the likely mode of inheritance [1]. Rare male cases [2] could reflect half chromatid mutations [3].

Pathology [4,5]. The foci of dermal hypoplasia show extreme reduction in thickness of the dermis, so that subcutaneous fat is situated almost immediately beneath the epidermis. There is debate [3] about whether the defect is primarily an atrophy of the dermis, with secondary fat 'herniation', or a complex developmental abnormality of connective tissue causing both dermal hypoplasia and the development of fat hamartomas [6]. The frequent presence of dermal elements, including collagen and elastin fibres, below the superficially situated fat and the ultrastructural demonstration of immature adipocytes within the fat tend to support the latter view.

Ishii *et al*. [5] reported a histopathological study of focal dermal hypoplasia and concluded that the adipose tissue in the dermis was the result of dermal dysplasia and not hypoplasia.

The papillomas show markedly acanthotic epithelium overlying a core of vascular connective tissue.

Clinical features [3,4,7–10]. Findings vary from easily overlooked mild skin atrophy to severe limb deformity and life-threatening complications. Skin involvement has been present in all but two of the reported cases [11] and is usually regarded as essential for the diagnosis. It remains possible that undiagnosed gene carriers occur with non-cutaneous features alone.

The typical skin lesions, which are present at birth, consist of asymmetrical linear streaks of atrophy and telangiectasia. The linear patterning follows Blaschko's lines. In racially pigmented skin, the lesions may be hypopigmented or hyperpigmented rather than erythematous. Soft reddish-yellow nodules represent the so-called 'fat herniations' (Fig. 12.19). Raspberry-like papillomas are common on the lips, perineum and at other sites, including the ears, fingers, toes, buccal mucosa and oesophagus [12]. Multiple giant papillomas have been reported [13]. In addition, generalized dryness of the skin and pruritus may be features. Nails may be absent or dystrophic. The hair is usually sparse and brittle, and there may be patchy alopecia of the scalp or pubic area. A case of focal dermal hypoplasia presenting as congenital localized alopecia has been reported [14].

Fig. 12.19 Focal dermal hypoplasia: herniation at the site of skin atrophy.

Short stature and slender build are usual, and mental development is sometimes retarded. The facial features are characteristic: the skull is small and rounded, the chin is pointed and the facial outline is triangular, with protruding ears. The alae nasi may be asymmetrical and notched. Face, trunk and limbs may be asymmetrical. Other skeletal malformations include scoliosis, but most characteristic is syndactyly, polydactyly or absence of one or more digits. A 'lobster-claw' type of deformity may result. Two girls have been reported with overlap features of focal dermal hypoplasia and EEC syndrome [15]. Ocular defects [12,16,17] are frequent and include microphthalmos, anophthalmos, coloboma, strabismus, keratoconus and corneal opacification.

Intestinal malrotation and mediastinal dextroposition have been described in association with focal dermal hypoplasia [18].

On radiological examination, osteopathia striata, seen as fine, parallel, vertical, radio-opaque stripes in the metaphyses of the long bones, are found in a large proportion of cases [19,20]. This finding is not pathognomonic, but is present in approximately 20% of gene carriers and can be a useful feature, particularly if the condition is suspected in minimally affected subjects [3]. Expansile bone lesions are also seen in some cases [21,22]. Osteochondroma of the humerus was diagnosed in a 12-year-old girl with focal dermal hypoplasia [23].

Diagnosis. The presence of the lesions from birth and the association of linear streaks of atrophy and telangiectasia with soft fatty nodules and malformations of the digits confirms the diagnosis. MIDAS syndrome (*mi*crophthalmia, *d*ermal *a*plasia and *s*clerocornea) has been reported as distinct from focal dermal hypoplasia [24,25].

Treatment. These children often require reconstructive surgery. Intubation for general anaesthesia must be undertaken cautiously, as papillomas may be present in the upper respiratory tract [26].

The telangiectatic skin lesions can be improved cosmetically with the vascular pulsed dye laser.

Nail–patella syndrome (MIM 161200)

SYN. HEREDITARY OSTEO-ONYCHODYSPLASIA (HOOD) SYNDROME

The nail–patella syndrome was first described by Turner in 1933 [1] and Aschner in 1934 [2]. It is determined by an autosomal dominant gene of variable expressivity but high penetrance. Linkage between the ABO blood group and nail–patella loci has been established [3,4] and the gene is located on chromosome 9q34.1 [5]. Mutations in the presumed transcription factor *LMX1B* cause nail–patella syndrome. Dreyer *et al.* [6] found *de novo* heterozygous mutations in the *LMX1B* gene in three unrelated patients with nail–patella syndrome. Functional studies showed that one of these mutations disrupted sequence-specific DNA binding, whereas the other two mutations resulted in premature termination of translation.

The syndrome combines nail and skeletal defects [7–12]. The nails are dystrophic in 95% of cases, either from birth or early childhood. The thumbnails are most severely involved and may be absent or small, thickened and depressed. Nails of other fingers, and sometimes of the toes, may also be affected. The lunula may be triangular.

In only 20% of cases is there aplasia of the patella, but in another 70% there is subluxation of the patella. Other skeletal defects include the presence of posterior iliac horns [13,14], clavicular horn [15], dislocation of the radial heads, scoliosis and thickened scapulae [16–18].

Hyperpigmentation of the pupillary margin of the iris (Lester iris) occurs in 45% of cases.

Various renal abnormalities have been recorded, including glomerulonephritis, renal dysplasia and Goodpasture's syndrome [19–22]. In cases with glomerulonephritis, there is damage to the basement membrane, with deposition of C3 and IgM in the mesangium. Electron microscopy of the skin has shown thickening and redundancy of the epidermal basement membrane, and it has been postulated that there may be a generalized defect in basement membranes [16]. Drut *et al.* [23] studied the kidneys of an 18-week spontaneously aborted fetus of a mother with nail–patella syndrome. Ultrastructural examination of the kidney showed irregular thickening of basement membranes with subendothelial fibrillar electron-dense deposits. Immunofluorescence showed fibrinogen deposition in glomerular basement membranes.

Clubbing of the fingers and toes (MIM 119900)

SYN. HIPPOCRATIC FINGERS; ACROPACHY

Definition. A swelling of the soft tissues of the terminal phalanx of a digit that obliterates the angle between the base of the nail and the digit. This can be quantified by a shadowgram technique [1].

Hypertrophic osteoarthropathy (HOA) is often associated with clubbing, but the prevalence of these two conditions in different diseases is very different. HOA can occur without clubbing, and whereas clubbing is almost universal in cyanotic congenital heart disease, HOA is very uncommon in this condition. Until further evidence is available, they should be considered as separate entities [2].

In thyroid acropachy, clubbing is associated with thickening of the soft tissues of the hands and feet, and periosteal new bone formation occurs in the hands and feet rather than the long bones [3–5].

Aetiology. Clubbing may occur early as a hereditary defect in otherwise healthy individuals. An autosomal gene of variable penetrance and expressivity is probably responsible [6,7], and there is suggestive evidence [8] that hereditary predisposition may play some part in the more common acquired forms.

The acquired form is associated with cyanotic congenital heart disease, bronchopulmonary disease, subacute bacterial endocarditis, cirrhosis, ulcerative colitis, Crohn's disease, chronic diarrhoea and malabsorption [9–11]. Clubbing does not occur in animals other than humans.

Pathology and pathogenesis. Increased fibrous tissue separates the nail from the phalanx, and there may be perivascular lymphocytic infiltration. The bone is not usually affected, but spurs of bone may occasionally form on the terminal phalanx. Many studies have shown that the blood flow to clubbed fingers is increased, except in hereditary clubbing [11]. The flow returns to normal if the clubbing improves after elimination of the causative pathology. It is possible that the increased blood flow travels through the central Suquet–Hoyer canals of the digital arteriovenous anastomoses. There is at present no single satisfactory theory to account for the hyperaemia and soft-tissue overgrowth, and there may be several mechanisms. Four hypotheses have been proposed [11].

1 A *circulating vasodilator*, which is normally inactivated by the lungs, could account for the clubbing due to those cases of cyanotic heart disease in which venous blood bypasses the lungs. Possible vasodilators include ferritin [1,11,12], prostaglandins [13], bradykinin and 5-hydroxytryptamine [14]. It has been suggested that mast cells might release vasoactive mediators that cause clubbing, although mast cells are not increased in clubbed digits [15].

2 *Tissue hypoxia* could account for some cases, and the occasional occurrrence of clubbing following frostbite, trauma and SLE may be due to vascular occlusion [11].

3 *Neural factors* have been postulated to account for the link with gastrointestinal disease, and the development of clubbing in Crohn's disease after vagotomy [6].

4 *Genetic factors* may explain why clubbing, which is secondary to acquired diseases, does not occur in every case of that disease. Acquired clubbing and inherited clubbing can occasionally occur in the same family [16].

Clinical features [8]. The normal nail projects from the digit at an obtuse angle of about 160°, most clearly seen

on the thumbs. In clubbing, this angle is obliterated, and sometimes reversed. The nail plate usually shows increased curvature in one or both planes and the volume of the distal phalanx may be increased.

In hereditary clubbing, these changes begin gradually at, or soon after, puberty and commonly involve all fingers and toes. Rarely, they may be evident in infancy or early childhood [16].

In acquired clubbing, the onset is also usually insidious and may occur at any age, but even in severe cyanotic congenital heart disease it is seldom noticeable before the second year. It may be bilateral or unilateral, or may affect only one or two digits. In malignant pulmonary disease, the onset may be rapid and painful.

Diagnosis. The distinction between hereditary and acquired clubbing may be of great clinical significance, for clubbing may precede any other evidence of pulmonary neoplasm by many months. Hypertrophic osteoarthropathy always shows bone and often joint changes, and clubbing is merely one feature of the syndrome. Familial osteoarthropathy [17], a manifestation of avascular necrosis of phalangeal epiphyses, presents before puberty as enlargement and impaired mobility of interphalangeal joints.

Pseudoclubbing may be produced by the shortening of the fingernail, which accompanies osteolysis of the terminal phalanges, such as has occurred in workers engaged in the polymerization of vinyl chloride [18].

Unilateral or unidigital clubbing is usually due to a vascular abnormality, such as an aneurysm in the affected limb. Unilateral clubbing can also be caused by neural damage, for example Pancoast's tumour, or prolonged hemiplegia.

Treatment. The secondary form may show some regression if the provocative disease is treated [19].

Pachydermoperiostosis (MIM 167100)

(see also Chapter 46)

Definition and terminology. Pachydermoperiostosis is a syndrome characterized by hypertrophic changes involving predominantly the skin and bones of the extremities. The term 'cutis verticis gyrata' describes a folded hyperplasia of the scalp that may accompany pachydermoperiostosis but also has other causes.

Aetiology [1,2]. *Primary pachydermoperiostosis* (syn. Touraine–Solente–Golé syndrome) is a rare developmental defect that has been reported in many races and which occurs predominantly in males. Its inheritance has been attributed to an autosomal dominant gene of variable expressivity [3]. Further studies should include a radiological survey of relatives. No chromosomal abnormality has been demonstrated.

Secondary pachydermoperiostosis (syn. secondary hypertrophic osteoarthropathy) may also depend on a hereditary factor, but is usually provoked by severe pulmonary disease, adenocarcinoma or epidermoid carcinoma of the bronchus, pleural mesothelioma, bronchiectasis, lung abscess or, less often, carcinoma of the stomach, oesophagus or thymus. In cyanotic congenital heart disease with clubbing, bone changes rarely develop.

Pathology [2,4]. Proliferative periostitis of the leg bones, especially in the diaphyses of the tibia, fibula, radius and ulna, leads to diffuse irregular periosteal ossification, increasing the circumference of affected bones without increasing their length. In severe cases, almost all bones may be involved, and ligaments, tendons and interosseous membranes may ossify. Abnormal ossification of the skull has been reported [5]. In the early stages, but not the

later stages, there is increased blood flow to the clubbed fingers [6,7]. The skin shows hypertrophy of collagen and of epidermis and epidermal appendages, and an increase of acid mucopolysaccharide.

Clinical features [2,8–11]. Primary pachydermoperiostosis usually begins soon after puberty. The skin of the face, forehead and scalp becomes grossly thickened and thrown into folds. The pattern of folds and furrows on the forehead and cheeks, and the heavy thickened eyelids, stamp the patients with a uniform expression of weariness and despair. The folding of the scalp produces one of the forms of cutis verticis gyrata. The skin of the hands and feet is also thickened, but usually not folded. Sebaceous activity is greatly increased on the face and scalp, and hyperhidrosis of hands and feet may be troublesome.

Thickening of the phalanges and of the bones of the limbs produces spade-like hands and feet on ungainly cylindrical arms and legs. The fingers and toes are clubbed. Acro-osteolysis of the fingers and toes may occasionally occur [7].

In one family, four members suffered from pachydermoperiostosis and peptic ulcer due to hypertrophic gastropathy (Ménétrier's disease) [12].

Skin and bone changes become progressively more severe for 5–10 years and then usually remain unchanged throughout life; exceptionally, they may continue to progress and the degree of sebaceous hyperplasia may become extreme. Sparse facial and pubic hair and gynaecomastia are present in some cases, but evidence of endocrine disturbance is equivocal. Many patients are mentally retarded, some of them severely. Expectation of life is reduced in such patients, although reliable figures for the less severely affected are not available. Working capacity is low.

Secondary pachydermoperiostosis occurs predominantly in men aged 30–70 years. The bone changes are the most obvious feature, develop more rapidly, and are often painful. The skin changes may be absent and are often relatively mild. If the primary disease can be treated effectively, the bone and skin changes will regress.

Radiological changes. The greatest periosteal thickening is seen in the diaphysis of metatarsals and metacarpals and the long bones of the limbs. There is some thickening of the cortex (Fig. 12.20).

Diagnosis. The primary and secondary forms of pachydermoperiostosis must be differentiated by the age of onset, the rate of progression and the presence of a pulmonary lesion. Although skin changes are more frequent in the primary form, their presence does not exclude a tumour.

Fig. 12.20 Pachydermoperiostosis: radiograph of the ankle. (Courtesy of Dr J. Savin, Edinburgh, UK.)

In acromegaly, the facial skeleton, jaw and skull as a whole are enlarged, and visual defects may be detectable. In thyroid acropachy, enlargement is confined to hands and feet, and exophthalmos and pretibial myxoedema are often present, with other signs of hyperthyroidism.

Acromegaloid phenotype with cutis verticis gyrata and corneal leukoma (MIM 102100) [1,2]

SYN. ROSENTHAL–KLOEPFER SYNDROME

In this rare syndrome, inherited via an autosomal dominant gene, there are acromegaloid facial features, for example a large jaw, but the sella turcica is normal in size. The horn-like projections of the lateral half of the supraorbital ridge are characteristic. There may be hyperplasia and folding of the facial skin. The scalp is enlarged, causing gyrate folds in the skin. The dermal ridges in the palms are split longitudinally. During the first decade of life, the cornea becomes opaque, often bilaterally. No endocrine abnormality has been detected.

The condition must be distinguished from cerebral gigantism (Sotos' syndrome) in which there is increased height and weight, with acromegalic features, large hands and feet, and mental retardation [2].

Short stature with pleonosteosis and periarticular fibrosis (MIM 151200) [1]

SYN. LÉRI'S SYNDROME

This rare condition is determined by an autosomal dominant gene. There is precocious and excessive ossification of the bones of cartilaginous origin (pleonosteosis), with short stature and mongoloid facies. From childhood onwards there is progressive periarticular fibrosis, especially in the hands. The palms and soles are thickened, with accentuated skin creases. There may be flexion contractures of the digits, broad thumbs and genu recurvatum.

The craniosynostoses

Craniosynostosis is the premature fusion of skull sutures in the neonate causing craniofacial malformation, often in association with other abnormalities. More than 100 syndromic forms of craniosynostosis have been described [1]. Most notable are the eponymously named, autosomal dominantly inherited syndromes of Apert, Crouzon, Pfeiffer, Saethre–Chotzen and Beare–Stevenson. There have been significant advances in understanding the genetic basis of many of these disorders, especially in relation to fibroblast growth factor receptor genes (Table 12.6).

Table 12.6 The main craniosynostosis syndromes.

Syndrome	Other features in addition to craniosynostosis	Chromosomal localization	Gene	Reference
Apert	Mid-face malformations, syndactyly of hands and feet, acne	10q26	*FGFR2*	[2]
Crouzon	Proptosis, acanthosis nigricans (AN)	10q26	*FGFR2* *FGFR3* (with AN)	[3] [4]
Pfeiffer	Broad halluces and thumbs	8p/10q26	*FGFR1/FGFR2*	[5,6]
Saethre–Chotzen	Ptosis, facial asymmetry, low hairline	7p21	*TWIST*	[7,8]
Beare–Stevenson	Cutis gyrata	10q26	*FGFR2*	[9]

FGFR, fibroblast growth factor receptor gene; *TWIST*, the human counterpart of the murine *Twist* gene, a basic helix–loop–helix transcription factor.

Apert's syndrome (MIM 101200) [1–4]

SYN. ACROCEPHALOSYNDACTYLY

Apert's syndrome is characterized by craniosynostosis, mid-facial malformations and symmetrical syndactyly. In a group of nine cases [5], all the seven who had reached puberty had severe or moderately severe acne vulgaris of unusually wide extent, with comedones on the arms and forearms as well as in the commonly affected sites. In a report by Henderson *et al.* [6], severe acne in two patients with Apert's syndrome responded well to isotretinoin therapy. Immunohistochemical studies of the skin showed no difference in the number of cells expressing androgen receptors between the patients with Apert's syndrome and controls. Other reported cutaneous associations with Apert's syndrome are hyperhidrosis [7] and oculocutaneous albinism [8].

Crouzon's syndrome (MIM 123500) [1]

SYN. CRANIOFACIAL DYSOSTOSIS

Crouzon's syndrome is characterized by craniosynostosis, maxillary hypoplasia, shallow orbits and ocular proptosis. Acanthosis nigricans is recognized to occur in some patients with Crouzon's syndrome [2].

REFERENCE

Pfeiffer's syndrome (MIM 101600)

In 1964, Pfeiffer [1] described a syndrome comprising craniosynostosis, broad thumbs, broad great toes and, in some, partial soft-tissue syndactyly of the hands. Other features may include umbilical hernia, malpositioned anus, bifid scrotum, widely spaced nipples, proptosis of eyelids, pre-auricular tag, absent external auditory canals, bifid uvula, supernumerary teeth and gingival hypertrophy. This is evidence of genetic heterogeneity.

Saethre–Chotzen syndrome (MIM 101400)

First recognized by Saethre in 1931 [1] and by Chotzen in 1932 [2], this syndrome is characterized by a broad and variable pattern of malformations, including craniosynostosis, low-set frontal hairline, facial asymmetry, ptosis, deviated nasal septum, brachydactyly, partial cutaneous syndactyly, especially of the second and third fingers, and various skeletal anomalies.

Beare–Stevenson cutis gyrata syndrome (MIM 123790) [1]

Beare–Stevenson cutis gyrata syndrome is characterized by the furrowed skin disorder of cutis gyrata, acanthosis nigricans, craniosynostosis, craniofacial dysmorphism, digital anomalies, umbilical and anogenital abnormalities and early death.

REFERENCE

1 Hall BD, Cadle RG, Golabi M *et al*. Beare–Stevenson cutis gyrata syndrome. *Am J Med Genet* 1992; **44**: 82–9.

Shprintzen–Goldberg syndrome (MIM 182212)

SYN. MARFANOID FEATURES AND CRANIOSYNOSTOSIS

This syndrome comprises a marfanoid phenotype with craniosynostosis. Associated features include scaphocephaly, facial dysmorphism, arachnodactyly, inguinal and umbilical hernias, and mental retardation [1]. Similar patients with normal mental development have been described [2,3]. Another patient had arachnodactyly, camptodactyly, clover-leaf skull, microcephaly, hydrocephaly, hypoplasia of the corpus callosum and choanal atresia/stenosis [4].

Curry Jones syndrome (MIM 601707) [1]

Five children were described with a striking asymmetrical facial appearance, craniosynostosis, pre-axial polysyndactyly, agenesis of the corpus callosum and unusual skin with streaky areas of atrophy. The gut and mucous membranes were involved in two of the patients.

REFERENCE

1 Temple IK, Eccles DM, Winter RM *et al.* Craniofacial abnormalities, agenesis of the corpus callosum, polysyndactyly and abnormal skin and gut development: the Curry Jones syndrome. *Clin Dysmorphol* 1995; **4**: 116–29.

Craniosynostosis and porokeratosis (MIM 603116)

A child with craniosynostosis and porokeratosis has been described [1]. In addition, he had hypospadias, anterior position of the rectum and incurving of the fourth toe bilaterally. Since the publication of the case report, a similarly affected sibling has been born, with the implication that this is a 'new' syndrome.

Cranio-ectodermal dysplasia (MIM 218330)

SYN. SENSENBRENNER SYNDROME

Sensenbrenner *et al.* [1] described an autosomal recessive syndrome of dolichocephaly, frontal bossing and antimongoloid palpebral fissures, hypertelorism, rounded cheeks and inverted lower lip, the teeth being grey, small and widely spaced, and the hair short and fine. The clinical features and neurosurgical management of a 9-month-old girl have been reported [2]. There have been other reports of craniosynostosis associated with different hair and bone abnormalities [3] and with short thin hair, dental abnormalities and short limbs [4].

SCARF (skeletal abnormalities, cutis laxa, craniostenosis, ambiguous genitalia, retardation, facial abnormalities) syndrome (MIM 312830)

Koppe *et al.* [1] reported two male maternal first cousins with a previously unreported pattern of malformations, including lax skin, joint hyperextensibility, umbilical and inguinal herniae, craniosynostosis, pectus carinatum, several abnormally shaped vertebrae, enamel hypoplasia and hypocalcification of the teeth, facial abnormalities and wide webbed neck, ambiguous genitalia, multiple nodular liver tumours, and mild psychomotor retardation. The possibility of X-linked recessive inheritance was proposed.

Sakati syndrome (MIM 101120)

Sakati *et al.* [1] described a syndrome consisting of acrocephalopolysyndactyly, short limbs, congenital heart defect, ear anomalies and skin defects. The ears were dysplastic and low set. A unilateral ear tag was noted. Patches of alopecia with atrophic skin were present above the ears. Linear scar-like lesions were observed in the submental area. The palate was narrow and arched, the neck short, the hairline low and the genitalia small.

Cornelia de Lange syndrome (MIM 122470)

SYN. TYPUS AMSTELODAMENSIS; AMSTERDAM DWARF

Aetiology. This syndrome was originally described in 1933 by Cornelia de Lange [1]. The cause is unknown. Most cases are sporadic, and it is difficult to reconcile the pedigrees of the occasional familial cases [2] with a pattern of inheritance, although it is probably autosomal dominant. Some features of the syndrome have occurred

in relatives [3,4]. Cornelia de Lange syndrome has been described in twins [5]. There is a high incidence of chromosomal abnormalities, although these are not consistent [6]. The dup(3q) syndrome simulates Cornelia de Lange syndrome but is probably fundamentally distinct [7,8].

Clinical features [2,6,9–14]. The child is underweight at birth and short stature becomes increasingly evident. Respiratory and feeding difficulties are frequent in infancy and the cry is feeble, low-pitched and growling. Mental retardation is usual, and is often severe.

The face is distinctive—grim, mask-like and expressionless—with a long upper lip and small nose with depressed bridge and anteverted nostrils. The eyebrows are bushy and confluent, and the eyelashes long and delicate. The lips are thin and the angles of the mouth turn down towards a receding chin. The teeth are widely spaced. The head, hands and feet are small, and a variety of skeletal anomalies may be present, usually of the upper limbs, including webbing and hyperextensibility of the digits. A distinctive radiological abnormality is a short, broad first metacarpal [15].

The hairline is low on the neck and forehead and there is hypertrichosis, which may be prominent on the forehead, the sides of the face, the back and shoulders and the extremities [16]. Marbling of the skin is conspicuous and persistent, and the skin around the eyes and nose may show a bluish tinge.

The nipples and the genitalia are sometimes hypoplastic.

The expectation of life is generally poor and most patients die in infancy or childhood, often from infections to which they are susceptible. However, some mildly affected individuals have shown relatively normal development [12].

Facio-digito-genital syndrome (MIM 305400 and 100050) [1–3]

SYN. AARSKOG SYNDROME

The inheritance is X-linked recessive. There are no pathognomonic features, but the condition is characterized by short stature and abnormalities of the face, digits and genitalia.

The facial changes include anteverted nostrils, a long philtrum, broad nasal bridge, hypertelorism and a 'widow's peak'. Various defects in the eyes and ears have been reported. The hands are short and broad, often with syndactyly and a simian line. There is a characteristic scrotal fold that extends dorsally to surround the base of the penis (the 'scrotal shawl'). Cryptorchidism and inguinal hernia also occur. Many patients also have skeletal defects and learning difficulties.

Positional methods have been used to clone the gene that is mutant in Aarskog syndrome. Pasteris *et al.* [3] isolated yeast artificial chromosome (YAC) clones spanning the t(X;8) break-point associated with the disorder. The *FGDY* gene contains more than 19 exons spanning 100 kb. The predicted length of the FGDY protein is 961 amino acids: it has strong homology to Ras-like Rho/Rac guanine nucleotide exchange factors and contains a cysteine-rich zinc finger-like region and two potential SH3-binding sites. Mutations in *FGDY* may result in perturbed signal transduction and, consequently, developmental growth anomalies.

Dubowitz syndrome (MIM 223370) [1,2]

This is an autosomal recessive condition in which there is low birth weight, slow growth, microcephaly, mental retardation and characteristic facies, with sparse hair, high sloping forehead, broad nasal bridge, ptosis, epicanthic folds and micrognathia. The voice is high pitched and hoarse. Eczema, vomiting and diarrhoea may occur.

Rubinstein–Taybi syndrome (MIM 180849) [1–3]

SYN. BROAD THUMB–HALLUX SYNDROME

Aetiology. Rubinstein–Taybi syndrome is due to a deletion at chromosome 16p13.3 [4–7], restricted to a region that contains the gene for the human CREB-binding protein (CBP), a nuclear protein that participates as a co-activator in cyclic AMP-regulated gene expression [8]. The occurrence of some features of the syndrome in relatives of patients has been interpreted as suggesting autosomal recessive inheritance. The majority of cases have been sporadic, although it has been reported in monozygotic twins [9,10]. Gillies and Roussounis [11] reported two families: in one, two siblings were affected; in the other, the uncle of the index case was affected and other members of the family were judged to show varying degrees of expression of the disorder.

Clinical features. The essential features of this complex and variable developmental syndrome are mental deficiency, small head, retarded somatic growth, broad thumbs and great toes, antimongoloid palpebral fissures, a high narrow palate and crowded irregular teeth [12]. The nose is often beaked and the ears may be malformed and low set.

A capillary naevus of the forehead or nape has been noted in over 50% of cases, and about the same proportion are said to develop hypertrichosis, especially of the back. The eyebrows may be heavy and highly arched, and the eyelashes long. Dermatoglyphic abnormalities are common. Patients with Rubinstein–Taybi syndrome seem to be prone to develop keloids [13–15]. There have been individual case reports of Rubinstein–Taybi syndrome associated with multiple pilomatricomas [16] and piebaldism [17].

Approximately one-third of cases have cardiac defects and the use of neuromuscular blocking agents such as succinylcholine during anaesthesia can provoke cardiac arrhythmias [18].

Marinesco–Sjögren syndrome (MIM 248800) [1,2]

Aetiology. The inheritance of this rare syndrome is determined by an autosomal recessive gene that has recently been shown to be allelic with the congenital cataracts–facial dysmorphism–neuropathy (CCFDN) syndrome. These disorders are caused by mutation in an as yet unidentified gene at 18qter [3].

Pathology. Degenerative changes occur in the central nervous system and are most severe in the cortex of the cerebellum [4,5]. There may also be involvement of the peripheral nervous system [6] and a myopathy [7,8]. Microscopy of the hair shows distinctive features [9]. The shafts show fractures, trichoschisis and points of impending fracture. In polarized light, irregular birefringence is seen. The internal root sheath fails to keratinize fully, and alkaline phosphatase activity persists above the normal level.

Clinical features [4,5,10,11]. Cerebellar ataxia is apparent as soon as the child begins to walk, and is associated with rotary and horizontal nystagmus and with dysarthria. Mental and physical development are retarded. Congenital cataracts and a variety of skeletal defects are commonly present. The teeth are malformed and the lateral

incisors may be absent. The nails are thin and fragile. The hair is sparse, fine, short, fair and brittle.

Seckel's syndrome (MIM 210600)

Definition and aetiology. The syndrome, defined but not first described by Seckel [1], is one of several to which the term 'bird-headed dwarfism' has been applied [2]. Its inheritance appears to be determined by an autosomal recessive gene. A distinct form of this syndrome [3] has been provisionally named the Montreal type. At least one form of Seckel's syndrome (SCKL1) can be caused by mutation in the gene encoding ataxia-telangiectasia and Rad3-related protein, which maps to chromosome 3q22.1–q24. Another locus for Seckel's syndrome has been mapped to chromosome 18p11–q11 [4].

Clinical features [2,5,6]. The constant features are growth retardation, microcephaly, mental deficiency, and a prominent beak-like nose dominating an otherwise hypoplastic face with large eyes. Skeletal defects are frequent [7,8]. The hair may be sparse and prematurely grey. The brain shows a grossly simplified cerebral structure.

Pigmentary changes, including streaks of brown pigmentation on the neck, groin and axillae, have been reported in a patient with Seckel's syndrome. Histological examination revealed pigment incontinence [9].

In the Montreal type [3], additional features include wrinkled and redundant skin of the palms, ptosis and cryptorchidism.

Diagnosis. The syndrome must be differentiated from others in which there is intrauterine dwarfism. Molecular genetic studies can be offered to families with known mutations in the *SCKL1* gene.

Russell–Silver syndrome (MIM 180860) [1–9]

This syndrome is a distinct form of intrauterine growth retardation associated with asymmetry. Over 150 cases have been reported; most are sporadic, although several familial cases have been described with the suggestion of heterogeneity [8]. Various chromosomal abnormalities have been found, with approximately 10% of cases showing maternal uniparental disomy for chromosome 7 [9].

The essential features are low birth weight at term, a relatively large head, shortness of stature, significant asymmetry, and elevated urinary gonadotrophins giving rise to premature sexual development [7]. Inconstant features are café-au-lait spots and other pigmentary changes, short incurved fifth fingers, syndactylism of the toes and a triangular face with down-turned corners of the mouth. The features are less marked in adult life.

Beckwith–Wiedemann syndrome (MIM 130650) [1–4]

SYN. EMG SYNDROME (EXOMPHALOS–MACROGLOSSIA–GIGANTISM)

This is a rare familial disorder, although most cases are sporadic and the aetiology is unknown. Inheritance is thought to be autosomal dominant with incomplete penetrance. Chromosome abnormalities have been reported, in particular relating to chromosome 11 [4]. It has been suggested that a placental endocrine defect may produce visceromegaly, which leads to various other complications.

The characteristic cutaneous changes are ear-lobe grooves and circular depressions on the rims of the helices, but the full syndrome includes macroglossia, omphalocele (umbilical hernia), visceromegaly (liver, spleen, pancreas, kidney, etc.), anomalies of intestinal rotation, neonatal hypoglycaemia, somatic gigantism, microcephaly and facial naevus flammeus. Many other metabolic and anatomical abnormalities have also been recorded, including immunodeficiency and a zosteriform rash at birth.

The hypoglycaemia, which is severe and resists simple therapy, is due to excessive insulin production by the enlarged pancreas. In some cases, pancreatectomy may be necessary to save the baby.

Children with this syndrome have an increased risk of developing hepatoblastoma, rhabdomyosarcoma and Wilms' tumour.

Cartilage–hair hypoplasia (MIM 250250)

SYN. METAPHYSEAL CHONDRODYSPLASIA OF MCKUSICK

This syndrome was first identified in the inbred Old Order Amish communities of the USA, among whom it occurs in around 1 in 700 live births; it is determined by an autosomal recessive gene [1]. The syndrome is not confined to these communities and its prevalence is high in Finland [2].

A high degree of dwarfism is associated with multiple skeletal deformities resulting from metaphyseal dysostosis. Sexual development is normal.

The hair is sparse, short, of very fine calibre and lighter in colour than in unaffected siblings, and is often very brittle [2–4]. Some affected individuals are almost bald. The filamentous and matrix proteins of the hair have no gross structural defects; decreased reactivity of some disulphide bonds may account for its abnormal biophysical and biochemical properties [3,5].

All patients show immunological defects, although only a proportion of them have increased susceptibility to infections. They have a decreased number of circulating T and B lymphocytes, although the immunoglobulin levels are essentially normal [2,6]. T-cell function is depressed, and studies of continuous T-cell lines have shown impaired interleukin-2 production and utilization, suggesting the presence of a G1-phase defect in the activation of T cells [7]. There is, however, preservation of spontaneous natural killer cell activity, and as not every patient suffers recurrent infections, this disease offers a unique model for studying the *in vivo* requirements for normal immunocompetence [8]. Using a positional cloning strategy and mutational analysis, Ridanpaa *et al*. [9] showed that mutations in the *RMRP* gene are responsible for this syndrome. Mitochondrial RNA-processing endoribonuclease cleaves mitochondrial RNA complementary to the light chain of the displacement loop at a unique site. The enzyme is a ribonucleoprotein whose RNA component is a nuclear gene product. The RNA component is the first RNA encoded by a single-copy gene in the nucleus and imported into mitochondria. The *RMRP* gene is untranslated, i.e. it encodes an RNA not a protein.

There are at least three other conditions in which metaphyseal chondrodysplasia occurs in association with immunodeficiency, but the hair is normal in these [6].

Popliteal pterygium syndrome (MIM 119500)

SYN. CLEFT LIP/PALATE; MUCOUS CYSTS OF THE LOWER LIP; POPLITEAL PTERYGIUM; DIGITAL AND GENITAL ANOMALIES

The first case was described by Trelot [1], but it was not until 1968 that Gorlin *et al.* [2] suggested the name 'popliteal pterygium syndrome'. Features of the syndrome include [3–5] popliteal pterygium (usually bilateral), intercrural pterygium, hypoplasia or agenesis of digits, valgus or varus deformities of the feet, syndactyly, cryptorchidism, absent or cleft scrotum, inguinal hernia, hypoplasia or aplasia of the labia majora, cleft lip and/or palate, lower lip pits, congenital bands of mucous membranes between the jaws, and filiform adhesions of the eyelids. Cunningham *et al.* [4] have reviewed the urological manifestations. The syndrome is inherited as an autosomal dominant trait and is known to show interfamilial and intrafamilial variable expressivity [5–7]. There is possibly an autosomal recessive form with more severe manifestations [8].

Van der Woude syndrome (MIM 119300) [1]

SYN. CLEFT LIP/PALATE WITH MUCOUS CYSTS OF THE LOWER LIP

This is an autosomal dominant condition in which there are lower lip pits, cleft lip and/or palate and hypodontia [2]. The penetrance is close to 100%, with variable expression [3,4]. Bocian and Walker [5] described a patient with congenital lower lip pits, who had an interstitial deletion of chromosome 1q. Wienker *et al.* [6] excluded linkage to a number of marker loci. Janku *et al.* [3] traced the syndrome through seven generations. Lip pits, the most common manifestation, were present in 88% of the affected cases and were the only manifestation in 64%. The pits, which vary from mere depressions to deep channels, may secrete small quantities of viscous saliva. Cleft lip/palate occurred in 21%. Other developmental defects, for example syndactyly, are sometimes associated. The recognition of lip pits, or a family history of lip pits, is important for genetic counselling [7].

Beals–Hecht syndrome (MIM 121050) [1–3]

SYN. CONTRACTURAL ARACHNODACTYLY

This condition, inherited as an autosomal dominant with variable expressivity, is characterized by tall stature, arachnodactyly and multiple congenital joint contractures of the fingers, knees, hips, elbows and ankles. The contractures tend to improve by adulthood. The ears are almost always 'crumpled'. Kyphoscoliosis is an inconstant feature. The condition must be distinguished from Marfan's syndrome (see Chapter 46) and from arthro-ophthalmopathy (Stickler's syndrome) [4].

Deafness and ear pits (MIM 125100) [1,2]

A dominantly inherited condition in which pre-auricular pits are associated with congenital deafness. The pinna may be normal or deformed, but there is a small pit anterior to the helix that frequently becomes infected and discharges. Injection of a radio-opaque dye may show that the pit communicates with the middle ear. The pits are bilateral and may be multiple.

In some cases, there may also be branchial cysts or cervical fistulae, and fleshy pre-auricular appendages also occur.

Repeated infections of the ear pit may be an indication for surgical excision, but it is important to ensure that the pit does not communicate with the middle ear or a deep sinus tract may ensue.

Dowling–Degos disease (MIN 179850) [1,2]

SYN. RETICULAR PIGMENTED ANOMALY OF THE FLEXURES

This rare condition is inherited via an autosomal dominant gene [3,4]. It usually presents in adult life (most frequently in the fourth decade) as numerous, small, round pigmented macules that resemble freckles. The axillae and groins are the usual sites, although other areas may be involved, including the intergluteal and inframammary folds, neck, scalp, trunk and arms [5]. Involvement of the genitalia, particularly pigmented lesions of the vulva, has been described [6]. Pigmentation is symmetrical and progressive, but is otherwise asymptomatic. The degree of pigmentation varies, but in some patients the lesions are almost confluent, giving a brown or black lace-like pattern.

Other features that may be present include scattered comedo-like lesions (dark dot follicles) and pitted acneiform scars near the angles of the mouth. One report described Dowling–Degos disease mimicking chloracne [7]. Dowling–Degos disease may be associated with hidradenitis suppurativa [8,9]. Occasional cases have been reported with mental retardation or trichilemmal cysts [10].

The histology is diagnostic, with a distinctive form of acanthosis, characterized by an irregular elongation of thin branching rete ridges, with a concentration of melanin at the tips. The condition involves the follicular infundibulum, and in some cases there is follicular plugging. The melanocyte count is normal [11].

These clinical and histological changes were memorably summarized by Wilson-Jones and Grice [12] as 'demonstrating dusky dappled disfigurements and dark dot depressions, and disclosing digitate downgrowths delving dermally'.

The histology distinguishes the disease from conditions such as acanthosis nigricans, multiple basal cell papillomas, epidermal naevi and the axillary freckles of neurofibromatosis.

It has been suggested that the Dowling–Degos disease as described above may be only one part of a spectrum of conditions that are characterized clinically by variable degrees of reticulate pigmentation, follicular plugging, pitted scars and facial erythema, and histologically by digitate budding and proliferation of the epidermis and follicular walls [10]. This would include some autosomal dominant conditions previously reported under different titles, such as Kitamura's acropigmentatio reticularis [13–18] and Haber's syndrome [19,20]. The latter is characterized by a rosacea-like eruption with keratotic plaques and pitted scars [21].

Chronic, infantile, neurological, cutaneous, articular (CINCA) syndrome (MIM 607115)

This syndrome was originally described by Ansell *et al.* in 1975 [1], and later termed CINCA syndrome by Prieur *et al.* [2]. It is characterized by a progressive arthropathy,

an urticarial rash usually present from birth, uveitis and mental retardation. Central nervous system involvement and deafness occur, although not necessarily apparent at presentation. Other features include short stature, delayed fontanelle closure, frontal bossing and a broad nasal bridge. Radiological findings are epiphyseal abnormalities, periosteal elevation along the shafts of the long bones and early patella ossification.

Dermo-chondro-corneal dystrophy (MIM 221800)

SYN. FRANÇOIS' SYNDROME

In 1949, François [1] described a brother and sister with the following features: firm nodular skin lesions on the dorsa of the hands and on the nose and ears; osteochondrodystrophy of the bones of the hands and feet, resulting in limitation of movement; and corneal dystrophy with white or brownish opacities. Since then, there have been other case reports [2–5], suggesting autosomal recessive inheritance.

A non-familial case of dermo-chondro-corneal dystrophy was reported in a 45-year-old woman who had severe involvement of the gingival and palatal mucous membranes [6]. Histology of an early skin lesion showed spongiocytes (large fibroblastoid cells), and in older skin nodules there was compact fibrous tissue with few cells and scarce vascularization. The authors proposed that this disorder was related to an abnormality of fibroblasts, with hyperproduction of type III collagen.

Oto-palato-digital syndrome (MIM 304120 and 311300)

Dudding *et al*. [1] first described this as a new syndrome, although the case reported by Taybi [2] probably had the same condition. It comprises short stature, distinctive facial appearance, cleft palate, hearing loss, and multiple skeletal abnormalities including short thumbs and short big toes. Wide spacing of the toes creates a resemblance to the foot of a tree frog. Inheritance is thought to be X-linked.

Fitch *et al*. [3] reported an infant with oral, cranial, facial and limb abnormalities in 1976. They presented a follow-up of their original patient in 1983 [4] and pointed out similarities to the oto-palato-digital (OPD) syndrome; they proposed that this be called OPD-II syndrome.

Congenital scalp defects with distal limb anomalies (MIM 100300)

SYN. ADAMS–OLIVER SYNDROME

There have been a number of reports [1–4] linking congenital scalp defects, often involving the underlying bone, with limb malformations ranging from hypoplasia of the fingers and toes to absence of the lower extremities below the knees. The inheritance pattern is unclear but is probably autosomal dominant with variable expression.

Cardio-acro-facial syndrome (MIM 122850)

SYN. RABENHORST'S SYNDROME

Grosse [1] described a syndrome comprising ventricular septal defect and pulmonary stenosis, narrow face with micrognathia, high and narrow nose with prominent septum, microstomia, attached earlobes and minor malformations of the hands and feet.

REFERENCE

1 Grosse FR. The Rabenhorst-Syndrome. *Z Kinderheilkd* 1974; **117**: 109–14.

Flynn–Aird syndrome (MIM 136300)

In 10 members of five generations of a family, Flynn and Aird [1] observed a neuroectodermal syndrome with similarities to the syndromes of Werner, Refsum and Cockayne. Clinical features included skin atrophy, ulceration, alopecia and dental caries.

REFERENCE

1 Flynn P, Aird RB. A neuroectodermal syndrome of dominant inheritance. *J Neurol Sci* 1965; **2**: 161–82.

Lacrimo-auriculo-dento-digital (LADD) syndrome (MIM 149730)

Hollister *et al.* [1] described a syndrome affecting a Mexican man and five of his eight children, the features of which were nasolacrimal duct obstruction, hypoplasia or aplasia of the lacrimal puncta, cup-shaped ears, hearing loss, hypodontia with enamel dysplasia, and various digital malformations.

Laryngo-onycho-cutaneous syndrome (MIM 245660) [1–3]

SYN. SHABBIR'S SYNDROME; LOGIC SYNDROME

Laryngo-onycho-cutaneous syndrome is an epithelial disorder confined to the Punjabi Muslim population. Shabbir *et al.* [1] described 22 patients from 12 families in Pakistan. The features included hoarseness, nail dystrophy and chronic skin ulceration, especially on the face. Inheritance is autosomal recessive. Similarity to junctional epidermolysis bullosa has been previously noted [3]. More recently, the gene has been localized to 18q11.2, the laminin α3 gene (*LAMA3*), in which loss-of-expression mutations cause the lethal skin blistering disorder Herlitz junctional epidermolysis bullosa. In laryngo-onycho-cutaneous syndrome there is N-terminal deletion of laminin α3a, confirmed by immunoprecipitation of secreted proteins from keratinocytes [4].

FG syndrome (MIM 305450)

The FG syndrome is an X-linked recessive syndrome comprising a number of congenital anomalies and mental retardation, first described by Opitz and Kaveggia [1]. The major features are mental retardation, mild facial dysmorphism, 'cowlicks' of the hairline, congenital hypotonia, relative macrocephaly and constipation [2]. Elia *et al.* [3] reported a boy with FG syndrome, who also had gingival hyperplasia and keloids.

Future directions

Every attempt has been made to provide an up-to-date overview of progress in the field of clinical and molecular genetics relevant to contemporary dermatological practice. However, no other field of medicine is changing more

rapidly than our understanding of the genetic basis of human diseases. The interested reader is strongly encouraged to consult the online information sources described, as these sites are continually updated.

It is also clear that significant ethical issues have emerged through such progress and great care will need to be taken to ensure that fundamental principles of privacy and confidentiality are maintained in the provision of excellence in medical care, particularly when issues relate not only to the individual seeking advice and treatment but also in relation to the extended family. It is also evident that prospects for improvement in therapeutic options for the amelioration of these disorders has never been greater.

Chapter 13

Prenatal Diagnosis of Genetic Skin Disease

R.A.J. Eady & J.A. McGrath

Introduction

Recent developments in clinical and molecular genetics and in fetal medicine have had an important role in the diagnosis, management and prevention of hereditary diseases and congenital abnormalities. Congenital malformations, single-gene defects and chromosomal abnormalities are increasing in their relative importance as causes of infant mortality and morbidity. In the USA, each year, 3–5% of more than 3 million live-born infants are affected by congenital defects or hereditary disease, and approximately 20% of all infant deaths today are the result of such disorders [1]. A total estimate of single-gene disorders could be between 1.3 and 1.7%, whereas chromosomal abnormalities with imbalance affect at least 0.5% of infants [2]. Such figures do not account for 'wastage' or the loss, by spontaneous abortion, of embryos and fetuses affected by developmental abnormalities. The impact of birth defects on society at large is thus very great, not least as a financial burden. Equally important is the effect on individual sufferers and families at risk of genetic disease.

Today, any couple planning to have a child cannot afford to ignore these new advances [3]. Prenatal diagnosis with appropriate counselling should be an integral part of the management of individuals or couples at risk of having children with a congenital or genetic disorder. Access to genetic counsellors is important for anyone seeking information about these risks, and the available options after the risk has been determined.

The purpose of prenatal diagnosis is the detection or exclusion of a hereditary disease or congenital defect *in utero*. The option of an elective abortion of affected pregnancies can help parents at risk of having affected children to produce normal offspring. A consequence of early prenatal diagnosis is that many pregnancies can proceed to term with the delivery of a normal child, instead of being terminated on the basis of a high risk.

The prenatal diagnosis of several genodermatoses is now well established. Over the past 20 years the techniques used have changed from being heavily reliant on the analysis of fetal skin biopsy samples acquired during the second half of the mid-trimester, to the examination of DNA from first-trimester chorionic villus samples [4]. Preimplantation genetic diagnosis is a further option that has more recently been introduced [5].

Methods in prenatal diagnosis

Previously, the techniques were largely limited to the detection of morphological or immunohistochemical abnormalities in fetal skin biopsies [1,2]. In addition, amniotic fluid and its cells may be used for diagnosing a variety of metabolic diseases with skin involvement. Fetal skin cells may also be used in the prenatal diagnosis of conditions that do not usually concern dermatologists. The biochemical analysis of skin-derived amniotic fluid

cells is discussed below. Fetal skin is also a potentially valuable source of fibroblasts, endothelial cells and Schwann cells.

Amniocentesis

Usually performed at about 16 weeks' gestation, amniocentesis is a convenient and relatively safe method of obtaining amniotic fluid and its cells for morphological, cytogenetic, biochemical or molecular (DNA) analysis. Amniotic fluid cells are derived from fetal epidermis, alimentary and genitourinary mucosa, and amnion. Gosden *et al*. [1] recognized at least 10 different types of amniotic fluid cell from normal fetuses. The proportion of viable cells derived from fetal epidermis is undetermined and may be no more than 10%. Examples of diseases that can be diagnosed *in utero* using amniotic fluid or cells include those exhibiting abnormalities of DNA synthesis and repair, usually in response to ultraviolet (UV) radiation (Table 13.1) [2–10], and inherited metabolic disorders, of which more than 100 have been diagnosed prenatally [11]. The demonstration of the primary protein defect in cultured amniotic fluid cells has the advantage of great reliability, but the disadvantage of a rather long waiting period for the parents, because the cultivation of sufficient fetal cells usually takes about 2–3 weeks [12].

Forming a major group in this second category are the storage diseases associated with a specific enzyme abnormality, such as Fabry's disease [13] or Farber's disease [14]. Other metabolic disorders that can be detected or excluded in the fetus include congenital erythropoietic porphyria [15], acute intermittent porphyria [16], X-linked ichthyosis [17] and Menkes' disease [18]. Raised maternal serum and amniotic fluid concentrations of α-fetoprotein have been reported in association with fetuses affected with epidermolysis bullosa (EB) simplex [19], or with EB and pyloric atresia [20].

Direct biochemical assays of chorionic villus samples obtained during the first trimester (see below) are feasible for nearly all enzyme defects that would otherwise be studied using amniotic fluid cells. In some cases, cultivation of chorionic villus cells is mandatory, otherwise direct examination is possible [12]. The prenatal diagnosis of Sjögren–Larsson syndrome has been based on the identification of a deficiency of the enzymes fatty aldehyde dehydrogenase and fatty alcohol oxidoreductase in cultured amniotic fluid cells or chorionic villus cells [21].

Table 13.1 Diseases exhibiting abnormalities of DNA or RNA synthesis or repair, or chromosomal instability.

Disease	Demonstrable abnormality
Bloom's syndrome	High numbers of sister chromatid exchanges in AFC [2]
Xeroderma pigmentosum	Abnormal DNA repair in AFC after UVR [3–5]
Cockayne's syndrome	Abnormal DNA repair [5], colony-forming ability [6] or RNA synthesis [7] of AFC in response to UVR
Fanconi's anaemia	Diepoxybutane-induced chromosomal breakage in AFC [8] and cultured trophoblast cells [9]
Ataxia telangiectasia	Clastogenic factor in AF and high spontaneous chromosomal breakage rate with translocation in AFC [10]

AF, amniotic fluid; AFC, amniotic fluid cells; UVR, UV radiation.

Ultrasonography

With the introduction of equipment capable of high-resolution and real-time operation, the potential information to be gained from ultrasound images of the fetus and other uterine contents is considerable. Ultrasonography is a powerful tool for the detection of central nervous system and skeletal disorders. The structural abnormalities present in a fetus affected with hereditary skin disease are usually microscopic and beyond the resolution of this technique. However, the 'snowflake sign' in the amniotic cavity may be a marker of fetal skin sloughing in certain disorders, including the form of epidermolysis bullosa that is associated with pyloric atresia [1,2] and a rare type of ichthyosis (see below).

Ultrasonography has been used successfully for fetal sexing [3] and in the diagnosis or detection of a variety of disorders including cutis gyrata syndrome [4], osteogenesis imperfecta [5], a thoracic cystic malformation associated with skin oedema [6], a benign facial skin tumour [7], a vascular abnormality [8], Neu–Laxova syndrome [9], Ellis–van Creveld syndrome [10] and harlequin ichthyosis [11]. Ultrasonography also has a key role in monitoring amniocentesis and fetoscopy, and is now largely used on its own (without fetoscopy) for fetal tissue sampling, including fetal skin biopsy.

Fetoscopy

This technique involves the insertion of a fibreoptic endoscope into the pregnant uterus (Fig. 13.1), using sedation and local anaesthesia, normally at 16–20 weeks' gestation. The main indications for fetoscopy are to enable direct visualization of the uterine contents, fetal blood sampling (usually from the umbilical cord) and tissue biopsy (e.g. from skin, liver or fetal tumour) [1,2]. Direct inspection has been of special value in identifying defects of facial features, limbs and digits, head and spine, anterior abdominal wall and genitalia, and has been used in prenatal exclusion of Cornelia de Lange syndrome and Goltz's syndrome [1,2]. Fetoscopy has also been used for taking samples of hair from the fetal eyebrow for the diagnosis of trichothiodystrophy [3].

The rate of fetal loss as a result of fetoscopy, in experienced hands, has been estimated at less than 5% [2]. Because other non-invasive methods for fetal imaging, such as high-quality ultrasonography, are constantly improving (see above), fetoscopy now has a more limited use. However, the newer microendoscopes are less invasive than the older, larger instruments, and may be preferred when direct inspection of the uterine contents is still required [4].

Fetal skin biopsy

This can be performed either with the aid of a fetoscope to visualize the fetus or, as is now becoming more widely practised, by relying solely on high-resolution imaging by modern ultrasound scanners. The samples are literally pinched out of the skin using a fine gauge forceps (Figs 13.1 & 13.2).

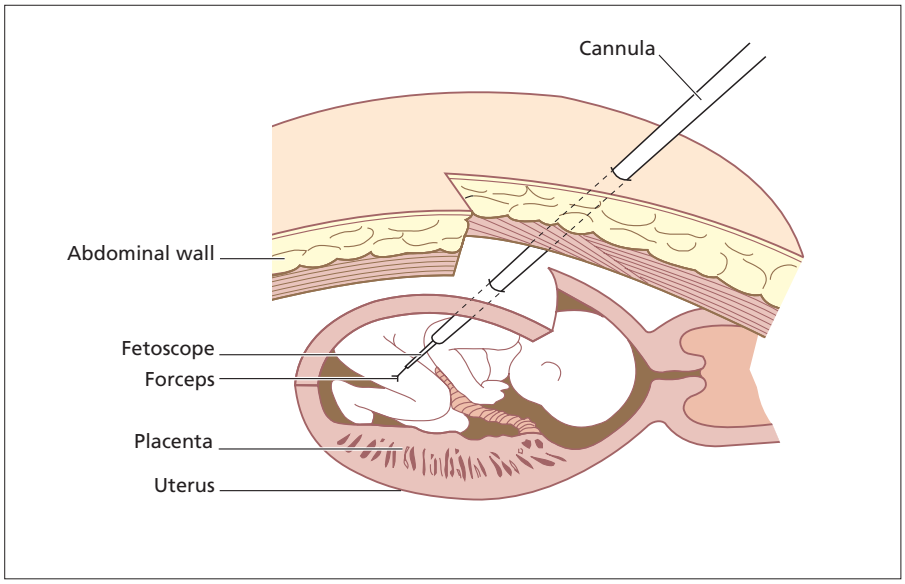

Fig. 13.1 Illustration of fetoscopy and fetal skin biopsy procedure.

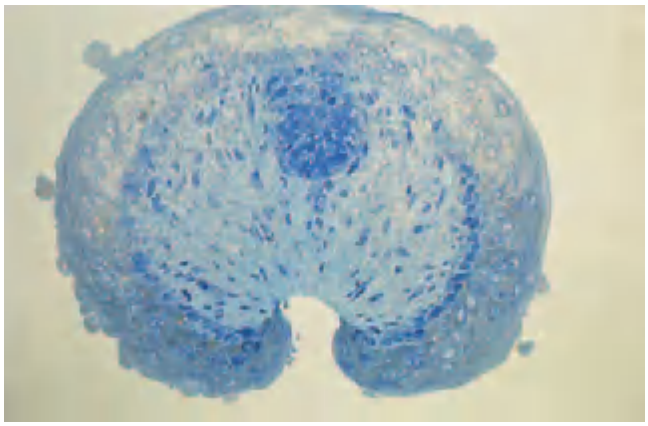

Fig. 13.2 Photomicrograph of semithin section of normal fetoscopic skin sample at 18 weeks' gestation (× 295).

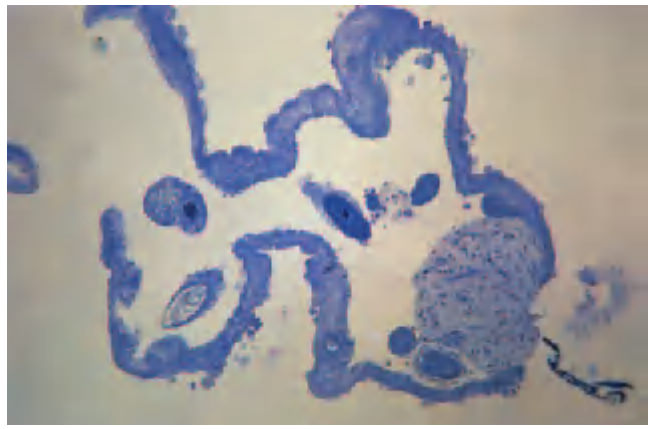

Fig. 13.3 Photomicrograph of fetoscopic skin sample from 18-week fetus affected with recessive dystrophic epidermolysis bullosa. Note extensive dermal–epidermal separation. Subsequent electron microscopy confirmed that the split was beneath the level of the lamina densa. Richardson's stain (× 150).

Light and electron microscopy

Fetal skin biopsy has been used to diagnose a variety of diseases associated with characteristic, if not specific, histological or ultrastructural changes [1–6]. The conditions include EB of the junctional [7] and dystrophic [8] types. The diagnosis is made at 15–18 weeks' gestation by finding a split in the dermal–epidermal junction by light microscopy (Fig. 13.3). The precise level of cleavage should then be determined by electron microscopy. Dermal–epidermal separation occurs in the lamina lucida of the epidermal basement membrane, and is associated with a hemidesmosome abnormality in Herlitz junctional EB (Fig. 13.4) [7], whereas in the dystrophic forms, separation takes place beneath the lamina densa [8]. Prenatal diagnosis of the Dowling–Meara form of EB simplex has also been made by light- and electron-microscopic demonstration of intraepidermal separation associated with clumping of keratin filaments [9].

Bullous congenital ichthyosiform erythroderma (epidermolytic hyperkeratosis) can be diagnosed at 20 weeks' gestation by detection of epidermal vacuolation and abnormal cellular inclusions (Fig. 13.5) [10] or, more specifically, highly characteristic tonofilament clumps in both fetal epidermal and amniotic fluid cells (Figs 13.6 & 13.7) [11,12]. Other types of ichthyosis amenable to this method of prenatal diagnosis include lamellar ichthyosis [13], Sjögren–Larsson syndrome [14] and harlequin ichthyosis [15,16]. For the latter, multiple skin samples are usually taken at 19–22 weeks' gestation from the scalp or other sites bearing hair follicles where the pathognomonic ultrastructural changes can be found (Figs 13.8a,b).

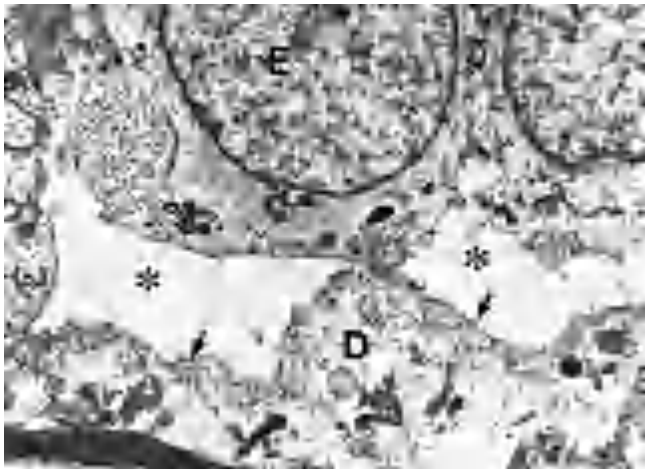

Fig. 13.4 Electron micrograph showing separation at level of lamina lucida (asterisks) between epidermis (E) and dermis (D) in fetal skin affected with junctional epidermolysis bullosa. Arrows indicate lamina densa at base of the split (× 6000).

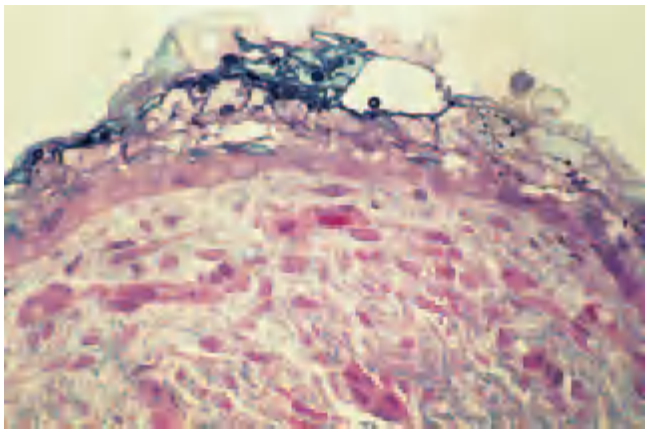

Fig. 13.5 Photomicrograph of semithin section of skin sample from 20-week fetus affected with bullous congenital ichthyosiform erythroderma. Note that severe vacuolation of the intermediate cell layers is present, even before the stratum corneum is formed. Periderm blebs are still evident at the epidermal surface (× 380).

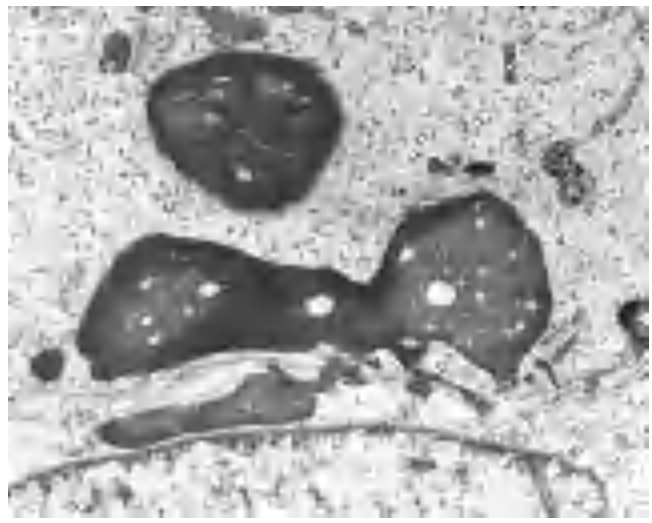

Fig. 13.6 Electron micrograph showing tonofilament clumps within epidermal cells of 20-week fetus affected by bullous congenital ichthyosiform erythroderma (× 17 500).

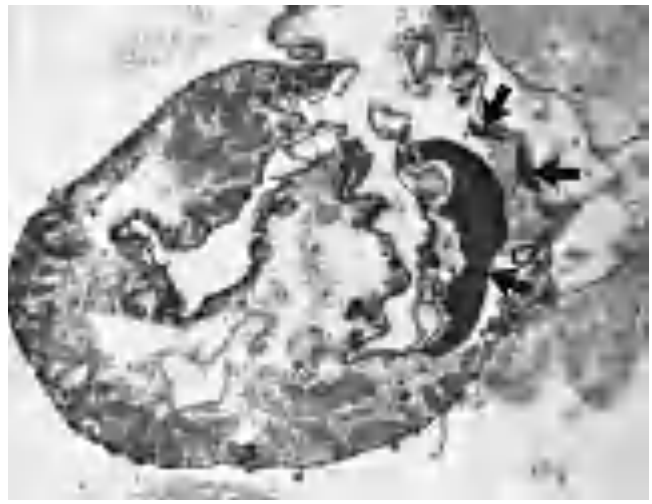

Fig. 13.7 Amniotic fluid cell derived from same fetus whose skin is shown in Figs 13.5 and 13.6, containing characteristic tonofilament clumps (arrows) (× 6720).

Another disorder in this group is a rare autosomal recessive form of ichthyosis in which the newborn is at high risk of asphyxia from aspiration of amniotic fluid with a high content of desquamated skin cells. This little-known skin disorder previously described as 'ichthyosis congenita type IV' [17] is characterized ultrastructurally by stacks of presumably lipid-rich membrane profiles in the cytoplasm of cells of the early keratinizing epidermis of the affected fetus (Fig. 13.9) and in amniotic fluid cells. A 'snowflake' type of appearance in the amniotic cavity may be seen by ultrasonography during the second trimester (D. Griffin, 1998, personal communication).

Ectodermal dysplasia [18] and tyrosinase-negative oculocutaneous albinism [19–21] have also been diagnosed at about 20 weeks' gestation using similar methods.

With rapid processing of the biopsy samples [21], the electron-microscopic findings can be reported within 24–48 h of obtaining the specimen in the laboratory.

Antibody probes [1]

A group of monoclonal antibodies reacting with components of the normal basement membrane zone has been invaluable, not only in the search for candidate genes and proteins in EB but also for diagnosis and prenatal diagnosis, especially when used with immunofluorescence microscopy (see Chapter 40). LH7.2 monoclonal antibody, which binds to the amino terminus of the type VII collagen molecule [2], has been used for the rapid prenatal diagnosis of recessive dystrophic EB (Hallopeau–Siemens) using indirect immunofluorescence microscopic analysis of skin samples from an 18-week fetus at risk for the disease [3] (Fig. 13.10). Using similar methods, a number of other monoclonal antibody probes may also be applied to EB diagnosis. These include GB3 (anti-laminin 5) and 19-DEJ-1 (anti-uncein) for the Herlitz form of junctional EB [4,5], anti-α6 and β4 integrin antibodies for the form of junctional EB associated with pyloric atresia [6,7], anti-bullous pemphigoid antigen 180 (BP180 or collagen XVII) for non-Herlitz junctional EB (generalized atrophic benign EB) [8] and anti-plectin for EB simplex associated with muscular dystrophy [9].

When fetal skin samples are being examined with these monoclonal antibodies, further sections from the same biopsies should be incubated with an anti-type IV collagen antibody to establish that the epidermal basement membrane is present and intact. This procedure may also be used for antigen mapping, to determine the level of splitting in the dermal–epidermal junction (see Chapter 40).

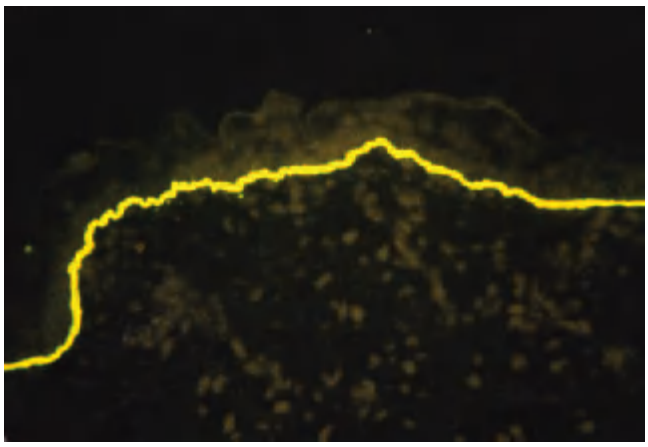

Fig. 13.10 Immunofluorescence photomicrograph of fetal skin at 15 weeks' gestation showing bright linear staining at the epidermal basement membrane using LH7.2 monoclonal antibody, which is directed against the amino-terminus of type VII collagen (× 264). Skin affected with severe recessive (Hallopeau–Siemens) dystrophic epidermolysis bullosa shows an absence of staining with this antibody.

Complications of fetal skin biopsy

Sampling error, inadequacy of samples for analysis, and difficulty in interpreting the morphological and immunohistochemical features can pose problems, according to the experience of the obstetrician and microscopist. Artefact caused by the biopsy procedure, and by processing the very small fetal skin samples, can be severe or mimic true pathology [1]. In one series of 83 pregnancies examined for a variety of genetic skin disorders, there were no sampling failures or incorrect diagnoses [2]. Complications such as sepsis or fetal death could not be directly related to the procedure, although these risks must be considered. Scarring has been reported [3], but it is rarely severe. Often, the biopsy sites are inconspicuous in healthy infants born at term, after a negative prenatal diagnosis. The rate of fetal loss may be no more than 1% over the background incidence of spontaneous abortions [4].

In summary, in experienced centres, fetal skin biopsy for the prenatal diagnosis of EB in particular, has enjoyed

an excellent track record, with a high degree of sensitivity and specificity of the analytical techniques used. However, the procedure is invasive, which will always be a concern to both the medical team and the patient.

Current indications for fetal skin biopsy

DNA-based techniques, first used in the early 1990s for the diagnosis and prenatal diagnosis of different genetic skin diseases, have now largely replaced fetal skin biopsy for the prenatal diagnosis of these disorders (see below). However, there is still a role for fetal skin biopsy in the prenatal testing of at-risk pregnancies, mainly for the following indications:

1 Where the causative gene is unknown but prenatal diagnosis has been shown to be possible in similar cases using fetal skin biopsies.

2 Where the causative gene is known, but informative DNA markers are unavailable, perhaps because an affected offspring had died before appropriate DNA samples could be obtained.

3 Where previously attempted DNA-based prenatal diagnosis has been equivocal or technically unsatisfactory.

DNA techniques

Fetal tissue sampling

A major disadvantage of both amniocentesis and fetal skin biopsy is that the parents have to wait until the middle of the second trimester before the procedure can be undertaken. A further delay of up to 4 weeks is required for cytogenetic or enzyme studies of amniotic fluid cells. A positive diagnosis may lead to a late termination, after fetal movements have been felt, which is always distressing. Direct DNA analysis has had an enormous impact on prenatal diagnosis of monogenic disorders, chiefly because it can exploit the rapid advances in gene mapping and sequencing, and because it removes the need to examine tissues in which the gene in question is expressed [1]. Theoretically, there is no limit to how early in pregnancy the diagnosis can be made. The main limiting factors for prenatal diagnosis include reliable access to the fetus with minimum risk to its viability, and the precision of the DNA tests. These new approaches enable diagnosis of genetic diseases in the fetus when the cause of the disease is unknown, and even when the disease locus is not fully determined [1]. Methods are now being developed for detecting genetic defects in eight-cell embryos, before implantation in the uterus (see below), or even in gametes, before fertilization.

After implantation of the embryo, the chorionic plate derived from the trophoblast layer of the blastocyst attaches to the uterine wall. Chorionic villi are of fetal origin and therefore a useful source of fetal DNA, as are amniotic cells that are released from various fetal epithelia [2]. Chorionic villus biopsy can be performed either transcervically or by the transabdominal route [3].

These methods allow for approximately 10–50 mg of tissue to be biopsied or aspirated. The risk of fetal loss following chorionic villus sampling (CVS) (performed after 10 weeks) is approximately 1.7% [4]. Initially, some reports suggested that CVS might increase the risk of severe limb reduction defects and the hypoglossia–hypodactyly syndrome [5], but this has not been borne out in subsequent more extensive international studies [6]. Nevertheless, it is recommended that CVS is not performed before 10 weeks. Tissue obtained from the CVS needs to be cleaned under a dissecting microscope to exclude maternal cells (decidua, blood) that could contaminate polymerase chain reaction (PCR) or biochemical analyses. It is also important that villi are collected in an appropriate medium. For example, the presence of heparin in the collection fluid may inhibit the activity of the Taq polymerase enzyme that is fundamental to PCR amplification. Chorionic villi can also be cultured for subsequent diagnostic confirmation of the findings obtained from direct analysis of the villi.

Use of DNA methods for prenatal testing in specific disorders

In the preparation for DNA-based prenatal testing, DNA samples should be available from both parents and the

affected family member to screen for the pathogenic mutations. The possibility of *de novo* mutations (a frequent cause of the Dowling–Meara form of EB simplex, for example), non-paternity, uniparental disomy and germline mutations must all be considered in determining the suitability of the prenatal test. Table 13.2 lists the disorders for which prenatal testing has been performed. Further details about the genetic and other aspects of these diseases can be found in the respective chapters describing them more fully. Because the two most requested indications for prenatal testing are Herlitz junctional EB and Hallopeau–Siemens dystrophic EB, a fuller account of the prenatal diagnosis of EB [1–9] is singled out here.

Because mutations in only one gene (the type VII collagen gene, *COL7A1*) are known to cause both recessive and dominant forms of dystrophic EB, prenatal diagnosis can be performed by linkage analysis using a combination of intragenic and flanking markers for the gene locus on chromosome 3p21. These genetic markers can be combined with microsatellite markers for haplotype analysis in predicting whether the fetus carries one, two or neither mutant *COL7A1* allele (Fig. 13.11). A potential pitfall of haplotype analysis using polymorphic markers is the possibility of the occurrence of a *de novo* mutation or parental germline mosaicism in one of the alleles inherited in a previously affected sibling [6]. To increase the accuracy of the test, DNA analysis of pregnancies at risk of recessive dystrophic EB should also, where possible, be based on direct mutation screening of both *COL7A1* alleles [6]. Under optimal conditions, the DNA analysis of key family members, including testing for informative polymorphic and microsatellite markers, in addition to mutational analysis, can be completed within 2 weeks. The analysis of fetal DNA can subsequently be accomplished within 48 h after its receipt in the laboratory [6].

Because junctional EB shows considerable molecular heterogeneity (see Chapter 40), DNA-based prenatal diagnosis of this disorder is dependent on direct mutation analysis instead of genetic linkage. In pregnancies at risk for the Herlitz form of junctional EB, prenatal testing includes analysis of the three laminin 5 genes, *LAMA3* [1], *LAMB3* [2] and *LAMC2* [3].

Mutations in other genes encoding molecular components of the hemidesmosome-anchoring filament complex are also known to cause subtypes of EB. For example, mutations in the α6 or β4 integrin chains underlie a form of junctional EB associated with pyloric atresia [4] and defects in the collagen XVII gene, *COL17A1*, cause a non-Herlitz form of junctional EB (see Chapter 40). Mutations in the plectin gene, *PLEC1*, cause EB simplex associated with a congenital muscle disorder (see Chapter 40). Prenatal diagnosis has also been achieved in fetuses at risk for the Dowling–Meara form of EB simplex by DNA sequence analysis of the keratin K5 and K14 genes [9].

DNA analysis has been used for prenatal diagnostic testing in several other hereditary disorders with cutaneous manifestations, several of which are included in Table 13.2.

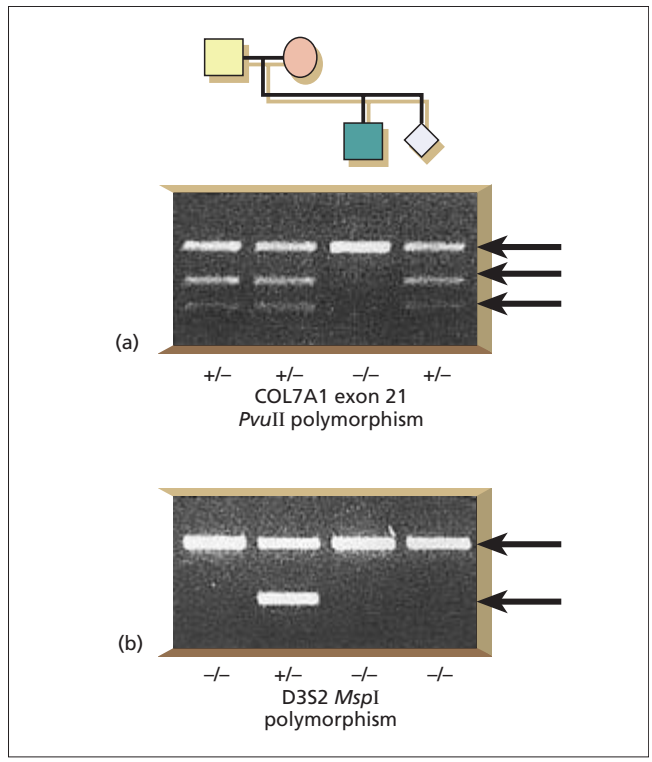

Fig. 13.11 Prenatal exclusion of dystrophic epidermolysis bullosa by linkage analysis. (a) *Pvu*II restriction endonuclease digestion for an intragenic *COL7A1* polymorphism in exon 21 shows a +/– haplotype in the maternal, paternal and fetal DNA in contrast to a –/– haplotype in the previously affected child's DNA. (b) *Msp*I restriction endonuclease digestion for a flanking polymorphism (D3S2) shows a +/– haplotype in the maternal DNA in contrast to a –/– haplotype in the paternal, previously affected child and fetal DNA. These findings indicate that the fetus has inherited the normal paternal *COL7A1* allele and the mutant maternal *COL7A1* allele, and is therefore predicted to be an unaffected carrier of one mutant *COL7A1* allele. (From McGrath *et al*. [7].)

Preimplantation genetic diagnosis

For some couples, termination at any stage of pregnancy is unacceptable. Others may find the stress of abortion after skin biopsy prenatal testing in the mid-trimester or even after chorionic villus biopsy in the first trimester is too great to bear, especially if they have experienced a termination previously. Preimplantation genetic diagnosis is an alternative method that is able to provide information about the genetic status of an early embryo [1]. The procedure involves assisted conception techniques to generate embryos *in vitro* (Fig. 13.12). A single cell is then sampled as tissue representative of the whole embryo (Fig. 13.13) and is analysed for the presence of a specific gene or chromosomal abnormality. Only embryos found to be free of a specific genetic defect are then implanted in the uterus. The first successful birth following preimplantation genetic diagnosis (to exclude cystic fibrosis) was reported in 1992 [2]. Subsequent use of this methodology for genetic skin diseases has been limited, but a small number of cases have been reported [3–5].

Fig. 13.12 *In vitro* fertilization using intracellular sperm injection (ICSI), as a prerequisite for preimplantation diagnosis. (Courtesy of the Assisted Conception Unit, Guy's and St Thomas' Hospital, London, UK.)

Fig. 13.13 Biopsy of a single cell from a blastocyst (3-day-old embryo) for preimplantation diagnosis. (Courtesy of the Assisted Conception Unit, Guy's and St Thomas' Hospital, London, UK.)

The methods used for preimplantation genetic diagnosis continue to evolve [1], but each test has to be individually optimized, for example in the selection of buffers to digest the single embryonic cells and also in the design of the PCR protocols [6]. A single cell can usually be removed from an eight-cell cleavage-stage embryo without affecting subsequent development [1]. The procedure is generally performed about 3 days after *in vitro* fertilization. Nested PCR techniques can be sufficiently reliable to amplify DNA from a single cell (containing just two copies of a particular gene) isolated from an eight-cell embryo [1,4,5,7]. Fluorescence *in situ* hybridization for the detection of X and Y chromosomes may be used to determine the sex of embryos [1,3]. This may be useful where there is a known risk of transmission of an X-linked disorder to a male embryo, especially in the absence of a specific diagnostic test.

Methods are currently being developed to separate X- and Y-bearing spermatozoa, which, if effective, could theoretically be used instead of sexing an embryo. Some DNA tests on unfertilized eggs are also possible by analysis of the first polar body, which is one of the products of the first meiotic division [1]. Pregnancy rates after preimplantation genetic diagnosis vary with the type of disorder and the experience of the practitioners involved, but data gathered from several centres on approximately 1200 cycles for the period 1999–2001 showed an overall clinical pregnancy rate of 22.4% per embryo transfer [8].

Preimplantation diagnosis is very much more complex than most methods of prenatal diagnosis, and the costs are also higher. Nevertheless, the method has been successfully used for a small number of conditions in the few centres currently able to offer this means of diagnosis. In time, preimplantation diagnosis will become more widely available for couples at risk of having children with certain genodermatoses, such as the junctional or more severe forms of recessive dystrophic EB. However, regulation of preimplantation genetic diagnosis varies throughout the world, and this method of prenatal testing is not permitted in several countries (e.g. Argentina, Austria, Switzerland or Taiwan) and is restricted in others (e.g. France or Germany) [1].

Ethical aspects of prenatal diagnosis

Present and future trends in prenatal and preimplantation diagnosis are bound to raise questions concerning moral, ethical, legal and economic aspects of these procedures [1,2]. Major questions concern the degree of fetal abnormality and the consequent level of physical or mental disability that may be considered as a justification for abortion [3]. These questions are important for those working in all branches of medicine, including dermatology. The recommendations of a Royal College of Physicians' working party on prenatal diagnosis [4] provides a useful summary of the major issues. Guidelines that should be stressed include those stating that prenatal diagnosis should be undertaken within the general principles of informed consent, including the possibility that after testing the question of terminating the pregnancy may have to be faced. Further, the choice of option and outcome following prenatal diagnosis should be made by informed couples: they are the best judges of what should be done.

Genetic tests are now available for disorders that generally might be regarded as mild, certainly in comparison with those associated with greater clinical severity or worse prognosis. For example, prenatal testing is now possible for the Weber–Cockayne form of EB. However, such a test has not yet been reported, probably because it has not been requested. Before long, it may be possible, in certain families, to carry out prenatal testing for psoriasis or atopic eczema. Most doctors and nurses may feel that aborting a fetus that has tested positive for one of the 'milder' disorders is unjustified [5]. However, society might say that any couple at risk has the right to know what options are available and possibly the right to have prenatal diagnosis with the intention of terminating an affected pregnancy. How these issues are to be resolved based on moral, ethical and legal considerations is by no means clear and will continue to be debated, along with other major issues involving genetic testing [6], created or influenced by recent advances in biomedical technology and reproduction medicine.

Chapter 14

The Neonate

D.J. Atherton, A.R. Gennery & A.J. Cant

Skin disorders in the neonate

[D.J. Atherton, pp. 14.1–14.50]

Nomenclature

The neonatal or newborn period is the first 4 weeks of extrauterine life, whereas infancy is the whole first year.

Infants born alive before the 37th week of gestation (i.e. 37 weeks after the first day of the mother's last menstrual period) are considered to be premature or preterm. Infants born with a birth weight of less than 2500 g are considered to be low birth-weight infants; this state may be the consequence of prematurity, a less than expected rate of intrauterine growth (small for gestational age), or a combination of both. The term intrauterine growth retardation is used when birth weight is low for gestational age; such infants are commonly described as dysmature or small-for-dates.

Infants born after 42 weeks' gestation are described as post-term, irrespective of birth weight. This expression is often used synonymously with postmature. Because the true period of gestation may not be known exactly by dates, the diagnoses of prematurity, smallness-for-dates and maturity are made principally on clinical grounds; the relevant cutaneous features are considered later.

Skin function in the neonate

Barrier function

Great interest has focused on skin barrier function, both in preterm and full-term neonates, because of the evidence that both are at high risk of toxicity from topically applied substances [1].

It is believed that the normal full-term infant has a completely functional stratum corneum, with fully developed barrier function [2–6]. Toxicity resulting from percutaneous absorption in the full-term neonate is more often therefore related to: (i) the greatly increased ratio of surface area to volume; (ii) the frequent presence of occlusive

conditions, such as exist under waterproof nappy covers; and (iii) high ambient temperatures and humidity, than to any impairment of barrier function *per se*.

There is, in contrast, definite evidence of impaired barrier function in preterm infants, especially those of less than 34 weeks' gestation, mirroring the anatomical immaturity of the epidermis and stratum corneum [3–5,7–11]. Percutaneous absorption correlates inversely with gestational age, but barrier function appears to improve rapidly after birth in the preterm infant, and will generally be normal by the end of the second or third week after birth [3,5,10,12].

It is clear that nothing should be applied to the skin of any baby without careful consideration of the potential hazards of percutaneous absorption, particularly in those with skin diseases. In the case of small, preterm neonates, one should be hesitant to apply anything at all to the skin. The best documented hazards relate to aniline dyes [13], hexachlorophene and related antiseptics [14–17], alcohol [18–21] and corticosteroids [22]. A number of other substances should never be used in neonates, especially not in preterm neonates; these include neomycin [23], boric acid [6,24–26], resorcinol (e.g. in Castellani's solution) [27,28], γ-benzene hexachloride [6,29], benzyl alcohol [30], benzyl benzoate [6], urea [31] and salicylic acid [6,32]. Antiseptics such as chlorhexidine [7] and iodine [33–35] should be used with the greatest caution. Care should also be taken with agents used to launder, sterilize or mark nappies and bed linen [13,36–39], also with mothballs used in their storage [40].

In view of the risk, it is of concern that a study undertaken in the USA a few years ago revealed that parents had applied over 48 different chemicals in over-the-counter preparations to the skin of their 1-month-old babies [41].

Conversely, the increased permeability of the skin in the preterm neonate has potential value for percutaneous administration of drugs [42].

Transepidermal water loss is greatly increased in preterm compared with full-term babies [3,43–45]. The resulting outward passage of water can lead to high rates of heat loss by evaporation, which may even exceed the baby's resting rate of heat production. These losses can be reduced by increasing the ambient humidity [43,46], although this leads to an increased risk of infection, by covering the child with a plastic bubble blanket [47,48], a Perspex shield [49], or by applying a lipid barrier [50,51].

It has been shown that oxygen absorption and carbon dioxide excretion rates through intact skin during the first few days of life are inversely correlated with gestational age [52]. There is, however, no increase in gas exchange in full-term neonates compared with adults, and rates in preterm neonates rapidly fall within 2 weeks of birth to those observed in full-term neonates. These studies raise the possibility of utilizing this increased gas permeability of preterm neonatal skin to deliver oxygen in the respiratory distress syndrome, particularly where there is severe pulmonary hypertension, when adequate oxygenation is exceedingly difficult to achieve.

It is possible that immaturity of the skin also predisposes the premature neonate to penetration of the skin by microorganisms leading to systemic infection. This may be the reason that the premature infant with congenital cutaneous candidiasis is at greater risk of disseminated candidiasis [53].

Eccrine sweating

A full complement of anatomically normal eccrine sweat glands is present by the 28th week of gestation [54], but these appear to be functionally immature in neonates born before the 36th week, in terms of their responses to intradermal injection of acetylcholine and epinephrine (adrenaline) [55], and to thermal stress [56]. However, responsiveness usually develops in such babies by 2 weeks after birth [55,57]. Neonates born after the 36th week of gestation sweat in response to thermal stress from birth [58,59], although such sweating is initially relatively inefficient as a thermoregulatory mechanism. Care must therefore be taken not to overheat any neonate, but particularly the preterm neonate, and although severe overheating leading to hyperpyrexia is probably rare, lesser degrees of iatrogenic overheating appear to be common and may even induce apnoeic attacks [60].

The forehead appears to be the principal site of thermally induced sweating in the neonate [59]. The palms and soles, however, are sites of 'emotional' sweating, occurring in response to arousal, which appears to be well developed at birth in full-term but not preterm neonates [56]. The rate of such 'emotional sweating' can provide a measure of stress in small babies [61].

Sebaceous gland secretion

The secretions of the fetal sebaceous glands make a significant contribution to the vernix caseosa [62]. Sebum secretion rates are high in neonates compared with older pre-adolescent children [63], and it is assumed that this sebaceous gland activity reflects stimulation by placentally transferred maternal androgen, particularly by dehydroepiandrosterone [63]. Sebaceous gland activity decreases from about the end of the first month to reach a stable level by the end of the first year [63].

The appearance of neonatal skin

A variety of skin lesions commonly seen in the newborn are regarded as 'physiological'. Their frequency has been studied by several authors, and varies somewhat in different racial groups [1–5].

At birth, the skin is covered with a whitish, greasy film, the *vernix caseosa*. The vernix may cover the entire skin surface, or it may be present only in body folds such as the groins. It normally dries rapidly and starts to flake off within a few hours of birth. The vernix appears to be comprised of lipids [6,7]. Little is known of its function, though recent evidence of its content of the pepide antibiotic LL-37 and of lysozyme support an antimicrobial role [8]. Its colour may reflect intrauterine problems, such as haemolytic disease of the newborn and post-maturity, both of which result in golden yellow staining. Fetal

distress *in utero* may lead to staining of the vernix by the bile pigments present in meconium.

Peripheral cyanosis (or acrocyanosis) is a feature of the newborn, particularly the full-term newborn, and is usually particularly marked on the palms and soles and around the mouth. In the absence of cyanosis of warm central parts such as the tongue, this may be regarded as normal during the first 48 h or so. It is made more obvious by hypothermia, and is improved by warming.

A few hours after birth, many babies develop a striking generalized hyperaemia usually known as *erythema neonatorum*, which fades spontaneously within 24–48 h.

In as many as 15% of neonates, a vivid colour difference may appear along the midline at some time during the first week of life [9–12]. This phenomenon occurs when the baby is lying on its side, the upper half of the body becoming pale, the lower half a deep-red colour, with a sharp midline demarcation between the two. The duration of the attack is highly variable, but generally is between half a minute and 20 min. If the baby is turned on the other side, the colour change may reverse. An individual neonate may have only a single episode, or it may recur on several occasions. This curious phenomenon has been called *harlequin colour change*. It appears to have no pathological significance in the great majority of cases, and is considered to reflect immaturity of hypothalamic centres responsible for the control of peripheral vascular tone [9]. If it persists beyond the end of the fourth week, it may be associated with hypoxia due to cardiovascular anomalies [13].

Newborn infants who are subjected to cooling will show distinct marbling of the skin. Although this more or less disappears on rewarming, many normal neonates demonstrate faint marbling, even under optimal environmental conditions. The marbling comprises a reticulate blue vascular pattern, which has often been called *cutis marmorata*. This response is a physiological one, and may be seen throughout infancy. *Cutis marmorata telangiectatica congenita* is an entirely distinct vascular developmental disorder, and is easily distinguished (see Chapter 15). Cutaneous marbling may be seen in older children with a variety of disorders, particularly athyrotic (congenital) hypothyroidism [14], the de Lange syndrome, the Adams–Oliver syndrome, in trisomy 18, trisomy 21, homocystinuria and the Divry–Van Bogaert syndrome (see Chapters 12 and 15).

Rather superficial cutaneous desquamation, often termed physiological scaling of the newborn, occurs in up to 75% of normal neonates [5,15]. This usually first appears around the ankles on the first day of life, and is most commonly more or less confined to the hands and feet [5]. It may remain very localized or may gradually become more widespread, usually reaching its maximum extent and intensity by the eighth day. Although it has been reported that this type of desquamation is unusual in babies born earlier than the 39th week of gestation, and that it occurs with increasing frequency the greater the gestational age [15], this was not confirmed in a more recent study, in which it was found to occur with equal prevalence at all gestational ages [5]. It tends always to be more severe in neonates who are small-for-dates, whatever their gestational age. Physiological scaling may occasionally be fairly pronounced, not generally sufficiently so to lead to confusion with any of the more serious types of congenital ichthyosis, but milder varieties of ichthyosis, such as ichthyosis vulgaris, may be difficult to distinguish, and it should be borne in mind that X-linked hypohidrotic ectodermal dysplasia may present with scaling of the skin in the neonatal period [16].

One or two solitary blisters or erosions are occasionally present at birth on the fingers, lips or forearms, and are believed to be caused by vigorous sucking *in utero*; hence the term sucking blister is often applied. These heal rapidly without sequelae [17].

The scalp hair is shed synchronously during the fifth month of fetal life, and having regrown enters telogen in a wave from front to back, starting about 12 weeks before term. After shedding of the telogen hairs from the frontal and parietal areas, the roots again enter the anagen phase in a similar wave from front to back [18–20]. The roots in the occipital area do not enter telogen until term, and therefore rather conspicuous alopecia may appear at this site.

There appear to be two waves of hair loss and regrowth from front to back during early infancy, but by the end of the first year the typical mosaic pattern of hair growth is established [21]. In some babies, there is unusually synchronous hair loss during the neonatal period resulting in obvious diffuse alopecia (telogen effluvium of the newborn), but, by the end of the first 6 months of life, most babies have a full head of hair [22]. At this stage, the hairline often extends to the lateral ends of the eyebrows, but the terminal hairs comprising this extension gradually convert to vellus hairs during the remainder of the first year of life, causing the hairline to recede to its characteristic childhood position.

Sebaceous gland hyperplasia is a physiological event in the newborn, reflecting the influence of maternal androgens. It is visible to the naked eye in the great majority of infants as multiple, uniform, pinpoint yellowish papules that are most prominent on the nose, cheeks, upper lip and forehead, but may also be visible on the upper trunk, especially the areolae, the genitalia and the limbs. The phenomenon is associated in about 40% of infants with *milia*, which represent minute follicular epidermal cysts [23]. The number of milia present may vary from one or two to many hundreds. They comprise 1–3 mm, white, globular papules, which occur at the same sites. Rather larger and usually single milia, often termed pearls, are seen sometimes on the areolae, scrotum and labia majora.

Both the sebaceous gland hyperplasia and the milia tend to disappear spontaneously during the first weeks of life, though a few may persist longer. Milia which are exceptionally extensive or persistent, or whose distribution is atypical, may be features of the orofacial–digital syndrome type I, Marie–Unna type congenital hypotrichosis or the X-linked Bazex–Dupré–Christol syndrome, which features hypotrichosis and milia [24] (see Chapter 12).

The influence on the fetus of maternal and placental hormones gives rise to a group of phenomena, varying greatly in degree, sometimes described as 'miniature puberty'. In the newborn female, the genitalia appear succulent, and the size of the clitoris in particular may lead the inexperienced to suspect intersex. A mucoid vaginal discharge is common. Vaginal smears at this stage may be indistinguishable from those of pregnant women. A few days after birth, the hyperplastic vaginal epithelium desquamates to leave a more normal infantile mucosa; this desquamation may be manifest as a creamy white discharge. Frank withdrawal bleeding may occur from the uterus on the third of fourth day, usually lasting 2 or 3 days. The male genitalia appear similarly large and well-developed at birth.

Both sexes show hypertrophy of the mammary glands at birth. After 2 or 3 days the breasts may become engorged and lactation of so-called 'witch's milk' may occur. The swelling subsides during the second week and has usually become undetectable by the end of the fourth week. In some girls, however, it may be more persistent, and it is these girls in particular who are at risk of infection because of the presence of stagnant milk, leading to mastitis and abscess formation.

In about 8% of babies, the linea alba becomes pigmented, and this pigmentation may persist for 2 or 3 months. Mongolian spots occur in about 85% of oriental neonates [2,25], and the frequency in black babies is also high [26]. Mongolian spots are rare in white neonates, around 3% [26]. Exaggerated pigmentation of the scrotum occurs in about 30% of oriental neonates [25]. A rare type of congenital linear and/or reticulate pigmentation has been reported on the limbs and/or trunk of black neonates [27].

One or more 1–2-mm, yellowish white, keratinous cysts, known as *Epstein's pearls*, may be seen in the mouths of up to 85% of all neonates, along the alveolar ridges and/or in the midline at the junction of the hard and soft palate [5,28,29]. These generally disappear without treatment within a few weeks. Other common oral findings in the neonate [29] include rather succulent gums, analogous to the hypertrophic gingivitis often seen in pregnant women, a whitish hue to the oral mucosa (termed 'leukoedema', but probably synonymous with what other authors have called 'suckling pads' [30]), alveolar lymphangioma [31], ankyloglossia, commissural lip pits [32,33] and a median alveolar notch.

The appearance of the preterm neonate

The skin of the preterm neonate tends to have a rather translucent, gelatinous quality, and the so-called 'miniature puberty' features are much less prominent.

Preterm infants are often covered in quite obvious lanugo hairs, which tend to be most dense on the face, limbs and trunk. This hair would normally be shed *in utero* about 1 month before term [1], to be replaced by a second coat of shorter lanugo, which is present at birth in full-term infants. Like the terminal scalp hair, this downy lanugo is shed during the first months of life and is itself replaced by vellus hair.

Appearance of small-for-dates and postmature neonates

The small-for-dates or dysmature neonate presents a characteristic appearance due to relative prenatal malnutrition. The baby is small and, from the dermatological point of view, the most striking feature is the lack of subcutaneous fat, which causes the baby to look thin and wrinkled. Vernix is absent in the extremely immature infant, but may be profuse nearer to term. The skin and vernix are often stained yellowish green by meconium. After birth, the skin dries quickly and becomes 'crazed' with long transverse splits on the trunk. It then peels off to reveal more normal-appearing skin beneath. The fingernails are often long.

The postmature infant is longer, but of otherwise similar appearance to the small-for-dates neonate, having also experienced intrauterine malnutrition due to placental insufficiency. Vernix is often absent [1].

Toxic erythema of the newborn

SYN. ERYTHEMA TOXICUM NEONATORUM

Terminology. The most widely used term for this condition is inappropriate in view of the complete absence of any evidence of a toxic cause.

Aetiology. The cause of toxic erythema of the newborn is unknown. It was at one time believed that the frequent finding of an associated blood eosinophilia implied an allergic origin, but there has never been any convincing support for the view that the condition is a manifestation of hypersensitivity to milk or drugs transmitted to the infant before birth via the placenta, or to vaginal secretions. Furthermore, the demonstration that tissue eosinophilia is a non-specific feature of inflammatory responses in neonates [1] adds little weight to such a view.

The intrafollicular location of mature pustules has led to the suggestion that the inflammatory response is elicited by some component of sebum [2].

Attempts to culture pathogenic bacteria from the lesions have always proved fruitless [3].

More recently, the suggestion has been made that toxic erythema of the newborn might represent a mild and self-limited acute graft-versus-host reaction due to maternal lymphocyte transfer to the neonate [4], but evidence for this is poor; in particular the histopathological features do not resemble those that have been demonstrated in acute graft-versus-host reactions in the skin.

Pathology [5,6]. Histologically, the macular erythema shows oedema in the upper dermis, associated with a sparse and largely perivascular inflammatory infiltrate comprising principally eosinophils. Papular lesions are characterized in addition by eosinophil infiltration of the outer root sheath of one or more hair follicles, above the point of entry of the sebaceous duct. Pustular lesions show intrafollicular accumulation of eosinophils immediately below the stratum corneum. Smears of the pustule contents demonstrate inflammatory cells, more than 90% of which are eosinophils [7,8].

There is an associated blood eosinophilia of up to 20% of the white cell count in around half the cases, and this is generally more marked when there is a prominent pustular element to the eruption [3,7].

Clinical features [3,7–11]. Up to 50% of full-term infants of all racial types will manifest some degree of toxic erythema during the first few days of life [9,12–15]. The incidence appears to decrease with both prematurity and smallness-for-dates [16]. In the majority of cases, the onset is during the first 48 h after birth, but it may occur at any time until about the fourth day. It is in rare instances present at birth [9,17,18].

Most commonly, the eruption initially takes the form of a blotchy, macular erythema, the number of individual lesions varying from one or two to several hundred. They are most profuse on the trunk, particularly the anterior trunk, but also commonly appear on the face and proximal parts of the limbs, especially the thighs. Lesions have been recorded, however, at almost any site except the palms and soles. In the mildest cases, these macules fade within a day. In more severe cases, urticarial papules arise within the erythematous areas, or, occasionally, independently of them (particularly on the back and buttocks).

These papules are, in about 10% of cases, surmounted by small pustules 1–2 mm in diameter.

Presentation with scrotal pustules present at birth has been reported more recently [18].

The infant appears well, and unperturbed by the eruption. Spontaneous recovery occurs rapidly, usually within 3 days, but recurrences are occasionally seen, and have been reported as late as the sixth week of life [19,20].

Diagnosis. Toxic erythema of the newborn has to be distinguished from several other disorders featuring pustular lesions during the neonatal period, particularly miliaria, transient neonatal pustular melanosis, incontinentia pigmenti, and, most importantly, herpes simplex virus (HSV) infection, varicella, impetigo neonatorum and *Malassezia furfur* pustulosis. Of these, perhaps pustular miliaria is the one most often confused clinically with toxic erythema. Toxic erythema can be rapidly distinguished from all of these by microscopic examination of a smear of pustule contents, stained with Giemsa, and by bacterial and viral culture.

Treatment. No treatment is required.

Miliaria

Aetiology. Miliaria occurs when the flow of eccrine sweat is impeded by obstruction of the intraepidermal portion of the sweat duct. Its aetiology and pathogenesis are presumed to be similar at all ages and are considered in Chapter 45. Relative immaturity of the sweat duct may be an important predisposing factor in early infancy, as may a tendency for infants to be nursed in excessively warm and humid conditions.

Miliaria crystallina appears to reflect obstruction of the sweat duct within the stratum corneum itself. It is particularly common during the neonatal period, probably principally because of delayed patency of the sweat pore.

Miliaria rubra appears to be caused by sweat duct obstruction deeper within the epidermis, induced perhaps by increased activity of the intraductal microflora [1,2].

Pathology. Miliaria crystallina is characterized by the presence of intracorneal or subcorneal vesicles in communication with sweat ducts [3]. In miliaria rubra, focal areas of spongiosis and spongiotic vesicle formation are seen in close proximity to sweat ducts, which often contain an amorphous, periodic acid–Schiff (PAS) stain-positive plug [1,4].

Clinical features [5]. Miliaria crystallina presents as crops of clear, thin-walled, superficial vesicles 1–2 mm in diameter, without associated erythema (Fig. 14.1), resembling drops of water. These are exceedingly delicate, and generally rupture within 24 h, and are followed by branny desquamation. They arise most frequently during the first

Fig. 14.1 Miliaria crystallina on the upper arm of a 7-day-old infant.

2 weeks of life, and are particularly likely to be seen on the forehead, scalp, neck and upper trunk. Though rare during the first 4 days, congenital cases have been reported [6,7].

Miliaria rubra ('prickly heat') comprises erythematous papules and papulovesicles about 1–4 mm in diameter, on a background of macular erythema. Sometimes, quite large, weal-like lesions occur. Frequently, some of the lesions are pustular (*miliaria pustulosa*), but this does not necessarily indicate secondary infection. Nevertheless, staphylococcal secondary infection of miliaria (periporitis) is not infrequent, and may lead to sweat gland abscesses.

Miliaria rubra is common and, although it may be seen throughout infancy, it probably occurs most frequently during the neonatal period. Crops of lesions arise fairly symmetrically, most often in flexural areas, especially around the neck and in the groins and axillae. The face, scalp and upper trunk are also frequently affected. It may also occur rather locally at sites that have been occluded, for example where there has been direct contact between skin and a plastic mattress cover or plastic pants. Where the eruption is profuse, the child may be restless and distressed. Each crop of lesions will subside within 2–3 days, but recurrences are common, unless the provocative environmental conditions are modified.

Recurrent bouts of miliaria pustulosa appear to be a rather specific finding in type 1 pseudoaldosteronism [8].

Diagnosis. Miliaria crystallina is distinguishable from viral infections of the skin by the lack of background erythema, and by the absence of inflammatory cells or giant keratinocytes on cytological examination of vesicle contents. When it occurs during the first few days of life, miliaria rubra is often confused with toxic erythema. However, miliaria rubra can generally be distinguished by its flexural predominance, by the frequent presence of vesicular lesions and by its tendency to recur. Where pustular lesions are seen in toxic erythema, a smear of their contents will reveal large numbers of eosinophils.

When pustular lesions are prominent in miliaria, there may be confusion with infantile acne or with folliculitis, but careful clinical examination of the individual lesions will show that they do not have a follicular distribution.

Transient pustular melanosis

SYN. TRANSIENT NEONATAL PUSTULAR MELANOSIS

Terminology and aetiology. Despite having first been described more than 25 years ago [1], whether this is really an entity remains unresolved. Nothing is known of its aetiology other than that it would appear, like toxic erythema of the newborn, to be non-infectious. It was first reported in black Americans, and appears to be commoner in, but not confined to black neonates (4.4% in black US neonates against 0.6% in white US neonates) [1]. This probably reflects the fact that its diagnosis is currently based on the appearance of typical macular post-inflammatory pigmentation, as the name seems to require. It has been suggested that it is merely a variant of toxic erythema of the newborn [2].

Pathology [1]. Pustular lesions show intra- or subcorneal collections of neutrophils and a few eosinophils. The underlying dermis may show no abnormality, or a sparse perivascular and perifollicular inflammatory infiltrate, also mainly of neutrophils with a few eosinophils.

The pigmented macules demonstrate basal and suprabasal increase in pigmentation only, apparently without pigmentary incontinence.

Smears of pustular contents show predominantly neutrophils, and bacterial culture is negative.

Clinical features [1,3–7]. Lesions are almost invariably present at birth. The most characteristic component of the eruption is 1–3-mm flaccid, superficial, fragile pustules, with no surrounding erythema. These pustules may occur at any site, but favour the chin, neck, forehead, back and buttocks. Sites where they have ruptured are marked initially by a detachable brown crust, and subsequently by a small collarette of scale, which may surmount a pigmented macule. Sometimes, pigmented macules are already present at birth. The pigmented macules are a prominent element in black infants, and are seen more rarely in other races [5]. The pigmentation may persist for about 3 months. Affected infants are otherwise entirely well.

It has been suggested that this condition is responsible for the freckling or '*lentigines neonatorum*' that have been reported in some 15% of black neonates [8].

Diagnosis. It remains to be established whether this is really just an early-onset variant of toxic erythema of the newborn occurring in the dark-skinned. Stained smears and microbiological studies will distinguish staphylococcal and herpetic infections. The differential diagnosis of neonatal pustular eruptions is given in Table 14.1.

Infantile acropustulosis

Aetiology. Infantile acropustulosis is an uncommon disorder of unknown aetiology. It occurs in all races [1], though it was first described in black infants [2,3]. It has been suggested that eosinophilic pustular folliculitis and infantile acropustulosis may be different manifestations of the same disease [4,5]. It has also been suggested that, at least in some cases, infantile acropustulosis occurs following successful treatment of scabies [6–8]. Interestingly, it has been reported in a 2-month-old infant whose mother was treated for scabies 4 months previously [9]. It has also been reported in siblings [9], and in only one of a pair of identical twins [10].

Pathology [2,11–13]. Biopsies of fully developed pustules have revealed well-circumscribed subcorneal or intraepidermal aggregations of neutrophils, with a sparse perivascular lymphohistiocytic infiltrate in the underlying papillary dermis. Biopsy of pre-pustular lesions shows focal intraepidermal vesiculation [13,14] with keratinocyte necrosis. This intraepidermal vesicle is subsequently invaded by neutrophils and/or eosinophils. The pustule starts its life deep in the epidermis, but does not become clinically fully developed until it reaches a subcorneal location.

Direct and indirect immunofluorescence is negative in lesional, perilesional and normal skin [1,3,15].

Stained smears of pustule contents generally show a predominance of neutrophils, but there may be a preponderance of eosinophils early in the course of the disorder [3]. The pustules are sterile [2,11,16]. Peripheral blood eosinophilia has been reported [14,17,18], but is not invariable [9,13,17].

Clinical features [2,3,9,12,15,19,20]. Recurrent crops of intensely itchy, 1–4-mm vesicopustules appear principally on the soles and sides of the feet, and on the palms, but may also occur on the dorsa of the feet, hands and fingers, and on the ankles, wrists and forearms. Scattered lesions may also be seen on the face, scalp and trunk, but a predominantly acral distribution is characteristic. Mucosal lesions do not occur.

Individual lesions appear to start as tiny, red papules, which evolve into vesicles and then pustules over about 24 h. Excoriation results in erosions and then crusts. Healing is frequently succeeded by macular post-inflammatory hyperpigmentation.

Pruritus may be intense, with restlessness, loss of appetite and interference with sleep.

In the majority of cases, the onset is in the first year of life, particularly during the first 6 months [9]; lesions may be present at birth. Each crop lasts for 7–14 days. They tend to occur at intervals of 2–4 weeks in most cases, often being more frequent and more numerous in the summer months. The attacks occur with gradually diminishing numbers of lesions, and with decreasing frequency, until they cease altogether, usually within 2 years of the onset [8].

Treatment. The early use of fairly potent topical corticosteroids with [9] or without [12] occlusion appears to abort attacks.

The intense pruritus may be lessened by large doses of oral antihistamines [2].

Though rarely justified, dapsone is usually effective in controlling this condition in a dose of 1–2 mg/kg/day in two divided doses [3], and usually reduces pruritus within 24 h. Higher doses are occasionally required [17]. Too hasty withdrawal of treatment may provoke severe exacerbations [11].

Diagnosis. The predilection for the palms and soles and the recurrent attacks differentiate this disorder from most other pustular eruptions seen in the neonatal period, particularly toxic erythema, miliaria and transient pustular melanosis.

Persistent palmoplantar pustulosis may be similar histologically but characteristically has a much later onset, a more persistent course, and the skin surrounding the pustules is dusky red and glazed.

Subcorneal pustular dermatosis may also resemble infantile acropustulosis histologically, and has occasionally had its onset during the first 3 months of life [21]. It is, however, likely to be associated with fever and neutrophilia, and has a different distribution, favouring the proximal flexures, although lesions on the palms and soles have been described.

Scabies may initially be extremely difficult to exclude, and where there is any doubt a therapeutic trial of an appropriate acaricide is clearly justified. The persistence of acral pustulosis for many months in children aged less than 3 years, and previously treated for scabies, has been reported [22].

Eosinophilic pustulosis

SYN. EOSINOPHILIC PUSTULAR FOLLICULITIS

Aetiology. This entity is now recognized as a characteristic skin disorder of infancy, with typical cases described from many different countries [1–5]. Its aetiology and its relationship to eosinophilic pustular folliculitis of adults [6] are unknown. It has been suggested that this condition and infantile acropustulosis may be different manifestations of a single disorder [5,7].

Pathology. Biopsy shows a dense perifollicular infiltrate of eosinophils, with some lymphocytes and histiocytes, in the mid- and upper dermis. The hair follicles themselves show spongiotic degeneration of the outer root sheath, and infiltration with eosinophils. The centre of the follicles is necrotic, and filled with eosinophils and eosinophilic debris. Smears of pustule contents show plentiful eosinophils. There is mild to moderate peripheral blood eosinophilia, and occasionally, neutrophilia.

Clinical features. The condition generally has its onset in infancy. Lesions occur predominantly in the scalp [2,4,5,7], comprising mildly pruritic, 1–3-mm-diameter pustules on an erythematous base, with prominent secondary crusting. However, pustules may also occur at almost any other site except the mucosae, occasionally even in areas lacking hair follicles [3]. Annular lesions resembling those seen in adults were reported in a 5 year old [8], but this is perhaps more likely to have been an early case of the adult form of eosinophilic pustular folliculitis. Patients are not systemically unwell.

A pattern of cyclical recurrences is characteristic, but the likely duration of the disease is unknown.

Diagnosis. Conditions that need to be considered in the differential diagnosis include infections, particularly impetigo and candidosis, and other non-infective pustuloses of infancy, particularly toxic erythema, infantile acropustulosis and transient neonatal pustulosis.

Infections are principally excluded by the sterile pustule contents, the absence of eosinophils in smears of pustule contents, and the lack of peripheral blood eosinophilia. While toxic erythema may initially be clinically and histologically similar, it does not show any predilection for the scalp, and lacks the cyclical recurrent course. Similarly, the pustular phase of transient neonatal pustulosis is confined to the neonatal period. Also, the pustules contain neutrophils rather than eosinophils. The lesions of infantile acropustulosis, while they do generally occur in recurring crops, tend to be larger and are located principally on acral sites including the palms and soles, rather than in the scalp.

Treatment. There is some evidence that higher-potency

topical corticosteroids and oral erythromycin may have some suppressive effect on the lesions seen in infants [3,4], but little treatment is required since the prognosis for spontaneous remission appears excellent.

Congenital erosive and vesicular dermatosis healing with reticulated supple scarring

SYN. EXTENSIVE CONGENITAL EROSIONS AND VESICLES HEALING WITH RETICULATE SCARRING

This is a rare disorder of unknown aetiology [1–6]. There is no evidence of genetic transmission. It appears possible that the condition reflects an as yet unidentified intrauterine infection.

The majority of affected infants have been premature. Some have also had microcephaly and neurological problems including convulsions and developmental delay.

At birth, there are extensive superficial erosions, with scattered vesicles and bullae, affecting up to 75% of the body surface [1–6]. These heal fairly quickly within the first few weeks of life, leaving rather characteristic soft, reticulated scarring. The trunk and limbs tend to be more severely affected than the face and scalp. Following healing of the skin lesions, there may be residual loss of eccrine sweating in scarred areas, with the potential for hyperthermia under appropriate conditions, patchy alopecia, partial loss of eyelashes, and absence or hypoplasia of nails. Teeth have been normal. Mild localized recurrent vesiculation may occur [6].

Biopsies of vesicular areas have shown spongiosis or epidermal necrosis with dermal haemorrhage and inflammation [6]. In another report, an eroded area showed loss of the epidermis with a superficial and deep dermal inflammatory infiltrate comprising mostly neutrophils [4]. Scarred areas have shown an increased density of dermal collagen, and absence of eccrine sweat glands [1,5]. Direct immunofluorescence does not show any specific pattern of deposition of immunoglobulins, C3 or fibrin [4]. Electronmicroscopy and immunohistochemical mapping of perilesional skin have shown nothing to suggest that this is a variant of epidermolysis bullosa [5].

'Cradle cap'

This term is applied, rather loosely, to almost any situation in which there is adherent scaling of the scalp during infancy. This type of scaling is very common, particularly on the vertex, during the first few weeks of life, and is generally believed to represent persisting vernix.

However, there is little doubt that such scaling may appear in early infancy in babies in whom the scalp was clear at birth [1]. The eyebrows are frequently affected in this acquired type of cradle cap, and lesions may also appear on the forehead and temples, the retro-auricular area and the folds of the neck. This rash is generally considered to be a manifestation of infantile seborrhoeic dermatitis.

If scaling or crusting is present during the neonatal period, the scalp should be regularly oiled with olive oil or arachis oil. In the more refractory case, Emulsifying Ointment BP, Aqueous Cream BP or any other water-dispersible emollient should be massaged into the scalp once or twice a day, left for several hours, and then rinsed out. Applications containing salicylic acid, and shampoos containing potentially toxic substances such as selenium sulphide should not be used on the scalp in neonates because of the dangers posed by their percutaneous absorption.

Complications of prematurity

Anetoderma of prematurity [1]

A series of infants have recently been described in whom

nummular areas of cutaneous atrophy appeared on the trunk and/or proximal limbs within a few weeks or months of birth. All these babies had been born between the 24th and 29th weeks of gestation and in almost all cases the lesions had first appeared while the child was still in the neonatal intensive care unit. Histologically these lesions demonstrated reduction or absence of elastic tissue, consistent with anetoderma. An aetiological role for trauma resulting from care procedures cannot be ruled out.

Complications of medical procedures on the fetus and neonate

Scarring following antenatal procedures

Amniocentesis comprises the insertion of a needle into the amniotic sac through the abdominal wall for the removal of amniotic fluid. Punctate scars and dimples may result from accidental puncture of the fetal skin during the procedure [1–4], although the frequency of such lesions can be greatly reduced by the routine use of ultrasound guidance. Generally, injuries are minor, but more substantial trauma can occur.

Other antenatal procedures on the fetus that may result in scarring include biopsies of skin, liver, tumours, aspiration of fluid collections, and a variety of therapeutic procedures, all of which are undertaken with ultrasound guidance.

Intrauterine blood transfusion

Gangrene of the skin of the abdominal wall has been reported following intrauterine red cell transfusion for haemolytic disease of the fetus due to rhesus incompatibility [1].

REFERENCE

Scarring acquired due to procedures during delivery

Scalp electrodes are very widely employed to monitor fetal heart rate during labour. The most commonly used type of electrode is curved and is implanted by being 'screwed' into the scalp. Lacerations are not an uncommon sequela [1]. Although these generally heal rapidly, they may leave localized areas of permanent scarring in the scalp, which may later be confused with cutis aplasia. Cephalohaematoma has also been reported [2].

Scalp blood samples are also often taken to establish fetal acid-base status; these are taken via small incisions using a special lancet. Either type of injury can lead to abscesses in up to 4% of neonates [3], usually becoming evident by the third day of life. These are generally a minor problem [4], but osteomyelitis [5] and necrotizing fasciitis [6] may, however, occur. Infecting bacteria have included group A streptococci and *Neisseria gonorrhoeae* [7]. HSV infection may also occur at the site of electrode implantation, reflecting infection of the mother's genital tract [8]. Vesicles appear within 4–10 days of birth. Recognition of such lesions is important, as localized infection of this type has occasionally been complicated by meningoencephalitis [9,10] and by lethal dissemination [11].

Forceps delivery may occasionally result in local subcutaneous fat necrosis. Vacuum extractors (ventouse) may rarely cause permanent alopecia, most typically in a circle that clearly corresponds to the site of its application. Scalpel laceration during caesarean delivery may require suturing and will generally result in scarring.

Complications of phototherapy

Phototherapy with blue light at 420–460 nm leads to the transcutaneous photo-oxidation of bilirubin, and has become firmly established as a safe and effective treatment for neonatal jaundice [1].

A number of minor cutaneous side effects have been described. Some babies develop a macular erythematous rash as the serum bilirubin level falls [2].

Darkening of treated areas of skin lasting for several months has been reported in racially black babies [3]. This effect may initially be due to the immediate pigment-darkening reaction, which is induced by visible as well as by long-wave UV radiation. However, the persistence of hyperpigmentation in these babies over several months implies that increased melanogenesis must also occur.

Unexplained UV burns have also been reported after phototherapy for neonatal jaundice [4].

Phototoxic reactions

Phototoxic reactions to a number of drugs given to the neonate, or injected into the amniotic cavity, may occur following phototherapy for neonatal jaundice. The best known of these drugs is furosemide (frusemide) [5].

Methylene blue is sometimes injected into the amniotic cavity to detect premature rupture of the fetal membranes at the end of pregnancy. Methylene blue is a photosensitizing compound, and the use of phototherapy for hyperbilirubinaemia in a neonate that has been exposed *in utero* can lead to erythema and blistering [6].

'Bronze baby' syndrome

This is a rare complication of neonatal phototherapy, in which a dark-grey-brown ('bronze') pigmentation of the skin, serum and urine follows phototherapy, and remains as the hyperbilirubinaemia fades [7,8]. Hepatic disease appears to be a prerequisite for the development of this complication, and is thought to cause abnormal accumulation of the responsible pigment. This pigment has not yet been precisely identified, but it has been suggested that it might be a photoisomer of bilirubin [9]. The abnormal hepatic function also leads to increased serum levels of porphyrin and copper, which in turn form copper–porphyrin complexes. Photodestruction of these complexes leads to the production of brown pigments, which might also be responsible for the 'bronze' colour [10]. A third suggestion has been that the pigment is biliverdin, which might accumulate as a consequence of reduced conversion of haem to bilirubin [11].

In making the diagnosis, other causes of similar pigmentation need to be considered, particularly central cyanosis secondary to congenital heart disease, the 'carbon baby' syndrome [12] and the 'grey baby' syndrome, due to chloramphenicol overdosage [13]. These can be ruled out, where appropriate, by skin biopsy, serum chloramphenicol level, blood gas analysis and serum spectophotometry [7].

The bronze pigmentation gradually fades after discontinuation of phototherapy, but death has been reported in several affected neonates, either from kernicterus or from extrahepatic biliary duct atresia [14].

Bullous and purpuric eruptions resulting from transient porphyrinaemia

Bullous photosensitivity reactions may be seen in neonates with congenital erythropoietic porphyria, hepatoerythropoietic porphyria, erythropoietic protoporphyria and harderoporphyria [1,2].

It is clear that under certain, probably exceptional, circumstances, a bullous eruption closely resembling epidermolysis bullosa may develop following phototherapy in a neonate, due to transient porphyrinaemia [3]. The circumstances in which porphyrinaemia may occur in neonates who do not have inborn errors of porphyrin metabolism are not fully defined, but probably include prematurity, cholestasis, disturbed hepatocellular function and renal failure.

More recently, localized purpuric eruptions have been described at exposed sites in a number of neonates who had all been transfused prior to phototherapy; it was proposed that the cause may also have been transient porphyrinaemia [4,5].

Umbilical artery catheterization

Umbilical artery catheters are often used in neonatal intensive care, for frequent blood sampling, for continuous Po_2 and blood pressure monitoring, for administration of fluids and drugs, and for exchange transfusions. Vascular complication may ensue, including aortic thrombosis, embolization and spasm. These may result in lower limb ischaemia, which may progress to gangrene or necrosis [1–7]. Analogous ischaemic changes may occur in the lower arm or hand following cannulation of the brachial and radial arteries, respectively.

Transcutaneous oxygen monitoring

Transcutaneous oxygen monitoring is frequently used in neonatal intensive care. This uses an electrode applied to the skin and maintained at 44°C in order to increase cutaneous blood flow. This generally causes a superficial burn, which usually resolves within 60 h [1], but occasionally, after longer periods of monitoring, there may be a more severe burn [2], sometimes with vesiculation [3]; such lesions may result in permanent scarring [2]. Measures have been recommended to reduce the risk of these injuries [4], but the transcutaneous Po_2 monitor has now been largely superseded by pulse oximetry, which uses an unheated sensor with no risk of burning.

Electrocardiographic electrodes [1]

Raised skin-coloured lesions approximately 5 mm in diameter on the forehead have been described at the age of 3 months following the use of electrocardiographic electrodes in intensive care monitoring of premature neonates. Biopsy demonstrated reduction of elastic fibres; hence the lesions were interpreted as an iatrogenic form of anetoderma, possibly provoked by hypoxia secondary to skin pressure.

Transillumination blisters [1]

Transillumination is used in neonatal intensive care units as a way of diagnosing pneumothorax and for finding arteries and veins for blood sampling. Occasionally this procedure provokes discrete 2–4 mm blisters with necrotic bases in acral locations close to common venous access sites, such as the wrists and the lateral malleoli. The occurrence of such lesions should arouse suspicions that the transilluminitor unit may be faulty, or that the infrared filters might be missing or switched off.

Cutaneous necrosis following extravasation of intravenous medications

Leakage of total parenteral nutrition and of a variety of medications have led to local skin and subcutaneous tissue necrosis in the neonate [1–4]. It appears that the risk is highest when intravenous cannulae are inserted in the lower limbs, particularly above the ankle. Severe lesions may lead to joint contractures requiring plastic surgical correction. Alopecia may result from extravation from cannulae placed in the scalp.

Iatrogenic dystrophic calcification

Iatrogenic dystrophic cutaneous calcification has been reported in three situations:
1 on the heel due to heel pricks during neonatal care [1,2];
2 at the site of extravasation of calcium-containing solutions given intravenously or by intramuscular injection [3–5];
3 on the scalps of children who have undergone electroencephalography with calcium chloride-containing paste on abraded skin [6].

Needle marks [1]

Children who have received neonatal intensive care will frequently have punctate white scars at sites of needle insertion. Individual lesions will generally be imperceptible, but groups of lesions at particular sites may be more apparent, resulting in curious speckled scarring.

Cutaneous necrosis following chemical burns

Cutaneous necrosis has been reported following skin contact with a variety of antiseptics in premature neonates, reflecting the increased rate of percutaneous absorption that is a feature in this age group [1–5].

Neonatal adnexal polyp

Solitary self-healing polypoid lesions have been observed in some 4% of neonates in a Japanese survey [1,2]; their occurrence in other racial groups has yet to be documented. These lesions are firm, pink, polypoid nodules, about 1 mm in diameter, usually found close and medial to one or other nipple. Histology shows a normal epidermis, a vascular dermis containing prominent hair follicles with vestigial sebaceous glands and well-developed eccrine glands. These lesions generally separate from the skin spontaneously after a few days.

Disorders caused by transplacental transfer of maternal autoantibodies

Clinical manifestations in the neonate have now been reported in a number of maternal disorders that are believed to be induced by circulating autoantibodies. Of particular interest to the dermatologist are those reports concerning lupus erythematosus (LE) (see below), pemphigus vulgaris [1–5], pemphigus foliaceus [6–7], herpes gestationis [8] and aphthosis [9].

Because IgA, IgM and IgE antibodies do not cross the

placenta in significant amounts, this phenomenon is restricted to diseases caused by autoantibodies of IgG class. Where complement is also involved in pathogenesis, this must be provided by the fetus, as it does not pass across the placenta. Complement can be detected in the fetus from about the 11th week of gestation [9]. Maternal IgG is catabolized more or less completely within the first 3–6 months of life, and antibody-mediated transplacental diseases can be expected to remit spontaneously within this period.

Neonatal lupus erythematosus

Definition. Neonatal LE is a rare syndrome comprising transient skin lesions resembling subacute cutaneous LE, and/or congenital heart block, occurring in the babies of mothers with clinical or subclinical autoimmune connective tissue disease, and associated with the transplacental passage of maternal autoantibodies to the ribonucleoproteins (RNPs), Ro-SSA, La-SSB, or U_1-RNP [1].

Aetiology. It is now accepted that this disease is provoked in the fetus or newborn infant by maternal IgG autoantibodies that have crossed the placenta [2,3]. In 95% of cases, these are of IgG1 class [4] and are directed against the Ro RNP antigen [5]. These antibodies are relatively prevalent in young women, and appear to be compatible with apparently normal health. For these reasons, neonatal LE is seen more commonly than neonatal pemphigus vulgaris or neonatal herpes gestationis. La, anti-native DNA, anticardiolipin or antinuclear antibodies, or rheumatoid factor, may be present in addition to Ro antibodies [6,7]. A small proportion of affected infants do not have detectable Ro antibodies but do have La, U_1-RNP (nRNP) antibodies [6–8]. Many affected infants fail to demonstrate a significant titre of circulating antinuclear antibodies, unless human tissue is used, when a speckled fluorescence pattern will be seen [9].

The presence of Ro and La antigens has been demonstrated in fetal skin and cardiac conducting tissue [10,11].

Up to 60% of the mothers of infants with neonatal LE have no clinical evidence of connective tissue disease at the time of the birth [3,7,12]. However, there is a substantial risk of subsequent development of symptoms of autoimmune connective tissue disease [13]. About 40% of the mothers do have signs or symptoms of systemic lupus erythematosus (SLE), subacute cutaneous LE or the sicca syndrome [14–17], although these may be minimal. More recently, it has been recognized that about 5% of women of child-bearing age who present with leukocytoclastic vasculitis will have Ro antibodies [18], and it is probable that about 5% of babies with neonatal LE have mothers with leukocytoclastic vasculitis [13,19].

Pathology. Skin biopsy specimens from infants with cutaneous lesions generally demonstrate the features of LE, i.e. epidermal atrophy, liquefaction degeneration of basal keratinocytes, colloid bodies and a perivascular and periappendageal lymphohistiocytic inflammatory infiltrate in the dermis [14,20,21].

Direct immunofluorescence is positive in about 50% of cases, showing dermal–epidermal junction and perivascular deposition of IgG, IgM and C3 [14,21].

Autoimmune haemolytic anaemia and thrombocytopenia are seen in a small proportion of affected infants [14].

Cardiac abnormalities occur in about 60% of infants with neonatal LE [1], although there appear to be some racial differences in this frequency, which is reported to be smaller, for example, in Japan [22]. Fibrosis of the conducting tissue of the heart commonly results in congenital heart block. It has recently been shown that anti-Ro antibodies can bind to cardiac conduction cells during mid- to late fetal development, leading to altered membrane repolarization and selective damage to the atrioventricular (AV) node [23]. Other developmental abnormalities of the heart may also occasionally occur, including subendocardial fibroelastosis and fibrinous pericarditis [24,25].

Asymptomatic central nervous system vasculopathy has been demonstrated in neonatal LE by ultrasound and colour Doppler flow imaging, but its longer term significance is unknown [26].

These antibodies disappear from the infant's serum within about 6 months, but are more persistent in the mother [14,21,27].

Clinical features [9,14–17,22,28–31]. Most infants with neonatal LE have either skin lesions or cardiac lesions; approximately 10% have both [13,32]. About 90% of infants with neonatal erythematosus have only skin lesions.

In about two-thirds of those infants who develop cutaneous lesions, these are already present at birth [15,30]. In

Fig. 14.2 Neonatal lupus erythematosus (LE): fading facial lesions in characteristic periorbital distribution, with residual atrophy, in a 4-month-old infant.

the remainder, the lesions appear during the first 2–3 months, although their appearance may be delayed as long as 5 months [13].

The skin lesions of neonatal LE generally take the form of well-defined areas of macular or slightly elevated erythema, frequently annular, occurring predominantly on the face, particularly the forehead, temples and upper cheeks, and on the scalp and neck (Fig. 14.2). A 'spectacle'-like distribution of lesions around the eyes is especially characteristic. The chest, back or limbs may also be affected.

Less commonly, lesions take the form of annular erythema without an epidermal component; this type of presentation has predominantly been reported in Japanese infants [22,27].

Subcutaneous lesions have also been described [33].

Occasionally, neonatal LE presents as extensive reticulate erythema with atrophy, closely resembling cutis marmorata telangiectatica congenita [34,35].

Depigmentation may be very prominent in racially pigmented infants [36].

Provocation or exacerbation of lesions by sun exposure has been reported in some cases.

Follicular plugging is not prominent, but scaling is a common early feature, and a degree of atrophy and/or telangiectasia are frequent long-term sequelae. Permanent hair loss may occur.

Lesions resembling morphoea have been reported [37].

In most cases, the skin lesions have resolved within the first year, but areas of atrophy and/or telangiectasia may be more persistent [38,39]. Long-standing depressions have followed subcutaneous lesions [33]. The most frequent sites for such lesions are the temples and scalp.

Systemic features are detectable in over half of all affected infants, of which cardiac involvement is the commonest, occurring in about 50% of cases. Cardiac involvement tends to affect a different group of infants, heart and skin abnormalities occurring together in only about 10% [9,13,32]. The reasons for this are unclear. Congenital heart block can be detected as early as the 18th week of gestation by ultrasound or electrocardiography [40]. The block is generally permanent, and is not associated with structural cardiac abnormalities such as septal defects. About a half of affected infants require pacemakers [29,40].

A smaller proportion of infants have combinations of hepatomegaly, splenomegaly, lymphadenopathy, autoimmune haemolytic anaemia, thrombocytopenia and pneumonitis, which are generally mild in degree and fairly transient.

Prognosis [41]. Infants with skin lesions alone, or with skin lesions and systemic features other than heart block, generally show little sign of residual disease after the age of 1 year. However, their long-term prognosis must remain slightly guarded in the light of reports of the later development by some of full-blown connective tissue disease [25,29,42–44]. Conduction defects of the heart tend to be permanent, and when severe are associated with a significant mortality [13,29,45].

The risk of recurrence in further pregnancies appears to about 25% [13,46]. This risk appears to be influenced by immunogenetic factors [47]. Spontaneous abortion and stillbirth do not appear to be more frequent in further pregnancies of mothers who have had a previous child with neonatal LE [13]. Mothers with Ro antibody may experience recurrent fetal loss if they do not have SLE, but do not appear to do so if they do have SLE [48].

Diagnosis [7]. The lesions of congenital rubella or cytomegalovirus infection may need to be considered, although these are of purplish colour and purpura is generally prominent. Congenital syphilis may also need to be excluded, but whereas mucosal, periorificial, and palmar and plantar lesions are common in congenital syphilis, these features are rare in neonatal LE. However, confusion may be caused by the false-positive antibody tests that are as much a feature of neonatal as of acquired LE.

Atrophy and telangiectasia of the cheeks is seen with photosensitivity in Bloom's syndrome, and without photosensitivity, in most cases, in the Rothmund–Thomson syndrome (see Chapter 12). In these disorders, skin lesions are not present at birth and generally appear later than in neonatal LE.

A skin biopsy will usually allow an accurate diagnosis of neonatal LE, particularly if combined with direct immunofluorescence studies, and tests for the appropriate circulating autoantibodies in both the mother and the child.

Treatment. The skin lesions of neonatal LE require no treatment, but sun protection is essential. Occasionally, thrombocytopenia, haemolytic anaemia or hepatitis may warrant systemic steroid therapy [49]. Up to 50% of infants with cardiac involvement will require a pacemaker [22].

The pregnancy of a woman who has Ro, La or U_1-RNP antibodies should be monitored to detect a slow fetal heart rate [50,51]. Treatment with high-dose systemic steroids may be indicated for fetal bradycardia where there are signs of heart failure [52].

Neonatal pemphigus vulgaris

Pemphigus vulgaris is unusual in pregnancy, because it is largely a disease of an older age group and because affected individuals receiving systemic treatment rarely become pregnant. Nevertheless, several cases of trans-

placentally transmitted pemphigus vulgaris have been reported [1–6]. Not all mothers have had clinically apparent disease during pregnancy [7]; in other cases the disease has been mild [8].

Affected infants have had cutaneous and/or mucosal erosions or bullae. Several have been stillborn [1,6]. Direct immunofluorescence has been positive in skin biopsies from all affected infants, and circulating IgG pemphigus antibodies have been found in the majority.

No treatment is required; lesions have resolved spontaneously within about 3 weeks, and circulating IgG antibodies have become undetectable by the end of the second month of life.

Transplacental pemphigoid (herpes) gestationis

Cutaneous lesions occur in about 10% of infants born to mother with pemphigoid gestationis, although maternal IgG antibasement-membrane autoantibody can be found in all infants of affected mothers [1,2]. The lesions may be present at birth or they may appear at any time up to the third day of life [3,4]. These lesions may vary from evanescent, non-specific, erythematous or urticarial papules to fully developed bullae [5,6]. Lesions in the infant may be extensive [7]. Spontaneous regression of lesions within 3 weeks is the rule. Direct immunofluorescence is normal by the end of the first month, and circulating IgG antibasement-membrane-zone antibody can no longer be found.

Earlier reports of increased fetal and infant morbidity and mortality when mothers have pemphigoid gestationis [8] have not been confirmed [9–11]. However, there does appear to be an increased risk of premature delivery when a mother has herpes gestationis [10,11]. The risk of adrenal insufficiency should be considered in neonates whose mothers have been treated with prednisolone for prolonged periods.

Transplacental transfer of maternal malignant disease

Transplacental transfer of maternal malignant disease is fortunately extremely rare, despite the fact that malignancy occurs in 1 in 1000 pregnancies [1,2], and it is well established that maternal cells regularly reach the fetus [3].

The malignancy transferred in this way has been malignant melanoma in about 90% of cases, although this particular malignancy accounts for only about 8% of those occurring in pregnant women [4]. Malignant melanoma transmitted in this way may result in the appearance of nodular skin deposits in the neonate. Spontaneous regression of transplacentally transferred malignant melanoma has been reported [5,6].

Transplacental transmission of acute monocytic leukaemia [7] and of natural killer (NK) cell lymphoma [8] have also been reported.

Disorders caused by transfer of toxic substances in maternal milk

When considering the cause of any rash in a young infant, the possibility that it reflects exposure of the mother to a toxic substance that has been transferred in her milk needs to be borne in mind. A good example is provided by two reports of bromoderma occurring in neonates whose mothers had taken bromide medicinally [1] or had been accidentally exposed in a photographic laboratory [2].

'Collodion' baby

SYN. LAMELLAR DESQUAMATION/EXFOLIATION OF THE NEWBORN

Aetiology and nomenclature. This term describes a highly characteristic clinical entity. It precedes the development of one of a variety of ichthyoses, the commonest of which are the autosomal recessive ichthyoses termed lamellar ichthyosis and non-bullous ichthyosiform erythroderma [1–3] (see Chapter 34). The collodion baby phenotype has been reported in the rarer autosomal dominant form of lamellar ichthyosis [4] and a possibly autosomal dominant form of non-bullous ichthyosiform erythroderma [5]. It is also characteristic of the trichothiodystrophy-ichthyosis syndrome [6,7].

There are other ichthyoses in which an initial collodion baby phase has occasionally been reported. These include ichthyosis vulgaris [2], X-linked ichthyosis [8], Netherton's syndrome [9], neutral lipid storage disease [10] and the Sjögren–Larsson syndrome [2], but the great majority of neonates with these disorders do not demonstrate the collodion baby phenotype. A transient collodion membrane has also been reported in two neonates with Gaucher's disease [11,12].

In at least 10% of cases, the collodion baby phase is followed by a relatively mild ichthyosis of lamellar type; this may be so mild as to be considered more or less normal [2,3,13–19]. Autosomal recessive inheritance has been reported in this type of case [17], but it remains possible that these cases are genetically heterogeneous.

Pathology [1,2,20,21]. It was at one time popular to regard the collodion membrane as retained periderm (epitrichium) [22]. Histologically, however, the membrane is essentially orthokeratotic, rather than parakeratotic like the periderm [1,2,16,21], making this a highly improbable explanation. Apart from a compact, thickened orthokeratotic stratum corneum, the epidermis is fairly normal, similarly the dermis.

Fig. 14.3 Lamellar desquamation of the newborn in a 7-day-old infant. This child required peritoneal dialysis for acute renal failure secondary to inadequate hydration. A year later, the skin was normal apart from minimal fine scaling.

Although the histology of the skin is identical at birth whether the child later develops a severe ichthyosis or not, at about 15 days it may be possible to make a prediction on histological grounds [16], even though the clinical features are still indistinguishable.

Electron microscopy of the epidermis at 2 days in a baby whose skin later became clinically normal showed several distinctive features [14]. The upper two-thirds of the stratum corneum were of abnormal appearance; the corneocytes were convoluted and irregular in shape, and contained unusual, small, dense intracellular granules. There were large numbers of intercellular lamellar (Odland) bodies and exceptionally well-preserved desmosomes.

Clinical features [1–3,9,21,23,24]. The severely affected infant is bright red and encased in a taut, glistening, yellowish translucent covering resembling collodion (Fig. 14.3). The face is immobilized; tension on the skin results in ectropion, eversion of the lips (eclabion), producing a rather fish-like appearance of the mouth, and effacement of the nose and ears. The nostrils may be blocked. The skin over the fingers, hands, toes and feet may result in immobility and may interfere with blood flow, occasionally resulting in the loss of parts of digits.

Within hours, this membrane dries and cracks, and bleeding may occur along the resulting fissures. Within 1 or 2 days, it starts to peel off, either in extensive sheets or as large, light-brown scales, but may reform several times. The shedding will generally be more or less complete within 4 weeks. Subsequently, the typical features of one of several varieties of ichthyosis gradually emerge over a period of weeks or months.

During the first day or two, tightness of the skin on the thorax may interfere with respiration, and very occasionally, respiratory distress may be caused by nasal obstruction.

Diagnosis. The appearance of the collodion baby is unmistakable.

A degree of cracking and desquamation is a characteristic cutaneous finding in babies who are small for gestational age and/or post-term, presumably due to placental insufficiency, but this is unlikely to be mistaken for true lamellar desquamation of the newborn because of the lesser severity of the skin changes and the presence of other clinical features of these two states. Babies who are erythrodermic at birth, due, for example, to Netherton's syndrome, or to the Conradi–Hünermann syndrome, may be mistaken for collodion babies, but careful examination will reveal no collodion membrane.

The appearance of the neonate with harlequin ichthyosis (see below) has much in common with the collodion baby, the principal difference being the greater thickness of the stratum corneum, which typically encases the baby like a suit of armour. However, clinical differentiation may be less straightforward in milder cases.

Restrictive dermopathy also results in a neonate with tight and immobilizing skin, but in this condition, the skin appears thin and transparent, with prominent underlying blood vessels. The mouth is also open, but ectropion is not generally present. The skin does not dry out and come away. Death occurs rapidly as a consequence of respiratory failure.

Neonates with the lethal autosomal recessive Neu–Laxova syndrome [25] may have skin changes closely resembling a collodion membrane. The condition is characterized by intrauterine growth retardation, and central nervous system, skeletal and cranial abnormalities.

Boys with hypohidrotic ectodermal dysplasia may show lamellar scaling at birth, but it is unlikely that this would be mistaken for a collodion membrane.

Prognosis. The collodion baby is at risk, largely because of the consequences of loss of skin barrier function, resulting in:

- impaired temperature regulation;
- increased insensible water loss [26–28], which may lead to acute renal failure and/or permanent brain damage [29] if fluid replacement is neglected;
- septicaemia [27].

Respiration may become compromised as a result of intrapartum aspiration of squamous debris shed into the amniotic fluid [30]. Interestingly, this debris can be seen on fetal ultrasound, and in such cases, early delivery by caesarean section may be protective of life.

Immobility of the chest may also compromise respiratory function, and predispose to pneumonia.

In the short term, mortality from these causes is substantial.

The longer-term outlook depends on which type of ichthyosis develops, and it is important to be aware that there is no correlation between initial severity in a collodion baby and the gravity of the ichthyosis that follows. At present, only observation over a period of months will reveal the ultimate fate of the skin in collodion babies. It has however been suggested that a skin biopsy at about the 15th day may be helpful in this respect [16].

Treatment. The most important element in treatment is an awareness of the possible complications, as outlined above.

The baby should be nursed in an incubator in a high-humidity atmosphere, with careful monitoring of body temperature. Great attention needs to be given to fluid and electrolyte balance. In severe cases, fluid therapy should be given intravenously, but in less severe cases oral or nasogastric fluid supplementation will suffice. Peritoneal dialysis may be indicated if renal failure occurs.

Fluid loss can be reduced by frequent applications of lipid; a 50 : 50 mixture of white soft paraffin and liquid paraffin is ideal for this purpose. Frequent oiling of the skin increases mobility and comfort, accelerates healing of fissures and may reduce the risk of infection.

Prevention of infection is of the greatest importance in saving these babies. Great attention should be paid to this aspect of care. Skin punctures should be kept to a minimum, and vascular access should be avoided as far as possible.

Bands of tight skin constricting digits, hands or feet may occasionally require surgical division.

Eczematous eruptions in the newborn

Eczematous eruptions are extremely common during the newborn period. Few are severe, and most are transient. However, in some babies they herald more chronic and possibly severe atopic dermatitis, and, in a few instances, they may provide an important clue to serious internal disease, as for example in the cases of zinc deficiency and the Wiskott–Aldrich syndrome (WAS). The following varieties of neonatal eczematous eruption will be considered here: contact dermatitis, particularly primary irritant napkin dermatitis and perianal dermatitis, intertrigo and infantile seborrhoeic dermatitis.

Contact dermatitis in the neonatal period

The skin of the newborn is particularly sensitive to irritants. Factors that contribute to the high incidence of primary irritant reactions in this age group include the widespread use of inappropriate toxic applications such as antiseptics, prolonged skin contact with urine and faeces, and the frequent presence of occlusive conditions. The commonest clinical patterns of primary irritant dermatitis seen in the newborn period are perianal dermatitis and napkin dermatitis. A non-allergic form of contact dermatitis to plastic identification bracelets has also been described in neonates [1]. The alcohol burn is a less common, but very important, form of acute irritant reaction.

True allergic contact dermatitis is exceedingly unusual in the neonatal period [2], partly because of the relative difficulty of sensitizing the skin for type IV hypersensitivity responses at this age [3,4] and partly because of the lack of appropriate antigen contact. Many authors have argued that reports of allergic contact dermatitis in neonates based on positive patch-test results require cautious interpretation, because the concentrations of allergens generally used for such tests may elicit irritant responses in small children [5–7], but relevant positive results have been described in early infancy to allergens such as nickel (from earrings), epoxy resin (from a plastic identification bracelet), and the components of various topical applications, particularly those used for the treatment of napkin dermatitis [7].

Perianal dermatitis of the newborn

Aetiology. Perianal dermatitis has been reported to have an overall incidence of 5–20% [1]. The incidence is lower in breastfed infants than in those fed cow's milk formulae [2,3]. It has been suggested that this difference might be explained by the higher faecal pH of the formula-fed infants [3], but this has not been confirmed [4]. Although the precise cause of perianal dermatitis in the newborn remains unknown, it is assumed that it represents an irritant response to faecal constituents. It is likely that there is considerable variation in susceptibility.

Clinical features. In the great majority of cases, erythema of the perianal skin makes its initial appearance during

the first 8 days of life [2]. In the mildest cases, the erythema is confined to a zone some 2 cm in diameter around the anus, but commonly it extends to 4 cm or more. In the more severe forms, the affected skin may be oedematous and superficially eroded. Healing occurs spontaneously in 7–8 weeks. Although it usually occurs alone, perianal dermatitis may sometimes be associated with primary irritant napkin dermatitis or seborrhoeic dermatitis of infancy.

Diagnosis. The site and the early age of onset usually establish the diagnosis, but other dermatoses that appear in the napkin area need to be considered. The presence of pain and bleeding suggests a possible developmental defect of the anal papillae [5].

Treatment. Little treatment is usually needed, other than attention to hygiene. The affected area should be washed with water and a water-miscible emollient as soon as possible after defecation, and a protective lubricant such as White Soft Paraffin BP should be applied immediately afterwards.

Primary irritant napkin dermatitis

SYN. DIAPER DERMATITIS

Terminology. The term napkin dermatitis implies an inflammatory eruption of the napkin area. Such an eruption may have many causes. The term is therefore best avoided except in this more general sense, and the term primary irritant napkin dermatitis should be preferred for the condition described here, even though its exact aetiology remains unestablished.

Aetiology [1–6]. It seems unlikely that every case of primary irritant napkin dermatitis has precisely the same combination of causes. It is, however, exceedingly rare in the absence of napkin wearing, and at least a degree of urinary or faecal incontinence. The following factors need to be considered in any discussion of the aetiology of primary irritant dermatitis.

Maceration by water. The stratum corneum is almost exclusively responsible for the water barrier function of the epidermis, containing cells that are continuously sloughed off and renewed in a cycle of 12–24 days [7]. The hydrophobic extracellular matrix acts as the water barrier, preventing water loss from the body, and the entry of water and other hydrophilic substances, while the hydrophilic cells of the stratum corneum ('corneocytes') provide mechanical protection from the external environment in the form of a waxy layer.

Excessive wetness has several effects on the stratum corneum. Firstly, it makes the skin surface more fragile, and therefore more sensitive to frictional damage [4,8]. Secondly, it interferes with the protective barrier function [8–10], allowing increased permeation of irritant substances into the sensitive living layers of the skin below the stratum corneum, and exposure of these layers to the drying effect of the air and to the entry of harmful microorganisms.

Prolonged occlusion of the skin can itself produce erythema, particularly if water is kept in contact with the skin surface [1], and it has been suggested that prolonged contact with water alone can provoke dermatitis [11].

Friction. It seems likely that friction between the skin and the fabric of the napkin will also be an important factor in most cases. This is supported by the frequent predilection of the eruption for sites where such friction would be maximal, i.e. the inner surfaces of the thighs, the convex surfaces of the genitalia, the buttocks and the waistline. Friction would be able to breach the stratum corneum in the presence of maceration.

Urine. Newborn babies pass urine more than 20 times in 24 h. This frequency reduces through infancy to an average of 7 times in 24 h at 12 months [12].

For many years it was believed that ammonia, produced by bacterial degradation of urea in the infants' urine, was the major cause of primary irritant napkin dermatitis [13,14]. It is now clear that this is not the case [4,15]. Neither the ammonia levels found in the first morning napkin nor the prevalence of urea-splitting microorganisms differ between infants with or without primary irritant napkin dermatitis [4]. The microorganisms isolated from affected infants are not able to release ammonia either faster or in greater quantity that those from unaffected infants [4]. It has been shown that urine containing various concentrations of ammonia does not cause significant erythema when applied under occlusion for 24 h to intact infants' skin, although it can do so when the skin has previously been abraded [4]. However, only about one in four of infants with primary irritant napkin dermatitis in this study had napkin ammonia levels in excess of the minimum concentration shown to cause such erythema. It appears, therefore, that the presence of ammonia is not mandatory, although it almost certainly will aggravate the eruption when the integrity of the skin is already compromised.

It has been suggested that urinary degradation products other than ammonia might also play a role. One study has shown that urine allowed to stand for 18 h at 37°C could induce dermatitis when applied to infants' skin, whereas fresh urine could not [16]. The effect was not related either to the pH or to the ammonia concentration, but the identity of the relevant irritant could not be established.

It is now clear that the role of urinary pH is critical. The higher the pH of the urine (i.e. the greater the alkalinity) the more liable an infant is to develop irritant napkin dermatitis. However, it seems that alkaline urine is not directly harmful; its harmful effect results from its interaction with faecal material in the napkin (see below).

In addition, urine appears to increase epidermal permeability more effectively than water alone [9].

Faeces. It has been known for many years that human faeces have an irritant effect on skin [17]. Infants' faeces contain substantial amounts of pancreatic protease and lipase, and similar enzymes are produced within the gut by a variety of bacteria [18,19]. These faecal enzymes appear to be important skin irritants [20,21]. The irritant effect of such enzymes may be enhanced by many factors, particularly impaired barrier function and high pH. One of the factors that have been shown to affect faecal pH is the infant's diet, a higher pH being found in the cow's milk formula-fed infant [22].

Ureases are produced by a variety of faecal bacteria [18], and have the effect of increasing pH when mixed with urine. Increased pH enhances the activity of faecal lipases and proteases [9]. This perhaps provides an explanation for the anecdotal observation that cow's milk formula-fed infants appear more liable to primary irritant napkin dermatitis than breastfed infants, as the faeces of the former group have been shown to be more heavily colonized by urease-producing bacteria [23].

A variety of other factors may lower the infant's threshold for development of irritant napkin dermatitis; or may worsen the eruption once it is established. These include:

Poor or misguided skin care. The use of liquid soap for washing [24] and of talcum powder remain surprisingly common; both will increase risk of an irritant dermatitis.

Microorganisms. Although it has often been claimed that bacterial infection plays an important role in the common primary irritant type of napkin dermatitis, quantitative studies have consistently shown that the bacterial flora isolated from such eruptions does not differ materially from that isolated from the same area of skin in normal infants [15,25,26]. Neither does the type of napkin appear to influence the bacterial flora [27].

On the other hand, the evidence for an aetiological role for *Candida albicans* seems somewhat stronger. This organism has been isolated from the affected area in many infants with the primary irritant type of napkin dermatitis, but only very infrequently from the same area in normal infants [15,26,28,29]. Furthermore, there appears to be a good correlation between the severity of primary irritant napkin dermatitis and the level of *C. albicans* in the faeces [3].

The question of a role for *C. albicans* is complicated by the issue of the relationship between primary irritant napkin dermatitis and the classical form of napkin candidiasis. It is possible that, in most cases, the latter is a complication of the former, and this view is supported by the fact that maceration of the skin is virtually a prerequisite for the establishment of *C. albicans* infections in human skin [30,31]. It is likely therefore that this organism will become established in the napkin area of infants who have primary irritant napkin dermatitis if it is present in the faeces.

Antibiotics. The use of broad-spectrum antibiotics in infants for conditions such as otitis media and respiratory tract infections has been shown to lead to an increased incidence of irritant napkin dermatitis [32]. This appears to parallel increased recovery of *C. albicans* from the rectum and skin in such infants.

Diarrhoea. The production of frequent liquid faeces is associated with shortened transit times, and such faeces are therefore likely to contain greater amounts of residual digestive enzymes.

Developmental anomalies of the urinary tract. Those anomalies that result in constant passage of urine will predispose to urinary tract infections.

In summary, the precise aetiology of primary irritant napkin dermatitis remains unestablished. Maceration and friction appear to be important in breaching the epidermal barrier. Faecal proteolytic and lipolytic enzymes appear able to act as irritants in skin whose barrier function is impaired, particularly if the ambient pH is high. The main factors in increasing the pH appear to be the action of faecal urease on urine, and the infant's diet. Secondary invasion by *C. albicans* appears to be a risk where this organism is present in faeces.

Pathology. The histological picture is generally that of primary irritant dermatitis with epidermal spongiosis and mild inflammatory changes in the dermis.

Clinical features [33,34]. Primary irritant napkin dermatitis is not often seen during the first 3 weeks of life. The onset is most often during the third to the 12th week, and the peak prevalence is seen between the seventh and 12th months [3,35]. Essentially the same condition has been reported in older children and adults who are incontinent of urine [36–38].

Fig. 14.4 Primary irritant napkin dermatitis, affecting the convexities predominantly with sparing of the groin creases.

The overall incidence of the condition is difficult to establish, and may now be less than in the past, due to a general change to disposable napkins, but there is evidence that some 50% of infants are affected to some degree at some stage [3]. Another index of the degree of the problem is provided by the fact that in one survey it accounted for some 20% of all skin consultations in children aged under 5 years in the UK [39]. Both sexes and all races appear to be equally affected.

The most common form of primary irritant napkin dermatitis comprises confluent erythema of the convex surfaces in closest contact with the napkin, i.e. the buttocks, the genitalia, the lower abdomen and pubic area, and the upper thighs. The deeper parts of the groin flexures are generally spared (Fig. 14.4).

In some infants, the eruption is more or less confined to the margins of the napkin area ('tidemark dermatitis') and may reflect either chafing against the edge of the napkin or prolonged skin contact with the edges of impervious napkin covers or pants.

Another distinctive pattern that has recently been described is one where the eruption is localized to the lateral parts of the upper thigh and buttock, most often unilaterally, but not infrequently bilaterally, in a position that corresponds to the areas where direct contact may occur with the bands that fasten the napkin [40,41]. It appears most often to be due to an irritant effect, but may also be a reflection of contact sensitization to rubber or glue chemicals [42].

Where the reaction is acute, the erythema may have a glazed appearance and be followed by peeling of the skin in sheets. A finer scaling is more commonly present in more long-standing cases. Post-inflammatory hypopigmentation may be a striking feature in racially pigmented infants.

Occasionally, an erosive form of primary irritant napkin dermatitis is seen, in which small vesicles and erosions may develop into rather characteristic, shallow, round ulcers with raised crater-like edges ('Jacquet's dermatitis').

In both sexes, involvement of the genitalia may lead to dysuria and occasionally, where the glans penis is severely affected, male infants may experience acute retention of urine [33].

Several fairly distinctive variants of primary irritant napkin dermatitis occur. When secondary invasion by *C. albicans* is present [15], the erythema may be more intense, and will no longer spare the deeper parts of the flexural folds. The margin tends to become more defined, scalloped with peripheral scaling. Within the marginal area small pustules are often visible, and these may also be seen scattered beyond the periphery of the erythema—so-called 'satellite' lesions. This clinical appearance is associated with faecal carriage of *C. albicans* [43].

In the second, less common variant, the erythematous areas are similarly well marginated but take on a markedly psoriasiform aspect with prominent scaling of a rather more adherent and micaceous type [39,44,45]. The onset of this eruption, commonly termed *napkin psoriasis*, may be quite sudden and its extension rapid. The relationship of this eruption to true psoriasis is discussed in Chapter 35.

A herpetiform presentation of primary irritant napkin dermatitis has occasionally been described [46]. This takes the form of an eruption of vesicles and pustules followed by shallow erosions, closely resembling herpes simplex clinically, but showing no evidence of this infection pathologically.

Rather rarely, one may see domed, reddish brown or purple nodules as an additional feature. These lesions, usually known as infantile gluteal granulomas, are discussed later in this chapter.

Not infrequently, primary irritant napkin dermatitis affects areas beyond the confines of the napkin area itself. This appears particularly likely where there has been prolonged contact between the skin, urine and an occlusive surface such as a plastic cot sheet. Thus, the lateral aspects of the thighs, the calves and the heels are especially commonly affected.

In other babies, rapid dissemination of the rash occurs without any clear explanation, most characteristically in the form of expanding nummular lesions on the trunk, and more confluent erythematosquamous plaques in the flexures of the axillae and neck. An 'id' reaction to *C. albicans* has been proposed as the explanation for some of these rashes, but without any convincing evidence being provided to support such a view [28,45,47]. Where a rash in the napkin area is the first manifestation of psoriasis, other lesions of psoriasis may eventually make their appearance elsewhere. Similarly, napkin dermatitis may be the first sign of atopic dermatitis (see Chapter 18), or of 'seborrhoeic dermatitis of infancy'.

In infants with racially pigmented skin, hypopigmentation may be very prominent, and is sometimes the

parents' principal anxiety. When there is an associated eczematous eruption on the face, this may similarly feature marked hypopigmentation, and this may be the presenting problem [48].

Prognosis. Primary irritant napkin dermatitis will almost always show some response to therapy, and, in the longer term, it will resolve when napkins are no longer worn. However, in some children the napkin area eruption is merely the first sign of a susceptibility to chronic skin disorders, particularly psoriasis and atopic dermatitis. Since atopic dermatitis often initially presents with a napkin dermatitis indistinguishable from simple primary irritant napkin dermatitis, one has to be cautious not to give too optimistic a prognosis to parents of any child with such a rash.

Differential diagnosis. A wide variety of skin disorders present with lesions in the napkin area during infancy.

A confluent glistening, sharply marginated erythematous rash with peripheral desquamation and/or pustulation, and usually with satellite pustules, is, together with oral candidiasis, the typical presentation of neonatal candidiasis, a superficial *Candida* infection transmitted to the baby during birth [49]. The rash normally appears during the second week of life, and is aetiologically distinct from napkin-area *Candida* infections secondary to primary irritant napkin dermatitis.

In the past, congenital syphilis was relatively common, and had to be considered seriously in any infant with a dermatosis in the napkin area. Congenital syphilis is now rare in many countries, but its continued existence must constantly be borne in mind. Reddish brown macules, sometimes slightly raised, arise principally on the extremities including the palms and soles, and on the face mainly around the mouth. The napkin area is also frequently affected. Bullous or erosive lesions may occur in the napkin area. Flexural condylomas, rhinitis, hepatosplenomegaly and low birth weight are regular features.

The important diagnosis of zinc deficiency must be considered in any infant with a napkin dermatitis which fails to respond to appropriate treatment. A history of prematurity should increase one's suspicion, and a normal plasma zinc level does not rule out the diagnosis. Infants with napkin eruptions caused by zinc deficiency usually have a concurrent facial dermatitis extending from the perioral area, an erosive paronychia and erosive lesions in the palmar creases of the hands.

Multiple carboxylase deficiency is a rare cause of rashes in the napkin area; however, the rash most characteristically starts on the face with a presentation resembling seborrhoeic dermatitis.

In infancy, one of the commonest presentations of Langerhans' cell histiocytosis (see Chapter 52) is intertrigo, which tends to be very persistent and to become eroded as the disease progresses. Although the intertriginous eruption of Langerhans' cell histiocytosis may appear very early, more often it does not do so until after the third month. Initially, the eruption comprises small, yellowish papules, which become confluent and subsequently may become ulcerated. The scalp is almost always concurrently affected, particularly the retro-auricular area.

Some diagnostic difficulty may be encountered by the occasional occurrence of dermatophyte infections in the napkin area [50–52]. It is important to bear in mind that the clinical appearances of such infections are likely to have been substantially modified by the application of topical corticosteroids.

Primary HSV infection of the genital area occurs from time to time in both boys and girls. The eruption is acute and accompanied by malaise and pyrexia.

Unusual infections causing eruptions in the napkin area should alert one to the possibility of primary or acquired immunodeficiency [53].

Treatment. Successful treatment of primary irritant napkin dermatitis depends on recognition of the relevant aetiological factors in the individual child, but can nevertheless generally follow a fairly standard pattern. The provision of topical medications without attention to such details as the frequency of napkin changes is often associated with therapeutic failure. The elements of successful treatment include the following:

Attention to the napkins

(a) *Disposable versus washable cloth napkins*. The use of good-quality disposable napkins, particularly those containing absorbent gelling materials ('super-absorbent' disposable napkins), is associated with a lower incidence and with lesser severity of napkin dermatitis compared with washable cloth napkins [3,54–56]. These gels are able to absorb about 80 times their own weight of water, and their use therefore results in reduced wetting, and, therefore, less maceration of the skin [57]. The use of such napkins is also associated with more normal skin pH values [54].

(b) *Continuous administration of emollient from certain disposable napkins*. Disposable napkins are now available in which the layer next to the skin (the 'topsheet') is impregnated with an emollient, usually predominantly white soft paraffin. The use of this type of napkin has been shown to reduce the severity of irritant napkin dermatitis [58].

(c) *Frequency of napkin changes*. The frequency of napkin changes is also important, but probably less so now, because the absorbency of disposable napkins has increased greatly over recent years. It remains important however to change napkins as soon as possible after defaecation.

(d) *Care of washable napkins*. The use of antiseptic solutions for the storage of cloth napkins prior to washing is more or less universal, and is safe as long as suitable agents are used and washing and rinsing procedures are adequate.

Poisoning of infants by antiseptics used in the laundering of napkins is well documented [59–61]. The quaternary ammonium compounds are now regarded as the best choice, of which benzalkonium chloride is perhaps the most widely employed. Antiseptics should never be used during the rinsing process.

Machine washing is generally preferable, as the cleaning and rinsing processes are reliable and thorough. A lower incidence of primary irritant napkin dermatitis has been demonstrated in babies whose napkins were laundered commercially rather than domestically [35]. 'Biological' detergents are best avoided, as are fabric 'conditioners' added during the rinsing. Tumble drying is preferable to air drying because it leaves the napkins softer, and therefore less liable to chafe.

Routine skin care in the napkin area. A routine of skin care should be instituted that will help prevent recurrence after the eruption has been successfully cleared. At each napkin change, a water-repellent emollient such as White Soft Paraffin BP, a half-and-half mixture of White Soft Paraffin BP and Liquid Paraffin BP, Zinc and Castor Oil Cream BP, or Bepanthen® [62] ointment should be applied.

When the napkin has been soiled, the area should be cleansed with water and a water-miscible emollient such as Aqueous Cream BP, and dried before applying a water-repellent emollient. Traditionally, cotton-wool balls have been used for this purpose. However, prewetted wipes are now available commercially which combine a very soft fabric with water, without the additives such as alcohol and fragrance that made such products undesirable in the past. It is very important that cleansing of the skin be undertaken as gently as possible, with the minimum of friction.

During remission, the baby should be bathed daily with a dispersible or semidispersible bath oil added to the water, and a water-miscible emollient should be used as a cleansing agent. While the eruption is under treatment, such baths should ideally be given twice a day.

The use of talcs and proprietary over-the-counter preparations containing potential irritants should be discouraged.

Specific therapy. Topical corticosteroids are helpful, and are indicated in all but the mildest cases. There is, however, virtually never any need to use applications containing anything more potent than 1% hydrocortisone. Such an application should be used twice a day after the bath, ideally in an ointment base.

It must be borne in mind that the rate of percutaneous absorption of corticosteroid from topical application in the napkin area will be considerably enhanced by the occlusive conditions found at this site. Fears that corticosteroid absorption might interfere with descent of the testes in male infants have not been confirmed in those of normal birth weight, but the possibility remains that such a problem could arise in low birth-weight babies [63].

As the eruption is often secondarily infected with *C. albicans*, the use of an ointment containing an anticandidal agent such as miconazole is justified and has been shown to be effective [64]. Systemic antibiotics are very rarely indicated, and there is no convincing evidence that oral nystatin has any additional therapeutic or prophylactic value when used in combination with a topical anticandidal agent [1,29,65].

In cases where flow of urine and especially of faeces over the skin is more or less continuous, topical sucralfate has been reported to provide a particularly effective barrier [37].

Infantile gluteal granulomas

This term has been applied to a condition that arises as a complication of the primary irritant type of napkin dermatitis [1]. The apparent absence of any reports of the disorder before 1971, in contrast to the substantial number published throughout the world during the next decade, implied that this may have been a modern phenomenon, perhaps related to changes in the care of the napkin area in general, and the treatment of napkin dermatitis in particular. Conversely, a decrease in the number of case reports during the last decade may reflect a real improvement in these aspects of infant care.

In most, but certainly not all [2,3] of the reported cases, rather potent topical corticosteroids had been used, and the authors believed them to have been important precipitating factors [4–7]. *Candida albicans* has also been considered as an aetiological factor [6], but cannot be isolated from the napkin area in such infants any more often than in uncomplicated cases of napkin dermatitis [5]. Intracutaneous intradermal tests to *C. albicans* antigen have not shown evidence of either immediate or delayed hypersensitivity, and serum precipitins to *C. albicans* and *C. parapsilosis* have not been found [8]. A role has also been proposed for the use of occlusive pants, but these are now rather rarely used in the developed parts of the world. Starch particles were found within lesions in one case [9], but were sought and not identified in others [3].

Histologically, there is a dense granulomatous infiltrate occupying the full depth of the dermis, comprising lymphocytes, plasma cells, neutrophils, eosinophils and histiocytes [4,5,8,10].

The characteristic lesions most commonly make their appearance between the fourth and ninth months of life in a child with primary irritant napkin dermatitis. There is no correlation between the severity of the napkin dermatitis and the incidence of these lesions, and they frequently appear to arise at a time when the napkin dermatitis is improving. The lesions comprise one or several, rather

Fig. 14.5 Infantile gluteal granulomas in the pubic area of a 6-month-old infant.

uniform, livid purple nodules, which are usually oval in outline with their long axis parallel to the skin creases [5] and up to about 3 cm in length. They tend to occur on the convexities of the napkin area, not in the flexures themselves, and are definitely not confined to the gluteal region, as the name might be taken to imply (Fig. 14.5). They have occasionally also occurred at other sites in affected infants [5]. They persist for some weeks and appear to regress spontaneously, even if the use of potent corticosteroid applications is continued [11], and may leave atrophic scars [5]. Analogous lesions have been described in incontinent older patients [12,13].

These lesions require little treatment other than the removal of likely provocative factors, especially the withdrawal of topical corticosteroid therapy other than hydrocortisone alone, if this is required for the treatment of persisting napkin dermatitis, and the restriction to a minimum of the wearing of occlusive plastic pants. Napkin-area care should be as outlined above for primary irritant napkin dermatitis.

These lesions have a superficial resemblance clinically and histologically to Kaposi's sarcoma [10]. However, the latter more commonly arises on the extremities, even in infants [14], and histologically shows characteristic interweaving bands of spindle cells, at least in well-developed cases.

Infantile 'seborrhoeic' dermatitis

Definition and nomenclature. The term infantile 'seborrhoeic' dermatitis is widely used to describe an allegedly distinctive eczematous or psoriasiform eruption seen in infants, having a predilection for the scalp and the proximal flexures, and a favourable prognosis compared with atopic dermatitis. The term nevertheless remains unsatisfactory, as the condition has no established relationship with seborrhoea or even with sebum; neither is there any convincing evidence that it is analogous to seborrhoeic dermatitis of adults. There must be some doubt whether the condition exists at all as a separate entity.

Aetiology. The authors regard the term *infantile seborrhoeic dermatitis* as a description of a somewhat distinctive but nevertheless highly variable clinical presentation rather than a single disease. It may be a presentation that can reflect a variety of different skin disorders, and that may therefore have a number of different causes. The term is used to describe cases that others would consider to be examples of cradle cap with intertriginous lesions, intertrigo, primary irritant napkin dermatitis with dissemination, atopic dermatitis, infantile psoriasis and multiple carboxylase deficiency, as well as rashes that may reflect primary immunodeficiency infants. Once all these have been excluded, how many cases of a genuinely distinct seborrhoeic dermatitis of infancy would remain is not clear. However, as there remains a considerable body of opinion that there is a true infantile seborrhoeic dermatitis, the condition is described in this chapter. It appears possible that disagreements on this subject might to some extent reflect regional variations in incidence, and possibly a dramatic fall in incidence in recent years.

The relationship between infantile seborrhoeic dermatitis and atopic dermatitis has been the subject of debate for many years. Some authorities have proposed that infantile seborrhoeic dermatitis is merely a characteristic pattern of atopic dermatitis and not a separate entity [1],

on the basis of the observation that apparently typical infantile seborrhoeic dermatitis not infrequently transforms into equally typical atopic dermatitis. The occurrence of such transformation is not disputed, only its frequency and interpretation. A prevalence of atopic dermatitis of 27.5% was reported in a group of children reviewed 5–13 years after a diagnosis of seborrhoeic dermatitis had been made in infancy [2]. In a more recent study [3], it was shown that 19% of a group of children, diagnosed as having seborrhoeic dermatitis of infancy about 12 years earlier, had atopic dermatitis on review, compared with a prevalence of 10% in a control group, and of 45% in a group of children diagnosed as having atopic dermatitis in infancy. Scientific resolution of this controversy is hampered by clinical overlap between the two conditions, at least in their earliest stages [4]. Furthermore, the incidence of atopic dermatitis is so high that a proportion of infants with infantile seborrhoeic dermatitis would in any case be expected to develop atopic dermatitis. Because the age of onset is similar, this would often occur before the seborrhoeic dermatitis had resolved. The most valid reasons for continuing to regard the two conditions as distinct entities are, firstly, a relative lack of association between infantile seborrhoeic dermatitis and atopic status in infancy [5] and, secondly, a better prospect of early resolution in infantile seborrhoeic dermatitis [4].

These problems are highlighted by the recent finding of a prevalence of psoriasis of about 27% in a group of children reviewed 2–13 years after a diagnosis of infantile seborrhoeic dermatitis had been made [6].

Controversy also surrounds the relationship between infantile seborrhoeic dermatitis and seborrhoeic dermatitis of adults. Sebum is no longer considered an important aetiological factor in the adult condition, although it is considered possible that seborrhoea plays a part in the seborrhoeic dermatitis seen in a relatively high proportion of patients with Parkinson's disease. As infants do secrete some sebum, at least in the first few months of life [7], an aetiological role for sebum in infantile seborrhoeic dermatitis is not entirely excluded and, it has been argued, without any scientific support, that the typical early resolution of the disorder is the direct result of decreasing levels of sebum production during the last 6 months of infancy. There is no evidence of an increased prevalence of seborrhoeic dermatitis in adult life among those who previously had a diagnosis of infantile seborrhoeic dermatitis.

A favoured view in the past was that infantile seborrhoeic dermatitis is an 'id' reaction to *C. albicans* skin and intestinal infection [8,9], but no convincing evidence has been put forward to support this hypothesis.

An aetiological role for *M. furfur* has been convincingly argued in adult seborrhoeic dermatitis [10], and is supported by the therapeutic benefit that follows therapy with ketoconazole [11]. It has been demonstrated that this organism can activate complement *in vitro* by the alternative pathway [12]. *Pityrosporum ovale* is part of the normal skin flora in adults, but is rare in prepubertal children; it is generally found in greatest density in the scalp and proximal flexures. The proportion of the normal scalp flora represented by *P. ovale* is increased in adults with seborrhoeic dermatitis [13], and the organism has been isolated with an increased frequency from several body sites in infants with infantile seborrhoeic dermatitis [14,15]. A possible aetiological role for this yeast in infantile seborrhoeic dermatitis is supported by reports of therapeutic response to topical ketoconazole [15,16].

In the past, there was a strong feeling that nutritional factors might be important in the aetiology of infantile seborrhoeic dermatitis, an impression that was strengthened by a report from Czechoslovakia of an increased incidence of the condition during the post-Second World War period of food shortage [17]. The appearance of an intertriginous dermatitis with some resemblance to infantile seborrhoeic dermatitis was described in infants fed a diet deficient in essential fatty acids [18], but evidence of essential fatty acid deficiency has not been demonstrated in infants with seborrhoeic dermatitis [19]. Data have been reported, however, that were interpreted as suggesting that affected children may have transiently impaired activity of the enzyme, δ-6-desaturase [20]. Seborrhoeic dermatitis has also been reported in breast-fed babies of malnourished mothers, in whom it improved when biotin injections were given to the mothers [21]. Dramatic responses have been described in infants with generalized seborrhoeic dermatitis who were themselves given oral or parenteral biotin [22,23]. In contrast, more recent controlled trials of biotin treatment provided no support for such claims [19,24], and biotin deficiency in infancy does not result in the clinical picture of seborrhoeic dermatitis [25,26].

Pathology. There have been very few studies of the histopathology of infantile seborrhoeic dermatitis. However, it seems clear that one finds patchy parakeratosis, with epidermal microvesicles and slight spongiosis, occasional lymphocytes, moderate acanthosis (often psoriasiform) and a poorly developed granular layer [27]. The dermis features a mild, patchy perivascular lymphocytic inflammatory infiltrate and prominent perivascular oedema. Direct immunofluorescence has been negative, and candidal antigen has not been identified.

Clinical features [4,28,29]. The eruption generally first appears between the second week of life and the sixth month, but perhaps most frequently between the third and eighth weeks. In some cases, it starts in the napkin area; in others, it starts on the face and scalp. Occasionally, the eruption first appears on the trunk outside the napkin area. Often, the rash occurs almost simultaneously on the

face, scalp and in the napkin area at its onset. It tends to spread fairly rapidly to involve the scalp, face, neck, napkin area and axillae. On the scalp, the vertex and frontal areas are the sites of predilection. On the face, the forehead, eyebrows, eyelids and nasolabial folds tend to be the worst affected areas. The eruption is often confluent around the neck and up the sides of the face to the temples, the area behind the ears tending to be the most severely affected. In the napkin area, the folds are confluently involved. On the trunk, the umbilical area is a favourite site.

The rash comprises well-defined areas of erythema and scaling with tiny vesicles. Papular and lichenified lesions are not seen. On the scalp and in the flexures, the eruption is confluent, but, elsewhere, the individual lesions usually start as small, round or oval areas, subsequently extending and coalescing to form patterns. The scales are rather adherent; they are yellow-brown in colour, large and greasy in the scalp, but smaller, whiter and drier in other areas.

Typically the infant is well, and pruritus appears to be relatively mild, in contrast to atopic dermatitis. As a consequence, feeding and sleep are generally undisturbed.

Differential diagnosis. The diagnostic features of seborrhoeic dermatitis are said to be its distribution in the scalp and proximal flexures, and the relative absence of pruritus, but these are not really sufficiently specific to define the disorder clinically.

Many of those diagnosed as having infantile seborrhoeic dermatitis could be given more satisfactory alternative diagnoses. These include cradle cap, intertrigo, disseminated primary irritant napkin dermatitis, atopic dermatitis, infantile psoriasis, zinc deficiency, multiple carboxylase deficiency and primary immunodeficiencies.

Perhaps the situation in which the diagnosis of infantile seborrhoeic dermatitis is most often incorrectly applied is that of disseminated primary irritant napkin dermatitis (see above). Some babies with typical primary irritant napkin dermatitis may experience progressive spread of the eruption beyond the confines of the napkin area. This generally only occurs when the napkin dermatitis is relatively intense. The pattern of dissemination in such cases may closely resemble the distribution of lesions regarded as characteristic for infantile seborrhoeic dermatitis.

It is likely that in a small proportion of cases, infantile seborrhoeic dermatitis is an early manifestation of psoriasis. There is certainly a suspicion that the dissemination of primary irritant napkin dermatitis is at least occasionally a reflection of underlying predisposition to psoriasis.

As discussed earlier in this chapter, there is a common, acquired type of cradle cap that is frequently associated with scaling lesions in the eyebrows, forehead and temples, and the retro-auricular area and neck, and occasionally with intertriginous lesions in the axillae and groins. This rash starts on the scalp and manifests relatively little inflammation. To some, this is a form of infantile seborrhoeic dermatitis; to others, it is a different entity.

Differentiation from atopic dermatitis may be particularly problematic, directly mirroring uncertainties about the existence of such an entity as infantile seborrhoeic dermatitis. There can be no doubt that rashes having the clinical characteristics of infantile seborrhoeic dermatitis may gradually transform into one that has the typical appearances of infantile atopic dermatitis, an observation that has led many to regard infantile seborrhoeic dermatitis as nothing more than a 'seborrhoeic pattern' of atopic dermatitis in infants [1]. The presence or absence of a family history of atopic disorders appears to be unhelpful in discrimination, as is the age of onset [4]. Pruritus is commoner and more severe in atopic dermatitis, but it should be borne in mind that pruritus may not in any case be evident in early infancy.

Langerhans' cell histiocytosis (see Chapter 52) may present with an eruption having features in common with infantile seborrhoeic dermatitis, particularly its distribution in the scalp, groins and axillae. However, careful examination will demonstrate that the eruption of Langerhans' cell histiocytosis comprises clusters of small, translucent, flesh-coloured papules, although these may become confluent at certain sites, particularly in the proximal flexures and in the retro-auricular area. There is often a petechial element in addition. Although the child may be pallid and unwell, this is not invariably the case. There may of course be other manifestations of the disease such as oral or anogenital lesions, soft masses in the scalp, or hepatosplenomegaly. Where there is any suspicion of Langerhans' cell histiocytosis, a skin biopsy should be undertaken.

Multiple carboxylase deficiency may present in infancy with a well-marginated erythematosquamous rash that starts in the scalp, on the eyebrows and at the eyelid margins, extending later to the perioral, perianal areas and to other flexural sites. There may be associated blepharitis, and keratoconjunctivitis causing photophobia. Vomiting is common. Neurological symptoms tend to be prominent, particularly convulsions, developmental delay, hypotonia and ataxia.

Certain primary immunodeficiency disorders may present with a progressive eczematous eruption having a predilection for the proximal flexures. Similar rashes may occur in secondary immunodeficiency disorders such as congenital human immunodeficiency virus (HIV) infection.

Prognosis. The outlook, even without treatment, is good, and clearance can be anticipated within a few weeks in the majority of cases. Relapses are unusual after clearance. Persistence suggests that the correct diagnosis is atopic eczema, psoriasis, zinc deficiency, Langerhans' cell histiocytosis or immunodeficiency.

Treatment. The treatment of this condition is similar to that of atopic dermatitis. Affected infants should be bathed at least once a day, and a dispersing bath oil may be added to the water. During the bath, affected areas should be cleaned with a water-dispersible emollient such as Ung. Emulsificans BP or Aqueous Cream BP. Soap should be avoided. After bathing, a topical anti-yeast agent should be given, because 2% ketoconazole cream has been shown to be effective in a high proportion of cases [16]. Treatment should be applied once or twice a day for 10–14 days. At other times during the day, a simple emollient cream or ointment should be applied, especially in the napkin area.

The scalp should be cleaned with 2% ketoconazole shampoo. Applications containing salicylic acid or corticosteroids should not be used, because of the very efficient absorption of these molecules at this site in infancy.

While it is reasonable to assess the nutritional value of the infant's diet, there is no evidence that either biotin or essential fatty acids are generally beneficial [19,24].

Infantile psoriasis and napkin psoriasis

While it is uncommon for psoriasis to appear in infancy, this undoubtedly does happen [1–3], and there is some evidence suggesting the occasional occurrence of congenital psoriasis [1,4,5]. However, the term napkin psoriasis has been used rather loosely to describe what should probably more correctly have been called *psoriasiform napkin dermatitis* or *psoriasiform seborrhoeic dermatitis of infancy* [6–8]. In some infants with primary irritant napkin dermatitis and infantile seborrhoeic dermatitis, the eruption shows psoriasiform features clinically (Fig. 14.6) [9–12]; it has been demonstrated that these children have an increased risk of genuine psoriasis many years later [9,12–15].

True psoriasis occurs in infancy, most typically in the napkin area as an isomorphic (Koebner) response in a

Fig. 14.6 Napkin psoriasis: confluent dry erythema with a sharp, scalloped margin in a 7-month-old infant.

genetically predisposed child with primary irritant napkin dermatitis [1]. While a fairly confident diagnosis of psoriasis can sometimes be made in such a case, it is more often appropriate to use the term 'psoriasiform' in this situation, as most infants with psoriasiform napkin dermatitis do not appear to go on to develop psoriasis [16]. Furthermore, it has been shown that the frequency of the three human leukocyte antigens (HLA), B13, B17 and BW37, is no different in infants with psoriasiform napkin dermatitis from their frequency in normal infants, whereas they are found with very significantly increased frequency in true psoriatics [17].

Psoriasiform napkin dermatitis has a mean onset at about 2 months, and generally lasts for 2–4 months [9,16]. The rash comprises psoriasiform plaques in the napkin area with smaller papular satellites of similar appearance. It frequently disseminates, to involve the trunk and limbs, where lesions will have the same morphology, and to the face and scalp, where affected areas tend to be more diffuse and covered with denser, adherent scale or crust. Frankly pustular lesions have been described in disseminated napkin psoriasis [18].

Generalized pustular psoriasis has also been described occasionally in infancy, including a case in which lytic bone lesions were present due to chronic recurrent multifocal osteomyelitis [19].

Congenital rhabdomyosarcoma
Other disorders
Neonatal lupus erythematosus (LE)

'Blueberry muffin' baby (dermal erythropoiesis)

Definition. This term has been used to describe a characteristic eruption in neonates, often present at birth, comprising widespread, purple, erythematous, oval or circular macules, papules and nodules reflecting dermal erythropoiesis.

Aetiology and pathology (Table 14.2). The 'blueberry muffin' type of lesion has been recorded in a number of congenital viral and bacterial infections, notably rubella [1–5], cytomegalovirus [1,6–9], coxsackie B2 infection, parvovirus B19 [10], and in congenital syphilis and toxoplasmosis [7,11]. These lesions have also been described in a variety of congenital haematological disorders, notably hereditary spherocytosis [12], rhesus incompatibility [13,14], ABO blood group incompatibility [6] and twin–twin transfusion syndrome [6,15]. Occasionally, clinically identical lesions have occurred in infants who appeared to have no underlying cause [6].

In the congenital infections and haematological disorders, the lesions have been shown histologically to comprise foci of dermal erythropoiesis [1,6,12,15,16]. The reticular dermis contains aggregates of nucleated and non-nucleated erythrocyte precursors, but generally no cells of myeloid or megakaryocytic type. It is possible that this process represents persistence and exaggeration of the dermal erythropoiesis that is a normal occurrence in early fetal development, but the reasons behind this persistence are unclear [8,12].

Clinical features. The skin lesions of dermal erythropoiesis are present at birth, comprising widespread or sometimes more local collections of macules and infiltrated domed papules up to about 1 cm in diameter, having a colour that is generally purple, but may vary from dark blue to magenta. There may be frank petechiae on the surface of some of the lesions. Favoured sites include the trunk, head and neck. The lesions generally fade into light-brown macules within a few weeks of birth.

Diagnosis. Clinically rather similar but more nodular lesions have occurred in a number of situations. Whether such lesions should be called 'blueberry muffin' lesions is debatable, as they do not show dermal erythropoiesis, but a variety of other histological appearances, in each case characteristic for their cause. Examples include congenital leukaemia [17–24], neonatal neuroblastoma [25,26], congenital rhabdomyosarcoma [27], congenital Langerhans' cell histiocytosis [28] and neonatal LE.

Neonatal purpura fulminans

Definition. Neonatal purpura fulminans is a potentially lethal disorder characterized by progressive haemorrhagic necrosis of the skin associated with cutaneous vascular thrombosis. It is usually due to a genetically transmitted thrombophilic disorder.

Aetiology. In the older child, purpura fulminans is a highly characteristic feature of meningococcal septicaemia, where it results from acquired deficiency of protein C or S [1], and it may occur as a sequel to a number of other infections, including common infections such as streptococcal infections, varicella and measles [2].

However, the occurrence of purpura fulminans in the neonate is almost always a reflection of homozygous deficiency of protein C or, less frequently, of protein S [3,4]. Protein C resistance has also been reported, due to mutations in the factor V gene [5,6].

Clinical features. The skin lesions most characteristically appear within the first 12 h of life [5,7], but their initial development may occasionally be delayed until later in infancy [8]. They generally comprise more or less symmetrical and well-defined 'lakes' of confluent ecchymosis, without petechiae. The lesions occur most often on the limbs, particularly at sites of pressure, but may also appear on the trunk and on the face and scalp. The onset is sudden, and the lesions enlarge rapidly, with coalescence and the development of haemorrhagic bullae and central necrosis. There is surrounding erythema and the lesions are tender. The patient is frequently febrile. These infants are also at risk of thrombosis in the central nervous system, and in the retinal vessels [7,9–11]. There is a substantial danger of internal haemorrhage, shock and death.

Diagnosis. Disseminated intravascular coagulation can also occur as in association with severe bacterial infections in infants as well as in older children [12].

Treatment. Initially, fresh frozen plasma should be given with the minimum delay, in a dose of 10–15 ml/kg/12 h. If protein C deficiency is confirmed, onward therapy with protein C concentrate should continue until the skin lesions have healed [13]. Longer-term treatment is with oral anticoagulants. Liver transplantation has been undertaken successfully [14].

Acute haemorrhagic oedema of childhood

SYN. FINKELSTEIN'S DISEASE

Definition. Acute haemorrhagic oedema of infancy is a distinctive type of leukocytoclastic vasculitis occurring in children under the age of 2 years. It was first described under this title by Finkelstein [1]. Clinically it is manifest by a combination of purpura, often in a cockade pattern, and an inflammatory oedema of the limbs and face, with a tendency to recurrence in the short term and subsequent spontaneous resolution [2].

Aetiology. The cause of infantile acute haemorrhagic oedema remains unknown, and there has been considerable debate about its relationship to Henoch–Schönlein purpura. Many regard it as an analogue of Henoch–Schönlein purpura, occurring in the very young, and this view is to some degree supported by a report of associated haematuria and proteinuria [3,4]. It is generally believed that infections, drugs and vaccines might all be precipitating factors in individual cases [2,5], and a recent case report provided evidence of provocation by a primary cytomegalovirus infection [6].

Pathology. Histopathology of the skin lesions has shown changes varying from a perivascular lymphocytic and histiocytic infiltrate with erythrocyte extravasation, to fully developed leukocytoclastic vasculitis with fibrinoid necrosis [4,7–9,10–12].

Direct immunofluorescence has generally demonstrated fibrin and C3 in and around dermal vessels [5]. IgM has been found in about three-quarters of cases and IgA in about one-quarter.

Haematological studies have invariably shown normal platelet counts and no abnormalities of coagulation. Serum complement levels have been normal.

Transient renal involvement may be revealed by the occurrence of microscopic haematuria and mild proteinuria [3,4].

Clinical features. The condition is seen almost exclusively in children between the ages of 4 months and 2 years. It is manifest by the sudden appearance of oedematous papules that feature petechial haemorrhage, and that extend to form ecchymotic plaques. These lesions most typically occur on the face, especially the cheeks, eyelids and ears, and the limbs, particularly the hands and feet. These plaques are usually of cockade (rosette) type, with scalloped margins, but occasionally small lesions join up to produce a more reticulate pattern. The lesions often follow immunizations or an upper respiratory tract infection (URTI). Accompanying oedema of the hands, feet or whole limbs is common.

Associated oedema of the penis and scrotum [3,13,14] or oral petechial lesions [13] have also been reported. Other occasional cutaneous findings have included ecchymotic [13] or necrotic lesions of the ear [9,11] and urticarial lesions [3,10,14].

In contrast to the rather dramatic cutaneous lesions, the patient generally remains well, apart from the frequent presence of pyrexia, which is usually mild. Visceral lesions are conspicuous by their general absence, although gastrointestinal complications have very occasionally been reported, including melaena [2] and lethal intussusception [9].

Differential diagnosis. Awareness of this disease should make diagnosis fairly straightforward. Meningococcal septicaemia will require consideration, but the well-defined symmetrical areas of confluent ecchymosis seen in this disorder are highly distinctive. Certain other disorders may produce annular lesions in infants, particularly urticaria and erythema multiforme, but these generally lack a haemorrhagic element and do not usually taken on a rosette configuration with scalloped margins. The same is true of the lesions of Sweet's syndrome, which may also occur occasionally in very young children [15,16]. Kawasaki disease characteristically causes oedematous induration of the hands and feet, and may result in a rash in which annular erythema may be a feature, but the skin lesions themselves are not as indurated, nor are

they purpuric. One of the most important differential diagnoses to consider in any disorder presenting with intracutaneous haemorrhage in the very young is non-accidental injury.

Prognosis. Recurring crops of lesions may occur, but spontaneous resolution normally follows within about 2 weeks. Recurrence must be rare, but has occasionally occurred [13]. No significant long-term sequelae have been reported.

Treatment. No specific therapy is required.

Disorders of subcutaneous fat

Terminological confusion has bedevilled the literature on disorders of subcutaneous fat in the newborn. The four conditions described below are essentially separate entities, although not without some clinical and pathological overlap.

Cold panniculitis (see also Chapter 55)

Definition. Cold panniculitis is a distinctive form of panniculitis provoked directly by cold exposure, to which infants appear particularly predisposed.

Aetiology. The fat of the newborn appears to be more highly saturated than that of older children and adults, with the effect that it solidifies at a higher temperature [1,2]. The possible clinical relevance of this phenomenon was demonstrated by experiments in which young pigs were fed fats of various degrees of saturation, producing corresponding differences in the saturation of their own subcutaneous fat [3]. The subsequent application of ice to the skin induced panniculitis only in the pigs fed saturated fat.

Applying ice for 50 s causes panniculitis in all newborn infants, in only 40% of 6-month-olds and almost never in 9-month-olds [4].

Cold panniculitis in infancy has most often followed exposure of the cheeks to: (i) extremely cold air [5–7]; (ii) ice bags applied as a therapy for supraventricular tachycardia [8,9]; or (iii) lollipops [10–12].

Pathology [10,13]. An early feature in skin biopsies is a lymphohistiocytic infiltrate around blood vessels at the junction of the dermis and subcutaneous fat. After a few days, lipocyte rupture leads to the formation of cystic cavities surrounded by areas of marked infiltration by lymphocytes and histiocytes, with a few neutrophils and eosinophils.

Clinical features. Indurated, warm, red, subcutaneous plaques and nodules appear within hours or days of appropriate cold exposure.

The lesions have generally occurred on the cheeks in infants, although they may be seen elsewhere in older children and adults [13,14].

Prognosis and treatment. The induration resolves over a period of a week or so, often leaving some residual post-inflammatory hyperpigmentation. No treatment is required, although it is clearly advisable for the child to avoid further cold exposure of the type that precipitated the lesions.

Neonatal cold injury

Definition. Neonatal cold injury is a disorder, now rare in developed countries, in which cold exposure of a small-for-dates neonate causes hypothermia associated with lethargy and generalized pitting oedema of the skin, clinically and pathologically distinct from sclerema neonatorum.

Aetiology [1–4]. Low environmental temperature has been the principal cause of virtually all reported cases of this disorder. Other factors that appear to have predisposed babies to this complication of cold exposure include intrauterine growth retardation, which results in a relatively thin panniculus, and tight wrappings, which would restrict muscular activity. Immaturity of either reflex shivering mechanisms or of protective vasomotor responses would also increase the risk. The condition seems to be much less common in the UK now than it was 40 years ago, probably because of improved heating in homes, very much reduced frequency of home delivery and abandonment of the previous habit of bathing babies at birth.

Pathology [5]. The panniculus is generally thin. Otherwise, there is little obvious abnormality apart from dilatation of dermal blood vessels. Profuse exudation of clear fluid from the cut surface at post-mortem suggests that the induration is due to oedema.

The dominant post-mortem finding in fatal cases has been massive pulmonary haemorrhage [2,4].

Clinical features [1–4]. The infant is usually a full-term neonate, born at home, but small for gestational age. In the great majority of cases, presentation is within the first 4 days of life, and usually during the first 24 h. The most striking features are intense erythema or cyanosis of the face and extremities, and firm, pitting oedema beginning at the extremities and spreading centrally, and becoming progressively more indurated in a proportion of cases. Petechiae have occasionally been observed.

The skin feels cold, and the baby is usually hypothermic. Associated non-cutaneous features of cold injury are generally present, and may occur in the absence of skin changes. These include immobility, drowsiness, poor feeding, vomiting, oliguria and gastrointestinal bleeding with vomiting of altered blood or melaena.

The condition appears to have been associated with a high mortality, around 25%.

Diagnosis. The main source of diagnostic confusion is with sclerema neonatorum. The generally healthy state of the infant before the onset of the cutaneous induration, its pitting nature, the history of cold exposure and a low rectal temperature all help to distinguish the two disorders. It is possible that the late non-pitting induration of the skin, which supervenes in some cases [2], may in fact be genuine sclerema.

Subcutaneous fat necrosis of the newborn

Definition. Subcutaneous fat necrosis of the newborn is an uncommon and transient disorder of neonates in which focal areas of fat necrosis cause nodular skin lesions. This nodular necrosis of subcutaneous fat may occasionally be associated with hypercalcaemia.

Aetiology. Subcutaneous fat necrosis generally occurs in full-term or post-term infants of normal birth weight during the first 6 weeks of life. The precise cause is unestablished, but a variety of insults appear to have contributed in individual cases. These have included birth asphyxia [1–4], maternal pre-eclampsia [5,6], maternal diabetes [7], obstetric trauma [8–10] and hypothermia [11–13]. In many cases, there is no convincing history of any of these putative predisposing causes. It has been suggested that localized tissue hypoxia—albeit transient—may be the common link in every case [14]. This might explain the predominant localization of lesions to sites such as the shoulders and buttocks, where mechanical pressure might further compromise the circulation. However, intermittent reports of an analogous type of fat necrosis occurring in infants undergoing hypothermic

cardiac surgery implies that the common factor is perhaps more likely to be cold.

It has been suggested that another important predisposing factor for the development of subcutaneous fat necrosis might be a protease inhibitor deficiency, analogous to the α_1-antitrypsin deficiency seen in some patients with panniculitis [15]. Such a deficiency might allow trauma to trigger development of lesions, but perhaps it would be more likely that lesions developing in this way would show the pathological features of panniculitis rather than fat necrosis.

An interesting concept [13] is that subcutaneous fat necrosis of the newborn might be a disorder of brown fat, which is present in those areas most frequently affected [16].

The appearance of subcutaneous fat necrosis has been reported after intravenous prostaglandin E_1 (PGE_1) administration for congenital heart disease, and the suggestion was made that the PGE_1 may have been responsible [17].

A number of infants have now been reported in whom subcutaneous fat necrosis was associated with hypercalcaemia [18–26]. This complication probably occurs in around a quarter of all cases, and appears to occur more frequently in infants with more extensive disease, and almost exclusively when the trunk is affected [4].

The cause of the hypercalcaemia is unknown. Suggested mechanisms have been reviewed by Hicks *et al.* [27] and by Burden and Krafchik [4]. It currently appears most likely that it reflects increased calcium absorption due to extrarenal production of 1,25-dihydroxyvitamin D, which has been observed in other granulomatous disorders including sarcoidosis [4,19,28,29]. Elevated parathormone levels have been reported in one case [24], but post-mortem studies have not revealed any evidence of parathyroid hyperplasia. The finding of increased urinary excretion of PGE_1 led to the suggestion that increased bone calcium resorption might be responsible [25,30].

Pathology [3,31–33]. Biopsies of the affected subcutaneous tissue show patchy fat necrosis, with a granulomatous inflammatory reaction of foreign-body type, and fibrosis. Both the fat cells and the giant cells contain needle-shaped clefts, which may be radially arranged. Fibrotic obliteration of small arterioles has also been observed [34]. Calcium deposits are commonly found in the necrotic fat.

Ultrastructural examination has shown parallel aggregations of electron-lucent needle-shaped spaces within adipocytes [33].

Similar changes in visceral adipose tissue have been reported in post-mortem studies of affected infants [5,9]. Widespread calcium deposition in internal organs has also been shown in post-mortem specimens from hypercalcaemic cases [6,21] and nephrocalcinosis has been observed in such infants during life [23,35].

Transient thrombocytopenia has been reported during the period of initial development of the lesions, possibly due to sequestration of platelets [6,14,36].

Plasma lipid abnormalities have been reported in a neonate with subcutaneous fat necrosis, but their relevance was unclear [37].

Clinical features. Infants who develop subcutaneous fat necrosis are generally full-term or post-term neonates of normal weight. Nodular thickening of the subcutaneous tissues is usually first detected between the second and 21st days of life. Sometimes, the changes are present at birth, and, rarely, they may appear as late as the sixth week. The nodules tend to be symmetrically distributed, and show a predilection for buttocks, thighs, shoulders, back, cheeks and arms. Lesions may single or multiple, rounded or oval, and pea-sized or many centimetres in diameter. They are initially discrete, but may fuse to form large plaques. The overlying skin is often red or bluish red. The nodules feel rubbery or hard, and are not attached to the deeper structures. The lesions may be painful [38]. New nodules may continue to develop for a week or more.

In most cases, the child's health is not substantially impaired, and within a few months the nodules disappear. Where calcium deposition is marked, the lesions may take rather longer to resolve [39]. Usually no trace of the nodules remains, but there may be slight atrophy [12]. Rarely, the nodules may ulcerate, discharge their fatty contents and leave scars.

The condition has occasionally been fatal, particularly when visceral fat has been involved [5], or where there has been complicating hypercalcaemia [24].

Diagnosis. Neonates delivered by forceps may develop subcutaneous nodules where the forceps were applied, presumably as a result of traumatic fat necrosis.

Subcutaneous fat necrosis of the newborn was in the past frequently confused with sclerema neonatorum. Occasionally, the two conditions may occur simultaneously [40].

All infants who have experienced subcutaneous fat necrosis should have their serum calcium measured on presentation and a few weeks later. If hypercalcaemia is present, its cause requires thorough investigation to exclude disorders such as primary hyperparathyroidism and vitamin D intoxication.

Treatment. None is generally required.

Hypercalcaemia may warrant treatment by administration of furosemide, dietary restriction of calcium and vitamin D, and sometimes also by oral corticosteroid administration. There may be a role for biphosphonate administration in some cases [41].

Subcutaneous fat necrosis following hypothermic cardiac surgery in infancy

There have been several reports of the occurrence of lesions analogous to those of subcutaneous fat necrosis of the newborn in children who have had cardiac surgery [1–5], and this may be a relatively frequent complication of such surgery. It appears likely that the principal provocative factor in these cases was the cutaneous application of ice to induce hypothermia, although trauma and/or hypoxia may have contributed. It is noteworthy that these children appear to have developed lesions of subcutaneous fat necrosis rather than cold panniculitis. The ages of the children at the time of surgery varied from 12 days to 20 months. Lesions appeared between 14 and 30 days later, principally at the sites subjected to the greatest cold exposure. Hypercalcaemia may occur [3]. The lesions resolve within a few weeks and no treatment is required.

Sclerema neonatorum

Aetiology. Sclerema neonatorum is a very rare disorder that almost always appears during the first week of life,

although it has occasionally been recorded later in infants born preterm. It has generally been considered a non-specific sign of grave illness, and has been associated with a mortality up to 75% [1,2]. Prematurity and smallness-for-dates appear to be frequent predisposing factors [2]. It has been recorded as already present at birth in infants subjected to placental insufficiency [3]. The disorder does not seem to occur in otherwise healthy infants, and most characteristically develops during the course of one of a wide variety of severe illnesses, particularly serious infections, congenital heart disease and other major developmental defects [2]. A proportion of these infants has been hypothermic, and occasionally sclerema has been described as a complication of neonatal could injury [4]; nevertheless, cold does not appear to be an important aetiological factor in the majority of cases.

Lipolytic mechanisms are poorly developed in the newborn, particularly in those born preterm [5]. The maturation of these enzyme systems might be further compromised by major infection or hypoxia. It has been suggested that sclerema might reflect defective lipolysis within adipose tissue, which would result in failure of fat mobilization, and an impaired capacity to maintain body temperature. It has been reported that the ratio of saturated to unsaturated fatty acids is relatively high in the adipose tissue of all neonates, and that this ratio was even higher in an infant with sclerema [6,7]. This would lead to a raised melting point, and it is possible that the induration of subcutaneous fat, which is the major clinical feature of sclerema, might reflect its solidification due to a fall in the temperature of the adipose tissue during peripheral circulatory collapse [8].

Pathology [7–9]. Often, surprisingly little abnormality has been apparent histologically. However, in most cases the subcutaneous fat layer appears to be thickened, due to an increased size of the individual lipocytes and to an increased width of the intersecting bands of connective tissue, probably due to oedema. There is very little evidence of fat necrosis and, generally, only the slightest indication of inflammation. The most characteristic histological feature of sclerema neonatorum is the presence of radially arranged, needle-shaped clefts in adipocytes and, occasionally, in multinucleate giant cells, reflecting the presence of crystals prior to processing.

Clinical features [8,10]. The affected infant is generally severely ill at the time of onset of sclerema. Woody induration of the skin starts on the buttocks, thighs or calves and extends rapidly and symmetrically to involve almost the whole surface, with the exception of the palms, soles and genitalia. This skin is hard and cold to touch, and yellowish white in colour, often with purplish mottling. It will not pit with pressure. Mobility is limited, and as a result the face may take on a mask-like expression.

The prognosis is poor, and is largely determined by the nature of the underlying disease. In spite of advances in the treatment of many of the predisposing disorders, particularly sepsis, the mortality probably remains in excess of 50%. In infants who survive, the appearance of the skin returns to normal without long-term complications such as calcification.

Diagnosis. The main area of diagnostic confusion has been between sclerema and subcutaneous fat necrosis. It is now clear that the two disorders are distinct pathologically and clinically [10], although they can occur together on occasions [11]. Table 14.3 outlines their distinguishing features.

Scleroedema has been reported in an infant at 2 weeks of age, and was distinguished from sclerema principally on histological grounds [12]. Turner's syndrome is often recognizable at birth by the presence in a female of firm non-pitting lymphoedema of the dorsa of the hands and feet, associated with low birth weight and loose folds of skin around the neck. Where primary lymphoedema occurs in neonates, it will already be clinically evident at birth. The condition may be familial, and generally first affects the legs, particularly the lower legs. The presence of oedema at birth, and its very slow progression in an

Table 14.3 Distinctions between neonatal cold injury, sclerema and subcutaneous fat necrosis.

	Neonatal cold injury	Sclerema	Subcutaneous fat necrosis
Frequency	Previously common, now rare	Rare, usually seen in neonatal intensive care units	Uncommon
Patient	Full-term neonates often small-for-dates, born at home	Usually severely ill neonates, often preterm or small-for-dates or post-term	Healthy infants, usually full term
Onset	During the first week	Almost always during the first week	1–6 weeks
Sites	Extremities, spreading centrally	Lower limbs initially becoming generalized	Trunk, buttocks, thighs, arms, face
Appearance	Pitting oedema initially with erythema or cyanosis of face and extremities	Diffuse yellow-white woody induration with immobility of limbs	Firm reddish violet subcutaneous nodules
Histology	Thin panniculus	Subtle; thickened connective tissue trabeculae; radial needle-like clefts	Granulomatous inflammation and fat necrosis
Prognosis	Mortality around 25%	Poor, mortality greater than 50% in past	Generally excellent

otherwise healthy neonate, distinguish primary lymphoedema from sclerema.

Treatment. Treatment is primarily that of any underlying disease. Systemic corticosteroids are probably not effective [1], but there is evidence that repeated exchange transfusions may substantially reduce mortality [13,14].

Infections

Although infectious diseases affecting the skin are described in detail elsewhere in this book, the clinical features of some of the more important infections affecting the skin during the neonatal period will be briefly considered here, because of their importance in the differential diagnosis of other dermatoses.

Viral infections

Neonatal herpes simplex

HSV infection in the newborn is generally a serious disease with a high mortality. The majority of such infections result from transmission of HSV of both types 1 and 2, by contact with an infected genital tract during delivery [1,2]. However, intrauterine HSV infection undoubtedly occurs occasionally [3], due either to transmission across the placenta [4], or to ascending infection related to prolonged rupture of the fetal membranes [5]. Infection may also occur postnatally by contact with non-genital sites, both maternal and non-maternal [6].

Fig. 14.7 Neonatal herpes simplex: congenital ulceration and scarring at 10 days. This infant responded rapidly to aciclovir therapy and is now entirely healthy apart from residual atrophy.

Over 70% of all infants with neonatal HSV have skin or mucosal lesions [7–9], but only in about 10% will the disease be confined to the skin. The skin lesions appear between day 2 and 20, unless intrauterine infection has occurred, in which case they will generally already be present at birth [3,10,11].

Isolated or grouped vesicles are the most common type of lesion, and the scalp and face are the most commonly affected sites, although lesions can occur at virtually any site (Fig. 14.7). Occasionally, the eruption may be generalized and bullous, and widespread erosions may occur without obvious vesicles or bullae, mimicking epidermolysis bullosa [11]. When infection is acquired during birth, the initial lesions have a predilection for the scalp in vertex presentations, and the perianal area in breech presentations [12]. Lesions may also be localized to areas of intrauterine or intrapartum skin damage [13], such as the area in which a fetal scalp electrode has been sited. Areas of cutaneous atrophy or scarring are not infrequent in the intrauterine form, and vesicular lesions may continue to appear within or at the periphery of these areas [3,14]. A zosteriform pattern has also been described [15], and, in some cases, localized or generalized non-vesicular erythematous macules. Congenital cutaneous calcification has been reported in a child with intrauterine HSV infection [16].

Oral lesions are also frequent, and take the form of erosions on the tongue, palate, gingivae and buccal mucosa.

A fatal outcome is unusual when infection is limited to the skin, mouth and eyes, but mortality and long-term damage are more likely when the central nervous system is involved or when infection is disseminated, even when appropriate antiviral therapy is given. Mortality is higher when infection is with HSV-2 [1].

Early recognition and adequate early treatment with aciclovir does appear to protect infants from dissemination of infection, where this is initially confined to the skin [13,14,17].

Fetal varicella syndrome (FVS)

Approximately 85% of adults are seropositive for the varicella-zoster virus antibody. If a woman is seronegative, she may develop chickenpox during pregnancy; this occurs in up to 10 per 10 000 pregnancies [1,2]. The infection may be transmitted to the fetus, probably in about 25% of cases. Such transmission of varicella-zoster virus infection to the fetus is considered to be very rare in mothers who develop herpes zoster during pregnancy [3].

When a mother develops varicella between the seventh and 20th week of pregnancy, spontaneous abortion may follow, or the child may be born with a variety of abnormalities considered characteristic of FVS [4–6] (Table 14.4), and this appears to be most frequent when maternal infection has occurred between weeks 13 and 20 [3]. This syndrome was first described in 1947 [7]; many other cases have been reported since [8–12]. However, most children of such mothers are born with no detectable abnormality, despite laboratory confirmation of intrauterine infection [6]. FVS therefore appears to be a relatively rare complication of maternal varicella early in pregnancy, with a fetal risk of approximately 2% [1,3,6,13].

Table 14.4 Principal clinical features of the fetal varicella syndrome.

Low birth weight
Cutaneous lesions:
Localized absence of skin, usually on a limb
Scars, often of dermatomal outline
Papular lesions resembling connective tissue naevi
Hypoplasia of one or more limbs (usually the limb affected by localized absence of skin or scarring), and/or malformed digits
Ocular anomalies, including chorioretinitis, cataracts, microphthalmia, Horner's syndrome
Central nervous system abnormalities, including seizures, mental retardation, hydrocephalus, cortical atrophy, encephalitis, encephalomyelitis, dorsal radiculitis

Localized scarring, presumed to be the sequel to intrauterine ulceration, is the most common cutaneous feature of the FVS. The larger single lesions have characteristically occurred on a limb, and have frequently been associated with hypoplasia of that limb; these lesions have generally followed infections occurring in early pregnancy [4,13–16]. Their segmental outline may be a direct consequence of damage to the fetal nervous system [5,15], as the varicella-zoster virus is known to be strongly neurotropic, or to fetal herpes zoster [8]. The occurrence of larger numbers of smaller lesions appears to result in the main from varicella later in pregnancy; their antecedents seem likely to be vesicular lesions, essentially the same as those occurring in postnatal varicella. If fetal infection has occurred in the last trimester, these smaller skin lesions, reflecting fetal varicella, may still be ulcerated at birth [17].

Areas of congenital localized absence of skin, without associated limb hypoplasia or other neurological abnormalities, have been a less well recognized consequence of intrauterine varicella [18,19], and may reflect fetal herpes zoster later in gestation. Similar skin lesions have been reported in cases of intrauterine infection with human HSV [20].

Skin-coloured papular lesions have been described in children with FVS [21], which are likely to be a direct response to cutaneous injury by intrauterine chickenpox.

Herpes zoster occurring in early infancy is likely to indicate that the child has been infected with the varicella-zoster virus *in utero* [22,23].

Pregnant women who are not immune (on the basis of history, and, preferably, serologically), and who experience exposure to varicella-zoster, should be given varicella-zoster immune globulin (VZIG) [24]. Although this can prevent or modify clinical varicella if given up to 3 days after contact, there is no definite evidence that it prevents fetal infection or damage [3]. Giving VZIG to neonates of mothers who have chickenpox at the time of delivery does

not appear to reduce the incidence of clinical infection but may reduce its severity [25]. But, as the risk of fetal damage is small, termination of pregnancy is not indicated. Ultrasound examinations can be performed to detect some of the abnormalities that occur in the cardiovascular system [26], but several of the important ocular and neurological sequelae cannot be diagnosed in this way. Amniocentesis, fetal blood and chorionic villus sampling can be performed to isolate the virus or to detect specific IgM, but may fail to identify infection [23,27].

There are no reports that establish a role for aciclovir therapy in the prevention of FVS. Therefore, the decision whether to treat the mother should be based solely on the severity of her illness [24].

A potentially dangerous situation relates to maternal development of varicella in the 4 days either side of delivery [28]. In this case, neonatal varicella may also occur, but in the absence of the protection offered by the maternal immune system, mortality may be as high as 30%. Where maternal infection occurs at this time, VZIG is recommended for the newborn. If overt varicella develops in the child, intravenous aciclovir should be added to the VZIG [29].

Congenital rubella

Rubella contracted by the fetus before the 20th week of gestation may result in disseminated infection, causing intrauterine growth retardation, microcephaly, microphthalmia and a wide variety of other abnormalities [1]. Cutaneous lesions are among the most prominent clinical features of congenital rubella [2–4]. The typical lesions are present at birth, or make their appearance during the first 48 h. They comprise discrete, rounded, red or purple infiltrated macules, 3–8 mm in diameter. Although such lesions may be seen at any site, they generally occur in largest numbers on the face, scalp, back of the neck and on the trunk. Occasionally, the lesions are slightly raised. They tend to fade over a period of weeks. These lesions have often been described as 'purpuric', and have generally been attributed to thrombocytopenia, which is another common feature of congenital rubella [3]. However, histological examination has shown them to comprise foci of dermal erythropoiesis [2,5,6]. Such lesions have frequently been described as 'blueberry muffin' lesions. Genuine thrombocytopenic purpura is probably rather uncommon.

Other reported skin manifestations of congenital rubella have included cutis marmorata, seborrhoea and hyperpigmentation of the forehead, cheeks and umbilical area [7], and discrete deep dimples over bony prominences, particularly the patellae [8].

Human immunodeficiency virus (HIV) infections

HIV infection may be transmitted to the infant *in utero*, during delivery or through breast-feeding. Because most infections are probably transmitted around the time of birth, clinical manifestations are not commonly seen for the first few months, and some infected infants will remain asymptomatic for many years before manifestations first appear.

Dermatological manifestations are common in infant HIV infection [1,2].

Persistent mucocutaneous candidiasis is the commonest of all. In addition to infection of oral and napkin areas, there may be extensive cutaneous involvement. Dermatophyte fungal infections are also characteristic, and infection with more unusual fungi may occur, including *Aspergillus* [3]. Bacterial infections include unusually severe or recurring impetigo, folliculitis, cellulitis and abscesses. Problems with viruses include atypical chickenpox, herpes zoster, herpes simplex, and unusually severe molluscum and human papillomavirus infections. Norwegian scabies may present in infancy.

A wide variety of non-infectious manifestations of HIV infection may also occur. Perhaps the most characteristic in infancy is seborrhoeic dermatitis affecting face and scalp, often also proximal flexures, occasionally disseminating more widely. Drug eruptions are also rather frequent, especially with trimethoprim–sulfamethoxazole.

Bacterial infections

Staphylococcus aureus infections

As in older children and adults, *S. aureus* causes a wide variety of cutaneous lesions in neonates.

Bullous impetigo

The neonate is peculiarly liable to the development of bullous impetigo, which is most often caused by phage group II strains of *S. aureus* [1]. The disorder in neonates differs in no significant way from that in older children and adults, although it was formerly distinguished by the rather confusing term, *pemphigus neonatorum*. Epidemics of bullous impetigo, in which some infants may develop staphylococcal scalded skin syndrome, have occurred in neonates due to transmission of infection in the nursery, principally via nursing or medical staff [2–4]. Although the infection is acquired in hospital following delivery, the lesions do not generally appear until the second week of life, when the child will now usually have left hospital.

The perineum, periumbilical area and the neck creases are predilection sites for the initial lesions. Rapidly enlarging bullae with thin, delicate walls and a narrow, red areola contain clear fluid at first, which may later become turbid or frankly purulent. The condition may remain localized or become widespread. Untreated generalized bullous impetigo in the neonate is associated with a significant mortality, and serious complications including lung abscess, staphylococcal pneumonia and osteomyelitis have been reported, even in cases treated with antibiotics [5,6].

The differential diagnosis of bullae and erosions in the neonate is illustrated in Table 14.5 [7–9].

Table 14.5 Differential diagnosis of bullae and/or erosions in the neonate.

More common disorders
Miliaria crystallina
Bullous impetigo
Thermal or chemical burns
Epidermolysis bullosa
Incontinentia pigmenti
Bullous ichthyosiform erythroderma
Mastocytosis
Rare disorders
Neonatal herpes simplex
Fetal varicella syndrome (FVS)
Herpes zoster
Congenital syphilis
Passively transferred
Pemphigus vulgaris
Herpes gestationis
Bullous pemphigoid [7]
Extensive congenital erosions and vesicles healing with reticulate scarring
Congenital erythropoietic porphyria
AEC syndrome
Sucking blisters
Congenital absence of skin
Porphyrias and transient porphyrinaemia [8]
Langerhans' cell histiocytosis [9]

Staphylococcal scalded skin syndrome

The staphylococcal scalded skin syndrome was first described in neonates by a German, Ritter von Rittershain [10]. It is caused by epidermolytic toxin A and/or B, which are elaborated by certain strains of *S. aureus*, most commonly of phage group II [1], particularly strains 71 and 55. These toxins reach the skin via the circulation from a distant focus of infection, usually in the umbilicus, breast, conjunctiva or the site of circumcision [11] or herniorrhaphy [12]. Transmission of the causative toxin through human milk has been reported [13].

The disorder is most often seen in young children, and particularly in neonates. The very much greater incidence of this condition in neonates is believed to reflect less efficient metabolism and excretion of the toxin [14]. Multiple cases can occur in a neonatal unit [15]. Cases occurring in later childhood tend to be associated with underlying disease, especially immunosuppression and renal failure [16].

It does not present at birth, although it may first appear within the first few hours thereafter [17]. The first sign of the disease is a faint, macular, orange-red, scarlatiniform eruption. The eruption generally becomes more extensive, and, over the next 24–48 h, turns to a more confluent, deep erythema with oedema. The surface then becomes wrinkled before starting to separate, leaving raw, red erosions. Sites of predilection for the development of erosions are the central part of the face, the axillae and the groins.

Extreme tenderness of the skin is an early feature, and may occur at a stage where cutaneous signs are not yet striking. The child is pyrexial and distressed. These features can lead to a suspicion that the child has arthritis or an acute abdomen. The presence of impetiginous crusting around the nose and mouth can be diagnostically helpful. Recovery is usually rapid, even without antibiotic therapy, although infants occasionally die in spite of such treatment [18]. Healing occurs without scarring.

The scalded appearance of the skin differentiates the disease from bullous impetigo, and the rapid onset with marked cutaneous tenderness distinguishes it from most of the other causes of erythroderma in infancy. The rarity of clinically apparent bullae and the confluent nature of the rash help differentiate it from those bullous disorders likely to be seen in young children.

The only real problem in differential diagnosis would be with toxic epidermal necrolysis, which, although clinically similar, has a worse prognosis. In the past, the staphylococcal scalded skin syndrome and toxic epidermal necrolysis were confused, but it is now clear that they are entirely distinct entities. Genuine toxic epidermal necrolysis does occur in young children but is relatively rare, and differs clinically by virtue of mucosal involvement. Wherever there is any doubt, the two conditions may be reliably distinguished by histology, as the level of skin separation is intraepidermal in the staphylococcal scalded skin syndrome and at the dermal–epidermal junction in toxic epidermal necrolysis. If the child's condition arouses anxiety, a frozen section will provide rapid differentiation [19].

Treatment is with either a penicillinase-resistant penicillin analogue, such as flucloxacillin or methicillin, or with an appropriate cephalosporin or sodium fusidate. If the attack is severe, the drug should initially be given intravenously. Systemic corticosteroids are contraindicated, on the basis of experimental [20] and clinical [21] evidence that they aggravate the disease. Appropriate compensation must be made for heat and fluid losses. Pain will also require treatment, and affected infants will generally be much more comfortable if the lesions are dressed rather than left open. In severe cases, it may occasionally be justifiable to ventilate the patient in order to obtain adequate relief of pain.

Periporitis staphylogenes and sweat gland abscesses

Periporitis staphylogenes is the term applied to pustular lesions appearing in neonatal skin as a result of secondary infection of miliaria by *S. aureus* [22–25]. Such lesions may progress to sweat gland abscesses, although it is not clear whether sweat gland abscesses are always a complication of miliaria. These disorders have in the past been incorrectly called 'folliculitis and furunculosis of the newborn'. Sweat gland abscesses are distinguished from furuncles clinically by a lack of any tendency to 'point', 'coldness' and absence of tenderness.

Periporitis must be distinguished from miliaria pustulosa, which is not an infective disorder, and from bacterial folliculitis, which in the neonate is usually caused by *S. aureus*. *Candida albicans* and *M. furfur* may also cause pustulosis in the neonate, and a number of non-infective conditions may cause confusion, such as eosinophilic pustulosis.

Mastitis and breast abscesses

Infection of the breast is common and is usually associated with *S. aureus*, but a variety of other bacteria may be responsible [26]. It is almost always unilateral; it occurs most commonly in the second or third week of life, more often in girls than boys, and only very rarely in the preterm infant. The affected breast is swollen, and often red and hot. Systemic toxicity is usually absent. Fluctuation implies abscess formation, which will require surgical drainage. The development of a breast abscess may lead to loss of breast tissue in the longer term [27].

Omphalitis

The umbilical cord may become colonized by a variety of potentially pathogenic bacteria, and an equally wide variety of topical antiseptics and antibiotics have been used in an attempt to reduce this colonization. The use of hexachlorophane was popular until it became apparent that this could lead to serious neurotoxicity, particularly in the preterm infant [1]. The best substitute may be chlorhexidine, applied as a dusting powder rather than as an alcoholic solution [2].

Occasionally infection of the umbilical cord becomes disseminated, either by bloodstream invasion or by direct extension via the umbilical vessels to the peritoneal cavity. Tetanus, diphtheria and necrotizing fasciitis [3] may also occur as complications of umbilical infection. Such infections are still responsible for a high proportion of deaths in the neonatal period in developing countries.

Preorbital and orbital cellulitis

Preorbital cellulitis is restricted to the part of the orbit anterior to the orbital septum and is manifest by eyelid swelling. Orbital cellulitis involves the structures deep to the septum and presents with painful proptosis, eyelid oedema and conjunctival erythema. A variety of bacteria can cause these infections, including *S. aureus*, group A and other streptococci.

Necrotizing fasciitis

This name is given to a distinctive form of cellulitis, in which infection tracks along the fascial planes, causing thrombosis of blood vessels running through the fascia with resulting necrosis of the skin, subcutaneous fat and even muscle [1,2]. In neonates, it may arise spontaneously, but more often is a complication of physical birth trauma, omphalitis [3], breast abscess, or iatrogenic skin wounds such as result from scalp electrodes [4] or circumcision [5]. The mother's genital tract is probably often the source of the infection [6].

Initially, the infant develops what appears to be straightforward cellulitis. However, the child becomes disproportionately toxic, and the area affected becomes indurated, discoloured and extends progressively [2,7]. The surface may show a peau d'orange appearance. Purpura and, occasionally bullae, may develop in the centre of the indurated area, often followed quite rapidly by frank necrosis. Destruction of superficial nerves results in local cutaneous anaesthesia. Gas and crepitation may be clinically apparent, or may be seen radiologically. Fever is not invariably present.

A wide variety of bacteria have been associated with necrotizing fasciitis, most commonly group A streptococci, but also group B streptococci, *S. aureus* and *Escherichia coli* [7–10]. In many cases, a synergistic infection by aerobic

and anaerobic organisms appears to be responsible. Occasionally, fungi have been responsible. Antibiotic therapy appears to be of limited value in this potentially lethal situation. The most important aspect of treatment is early surgical excision of necrotic tissue [3,10].

Neonatal listeriosis

Listeriosis during the neonatal period is uncommon, but dangerous. The responsible organism, *Listeria monocytogenes*, may be transmitted to humans principally through contaminated foods [1]. In pregnancy, it causes a rather non-specific and generally mild, influenza-like illness in the mother [2], but it may lead to transplacental infection of the fetus. Maternal HIV infection may predispose to neonatal listeriosis [3].

Clinically, there are early-onset and late-onset forms of neonatal listeriosis [4]. The early-onset form results from the development of miliary granulomas following bloodborne dissemination of infection. Severely affected babies tend to be born prematurely, and there is a high mortality [5,6]. Post-mortem studies reveal miliary granulomas in many organs. A few infants will have analogous miliary skin lesions during life, manifest as scattered, discrete grey or white papules or pustules, about 1–2 mm in diameter, with a red margin [7,8], which will provide a source of organisms for culture [9]. The back appears to be the site of predilection for such lesions, which are also seen in the mouth and on the conjunctiva. Other cutaneous lesions have been described in such babies, including purpura and morbilliform rashes [3,5].

The late form of the disease is commoner, taking the form of meningitis, occurring a week or two after birth [10].

Diagnosis is by culturing the organism from a variety of sites, including cerebrospinal fluid, blood, urine and from biopsy material, including the skin. Treatment is most frequently with a combination of parenteral ampicillin and gentamicin or kanamycin [5], followed by a longer course of ampicillin or penicillin given alone.

Pseudomonas aeruginosa infections

Ecthyma gangrenosum [1,2]

Pseudomonas aeruginosa is common in the hospital environment and infections are encouraged by the widespread use of broad-spectrum antibiotics. Most, but not all neonates who develop the skin lesions of ecthyma gangrenosum have *P. aeruginosa* septicaemia, usually in the context of predisposing factors that include prematurity, neutropenia and other immunodeficiencies, necrotizing enterocolitis and bowel surgery. Occasionally the lesions develop directly at the site of direct inoculation of the causative organism.

Histologically, the presence of vasculitis, due to bacterial infiltration of vessel walls, is characteristic [3], together with haemorrhage and necrosis; for this reason skin biopsy can be very helpful in diagnosis.

Clinically, lesions initially take the form of painful macular erythema or purple ecchymosis. The centre then generally develops either vesicles (or less commonly bullae) or pustules which rapidly ulcerate. One subsequently sees one or more ulcers with a depressed, necrotic, often black, crusted centre and a raised edge. The perioral and perianal areas may show grouped lesions.

This infection is potentially dangerous when it occurs in the setting of septicaemia. Appropriate parenterally administered combination antibiotic therapy will be required.

Noma neonatorum

Noma neonatorum is a gangrenous disorder of the nose,

lips, mouth, perianal area and, occasionally, the scrotum and eyelids, occurring in low birthweight and/or premature neonates, almost exclusively in underdeveloped parts of the world. It is frequently caused by *P. aeruginosa* and is almost invariably lethal in the absence of appropriate antibiotic treatment [4]. A similar condition may be seen in older children and adults in the context of immunodeficiency, most commonly in HIV infection [5].

Purpura fulminans

Although in the newborn this condition is most often a reflection of genetically transmitted thrombophilic disorder, it may be caused by acute infections, particularly with endotoxin-associated Gram-negative bacteria such as *Neisseria meningitidis* [6,7].

Congenital syphilis

Congenital syphilis is described in detail in Chapter 30, but its cutaneous manifestations in the neonate will be considered here briefly, because of their importance in differential diagnosis.

The skin is clinically affected in about 40% of neonates with congenital syphilis. In such cases, the skin is usually of normal appearance at birth, the initial lesions occurring between the second and eighth week, and occasionally later. Sites of predilection are the anogenital area, the face and the palms and soles. The lesions themselves are reddish brown in colour; they may be macular or papular, and tend to be larger and firmer than those seen in acquired secondary syphilis (Fig. 14.8). In about 3% of cases the lesions are bullous. Paronychia is commonly present. Small, round, moist, papular lesions, traditionally termed mucous patches, are frequently present in the mouth and on other mucosal surfaces. Condylomata lata may be present in the anogenital flexures or at other flexural sites, for example between the toes or in the angles of the mouth.

Birth weight is below 2500 g in approximately 50% of affected infants. Apart from the cutaneous features, the most frequent clinical manifestations of congenital syphilis in the newborn are hepatomegaly, splenomegaly, jaundice, pneumonia and rhinitis, often with a blood-stained discharge.

Fig. 14.8 Congenital syphilis: nummular erythematosquamous lesions in a 4-week-old infant.

Congenital tuberculosis

Tuberculosis in the newborn due to transmission of infection *in utero* is relatively rare. The lungs and/or liver tend to be the predominant sites of involvement, and skin manifestations are unusual. However, cutaneous lesions have occasionally occurred, in the form of small numbers of discrete, umbilicated, erythematous papules up to 4 mm in diameter [8].

Fungal infections

Candida infections in the neonate

There are two distinct forms of candidiasis seen in the first weeks of life, which have been called *neonatal candidiasis*, which appears after birth, and *congenital candidiasis*, which is present at birth.

Neonatal candidiasis

This is a relatively common disorder that occurs in the early weeks after birth, in the form of oral candidiasis with or without candidiasis in the napkin area. The rash usually focused in the perianal area, and is a deep 'beefy' red colour, with a moist appearance, often with pustules at the periphery, which is often scalloped in outline. Just beyond the margin, in as yet unaffected skin, there may

be punctate erythematous lesions, sometimes pustular ('satellite' lesions).

It is assumed that the infection is acquired during delivery from the mother's genital tract, and it should be borne in mind that the frequency of vaginal candidiasis at the time of delivery is between 20% and 25% [1].

Occasionally, the rash may become more generalized. The occurrence of localized palmar pustules in an infant with neonatal oral candidiasis was believed to reflect the inoculation of *Candida* from the mouth into the skin as a result of sucking [2].

The most reliable treatment is generally a combination of a non-absorbed oral anticandidal agent, usually amphotericin drops or miconazole 2% oral gel, and a topical anticandidal agent such as ketoconazole 2% cream.

Congenital candidiasis

This is a rarer condition, seen at birth, which is generally believed to reflect maternal *Candida* chorioamnionitis resulting from ascending infection from the genital tract [3,4,5–9]. It appears that *Candida* is however able to find its way into the amniotic fluid without prior rupture of membranes [10]. Foreign bodies in the uterus or the cervix increase the risk, particularly intrauterine contraceptive devices [10,11]. There is no evidence that maternal antibiotic therapy or immunodeficiency in the infant play a role in predisposition [9,12].

An extensive eruption of scattered pinkish red macules and papules is present at birth or appears within a few hours. The lesions generally progress to a vesicular phase, and then either to a pustular or a bullous phase, over a period of 1–3 days. More or less any part of the skin surface may be affected, including the nails, palms and soles. In fact, palmar and plantar pustules are regarded as a hallmark of congenital cutaneous candidiasis. Isolated involvement of the nail plates has been described [13]. Oral involvement is usually absent, and the napkin area tends to be spared, at least initially.

Very-low-birth-weight infants may have a scalded appearance, and are particularly at risk of systemic infection.

When infection is confined to the skin, affected infants have generally been otherwise well, and the rash clears within a week with appropriate topical antifungal therapy, for example with topical ketoconazole. The rash clears with prominent post-inflammatory desquamation.

Skin and mucosal involvement may be complicated by systemic candidiasis, particularly in the premature [4,14]. The lungs may be affected [15]; hepatosplenomegaly and abnormal liver function have also been recorded [9]. Candidal meningitis is another potential complication [16]. Criteria have been proposed that indicate high risk of systemic involvement. Systemic antifungal therapy should be considered in at-risk infants [12]; amphotericin B is probably the drug of choice [11,14].

Malassezia pustulosis

Colonization of the skin by *M. furfur* starts soon after birth and progresses until the age of about 3 months, probably reflecting the activity of the sebaceous glands during this period [1–3]. This yeast has been a cause of systemic infections in infants receiving intravenous lipids, and it is presumed that the source of organisms in such cases was the skin [4].

It is now believed that *M. furfur and M. sympodialis* may be a frequent cause of erythematous papulopustular eruptions occurring on the face and scalp in neonates, a condition now widely termed *neonatal cephalic pustulosis* [3,5–7], though not all neonates with this clinical presentation had detectable *Malassezia* in the lesions [8]. This type of rash was reported to have a frequency of 10% in neonates seen as outpatients in a paediatric dermatology department [7], with pustule contents showing *M. furfur* yeasts in over half of these, associated with a good therapeutic response to topical application of 2% ketoconazole cream for 15 days in almost every case. A frequency of 66% was reported in a recent study, with 62% being culture-positive for *Malassezia* [8].

There is reason to believe that some of the *Malassezia*-negative cases in these studies may have had genuine

neonatal acne, which is generally easily distinguished by the concurrent presence of comedones.

Certainly, *M. pustulosis* clearly needs to be considered in neonates presenting with pustular lesions on the face and/or in the scalp, in cases that might otherwise be diagnosed as eosinophilic pustulosis of the scalp, transient pustular melanosis, scabies, neonatal acne vulgaris, or cutaneous infections such as *S. aureus* or *C. albicans* [9].

Primary immunodeficiency disorders

[A.R. Gennery & A.J. Cant, pp. 14.50–14.87]

Introduction

The immune system protects against a huge variety of infective agents, which bear a vast number of different surface proteins or antigens. To achieve this, a series of defence mechanisms have evolved, from simple mechanical barriers, through non-specific second-line defences which recognize certain proteins, to highly specific directed responses with 'memory' which are refined on repeated exposure and afford long-term protection. The interaction of man and microbe is an ongoing evolutionary struggle, each attempting to outwit the other, so that as existing systems become redundant, new defensive pathways evolve.

Increased understanding of immune mechanisms has given greater insight into the causes of primary and secondary immunodeficiency. Indeed, many aspects of immune function have been elucidated by the recognition of specific defects in individuals with immunodeficiency. It is therefore helpful to describe briefly the mechanisms of the immune response with examples of specific defects that result in primary or secondary immunodeficiency. Immunodeficiency states will then be reviewed in more detail, with particular reference to dermatological manifestations.

The importance of understanding the dermatological features of immunodeficiency within the context of specific immune defects cannot be overemphasized. Because many of the more severe primary defects of immunity have their initial clinical manifestations early in life, the dermatological features of these disorders will be considered in this chapter. The descriptions of cutaneous findings in the primary immunodeficiencies in the medical literature are often vague, probably reflecting the limited input from dermatologists both in the care of such patients, and the preparation of papers for publication.

The innate immune system

Physical barriers such as epithelial surfaces and mucous membranes employ many defences including hairs, cilia, and the secretion of sticky mucus, enzymes and acids, as well as antibiotics produced by commensal flora. The importance of these barriers is demonstrated by the greatly increased risk of sepsis that occurs when they are significantly breached such as occurs following severe burns, or in epidermolysis bullosa.

On breaching these barriers, and invading tissues, pathogens are confronted by the innate immune response, an early evolutionary adaptation. This response lacks immunological memory, so that its magnitude is the same no matter how many times the antigen is encountered. Pathogens are recognized by genetically pre-determined receptors which detect a limited range of highly conserved structures (known as *pathogen-associated molecular patterns*), such as bacterial lipopolysaccharide, mannan and peptidoglycan, which are present on many microorganisms but not on the host. Recognition of one of these pathogen-associated molecular patterns by complementary receptors on effector cells such as monocytes and macrophages causes immediate activation, accounting for the rapid response of the innate system.

Pattern-recognition receptors include:

- mannan-binding lectin, absence of which has been associated with a susceptibility to meningococcal infection;
- the macrophage scavenger receptor, which binds to bacterial cell walls and clears circulating bacteria;
- toll-like receptors, which induce release of chemical messengers such as cytokines and chemokines, which attract phagocytes, antigen-presenting cells (APCs) and lymphocytes to the area of infection.

Neutrophils are part of the innate response, endocytosing and killing invading pathogens. Macrophages and monocytes also endocytose pathogens, but in addition process antigen before presenting it to lymphocytes to initiate the adaptive response.

The innate system responds to activation of a limited number of receptors specific for conserved microbial structures, and also plays a pivotal role in activating the adaptive immune system, which responds only to antigen that has been presented by the innate system.

Soluble plasma proteins such as mannan-binding protein and complement play an important first-line role in innate defence once the epithelial surfaces are breached.

Complement is a series of plasma proteins that act in a cascading sequence to attack extracellular organisms. Direct activation by microorganisms proceeds through the alternative pathway and whilst the classical pathway acts in the same way, it requires activation by antibody. Coating by complement can kill pathogens directly, or can facilitate their removal by phagocytes, which bind complement to complement receptors.

Non-function or absence of components of the alternative pathway or terminal pathway lead to recurrent infection with extracellular pathogens, particularly *Neisseria* spp. Defects in the classical pathway, which plays a role in the clearance of immune complexes, lead to immune complex-mediated disease, chronic inflammation and SLE.

Neutrophil defects include severe congenital neutropenia (Kostmann's syndrome), associated with an absolute neutrophil count below 500 cells/mm^3, and cyclical neutropenia, in which neutropenia occurs at intervals of approximately 3 weeks. Patients with these conditions are at risk of bacterial and fungal infections. Once activated, neutrophils migrate from blood vessels to the site of infection.

In leukocyte adhesion deficiency (LAD), neutrophils lack integrin molecules, which are necessary for their adherence to blood vessel walls and for their subsequent migration between vascular endothelial cells to the site of infection. Affected patients can mobilize very large numbers of neutrophils, but these are unable to migrate into tissues. Patients present with delayed umbilical cord separation, rapidly enlarging and infected skin ulcers with no pus, and recurrent soft tissue, respiratory and gastrointestinal infection. Without bone marrow transplantation (BMT), the severe form of the disease is invariably fatal. To eliminate infection phagocytes must both ingest microorganisms and then kill them once ingested.

Intracellular killing is defective in chronic granulomatous disease (CGD) where patients cannot generate intracellular hydrogen peroxidase as the enzyme nicotinamide adenine dinucleotide (NADPH) oxidase is defective. Affected patients are susceptible to recurrent infections with catalase-positive bacteria and fungi, and suffer recurrent soft tissue, respiratory and gastrointestinal infection with tissue scarring due to granuloma formation.

Much of the immune response is mediated by soluble protein messengers called cytokines, which are secreted by the liver, vascular endothelium and white blood cells. Defects in cytokine signalling pathways may have serious consequences. Macrophages produce interleukin-12 (IL-12) in response to infection, leading to interferon-γ (IFN-γ) release by T lymphocytes and NK cells, which in turn activates hydrogen peroxide production by the macrophages. Defects in IL-12, IL-12 receptor chains and IFN-γ have been identified in patients with severe or recurrent atypical mycobacterial or bacille Calmette-Guérin (BCG) infection. Overproduction of cytokines due to genotypic polymorphisms can also lead to problems. Increased tumour necrosis factor-γ (TNF-γ) production gives increased protection to mycobacterial infection but leads to an overwhelming pro-inflammatory cascade and severe septic shock in meningococcal infection.

The adaptive immune system

T (thymus-derived) and B (bone marrow-derived) lymphocytes, which are responsible for the adaptive immune response, are generated in specialized lymphoid organs, namely the lymph nodes, spleen and mucosal-associated lymphoid tissue. Characteristics of the adaptive response include proliferation of antigen-specific T and B lymphocytes following activation by cells of the innate system. T lymphocytes act directly whilst B lymphocytes produce specific antibody. To respond to the vast number of possible antigens, B lymphocytes produce approximately 10^{16} different antibody variable regions, with a similar number of T-cell receptor (TCR) variable regions from fewer than 400 germ-line genes. This remarkable diversity means that there is a T or B cell with a receptor complement to every protein antigen that could be made. This variety is achieved by promiscuous recombination processes that cut, splice and modify variable region receptor genes. This randomly generated receptor diversity produces self-reactive lymphocytes as well as lymphocytes generated against specific microorganisms. Early lymphocyte development enables receptor rearrangement, but following expression of a mature receptor, continued survival is antigen-dependent, and self-reactive lymphocytes are usually eliminated.

B-lymphocyte development

The diverse repertoire of T- and B-cell receptors is generated by recombination of a small number of gene segments. B-lymphocyte receptors (BCRs) are membrane-bound immunoglobulin.

Immunoglobulins are comprised of two identical heavy (H) chains and two identical light (L) chains, held together by disulphide bonds. Immunoglobulins have two separate functions. The first is to bind to specific antigen through the variable (V) domain, and the second is to recruit other cells to the immunoglobulin-bound antigen to effect killing and destruction. This second function is mediated through the constant (C) domain. The constant region is invariable for each immunoglobulin class, although it has five main forms or isotopes which determine the immunoglobulin class (IgM, G, A, E, D). Small variations lead to four IgG and two IgA subclasses. Both heavy and light chains have C and V domains.

Variable domains are constructed from the recombination of gene segments from two or three 'families' of

genes. In L chains, a V (variable) segment is joined to a J (joining) segment. These are then joined to the light chain C domain. A similar process occurs in the heavy chain, but there are three different gene segments in the variable region, a V (variable) segment, a J (joining) segment and a D (diversity) segment, which join to the heavy chain C domain. There are a number of different gene segments in each 'family' and so diversity is generated by varying the combination in which the V (D) J segments are arranged. Further diversity is introduced by pairing different heavy and light chain variable regions, and by imprecise splicing and rejoining of different gene segments which give rise to different nucleotide sequences at the joining junction. These recombination events occur in the bone marrow. 'Fine tuning' of the response to produce antibody exactly complementary to antigen (somatic hypermutation) requires T-cell cooperation (see below). This unique and complex system is very prone to genetic faults which are not lethal *in utero*. Mutations in genes encoding B-cell heavy or light chains, or in the associated signalling molecules lead to absence of B cells and agammaglobulinaemia, as seen in X-linked agammaglobulinaemia (XLA; Bruton's disease), or to hypogammaglobulinaemia due to μ-chain deficiency. Defects in specific immunoglobulin heavy or light chain translation lead to individual class or subclass deficiency, although some humoral immunity is preserved.

T-lymphocyte development

TCR development is very similar to that of B cells, but occurs in a specialized microenvironment, the thymus. Precursor cells migrate to the thymus and undergo TCR chain rearrangements. The TCR consists of α/β or γ/δ heterodimers. Each α, β, γ, δ chain contains a variable and a constant domain. As in the BCR, the variable domains are constructed from gene segments from different V, (D) and J 'families'. TCR α and γ loci do not contain D segments. The BCR differs from the TCR in that TCRs only recognize antigen that is bound to an individual's own major histocompatibility complex (MHC) tissue type molecule expressed on the surface of their cells. Thus, during thymic development, T cells that recognize antigen/self MHC complex are positively selected (self MHC restricted) and survive, whereas those that recognize self-antigen/MHC complex are negatively selected (self-tolerance) and undergo apoptosis. Only about 2% of T-cell precursors entering the thymus pass this rigorous selection process and leave as mature, naïve T cells.

T and B cells use similar signalling and enzymatic processes to rearrange gene segments and construct antigen receptors. Some of the enzymes are the same as those used to repair damaged DNA. Many are critical to lymphocyte development, and lymphocytes cannot develop in their absence, which results in the various forms of severe combined immunodeficiency (SCID). For example, mutations of recombination-activating genes 1 and 2 (*RAG1* and *2*) results in T-negative, B-negative SCID.

The important role of the thymus is illustrated by the complete DiGeorge's syndrome, where congenital thymic absence leads to a SCID phenotype with absence of T cells. A number of signalling molecules and their receptors, particularly those for cytokines and their receptors, are also critical in lymphocyte development and survival. Thus, absence of the common cytokine receptor γ chain (which is integral to the IL-2, -4, -7, -9 and -15 receptors) leads to T-cell negative, B-cell positive, NK-cell negative SCID. Absence of Janus-associated kinase 3 (JAK3), a signalling molecule associated with the cytokine receptors, has the same consequence. Other defects can lead to dysregulation of thymic selection.

A cell that fails either negative or positive selection undergoes apoptosis. Defects in the apoptosis pathway, particularly the molecules Fas or Fas ligand, lead to the escape of autoreactive lymphocytes; this can result in autoantibody production and autoimmune disease.

Antigen presentation and lymphocyte interaction

Mature T and B lymphocytes circulate through the blood, lymphatics and tissues looking for the antigen which is specific for the particular receptor. Microorganisms are taken up by cells of the innate response, such as macrophages. They are broken down in lysosomes to small polypeptide fragments of 8–12 amino-acids long, combined with MHC class I or II molecules and presented at the cell surface as an antigen/MHC complex, with antigen bound within the groove of the MHC molecule. Defects in the MHC class II transcription molecules, or in the MHC class I transporter proteins (which transport antigen peptide to MHC class I molecules) occur, and although affected individuals have functionally normal lymphocytes, they suffer repeated life-threatening infections because antigen cannot be presented to their T- and B-lymphocyte receptors.

Most adaptive immune responses occur in lymphoid tissue, where lymphocytes and APCs (macrophages, dendritic cells) are concentrated. There are at most only a few hundred lymphocytes with a receptor complementary to a specific antigen. When a T lymphocyte interacts with a matching antigen/MHC complex (MHC class I with CD8 cytotoxic T cells, for intracellular organisms, MHC class II with CD4 helper T cells for extracellular organisms), a second signal is delivered from the APC to the T cell, via a B7 molecule on the APC interacting with a CD28 molecule on the T cell. The combination of these two signals (TCR/MHC-antigen and B7/CD28) activates the T cell causing repeated replication of T cells bearing the same antigen-specific receptor; a process called clonal expansion. Conversely, delivery of the first signal without

the second renders the T cell unable to respond to antigen, and this unresponsive state is known as T-cell anergy. Because only a few T lymphocytes have the receptor for the specific antigen, only a few are activated for that antigen. However, as each microorganism carries many antigens, infection will cause the proliferation and clonal expansion of many different T lymphocytes, leading to a polyclonal response.

As well as triggering clonal T-cell proliferation, an activated CD4 T cell can interact with a B cell carrying the BCR specific for the antigen, triggering clonal B-cell expansion. Initially the B cell responds by secreting IgM. In lymph node germinal centres, as the adaptive response matures, interactions between T cells via CD40 ligand (expressed on T cells) and CD40 expressed on B cells enables B cells to switch from making IgM to making IgA, IgG and IgE. This follows substitution of the appropriate C domain on the heavy and light chains, encoding for IgM, A, G or E respectively, a process known as isotype switching. Point mutations, deletions and insertions in the variable domain of the immunoglobulin molecule (somatic hypermutation) modify the immunoglobulin molecule further (the fourth method of creating antibody diversity). B cells making immunoglobulin that 'fits' the antigen most precisely are generated in great number (affinity maturation), whereas B cells that produce immunoglobulin of inferior 'fit' undergo apoptosis.

Once activated, these T cells and B cells are long lived, and act as memory cells. Thus, when the same antigen is encountered again, these cells react immediately, not requiring activation by the innate system. The immunoglobulin that is produced attaches to the microorganism via the antigen-binding region. The effector portion of the immunoglobulin attaches to immunoglobulin receptors on phagocytes and macrophages, facilitating phagocytosis, antigen processing and elimination.

Defects in these mechanisms illustrate their importance. In X-linked hyper-IgM syndrome, CD40 ligand is deficient, so B cells are unable to switch from making IgM to other immunoglobulin isotypes. T cells are also unable to interact with macrophages (which also express CD40), which are therefore unable to kill ingested intracellular pathogens such as *Pneumocystis carinii* and *Cryptosporidium parvum* resulting in opportunistic infections. An autosomal recessive form of hyper-IgM syndrome is due to mutations in the activation-induced cytidine deaminase gene, which encodes for a protein that is involved in the isotype switching and hypermutation processes.

Once switched on by antigen presentation, T cells develop in one of two different ways:

1 *Th1 cells* produce IL-2 and IFN-γ, whose main role is to stimulate macrophage function and cell-mediated immunity, but which also induces B lymphocytes to switch the class of antibody produced, particularly to IgG2.

2 *Th2 cells*, in contrast, predominantly produce IL-4 and IL-10, which promote antibody responses and class switching, particularly towards IgG1, IgG4 and IgE.

Allergic responses and responses to parasites are of Th2 type. Responses to an antigen may follow either a Th1 or Th2 route, depending on a complex set of circumstances. Once established, these responses are self-amplifying in that production of IFN-γ or IL-4 promotes Th1 and Th2 responses respectively, while inhibiting the other.

Over-activation of the antigen/TCR- or BCR-binding process can also cause disease. Bacterial toxins and some viruses act as 'superantigens', binding to the outside of the MHC molecule, and in particular to the outside of a V chain (one of the V segments of the β chain of the TCR), regardless of the antigenic specificity of the V domain of the β chain, or of the DJ segments of the V domain of the β chain. Thus, instead of activating say only 20 out of 10^{16} naïve T cells, a single superantigen is able to activate up to 20% of the T-cell pool. This leads to massive lymphocyte activation and cytokine release, and is the process that is responsible for the marked inflammation seen in superantigen-mediated diseases like toxic shock syndrome and Kawasaki disease.

The complex mammalian immune system has evolved a variety of mechanisms to counter invasion by microorganisms. Our understanding of its function has greatly increased by recognizing defects in 'knockout' laboratory animals, and in their human equivalent, individuals with congenital primary immunodeficiency. Elucidation of the molecular pathways has enhanced our understanding of the immune response, and identification and clarification of precise molecular mechanisms has led to advances in treatment of primary immunodeficiencies. Thus, X-linked hyper-IgM syndrome used to be considered an antibody deficiency, even though immunoglobulin replacement did not prevent liver disease secondary to *C. parvum* infection. Recognition that it is in fact a primary T-cell defect has led to BMT in selected patients. Identification of the genetic defect in X-linked SCID has lead to successful gene therapy for this condition.

The skin is a vital component of the innate immune system and the 'battleground' for many innate and adaptive immune responses to infection. It is not surprising, therefore, that skin sepsis and other dermatological manifestations are common features of primary immunodeficiency. Understanding the context of these responses ought to give a clearer view of these conditions and their treatment.

Immunodeficiency disorders: general principles

Classification and genetics

The risk of significant immunodeficiency (excluding selective IgA deficiency) has been estimated at 1 in 10 000. Table 14.6 shows an adapted version of the classification

Table 14.6 Combined immunodeficiencies. (Adapted from Rosen *et al.* [1].)

Immunodeficiency	Defect	Inheritance
CD40 ligand deficiency	CD40 ligand	XL
WAS	WASP	XL
XLP	SLAM-associated protein	XL
DiGeorge's anomaly	Developmental field defect chromosomal deletion (usually 22q11.2)	Sporadic (some AD)
Cartilage hair hypoplasia	*RMRP* gene	AR
Immunodeficiency with albinism:		
1. CHS	*LYST* gene	AR
2. Griscelli's syndrome	Myosin 5a gene	AR
Familial haemophagocytic lymphohistiocytosis	Perforin gene	AR
Ataxia–telangiectasia	*ATM* gene	AR
Nijmegen breakage syndrome	*NBS1* (nibrin) gene	AR
Ligase IV deficiency	DNA ligase IV	AR
Fanconi's anaemia	*FAND2* gene	AR
Ectodermal dysplasia—immunodeficiency	*NEMO* gene	AR

AD, autosomal dominant; AR, autosomal recessive; CHS, Chediak–Higashi syndrome; WAS, Wiskott–Aldrich syndrome; WASP, Wiskott–Aldrich syndrome protein; XL, X-linked; XLP, X-linked lymphoproliferative disease.

of primary disorders suggested by the World Health Organization working party on immunodeficiency [1].

Diagnosis and investigation of immunodeficiency

A careful history and examination should precede laboratory tests, as the important clues obtained help determine which children should be investigated and which tests should be performed.

Most children present because of a problem with infection. An immunodeficient child is likely to have more infections, which take longer to resolve, or which follow an atypical course. Cutaneous infections in immunodeficient patients may be caused by microorganisms which are not usually pathogenic, or which follow a more severe course than in those with normal immunity. Such infections may not immediately suggest a primary immunodeficiency unless this diagnosis is actively considered.

When several members of the same family suffer from furuncles, nasal carriage of staphylococci and cross infection are more likely causes than immunodeficiency. Frequent upper URTIs alone in a young child are not indicative of an underlying immune defect unless associated with frequent bacterial infections. Clinical experience suggests that up to eight URTIs per year are normal in the pre-school years [1]. Infections with common organisms may run an atypical course (e.g. haemorrhagic chickenpox), or they may fail to respond to standard treatments, (e.g. a bacterial pneumonia which fails to respond to appropriate antibiotic therapy). Alternatively, infections may be caused by uncommon organisms which are in themselves highly suggestive of immunodeficiency, such as *P. carinii* pneumonia [2].

Failure to thrive is a common finding, and this may or may not be associated with diarrhoea due to chronic or recurrent infection or autoimmune enteropathy [3]. Evidence of end-organ damage, such as a cough productive of sputum, consistent with bronchiectasis, should also be sought. Allergic symptoms are common and may be unusually severe. Autoimmune and malignant diseases, though not common, have an increased incidence.

Delayed separation of the umbilical cord in the absence of local infection may suggest a neutrophil defect.

Taking a careful family history may indicate unusual or fatal infectious complications in siblings, suggestive of an autosomal recessive or X-linked pattern of inheritance. A history of consanguinity should be sought.

In some disorders, e.g. IgA deficiency, there may be a family history of collagen vascular or other immunopathological disease [4]. Older relatives who are carriers of an inherited immunodeficiency or who are affected by milder variants of primary immune defects may have autoimmune manifestations (e.g. mouth ulcers and SLE variant in CGD [5]), or have a history of malignant disease (lymphoma in X-linked lymphoproliferative disease (XLP) or Wiskott–Aldrich syndrome (WAS)).

Furuncular lesions or abscesses can be an overlooked manifestation of a primary immunodeficiency. They are most characteristically seen in neutrophil disorders such as CGD [6], Chediak–Higashi syndrome (CHS), LAD [7] and neutrophil-specific granule deficiency, but also in

Fig. 14.9 Progressive cutaneous ulceration due to herpes simplex in a 9-year-old child with T-lymphocyte immunodeficiency.

hyper-IgE syndrome [8] and antibody deficiencies such as XLP, or in complement disorders. In these disorders it is, however, usual for infections of the skin to be accompanied by infection at other sites.

Cutaneous and mucosal ulceration are features of several immunodeficiency states and are the hallmark of LAD. Although infection is believed likely to be the cause of the ulceration, it can be difficult to identify the microorganisms responsible, and accumulation of neutrophils in small blood vessels to the point where blockage and tissue necrosis occurs probably plays a big part in their genesis. Such ulcers are a characteristic feature of disorders featuring neutropenia, including congenital neutropenia, cyclical neutropenia and CHS. Gradually extending cutaneous ulcers due to HSV (Fig. 14.9) are suggestive of T-lymphocyte defects, but have also been reported in XLA.

Unusually severe or extensive infections with HSV or varicella-zoster virus, including the haemorrhagic vesicles seen in haemorrhagic chickenpox, are characteristic of T-lymphocyte defects. Bullous impetigo with clear blisters may be a presentation of neutropenia. A vesicular presentation of the hyper-IgE syndrome in infancy has been described [9].

Ordinary viral warts are virtually never indicative of immunodeficiency. However, exceptionally rapid growth of warts, exceptionally large size or unusually extensive infections are suggestive of underlying defects of immunity (Fig. 14.10). Severe extensive persistent molluscum contagiosum is seen in similar disorders such as WAS, CD40 ligand deficiency and less well characterized combined immune deficiencies (Fig. 14.11).

Fig. 14.10 Unusually large and rapidly proliferating viral warts in a child with combined immunodeficiency.

Fig. 14.11 Severe, extensive molluscum contagiosum in a child with Wiskott–Aldrich syndrome (WAS). (Reproduced with permission from the Audiovisual Centre, University of Newcastle, Newcastle, UK.)

Refractory mucosal and cutaneous *Candida* infections are a characteristic presenting sign of several immunodeficiency disorders, particularly SCID and severe T-lymphocyte defects. Surprisingly, systemic *Candida* infections are rather rare in these conditions. Persistent mucosal and cutaneous *Candida* infection, responding

Fig. 14.12 Acute graft-versus-host disease (GvHD) following transfusion of non-irradiated blood in a child with severe combined immunodeficiency (SCID).

poorly to systemic treatment, suggests chronic mucocutaneous candidiasis (CMC).

Non-specific, non-infectious manifestations of immunodeficiency

Morbilliform eruptions are sometimes caused by viral infections, as in other children, but in SCID they are quite frequently manifestations of acute graft-versus-host reactions, due either to materno–fetal engraftment, or to the transfusion of non-irradiated blood products after birth (Fig. 14.12).

Petechiae due to thrombocytopenia are a highly characteristic feature of WAS and may also occur in Fanconi's anaemia, dyskeratosis congenita, Schwachman's syndrome and CHS.

A combination of early-onset erythroderma and failure to thrive in early infancy is highly suggestive of immunodeficiency, and often results from dysregulated activated T lymphocytes invading the skin. In some cases, these are maternally derived and represent true graft-versus-host disease (GvHD) [10]. In other cases, aberrant clones of the infant's own T lymphocytes cause a similar reaction, resulting in the condition known for many years as Omenn's syndrome, but now more precisely described as 'leaky' T-B-SCID.

If one considers atopic eczema to be an immunodeficiency disease, eczema would certainly be the commonest of all cutaneous manifestations of immunodeficiency. Eczema is also a characteristic cutaneous feature of certain well-established immunodeficiency disorders such as WAS, and has been recorded as occurring more frequently than one would expect in various other disorders, including selective IgA deficiency, selective IgM deficiency, ataxia–telangiectasia and combined immunodeficiency.

Patients with several different primary immunodeficiencies have featured indurated erythematous papules and plaques with central scaling, scarring, atrophy or ulceration, which have demonstrated caseating granulomas histologically. The conditions in which these have been reported include common variable immune deficiency (CVID) [11], XLA [12], ataxia–telangiectasia [13] and CGD [14].

As well as classical systemic and discoid LE, a syndrome resembling SLE from the cutaneous point of view but having only very mild non-cutaneous manifestations and either absent or very low-titre plasma antinuclear antibodies has been described in patients with a variety of complement deficiencies. In such patients, this syndrome can occasionally have its onset as early as the first year of life, and, because many of these patients are susceptible to certain infections, such as meningococcal meningitis, the association of a disorder resembling LE and recurrent infections of appropriate type is highly suggestive of a hereditary complement deficiency.

There is an increased incidence of SLE in patients with IgA deficiency, and skin lesions closely resembling discoid LE have occurred in female carriers of the gene for X-linked CGD.

General examination

General physical examination should be directed towards potential sites of infection, including the throat, ears and sinuses, and examination of the oral cavity and nappy area for candidiasis. The presence or absence of lymphoid tissue should be noted, as should cutaneous problems consistent with defective immunity. In more severe antibody deficiency states such as XLA, there is a lack of tonsils and lymphoid tissues. Signs of end-organ damage from infections, such as clubbing and respiratory abnormalities, must be sought.

Some diseases may have specific physical signs, such as oculocutaneous albinism in CHS, typical facies and/or cleft palate in DiGeorge's syndrome, telangiectasia or neurological abnormalities in ataxia telangiectasia, and disproportionate short stature in some forms of combined immunodeficiency (see Immunodeficiency and short-limbed dwarfism below).

Radiological evaluation

Evidence of bony abnormalities may support a diagnosis of adenosine deaminase (ADA) deficiency [1], Schwachmann–Diamond syndrome [2] or other dysplasias associated with immune defects. Dilatation of the common bile duct may be suggestive of sclerosing cholangitis, associated with a number of combined immune deficiencies, especially X-linked hyper-IgM syndrome [3]. Careful review of chest X-rays may suggest bronchiectasis, and should prompt high-resolution computed tomography (CT) imaging. Although absence of a thymus on anterior posterior and lateral chest X-rays is consistent with a combined immune defect in infants and young children, thymic atrophy may also occur in response to stress (e.g. infection) and this finding is not diagnostic.

Laboratory investigation

Two main questions need to be addressed, which children to investigate, and how extensively?

Investigation should be triggered by any of the following:

1 a family history consistent with immune deficiency;
2 a single infection with an unusual/opportunistic organism;
3 an usually severe single infection or one that runs an atypical course or occurs at an atypical age;
4 recurrent minor bacterial infections (e.g. otitis media more than two times per year despite appropriate Ear, Nose and Throat management, resulting in significant school absence);
5 more than one episode of serious bacterial infection [1].

Table 14.7 Examples of association between most likely type of immune defect and infecting organisms.

Candidate immune defect	Typical infecting organism
Antibody	*Streptococcus pneumoniae* *Haemophilus influenzae* *Giardia lamblia* *Mycoplasma* spp. Enteroviruses
Cell-mediated	*Salmonella* *Cryptosporidium* *G. lamblia* *Candida albicans* Herpesviruses (e.g. cytomegalovirus) Other viruses, e.g. measles Bacille Calmette-Guérin (BCG)
Neutrophil	*Staphylococcus* Gram-negative bacteria *C. albicans* *Aspergillus* spp. BCG
Type 1 cytokine defects	*Salmonella* Mycobacteria (typical and atypical) BCG
Monocyte	*C. albicans*
Natural killer cell	Herpesviruses
Complement	*Neisseria meningitidis* *S. pneumoniae* *H. influenzae*

Laboratory investigations can be directed to a certain extent by the organism causing infection (Table 14.7) and the age of the child.

Laboratory investigations range from those readily available in all centres, to highly specialized tests performed in research centres. Only a small proportion of children presenting with recurrent infections require complex investigation; most can be adequately investigated with a few relatively straightforward tests.

Haematology

A full blood count and blood film examination can be very revealing.

Neutropenia is readily detected, and a bone marrow aspiration will distinguish failure of production from increased peripheral destruction. Bone marrow aspiration will also exclude a myelodysplastic or malignant process.

Neutrophilia in the absence of overt infection may be suggestive of a neutrophil adhesion defect or functional problem (e.g. CGD).

Lymphopenia, using appropriate age-related ranges, strongly suggests a combined immunodeficiency of primary or secondary aetiology [1], although SCID can occur in the presence of a normal lymphocyte count. Nucleated red cells in infants and abnormal leukocyte morphology in sick children may be detected as lymphocytes on the Coulter counter, and thus erroneously suggest a normal lymphocyte count. Abnormal leukocyte granules are seen in CHS, whilst a platelet volume is invariably low in WAS, making this the most rapid and reliable diagnostic pointer in this condition.

Tests of innate immunity

Complement

C3 and C4 are easily measured. However, null alleles for C4 are relatively common, so that the significance of an isolated low C4 in an individual with recurrent infections is less certain. Furthermore, normal levels of C3 and C4 do not exclude deficiencies of other complement components. It is therefore better to screen the whole complement system by assessing the functional integrity of the classical and alternative complement pathways, using assays which test the ability of patient serum to lyse sensitized red blood cells (CH50/100 and AP50 respectively). Deficiency in any one component will result in a failure of lysis. Low values may be seen in the presence of active infection, when complement components are being consumed, or if degradation of complement components has occurred because the sample was not separated and frozen within 2 h of venesection. However, if repeat testing shows a persistent abnormality, measurement of the levels of individual complement components should be performed until the defective component is identified.

Neutrophil function tests

Neutrophil function has three main components: chemically mediated movement towards microorganisms (chemotaxis), ingestion of microorganisms into a phagocytic vacuole (phagocytosis), and activation of the respiratory burst within the phagolysosome to produce free oxygen radicals that kill microorganisms.

Neutrophil function tests are fraught with technical pitfalls, as neutrophils rapidly activate upon venesection and also die quickly. Neutrophil chemotaxis testing is now recognized to be unreliable and only performed in a research setting.

Chemiluminescence measures all three phases of neutrophil activity, and such assays are now being superseded by flow cytometric assays (see below).

Nitroblue tetrazolium (NBT) is a yellow dye that is readily taken up by phagocytes and upon stimulation (e.g. with phorbol myristate acetate) is reduced to the purple dye formazan by the oxidative burst. Normally at least 95% of neutrophils should contain a purple deposit in stimulated cells. In CGD, less than 1% of neutrophils reduce NBT. Carrier mothers of the X-linked disease can also be detected by this method, as they show an intermediate level of NBT reduction (20–80%). In experienced hands, this is a rapid and sensitive test for CGD, but false normal results can be seen when the test is performed infrequently.

Flow cytometric assays of neutrophil function

Fluorescently labelled microorganisms can be used to assess the phagocytic ability of neutrophils, seeing what proportion of cells have ingested the labelled organisms. Comparison of phagocytosis using the patient's own serum with that using control serum gives a measure of the effectiveness of patients' antibody and complement systems to aid phagocytosis (opsonization).

Phagocytosis of organisms by neutrophils and monocytes normally leads to activation of the respiratory burst, and to the production of free oxygen radicals. If neutrophils take up dihydrorhodamine and, using a suitable stimulus, the dihydrorhodamine is reduced, it fluoresces within cells. This fluorescence can be assessed using a flow cytometer, absence of fluorescence indicating failure of the respiratory burst. This is the best test for identifying patients with CGD. It can also detect carriers for X-linked CGD, who exhibit a dual population of normal and abnormal cells. The test has the advantage that more laboratories are experienced in the interpretation of flow cytometric readouts than reading slide NBTs, so that false normal results are much less likely. It is, however, more sensitive than an NBT, so neutrophil function defects other than CGD may also be detected. Neutrophil killing defects may also occur in myeloperoxidase deficiency and in glucose-6-phosphate dehydrogenase deficiency, both of which can be assayed separately.

Adaptive immune system

Tests of humoral immunity

Immunoglobulins G, A and M are routinely measured by nephelometry which measures light scattering, the

amount of light scattered being proportional to the quantity of immunoglobulin within the sample. Results must be evaluated with reference to age-specific normal ranges, as production of all five classes of immunoglobulin is low at birth and gradually matures over the first 5 years of life [1]. Low levels of immunoglobulin can only be attributed to a production defect if gut or renal losses have been excluded, and if the serum albumin is within the normal range. Catabolic states, such as myotonic dystrophy, can also lower total immunoglobulin levels.

Immunoglobulin E is measured using a variety of techniques, including enzyme-linked immunosorbant assays (ELISAs), and automated solid-phase ELISAs.

Immunoglobulin G subclasses are commonly measured by nephelometry or radial immunodiffusion. Results should be compared with age-specific normal ranges, but the value of measuring IgG subclasses in children under 2 years of age, or if the total IgG is low, is debatable. Approximately 10% of the normal population have undetectable IgG4, and normal ranges should be adjusted to reflect this.

Measures of in vivo antibody responses

The ability of the immune system to produce functional antibody is more important than the amount of circulating antibody. Functional tests of IgG production rely on measuring antibody titres to antigens to which the child is known to have been exposed, either naturally or by vaccination. Responses to protein antigens such as tetanus, diphtheria and the conjugated Hib vaccine are easily measured. However, although normal ranges for antibody titres exist, these are not well validated for antigens other than Hib, and may not be a true reflection of immunological memory. If antibody titres are low, booster vaccinations should be given to assess the memory response. The most reliable results are obtained when pre- and post-vaccination samples are assayed at the same time. In children over 2 years of age, administration of Pneumovax® (23 serovalent polysaccharide vaccine) is useful to assess the ability to respond to carbohydrate antigens. Loss of this response may be the first sign of an evolving immune deficiency in patients with CVID or WAS. Assessment of antibody responses to common respiratory viral pathogens and to varicella zoster may also provide useful additional information, although negative tests in the absence of microbiologically proven disease are difficult to interpret.

The optimal test of *in vivo* antibody production is assessment of IgM and IgG responses.

Cell-mediated immunity

Cell-mediated (T-lymphocyte) defects are usually accompanied by a degree of humoral immune deficiency, as T-lymphocyte help is crucial in making an antibody response with memory.

Quantification of cell numbers. Lymphocytes can be enumerated using flow cytometry, which detects the different light scatter properties of cells passed through a laser beam and enables populations of neutrophils, monocytes and lymphocytes to be differentiated. Lymphocytes can be characterized further by their cell surface markers, which are identified by specific monoclonal antibodies. The number of cells staining with a particular monoclonal antibody can be expressed either as a percentage of the lymphocyte pool, or as an absolute number. As with all immunological parameters, both proportions of different T lymphocytes and absolute numbers vary with age and reference should be made to published age-related normal ranges [1]. Approximately 60–80% of circulating lymphocytes are T lymphocytes, with 10–20% B lymphocytes and 5–15% NK cells.

1 Comans-Bitter WM, de Groot R, van den Beemd R *et al.* Immunophenotyping of blood lymphocytes in childhood. Reference values for lymphocyte subpopulations. *J Pediatr* 1997; **130**: 388–93.

Functional tests of cell-mediated immunity: in vitro lymphocyte proliferation assays. When lymphocytes encounter antigen *in vivo* they respond by upregulation of activation markers and proliferation, without which an effective immune response cannot occur. This can be mimicked *in vitro* by culturing lymphocytes with a non-specific stimulus such as plant lectins, using the incorporation of tritiated thymidine or a non-radioactive marker such as bromodeoxyuridine into the DNA of dividing cells as a surrogate measure of cell proliferation.

Definition of molecular defects

Protein assays

The genetic basis of an increasing number of immunodeficiencies is now well defined; many occur because a surface or cytoplasmic signalling protein is absent or defective. These abnormalities can be detected using a combination of western blotting and flow cytometry [1].

REFERENCE

1 Gilmour KC, Cranston T, Jones A *et al.* Diagnosis of X-linked lymphoproliferative disease by analysis of SLAM-associated protein expression. *Eur J Immunol* 2000; **30**: 1691–7.

Genetics

In the presence of an appropriate history or abnormal protein expression, molecular genetic analysis may be undertaken. Genes can be screened using single-stranded conformational polymorphism analysis, or by direct sequencing using automated sequences. It should be remembered however, that some polymorphisms within the human genome may have no clinical effects.

Once mutations have been defined, parents can be tested for carrier status. Carrier testing of siblings raises a number of ethical issues, and children should reach the age of informed consent before any tests are undertaken.

Antenatal diagnosis

Appropriate counselling by an individual conversant with the current prognosis of immunodeficiency states should be undertaken before antenatal diagnosis is undertaken. Due to the small risk of miscarriage, screening should only be offered to mothers when the parents would elect to terminate an affected pregnancy. Where the genetic defect is known, study of chorionic villus biopsy material can be performed in the first trimester. In other conditions, fetal blood sampling is performed at 18–20 weeks.

Disorders of cell-mediated immunity

Combined immunodeficiencies (severe combined immunodeficiency)

Failure to develop normal T lymphocytes, usually due to specific gene defects affecting early T-lymphocyte development or subsequent signalling pathways, leads to T-cell immunodeficiency, generally with concomitant humoral deficiency. In some combined immunodeficiencies, single gene defects affect both B- and T-lymphocyte development. The severity of the humoral deficiency varies from a subtle defect of specific antibody response to complete hypogammaglobulinaemia. Combined immunodeficiency results from a large number of disorders with X-linked or autosomal recessive inheritance [1]. The molecular basis of many, but not all, combined immunodeficiencies has now been elucidated (Tables 14.6, 14.8 & 14.9).

The most severe phenotype is SCID, and is associated with a profound T lymphopenia and panhypogammaglobulinaemia with early death from infection. Whilst the usual clinical features of this group of diseases are well characterized, atypical presentations and 'leaky' forms, with an attenuated phenotype, are increasingly recognized. Circulating T-lymphocyte numbers are usually low or absent but may be normal. In the classic SCID presentation, lymphocyte responses to mitogen are generally absent. Tests of antigen specific T-lymphocyte proliferation and antibody production are defective, and there will be cutaneous anergy. Patients usually have a limited diversity of T-lymphocyte receptors and immunoglobulin gene rearrangements.

Diagnosis may be more difficult in atypical patients. Identifying the molecular defect in specific patients with combined immunodeficiency or SCID is important for prognosis, treatment, genetic counselling and increasing our knowledge about these rare diseases.

General features of SCID

Although affected infants appear well at birth, they suffer persistent respiratory tract or gut infection and progressive failure to thrive from the first months of life [2]. Chronic diarrhoea and failure to thrive are due to persistent and sometimes multiple gastrointestinal viral infections, often with associated food intolerance.

Table 14.8 Defects of phagocytic function.

Immunodeficiency	Defect	Inheritance
XL CGD	Killing gp91^{phox}	XL
AR CGD	Killing defect p22^{phox}, p47^{phox}, p67^{phox}	AR

Non-host T lymphocytes (MFE or transfusion GvHD)	+	+/–	+/–	

ADA, adenosine deaminase; AR, autosomal recessive; CgC, common interleukin-γ chain; GvHD, graft-versus-host disease; IL-2/IL-15Rb, interleukin-2/15 receptor b; IL-7Ra, interleukin-7 receptor a; JAK3, janus-associated kinase 3; MFE, materno–fetal engraftment; MHC class II, major histocompatibility complex class II; RAG, recombination activating genes; RS, radiosensitive; WHN, winged-helix-nude; XL, X-linked; ZAP-70, zeta-associated kinase-70.

Persistent respiratory tract infection with *respiratory syncitial virus* or parainfluenza viruses are common, with failure to clear virus being accompanied by persistent bronchiolitis-like signs. An insidiously progressive persistent respiratory infection with radiological evidence of interstitial pneumonitis should raise the suspicion of *P. carinii* infection, often a co-pathogen with respiratory viruses.

Other presentations include prolonged otitis media and invasive bacterial infections, particularly staphylococcal or *Pseudomonas* septicaemia and pneumonia, which may respond poorly to appropriate treatment.

Severe invasive fungal infection is rare, but often fatal. Persistent, treatment-resistant superficial candidiasis is the commonest dermatological feature. This may start in the napkin area, but will often extend rapidly to produce a picture resembling severe seborrhoeic dermatitis. Systemic *Candida* infections do not usually occur unless central venous lines are used.

Pyogenic cutaneous infection due to *S. aureus* or group A streptococci are not uncommon, and will often provoke lesions having a necrotic ecthymatous appearance. Resistance to appropriate antibiotic therapy should raise suspicion [3].

Occasionally babies present with disseminated BCG or vaccine strain poliomyelitis virus. Children presenting within the first 6 months or so of life are more likely to have SCID or a severe T-lymphocyte defect.

Non-infectious cutaneous manifestations of SCID may result from GvHD, caused by the inability to reject foreign lymphocytes acquired either from the mother *in utero* or from an unirradiated blood transfusion. Engraftment of transplacentally acquired maternal lymphocytes (materno–fetal GvHD (MFGvHD)) sometimes, but not always provokes the clinical signs of GvHD, typically with a mild reticular skin rash with or without slightly deranged liver function tests. Surprisingly, up to 50% of children with SCID have clinically silent MFGvHD [4]. In other cases GvHD will severe, even fatal, and in these cases the skin rash is more severe and lymphadenopathy and hepatosplenomegaly may be present. Such cases may be clinically indistinguishable from Omenn's syndrome (see below), but identification of maternal cells by karyotype or DNA fingerprinting will distinguish MFGvHD from Omenn's syndrome [5].

Investigations usually show a severe lymphopenia, with depletion of T lymphocytes; B lymphocytes and NK cells may be present or absent, depending on the genetic defect in the particular form of SCID. Some patients show unusual patterns of immature T-lymphocyte markers; in such cases maternal engraftment should be excluded. Mitogen responses, mixed lymphocyte reaction, *in vitro* antigen-specific responses and delayed hypersensitivity skin testing to common antigens are usually absent. Immunoglobulin G, A and M are low, but laboratory results may be misleading as residual maternal IgG may give a falsely reassuring result. Also, it can be difficult to distinguish IgA and IgM levels in SCID from the low levels seen in normal infants.

Isohaemagglutinins are a useful measure of IgM production. If SCID is suspected, lymphocyte phenotyping is more reliable than immunoglobulin estimation. Chest X-rays show an absent thymus with hyperinflation and/or interstitial pneumonia when respiratory infection is present.

Without treatment, most patients die from infection by 12 months of age. Currently, the only curative treatment is BMT [6,7], although clinical gene therapy trials for common γ chain deficiency are in progress [8]. Supportive interim treatments include antibiotic prophylaxis with co-trimoxazole as antipneumocystis treatment, antifungal prophylaxis and antibody replacement (intravenous immunoglobulin). Live vaccines should be avoided. The diagnosis of SCID is a paediatric emergency, and suspected cases should be urgently referred to a designated treatment centre for further assessment and treatment.

Types of severe combined and combined immunodeficiencies

Severe combined immunodeficiency can be subdivided according to the presence or absence of T, B and NK cells, each phenotype being due to a number of distinct molecular defects.

T-negative, B-positive, NK-negative SCID is characterized by severe lymphopenia, absence of mature T and NK lymphocytes but normal numbers of circulating B lymphocytes.

The X-linked form is caused by a deficiency of the γ chain common to the IL-2, IL-4, IL-7, IL-9 and IL-15 receptors [1]. This is the easiest form of SCID to treat, and the first successful gene therapy was performed for this condition [2].

The autosomal recessive form is due to mutations in the gene encoding JAK3, a protein which binds to the common γ chain and through which signals are transduced following cytokine binding [3].

Another autosomal recessive form of SCID is characterized by a T-negative, B-positive, NK-positive phenotype, and is due to deficiency of the α chain of the IL-7 receptor [4].

Two forms of T- and B-negative, NK-positive SCID have been described, both with autosomal recessive inheritance. Phenotypically, they are identical, with absent T and B lymphocytes, but normal numbers of NK lymphocytes. The first form is due to a defect in the *RAG* genes which are necessary for the development of diverse T- and B-lymphocyte antigen receptors [5]. In the second form, cells cannot repair DNA normally following radiation damage and patients' fibroblasts show *in vitro* radiosensitivity. Recent studies have identified a defect in the *artemis* gene, which is necessary for rejoining DNA following TCR and BCR recombination [6]. Whilst treatable by bone marrow transplant (BMT), results are not as good as in the T-negative, B-positive form of SCID. 'Leaky' *RAG* defects have been shown in some patients with Omenn's syndrome.

Omenn's syndrome

Omenn's syndrome is characterized by a generalized erythematous rash, often with scaling and erythroderma, lymphadenopathy, hepatosplenomegaly, increased serum IgE levels, with a marked eosinophilia and combined immunodeficiency [1]. The cutaneous abnormality is often the first sign of the disorder; a scaly erythematous rash appearing and evolving into a confluent erythema. The initial appearances may be papular, becoming confluent and the skin often becomes thickened with a 'leathery' consistency. Hair, including eyebrows, is often lost as the rash evolves (Fig. 14.13). The rash may be present at birth, or evolve over the first 2 weeks of life. Children usually present in early infancy, but atypical forms may present later in the first year of life. As well as the clinical features described, children suffer diarrhoea, failure to thrive and persistent infection. There are normally high numbers of activated oligoclonal poorly functional T lymphocytes of the Th2 phenotype, explaining the eosinophilia and exclusive IgE production [2]. B-lymphocyte numbers are low as are levels of immunoglobulin classes other than IgE. The syndrome has been called a 'leaky'

Fig. 14.13 Newborn infant with Omenn's syndrome due to a mutation in the *RAG1* gene. Note the confluent erythematous exfoliating, thickened rash with a 'leathery' consistency and loss of hair and eyebrows. (Reproduced with permission from the Audiovisual Centre, University of Newcastle, Newcastle, UK.)

form of SCID in that small numbers of very abnormal T lymphocytes 'leak' past the block in T-lymphocyte development [3]. The underlying defect, at least in some cases, is a mutation in the *RAG* genes [4]. In some families, one affected individual has presented with T-negative, B-negative, NK-positive SCID, whilst another has presented with Omenn's syndrome [5]. The clinical picture may resemble SCID with materno–fetal engraftment, when maternal T lymphocytes crossing the placenta cause a GvHD-like reaction in an immuno-incompetent patient. Molecular genetic studies to identify the origin of the T lymphocytes infiltrating the dermis will differentiate these two disorders [6]. Activated oligoclonal lymphocytes in skin seemingly provoke Langerhans' cells to migrate to lymph nodes, liver and spleen where lymphoid tissue architecture is severely disrupted. It has been suggested that IFN-γ may ameliorate the clinical symptoms, but BMT is the only curative treatment [7].

Histology of the skin shows a dense dermal perivascular lymphohistiocytic infiltrate, comprising activated T lymphocytes, with numerous eosinophils. S100-staining Langerhans' cells are usually absent, and there is no epidermotropism. Lymph node architecture is disordered, being replaced by a similar massive infiltrate of cells of S100-staining interdigitating reticulum cells with absence of germinal centres, absent B cells and a scarcity of T lymphocytes [8].

Omenn's syndrome has been reported in association with non-cartilage-hair short-limbed dwarfism [9] and DiGeorge's anomaly [10,11]. In the older literature this condition has been confused with Langerhans' cell histiocytosis (Letterer–Siwe disease). It is likely that several cases reported in the literature under other names were in fact examples of this disorder [12].

Reticular dysgenesis

This rare form of SCID, inherited as an autosomal recessive trait, is characterized by defective lymphoid and myeloid differentiation. Bone marrow examination confirms the absence of myeloid precursors. Platelets and red cells are formed normally. There is some evidence that this is not a discrete entity, but due to other forms of SCID, and complicated by transplacental engraftment of maternal lymphocytes that cause severe bone marrow GvHD [1] and, in some affected infants, skin rashes. The absence of the non-specific cellular elements of the immune system makes the immune deficiency even more severe than in other forms of SCID. Clinical presentation often occurs earlier, as does the inevitable fatal outcome if immune reconstitution cannot be achieved.

Lymphocyte metabolism defects

ADA deficiency [1] and purine nucleoside phosphorylase (PNP) deficiency [2] are both single gene defects inherited in an autosomal recessive manner. Both result in defective metabolism of DNA, allowing the accumulation of toxic purine metabolites that destroy immature lymphocytes.

ADA-deficient patients typically present earlier than other forms of SCID, with very low numbers of T, B and NK lymphocytes. Skeletal abnormalities (cupping deformities of the ends of the ribs, as well as abnormalities of the transverse vertebral processes and the scapulae) are reported in up to 50% of cases and can be correlated with histological changes [3]. Neuro-developmental problems may also occur in some patients [4]. Very rarely, partial forms of ADA deficiency occur, where some lymphocyte function is preserved. Interestingly, such patients have clinical features similar to those seen in hyper-IgE syndrome [5]. Treatment is by BMT [6] or by use of replacement polyethylene glycol-coupled ADA [7]. Gene therapy is being attempted in this condition [8].

PNP deficiency is initially less severe than ADA deficiency, and the onset of symptoms may be delayed for several years [9]. Most cases present in early childhood with recurrent and severe infections, particularly with viruses and fungi, accompanied by diarrhoea and failure to thrive. There is a marked tendency to autoimmune disease, especially haemolytic anaemia [10], which can progress to red cell aplasia, and also to GvHD following non-irradiated blood transfusion. Skeletal abnormalities do not occur, but neuro-developmental problems are found in over half of all patients, particularly spastic paresis, dysequilibrium and ataxia [10]. There may also be more general neuro-developmental and behavioural problems. In one series 20% of patients presented primarily with neurological disorder [11].

Laboratory tests show a progressive fall in T-lymphocyte numbers and function with time, poor *in vitro* mitogen responses and negative delayed hypersensitivity skin tests. Immunoglobulin levels and antibody responses are initially normal, but in the late stages, levels fall. Serum uric acid levels are very low. The diagnosis is confirmed by demonstrating absent PNP activity in red cells or fibroblasts, and deoxyinosine and deoxyguanosine in the urine.

The prognosis without corrective treatment is poor with most cases dying in early childhood. BMT is therefore indicated as early as possible.

Other combined immunodeficiencies

Other rare immunodeficiencies have been described in only a few patients to date, with defects in other surface and signalling molecules such as ZAP 70 kinase. It is likely that these will become increasingly recognized as more laboratories are able to offer diagnostic testing.

Major histocompatibility complex antigen deficiency

Major histocompatibility complex class II

MHC class II antigens (HLA-DR, DP and DQ) are expressed on a limited repertoire of cells, and present antigen to $CD4^+$ T lymphocytes. With the help of an appropriate second signal, this activates T-helper lymphocytes specific for that antigen. Expression of MHC class II in the thymus is also essential for positive selection of $CD4^+$ T lymphocytes. Since HLA antigens are of vital importance for lymphocyte development and function, lack of MHC class II expression, previously described as a variant of the 'bare lymphocyte syndrome', results in a profound susceptibility to viral, bacterial, fungal and protozoal infections [1]. Lack of MHC class II expression results from defects in genes coding for regulatory factors that control transcriptional activation of MHC class II molecules [2].

The clinical picture resembles SCID, although sometimes infections develop slightly later. Intestinal and hepatic complications due to cryptosporidial infections are more common than in other immune defects. Neurological manifestations due to a range of viral infections are also well described. Coxsackievirus, adenovirus and poliovirus were the most frequently reported causes of meningoencephalitis [2].

The laboratory phenotype is very variable, but most patients will have a CD4 lymphopenia and hypogammaglobulinaemia, but lymphocyte proliferation responses are usually normal. The diagnosis can be confirmed flow cytometrically by showing absent or significantly reduced levels of class II molecules, e.g. DR, on cells that constitutively express class II (B lymphocytes and monocytes).

Affected children require initial treatment with replacement immunoglobulin, co-trimoxazole and antifungal prophylaxis. While BMT is the definitive treatment, it has to date had only limited success [3].

Major histocompatibility class I deficiency

Although described before MHC class II deficiency, SCID due to abnormal expression of the A, B and C components of the MHC class I complex is much less common. MHC class I is required for development of $CD8^+$ T lymphocytes, and affected children have low numbers of these cells. Mitogen responses are frequently normal [4]. MHC class I deficiency is due to mutations in the peptide transporter genes, which code for proteins that transport degraded protein antigen from the cytosol to the endoplasmic reticulum where they associate with MHC class I complex [5].

Clinically, this disease has a milder phenotype than MHC class II deficiency, with symptoms often not beginning until late childhood. Recurrent respiratory tract infections leading to bronchiectasis and sinus problems are common. Gastrointestinal disease is rare. The most striking clinical manifestation is necrotizing granulomatous skin lesions which are located on the extremities [6,7] and also in the mid-face [8]. The skin lesions begin as small pustules or subcutaneous nodules which slowly expand and ulcerate. The lesions are slow to heal, and usually leave hyperpigmented scars. Mid-face lesions can be particularly mutilating, and resemble midline granuloma. Diagnosis is confirmed by showing absent HLA class I expression in peripheral blood. Treatment is directed towards prevention/limitation of lung disease with judicious use of antibiotics (directed by sputum cultures), physiotherapy and bronchodilators as required. Prophylactic continuous antibiotics are of unproven benefit, but may be helpful. The majority of cases do not require replacement immunoglobulin therapy or BMT.

Combined immunodeficiency forming part of other syndromes

DiGeorge's anomaly

This condition results from abnormal cephalic neural crest cell migration into the third and fourth pharyngeal arches in early embryological development. A microdeletion at chromosome 22q11.2 is present in 90% of cases; the remainder are associated with other chromosomal anomalies.

DiGeorge's syndrome belongs to a group of disorders which have been described as developmental field defects [1]. The syndrome is extremely heterogeneous with partial forms more common than the complete phenotype [2]. Whilst classically recognized by the triad of congenital heart defects, immunodeficiency secondary to thymic hypoplasia and hypocalcaemia secondary to parathyroid gland hypoplasia, an expanded phenotype is increasingly recognized, with dysmorphic facies (low-set, abnormally formed ears, hypertelorism and antimongoloid slant, micrognathia, short philtrum to the upper lip and high arched palate), palatal abnormalities (cleft palate, velopharyngeal insufficiency), autoimmune phenomena, learning difficulties (particularly speech delay), renal anomalies, neuropsychiatric disorders and short stature. Conotruncal heart defects are classically associated with the syndrome, but other defects are seen including tetralogy of Fallot, septal defects, pulmonary atresia and aberrant subclavian vessels. Some patients have normal hearts.

Severe T-lymphocyte immunodeficiency presenting with a SCID phenotype of profound lymphopenia and

poor lymphocyte proliferation is rare and accounts for less than 1.5% of cases [3]. Humoral immunodeficiency is more common than previously thought, presenting with recurrent sinopulmonary infection, which may improve with time [4]. Occasionally significant lung damage may occur due to repeated infection. Autoimmune features are increasingly recognized, including juvenile chronic arthritis and autoimmune cytopenias [5,6]. The long-term immunological outlook is not well defined, particularly in children with mild cardiac or palatal phenotypes. An Omenn's syndrome phenotype has been described in patients with DiGeorge's syndrome [7], and at least some of these have been secondary to engraftment of maternal T cells causing an MFGvHD [8].

Wiskott–Aldrich syndrome

Immunodeficiency, thrombocytopenia, eczema and an increased risk of autoimmune disorders and malignancy characterize this X-linked recessive condition. The gene responsible for WAS codes for a novel 501 amino acid protein, the Wiskott–Aldrich syndrome protein (WASP) [1], which is only found in bone marrow derived cells, and is implicated in actin cytoskeleton polymerization [2]. Mutations in the same gene are found in patients with X-linked thrombocytopenia (XLT) [3] and, more recently, in X-linked severe congenital neutropenia [4]. Patients usually exhibit the classical triad of thrombocytopenia, recurrent infections and eczema (Fig. 14.14) but these vary in severity, and in some patients the eczema is surprisingly mild [5]. In general, it is indistinguishable from standard atopic eczema, apart from the presence of purpura and bleeding from excoriation in many patients. The condition usually presents in early life with bruising, petechiae and bleeding.

Fig. 14.14 Severe eczema in a patient with Wiskott–Aldrich syndrome (WAS). (Reproduced with permission from the Audiovisual Centre, University of Newcastle, Newcastle, UK.)

In XLT, thrombocytopenia with small platelet volume is the only symptom, perhaps with mild eczema. In WAS, bacterial and/or viral infections of the upper and lower respiratory tract are common [6] and opportunistic infection, such as *P. carinii* may occur. Herpesviruses, including HSV and varicella-zoster virus, are poorly handled and may cause severe and recurrent disease. Impetigo, cellulitis and skin abscesses are surprisingly common. Molluscum contagiosum and viral warts may be very extensive and, together with excessive bruising, help to clinically distinguish WAS from uncomplicated eczema. Indeed, very extensive molluscum contagiosum is quite characteristic of WAS (see Fig. 14.11). Infection exacerbates the bleeding tendency, and early death may result from bleeding. With increasing age, infective problems replace bleeding as the major cause of death [7]. Immunization with polysaccharide and typhoid vaccines is ineffective [8] and can cause severe, even fatal, reactions. The median survival is between 3–15 years.

Autoimmunity, particularly autoimmune haemolytic anaemia and vasculitis, and malignancy, particularly of the lymphoreticular system, become more common with increasing age [6] and in many cases are related to abnormal persistence of Epstein–Barr viral infection [9]. Scoring systems have been used to distinguish the milder phenotype of XLT from classical WAS. Heterozygous female carriers are clinically normal and demonstrate non-random X-inactivation in all haemopoietic cells.

Thrombocytopenia with an abnormally small mean platelet volume (mean platelet volume less than 5 fl) is pathognomonic [8]. The severity of immunodeficiency is variable, but affects cellular and humoral responses. T lymphopenia is progressive, with depressed responses to mitogens and antigens and delayed-type hypersensitivity skin test responses [6]. Serum immunoglobulins show a characteristic pattern with a very low IgM, normal IgG and raised IgA and IgE [8]. Antibody responses to tetanus, *Haemophilus influenzae* type B and *Pneumococcus* are often low, as are isohaemagglutinin titres. The direct Coombs' test is frequently positive, with or without a haemolytic anaemia. *In vivo* neutrophil and monocyte chemotaxis is impaired [8]. Electron microscopy shows greatly reduced numbers of microvilli on lymphocytes and platelets, due to failure of the normal binding of actin bundles which is critical to the organization of the cytoskeleton. Lymphoid and myeloid cell lines are all affected, so that phagocytes migrate poorly to sites of inflammation and do not put out normal filopodia, dendritic cells do not present antigen effectively, lymphocytes do not signal to each other normally and platelets form imperfectly from megakaryocytes [10].

The WASP has a number of unique domains, suggesting multiple functions, which may explain the complex phenotype of a single gene mutation. Missense mutations in exons 1–3 which lead to normal or truncated sized protein result in the milder phenotype of XLT, whereas most other mutations result in the classic WAS phenotype.

Acute bleeding episodes may be controlled by platelet transfusions (irradiated to prevent GvHD). Splenectomy and systemic steroids should be avoided if possible, as they will increase the risk of infection. Intravenous immunoglobulin, with or without prophylactic antibiotics, reduces bacterial sinopulmonary infections and in high dose may help treat autoimmune phenomena [11].

Despite these supportive measures, the prognosis is poor. Immunological and haematological reconstitution can be achieved by BMT, and despite a higher risk of Epstein–Barr virus (EBV)-driven lymphoproliferative disorders, 5-year survival is 87% after HLA-identical sibling donor BMT and 71% after unrelated-donor BMT. Results for unrelated-donor BMT after 5 years of age are much poorer [12].

X-linked hyper-IgM syndrome (CD40 ligand deficiency)

X-linked hyper-IgM syndrome is a T-lymphocyte immunodeficiency caused by a defect in the gene encoding for the CD40 ligand glycopeptide (CD154), expressed on activated T lymphocytes [1,2]. CD40L binds to CD40, expressed on B lymphocytes and monocyte/macrophage-derived cells [3]. Lack of binding prevents immunoglobulin isotype switching from IgM to IgA, IgG and IgE as well as activation of Kupffer cells and pulmonary macrophages. Lack of IgA and IgG results in a similar clinical picture to XLA with sinopulmonary and invasive bacterial infection, but in contrast to XLA, opportunistic infections also occur. Failure of T lymphocytes to activate pulmonary macrophages results in *P. carinii* pneumonia, whilst ineffective Kupffer cell function allows repeated infections of bowel, pancreas and biliary tree with *C. parvum* and similar organisms. These infections lead to sclerosing cholangitis, cirrhosis, pancreatitis and hepatic malignancy in the second or third decades [4]. Neutropenia with oral ulceration is seen in as many as 66% of patients. Fatal cytomegalovirus infection or enteroviral meningoencephalitis can occur [5]. Autoimmune phenomena are relatively common, and include haemolytic anaemia, thrombocytopenia, hypothyroidism, arthritis and liver disorders [4]. Severe soft tissue infection due to *P. aeruginosa* may occur [6].

Laboratory findings include low or absent IgA and IgG with normal or raised levels of IgM [7]. Neutropenia may be present, but T- and B-lymphocyte numbers are normal.

Patients should receive co-trimoxazole prophylaxis for *P. carinii* and immunoglobulin replacement therapy. The neutropenia sometimes responds to granulocyte colony-stimulating factor (G-CSF) and intravenous immunoglobulin. All drinking water, including bottled water, should be boiled. Azithromycin prophylaxis may lessen the risks of *C. parvum* infection. Despite conventional treatment, many patients do not survive beyond the second decade

of life. A few patients demonstrate a CVID-like clinical course and no biliary or liver disease, often remaining relatively well into middle life. BMT is increasingly being recommended for this condition, and combined bone marrow and liver transplantation has been successful [8,9].

Defects of lymphocyte apoptosis (autoimmune lymphoproliferative syndrome (ALPS))

Apoptosis, or programmed cell death, is important for regulating immune responses once an infection has been countered. Defects in this process lead to the autoimmune and lymphoproliferative features which characterize ALPS [1]. There are a number of pathways through which apoptosis can be induced [2]; one of the most important is initiated through the cell surface molecule termed Fas (CD95). Ligation of this molecule initiates a cascade of intracellular reactions that culminate in apoptosis, induced by proteolytic enzymes including caspases. Mutations in molecules in this cascade result in molecularly distinct, but clinically similar forms of ALPS.

Fas is expressed as a trimeric surface protein. Heterozygotes with a Fas mutation in one allele often develop the full clinical syndrome, as one abnormal protein chain is sufficient, by a dominant-negative effect, to significantly impair the trimer's function. Most of the cases are heterozygotes, though a few homozygous cases have also been reported.

Many present in early childhood, but adult presentation and asymptomatic cases may also occur. Haematological autoimmunity is most common [3], but any system can be involved. Chronic bullous dermatosis of childhood and localized purpura fulminans have been recorded in isolated cases. Other dermatological manifestations include vasculitis and urticaria [4].

Lymphoproliferation leads to massive asymmetric anterior cervical lymphadenopathy, with splenomegaly in nearly all cases, and hepatomegaly in some [3,4,5]. Malignant disease of the lymphoid system (both Hodgkin's and non-Hodgkin's) is reported with increased frequency, but has probably been over-diagnosed because the histological picture of proliferation resembles malignancy; clonality studies distinguish the two [6]. Affected individuals usually have high lymphocyte counts and normal or high immunoglobulin levels. Autoantibodies are usually present. The presence of circulating $CD3^+$ T lymphocytes expressing the α/β-receptor but not expressing CD4 or CD8 (the so-called double-negative T lymphocytes), and usually constituting between 5 and 20% of the total CD3 cell count, is a very important diagnostic clue.

Autoimmune phenomena usually respond to standard treatments, including corticosteroids and dapsone in the case of ALPS-associated chronic bullous dermatosis of childhood. Splenectomy should be avoided if possible, as severe infective complications may follow.

BMT has been successful in patients with homozygous Fas deficiency, but currently not enough is known of the long-term prognosis to justify elective BMT in (milder) heterozygous case, especially as some patients improve with age.

X-linked lymphoproliferative disease

An X-linked immunodeficiency associated with fulminant fatal EBV-driven infectious mononucleosis was first recognized in the Duncan kindred [1]. There are three common clinical presentations: fulminant infectious mononucleosis (58%), dysgammaglobulinaemia, often evolving to CVID (31%), and EBV-driven B-lymphocyte lymphoma, usually extranodal, and affecting the gastrointestinal tract or central nervous system (20%). Less commonly, patients present with vasculitis, aplastic anaemia, haemophagocytic lymphohistiocytosis (HLH), pulmon-

ary lymphomatoid granulomatosis or vasculitis [2]. Few cases of XLP-associated vasculitis have been published. Polyarteritis nodosa-like vasculitis has been reported in one case [3]. Vasculitic changes in small- and medium-sized muscular arteries have also been reported [4].

The prognosis is poor, with a high risk of death during initial EBV infection, and no recorded survivors after 40 years of age [5]. Most patients are well until infected with EBV, although other viruses may act as triggers.

The gene responsible for the disease, on the X chromosome, codes for a small protein, SAP (signalling lymphocyte activation molecule (SLAM)-associated protein) which is expressed on the surface of T lymphocyte and is critical for T lymphocyte and NK cell control of EBV-infected B lymphocytes [6,7].

Confirmation of the diagnosis involves demonstrating EBV genome in blood by polymerase chain reaction (PCR), together with immune defects outlined above and an abnormal response to the EBV with absent antibody response to EB nuclear antigen (EBNA). SAP protein is absent or abnormally expressed in many cases, although a gene mutation is not apparent in up to 40% of patients. HLH episodes are treated with immunosuppression with cyclosporin, and intravenous immunoglobulin is beneficial, particularly when hypogammaglobulinaemia is present. BMT is the only curative treatment.

Chronic mucocutaneous candidiasis

CMC is the name given to a group of disorders characterized by chronic infection of skin, nails and mucous membranes by *Candida* species, most commonly *C. albicans*. Recurrent and persistent candidiasis of the mouth, napkin area, skins and nails is the hallmark of this condition, but the severity varies considerably. Invasive disease almost never occurs. Failure of usually effective antifungal drugs to clear *Candida* distinguishes CMC from other conditions that predispose to candidiasis, such as secondary immunodeficiency, steroid treatment or systemic antibiotics.

Candidiasis is usually first noticed early in infancy. In severe cases, oesophageal involvement causes dysphagia, gastro-oesophageal reflux and failure to thrive, whilst skin lesions may be extremely disfiguring and distressing. As a patient becomes older, infections may become less severe.

In about half the patients, there is an associated endocrinopathy (with, in order of frequency, hypoparathyroidism, Addison's disease, pernicious anaemia, hypothyroidism and diabetes mellitus), which generally becomes apparent from the second decade onward.

Cases may be familial or sporadic with recessive or dominant patterns of inheritance. Nail dystrophy and dental enamel hypoplasia associated with autoimmune endocrinopathy, suggests that CMC is part of an autosomal recessive syndrome known as APECED (autoimmune polyendocrinopathy, candidiasis, ectodermal dystrophy) [1]. A minority of patients suffer from invasive bacterial sepsis, opportunistic infection, autoimmune haemolytic anaemia, malabsorption and chronic active hepatitis. Bronchiectasis and restrictive lung disease can occur [2].

The underlying defect is poorly defined, and immunological abnormalities are very variable. There may be diminished T-lymphocyte proliferation and cytokine production in response to *Candida* antigens, with impaired antibody production to polysaccharide antigens, and sometimes IgG2 subclass deficiency [3].

Treatment with azole antifungals, such as fluconazole, can be very effective, even in severe cases, but infection usually recurs after treatment has been discontinued. Continuous treatment may be necessary in severe cases.

Immunodeficiency and short-limbed dwarfism

Cartilage hair hypoplasia, the best described of the osteochondrodysplasias, is inherited in an autosomal recessive manner. It is caused by mutations in the *RMRP* gene, which encodes endoribonuclease RNAse MRP [1]. Severe short-limbed short stature, with metaphyseal and spondyloepiphyseal dysplasia, is always present, and most patients have sparse light hair [2]. Severe anaemia and Hirschsprung's disease [3] are less common but

well-recognized associations, as are malignancies, notably lymphoma and skin carcinoma [4].

The immunodeficiency is surprisingly variable. Most have T lymphopenia, and impaired *in vitro* mitogen proliferative responses, but only half suffer recurrent infection [5]. However, some have IgA and/or IgG subclass deficiencies with frequent ear infections. Patients are excessively vulnerable to viral infections, particularly varicella-zoster virus, EBV and other human herpesvirus infections; the risk of infective death is 300 times greater than normal [2]. This condition should be considered in any child with severe chickenpox or herpes simplex infections who is short and has fine sparse hair.

Severely affected patients should be assessed for BMT, which has been successful in correcting the immunodeficiency.

DNA repair defects and immunodeficiency

A huge number of genetically diverse lymphocytes, each bearing a unique receptor are needed for recognition of a wide array of foreign antigens. These are created by rearranging the variable (V), diversity (D) and joining (J) gene segments that code for T- or B-lymphocyte receptor genes (VDJ recombination). To do this, DNA double strand breaks are made between the gene segments, and are then rejoined after the segments have been re-arranged. This uses the DNA repair machinery found in all cells, which originally evolved to repair damage from UV light or toxic agents, but which the immune system has also exploited to generate the diversity of specific immune responses. Without fully effective DNA repair mechanism, cells with damaged DNA are more likely to apoptose or undergo malignant proliferation. Thus, individuals with defective DNA repair mechanisms have a predisposition to photosensitivity and skin abnormality, neurodegeneration, developmental anomalies and cancer as well as defective immunity [1]. As DNA repair mechanisms involve many control proteins, there is scope for many single gene defects causing distinct clinical entities. Only a few of these conditions are well understood, but several manifest both dermatological and immunological features. With the rapidly increasing understanding of their molecular basis, it is likely that these conditions will now be better delineated.

Ataxia telangiectasia

This multisystem autosomal recessive disorder, the best known of the DNA repair disorders, is characterized by progressive cerebellar ataxia, oculocutaneous telangiectasia, variable immunodeficiency and an increased risk of lymphoid malignancy [1]. It is associated with chromosomal instability, and cellular radiosensitivity.

Diagnosis remains chiefly clinical, and depends on the age of presentation. In the absence of a family history, patients usually present with gait anomalies before telangiectasia becomes apparent. Ataxia and cerebellar signs are usually present by the second year of life. Neurological degeneration is progressive, resulting in severe disability by late childhood, although intellectual function is usually preserved. Telangiectases usually appear between 2 and 8 years of age, first on the bulbar conjunctivae but later elsewhere, particularly on the nose, the ears and in the antecubital and popliteal fossae. Other cutaneous manifestations include spotty hypo- or hyperpigmentation, cutaneous atrophy and atopic dermatitis [2–5]. Gonadal atrophy occurs in both sexes, and growth failure is also prominent in the later stages. Cellular and humoral immunodeficiency affects 60–80% of cases; low levels of IgA, IgG2 and poor antibody responses to viruses and *Pneumococcus* are seen most often [5].

Recurrent sinopulmonary infection is common, and may lead to bronchiectasis and clubbing, but clinical manifestations are extremely variable [6]. Lymphoreticular malignancies and, unusually for immunodeficiency, carcinomas, occur with increased frequency [7]. Radiosensitivity means that inadvertent treatment with radiotherapy is toxic and often lethal.

Irrespective of the development of malignancy, survival beyond early adult life is unusual.

Heterozygosity for the *AT* gene confers an increased risk of developing breast cancer [8].

A raised α-fetoprotein supports the diagnosis, as does increased chromosome breakage on exposure to ionizing radiation. The *ATM* gene has been located to chromosome 11q22.23 and codes for a phosphatidyl kinase, which is involved in meiotic recombination and cell cycle control [9]. This protein detects DNA damage and signals to proteins involved in DNA repair and cell cycle control [10]. Prophylactic antibiotics or intravenous immunoglobulin can reduce the morbidity of sinopulmonary infection in some patients.

Nijmegen breakage syndrome

Other DNA repair defect disorders include Nijmegen breakage syndrome (NBS), an autosomal recessive disorder first described in the Dutch town of that name, and characterized by microcephaly with mild to moderate mental retardation, 'bird-like' facies, immunodeficiency, clinical radiation sensitivity and chromosomal instability. Bacterial sinopulmonary infection is common, as is hypogammaglobulinaemia and $CD4^+$ T lymphopenia with diminished T-lymphocyte proliferative responses. Absence of ataxia, together with normal α-fetoprotein levels distinguishes NBS from ataxia–telangiectasia.

Specific dermatological features include café-au-lait spots and vitiligo [1], as well as skin infections due to fungal and virus infections, particularly herpesviruses [2]. Sun sensitivity of the eyelids and cutaneous telangiectasia have been described [1].

Treatment with antibiotic prophylaxis or intravenous immunoglobulin may be helpful.

Other disorders of DNA repair associated with immunodeficiency

Bloom's syndrome is a rare autosomal recessive disorder associated with increased sister chromatid exchange, severe growth failure, increased malignancy and immunodeficiency. Affected individuals are photosensitive and may develop telangiectases on the face, dorsa of the hands and forearms. Hypo- and hyperpigmented lesions may also develop.

Recurrent bacterial sinopulmonary infections associated with hypogammaglobulinaemia, most often low IgM, are the most common clinical manifestation of immunodeficiency, and may lead to bronchiectasis.

Bloom's protein, the gene for which is mutated in the disease, unwinds the DNA helix, but the exact mechanism by which this causes immunodeficiency is unclear [1].

DNA ligases are also involved in DNA repair. Defects in DNA ligases I and IV have been described in rare individuals with radiosensitive cell lines and combined immunodeficiencies. An immunodeficient individual with mutations in DNA ligase I had photosensitivity and developed venous dilatation on the skin, mainly on the limbs. Bulbar telangiectasia were also present [2]. Other individuals with microcephaly and immunodeficiency have mutations in the DNA ligase IV gene. Two individuals were described with skin photosensitivity and psoriasis, and a further patient developed multiple psoriasiform lesions [3].

Fanconi's anaemia

Fanconi's anaemia is a chromosomal instability disorder characterized by developmental defects, progressive bone marrow failure and cancer susceptibility. Children with Fanconi's anaemia are generally small, and elfin like with a history of low birth weight. The central clinical manifestation of Fanconi's syndrome is progressive bone marrow failure during childhood and adolescence [1–3]. Easy bruising is generally the presenting symptom, and most often first becomes apparent between the ages of 4 and 10 years. In addition to thrombocytopenia, anaemia and leukopenia are usual, and the bone marrow is aplastic.

Cutaneous hyperpigmentation and skeletal anomalies are characteristic. Unfortunately, the dermatological findings are not well described, and there is considerable confusion with dyskeratosis congenita in the older literature. However, they comprise macular brownish pigmentation either resembling freckles and occurring mainly in sun-exposed areas or occurring more diffusely, in which case the abdomen, genital area and flexures appear to be predominantly affected [4]. Guttate macular

hypopigmentation is often also present in affected areas. Hypopigmentation and café-au-lait spots are reported. Persistent and exceptionally severe viral wart infection has been reported [4].

The principal skeletal abnormality is the absence or hypoplasia of at least one of the thumbs; hypoplasia or absence of the radius is also common. Structural renal abnormalities, endocrinopathies, genital hypoplasia, microcephaly and microphthalmia are other common features.

There is a high risk of leukaemia and other malignancies in these children [5], probably due to the structural instability of chromosomes observed in Fanconi's anaemia, which leads to a high frequency of chromosomal breaks and rearrangements [6]. Cultured cells are unusually sensitive to DNA cross-linking agents such as mitomycin C, but they are not sensitive to ionizing radiation, although cells from the Fanconi's D2 subgroup do show ionizing radiation sensitivity.

The disorder is transmitted as an autosomal recessive trait. Eight complementation groups (A–G) have been described [7] and six genes discovered. The Fanconi's proteins are involved in repair of DNA cross-linking damage and some interact with other DNA repair pathways. In particular, the Fanconi's D2 subgroup appears to interact with *ATM* and nibrin, mutated in ataxia–telangiectasia and NBS, respectively [8,9]. The induction of chromosomal breakage by the alkylating agent, diepoxybutane, can be used to detect heterozygotes and for prenatal diagnosis [10], although chorionic villus biopsy and genetic diagnosis is now possible if the specific gene defect within the family is known. There is a high incidence of diabetes [11] and of neoplastic disease [12] in heterozygotes.

The outlook for untreated patients with Fanconi's anaemia is poor, with death usually occurring within a few years of the first signs of marrow failure. Initially, bone marrow function can be stimulated with corticosteroids and with the androgenic steroid, oxymethalone. Bone marrow transplantation has been used successfully to treat patients, but care must be taken to avoid the use of alkylating agents in pretransplant conditioning [13].

Other immunodeficiencies

A number of syndromes have been described which include primary immunodeficiency as part of the phenotype. In some, the syndrome is well described, and in a few the underlying molecular defect has recently been elucidated. Most lack clear definition.

Hoyeraal–Hreidarrson syndrome

This X-linked disorder is characterized by microcephaly, cerebellar hypoplasia, aplastic anaemia and growth retardation [1,2]. A progressive combined immunodeficiency, with hypogammaglobulinaemia and lymphopenia is a well-recognized association [3]. Mutations in the dyskeratosis congenita gene (*DKC1*) have been found and Hoyeraal–Hreidarsson syndrome probably represents a severe phenotype of dyskeratosis congenita [4]. Cutaneous manifestations include leukoplakia, oral and gastrointestinal ulceration, and reticulated hyperpigmentation, primarily in the regions of the neck, upper thorax and upper extremities [5]. Other cutaneous features include nail dystrophy, which begins with longitudinal striations, increasing brittleness, deformation, onychoclasis and nail loss. Palmar and plantar hyperhidrosis, blistering, hyperkeratosis, acrocyanosis and alopecia may also occur.

Netherton's syndrome

This triad of generalized infantile erythroderma, diarrhoea and failure to thrive may be associated with a variable immunodeficiency including mild lymphopenia and polysaccharide antibody deficiency [1]. The clinical features are similar to those seen in Omenn's syndrome and SCID and materno–fetal engraftment, with erythroderma and ichthyosis characterized by abnormal cornification, dryness and fish-like scaling of the skin. Hair shaft abnormalities (trichorrhexis invaginata) are described which may not be seen until several months of age [2]. Distinguishing these entities is important as the other conditions are treated by BMT, whereas Netherton's syndrome is not. Hair shaft abnormalities are diagnostic (bamboo hairs). Squamous cell carcinoma has been described in Netherton's syndrome [3]. Mutations in the serine protease inhibitor gene *SPINK5* have been described [4].

Anhydrotic ectodermal dysplasia, incontinentia pigmenti and defects in the *NEMO* gene

X-linked anhydrotic ectodermal dysplasia and immunodeficiency have been associated in an ill-defined manner for some time, but only recently has the pathology begun to be elucidated. Patients present with sparse scalp hair, conical teeth and absent sweat glands. Some suffer from recurrent sinopulmonary infection, often with encapsulated organisms, and have poor antibody responses to polysaccharide antigens, or frank hypogammaglobulinaemia [1]. Incontinentia pigmenti is a rare X-linked dominant condition characterized by developmental abnormalities in skin, hair, teeth and the central nervous system. Carrier mothers demonstrate well-recognized cutaneous features of Blashko's linear skin lesions occurring in four successive, sometimes overlapping stages: (i) erythema, vesicules, pustules; (ii) verrucous hyperkeratotic lesions; (iii) hyperpigmented whorls and streaks following lines of Blaschko; and (iv) pallor and scarring. In other respects, affected females are healthy. Previously affected males were all reported to die soon after birth, but some have now been described who survive albeit with a progressive combined immunodeficiency [2]. Recently, hypo-functional mutations in the *NEMO* gene encoding a protein required to activate the transcription factor NF-kB have been described in male patients with both X-linked anhydrotic ectodermal dysplasia and incontinentia pigmenti, suggesting that these conditions represent variants of the same disorder [3]. Such infants share many of the clinical features of ectodermal dysplasia, although they appear less severe than in children with 'classical' ectodermal dysplasia without immunodeficiency, and the majority of patients have normal or sparse scalp hair. Of 33 patients from 23 kindred reported to date, two unrelated children manifested a more severe phenotype with features including osteopetrosis and lymphoedema, so-called osteopetrosis lymphoedema ectodermal dysplasia immunodeficiency (OL-EDA-ID) [2–5]. Two related children from another kindred have been described with EDA-ID and increased bone density [6], suggesting that 'osteopetrosis' could be a variable clinical part of this syndrome. Only a few of the mothers of affected boys from EDA-ID kindreds showed variable features of EDA or incontinentia pigmenti (dry and/or hyperpigmented skin, hypodontia, conical teeth), as well as elevated IgA levels, whilst mothers of both children with OL-EDA-ID phenotype showed mild features of incontinentia pigmenti.

From early childhood affected boys suffer from unusually severe, life-threatening and recurrent bacterial infections of the lower respiratory tract, skin and soft tissues, bones, and gastrointestinal tract, including meningitis and septicaemia. Causative pathogens are most often Gram-positive bacteria (*Streptococcus pneumoniae*, *Staphylococcus aureus*), followed by Gram-negative bacteria (*Pseudomonas* spp., *H. influenzae*) and *Mycobacteria*. Interestingly, two children had *P. carinii* infection and another two had severe adenovirus and cytomegalovirus infections, suggesting a more profound combined T- and B-lymphopenia immunodeficiency. The two children with XL-OL-EDA-ID had a particularly severe phenotype as they acquired mycobacterium infections in the first year of life and died. A comprehensive description of the clinical features of children with XL-EDA-ID and XL-OL-EDA-ID is not available as yet, but an international survey has been undertaken.

The immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome

The IPEX syndrome [1] is characterized by early-onset type I insulin-dependent diabetes mellitus, infantile ichthyosiform dermatitis, protracted diarrhoea and severe enteropathy and thyroiditis. Mutations in the *FOXP3* gene have recently been described in affected patients [2,3]. Insulin-dependent diabetes develops in early infancy. Atopic eczema and exfoliative dermatitis are the third most common presenting features after diabetes and enteropathy. Bruising may occur, leading to thrombocytopenia. BMT has been tried as a curative treatment [4].

Immunodeficiency, centromeric instability and facial anomalies (ICF) syndrome

The ICF syndrome is an autosomal recessive disorder in which there are characteristic structural chromosomal abnormalities in chromosomes 1, 9 and 16 in lymphocytes. Other cells do not show these changes. Affected children develop severe recurrent infections and have immunoglobulin deficiency, often with agammaglobulinaemia, but with normal T- and B-lymphocyte numbers [1]. T-lymphocyte immunity is not normal and *P. carinii* infection, severe viral warts and cutaneous fungal infection are described. Facial dysmorphism is variable, but common features include low-set ears, hypertelorism, flat nasal bridge, epicanthic folds, tongue protrusion and micrognathia. Triangular facies are described. Mental retardation has been described, with speech delay being a common feature. This diagnosis should be considered in a child with very extensive warts or spreading cutaneous fungal infection (Fig. 14.15) and the characteristic facial features. The differential diagnosis is CVID. Mental retardation may occur but there is no increased risk of malignancy.

Defects of antibody production

X-linked agammaglobulinaemia (Bruton's disease)

First described by Bruton in 1952 [1], this X-linked intrinsic B-cell defect prevents B-lymphocyte development beyond the pre-B lymphocyte stage. It is caused by a defective gene that encodes a cytoplasmic enzyme, Bruton tyrosine kinase (btk) [2,3]. Classically affected boys produce no immunoglobulins and make no antibody responses but have normal cell-mediated immunity. Since the molecular basis has been defined milder phenotypes have been recognized where some antibody function is present [4]. Typically, recurrent pyogenic infections commence in the latter half of the first year of life, after maternal IgG levels have declined. The diagnosis is often made surprisingly late; in one series, the average age at diagnosis was 3 and a half years, and 2 years when there was a positive family history [5]. Sinopulmonary infections are most common, but pyoderma, gastroenteritis, arthritis, meningitis and osteomyelitis may be presenting features. Boils or impetigo are the most common dermatological features, frequently due to *S. aureus* or *Pseudomonas* (Fig. 14.16) and usually associated with neutropenia. Chronic ulcerative cutaneous HSV infection has been reported [6]. Asymptomatic papular lesions developed on the trunk and arms of a 34-year-old patient in which caseating granulomas were demonstrated on biopsy, but no infectious agent was identified [7]. Pyoderma gangrenosum may be a feature [8], and Stevens–Johnson syndrome [9], vitiligo

Fig. 14.16 Cellulitis due to *Pseudomonas aeruginosa* in a patient with X-linked agammaglobulinaemia (XLA). (Reproduced with permission from the Audiovisual Centre, University of Newcastle, Newcastle, UK.)

[9] and total alopecia areata [10] have also been described. Recovery from viral infections is normal with the notable exception of those caused by enteroviruses (especially echoviruses) [11], which can cause a chronic meningoencephalitis or dermatomyositis-like picture [12]. Non-purulent arthritis affecting predominantly large joints is occasionally seen, in some cases due to mycoplasma infection. Amyloidosis is an infrequent complication.

Usually there is absence or severe depletion of all serum immunoglobulin classes, and antibody responses to vaccines are absent. There are normal numbers of T lymphocytes but no B lymphocytes in peripheral blood, although pre-B lymphocytes (containing cytoplasmic μ chains) are found in bone marrow. Lymph nodes show absent follicles and germinal centre, and plasma cells cannot be demonstrated at any site. The diagnosis can be rapidly confirmed by demonstrating absence of the btk protein in cell lysates [13].

Immunoglobulin replacement therapy is the mainstay of treatment. Chronic lung damage and sinus disease may also progress on treatment, and for this reason vigorous and early antibiotic therapy should be used for respiratory tract infections. Since the introduction of intravenous immunoglobulin therapy, lung disease seems less common, and the patients developing progressive lung and sinus disease while on treatment appear to be those with damage sustained before immunoglobulin therapy was commenced [14], which emphasizes the importance of early diagnosis and treatment.

Autosomal recessive forms of agammaglobulinaemia

When hypogammaglobulinaemia is found in a girl or a child with consanguineous patients, one of the recently recognized autosomal recessive genetic defects affecting B-lymphocyte differentiation should be considered. Mutations have been described so far in genes coding for: μ heavy chain [1], Ig α (part of the signal transduction complex of the B-lymphocyte-antigen receptor) [2], λ5 light chain [3] and B-lymphocyte linker protein (BLNK) [4]. These molecules are all required for early B-lymphocyte development from pro-B lymphocyte to pre-B lymphocyte stage. Unlike in XLA, pre-B lymphocytes are therefore not detectable in marrow samples. Other families have also been described in whom the molecular defect is yet to be identified. In all cases the defect is B lymphocyte specific. The number of cases described is too small to draw firm conclusions, but the clinical picture would seem to be similar to XLA, although patients with μ heavy chain deficiency may have more serious life-threatening infections than those with XLA with an earlier onset of symptoms [5]. Skin sepsis is described as a feature but less commonly than in XLA.

Common variable immune deficiency

CVID is a poorly defined entity characterized by the presence of quantitative or qualitative hypogammaglobulinaemia. The incidence is described as between 1 : 10 000 and 1 : 50 000 of the population, and although the onset of symptoms typically occur in adolescence or early adult life, it is increasingly being diagnosed in childhood.

Selective IgA deficiency with or without IgG2 deficiency may be one end of the spectrum of this disease [1], and families are described where some members have CVID whilst others have selective IgA and/or IgG2 deficiency. Now that other immune deficiencies are being defined by their molecular defections, it has become apparent that at some patients with CVID have mild phenotypes of other immune deficiencies such as XLA, CD40 ligand deficiency or XLP [2,3]. Autoimmune diseases, such as rheumatoid arthritis, dermatomyositis and SLE [4,5] also have an increased incidence in these kindreds.

As with all patients with humoral immune defects, patients with often present with recurrent sinopulmonary and gastrointestinal infections. Other clinical manifestations in this disease exemplify the inherent immune deregulation, with an increased incidence of autoimmune disease, particularly autoimmune haemolytic anaemia, thrombocytopenia and neutropenia. Non-malignant granulomatous lymphadenopathy, hepatosplenomegaly and involvement of the gastrointestinal tract is a frequent finding in a subgroup of patients [6], and clinical differentiation from malignancy may be difficult, although histologically lesions resemble those seen in sarcoidosis. These granulomas are normally sensitive to steroid treatment. Patients with CVID also have a significantly increased risk of lymphoreticular and gastrointestinal malignancies [7,8]. Cutaneous manifestations are common and non-specific and include impetigo, boils, furuncles and cellulitis. Severe viral wart infection has been reported. Atopic eczema, vitiligo, alopecia areata and psoriasis have been described in CVID patients, and are probably more common than expected. Skin manifestations with other associated symptoms should raise suspicion of this diagnosis.

All patients have defective antibody function with hypogammaglobulinaemia, which varies from a failure to respond to vaccines to panhypogammaglobulinaemia. B-lymphocyte numbers are frequently normal, but a significant proportion of patients have T-lymphocyte abnormalities, in particular a reversed CD4/8 ratio and generalized lymphopenia. Mild phenotypes may require only prophylactic antibiotics. Significant degrees of hypogammaglobulinaemia should be treated with immunoglobulin replacement therapy. Granulomatous lesions and autoimmune phenomena may respond to treatment with steroids.

IgA deficiency

Studies in healthy blood donors have shown that 1 in 600–700 white people have no demonstrable serum IgA, and whilst there is almost always concomitant lack of salivary IgA, many affected individuals are asymptomatic [1]. However there is increased incidence of IgA deficiency in populations of patients with chronic lung disease and autoimmune diseases [2,3], suggesting that it may be associated with disease, perhaps when there are other immunological abnormalities.

Recurrent upper respiratory tract and ear infections are the commonest symptoms in young children with IgA deficiency, and in the majority the frequency and severity of infections improves with age, regardless of the IgA level [4].

There is a strong correlation between autoimmune disease of all types and IgA deficiency [3], which appears independent of the infection suffered. It may be that abnormalities of antigen handling in the gut account for these autoimmune phenomena, and the increased incidence of gastrointestinal infection and coeliac disease seen in IgA deficiency, although the true incidence of these problems is not been well defined. Skin manifestations may be non-specific, and include atopic eczema, in association with sinopulmonary disease. Cutaneous features due to autoimmune disease including psoriasis, vitiligo and dermatomyositis have been reported [5].

Other forms of antibody deficiency

Other forms of antibody deficiency are described (Table 14.10) but the cutaneous features are no different to those described above.

Disorders of phagocytic cells

Chronic granulomatous disease

CGD is an inherited defect of the phagocyte NADPH oxidase enzyme complex which generates superoxide and other reactive oxygen species that are toxic to organisms ingested into phagosomes. The gene defect for the most common form is found on the X chromosome, and codes for the major membrane component gp91^{phox}, and accounts for up to 60% of cases. Defects in the genes coding for the cytoplasmic components p67^{phox}, p47^{phox} and p22^{phox} are inherited in an autosomal recessive pattern [1].

The disease has protean clinical manifestations, but the hallmark is acute, and potentially fatal, bacterial or fungal infection [2]. The disease becomes apparent during the first 2 years of life in the great majority of cases [3], but the onset may occasionally be delayed into the second decade [4–6]. The earliest manifestations are often seen in the skin. Neonatal pustulosis is commonly the first sign of the disease. Subsequently, a rather non-specific, impetiginized periorificial rash is highly characteristic. This is most commonly seen around the nostrils, ears, mouth and eyes, and has sometimes been described as 'eczematous' or 'seborrhoeic'. Any area where the skin has been broken, by abrasion, for example, tends to become impetiginized or ecthymatous. Nodular lesions may follow, and these frequently break down to form necrotic ulcers.

Firm translucent papular lesions around the nose, eyes, lips and on the cheeks may mimic lupus vulgaris or sarcoidosis. A common manifestation is acute suppurative lymphadenitis in the neck, axilla or groin. Other frequent pyogenic infections include liver abscesses, osteomyelitis, arthritis, pneumonia, skin sepsis and perianal abscesses. Pathogens, such as *S. aureus*, *Burkholderia cepacia*, *Aspergillus* spp. and *Serratia marcescens*, are most commonly seen [7].

Subcutaneous nodules may develop at immunization sites, and these also tend in time to ulcerate. Poor healing of surgical wounds, and of these discharging nodular skin lesions, is highly characteristic. Perianal abscesses are a regular feature. Other frequent findings include chronic suppurative paronychia, folliculitis of the scalp and ulcerative stomatitis. Acute febrile neutrophilic dermatosis (Sweet's syndrome) have been rarely described [8], as has chronic bullous disease of childhood [9]. Fungal infection often causes pulmonary disease with pneumonia, lung abscess formation followed by empyema and spread across tissue planes into paraspinal tissue and vertebrae [10,11]. Discrete areas of persistent consolidation may be

Table 14.10 Classification of antibody deficiency.

Antibody deficiency	Gene defect	Inheritance
XLA (Bruton's disease)	btk	XL
XL hyper-IgM (see CD40L deficiency)		
Autosomal recessive hyper-IgM syndrome	AID	AR
	CD40	AR
	NEMO	XL
Autosomal recessive agammaglobulinaemia	μ chain	AR
	BLNK	AR
	λ5/14.1 gene	AR
	Igα (CD79a) gene	AR
Ig heavy-chain deletions	Chromosome 14q32 deletion	AR
Selective Ig deficiency:		
1. IgG subclass deficiency	Defect of isotype differentiation	Unknown
2. IgA deficiency	Terminal differentiation failure in IgA-positive B cells	Unknown
3. Polysaccharide antibody deficiency	Variable, described in some btk, *NEMO*, *DGA* patients	Unknown, specific diseases, XL
Common variable immunodeficiency	Unknown	Variable, may be AD, AR, XL
Transient hypogammaglobulinaemia of infancy	Unknown	Unknown

AD, autosomal dominant; AID, activation-induced cytidine deaminase; AR, autosomal recessive; XL, X-linked; XLA, X-linked agammaglobulinaemia.

seen radiologically and are often termed 'encapsulating pneumonia'; this sign is highly distinctive. Less specific reticulonodular shadowing and hilar lymphadenopathy are also frequent. Liver abscesses are rare in childhood, and when seen CGD should always be looked for [12,13].

The importance of non-infectious inflammatory complications is increasingly recognized. These include inflammatory bowel disease, which clinically and histologically can be indistinguishable from Crohn's disease, restrictive lung defects, genitourinary obstruction and cutaneous granulomas particularly at the vaccination sites. These non-infective manifestations sometimes respond well to corticosteroid treatment [14], but this may increase the risk of infectious complications.

Female carriers of X-linked CGD do not generally show increased susceptibility to infection. However, some carriers have experienced subcutaneous abscess, hidradenitis suppurativa and ulcerative stomatitis [15]. Carrier females are also prone to the development of erythematous macular, papular and urticarial skin lesions following light exposure, and to discoid LE or Jessner's lymphocytic infiltrate [7]. The carrier state for X-linked CGD should be considered in all women presenting with discoid LE, and appropriate attention should be paid to their family history. Identification of the carrier state offers such women the possibility of genetic counselling, and prenatal diagnosis of CGD in their sons.

Diagnosis is suggested by failure of reduction of nitrobluetetrazolium or dihydrorhodamine by neutrophils. X-linked carriers have both normal and abnormal neutrophils, and the presence of abnormal neutrophils may lead to abnormal clearance of cellular debris, which may in turn account for their excess risk of autoimmune disease.

Prophylactic antibiotics, in particular co-trimoxazole which is concentrated in neutrophils, has significantly reduced morbidity and mortality from bacterial infections in CGD [3]. Children should also be given antifungal prophylaxis; itraconazole is currently the best available agent, and this may help reduce the risk of fatal fungal disease in these patients [14].

Infections or unexplained fevers should be treated aggressively. IFN-γ is a useful adjunctive treatment in severe bacterial or fungal infections. Although used as prophylactic therapy in the US, in Europe it is mainly used for prophylaxis only after documented failure of oral antibacterial and antifungal agents [2]. White cell infusions may also be used as adjunctive therapy in severe infection. Registry data suggests that the outlook in early childhood has improved considerably in recent years, but considerable morbidity and mortality occurs, and consideration should be given to BMT when a suitable donor is available [7].

Survival is variable, but improving, with prophylactic administration of antibacterial and antifungal agents, but the risk of severe or fatal fungal infection resistant to antifungal prophylaxis remains. Increasingly, BMT is recommended, and even in those with active fungal infection, a good outcome can be achieved [16].

Neutropenia

Neutropenia can result from reduced bone marrow production or increased peripheral destruction, which can be distinguished by bone marrow examination. Neutropenia most frequently follows decreased production induced by disease processes or drug treatments. Increased consumption may occur in autoimmune states, including those associated with immune deficiency. The degree of neutropenia will influence the clinical picture: neutrophil counts of less than 0.5×10^9/L carry a major risk of infection, whilst counts below 0.2×10^9/L are associated with a significant incidence of life-threatening sepsis.

Cyclical neutropenia

In cyclical neutropenia, decreases in haematopoiesis at

intervals of about 3 weeks (range 13–35 days) leads to neutropenia and susceptibility to infection. Patients are normally asymptomatic, but during the period of severe neutropenia, apthous ulcers, gingivitis, stomatitis and cellulitis may develop. Death from overwhelming infection occurs in a small proportion of patients. Symptoms resolve over 3–4 days as the neutrophil count rises. Thus, neutrophil counts taken after the onset of symptoms are usually normal, and to make the diagnosis neutrophil counts should be taken two or three times a week over a 4 or 5 week period. In some families, this is inherited in an autosomal dominant manner and mutations in the neutrophil elastase gene (*ELA2*) have been identified in patients with cyclical neutropenia [1].

Severe congenital neutropenia

This was originally described by Kostmann in 1956 as an autosomal recessive disease [1]. Onset is within the first year of life, with recurrent and life-threatening infections. Symptoms include omphalitis, cellulitis, perirectal abscesses, peritonitis, stomatitis and meningitis. Examination of bone marrow shows an arrest at the promyelocyte to myelocyte maturation stage. Treatment with G-CSF results in increased counts and fewer infections in almost all patients with neutropenia not secondary to peripheral destruction. Concerns about the induction of leukaemias with the prolonged use of G-CSF have not been borne out, although pre-treatment and annual bone marrow aspirates are recommended to screen for the development of myeloid leukaemia [2]. BMT may be indicated in selected cases. A small number of patients with congenital neutropenia inherited in an X-linked manner have mutations that result in over-activity of WASP [3], whilst dysregulated expression of the guanosine triphosphatases (GTPases) RhoA and Rac2 has been described in families where inheritance is autosomal recessive [4].

Shwachman–Diamond syndrome

This rare autosomal recessive disorder is characterized by exocrine pancreatic insufficiency, skeletal abnormalities characterized by metaphyseal chondrodysplasia, bone marrow dysfunction and recurrent infections [1]. Skin sepsis is a feature. Neutropenia occurs in all patients, whilst 10–25% of patients also have pancytopenia. There is an increased incidence of myeloid leukaemia inheritent to this condition. Cutaneous features are common, although not well documented. They may be due to pancreatic insufficiency with resultant malabsorption of fat-soluble vitamins, essential fatty acids and other nutrients. Patients may show xerosis and follicular keratosis. Facial skin in particular may be dry with associated perioral dermatitis. A widespread symmetrical eczematous rash has been reported, and with associated thrombocytopenic purpura, the diagnosis of WAS may be erroneously suggested. Palmoplantar hyperkeratosis and nail thickening may occur. A defect in the *SBDS* gene, a possible RNA-processing gene, has been described in these patients [2]. BMT has been successfully performed in this condition [3].

Neutrophil-specific granule deficiency

This rare disorder is characterized by recurrent skin and lung infections with staphylococci and enteric bacteria [1]. Electron microscopy of patient neutrophils shows reduced or absent secondary granules; specific stains demonstrate lack of the secondary granule proteins such as lactoferrin and vitamin B_{12} binding protein. Proteins that reside in azurophilic (primary) granules, such as lysozyme and myeloperoxidase are present. Neutrophils also show abnormalities in migration and nuclear morphology. Mice lacking the transcription factor CCAAT/enhancer binding protein have a similar phenotype, and case reports of patients with mutations in this gene have now been published [2].

The clinical course of patients is variable. Treatment options include prompt institution of antibiotic therapy for infections and prophylactic antibiotic treatment. BMT should be considered in patients with a severe phenotype.

Hyper-IgE syndrome

The hyper-IgE syndrome (previously Job's syndrome) is of special relevance to the dermatologist, as the initial presentation may be cutaneous. It is a complex disorder characterized by extreme elevation of the serum IgE level (usually in the range 2000–40 000 U/L), chronic dermatitis and repeated lung and skin infections [1]. The initial description was of severe recurrent staphylococcal skin abscesses in fair-skinned red-headed girls with eczema [2]. Both sexes and all races are affected equally.

In the literature, these patients are frequently described as having eczema, although authorities on the condition point out that this is different from typical atopic eczema [3]. Affected children develop a rather non-specific, excoriated, papular and pustular eruption in the first year of life, often within the first month, which favours the scalp, the scalp margins, the buttocks and the proximal flexures, such as the axillae, groins and neck [4,5]. The rash may appear as early as the first few days of life, at which stage it may be vesicular [6], but crusting becomes a prominent feature. Features of lichenification or scales are absent or mild in hyper-IgE.

There is almost invariably a long history of furunculosis and staphylococcal lung infections, abscesses and empyema. Many patients develop staphylococcal pneumatocoeles, which strongly suggest the diagnosis [7,8]. Although skin and lung infections predominate, infections of the ears, sinuses, joints and viscera are not uncommon. Skin abscesses tend to favour the scalp, face and neck and are sometimes cold (i.e. with little surrounding inflammation), but this is not always the case. Ulceration is frequently present. Lymphadenopathy may be complicated by the development of lymph node abscesses. *Staphylococcus aureus* is the predominant pathogen, but infection is also seen with *H. influenzae*, pneumococci, group A streptococci and *Candida*. Oral candidiasis and *Candida* nail infections are common [8]. Pneumatocoeles may provide the focus for the development of aspergillomas.

Non-immunological features of the condition which are variably present include abnormal, coarse facies with a wide nasal bridge and large head (Fig. 14.17); fragile bones leading to frequent fractures; joint laxity, a high incidence of scoliosis, and delayed resorption of primary dentition with consequent delayed eruption of secondary teeth [8]. While the immunological features can be explained as the consequence of a T-cell regulatory defect, the other features are not easily explained. Abnormal bone and connective tissue turnover as a consequence of abnormal cytokine profiles or a mesenchymal cell defect have been postulated to explain these disparate features

Fig. 14.17 A patient with hyper-IgE syndrome who presented with staphylococcal pneumatocoeles. Coarse facial features and an infected eczematous-like rash are demonstrated. (Reproduced with permission from the Audiovisual Centre, University of Newcastle, Newcastle, UK.)

[9]. The mode of inheritance is thought to be autosomal dominant with incomplete penetrance. The gene for the disorder has not been identified, but studies on familial cases have found linkage to the proximal part of chromosome 4q [10].

Peripheral blood eosinophilia may be marked, up to 50–60%. Serum IgE levels are consistently very high (more than 10 times the upper limit of normal), even in infancy, and most patients also have elevated IgD levels. Total IgE levels may fall in adults; however, IgG, IgA and IgM levels are usually unremarkable. In a significant proportion of patients, there is a failure of antibody response to polysaccharide antigens, which contributes to the susceptibility to infection [1,8]. In keeping with the great increase in circulating total IgE, patients show strongly positive immediate weal-and-flare responses on skin-prick testing with foods and commonly inhaled allergens, as well as bacterial and fungal antigens [11]. Circulating levels of IgG anti-IgE are also high, as they are in atopic eczema [12]. It is rather characteristic for patients to have excessive production of IgG specific for *S. aureus* [13].

Peripheral blood lymphocyte subsets are generally normal, and no consistent abnormality of T cells has yet been identified. Patients are not neutropenic and their neutrophils ingest and kill bacteria normally [14]. However, neutrophil chemotaxis is reduced but in rather an

inconsistent way, and it has been suggested that mononuclear cells from hyper-IgE patients produce a factor that is inhibitory to neutrophil chemotaxis [14,15]. There appears to be a defect in mononuclear cell response to IL-12, and a specific impairment of IFN-γ release following stimulation of lymphocytes with *S. aureus* in patients with hyper-IgE syndrome [16].

Hyper-IgE syndrome is not merely atopic eczema with predisposition to cutaneous staphylococcal infections but a very characteristic immunodeficiency disorder with specific diagnostic criteria, which include staphylococcal lung infections with an onset in infancy. However, individuals have been reported who appear to have a milder variant of the hyper-IgE syndrome, with a later onset, with typical cutaneous and immunological abnormalities but without lung involvement [3]. Nevertheless, it must be borne in mind when considering this diagnosis that the disorder does not feature atopic eczema but a recurrent pyodermatous eruption often associated with ulceration and/or lymph node abscesses. The serum IgE level alone does not allow clear differentiation between atopic eczema and the hyper-IgE syndrome, because it can be equally high in both disorders. A similar clinical picture has been described in older patients with partial ADA deficiency [17].

The mainstay of treatment is long-term anti-staphylococcal antibiotic prophylaxis, usually with flucloxacillin. Attention to skin hygiene is important, with judicial use of topical antimicrobials. *Candida* infections should be treated topically, or when refractory, with oral ketoconazole or fluconazole [18].

Histamine-2 receptor blockers such as cimetidine have been used, though their value is disputed. Interferon-γ treatment has been tried in a few patients, but although there was some lowering of the IgE levels, there was no clinical benefit [19]. Intravenous immunoglobulin therapy may be useful in those with a demonstrable antibody production deficit. Persistent pneumatocoeles should be excised. BMT failed to correct the disorder in the one patient in whom it has been reported as being attempted, despite successful engraftment of donor myeloid and lymphoid cells, an observation that suggests this disorder is not due to a haemopoietic stem cell defect [20].

Leukocyte adhesion disorders

To counter infection in tissues, leukocytes egress from the circulation toward sites of inflammation. To do this, cells roll along the capillary endothelium, then adhere to endothelial cells, and finally pass between endothelial cells into tissues. A range of cell surface adhesion molecules are responsible for different stages of this process, as well as binding of different leukocytes to each other whilst immune responses occur. It is therefore not surprising that defects in the cell surface molecules responsible for the process result in life-threatening infection and dramatic cutaneous manifestations. In LAD type I, deficiency of the 95 kDa β chain (CD18), common to the β2 integrin family of cell surface adhesive molecules, leads to a profound immunodeficiency affecting the function of neutrophils, monocytes, T lymphocytes and NK cytotoxic cells [1,2]. Inheritance is autosomal recessive. Chemotaxis, adherence and phagocytosis are markedly depressed. Different mutations result in phenotypes of variable severity, and occasional patients express normal levels of CD18 but have a mutation affecting the function of the molecule. The β2 integrin family is also involved in the platelet function molecule Gp2b3a, and patients with a

combined leukocyte and platelet defect have been found [3]. The clinical picture is almost entirely explained by the way in which leukocytes are attracted to areas of infection and attach to the vessel walls at sites of inflammation in the usual way, but cannot pass out into the tissues. This leads to blockage of small vessels and rapidly expanding necrotic lesions without pus. Individuals with the most severe phenotype (less than 1% expression) present in the first weeks of life with delayed umbilical cord separation (the cord fails to shrink down and may not separate until 3–4 weeks of age), and omphalitis together with rapidly progressive erosive perianal ulcers. Delayed umbilical cord separation does not seem to occur in patients with some expression of the molecule (usually in the range 2–10% of normal expression). In all forms, there is excessive susceptibility to bacterial and fungal infections, with recurrent cellulitis and abscesses in the skin and other soft tissues. Deep-seated infections of bone, respiratory and gastrointestinal tracts are also seen. Gingivitis, ulcerative stomatitis and periodontitis are common and severe, leading to loss of teeth. Inflammatory lesions, particularly affecting the skin and resembling pyoderma gangrenosum, can occur in the partial forms of the deficiency, and may respond to steroids. Investigations almost invariably show a circulating neutrophilia (because of failure of the cells to migrate out of the circulation) and a profound neutrophil chemotactic defect. Diagnosis is confirmed by demonstrating the absence of the cell surface markers recognized by the anti-CD11/CD18 monoclonal antibodies. Treatment is with antibiotics in the first instance. Surgery should be avoided because of the poor healing. Neutrophil infusions appear helpful in the control of severe infections, but their use is limited by the production of alloantibodies to the transfused cells.

In the severe form, early death from infection is the rule unless a successful BMT can be performed. In the partial forms, supportive and expectant management is pursued in the first instance, but BMT may become necessary.

LAD type II is extremely rare and results from a defective fucose metabolism, whereby a failure to generate sialyl lewis X (CD15s) and other ligand molecules prevent the binding of selectin molecules. This results in a failure of the 'rolling' type weak adhesion of leukocytes to endothelium, which normally slows down the circulating leukocytes before β2 integrin binding can occur. There is a neutrophilia, and neutrophil chemotaxis and migration from the circulation is severely impaired. There is no deficiency in specific immune responses. As in LAD type I deficiency, patients have a neutrophilia and suffer repeated bacterial infections and periodontal disease. Delayed umbilical cord separation is however not seen; other features peculiar to LAD type II include mental retardation, short stature and the Bombay (hh) blood phenotype [4].

Haemophagocytic lymphohistiocytosis (familial)

HLH is universally fatal without treatment. Patients present with high swinging fevers, hepatosplenomegaly, jaundice and erythematous rash, respiratory distress and pancytopenia; they appear septic, but blood cultures are usually sterile. Laboratory findings include an acute phase response, elevated ferritin and elevated fasting triglycerides with prolonged prothrombin time and reduced fibrinogen levels. Examination of bone marrow, cerebrospinal fluid, pleural effusions or ascitic fluid may demonstrate haemophagocytosis. This may be very difficult to find, and repeated sampling may be required. Haemophagocytosis may occur secondary to a number of infections, in particular viral infections, and careful exclusion of infections by serology/PCR methodology should be undertaken. Haemophagocytosis is also seen in a number of immunodeficient states, including Griscelli's syndrome, CHS and XLP. Diagnosis of familial HLH should be suspected in an infant with an appropriate clinical picture. Older children are more likely to have secondary HLH.

Twenty to thirty per cent of patients with familial HLH will have a mutation in the gene coding for perforin, which is normally found in the granules of NK and cytotoxic T lymphocytes. Perforin is important for cell lysis and apoptosis and so may be important for all cells that regulate immune responses with absence allowing dysregulated immune activation [1].

Treatment with a combination of chemotherapeutic agents, steroids and monoclonal antibodies that deplete lymphocytes may induce remission, but only BMT is curative.

Chediak–Higashi syndrome

CHS is a rare autosomal recessive disease with partial

oculocutaneous albinism, recurrent bacterial infections with organisms such as *S. aureus*, streptococci and pneumococci, and approximately 85% of patients develop an accelerated lymphocyte and macrophage activation syndrome (similar to that seen in HLH and XLP), which untreated is usually fatal. Skin, hair and eyes are affected in most cases [1]. Recurrent skin infections are common, generally starting in early childhood [2]. Deficient cutaneous pigmentation may be obvious, but in some cases it is more subtle and only apparent if nipples and genitalia are carefully examined. The hair generally has a silver sheen and shows clumped pigment on microscopy. Photophobia and nystagmus are regular features due to ocular pigment dilution. Severe gingivitis and oral mucosal ulceration are well described [3].

Patients usually, but not invariably, enter an accelerated phase of the disease, with widespread infiltration with activated lymphocytes and macrophages resulting in rapid enlargement of liver, spleen and lymph nodes, together with jaundice, hepatic failure, respiratory distress, pancytopenia and bleeding, and so death usually occurs in the first decade; survival into the second and third decades has been recorded. Progressive neurological deterioration is common in patients who survive early childhood [4].

Characteristic giant lysosomal granules are seen in the cytoplasm of all cells containing these organelles, and are easily detected on a peripheral blood film. The gene for this disease codes for a regulator of lysosomal transport [5]; proteins normally transported through lysosomes enter these organelles but cannot exit, with subsequent lysosomal hypertrophy. In melanocytes this results in abnormal melanin transport and consequent albinism. Neutrophil lysosomes cannot degenerate and release bactericidal proteins into the phagosome, and so intracellular killing is defective. NK cell function is also defective as is monocyte function, probably because giant lysosomes interfere with the processing of MHC class II in endosomes, and thus antigen presentation is defective. The activation syndrome may result from failure to transport inhibitory molecules such as CTLA4 to the surface of leukocytes, with consequent failure of negative feedback mechanisms after T-lymphocyte and macrophage activation.

Prophylactic co-trimoxazole should be given to prevent bacterial infection. The accelerated phase cannot be predicted, and patients should be closely monitored, particularly if febrile. Symptoms, signs, laboratory and clinical findings, and diagnosis and treatment of the accelerated phase are as for HLH. The only definitive treatment is BMT. This should be considered early if there is a matched sibling donor. Although BMT prevents further episodes of macrophage activation it may not prevent later neurological deterioration.

Griscelli's syndrome

This rare autosomal recessive disorder results in a partial albinism and a combined immunodeficiency [1]. Individuals with Griscelli's syndrome resemble those with CHS in that they have variable hypopigmentation of the skin and hair and recurrent pyogenic infections.

Skin colour seems to have been more or less unremarkable, without photosensitivity, in the few patients so far reported, but affected individuals are paler than their siblings [2] and the hair, including eyebrows and eyelashes, is silvery grey from early childhood.

Delayed type cutaneous hypersensitivity is absent, T-cell numbers may be reduced and NK cell function is impaired. Hypogammaglobulinaemia is often seen as a secondary phenomenon, although B-cell numbers are usually normal. In contrast to CHS, large lysozomal granules are not seen, and examination of hair by electron microscopy shows large clumps of pigment, with the accumulation of normal mature melanosomes in basal layer melanocytes in the epidermis. The liver, spleen and lymph nodes are infiltrated with histiocytic cells. Neurological abnormalities do not occur, but patients do develop an accelerated phase, which is fatal unless treated by BMT [3]. Two male siblings have been reported in whom immunodeficiency was combined with partial albinism, as in Griscelli's syndrome, but in which agenesis of the corpus callosum, cleft lip and palate and bilateral congenital cataracts were also features [4].

Two gene defects have been described in *MYO5A*, which codes for myosin 5a [5] and RAB27A [6].

Defects in the IL-12-dependent IFN-γ pathway

Defects in the IL-12 dependent IFN-γ pathway have recently been described in patients affected by persistent, severe bone and soft tissue abscesses with discharging sinuses due to BCG or weakly pathogenic environmental non-tuberculous mycobacteria, which can be fatal [1]. There is also susceptibility to invasive non-typhi salmonella infections and severe viral infection, particularly due to herpesvirus. Oral ulceration and cutaneous vesicular eruptions have been described in those with viral infection [2]. Two patients with lesions mimicking those seen in Langerhans' cell histiocytosis, who were subsequently shown to have IFN-γ receptor deficiency, have been described. Osteolytic lesions were present in the skull and humerus, with granulomatous inflammation and central necrosis on biopsy [3], from which BCG was cultured. Infections result from a failure of upregulation of macrophage killing. The clinical picture depends on the precise molecular defect that is present. Defects have been described in a number of constituents of the IL-12/IFN-γ pathway, including complete or partial IFN-γ-R1 deficiency, IL-12p40 subunit deficiency and complete IL-12b1 deficiency. The outcome of patients with complete IFN-γ-R1 deficiency is poor, but BMT has been successfully attempted.

Complement disorders

Complement deficiencies

Deficiencies of isolated complement components are rare, deficiency of C2 being the most frequent, and, with the exception of properdin and C1 esterase inhibitor deficiency, are generally transmitted in an autosomal recessive manner, severe disease occurring when both alleles are defective. However, heterozygosity results in approximately half the normal levels of the protein, which can sometimes be clinically important. A number of clinical patterns can occur depending upon which factor is deficient.

Deficiency of the early components of the classical complement activation pathway, i.e. C1, 4 and 2, tend to predispose to autoimmune disease, particularly SLE [1]. Photosensitivity and cutaneous manifestations of LE occur in association with mild non-cutaneous disease and absent or unimpressive plasma levels of antinuclear antibody.

Evidence, based on the finding that null alleles for a number of complement components (notably C2 and C4) occur with greater frequency in patients with autoimmune diseases such as SLE, suggests that heterozygosity for deficiency is also a risk factor. In general, the course of these diseases is similar to that in patients without complement deficiency. Partial deficiencies of certain complement components, particularly C2 and C4, is associated with an increased risk of certain diseases, notably SLE, discoid LE, juvenile rheumatoid arthritis, membranous glomerulonephritis and angio-oedema [2–4].

Recurrent pyogenic infections are a feature of complement deficiencies. Organisms such as streptococci and *H. influenzae* are the main problem, as opsonization/binding of antibody and complement to bacteria is critical for their elimination. C3 deficiency is the most severe. Deficiency of the classical pathway components C1q and C2 and of factor D in the alternative pathway also predisposes to infection; the first two also carry a predisposition to autoimmune phenomena. Deficiencies of the alternative pathway control proteins, factors H or I, lead to uncontrolled consumption of C3, resulting in increased susceptibility to pyogenic infections including meningococcal disease [5].

Deficiency of one of the later complement components, C5–C9 (leading to failure of membrane lysis), or of the control factor properdin (the only deficiency inherited in an X-linked manner) leads to a specific deficiency in handling *Neisseria* spp. (*N. meningitidis* and *N. gonorrhoeae*), but not to a generalized increase in susceptibility to pyogenic infections. There is a predominance of disease caused by rare serogroups of meningococci (W135, X, Y and Z) in these patients. In a Dutch study [6], complement deficiency (most commonly late components or properdin) was found in 33% of survivors of meningococcal disease due to rare serogroups compared to 2%, 0% and 7% in patients who suffered group A, B and C disease respectively. Recurrent attacks of meningococcal septicaemia/meningitis and severe invasive gonococcal disease are also associated with late complement deficiencies. C9 deficiency in Japan affects up to 0.1% of the population [5] but is less common in white people. Screening for deficiencies should be undertaken in patients and their immediate families where there has been recurrent meningococcal disease due to common serogroups or single episodes caused by a rare serogroup. In the UK, screening children with single episodes of meningococcal disease due to common serotypes is unlikely to reveal a

complement defect [7]. Where infections occur in children with deficiencies of the early complement components, these are predominantly caused by encapsulated bacteria, such as *Pneumococcus*.

Several proteins have been identified that have regulatory effects on the complement system. The existence of these activities has generally come to light through the profound clinical effects that may result from their deficiency. The best known of these deficiencies is that of C1 esterase inhibitor, which results in hereditary angio-oedema (see Chapter 47). Deficiency of factor 1, previously termed C3b inactivator, leads to unchecked cleavage of C3, and therefore to clinical manifestations closely resembling those seen in C3-deficient individuals [8,9]. In this condition, plasma infusions may provoke anaphylaxis, because the contained C3 is so rapidly cleaved to form the anaphylotoxin, C3a [10].

C1q deficiency

A variety of clinical manifestations have been described in patients with C1q deficiency, including cutaneous vasculitis, SLE, membranous glomerulonephritis and problems with infections, particularly meningitis and septicaemia but also including stomatitis, pyoderma and persistent candidiasis of mouth and nails [1–5].

C1r and C1s deficiencies

SLE, or a disorder clinically suggestive of SLE but lacking confirmatory serological findings, and/or membranous glomerulonephritis have similarly been reported in patients with deficiencies either of C1r [1] or C1s [2]. Infections have not been prominent, except in the case of an infant with C1r deficiency who had lung infections and hepatic abscesses [3].

C4 deficiency

The majority of patients reported with C4 deficiency have been children or adolescents [1]. Their principal clinical abnormalities have comprised SLE, or a SLE-like syndrome, Henoch–Schönlein purpura or Sjögren's syndrome. Infections have only occasionally been a problem [2,3].

C2 deficiency

This is the commonest complement deficiency. It has now been shown to be associated with a variety of diseases, but deficient individuals are often entirely healthy. Disorders occurring in C2-deficient patients have included SLE, discoid LE, membranous glomerulonephritis, Henoch–Schönlein purpura, rheumatoid arthritis, dermatomyositis, Crohn's disease and idiopathic thrombocytopenic purpura [1–5]. Serious bacterial infections may also occur, particularly pneumococcal, *H. influenzae* and meningococcal infections, in that order, although it is unclear why some patients are prone to such infections and others are not.

C3 deficiency

C3 deficiency is the most serious of all the isolated complement deficiency states. Infections are the main hazard, particularly infections with organisms that require opsonization. Thus, meningococcal meningitis and pneumococcal pneumonia have been major problems [1]. The clinical picture is in many ways similar to that of hypogammaglobulinaemia. Transient maculopapular rashes have been reported to occur in association with infections; histologically these have shown the features of leukocytoclastic vasculitis [2]. Other manifestations such as SLE and membranous glomerulonephritis have also been reported [1].

C5, C6, C7, C8 and C9 deficiency

Recurrent meningococcal meningitis and disseminated gonococcal infections have been the principal clinical consequence of deficiencies of all these complement components [1–3]. One patient has been reported in whom frequent cutaneous infections and subcutaneous abscesses were the presenting problem, as one would expect from the defective generation of C5a chemoattractant [4], but it is now clear that cutaneous infections are generally not a problem in these patients [5].

SLE, discoid LE, Sjögren's syndrome, rheumatoid arthritis and ankylosing spondylitis have also been associated with these deficiencies [1,4]. An affected 43-year-old woman has been reported in whom Raynaud's phenomenon, sclerodactyly and telangiectasia were associated with hereditary deficiency of C7 [6].

Interaction of antibody and complement deficiencies

Deficiency of the early classical pathway complement components has been shown to be associated with poor antibody responses, presumably because the resulting poor opsonization leads to impaired antigen penetration. Later components are not implicated.

Alternative pathway opsonization is less efficient in the absence of specific antibody to bacterial surfaces. There is evidence that antibody may 'neutralize' surface molecules, such as sialic acid, which otherwise inhibit alternative pathway activation.

Deficiencies of C3 receptors

The distribution and function of cell surface receptors for C3b and its derivatives have been described above. Specific clinical syndromes have been attributed to deficiencies of some of these receptors. A dominantly inherited CR1 deficiency is associated with SLE and other immune complex disorders, presumably related to failure of the immune complex clearing function of this molecule.

Deficient expression of the CR3 receptor occurs as part of the LAD type I syndrome since it is a member of the β integrin family affected in this disorder, though what contribution this makes to the overall clinical picture in that condition is unclear.

Management of complement deficiencies

Apart from C1 esterase inhibitor, there are no specific replacement factor preparations. Fresh plasma infusions have been used prophylactically or can be reserved for the treatment of serious episodes of infection. Lifelong prophylactic penicillin and meningococcal vaccination are advised in those complement deficiencies resulting in susceptibility to neisserial infections. A polyvalent vaccine (A, C, W135 and Y) should be given. Prophylactic cotrimoxazole can be used in deficiencies which result in an increased susceptibility to a wider range of organisms. Clinical monitoring may allow earlier diagnosis and treatment of autoimmune disorders, should they emerge.

Chapter 15

Naevi and other Developmental Defects

D.J. Atherton & C. Moss

Definitions

Developmental defects are errors in morphogenesis arising during intrauterine life. Most are *congenital*, i.e. present at birth, and some are inherited. The term embraces *malformations*, *deformations* and *disruptions* [1,2]. There is clearly considerable overlap between these three categories.

A *malformation* is a primary anatomical defect resulting from abnormal development of an organ or tissue. It may be *isolated*, occurring in an otherwise normal child, or multiple, affecting several body systems. A *malformation syndrome* is the occurrence of multiple malformations in a recognizable pattern, frequently accompanied by mental retardation, e.g. Down's syndrome. A *malformation sequence* occurs when a primary malformation produces secondary defects, e.g. hydrocephalus secondary to spina bifida.

Deformation reflects abnormal intrauterine moulding by mechanical forces, e.g. positional deformation of the legs and feet in spina bifida. Severe oligohydramnios may result in a characteristic combination of congenital deformations referred to as Potter's syndrome, one cause of which is renal agenesis [3].

Disruption indicates intrauterine damage or destruction to a developed organ by agents such as infection, circulatory compromise or amniotic bands.

A *teratogen* (from the Greek, *teres*, a monster) is any extrinsic factor operative during fetal life that is capable of inducing developmental abnormalities.

Naevus is the Latin word for 'maternal impression' or 'birthmark' and indicates a circumscribed, non-neoplastic skin or mucosal lesion, usually present at or soon after birth, and fixed. The term should always be qualified according to the cell or tissue of origin, e.g. 'connective tissue naevus' and 'vascular naevus'. Confusingly, 'naevus', 'naevo-' and 'naevoid' are often used without qualification to imply melanocytic naevus. Thus 'naevus cell' means the cell type found in a melanocytic naevus, 'naevocytic naevus' means a melanocytic naevus, and 'naevoid basal cell carcinomas' look like melanocytic naevi.

The term 'naevus' is synonymous with *cutaneous hamartoma* (e.g. smooth muscle naevus/hamartoma), both comprising an abnormal mixture of a tissue's usual components (the word 'hamartoma' was coined by Albrecht from the Greek word *hamartia*, meaning 'to err' [4]).

Many, possibly all, naevi represent clones of genetically altered cells arising from mosaicism [5–9]. *Genetic mosaicism* (see also Chapter 12) denotes the presence of two or more genetically different cell populations in an individual derived from a single zygote. The differences can be between single genes, groups of genes or entire chromosomes. *Chimerism* denotes the presence of two or more genetically distinct cell populations in an individual derived from two different zygotes. Chimeras can result from the fusion of dizygotic twin embryos, or from the fertilization by two spermatozoa, and subsequent splitting, of an ovum containing a polar body. While mosaicism

generally involves an abnormal clone within a normal individual, chimaerism involves two different normal clones. Cutaneous anomalies due to mosaicism affect any skin cell type, but the cutaneous abnormalities observed in human chimeras are always pigmentary [10–12].

The word 'naevoid' is sometimes applied to mosaic forms of inherited skin conditions following Blaschko's lines, e.g. naevoid psoriasis.

The imprecise term *systematized*, applied to an extensive naevus, implies a linear, segmental or dermatomal distribution. The terms *segmental* and *zosteriform* should be confined to naevi following body segments and dermatomes respectively. In practice 'segmental' usually conceals ignorance about whether the pattern follows dermatomes or Blaschko's lines.

Aetiology

Congenital malformations may be caused by environmental or genetic factors, or combinations of the two independently or interacting. Some abnormalities have different causes in different patients, e.g. aplasia cutis. It is important to recognize parents' tendencies to attribute neonatal defects to antenatal and perinatal events: the question 'What did you think might have caused this?' may reveal surprising and irrational concerns.

Environmental factors. Those provoking congenital malformations (teratogens) are listed below. In fact remarkably few cutaneous developmental defects have been attributed to teratogens: they include aplasia cutis congenita of the scalp due to methimazole and segmental aplasia cutis following first-trimester varicella.

1 *Intrauterine infections*: rubella [1–5], cytomegalovirus [6], toxoplasmosis [6] and herpes simplex virus [7], are well-known causes of non-cutaneous defects. First-trimester varicella can cause segmental aplasia cutis [7–9].

2 *Ionizing radiation* from X-rays, radiotherapy or accidental contamination [10,11].

3 *Drugs taken during pregnancy* [12–15], particularly cytotoxic and immunosuppressive agents, anticonvulsants, anticoagulants, androgens, lithium carbonate, thalidomide, vitamin A derivatives and methimazole [16] which can cause aplasia cutis congenita of the scalp.

4 *Alcohol* [17,18] *use during pregnancy* may result in a characteristic dysmorphic appearance (fetal alcohol syndrome) an occasional feature of which is neonatal hypertrichosis. Haemangiomas (mostly small, raised strawberry angiomas) were found in 12/41 (29%) infants with fetal alcohol syndrome [17].

5 *Trace metal excesses or deficiency during pregnancy*, particularly mercury exposure [19] and zinc deficiency [20].

6 *Exposure to other toxins during pregnancy*. Congenital polychlorinated biphenyl (PCB) poisoning occurred following exposure of mothers in two industrial accidents, in Japan and Taiwan, in which cooking oil was contaminated during its manufacture [21]. Affected babies had 'cola-coloured skin', with dark brown pigmentation of flexures, nails, mouth and sclerae that cleared in 2–5 months.

7 *Maternal diseases*, such as diabetes mellitus [22] and phenylketonuria [23].

8 *Paternal occupational exposure to toxins* can adversely affect the fetus either by direct effects on spermatozoa, or indirectly by maternal contamination. Paternal occupations that have been linked with birth defects include janitors, painters, printers, and occupations related to solvents or agriculture [24].

Genetic factors. Most developmental defects involving the skin probably have a genetic basis. The types of genetic abnormality, in descending order of size of the mutation, are summarized below:

1 *Chromosomal syndromes*: major abnormalities of chromosome number include trisomy 21 (Down's syndrome), and sex chromosome defects. Syndromes due to structural anomalies of chromosomes include Wolf–Hirschhorn syndrome, in which there is loss of the short arm of chromosome 4. Chromosomal syndromes involving an autosome are usually accompanied by mental retardation. Skin anomalies are unusual in this group, but include keratosis pilaris in Down's syndrome. Localized skin anomalies are even more unusual: an example is aplasia cutis in Wolf–Hirschhorn syndrome. Chromosomal anomalies may be inherited, or may arise after conception from chromosomal non-disjunction during mitosis, in which case they will be mosaic.

2 *Microdeletion syndromes*: submicroscopic deletion of contiguous genes can produce syndromes combining features caused by the individual genes. A dermatological example is X-linked ichthyosis with hypogonadotrophic hypogonadism, due to a microdeletion at Xp22 affecting both the steroid sulphatase and Kallmann's syndrome loci. Microdeletions are detected by fluorescence *in situ* hybridization (FISH).
3 *Mutations in specific genes*: this is the major cause of both inherited and mosaic syndromes and anomalies.

Genetic mechanisms in localized and isolated defects

Genetic skin disorders are usually generalized. The patchy and localized conditions that are the subject of this chapter can be produced and transmitted by the following genetic mechanisms:
1 Mutations in genes acting on morphogenesis may cause abnormal cell migration resulting in patchy defects. Examples include dominantly inherited scalp aplasia cutis, and white patches in autosomal dominant piebaldism.
2 Patchy skin manifestations in some generalized autosomal dominant and recessive disorders can be attributed to a genetic 'second hit' [25] (loss of heterozygosity), e.g. hamartomas in tuberous sclerosis, and the tumours of xeroderma pigmentosum.
3 Some localized anomalies represent a 'forme fruste' or minimal expression of a generalized disorder. For example, lower-lip sinuses, which most often occur alone, represent the minimal manifestation of an autosomal dominant gene, whose full expression results in Van der Woude's syndrome, with associated cleft lip and palate [26]. It is possible that isolated ash-leaf macules and café-au-lait macules have a similar significance.
4 Genetic mosaicism resulting from somatic mutation is probably the major cause of naevi and other localized skin defects [27–31]. The embryo is normal at conception, but at some point during early embryogenesis a mutation gives rise to a clone of cells in which the genetic change manifests as a localized cutaneous abnormality. Naevi caused by genetic mosaicism arising after conception are by definition not inherited from the parents. Occasional reports of familial clustering of mosaic conditions (such as epidermal naevus and segmental neurofibromatosis) may be attributable to inheritance of an unstable premutation. Happle has suggested two other mechanisms to explain familial clustering of mosaic conditions: 'paradominant inheritance' [32] in which a recessive gene is unmasked by loss of heterozygosity, and the silencing and activation of different genes by 'transposable elements' [33]. A particular risk of mosaic disorders is transmission of the generalized condition to the patient's offspring (e.g. generalized neurofibromatosis type 1 in offspring of patients with segmental neurofibromatosis). Some localized defects (e.g. Sturge–Weber syndrome) have been attributed to serious mutations compatible with survival only in the mosaic state, so that if the mutation were passed on it would cause miscarriage [34]: this has never been documented. Epidermal mosaicism is manifest as Blaschko's lines (see below).

Classification of naevi

The classification of naevi is historical and not entirely logical. In general, naevi are classified according to the component cell, tissue or organ, and subdivided according to the macroscopic or histological nature of the abnormality (Table 15.1). The existing categories have stood the test of time, enabling dermatologists to distinguish naevi with different biological behaviour, and to advise patients

Table 15.1 Classification of naevi.

Epidermal naevi	Dermal and subcutaneous naevi
Keratinocyte naevi	*Connective tissue naevi*
Verrucous epidermal naevus	Collagen naevi
Epidermolytic verrucous epidermal naevus	Familial cutaneous collagenoma
Non-epidermolytic verrucous epidermal naevus	Eruptive collagenoma
Sebaceous naevi	Tuberous sclerosis
Naevus sebaceus	Other collagenomas
Follicular naevi	Elastic naevi
True hair-follicle naevus	Pseudoxanthoma elasticum
Comedo naevus	Perforating elastoma
'Acne-free' naevus	Juvenile elastoma and the Buschke–Ollendorff syndrome
Basaloid follicular hamartoma	Naevus anelasticans
Dilated pore naevus	Other elastomas
Hairy malformation of the palms and soles	Proteoglycan naevi
Apocrine naevi	Mucinous naevus
True apocrine naevus	*Smooth muscle naevi*
Naevus syringocystadenomatosus papilliferus	Congenital smooth muscle hamartoma
Eccrine naevi	Diffuse smooth muscle hamartoma
True eccrine naevus	Congenital leiomyoma
Eccrine angiomatous hamartoma	*Fat naevi*
Porokeratotic eccrine ostial and dermal duct naevus	Naevi lipomatodes cutaneous superficialis
Becker's naevus	Encephalocraniocutaneous lipomatosis
Inflammatory epidermal naevi	Congenital lipoma
ILVEN	Congenital lipomatosis
CHILD naevus	Neurolipomatosis
Other naevoid epidermal disorders	Congenital lipoma
Linear lichen planus	'Michelin tyre' baby
Naevoid psoriasis	*Vascular naevi*
Darier-like epidermal naevus	Haemangiomas
Hailey–Hailey-like epidermal naevus	Infantile haemangioma
Linear porokeratosis	Verrucous haemangioma
Atrophoderma of Moulin	Angioblastoma
'Blaschkitis'	Vascular malformations
Epidermal naevus syndrome	Capillary vascular malformations
	'Salmon' patch
	'Port-wine' stain
	Naevus anaemicus
	Naevus oligaemicus
	Mixed vascular malformations
	Cutis marmorata telangiectatica congenita
	Klippel–Trenaunay syndrome
	Venous malformations
	'Blue rubber bleb' naevus syndrome
	Maffucci's syndrome
	Zosteriform venous malformations
	Gorham's disease
	Other multiple vascular malformation syndromes
	Angiokeratoma

Fig. 15.1 Multiple verrucous epidermal naevi with the histological changes of epidermolytic hyperkeratosis.

accordingly. However, there are many areas of uncertainty, reflecting variability within and between lesions and patients. As we learn more about the molecular basis of naevi some of these uncertainties resolve. For example, we now know that epidermolytic and non-epidermolytic verrucous epidermal naevi are different entities, while Darier-like and acantholytic epidermal naevi are the same. The classification used here combines established clinical divisions with newer molecular definitions.

Blaschko's lines

Almost all epidermal naevi follow the pattern of lines painstakingly documented by Blaschko from drawings of epidermal naevi [1]. Blaschko's lines are characteristic of mosaic conditions of the epidermis and probably represent the routes of ectodermal cell migration from the neural crest [2,3]. On the trunk, these lines tend to take the form of transverse bands, differing from dermatomes in being more numerous, and in their S-shaped wave form on the lateral trunk (Fig. 15.1) and V-shape in the middle of the back. On the arms and legs, lesions follow lines roughly parallel with the axis of the limb. The lines spiral on the scalp, are vertical in the mid-face, and extend laterally from the angles of the mouth [4–6]. They never cross the anterior truncal midline, but run along it. Posteriorly, the 'Blaschko' midline is often shifted from the anatomical midline.

The shape and distribution of epidermal naevi probably reflect not only paths of cell migration but also the timing of mosaicism and cell type. Abnormal clones arising at the very early blastocyst stage will be widely distributed along the paths of migrating cells and appear linear, while those arising in the fully formed fetus are more likely to be single, small, round or oval lesions. Keratinocytes which migrate by directional proliferation produce linear lesions, whereas melanocytes which migrate singly more often form leaf-shaped (phylloid) or block-like lesions.

Epidermal naevi

The term epidermal naevus is used for naevi composed of keratinocytes. Recently, the molecular causes of certain epidermal naevi have been elucidated, enabling us to differentiate between them. However, the older literature does not differentiate between, for example, epidermolytic and non-epidermolytic naevi, and therefore clinical descriptions must be read in this light.

Probably all epidermal naevi comprise an abnormal clone of cells, reflecting genetic mosaicism arising from somatic mutation (see above). The clinical implications of mosaicism are firstly that it is unlikely to recur in the same family, and secondly that there is a theoretical risk of the condition being passed on to the patient's offspring in a severe or even lethal generalized form. Curiously these predictions are not always borne out, as is discussed under the individual headings.

Verrucous epidermal naevus

SYN. NAEVUS VERRUCOSUS; NAEVUS UNIUS LATERIS

Definition. Verrucous epidermal naevi are congenital, non-inflammatory cutaneous hamartomas composed of keratinocytes. They are distinct from inflammatory, acantholytic and porokeratotic epidermal naevi, from sebaceous naevi, and from epidermal naevi derived from skin appendages. Their prevalence in adults is probably 0.1–0.5%, and they occur equally in males and females. They are divided into epidermolytic and non-epidermolytic types.

Fig. 15.2 Linear verrucous epidermal naevus on the neck.

Epidermolytic verrucous epidermal naevus

Aetiology. The histological similarity between epidermolytic verrucous epidermal naevi and autosomal dominant bullous ichthyosiform erythroderma (BIE) led to the idea that the former represents a clone of cells expressing a mutation in one of the BIE genes. This was confirmed by the finding of mutations in keratin 10 in such naevi but not in the adjacent normal skin [1,2] and more recently mosaicism for a keratin 1 mutation in a woman with verrucous epidermal naevi [3]. Such epidermal naevi are sporadic and cannot be passed on from parent to child. However a parent with an epidermolytic verrucous epidermal naevus is likely to have gonadal mosaicism as well as cutaneous mosaicism, and can therefore produce offspring with generalized BIE [2–4].

Pathology. Epidermolytic verrucous epidermal naevi show hyperkeratosis, acanthosis and papillomatosis with epidermolytic hyperkeratosis [1–5] identical to that seen in BIE. This comprises perinuclear vacuolization of the keratinocytes, associated with premature and excessive formation of irregular keratohyalin granules, indistinct cell borders and hyperkeratosis.

Clinical features [1–5]. By analogy with BIE, epidermolytic verrucous epidermal naevi at birth would be expected to be blistered, and only later to become verrucous. However there is no specific report of this. In young children they appear as slightly pigmented velvety or warty streaks or plaques. With age they darken and the surface becomes more warty (Fig. 15.2), sometimes with an erythematous base. They may be single or multiple, and size and site are variable. Flexural lesions may become macerated and foul smelling, which can cause the patient substantial social problems. Epidermolytic verrucous epidermal naevi are not associated with extracutaneous abnormalities (epidermal naevus syndrome: see below). This is because they are due to mutations in keratin genes which are expressed only in the skin. They probably do not have the malignant potential of sebaceous naevi [6].

Diagnosis. Epidermolytic and non-epidermolytic verrucous epidermal naevi are sometimes indistinguishable except on histology. Their lack of inflammation, presence at birth, warty, brown appearance and persistence distinguish them from most other types of epidermal naevus. They may be confused with linear viral warts, particularly filiform or digitate warts on the neck, scalp or body folds.

Non-epidermolytic verrucous epidermal naevus

Aetiology. Non-epidermolytic verrucous epidermal naevi are probably heterogeneous, representing mosaicism for different, and as yet unidentified, mutations. Stosiek *et al*. [1] reported chromosomal mosaicism in two otherwise normal men with non-epidermolytic verrucous epidermal naevi. Several chromosomal abnormalities were found in the abnormal skin, with a breakpoint common to both patients at 1q23. This lies intriguingly close to a locus known as the epidermal differentiation complex, which includes a cluster of over 25 genes encoding structural components of the cornified envelope [2]. Other candidates for acanthosis nigricans-like epidermal naevi [3] include the fibroblast growth factor receptor (FGFR) genes [4]. A palmoplantar verrucous naevus has been reported which was due to mosaicism for a mutation in keratin 16, the gene responsible for pachyonychia congenita [5], but since hyperkeratosis in pachyonychia congenita is confined to the palms and soles, it is unlikely that verrucous epidermal naevi at other sites are caused by pachyonychia congenita gene mutations.

Pathology [6,7]. The most common histological pattern is sharply demarcated hyperkeratosis and acanthosis, often associated with papillomatosis, and occasionally by focal hypergranulosis and/or columns of parakeratosis. About 10% of lesions show a distinctive 'church-spire' pattern of acanthosis and hyperkeratosis, resembling acrokeratosis

verruciformis, and about 5% show features resembling seborrhoeic keratoses, i.e. hyperkeratosis, papillomatosis, acanthosis and horn pseudocysts, with a flat lower base. Rarely, they may show histological features more characteristic of common viral warts, acanthosis nigricans [3], or of the verrucous phase of incontinentia pigmenti [8].

Several other changes have been reported in verrucous epidermal naevi. Appendageal anomalies seen in early childhood include immature hair follicles, sebaceous, eccrine or apocrine glands. In later childhood and adult life, comedo-like dilated follicles, and sebaceous, eccrine and apocrine hyperplasia occur [9]. It is not at all clear to what extent these represent age- and site-related differences in the same disorder [9,10] or different naevi. The same difficulty applies to occasional reports of basal cell [11–13], squamous [13–18], verrucous [19] and adnexal carcinomas [20], and Bowen's disease [18], within epidermal naevi: usually they are those showing sebaceous or apocrine differentiation.

Clinical features. Verrucous epidermal naevi are usually present at birth but may appear or extend during childhood. A verrucous epidermal naevus in a 60-year-old woman reported to have developed only 5 years previously was highly atypical, with bilateral crusted, hyperkeratotic plaques on the head and upper trunk and histological signs of inflammation [21]. At birth they have a white, macerated appearance, but within a few days take the form of pink or slightly pigmented velvety streaks or plaques. Later, they darken and the surface becomes more warty (see Fig. 15.2), sometimes with an erythematous base. Their extent and distribution are highly variable, but sebaceous naevi are especially common on the face and scalp. They may extend on to an adjacent mucosal surface [22]. Nail ridging, splitting, discoloration or dystrophy may occur where the nail fold is involved. The lesions are as a rule asymptomatic, except, for example, when they impinge upon the nail fold, where they may cause recurrent paronychia, and may split or distort the nail plate. Flexural lesions may become macerated and foul smelling. Verrucous epidermal naevi have been associated with scalp woolly hair naevi [23], and in some cases the woolly hair directly overlies a verrucous epidermal naevus [24,25]. Tumours may develop within the naevi (see above). While most of the patients in whom this has occurred have been over 40 years of age, malignant tumours have been reported in patients as young as 17 years of age [14].

A wide variety of developmental anomalies may occur in association with verrucous epidermal naevi and are discussed in more detail in the section on epidermal naevus syndrome. They include localized anomalies such as megalopinna [26] and aplasia cutis of the scalp [27], and syndromes such as epidermal naevus syndrome, Proteus syndrome, McCune–Albright syndrome [28,29], Klippel–Trenaunay syndrome [30], and phakomatosis pigmentokeratotica. Tumour-induced rickets and osteomalacia sometimes accompany verrucous epidermal naevi [31].

Diagnosis. Epidermolytic and non-epidermolytic verrucous epidermal naevi must be distinguished histologically. Non-epidermolytic verrucous epidermal naevi can be differentiated clinically from other types of epidermal naevus as they are usually present at birth, asymptomatic, non-inflammatory and persistent. If the age of onset is uncertain they can be confused with viral warts. Historically verrucous epidermal naevi have been confused with a variety of epidermal naevi whose true identity has been recognized more recently, for example CHILD (*c*ongenital *h*emidysplasia with *i*chthyosiform naevus and *l*imb *d*efects) naevus.

Management of epidermolytic and non-epidermolytic epidermal naevi

Reports of the responses of epidermal naevi to various therapies have rarely distinguished between the different histological types. Therefore both are considered together here.

Topical applications are rarely curative and therefore have a limited place in the treatment of verrucous epidermal naevi [1]. Preparations containing salicylic acid, lactic acid or retinoic acid [2] may decrease the keratotic element to some extent but require persistent application to maintain any improvement. Podophyllum may help [3] but its toxicity precludes its use in larger lesions [4]. Successful treatment with topical 5-fluorouracil and retinoic acid has been reported [5,6].

Cosmetically significant lesions may justify systemic retinoid therapy. Etretinate [7] and acitretin can produce worthwhile reduction of hyperkeratosis in epidermolytic lesions. Patients and carers must understand that retinoids are not curative and the condition will relapse if the treatment is stopped.

Even surgery is not curative unless underlying dermis is removed or destroyed at the same time as the epidermal component. Large lesions may require multistage, multimodality procedures, adapted according to anatomical site [8]. Skin-shaving procedures or dermabrasion thus tend to produce only temporary benefit. Cryotherapy is a simple alternative for smaller lesions. Problems with laser treatment include hypertrophic scarring, pigmentary changes and partial recurrence. However, improvments in laser technology are gradually overcoming these problems. The argon laser is helpful for softer, less hyperkeratotic lesions [9]. Continuous-wave carbon dioxide laser vaporization has been used successfully for extensive verrucous epidermal nevus [10], and pulsed carbon dioxide laser for thinner verrucous epidermal naevi [11]. Staged carbon dioxide laser treatment using different modalities for thick and thin lesions cleared an extensive verrucous epidermal naevus with no recurrence in 2 years of follow-up [10]. Newer erbium : yttrium aluminium garnet (Er : YAG) lasers with greater coagulative capacity can also be used with good effect [12]. The pulsed ruby laser may reduce and lighten dark-coloured epidermal naevi, but patients with a darker skin type risk post-irradiation depigmentation [13].

Patients with epidermolytic verrucous epidermal naevi are at risk of parenting a child with BIE. If the patient is a child the carers should probably be informed of this risk, and of the possibility of first-trimester antenatal diagnosis. Arrangements should be made to counsel the affected individual at a suitable age. Currently we lack data that allow quantification of the risk. Patients with non-epidermolytic epidermal naevi can be counselled that these are sporadic lesions and are not passed on as a generalized skin condition. It has been suggested that the generalized condition is lethal [14], and affected individuals survive only if they are 'rescued' by mosaicism.

Sebaceous naevus

SYN. NAEVUS SEBACEUS OF JADASSOHN

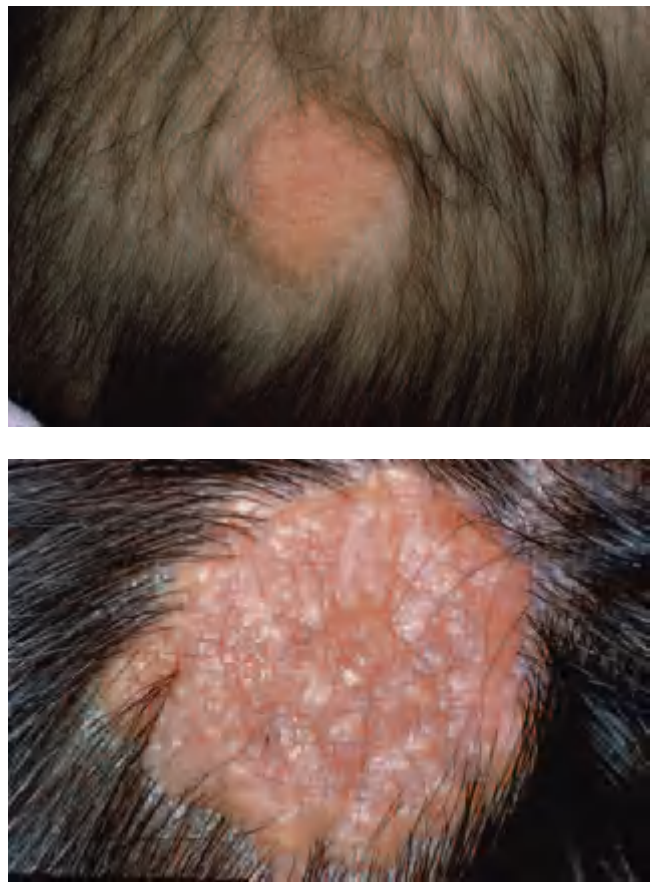
Definition and aetiology. Sebaceous naevi are epidermal hamartomas comprised predominantly of sebaceous

glands. The view that sebaceous naevi and verrucous epidermal naevi are variants of the same disorder, those on the head and neck being more sebaceous and those elsewhere more verrucous, is supported by the occurrence of both types in individuals and in the epidermal naevus syndrome [1–3].

Sebaceous naevi are usually sporadic, probably reflecting lethal genes rescued by mosaicism (see above). There have been occasional reports of familial cases [4,5] perhaps reflecting inheritance of an unstable premutation, but attributed by Happle and Konig to paradominant inheritance [6]. Because sebaceous naevi have a tendency to develop tumours, various tumour genes have been implicated in their aetiology. Constitutive activation of the patched-hedgehog signalling pathway (involved in Gorlin's syndrome and basal cell carcinomas) was suggested by Xin *et al.* [7] who found loss of heterozygosity at the *PTCH* locus 9q22.3 in sebaceous naevi. However, this finding was refuted by Takata *et al.* [8] who also found lack of expression of *Gli-1*, another gene in the patched-hedgehog signalling pathway expressed in basal cell carcinomas.

Pathology [9–11]. Before puberty, the sebaceous and apocrine glands in these lesions are sparse and underdeveloped, so that the lesions may be indistinguishable from verrucous epidermal naevi [10]. Cords and buds of poorly differented epithelial cells representing primordial pilosebaceous follicles are, however, a distinctive and diagnostic feature at this stage [9]. After puberty the characteristic mature sebaceous glands and associated papillomatous hyperplasia of the overlying epidermis are seen. Hair follicles are inconspicuous. Buds of undifferentiated epithelial cells resembling foci of basal cell carcinoma probably represent primordial hair follicles [11]. Merkel cells may be abundant [12]. Some lesions feature hypoplastic sebaceous glands, or sebaceous glands situated at an abnormally high level in the dermis. Ectopic apocrine glands are very commonly observed deep in the dermis beneath the sebaceous glands [9,11].

A variety of appendageal tumours may develop within sebaceous naevi [9,11,13–29]. The most commonly reported are syringocystadenoma papilliferum and trichoblastoma; less common tumours include nodular hidradenoma, apocrine cystadenoma, syringoma, infundibuloma and trichilemmoma. Locally invasive and malignant tumours include keratoacanthoma, proliferating trichilemmal cyst, and basal cell, sebaceous, apocrine, eccrine and squamous carcinomas. The true incidence of malignancy in sebaceous naevi is difficult to determine for several reasons, but mainly because different criteria were used to gather cases in each of the larger series. Furthermore basaloid proliferation has almost certainly been misinterpreted as basal cell carcinoma, the commonest malignancy reported in sebaceous naevi (see below). Takata *et al.* [8] found clear molecular differences between the basal cell carcinoma-like trichoblastomas arising in sebaceous naevi and true basal cell carcinomas.



(a) (b)

Fig. 15.3 Sebaceous naevus: (a) in a 6-month-old infant; (b) in an adult.

Clinical features. Sebaceous naevi occur in about 0.3% of all neonates [30,31]. They comprise circumscribed, slightly raised, pinkish, yellow, orange or tan plaques, with a smooth or somewhat velvety surface. Although usually congenital, they are occasionally first reported later in life [32]. The sex incidence is equal.

The lesions may be round, oval or linear, varying in length from under 1 to over 10 cm. Their shape may be determined by the stage at which they arise, early lesions conforming to embryonic epidermal migratory lines, while later lesions arising in a more fixed epidermis are round (see Blaschko's lines, above). They most commonly occur singly, but may be multiple and extensive, like verrucous epidermal naevi. Most occur on the head and neck, favouring the scalp, the areas around the ears, the temples, forehead and the central part of the face. They occasionally occur elsewhere [33]. Sebaceous naevi of the scalp are devoid of hair, and usually present with the complaint of a bald patch (Fig. 15.3).

Following birth, the lesions tend to become less prominent and then to remain unchanged until puberty, when they become thickened and more elevated. For this reason, many patients present at this stage. Gradually they become more nodular during adult life (see Fig. 15.3).

Development of an exophytic nodule on a naevus sebaceus usually represents a benign appendageal tumour or viral wart [26,27]. Rapid, circumscribed enlargement or ulceration should arouse suspicion of malignant transformation. This usually occurs in middle age, but can undoubtedly occur in adolescence, or even in childhood [13,34–37]. The lifetime risk of malignant transformation is probably less than 5%, but is difficult to establish with any precision because the major studies have varied considerably in methods of selection and in ages of the patients [9,11,15,27]. The most common malignancy is basal cell carcinoma, but the incidence of this tumour has been overestimated because of misinterpretation of trichoblastoma [26] and basaloid proliferation as basal cell carcinoma. Other malignant tumours reported include squamous, sebaceous and apocrine carcinomas. Despite occasionally aggressive histopathological features, most of these tumours are of low-grade malignancy. Nevertheless, local recurrence after excision, metastasis and a lethal outcome have all been reported [15,38].

Associated abnormalities occur in a small proportion of cases: these are considered under the heading of 'epidermal naevus syndrome'.

Diagnosis. Diagnosis is usually straightforward on clinical grounds alone. In early infancy, lesions in the scalp must be distinguished from aplasia cutis, which has a smoother papyraceous surface. Syringocystadenoma papilliferum may be very difficult to distinguish clinically, although the surface tends to be pink and nodular, rather than yellow and velvety. Early juvenile xanthogranulomas may be similar in their clinical appearance, although these generally develop rapidly into distinctive domed, papular or nodular lesions. Solitary mastocytomas may also be confused clinically during infancy, but histological examination will clearly identify all these disorders.

Very rarely, heterotopic brain tissue or an encephalocoele may result in a congenital bald patch overlying a subcutaneous nodule [39]. They may communicate with the brain so it is important to distinguish them from sebaceous naevus.

Treatment. Removal during childhood may be necessary for cosmetic reasons but is difficult to justify on grounds of risk of malignancy [26,27]. Excision of scalp lesions with primary closure gives an excellent cosmetic result, but larger lesions may require tissue expansion. Simple excision is generally adequate even in the presence of histological malignancy. Superficial removal by dermabrasion or carbon dioxide laser is likely to be followed by partial recurrence but may be helpful where excision is not feasible [40]. An extensive naevus sebaceus of face and scalp in a 38-year-old woman was cleared with 13 sessions of photodynamic therapy, with no recurrence 16 months later [41].

Follicular naevi

True hair-follicle naevus [1–7]

SYN. CONGENITAL VELLUS HAMARTOMA

In the past, the lesions that are now more usually termed trichofolliculomas were often described as 'hair-follicle naevi' [1]. The term should be confined to a hamartoma comprising an excessive concentration of normal hair follicles. This rare tumour, sometimes also called *congenital vellus hamartoma*, generally takes the form of a small, skin-coloured papule on the face, usually present from birth. Histologically, the lesion contains numerous small but well-differentiated vellus hair follicles in the dermis, with a few sebaceous glands and eccrine sweat glands. Subepidermal calcified nodule of the ear has been reported in a child with hair follicle naevus [8]. The treatment of choice is simple excision.

Comedo naevus

SYN. COMEDONE NAEVUS; NAEVUS COMEDONICUS; FOLLICULAR NAEVUS; ACNE NAEVUS

Definition. First described in 1895 [1], the comedo naevus is a linear lesion comprising numerous keratin-filled pits, sometimes with acneiform pustules.

Aetiology. This is probably a mixed group, reflecting mosaicism [2] for a variety of mutations that can predispose to acne. Acneiform naevi with predominantly inflammatory lesions may represent a clonal sensitivity to androgens [3–5]. The occasional histological finding of rudimentary hair follicles, sebaceous glands and trichilemmal cysts suggests a primary defect within the pilosebaceous gland. In naevi where comedones predominate, interfollicular histological changes typical of common verrucous epidermal naevi [6] or epidermolytic hyperkeratosis [7] suggest that follicular blockage is secondary to a keratinocyte defect. Comedo naevus on hair-bearing limbs contiguous with lesions involving eccrine ducts on the palms and soles, resembling *porokeratotic eccrine ostial and dermal duct naevus* [8–11], and glans penis [12], also supports a non-appendage-specific epidermal problem causing duct blockage. The suggestion that such lesions represent developmentally abnormal and ectopic pilosebaceous follicles [10] is less likely.

Munro and Wilkie hypothesized that mosaicism for a dominantly inherited disorder featuring severe acne might account for some acneiform naevi [13]. Apert's syndrome, characterized by acne, craniosynostosis and other bony defects, seemed a good candidate. This would explain the occasional association with skeletal abnormalities, as well as the linear distribution of acneiform lesions, and was confirmed by demonstrating an *FGFR2* mutation in lesional epidermis but not in adjacent normal skin [13]. Comedo naevi might also result from mosaicism for mutations, as yet unidentified, causing two other autosomal disorders featuring widespread comedones. The first of these is most commonly called *familial diffuse comedones* [14,15], but has been reported under the term 'nevus comedonicus' [16]. The comedo-like lesions appear progressively and in a diffuse bilateral distribution. Sporadic cases also occur [17]. In the second, called *familial dyskeratotic comedones*, the comedones are less extensive and demonstrate dyskeratosis histologically [18–20].

Pathology [9,21,22]. The characteristic histological feature of a comedo naevus is the deep, wide invagination of acanthotic epidermis, filled with concentric lamellae of keratin. These probably represent dilated hair follicles, as hair shafts are occasionally seen in the lower part of the invagination [6,22,23], and rudimentary sebaceous glands may open into them [22]. Arrector pili muscles are absent. The interfollicular epidermis may be histologically

normal, acanthotic and hyperkeratotic [6], or even epidermolytic [7,24,25]. Other reported histological associations have included trichilemmal cysts [26].

Clinical features [1–17,21–50]. This is a rare naevus: in their series of 235 epidermal naevi, Rogers found only four comedo naevi [2]. Acne naevus appears as a circumscribed asymmetrical area of skin demonstrating otherwise typical lesions of acne vulgaris in normal skin, or an area in which acne vulgaris is more severe. Comedo naevus comprises groups of pits filled with black keratinous plugs resembling blackheads with inflammatory acne lesions developing later. The intervening epidermis may appear normal, hyperkeratotic, or slightly hypo- or hyperpigmented [22,27]. Areas of more marked hypopigmentation have been reported by several authors [10,28]. There may be one or several lesions in a linear, unilateral [27,31–33] or, more rarely, bilateral distribution [23]. Lesions may be very extensive [28,33]. The commonest site is the face, followed by the neck, trunk and upper arm. Palms, soles and the glans penis, from which pilosebaceous follicles are normally absent, may occasionally be involved, usually in association with lesions in more characteristic sites, and often contiguous with them [8,9,12,28,34]. Curiously, the scalp is rarely affected [21,33,34].

Predominantly comedonal naevi are occasionally present at birth, but inflammatory acneiform naevi more often appear during childhood [2,30] or adolescence. They may be complicated by acneiform chronic inflammation, suppuration, fistula formation and hypertrophic scarring [6,27,30,33,35,36]. The development of multiple nodules within a comedo naevus may reflect the presence of associated trichilemmal cysts [26]. Benign or malignant tumours rarely complicate comedo naevi.

There have been occasional reports of associated developmental anomalies, including ipsilateral cataract [2,37], extensive naevus flammeus [38], transverse myelitis [39] and perforating elastoma [40]. While some of these are probably coincidental, skeletal malformations [28,39,41,42] may be manifestations of mosaicim for an *FGFR2* mutation, causing patchy manifestations of Apert's syndrome. The characteristic features of Apert's syndrome include craniosynostosis, mid-face hypoplasia, syndactyly and broad distal phalanx of thumb. The patient reported by Patrizi *et al.* [42] had a comedo naevus on the right cheek, syndactyly and a broad right thumb, and is very likely to have been mosaic for Apert's syndrome, although this was not investigated. Rogers' patient with extensive comedo naevus and syndactyly [2] may also have been mosaic for Apert's syndrome.

Diagnosis. Porokeratotic eccrine ostial and dermal duct naevus can be distinguished clinically by its occurrence on the palms and soles, and also histologically. Familial diffuse comedones and familial dyskeratotic comedones may be pathogenetically identical to comedo naevi (see above) but are symmetrical and widespread rather than linear. Atrophoderma vermiculata and keratosis pilaris atrophicans may show comedones, but can be distinguished from comedo naevus by their symmetry. The dilated pore naevus [43] can only be distinguished histologically. Comedones may occur in linear basal cell naevus. Comedo naevi have been reported as sequelae of lichen planus [44], herpes zoster [45], vaccination [46] and trauma [47], but the lesions described in these reports may simply represent an unusual pattern of scarring. Extensive comedones due to chloracne and sun damage are distinguishable from comedo naevus by their non-linearity.

Treatment. As with other epidermal naevi, surgical excision is more effective in the long term than superficial shaving or dermabrasion [27,48], but the latter can occasionally be useful cosmetically if the lesions are extensive [47], as can the regular use of a comedo extractor [27]. Both topical retinoic acid and 12% ammonium lactate may sometimes improve the appearance of lesions [36,49], and may help prevent secondary inflammation. Although oral isotretinoin has been reported to be ineffective [50,51], it is logical to treat extensive, inflamed acneiform naevi with anti-acne medication instead of, or in preparation for, surgical treatment.

'Acne-free' naevus

A single case has been reported of an adolescent male with severe papulopustular acne vulgaris of the back, who had, within the affected area, four well-defined bilaterally symmetrical zones, which were completely free of acne [1]. Investigation revealed smaller sebaceous glands, reduced sebum excretion rate, decreased counts of *Propionibacterium acnes* in the pilosebaceous ducts and reduced conversion of testosterone to 5α-dihydrotestosterone in the 'acne-free' zones. This may be another type of 'functional' naevus, possibly due to abnormal end-organ androgen responsiveness, and could be regarded as the converse of the situation in acne naevi.

Basaloid follicular hamartoma

SYN. LINEAR BASAL CELL NAEVUS; BASAL CELL NAEVUS WITH COMEDONES

Definition. A rare variety of epidermal naevus composed of multiple benign basal cell hamartomas.

Aetiology. Most cases probably represent mosaicism for autosomal dominant basaloid follicular hamartomas [1–3]. Those associated with skeletal malformations and palmar pits may reflect mosaicism for Gorlin's syndrome (linear basal cell naevus syndrome) [4].

Clinical features [5–17]. This benign, localized, usually linear naevus is generally present from birth and may be extensive. The lesion consists of numerous, translucent or brown, telangiectatic, hemispherical nodules up to about 0.5 cm in diameter, which occasionally demonstrate central ulceration, often associated with small areas of macular hypopigmentation. Some have the appearance of comedones, and other reported abnormalities in the affected area have included cysts, verrucous papules and stria-like areas of cutaneous atrophy. The face is a common site. Scalp lesions are usually associated with localized alopecia [11]. Normal hair growth on a scalp follicular hamartoma has been reported but the histology in that case was also atypical [15]. Malformations of the spine are rarely associated [7,8].

Pathology. Basaloid follicular hamartoma is characterized by anastomosing strands of well-differentiated basaloid or squamoid cells extending from the upper portions of follicles into a loose connective tissue stroma [15–17]. It can be distinguished from basal cell carcinoma by its low proliferative index (Ki-67 expression) and by circumferential expression of CD34 around the epithelial strands [17].

Differential diagnosis. Confusion may arise with other

adnexal tumours, particularly on the face. It must be differentiated from linear basal cell carcinomas.

Treatment. Treatment, if required, is usually surgical.

Dilated pore naevus

While clinically indistinguishable from comedo naevus, histologically the dilated pore naevus shows aggregated dilated follicular cysts [1]. These cysts individually are indistinguishable from the dilated pore of Winer, a solitary lesion usually occurring on the face in middle-age. Steffen [2] has argued that the dilated pore of Winer is a primary neoplasm (infundibloma) rather than a cyst.

Hairy malformation of the palms and soles

This rare disorder appears to be transmitted as an autosomal dominant trait. Asymptomatic areas of skin, having a somewhat altered texture and bearing hairs, are present bilaterally on the palms near the wrists, and on the medial aspect of the longitudinal arch of the feet [1,2]. Histologically, these show no abnormality other than the presence of hair follicles. A sporadic case has been reported in which the abnormality occurred on one palm only [3]. Differential diagnosis will include congenital melanocytic naevus and smooth muscle hamartoma.

Apocrine naevi

True apocrine naevi

SYN. APOCRINE GLAND HAMARTOMA

True apocrine naevi are rare, although apocrine structures are frequently seen in sebaceous naevi [1] and are a component of the lesions known as naevus syringocystadenomatosus papilliferus. The clinical appearance is variable and includes solitary nodules on the scalp [2], and bilateral soft tumours in the axillae or upper chest [3–6]. In a patient with focal dermal hypoplasia, the lesions comprised multiple papules in the sternal area [7]. Histologically, true apocrine naevi comprise large numbers of mature apocrine glands extending from the upper dermis to the subcutaneous fat. Decapitation secretion and periodic acid–Schiff (PAS)-positive diastase-resistant granules in the luminal cells differentiate apocrine from eccrine gland differentiation [8]. There is only one report of malignant transformation: an apocrine gland carcinoma was excised within an area of skin histologically consistent with apocrine nevus, but a preceding clinical lesion was not described [9].

Naevus syringocystadenomatosus papilliferus

SYN. SYRINGOCYSTADENOMA PAPILLIFERUM

Definition. Naevus syringocystadenomatosus papilliferus is a skin hamartoma with predominantly apocrine differentiation.

Aetiology. The histogenesis of these lesions is controversial. They show features of apocrine glands, or occasionally eccrine glands. However, associated hamartomatous malformations of hair follicles and sebaceous glands are common [1], and naevus syringocystadenomatosus papilliferus is a frequent component of sebaceous naevi [2]. Yamamoto *et al.* [3] postulated an origin in pluripotent cells on immunohistochemical and ultrastructural grounds. Boni *et al.* [4] showed mutations in *PTCH* or *P16* tumour suppressor genes in syringocystadenoma papilliferum.

Pathology. Histologically, a number of cystic invaginations extend downwards from a papillomatous epidermis. Numerous villous papillary projections extend into the lumen of the lower portion of these invaginations [1,2,5–9]. Both the invaginations and the papillary projections are lined by a glandular epithelium, comprising an inner cylindrical and an outer cuboidal layer; the latter occasionally demonstrating 'decapitation' secretion. Apocrine glands are prominent deep in the dermis below the invaginations, and the two can be shown by serial sectioning to be connected [9]. An inflammatory infiltrate is present, particularly in the stroma of the papillary projections, which typically is composed almost entirely of plasma cells. Secondary basal cell carcinoma has been reported in about one in 10 cases of this type [2].

Clinical features. These lesions occur either as a nodular plaque, a linear group of nodules, or as a solitary nodule [1,2,10,11]. The plaque and linear varieties are usually present at birth, or appear during infancy, while the less common solitary nodular form usually develops at puberty. The plaque form is most characteristically seen as a hairless area in the scalp, while the linear form is more often seen on the neck or face. These lesions will generally become more elevated and nodular, verrucous or crusted at puberty. Such lesions closely resemble sebaceous naevi. Close examination of a mature lesion demonstrates that it comprises clusters of generally pinkish brown nodules 2–10 mm in diameter, some of which have a central opening. The solitary nodular form predominates on the trunk, where it favours the shoulders, the axillae and genital areas. Occasionally it occurs on the limbs. Each nodule is up to 1 cm in diameter, domed, umbilicated or pedunculated, often having a friable or crusted surface. Several lesions may be scattered over an area.

Ulceration or rapid enlargement may indicate malignant transformation, usually a basal cell carcinoma [2], but occasionally a squamous carcinoma [12]. In the majority of such cases, there is a coexistent sebaceous naevus.

Naevi of this histological type may be associated with non-cutaneous abnormalities (see epidermal naevus syndrome).

Diagnosis. The plaque and linear forms on the head and neck may be difficult to distinguish clinically from the closely related and commoner sebaceous naevus, although syringocystadenoma papilliferum tends to be pinker and more nodular. The umbilication of individual nodules, particularly in the linear form, may cause some confusion with molluscum contagiosum [10].

Management. Because of the not infrequent development of secondary basal cell carcinoma, these lesions should be excised wherever possible. Pulsed carbon dioxide laser treatment of a surgically difficult lesion in and below the ear in a $2^1/_2$-week-old baby produced 'reasonable cosmesis' with minimal recurrence at 3 years [13].

Eccrine naevi

Pure eccrine naevi

SYN. NAEVUS SUDORIFERUS; SUDORIFEROUS HAMARTOMA

Although an eccrine component is a not-infrequent feature of sebaceous naevus, purely eccrine naevi appear to be very rare, with fewer than 20 cases reported in the literature. The clinical appearance is variable. In one case a solitary pore that discharged a mucoid secretion showed histologically numerous coils, comprising both secretory and ductal elements, situated deeply in the dermis and leading to a central dilated pore on the surface [1]. A second comprised an otherwise unremarkable area of diffusely increased sweat production, with histologically prominent eccrine glands, which has been termed 'naevus sudoriferus' [2,3]. Other cases have taken the form of a small plaque [4], a congenital perianal skin tag [5], and grouped skin-coloured or brown papules, sometimes in a linear distribution [6].

Eccrine angiomatous naevus

SYN. ECCRINE ANGIOMATOUS HAMARTOMA; SUDORIPAROUS ANGIOMA

Definition. Eccrine angiomatous naevus is a rare condition characterized histologically by numerous eccrine structures and capillary channels, most commonly found in acral skin where eccrine glands are numerous. The term covers a spectrum of lesions ranging from the predominantly angiomatous 'sudoriparous angioma' [1] up to the normally vascularized nevus sudoriferus.

Pathology. Histologically, lesions show nests of large, but otherwise normal eccrine glands [2], enmeshed in loose fibrous tissue, which contains numerous thin-walled blood vessels and lymphatics [3]. There may be a very intimate association between the glandular and vascular elements [4,5]. The overlying epidermis may be mildly acanthotic. Other components, particularly hair follicles, may also be closely associated with the eccrine angiomatous complexes [6,7]. Some have shown lipomatous involvement [8]. Immunohistochemical findings are similar to normal eccrine glands [8].

Clinical features [1–11]. These lesions are present at birth or arise during childhood in 77% of cases and affect both sexes equally [8,12]. They take the form of a nodule or plaque, often with a bluish colour and angiomatous appearance. Eighty per cent occur on the extremities [12], particularly the palm and sole, but also on other parts of the feet, on the face, neck and on the trunk. Occasionally, there are multiple lesions [1,12,13]. Most are painful on pressure [3,8,14]. Some demonstrate hypertrichosis and/or hyperhidrosis, but not all [15]. Generally, they enlarge very gradually; more rapid growth has been described during pregnancy and adolescence [16]. One atypical case presented at the age of 73 years, on the buttock, and was verrucous [17]. There have been no reported complications.

Treatment. Painful lesions may require removal, particularly those on the palm or sole; this has been successfully achieved by deep excision with full-thickness grafting [3], or by amputation [16]. Pulsed dye laser was helpful in only one of two patients [18].

Porokeratotic eccrine ostial and dermal duct naevus

Definition. Porokeratotic eccrine ostial and dermal duct naevus (PEODDN) is a localized area of plugged pores usually on the palm or sole. It has been recognized only since 1980 [1], early cases having been reported as comedo naevus of the palm [2], or linear eccrine naevus with comedones [3]. Several cases have been reported since [4–15].

Aetiology. This is presumably a mosaic defect. As for comedo naevus, debate centres on whether the primary abnormality involves the epidermis or the appendage. Staining with carcinembryonic antigen (CEA) which labels the acrosyringium and dermal eccrine duct suggests that PEODDN represents an abnormally keratinizing epidermal invagination traversed by an acrosyringium-like duct, rather than a primary abnormality of the acrosyringium and dermal duct [11].

Pathology. Histologically, these lesions are characterized by dilated comedo-like epidermal invaginations filled with parakerotic plugs. The neighbouring epidermis demonstrates parakeratotic columns, which protrude above the rest of the stratum corneum. The granular layer is absent at the base of these columns, and in the lining of the comedo-like structures; keratinocytes with vacuolated cytoplasm and pyknotic nuclei may also be a feature. In the lower portion of the invaginations, intraepidermal eccrine ducts are generally visible, and there may be associated hyperplastic intradermal eccrine ducts with comma-shaped extensions.

Clinical features. The lesions are asymptomatic and are usually present from birth, although onset later in childhood is reported in 26% [12]. PEODDN resembles comedo naevus, comprising small keratotic papules, with a central plugged pit, in a linear distribution, usually on the palms and soles [13]. At other sites, the lesions tend to be more verrucous, resembling verrucous epidermal naevi, sometimes with filiform vegetations. PEODDN is occasionally quite extensive [1]. Involvement of all four limbs has been reported [10]. The lesions may be anhidrotic [1] or hyperhidrotic [2]. There are no known associated abnormalities.

Diagnosis. The entity described as *porokeratotic eccrine duct and hair follicle nevus* [16,17] is probably very closely related, the only real distinction being that hair follicles were affected as well as eccrine sweat ducts. Comedo naevi can be distinguished histologically, because they lack the characteristic intraepidermal and dermal eccrine ducts, and the parakeratotic columns. This disorder also appears to be distinct from *punctate porokeratosis* [18–20] in which multiple punctate seed-like keratoses and/or pits are present on the palms and soles, occasionally in a linear configuration, and sometimes associated with linear porokeratosis. Punctate porokeratosis does not resemble comedones, either clinically or histologically, and the cornoid lamellae are not obviously associated with eccrine duct ostia.

Treatment. As for other epidermal naevi, simple excision is usually the treatment of choice. An adult-onset lesion on the hand resistant to topical keratolytics and cryotherapy responded to four treatments with the carbon dioxide laser and remained clear 9 months later [14].

Becker's naevus [1]

SYN. BECKER'S MELANOSIS; PIGMENTED HAIRY EPIDERMAL NAEVUS

Definition. An acquired and persistent asymmetrical area of skin pigmentation, sometimes showing evidence

of increased androgen sensitivity, and colocalizing with other developmental anomalies.

Aetiology. The sporadic occurrence and asymmetrical distribution of most Becker's naevi suggest cutaneous mosaicism. Indeed, chromosomal mosaicism was reported in one patient with Becker's naevus [2]. The lack of conformity to Blaschko's lines may be due to the relatively late occurrence of a causative mutation (see above). The mutant skin clone is presumably predisposed not only to pigmentation but also to androgen sensitivity, since Becker's naevus is prone to acne and hypertrichosis [3]. While most cases occur sporadically, Becker's naevus has been reported in siblings [4], father and son [5], and uncle and nephew [6]. As discussed above, familial occurrence of a mosaic disorder can be reconciled with mosaicism by mechanisms such as inheritance of an unstable premutation, paradominant inheritance [7] and chance. Colocalization with other developmental anomalies suggests a clonal defect in morphogenesis. Becker's naevus may be pathogenetically related to congenital smooth muscle hamartoma, which also shows hypertrichosis, hyperpigmentation and increased smooth muscle, albeit in different proportions [5].

Clinical features. Becker's naevus is a relatively common anomaly found in about 0.5% of young men, affecting most racial groups, and is about five times more frequent in males than females [8]. It may present in childhood, but is usually first noticed during adolescence, initially pale in colour and becoming more conspicuous after sun-exposure. The usual site is shoulder, anterior chest or scapular region, but lesions on face, neck and distal limbs have been reported [8,9]. It starts as an area of irregular macular pigmentation, which spreads to a diameter of several centimetres, new macules developing beyond the margin and fusing with it, giving a geographical contour. Later, thick, dark hairs may appear, on and around the lesion. The skin may thicken towards the centre of the lesion. Once present, Becker's naevi remain indefinitely.

Becker's naevus is more prone to acne vulgaris than the adjacent normal skin [3,10–12]. Tinea versicolor localized to a Becker's naevus has also been reported [13]. In one patient lichen planus was confined to a large Becker's naevus affecting the whole of one lower limb [14]. Other cutaneous anomalies may occur in the affected area, for example lymphangioma [15].

Although Becker's naevi generally occur without any associated pathology, several ipsilateral developmental abnormalities have been described, particularly breast hypoplasia [9,12,16–18] and supernumerary nipples [19], and also aplasia of the pectoralis major muscle [20] limb reduction [9], segmental odontomaxillary dysplasia [21] and lipoatrophy [17]. Spina bifida [16,22], scoliosis [20], pectus carinatum [16], congenital adrenal hyperplasia [2] and an accessory scrotum [23] have also been reported. The term *Becker's naevus syndrome* has been proposed to describe the association of a Becker's naevus with ipsilateral non-cutaneous abnormalities [18,24].

The possibility of an increased risk of malignant melanoma in patients with Becker's naevus was raised in a recent report [25].

Pathology. Histological changes may be subtle. Well-developed lesions show hyperkeratosis, acanthosis and papillomatosis, with hyperplasia of hair follicles and sebaceous glands. The basal and suprabasal keratinocytes are heavily pigmented, and melanocyte density is variably reported as increased [26] or normal [27], with a few melanophages in the upper dermis. There are no junctional or intradermal naevus cells. The dermis is thickened, and contains numerous, but often inconspicuous, bundles of smooth muscle fibres, unrelated to hair follicles or blood vessels [27]. Ultrastructurally there is evidence of enhanced melanin synthesis, with increased melanocyte activity and increased numbers of melanosome complexes in keratinocytes [28,29]. Giant melanosomes have been reported both in melanocytes and keratinocytes [30]. Increased numbers of androgen receptors [3] and androgen receptor messenger RNA (mRNA) [31] have been found in lesional skin.

Diagnosis. A well-developed Becker's naevus is unmistakeable. In early lesions, age of onset, geographical outline and site help to distinguish Becker's naevus from a café-au-lait macule and from linear and whorled naevoid hyperpigmentation. Whether *progressive cribriform and zosteriform hyperpigmentation* [32] should be regarded as a non-hypertrichotic variant of Becker's naevus is unclear.

Treatment. Benefit from the Q-switched ruby laser has been reported [33], but reactive patchy hyperpigmentation may recur [34]. In a 27-year-old man, three treatments with the 694-nm long-pulsed ruby laser decreased hair density as well as pigmentation, the improvement lasting for the 10 months of follow-up [35].

Inflammatory epidermal naevi

Inflammatory linear verrucous epidermal naevus (ILVEN) and CHILD naevus present at or soon after birth and usually persist lifelong. They can thus be distinguished from naevoid variants of inflammatory dermatoses which occur later and often resolve, including linear lichen planus, naevoid psoriasis, lichen striatus and adult Blaschkitis. However all comprise hyperkeratotic lesions following Blaschko's lines, with histological evidence of inflammation. Probably all reflect genetic mosaicism, the former for potentially lethal dominant mutations rescued by mosaicism, and the latter for multifactorial dermatoses with an autosomal dominant component.

Inflammatory linear verrucous epidermal naevus

SYN. DERMATITIC EPIDERMAL NAEVUS

Definition. A pruritic, erythematous scaly lesion following Blaschko's lines [1].

Aetiology. ILVEN is probably due to mosaicism for a dominant mutation, as yet unidentified, which would be lethal if it affected all cells and is 'rescued' by mosaicism [2]. More recently Happle [3] has suggested that linear skin disorders such as ILVEN might reflect the action of a retroviral transposable element ('retrotransposon') that is partly expressed and partly silenced at an early developmental stage. ILVEN is usually sporadic, in keeping with both hypotheses, but there have been reports of familial cases, including two in which mother and daughter were affected [4,5] and one involving mother, two sons and (reportedly) maternal grandfather [6]. Two cases in patients positive for human immunodeficiency virus 1 (HIV-1) [7], suggested clonal dysregulation of growth triggered by infection. However, the histology of these two lesions resembled psoriasis, which is known to be associated with HIV infection. Absent involucrin expression in the parakeratotic epidermis has been reported, a finding that appears to distinguish ILVEN from psoriasis [8].

Pathology. The characteristic histology shows columns of hypergranulosis with orthokeratotic hyperkeratosis alternating with equally well-defined columns of agranulosis and parakeratotic hyperkeratosis [9,10]. Other cases simply show a rather psoriasiform chronic eczema. Spongiosis is occasionally seen. An associated upper dermal lymphohistiocytic inflammatory infiltrate is regularly present.

Clinical features. About 75% of ILVENs appear during the first 5 years of life, most often in the first 6 months, although later onset has been recorded [4,5,11–13]. They are characterized by pruritus, which may be intense. The lesions are linear, most commonly on a limb, and comprise eczematous or psoriasiform papules (Fig. 15.4). ILVEN can be of any length, occasionally extending the whole length of a limb. As with other epidermal naevi, nail dystrophy may occur when the nail fold is affected [14]. Occasionally ILVEN is bilateral and widespread [12,14–16]. Occasional reports of limb reduction anomalies associated with ILVEN on the adjacent skin have led to the

Fig. 15.4 Inflammatory linear verrucous epidermal naevus on the posterior thigh.

suggestion that ILVEN represents a limited form of CHILD naevus. Accordingly, it has been suggested that ILVEN and CHILD would more appropriately be named, respectively, PEN and PENCIL, indicating *p*soriasiform *e*pidermal *n*aevus with or without *c*ongenital *i*psilateral *l*imb defects [17]. A report of two girls with ILVEN and arthritis suggested a new association [18], but linear psoriasis with psoriatic arthropathy seems a more likely diagnosis for their symmetrical, distal, methotrexate-responsive arthritis, particularly since skin histology was not reported.

Although generally persistent and resistant to treatment, some lesions have been reported to resolve spontaneously [11].

Differential diagnosis. Earlier reports confused ILVEN with naevoid psoriasis, and with epidermal naevi in which psoriasis had developed as an isomorphic phenomenon [19–22]. Several patients have been reported in whom naevoid psoriasis and ILVEN both appeared to be present [23–25]. In one patient, transient inflammation of the ILVEN coinciding with an outbreak of guttate psoriasis probably reflected koebnerization of psoriasis by the ILVEN [25]. ILVEN can be distinguished from true naevoid psoriasis by pruritus and lack of response to antipsoriatic treatments [23,26]. Sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS-PAGE) has allowed the identification of stratum corneum fibrous polypeptide patterns that are distinct from that seen in psoriasis, but it is doubtful whether this will prove a useful test in normal clinical practice [27,28]. Lichen striatus is distinguished by its rapid development, generally after the first year of life, by its relative lack of pruritus, by its more lichenoid clinical and histological features, and, eventually, by its spontaneous involution. The distinction between CHILD syndrome and ILVEN is uncertain [29,30].

Treatment. ILVEN is notoriously resistant to treatment, although occasionally spontaneous resolution occurs. Potent topical corticosteroids applied under occlusion, or intralesional steroid injections, provide little more than temporary symptomatic relief [13]. Similarly, topical retinoids appear to provide no benefit [31]. Successful treatment with dithranol [23] has been reported. Calcipotriol or tacalcitol in some cases merely reduce the redness and itching, while in others have produced prolonged clearance [32–36]. Cryotherapy may be a reasonable approach, particularly for smaller lesions [37]. Surgical excision tends to be followed by rapid recurrence unless a generous depth of underlying dermis is removed [14,38]. Successful treatment has been reported with the flashlamp-pumped pulsed tunable dye laser [39]. ILVENs treated with the carbon dioxide resurfacing laser have remained clear for 2 years of follow-up [40,41], but this laser is less effective for ILVEN than for non-inflammatory verrucous epidermal naevi [41].

The CHILD naevus

Definition. CHILD is an acronym for *c*ongenital *h*emidysplasia with *i*chthyosiform naevus and *l*imb *d*efects [1]. Internal organs are often hypoplastic on the affected side. The CHILD naevus is the characteristic skin lesion observed in this disorder.

Aetiology. CHILD syndrome is an X-linked dominant trait, with a strong female predominance and antenatal lethality in males. Survival of a karyotypically normal male can be attributed to a somatic mutation on the X chromosome [2]. It is usually sporadic but has been reported in a mother and daughter [3]. Initially it was thought to be allelic to X-linked dominant Conradi–Hünermann syndrome. Both conditions share the clinical features of linear scaling and asymmetric limb reductions. Both have shown peroxisomal deficiency in fibroblasts from involved areas of skin [4] and elevated plasma 8-dehydrocholesterol and 8(9)-cholestenol levels [5]. Grange *et al*. [5] indeed found, in a patient with CHILD syndrome, a nonsense mutation in the X-linked dominant Conradi–Hünermann syndrome gene, 3β-hydroxysteroid-δ8,δ7 isomerase, or emopamil binding protein (EBP). The EBP gene is located at Xp11.22–23. However, this finding has not been repeated, and Grange's patient may in fact have had the X-linked dominant Conradi–Hünermann syndrome, a diagnosis in keeping with her widespread punctate calcifications of bones and improvement in her ichthyosis. Simultaneously, Konig *et al*. [6] found, in both sporadic and familial patients with CHILD syndrome, mutations in *NSDHL* (NAD(P)H steroid dehydrogenase-like protein) gene at Xq28. *NSDHL* functions upstream of EBP in cholesterol biosynthesis. *NSDHL* mutations in mice produce the 'bare patches' and 'striated' phenotypes [7]. The extreme lateralization of CHILD syndrome contrasts with symmetry of X-linked dominant Conradi–Hünermann syndrome and has not yet been explained satisfactorily. CHILD syndrome might be an extreme form of ILVEN, an alternative name covering the whole spectrum being PEN or PENCIL [8]. This idea has been contested by Happle [9]. It could now be tested, knowing the defect in CHILD syndrome.

Pathology. Light microscopy [10] shows marked acanthosis, and areas of parakeratosis within a largely orthokeratotic epidermis. There is exocytosis of neutrophils, with focal collections resembling Munro microabscesses. The dermis contains a patchy lymphohistiocytic infiltrate. Some biopsies, particularly those taken from flexural sites, may show enlarged dermal papillae containing foamy lipid-laden histiocytes (verruciform xanthoma) [9,11–13]. Although verruciform xanthoma is very characteristic of CHILD naevi, it can also occasionally be seen in severe dystrophic epidermolysis bullosa and pemphigus vulgaris, and it may also be a feature of biopsies taken from the mouth, vulva or penis.

Ultrastructurally [10,12], many corneocytes contain lipid vacuoles. Vesicular structures are seen in the intercellular spaces of the epidermis, and become more numerous as

cornification progresses. Large intracytoplasmic vacuoles are seen within papillary dermal foamy cells.

Clinical features. Most affected individuals are female. CHILD naevi are generally present at birth, but occasionally first develop during the first few months of life or even later. Lesions may extend during life, and rarely partly disappear. The lesions are generally asymptomatic, comprising well-circumscribed areas of erythema covered in waxy scales, sometimes with a verrucous surface. There is a marked preference for flexural areas (*ptychotropism*) [14], where oozing vegetations may develop. Characteristically, lesions are confined or concentrated on one side of the body, with sharp midline demarcation. In more severe cases, one side of the body may be diffusely affected, generally but not always [15] with sparing of the face and the oral mucosa. In other patients, the distribution is more streaky, with lesions following Blaschko's lines, but not uncommonly both linear and diffuse unilateral patterns coexist in the same patient. Konig *et al.* [16] reported bilateral, almost symmetrical involvement in a woman with a novel missense mutation of *NSDHL*.

A wide variety of non-cutaneous anomalies have been reported in the CHILD syndrome [1,15,17,18]. Unilateral bone defects are particularly characteristic, and most likely to affect the long bones. The severity of limb lesions varies from hypoplasia of a few metacarpals or phalanges to complete absence of an entire limb. Hands or feet may be grossly deformed. Scoliosis may be present. In some cases, punctate epiphyseal calcifications have been shown radiologically in the first few months after birth; these disappear later.

Unilateral hypoplasia of the brain, cranial nerves or spinal cord may be present, with mental retardation, electroencephalogram (EEG) abnormalities and sensory defects.

Congenital cardiac defects may be present, and are perhaps the main cause of early death of children with the CHILD syndrome. Other anomalies of the kidneys, lungs and other internal organs have been described.

Diagnosis. Naevoid psoriasis, ILVEN and epidermal naevus syndrome can be confused with CHILD syndrome. Psoriasis is less persistent and does not show waxy scales clinically or verruciform xanthoma histologically. In contrast to CHILD naevi, ILVEN does not show flexural preference, and tends to be exclusively linear. The distinction from epidermal naevus syndrome is perhaps semantic. CHILD syndrome when first delineated had to be distinguished from epidermal naevus syndrome as it was then understood [19–21]. More recently, Happle has reclassified CHILD syndrome as an epidermal naevus syndrome [22].

Treatment. CHILD naevi appear to be highly refractory to all treatment, except occasionally oral retinoids [3].

Other naevoid epidermal disorders

Several generalized dermatoses occasionally follow Blaschko's lines, probably reflecting a clonal 'susceptibility mutation'. Linear lichen planus, psoriasis, Darier's disease, Hailey–Hailey disease, porokeratosis, atrophoderma of Moulin, and 'adult Blaschkitis' or BLAISE (*B*laschko *l*inear *a*cquired *i*nflammatory *s*kin *e*ruption) are described

below. Linear lichen nitidis [1], lichen striatus (eczema) [2], segmental vitiligo [3] and linear morphoea [4] are discussed elsewhere in relation to the appropriate generalized disorder. The following have also been reported in a linear or naevoid distribution: linear lupus erythematosus [5], linear fixed drug eruption [6] and linear chronic graft-versus-host disease [7].

Linear lichen planus

Some epidermal naevi show, in addition to histological features compatible with verrucous epidermal naevus, a lichenoid band-like lymphohistiocytic infiltrate at the dermal–epidermal junction, plus Civatte bodies and dermal melanophages [1]. Clinically such lesions resemble lichen planus except in their linear distribution. They can occur at any age and resolve leaving post-inflammatory pigmentation. If they exend to the end of a digit there may be associated nail dystrophy, and similarly there may be mucous membrane involvement [2]. Linear lichen planus is sometimes mutifocal [3] and in one female recurred three times after successive deliveries [4]. It seems likely that this entity represents lichen planus localized to Blaschko's lines by a clonal 'susceptibility mutation'.

Naevoid psoriasis

Psoriasis rarely occurs in a 'naevoid' form, possibly reflecting mosaicism for a gene responsible for psoriasis [1]. The lesions present in the 6-year-old boy whose case was reported appeared clinically and histologically indistinguishable from ordinary psoriasis other than in their distribution. The lesions could be distinguished from invasion of a verrucous epidermal naevus by psoriasis as a result of the isomorphic phenomenon [2–5] and from dermatitic epidermal naevi, by their minimal pruritus and their therapeutic response to ultraviolet radiation. Further similar cases have been reported [6,7]. In one case, topical dithranol was therapeutically beneficial [8]; this patient appeared to have a small coexisting dermatitic epidermal naevus, which failed to respond to this treatment. Linear psoriasis is easily confused with ILVEN (see above).

Linear Darier's disease

SYN. ACANTHOLYTIC DYSKERATOTIC EPIDERMAL NAEVUS

Several cases have been reported of acantholytic epidermal naevi comprising crusted keratotic papules, clinically and histologically resembling those seen in Darier's disease [1–8]. Such naevi appear relatively late, frequently after the age of 20 years [1], in individuals who lack a family history of Darier's disease. The lesions can extend over many years and are aggravated by UV exposure [1,3]. If the affected area includes the nails, typical nail changes of Darier's disease may occur [4], and if the hands are affected, pits and keratoses may be observed within the involved zone [4].

The suggestion that such naevi represent mosaicism for Darier's disease has now been confirmed by finding a mutation in the Darier's disease gene *ATP2A2* in the naevus, but not in unaffected skin [7].

Treatment is as for other linear epidermal naevi. It appears that topical retinoic acid may be useful [1], and it would be anticipated that oral acitretin might be of value where the distribution is extensive.

Linear Hailey–Hailey disease

SYN. RELAPSING LINEAR ACANTHOLYTIC DERMATOSIS

A distinctive form of epidermal naevus has been reported, in which well-defined linear erythematous plaques demonstrate vesiculation, erosion and crusting, and the typical histological features of benign familial chronic pemphigus (Hailey–Hailey disease) [1,2]. This type of naevus appears to have an early onset, and a highly characteristic course, with periods of spontaneous improvement followed by relapse.

The suggestion that such naevi represent mosaicism for Hailey–Hailey disease can now be tested by seeking a mutation in the Hailey–Hailey disease gene *ATP2C1* [3] in the naevus but not in unaffected skin.

Curiously, the 5-year-old patient reported by Vakilzadeh [1] apparently inherited the condition from her mother and grandmother. In the older generations, the disease was manifest only in the perianal area. A possible explanation is that the Hailey–Hailey mutation was transmitted in the usual autosomal dominant manner, with limited flexural disease presenting in early adult life, while the child was mosaic for a loss-of-heterozygosity (Happle type 2 mosaicism [4]), and accordingly developed more severe and earlier onset disease in a linear distribution.

A single case of a distinctive type of keratinocyte naevus has been reported as 'naevus corniculatus' [5]. Clinically, the naevus featured filiform and horn-like keratoses, and giant comedones. Histologically, the lesion showed acantholytic changes more closely resembling those seen in Hailey–Hailey disease than in Darier's disease.

Linear porokeratosis

Definition. This naevus, distributed along Blaschko's lines, is characterized by annular plaques clinically and histologically indistinguishable from the lesions of generalized porokeratosis [1].

Aetiology. Linear porokeratosis probably reflects mosaicism for a gene responsible for generalized porokeratosis. This idea is supported by the fact that the generalized forms of porokeratosis (porokeratosis of Mibelli, disseminated superficial actinic porokeratosis (DSAP), and porokeratosis plantaris palmaris et disseminata) can be inherited as autosomal dominant genes, whereas the linear variant usually occurs sporadically. The report of linear porokeratosis in monozygotic twins [2] can be reconciled with the idea of mosaicism by postulating that the somatic mutation in the porokeratosis gene occurred before the twinning division, so that the aberrant clone was present in both embryos. Reports of pre-existing linear porokeratosis in patients later developing DSAP [3–7], and the occasional occurrence of linear porokeratosis in the children or siblings of patients with DSAP [3,4,8] can be explained by loss of heterozygosity for this dominant gene, that is Happle type 2 mosaicim [9]. According to this hypothesis, an individual with inherited generalized porokeratosis undergoes a somatic mutation in the normal allele resulting in clonal loss of heterozygosity. The resultant line contrasts with the background skin because it has 'double the dose' of porokeratosis. Skin cancers in porokeratosis are particularly associated with the linear variant [10–12], in keeping with Happle's suggestion of loss of heterozygosity [9]. The role of *p53* is uncertain: overexpression of *p53* has been reported in linear porokeratosis [13,14] and in a superimposed squamous carcinoma, but not in the adjacent porokeratosis [12].

Generalized porokeratosis can be provoked by immune suppression [1]. Hunt *et al*. [15], however, reports exacerbations of linear porokeratosis during episodes of liver failure, and improvement following transplantation.

Clinical features. The lesions of linear porokeratosis comprise grouped hyperkeratotic plaques, each with a fine, rounded, annular rim and an atrophic centre. Lesions may be hyper- or hypopigmented and/or erythematous, and are disposed in an interrupted linear fashion along Blaschko's lines [16–23]. The lesions are often present at

birth, when they may be ulcerated [24]. Occasional spontaneous resolution has been described [25,26], but generally the lesions are lifelong, with increasing hyperkeratosis and a definite predisposition to skin cancer within the lesions [10].

Management. A variety of treatments have been used with variable success; of these the most consistently successful have been surgical excision [10,17,27] and ablation with the carbon dioxide laser [16]. Other helpful treatments have included cryotherapy [28], dermabrasion [27,29], oral retinoids [30,31], topical 5-fluorouracil [32], vitamin D analogues, urea [20] and dithranol [2]. In one case, etretinate worsened the porokeratosis [33].

Linear atrophoderma of Moulin

In some patients, clearly demarcated cutaneous atrophy and pigmentation with minimal inflammation and sclerosis is distributed along Blaschko's lines [1]. This might represent a late 'burnt out' stage of linear morphoea, since some inflammatory cells are usually present.

REFERENCE

Adult Blaschkitis

SYN. BLASCHKO LINEAR ACQUIRED INFLAMMATORY SKIN ERUPTION; BLAISE

This remitting and relapsing eruption of itchy inflammatory vesicles and papules occurs usually on the trunk in adults [1]. The histology is more eczematous (spongiotic) than lichenoid. It would be difficult to distinguish from linear Grover's disease [2]. Taieb *et al*. [3] considered that 'adult Blaschkitis' represents an adult version of lichen striatus, and proposed the acronym BLAISE to cover both. BLAISE should perhaps be regarded as a description rather than a diagnosis, a useful category for many of the disorders in this section, pending more precise identification.

The epidermal naevus syndromes

Non-epidermolytic epidermal naevi can be associated with a wide range of abnormalities in other systems (epidermolytic verrucous epidermal naevi are not, as the causative keratin gene mutations are expressed only in skin). Historically [1,2], the term 'epidermal naevus syndrome' referred to the association of sebaceous naevus with neurological, ocular and sometimes other abnormalities. Later, the term was extended to cover almost any multisystem disorder featuring sebaceous or verrucous epidermal naevus [3]. More recently, Happle has used the term 'the epidermal naevus syndromes' to include at least six separate disorders, namely: Schimmelpenning's syndrome, Proteus syndrome, comedo naevus syndrome, CHILD syndrome, Becker's naevus syndrome and phakomatosis pigmentokeratotica [4,5]. This has created two difficulties: firstly, most dermatologists would not regard Becker's naevus as an epidermal naevus; secondly, changing the meaning of 'epidermal naevus syndrome' leaves us without a name for the entity well established in the literature as 'epidermal naevus syndrome', none of the historical eponyms being satisfactory.

Therefore, this account maintains the original and well-established use of the term 'epidermal naevus syndrome' as 'the association of sebaceous and/or verrucous epidermal naevi with other developmental defects, particularly of the CNS, eye and skeleton'. It does not include syndromes where the naevus is not a sebaceous or verrucous epidermal naevus (e.g. Becker's naevus, CHILD naevus). Neither does it include those conditions which have been clearly defined in molecular terms (comedo naevus syndrome), or which feature epidermal naevi but are sufficiently distinctive to merit their own name (Proteus syndrome and phakomatosis pigmentokeratotica). It remains a heterogeneous group, within which further conditions will be defined in the future. Eventually, when all the different mutations responsible for epidermal naevus syndrome have been defined, the term will become redundant, but for the moment it remains useful.

Epidermal naevus syndrome

SYN. SEBACEOUS NAEVUS SYNDROME; SCHIMMELPENNING'S SYNDROME; FEUERSTEIN–MIMS SYNDROME; EPIDERMAL NAEVUS SYNDROME; ORGANOID NAEVUS SYNDROME; JADASSOHN'S NAEVUS PHAKOMATOSIS

Definition. Epidermal naevus syndrome describes the association of sebaceous and/or verrucous naevi with other developmental defects, particularly of the central nervous system (CNS), eye and skeleton, first reported by Feuerstein and Mims [1] and Schimmelpenning [2]. Other authors have used the term *Jadassohn's naevus phakomatosis* to describe this association [6]. Although early reports only included sebaceous naevi, the term is now used to include patients with verrucous naevi. The associations with both types of naevi are very similar, and some patients have both verrucous and sebaceous naevi, differentiation depending largely on the site, lesions on the head and neck being more often sebaceous [7].

Aetiology. Epidermal naevus syndrome is a sporadic disorder, probably reflecting genetic mosaicism for an autosomal dominant mutation which would be lethal if not 'rescued' by mosaicism [8]. To explain discordance in monozygotic twins, the mosaicism must have arisen after conception [9] and after the division into twin zygotes. The limited involvement (right eye and right side of the scalp only) in the affected twin [9] is also consistent with a relatively late mutation. Occasional occurrence in successive generations can be explained by inheritance of an unstable pre-mutation, or by loss of heterozygosity for a recessive mutation ('paradominant inheritance' [10]).

Clinical features. The cutaneous element of epidermal naevus syndrome can be sebaceous naevus, verrucous epidermal naevus [3,7,11–13] or syringocystadenoma papilliferum [14]. The naevus may grow abnormal hair, such as woolly hair [15], long, pale 'angora' type hair [16] or hair associated with follicular hyperkeratosis [17].

Additional cutaneous abnormalities seen in some patients include infantile haemangiomas, naevi flammei, hypochromic naevi, café-au-lait macules [18,19], congenital melanocytic naevi [19–21], Spitz naevi [22], follicular hyperkeratosis and dermatomegaly [11,13]. Ipsilateral facial lipoma with hemimegalencephaly has been reported in three cases of epidermal nevus syndrome [23].

Sometimes, the epidermal naevus involves the mucosae of the mouth, anus or genitalia [7,13,24,25]. Oral involvement may include dental enamel hypoplasia, malformations of the teeth and hypodontia [11,24] and maxillary giant cell granuloma [26].

Significant developmental anomalies occur in approximately 1.7% of all neonates [27] and 10% of children with epidermal naevi, the risk correlating poorly with number and extent of lesions. Skeletal deformities reported in the epidermal naevus syndrome include kyphosis, scoliosis, cystic and lytic changes, hypertrophy and atrophy, short limbs and syndactyly [7,11–13,28].

A similarly wide variety of neurological abnormalities have been identified in about 50% of patients with epidermal naevus syndrome [6,13,14,29–40]. Neurological abnormalities are much more frequent in patients who have sebaceous naevi on the head and neck [12,13,29,40], but the location of the skin lesions does not provide reliable prediction of the laterality of intracranial brain anomalies [41]. Seizures, especially infantile spasms, occur in some 50% of patients, many of whom have underlying structural abnormalities of the CNS [42]. Mental retarda-

tion also occurs in about 50% of cases; it varies in degree, but may be profound. Spastic hemiparesis affects about 20% of patients and may have its onset at any time from birth to adolescence; spastic tetraparesis has also been described. Conductive [43] and sensorineural deafness occur [11]. The commonest structural CNS abnormalities have been ipsilateral gyral malformations and complete or partial hemimegalencephaly [32,42,44–46], but others have included vascular malformations [31,35,47,48], hemiatrophy [34,37,49,50], posterior fossa abnormalities, lateral ventricle enlargement [34,51], porencephaly [52], agenesis of the corpus callosum [42] hamartoma [53] and intracranial or intraspinal lipomas [54]. Neuroimaging is surprisingly often normal, even in patients with clinical neurological abnomalities [40]. Cranial nerve palsies have also been described fairly commonly.

Some 35–70% of patients have ocular abnormalities [11,13,34,37,47–51,55–65], the commonest of which is involvement of the eyelid or conjunctiva by the epidermal naevus, sometimes causing trichiasis or interfering with lid closure. Other ocular problems have included colobomas of the eyelid, iris and retina, retinal dysplasia, conjuctival lipodermoids and choristomas. Cortical blindness, microphthalmia, macrophthalmia, anophthalmia, corneal opacities and cataracts have also been reported.

Many other non-cutaneous abnormalities have now been reported in association with epidermal naevi, including a variety of cardiac and genitourinary abnormalities [6,11,12], and endocrine disease [66,67], including inappropriate antidiuretic hormone (ADH) secretion [66] and precocious puberty [21,68,69]. In several patients, bone disease and/or muscle weakness has occurred secondary to vitamin D-resistant rickets [13,22,49,68,70–77]; some of these patients [22,74,76] have had radiolucent bone lesions, which were shown in one case to be angiomatous [76]. Debulking the epidermal naevi leads to biochemical improvement [68], suggesting that these epidermal naevi, or the associated intraosseous angiomatous tumours, secrete a substance that induces renal phosphate loss. A similar phenomenon occurs with a variety of benign mesenchymal tumours and occasionally with malignant tumours [78]. A strong candidate gene for 'phosphatonin', the postulated humoral factor responsible for tumour-induced rickets/osteomalacia, is fibroblast growth factor-23, localized to 12p13 [78]. One patient suffered both hypophosphataemic vitamin-D resistant rickets and precocious puberty [68]. An overlap has been suggested with the McCune–Albright syndrome [18], but radiologically the polyostotic fibrous dysplasia of the McCune–Albright syndrome is indistinguishable from the intraosseous angiomas reported with epidermal naevi [76].

Benign and malignant transformation may occur in these patients' epidermal naevi, exactly as it may when such naevi exist without associated abnormalities. However, insufficient attention has been drawn to the relatively high incidence of systemic malignancies that have arisen in patients with epidermal naevi, often at a very early age [13]. These have included nephroblastoma [13,28,36], salivary gland carcinomas [79], carcinoma of the oesophagus and stomach and breast [80], astrocytoma [81], glioma [82], mandibular ameloblastoma [25,83], transitional cell carcinoma of the bladder [84], rhabdomyosarcoma of the bladder [85] and intrathoracic teratoma [11].

Diagnosis. Epidermal naevus syndrome can be confused with the other epidermal naevus syndromes featuring verrucous epidermal naevi, such as Proteus syndrome, naevus comedonicus syndrome and phakomatosis pigmentokeratotica. CNS lipoma may lead to confusion with encephalocraniocutaneous lipomatosis [54].

Treatment. The management of a child with epidermal naevus requires careful clinical judgement. Most children with epidermal naevi are otherwise perfectly well and it is inappropriate to investigate a child who is thriving and developmentally normal. Parents can be informed of the 10% risk of associated abnormalities, but also reminded that most of these will be picked up on routine child health surveillance, such as problems with vision, hearing, growth and neurological development. There should be a low threshold for following up any reported problems, for example a disproportionate rise in head circumference, which may be the first sign of raised intracranial pressure. Children with epidermal naevus syndrome tend to have several associated abnormalities, so if a second developmental anomaly is detected it is appropriate to look for others. Reasonable non-invasive investigations would include ophthalmological assessment and cranial ultrasound. If the naevus is extensive, serum calcium and phosphate should be measured to exclude tumour-induced osteomalacia/rickets.

Phakomatosis pigmentokeratotica

The concurrence of sebaceous or verrucous epidermal naevus with speckled lentiginous naevus has been called 'phacomatosis pigmentokeratotica' [1–3]. It could be argued that speckled lentiginous naevus is simply one of the many localized anomalies associated with verrucous and sebaceous epidermal naevi, and that there is no justification for separating this particular association from epidermal naevus syndrome. Multiple melanocytic naevi have frequently been reported in association with epidermal naevus syndrome (see above). Intriguingly, hypophospataemic rickets, which has been reported in several patients with multiple melanocytic naevi and widespread verrucous epidermal naevi, has occurred in phakomatosis pigmentokeratotica [2].

Happle and colleagues have argued not only that phakomatosus pigmentokeratotica is a distinct syndrome with its own spectrum of associated abnormalities, but further that the lentiginous element might occur without the verrucous element as the (so far unrecognized) 'speckled lentiginous naevus syndrome' [4]. Happle suggests that phakomatosis pigmentokeratotica represents twin-spotting [1,2,4].

Dermal and subcutaneous naevi

Connective tissue naevi

Connective tissue naevi are circumscribed hamartomatous malformations of the dermal extracellular matrix, i.e. of collagen, elastic fibres or glycosaminoglycans [1,2]. They form a characteristic component of a number of well-defined inherited disorders, such as tuberous sclerosis and the Buschke–Ollendorff syndrome, but may also occur as isolated lesions without any identifiable genetic basis.

A wide variety of connective tissue naevi have now been described. The provisional classification in Table 15.2 is based on those proposed by Uitto *et al.* [1] and Pierard and Lapiere [2].

Table 15.2 Classification of connective tissue naevi.

Naevi of reticular connective tissue
Collagen naevi
Familial cutaneous collagenoma
Eruptive collagenoma
Plantar cerebriform collagenoma
Shagreen patch (tuberous sclerosis)
Knuckle pads
Other collagenomas
Elastic naevi
Pseudoxanthoma elasticum
Perforating elastoma
Juvenile elastoma and the Buschke–Ollendorff syndrome
Naevus anelasticus
Other elastic naevi
Proteoglycan naevi
Mucinous naevus
Dermal nodules in Hunter's syndrome
Naevi of adventitial connective tissue
Fibrous papule of the face
Angiofibromas and subungual fibromas in tuberous sclerosis
Pearly papules of the penis
Perifollicular fibromas and trichodiscomas

Collagen naevi

Familial cutaneous collagenoma

Several families have been reported showing autosomal dominant inheritance of a condition termed *familial cutaneous collagenoma* [1–3]. Similar skin lesions have also been reported under this title in the absence of documented family involvement [4].

Affected individuals present with multiple, asymptomatic, indurated dermal nodules distributed symmetrically on the trunk and upper arms, but particularly on the upper two thirds of the back. Individual lesions vary in diameter from a few millimetres to a few centimetres. The condition generally first becomes manifest during adolescence, and an increased rate of appearance of new lesions has been noted during pregnancy.

Histologically, the nodules showed an accumulation in the dermis of dense, coarse collagen fibres, with an apparent reduction in the number of elastic fibres.

Cardiological abnormalities were reported in some of these patients, and the suggestion was made that these might be a reflection of fibrosis within the heart.

None of these patients have had osteopoikilosis, distinguishing this disorder from the Buschke–Ollendorff syndrome.

Eruptive collagenoma

Other cases have been reported in which cutaneous nodules, more or less indistinguishable from those seen in familial cutaneous collagenoma, have arisen in the absence of any family history. The term *eruptive collagenoma* has generally been applied to such cases, because of the abrupt development of these lesions [5–10]. The same term has been used, however, for cases which would seem, on clinical and histological grounds, to fall more correctly into the category of *lichen myxoedematosus* [11].

Plantar cerebriform collagenoma

This rare lesion, imaginatively termed 'paving-stone naevus' [12], comprises a flesh-coloured cerebriform mass on the sole of variable size. Although this condition may occur in isolation [13–15], it is probably more often a component of the Proteus syndrome, in which they would be associated with a variety of other anomalies including macrodactyly and hemihypertrophy [16–18].

Tuberous sclerosis

The shagreen patch is a mamillated plaque-type collagenoma occurring, most often in the lumbosacral area, as a common and highly characteristic component of tuberous sclerosis [19–21].

Other collagenomas

A variety of other clinical types of collagenous connective tissue naevus have been described [22–25]. Association with Down's syndrome [22] has been recorded. A large collagenoma resembling a shagreen patch has been reported in a patient with multiple fibrofolliculomas [26]. A family has been reported in which scalp lesions diagnosed histologically as collagenomas were associated with cardiomyopathy and hypogonadism [27].

Elastic naevi

Juvenile elastoma and the Buschke–Ollendorff syndrome

SYN. DERMATOFIBROSIS LENTICULARIS DISSEMINATA

The association between connective tissue naevi of the skin and osteopoikilosis is now well recognized, and is generally known eponymously as the Buschke–Ollendorff syndrome [1,2].

The histological features of the skin lesions in such patients are highly characteristic [3,4]. While haematoxylin and eosin stained sections may fail to reveal any abnormality at all, those stained to demonstrate elastin will show thick, interlacing tracts of elastic fibres running between fairly normal collagen in the reticular dermis, an appearance to which the term juvenile elastoma has been applied. Ultrastructurally, the elastin comprises clumps, coated with fine fibrils, and the fibroblasts contain swollen endoplasmic reticulum containing abnormal fibrillar material [4–6].

Elevated elastin production [4] and elastin mRNA levels [7] have been demonstrated in cultured fibroblasts from individuals with the syndrome, suggesting a possible defect in pre-translational control of elastin production.

Two rather different clinical presentations have been described in the Buschke–Ollendorff syndrome. In some patients, there is a symmetrical eruption of uniform, small, asymptomatic lichenoid papules, sometimes reminiscent of pseudoxanthoma elasticum [5,8]; this type of eruption has been termed *dermatofibrosis lenticularis disseminata*. However, a second type of cutaneous presentation is more usual, comprising larger, yellowish nodules, often grouped and sometimes coalescing to form plaques [9–12] (Fig. 15.5). The distribution of these lesions is generally asymmetrical, and they may appear at any age, although most are present before puberty. Mixtures of these two types of lesions probably also occur. Although generally asymptomatic, occasional patients complain of pain, tenderness or pruritus in affected areas of the skin [12–14].

The second component of the Buschke–Ollendorff syndrome is a radiological abnormality termed *osteopoikilosis*, which comprises multiple, circumscribed, roundish or oval areas of increased opacity within bones, each usually measuring between 1 and 10 mm across [15] (Fig. 15.6). Such areas are found particularly frequently in the carpal and tarsal bones, in the phalanges, the epiphyses and metaphyses of the long bones and in the pelvis. They take several years to develop, but, after puberty, the appearances change very little. Histologically, these lesions are foci of tightly meshed bony trabeculae [16]. Osteopoikilosis has been identified in otherwise normal relatives of patients with the Buschke–Ollendorff syndrome; in such cases it presumably represents incomplete expression of the Buschke–Ollendorff gene. One imagines that, in at least some of these individuals, typical skin lesions will later make their appearance. Conversely, characteristic skin lesions have been reported in the absence of osteopoikilosis, even after puberty [10,17].

It is now clear that the Buschke–Ollendorf syndrome is transmitted as an autosomal dominant trait, albeit with

Fig. 15.5 Juvenile elastoma in the sacral area in the Buschke–Ollendorff syndrome.

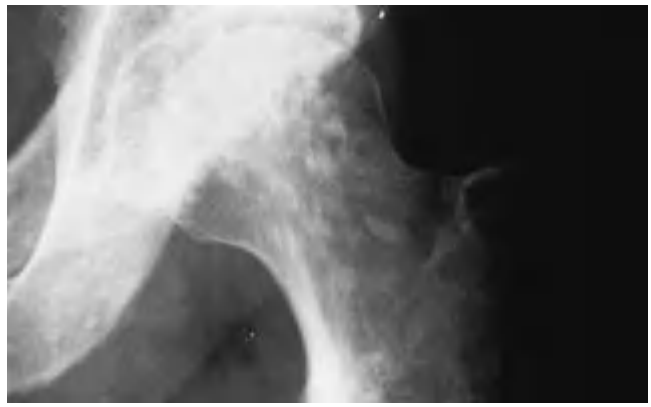

Fig. 15.6 Osteopoikilosis in the Bruschke–Ollendorff syndrome (X-ray of femoral head).

very variable expressivity. There is little evidence to suggest any overall increase in morbidity or mortality in this syndrome, although a number of possible associations have been reported. Otosclerosis has occurred in several cases; it seems likely that this association is a genuine one [18,19]. Muscle fibrosis or contractures have been reported in several cases [2,10,13,20] and are unlikely to be merely coincidental. Other possible associations have included spinal anomalies [18,21], short stature with or without precocious puberty [18,21] and peptic ulceration [13]. In one patient, the Buschke–Ollendorf syndrome was associated with protein C deficiency; it was suggested that this might reflect the fact that the genes for elastin and protein C are both located on chromosome 2q [22].

Papular elastorrhexis

Papular elastorrhexis is the name given in 1987 [23] to a distinctive condition that should probably be provisionally categorized as a type of elastic tissue naevus.

The clinical presentation [24,25] is with multiple small (1–3 mm) white papules, which are not follicular and are symmetrically distributed, predominantly on the trunk and, to a lesser extent on the limbs. The lesions tend to appear in the second decade of life. They show no tendency to group, or to merge into plaques. Biopsies consistently demonstrate diminution and fragmentation of dermal elastic fibres.

Although it has been suggested that it may be a variant of the Buschke–Ollendorff syndrome, cases so far reported have only once been familial [26], and in no case has osteopoikilosis or any other extracutaneous feature been associated.

Naevus anelasticans

Several authors have reported cases in whom groups of small, yellowish or pink, perifollicular papules were present on the trunk, sometimes resulting in a 'wrinkled' appearance of the skin [27–29]. Histologically, these lesions have demonstrated focal absence of elastic fibres. In the past, this condition was known inaccurately as *naevus elasticus of Lewandowsky* [28].

Other elastomas

Some cases reported under a variety of titles, including juvenile elastoma and naevus elasticus [29–31], may represent *formes frustres* of the Buschke–Ollendorf syndrome, but they may alternatively be genuinely unrelated forms of elastoma. An exophytic form has been reported [32].

A distinctive condition comprising bilateral, thickened and furrowed plaques on the cheeks with an increase in elastic tissue histologically has been described in two separate reports [33,34]. The patients were both young, and lacked any relevant family history. It is possible that sunlight played a role in the aetiology of these lesions.

Differential diagnosis of connective tissue naevi

Several conditions need to be considered in the differential diagnosis of connective tissue naevi. Among these are congenital smooth muscle hamartoma, leiomyomas, naevus lipomatodes superficialis and neurofibromas.

Proteoglycan naevi

Mucinous naevus

SYN. NAEVUS MUCINOSUS; LINEAR CONNECTIVE TISSUE NAEVUS OF THE PROTEOGLYCAN TYPE

There have been a very small number of reports of lesions of this type in recent years [1,2], but it is likely that in the past such lesions were at least occasionally reported under the broader title of cutaneous mucinosis of infancy [3]. Histologically, these lesions are characterized by the presence of large amounts of proteoglycan in the superficial dermis, associated with variable overlying hyperkeratosis, acanthosis and elongation of rete ridges. Van Gieson staining shows a broad band in the upper third of the dermis in which elastic and collagen fibres are virtually absent, and alcian blue staining at pH 2.5 shows that there is accumulation of proteoglycan in this area, which disappears following pretreatment with hyaluronidase.

Clinically, the lesions comprise asymptomatic groups of flesh-coloured or slightly pigmented papules having a firm velvety surface and a tendency to coalesce to form plaques. They are generally linear in disposition. Lesions may be present from birth but may also develop some years later.

Clinically, the differential diagnosis includes epidermal naevi, connective tissue naevi of other types, the skin lesions of Hunter's syndrome (mucopolysaccharidosis type II) (see Chapter 57) [4] and naevus lipomatosus cutaneous superficialis. Histologically, one would need to consider papular mucinosis (lichen myxoedematosus), acral persistent papular mucinosis, self-healing juvenile cutaneous mucinosis, cutaneous focal mucinosis and papular mucinosis of infancy. At least some of the cases described as linear or localized papular mucinosis of infancy should probably be regarded as examples of mucinous naevus.

Fibrous hamartoma of infancy

Histologically, fibrous hamartoma of infancy comprises a mixture of spindle cells forming fascicles, clumps of round cells resembling immature mesenchyme, and mature adipose tissue, located in the deeper part of the dermis and/or the subcutis [1].

It is a lesion that first appears during the first 2 years of life, but which can occasionally be present at birth [1,2]. It may be more common in boys [1,3]. It occurs most characteristically on the trunk, particularly in the axilla, and the upper limbs [2,3] but it may occur at almost any site, including the scrotum [4]. Lesions are almost always single. It generally takes the form of a slowly enlarging asymptomatic dermal nodule.

It can be cured by local excision.

Muscle naevi

Congenital smooth muscle hamartoma

SYN. CONGENITAL ARRECTOR PILI HAMARTOMA

Definition. Congenital smooth muscle hamartoma is a malformation of pilar smooth muscle, first described by Sourreil *et al*. [1]. It is relatively common, occurring in about one in 3000 births [2]. Familial cases have recently been reported [3], but the great majority of cases occur in a sporadic fashion.

There appears to be a rare acquired type of smooth muscle proliferation that has occasionally been described under the title *smooth muscle hamartoma* [4] or *acquired smooth muscle hamartoma* [5,6]. It is distinct from the congenital smooth muscle hamartoma as described below.

Pathology. The histology shows well-defined bundles of smooth muscle fibres, which stain with Masson's trichrome [7–9]. The fibres themselves are generally long and straight, and extend in different directions. Each bundle is surrounded in turn by a clear space and by collagen. They

Fig. 15.7 Congenital smooth muscle hamartoma on the thigh.

are scattered over a wide area in the reticular dermis, and may extend into the subcutaneous fat. Sometimes, there is associated hyperkeratosis, papillomatosis and increased epidermal pigmentation [9]. Electron microscopy has shown characteristic wavy or whorled myofilaments within the smooth muscle cells, and axons, mostly unmyelinated, adjacent to the smooth muscle bundles [7,8,10,11].

Clinical features. Lesions are generally single and are initially noted at birth or during the first few weeks of life, most often on the trunk or proximal limbs.

Smooth muscle hamartoma presents as a variably indurated, asymptomatic plaque, with irregular poorly defined margins, 1–10 cm across (Fig. 15.7), often showing prominent follicular papulation [2,7–10,12–14]. Usually skin-coloured or faintly erythematous initially, subtle bluish brown pigmentation is a feature of the established lesion [15]. Firm stroking may provoke temporarily increased induration or piloerection, sometimes called the 'pseudo-Darier sign' [2,12,16]; this may diminish with age [17]. Occasionally, fasciculation has been reported [13,18]. In the majority of cases, there is a single plaque, but more extensively distributed multiple lesions have also been reported [3,16,19,20].

Linear variants of congenital smooth muscle hamartoma have been reported, either with an atrophic appearance [21], or with hyperpigmentated perifollicular papules [22].

The natural course of congenital smooth muscle hamartomas is not firmly established, but they probably persist indefinitely [10], perhaps with gradual slight diminution in induration and hypertrichosis [2]. No significant associated abnormalities have been reported.

Diagnosis. Differential diagnosis is from solitary mastocytomas, pilar leiomyomas and connective tissue naevi, which are not hypertrichotic, and from congenital melanocytic naevi [15], simple hypertrichotic naevi and Becker's naevi. The greatest confusion has been with Becker's naevi, which may feature smooth muscle bundles in the dermis [23]. Lesions described in the literature as '*congenital Becker's naevi*' have been congenital smooth muscle hamartomas [24,25], and the two conditions are generally distinguishable by their age of onset, and by their characteristic histological features [7,16].

Congenital plexiform neurofibromas are frequently hypertrichotic [26], but are generally softer than congenital smooth muscle hamartomas, and are of course histologically distinctive.

Diffuse smooth muscle hamartoma

Several children have now been reported with an unusual diffuse type of smooth muscle hamartoma, presenting a unique clinical appearance [1–7]. Histology shows changes identical to the solitary type of congenital smooth muscle hamartomas, frequently associated with fragmented elastic fibres [7]. The baby is born with excess folds of rather firm skin on the limbs, particularly at the ankles and wrists, giving a 'Michelin baby' appearance. There is associated diffuse hypertrichosis, which may be especially marked at birth [1]. The palmar skin may have a rather cerebriform appearance [1]. One child also had cutaneous mastocytosis of urticaria pigmentosa type [8]. Another child had a paracentric inversion of chromosome 7q [9], suggesting that the gene responsible for the condition may be located on this chromosome. Personal experience with a case reported by one of us [1] suggests that the hypertrichosis and dermatomegaly will gradually diminish with time.

Congenital leiomyoma

Cutaneous leiomyomas are only very rarely present at birth. However, a case has been reported recently of a neonate born with a pedunculated, firm, purple, spherical mass attached to the heel, which proved to be a pilar-type leiomyoma histologically [1].

Striated muscle hamartoma

SYN. CONGENITAL RHABDOMYOMATOUS MESENCHYMAL HAMARTOMA; CONGENITAL MIDLINE HAMARTOMA

This entity has been recognized since 1986 [1]. A small number of cases have been reported since, occasionally under the title of *rhabdomyomatous mesenchymal hamartomas* or *congenital midline hamartoma* [2–7]. It has been suggested that it may be a first branchial arch anomaly.

Lesions are generally congenital and solitary. They occur at sites where striated muscle is found superficially. Most reported cases have occurred on the face, particularly on the chin [3,6,7], in a nostril [8] or on a lip [1], but others have been recorded on the anterior chest and in the perianal area [2]. They are usually soft and pedunculated or polypoid. Some may be elongated, and some have been branched.

Histologically these lesions show bundles of striated muscle fibres in the reticular dermis and the subcutis. They may also contain well-developed appendageal structures such as hair follicles, sebaceous glands, eccrine glands and ducts, nerve bundles and intradermal lobules of fat. It is the characteristic presence of these elements that is highlighted by the term rhabdomyomatous mesenchymal hamartoma [9].

Many of the cutaneous appendages that are a major cutaneous feature of *Delleman's syndrome* are striated muscle hamartomas, and any child in whom striated muscle hamartoma has been found should be examined carefully for other features of this syndrome [10]. Some cases of striated muscle hamartoma have occurred in association with a limited number of features that suggest the child may have had an incomplete form of Delleman's syndrome [11].

Striated muscle hamartomas need particularly to be distinguished from *fetal rhabdomyoma* and *neuromuscular hamartoma*. Fetal rhabdomyoma is a tumour of the subcutis that occurs in the neonate, and comprises a myxoid stroma containing undifferentiated mesenchymal cells with some that show differentiation towards embryonic skeleton [12]. Neuromuscular hamartoma, or a Triton tumour, occurs as a nodule in the subcutis comprising striated muscle mixed with nerves [13].

Delleman's syndrome

This rare syndrome was first described in 1981, and is now reasonably well defined [1,2].

There has been no evidence of genetic transmission in any of the cases so far reported, and the syndrome may be a reflection of mosaicism for a lethal autosomal dominant gene [3].

The condition is characterized by orbital cysts, cutaneous appendages which are most frequently seen in the periorbital and postauricular areas, focal cutaneous hypoplasia, developmental delay, convulsions and skull defects. Most frequently, the disorder is unilateral, and in those cases in which it is bilateral there tends to be unilateral predominance. The cutaneous appendages, which may take on bizarre finger-like or tubular forms, are histologically indistinguishable from striated muscle hamartomas [4]. The severity of Delleman's syndrome may be more variable than is currently recognized, and it is possible that, in at least some cases, striated muscle hamartomas are its minimal expression. The focal cutaneous hypoplastic lesions may comprise cutis aplasia, areas of atrophy and distinctly punched-out defects.

Delleman's syndrome requires differentiation from focal dermal hypoplasia, encephalocraniocutaneous lipomatosis [5,6] and from Goldenhar's syndrome.

Fat naevi

Naevus lipomatodes cutaneus superficialis

In this rare disorder, collections of mature lipocytes are situated ectopically within the dermis [1]. Associated histological abnormalities of the dermal connective tissue, blood vessels and epidermal appendages may also be seen within the lesions [2,3]. Electron microscopy has shown that the lipocytes are closely associated with capillaries, and it has been suggested that they may originate from pericytes, as in fetal lipogenesis [4].

Clinically, there are two principal presentations [3]. The first is the classic form, as originally described by Hoffman and Zurhelle [5], after whom these lesions are often eponymously known. In this type, a clustered group of soft, fleshy, skin-coloured or yellow nodules is found, most commonly on the lower trunk, especially on the back, buttocks or hips or abdomen, and on the upper posterior thighs [1,3,6–8]. Lesions have also been reported less frequently at other sites including the face [9] and scalp [10]. These nodules may be domed, sessile or pedunculated. Their surface is most often smooth, but can be wrinkled, cerebriform or they may have a peau d'orange texture. They are occasionally hairy [6], may contain comedo-like plugs [3,11] and have been associated with café-au-lait [12] or hypopigmented [13] macules. Although almost invariably asymptomatic, occasionally ulceration may occur [14]. They are generally present at birth, but may first appear during childhood or adolescence [6,15], and usually remain unchanged thereafter.

The second form comprises a solitary, domed or sessile papule, which develops in adult life, and has been reported at sites other than the lower trunk including the knee, axilla, arm, ear and scalp [3,16–19].

From a histological viewpoint, it should be borne in mind that similar dermal collections of adipose tissue may occur as a component of intradermal melanocytic naevi [3], and in the acquired lesion known as pedunculated lipofibroma [20]. Fat also tends to be found very superficially in the skin lesions of focal dermal hypoplasia, although clinically this condition is unlikely to be mistaken for naevus lipomatodes superficialis.

Lipoblastomatosis

Lipoblastomatosis is a rare, benign tumour of embryonic adipose tissue that occurs principally in infancy and early childhood. Around 90% of cases present in the first 2 years of life, generally in infancy [1]. Occasionally these tumours are already present at birth [2,3]. There appears to be a male : female preponderance of about 3 : 1 [4].

Most lesions occur on the extremities [1]. The clinical appearance of these tumours is not consistent, though they generally take the form of flesh-coloured or reddish swellings or plaques that are generally asymptomatic unless they are locally compressing important structures. The diagnosis is based on histology. The tumour may or may not be encapsulated, and may be well-circumscribed or infiltrative [2]. Lobules of lipocytes and lipoblasts are mixed with spindle and stellate mesenchymal cells, separated by fibrous septa. Serial biopsies have demonstrated maturation of the immature lipoblasts into lipocytes [1,5]. There may be foci of extramedullary haematopoiesis and prominent capillaries [3,4]. There may be an Alcian blue-positive myxoid stroma, leading to possible confusion with myxoid liposarcoma, a tumour that is extremely rare in early childhood.

Magnetic resonance imaging (MRI) can be helpful in gauging the degree of infiltration of these tumours and the quality of the signals may provide diagnostic clues [6].

Both localized and diffuse variants of this condition are benign, and, while there may be infiltration of neighbouring tissues, metastasis has never been reported. Where feasible, surgical excision is the recommended form of treatment, though recurrence may occur if this is incomplete, particularly in the diffuse variant [1].

Encephalocraniocutaneous lipomatosis

This neurocutaneous disorder has been recognized since 1970 [1]. To date, all reported cases have occurred sporadically, and both sexes have been affected [1–5]. Happle and Steijlen [6] have suggested that the disorder is due to a lethal autosomal mutation that can survive only in a mosaic state. Recently, a case has been reported in which a *de novo* mutation was demonstrated in the neurofibromatosis type 1 gene [7].

The principal cutaneous feature is multiple lipomatous hamartomas, which may be present from birth [4,5]. These comprise soft, skin-coloured or yellow, domed papules and nodules, which vary in diameter from a few millimetres to several centimetres. Most reported lesions have occurred on the head and neck, particularly in the scalp, where they may take the form of hairless plaques. Lesions have in most cases been unilateral, but bilateral lesions do occur. Histologically, most lesions demonstrate dermal fibrosis associated with increased amounts of subcutaneous fat, which extends into the reticular dermis, but some of the smaller papular lesions may show changes more closely resembling those seen in angiofibromas [5].

These cutaneous lesions are almost always accompanied by ocular anomalies, most often fleshy desmoid tumours [8], and a variable degree of mental retardation with or without convulsions. Intracerebral abnormalities also tend to be unilateral, on the same side as the cutaneous lesions; the most frequent finding is of unilateral cerebral atrophy with ventricular dilatation. Pathological studies in one case showed that lipomatous hamartomas were also present in the brain and leptomeninges [1].

Differential diagnosis will include focal dermal hypoplasia, oculo-auriculovertebral dysplasia (Goldenhar's

syndrome), oculocerebrocutaneous syndrome (Delleman's syndrome), Proteus syndrome and epidermal naevus syndrome.

Congenital lipoma

Rarely, one may find rounded, soft, smooth, skin-coloured masses, histologically lipomatous, in the neonate.

The most characteristic and important site for such anomalies is the lumbosacral area, though analogous lesions may, more rarely, occur further up the midline of the back [1]. Lumbosacral lipomas tend to have extensions into the spinal canal which attach to the spinal cord [2–7]. These extensions will generally pass through bone defects in the spine, and lumbosacral lipomas are therefore markers of spinal dysraphism. One should consider this diagnosis in any child with a lumbosacral swelling with normal overlying skin, though a wide variety of other skin lesions may commonly be associated [8,9], particularly infantile haemangiomas [10–12], macular vascular stains [13] and localized hypertrichosis [14]. The swelling will often cause deviation of the upper end of the gluteal cleft.

Lumbosacral lipomas may show some characteristic histological features, including absence of a capsule, fibrous tissue scattered within the mass, and a variety of unusual ectopic neuroectodermal and mesodermal tissues [15].

The vulva appears to be another predilection site [16,17].

Congenital lipomatosis

Congenital lipomatosis is a rare adipose tissue malformation in which accumulations of mature lipocytes are present in the subcutis and show a tendency to infiltrate adjacent tissues, particularly muscle [1,2]. The commonest site is the trunk, particularly the chest. The subcutaneous lesions form soft, usually mobile masses, which may be of substantial size. There may be underlying hypertrophy of bone and hemihypertrophy.

Although such lesions have been associated in some cases with haemangiomas and with macrodactyly, this disorder can be distinguished from both the Proteus and Bannayan–Riley–Ruvalcaba syndromes.

Neurolipomatosis

SYN. NEURAL FIBROLIPOMA; FIBROLIPOMATOUS HAMARTOMA OF NERVE

This is a rare condition in which mature fat and fibrous tissue accumulate around peripheral nerves of an extremity [1]; the median nerve is most often affected. There is a sausage-shaped tumour in the skin without muscle infiltration.

'Michelin tyre' baby

SYN. GENERALIZED FOLDED SKIN

Generalized folding of redundant skin results in an appearance that has fancifully been likened to the symbol of the French tyre manufacturer [1]. This rare cutaneous malformation was first reported in an otherwise normal baby girl in whom it had been present from birth [1]. The skin biopsy demonstrated diffuse lipomatous hypertrophy. A follow-up report recorded that the condition had gradually improved spontaneously [2,3]. Another baby girl has since been described in whom a more localized area of folded skin with similar histological features, was associated with microcephaly, mental retardation and deletion of the short arm of chromosome 11 [4,5].

There have been further reports of a similar folded 'Michelin tyre' appearance in otherwise healthy babies in whom the underlying lipomatous changes were histologically absent. Generalized smooth muscle hamartomatosis appears to be a cause in some cases, in which the redundant skin folds are associated with hypertrichosis. In another case, no histological abnormality whatsoever was identifiable, but a distinctive associated clinical feature was the presence of widespread stellate scarring [6]. Two further reports described the occurrence of folding of the skin in several family members, suggestive of autosomal dominant transmission [7,8].

Congenital generalized folding of the skin may also be a prominent feature of the Beare–Stevenson cutis gyrata syndrome [9]. However, most cases show more localized corrugation of the skin, particularly on the scalp, forehead, face and neck with furrowing of the palms and soles. In addition, patients show acanthosis nigricans, craniofacial anomalies, anogenital anomalies, skin tags and a prominent umbilical stump.

Vascular naevi

A number of useful reviews of this subject have been published in recent years [1–6].

Classification. Abnormalities of cutaneous vascular development have been classified mainly on clinical grounds. A great number of alternative names are used to describe identifiable varieties. In practice, it is not uncommon for lesions of different types to coexist in the individual patient [7,8].

The broad classification in Table 15.3 [5] will be used in this chapter.

Table 15.3 Classification of vascular naevi. (Based on Requena and Sangueza [5].)

Vascular tumours of infancy and childhood
Infantile haemangioma
Congenital haemangioma
Miliary haemangiomatosis of infancy
Tufted angioma
Kaposiform haemangioendothelioma
Verrucous haemangioma
Haemangiopericytoma
Glomangioma
Vascular malformations
Low flow
Capillary
'Salmon' patch
'Port-wine' stain
Naevus anaemicus and naevus oligaemicus
Mixed vascular malformations
Reticulate vascular naevus
Klippel–Trenaunay syndrome
Venous malformations
Blue rubber bleb naevus syndrome
Maffucci's syndrome
Zosteriform venous malformations
Gorham's disease
Other multiple vascular malformation syndromes
Lymphatic malformations
Microcystic
Macrocystic
Rapid flow (arteriovenous malformations)
Angiokeratomas
Angiokeratoma circumscriptum
Angiokeratoma of Mibelli
Solitary papular angiokeratoma
Angiokeratoma of the scrotum and vulva

Vascular tumours of infancy and childhood

Infantile haemangioma [1–3]

SYN. CAPILLARY HAEMANGIOMA; COMMON HAEMANGIOMA OF INFANCY

Definition. Infantile haemangiomas are benign developmental vascular tumours that appear during the first months of life, and which characteristically have an initial proliferative and a later involutional phase.

Nomenclature and classification. The nomenclature and classification of vascular developmental disorders has been the subject of great confusion. It is important to distinguish between genuinely angiomatous lesions, i.e. haemangiomas, and vascular malformations, although these may occasionally be difficult to differentiate on clinical grounds alone.

The term haemangioma designates a proliferative blood vessel tumour. As such tumours may occur in older children and adults, for example granuloma telangiectaticum and angiolymphoid hyperplasia with eosinophilia, the term 'infantile haemangioma' is preferable to describe the developmental type of haemangioma that arises in early infancy. This type of haemangioma has colourfully been called *strawberry naevus* or *strawberry haemangioma*, although in practice not all such lesions have a strawberry-like clinical appearance. The terms *capillary naevus* and *capillary haemangioma* have been used to describe infantile haemangiomas, but, although the description capillary haemangioma is perfectly correct and acceptable, the frequent and widespread misapplication of these terms to describe macular vascular stains of port-wine-stain type means that it is probably best to avoid their use altogether.

Infantile haemangiomas must be differentiated from other haemangiomas of infancy such as tufted angiomas, and from vascular malformations, whose clinical appearance may be similar in some cases, but whose aetiology, pathology and natural history are entirely different [4–6]. Lesions that were previously called *cavernous haemangiomas* were frequently not haemangiomas at all but vascular developmental malformations, and this term should probably therefore also be abandoned.

It is not uncommon for infants to develop more than a single infantile haemangioma, and most often the number of such lesions is fewer than 10. On the other hand, more rarely the situation arises in which an infant develops very large numbers of lesions, usually small (generally less than 1 cm) and numbering in the hundreds, an occurrence for which a wide variety of terms have been used, including *diffuse neonatal haemangiomatosis* [7], *disseminated haemangiomatosis* [8], *disseminated eruptive haemangiomas* [9] and *miliary haemangiomas* [10]. Whereas the term *multiple infantile haemangiomas* could reasonably be used to describe both the occurrence of small numbers of otherwise typical infantile haemangiomas and the presence of very large numbers of small lesions, the authors prefer to highlight the special problems that may arise in the latter situation by applying the term *miliary haemangiomatosis of infancy*. Cutaneous haemangiomas of this miliary type are particularly likely to be associated with systemic haemangiomas and an increased mortality, though in most cases complications due to systemic lesions do not occur. An attempt has been made to separate cases with systemic lesions from those without using the term *disseminated eruptive neonatal haemangiomatosis* for the former and the term *benign neonatal eruptive haemangiomatosis* [11] for the latter. A distinction of this type is highly artificial, as one cannot exclude the presence of systemic lesions without employing intensive investigation to do so, an approach that most clinicians would regard as unnecessary. The management of such cases requires a high level of awareness of the possible presence of visceral lesions, alertness for the development of symptoms resulting from such lesions, and limited investigations to identify cases at particular risk of high-output cardiac failure. Exclusion of visceral lesions in every case as a matter of routine is neither practical nor necessary.

Aetiology. Infantile haemangiomas are benign proliferations of vascular elements. Familial transmission has been recorded exceptionally [1,2]; in the vast majority of cases, infantile haemangiomas occur sporadically.

While many of the cells appear to be endothelial in nature, forming readily visible blood vessels, a large population of cells is present in these lesions that have not been fully categorized. Because pericytes and dermal dendrocytes have been identified in infantile haemangiomas in addition to endothelial cells [3], it has been suggested that they are tumours of a primitive cell type capable of differentiating in all these directions [4].

It is generally agreed that vascularization of fetal skin begins during the third month of intrauterine life, but these vessels do not anastomose with the deeper vasculature until later in gestation [5]. It has been suggested that infantile haemangiomas arise where islands of embryonic cutaneous angioblastic tissue fail to establish normal contact with the rest of the developing vascular system [6]. It has also been suggested that there may be analogies with the retrolental fibrovascular proliferation seen in premature infants given oxygen therapy, and this concept receives some indirect support from the higher incidence of infantile haemangiomas in infants born prematurely [7,8].

Capillary endothelium has the capacity to develop new vessels under certain conditions [9]. In particular, this requires the presence of angiogenic factors [10], and it is possible that infantile haemangioma cells are able to secrete such a factor themselves, as has been shown to be the case in certain other types of tumour [11]. An imbalance has been demonstrated between expression of angiogenic and anti-angiogenic factors within infantile haemangiomas and adjacent normal tissue [12]. Certain other types of cell may play a 'helper' role in endothelial proliferation. The mast cell has been an important candidate for such a role [13,14]; the finding that mast cell numbers are high in proliferating haemangiomas is therefore of considerable interest [15].

It has also been proposed that endogenous steroid hormones may play a role in the growth of infantile haemangiomas. Both increased serum levels of 17β-oestradiol and increased numbers of tissue receptors for this hormone in proliferating infantile haemangiomas have been demonstrated [16].

Recently, it has been recognized that infantile haemangiomas are a common sequel to chorionic villous sampling; one study reported a 21% incidence, and in a third of the cases, the haemangiomas were multiple [17,18]. It would be anticipated that placental injury would lead to increased detachment of placental cells into the blood. Infantile haemangiomas might therefore result from embolization of fetal placental endothelial cells via the right-to-left shunts characteristic of the fetal circulation. This hypothesis is supported by the finding that infantile haemangiomas share immunoreactivity for tissue-specific markers with placental endothelium, in contrast with other vascular tumours and malformations [19].

Pathology [3,15,20–23]. In the earliest phase of growth of infantile haemangiomas, there is a solid mass of proliferating endothelial cells, with few if any lumina. The nuclei are not pleiomorphic, and only occasional mitoses are visible. Later in the proliferative phase, capillary-sized lumina are apparent, lined by plump endothelial cells. Reticulin staining confirms that each group of endothelial cells is surrounded by a limiting membrane of reticulin fibres. PAS staining shows a thickened basement membrane beneath the endothelial cells lining the lumina. Initially, these lumina are slit-like, but gradually they become more dilated. Mast cells are plentiful during the proliferative phase.

The onset of involution coincides with an increase in apoptosis [24]. As involution proceeds, the haemangioma becomes progressively more organized, with distinct lobules separated by fibrous septa containing the larger feeding and draining vessels. In children aged 2 years and older, the number of vascular channels decreases, and the diameter of the lumina increases with flattening of the endothelial lining, resulting in a 'cavernous' appearance, which must not be confused with the appearance of a venous malformation. There is a simultaneous progressive increase in intra- and interlobular connective tissue and fat.

Expression of a wide variety of cellular markers alters during the lifecycle of haemangiomas. Immunohistochemical studies have documented increased expression of basic fibroblast growth factor (BFGF) within proliferating infantile haemangiomas, and its excretion in increased quantities in the urine, which fall as involution progresses [25].

The endothelial cells comprising infantile haemangiomas show intense and persistent immunoreactivity for a number of tissue-specific markers termed FcγRII, Lewis Y antigen (LEY), merosin and GLUT1. This group of markers is highly characteristic of placental microvasculature [19]. However, infantile haemangiomas failed to show immunoreactivity for markers of placental trophoblasts [26].

The location of individual lesions varies. The most superficial are confined to the papillary and subpapillary dermis, while deep lesions may partly extend into the subcutis.

Ultrastructural studies show the proliferative phase lesion to comprise highly active endothelial cells, with multilaminated basement membrane [27]. Mast cell microvillous projections can be observed alongside the vessel walls, parallel to the basement membrane laminations [28]. During the involutional phase, there are signs of vessel degeneration.

Histology of the small multiple type of infantile haemangioma is essentially identical [29–31].

Clinical features [1–6]. Infantile haemangiomas are the commonest tumours of infancy, with a prevalence of about 1–3% after the first few days of life [7–10], and up to 12% by the end of the first year [3,11]. There is good evidence of a higher incidence in infants born prematurely, about 13% at 1 year for all preterm infants, increasing in inverse relationship to birth weight [12,13]. Thus, at 1 year, the prevalence in preterm babies with a birth weight below 1500 g is about 16%, and, in preterm babies with a birth weight below 1000 g about 23%. Conversely, the prevalence in preterm babies with a birth weight over 1500 g is no different from that of full-term babies [11–13]. In another recent study, the prevalence of infantile haemangiomas at 1 year in preterm infants was shown to be inversely related to gestational age at birth, being recorded as 8% for babies born after the 35th week, 11% for those born between the 30th and 35th weeks, and 19% for those born between the 25th and 29th weeks [14]. Superficial infantile haemangiomas, sometimes multiple, have also been reported to occur with increased frequency in the fetal alcohol syndrome [15]. Very occasionally, apparently typical infantile haemangiomas have appeared for the first time in adult life [16].

Infantile haemangiomas become apparent during the first month of life in about 90% of cases, and virtually 100% by the ninth month. Approximately 65% of infantile haemangiomas are superficial, 15% deep and 20% mixed. The term 'deep' is preferable to 'subcutaneous' as most of those infantile haemangiomas that are covered with normal epidermis are situated largely in the dermis rather than in the subcutis, although they may extend to this depth.

In the case of superficial infantile haemangiomas, an initial 'precursor' lesion is often visible on the first day of life. These precursor lesions may be quite subtle, and most characteristically take the form either of a macular area of hyperaemia resembling a salmon patch or a pale port-wine stain, or a macular area of pallor resembling a naevus anaemicus [17–20]. The latter, pallid type of precursor

(a) (b) (c)

Fig. 15.8 Large, mixed infantile haemangioma at: (a) 3 months; (b) 16 months; and (c) 3 years. A course of oral prednisolone was given at 3 months.

lesion area may contain grouped punctate telangiectases from the outset, or these may develop within a day or two. A group of small, closely packed angiomas usually then develops within the area, rapidly enlarging and coalescing until the lesion is mature. However, apparently typical precursor lesions occasionally fail to progress into infantile haemangiomas. In about 20% of cases, infantile haemangiomas are present at birth without a precursor lesion.

The superficial infantile haemangioma is most commonly known as a 'strawberry' naevus or 'strawberry' haemangioma, on account of its usual clinical appearance in the form of a sharply circumscribed oval or round, soft, domed swelling of intense scarlet-red colour. The surface may be smooth or lobulated. A thin plaque type is a distinctive variant of superficial haemangioma.

Infantile haemangiomas may occur at any site, but about 60% occur on the head and neck. Next in frequency are lesions on the trunk, about 25% of the total, where favoured sites are the perianal area in both sexes, and the vulva in girls.

In some 80% of cases, a single lesion only is present, but in the remaining 20% lesions are multiple; occasionally, very large numbers may occur (see miliary haemangiomatosis of infancy) [21–23]. Apart from the occasional lesion that is fully developed at birth (congenital infantile haemangiomas), infantile haemangiomas increase in size over a period that varies from about 3 to 18 months. However, the great majority will have reached their maximum size within 6–12 months of their first appearance. It is only exceptionally that lesions continue to enlarge beyond the first year of life [24,25]. The final diameter may vary from less than 1 to 25 cm or more. Very large congenital lesions can obstruct delivery if they are not previously detected.

There is frequently a deep element to superficial infantile haemangiomas of strawberry type, particularly when these are large; such lesions should be termed mixed infantile haemangiomas (Fig. 15.8). In other cases, the infantile haemangiomas are entirely, or more or less entirely deep. Exclusively deep infantile haemangiomas take the form of soft, warm, round bluish masses beneath normal skin, although there may be a few branching telangiectases or an area of vascular staining on the surface. Deep infantile haemangiomas often feel like a 'bag of worms', and a useful feature in their distinction from other tumours is that they can generally be compressed to about half their original size, quickly regaining their original dimensions on release of pressure. Similarly, they often become larger and darker when the child screams or cries. Only about 7% of infantile haemangiomas are exclusively of this deep type. Where the naevus is mixed, it may be principally deep or principally superficial. The superficial element usually emerges from the centre of the swelling, often in several places.

It is commonly stated that deep infantile haemangiomas are more likely than superficial infantile haemangiomas to have been present at birth, and that they are more likely to be of 'cavernous' type histologically. However, such statements result from the previously widespread tendency to confuse deep infantile haemangiomas

with venous vascular malformations, which are not angiomas at all and have an entirely different natural history.

Large superficial veins may be present in the skin at the periphery of larger infantile haemangiomas.

Virtually 100% of infantile haemangiomas undergo spontaneous regression, which is complete or almost complete in about 95% [5,9,26–29]. Although there is considerable variation in the rate of involution of individual lesions, there is no evidence to suggest that deep lesions generally involute more slowly than superficial ones. About 30% of infantile haemangiomas lesions will have resolved by the fourth birthday, about 50% by the fifth and 75% by the seventh. Age at first appearance does not appear to affect materially the likely speed of resolution. Smaller lesions probably resolve more rapidly. An early onset of resolution is generally associated with a more rapid disappearance and a superior cosmetic result. Conversely, a late start to resolution is generally associated with a higher chance of incomplete regression. Lesions that resolve completely have almost always started to regress by the age of 5 years. There is very little evidence to support the widely held theory that ulceration accelerates the initiation of resolution.

Resolution of superficial infantile haemangiomas is heralded by a softening of the lesion and by the appearance of focal areas of greyish opacification in the central part of the surface. These foci gradually become confluent and extend towards the periphery of the lesion. When resolution has ceased, the affected area may be perfectly normal, but commonly it shows subtle atrophy and telangiectasia. With larger superficial lesions and at certain sites, particularly the lips, eyelids and upper chest, a residual sac of redundant and slightly atrophic skin commonly remains. Areas of previous ulceration frequently leave yellowish scars. Lesions in the scalp usually resolve without permanent alopecia in the affected area, unless previous ulceration has occurred.

Infantile haemangiomas at certain sites appear to regress particularly slowly and generally incompletely. This is certainly true of lesions on the nose (sometimes termed the 'Cyrano' or 'Pinocchio' nose), the lips and the parotid area.

The engorged superficial veins that may be prominent around larger infantile haemangiomas also seem to disappear when resolution is complete.

Diagnosis. There is rarely any difficulty making the diagnosis of infantile haemangioma, particularly in the case of the superficial type. The main problem has been to distinguish vascular malformations from deep or mixed deep and superficial haemangiomas of infancy. The literature contains many reports in which lesions called 'haemangioma', often 'cavernous' haemangioma, clearly relate to vascular malformations; these reports are frequently concerned with the failure of such lesions to resolve spontaneously, or the fact that they may enlarge, at puberty for example [1]. The principal features distinguishing vascular malformations are: (i) the history of a lesion present since birth; (ii) the lack of any tendency to spontaneous resolution, and (iii) the frequent presence in the area of the lesion of other elements such as port-wine staining,

eccrine angiomatous naevus and lymphangioma circumscriptum. Currently, ultrasound, computed tomography (CT) and MRI are of limited value in making the distinction, as both lesions tend to be reported as 'haemangioma'. However, the distinction is a very important one, and fundamental to the patient's correct management as it has such great effects on prognosis and therapy.

Several types of tumour occurring in infancy may present with cutaneous nodules resembling superficial, deep or mixed haemangiomas; these include congenital haemangioma, granuloma telangiectaticum [2], neuroblastoma [3,4], infantile myofibromatosis [5,6], rhabdoid sarcoma [7,8], fibrous hamartoma of infancy [9], fibrosarcoma [10], congenital leukaemia [11], haemangiopericytoma [12,13], rhabdomyosarcoma [14,15] and leiomyosarcoma [16].

Recent studies suggest that ultrasound can be useful in distinguishing infantile haemangiomas from other soft tissue tumours and from vascular malformations [17]. CT and MRI can also be useful in delineating the extent of an infantile haemangioma and in evaluating response to therapy [18,19].

Fig. 15.9 Small ulcerated infantile haemangioma on the nose, which will result in substantial disfigurement.

Complications of infantile haemangioma

Ulceration and haemorrhage

Ulceration is a frequent complication of superficial infantile haemangiomas, and occurs almost exclusively during the proliferative phase. The commonest type of haemangioma to ulcerate is the plaque type [1]. Ulceration is commonest at sites which are vulnerable to trauma or maceration. It is for this reason that lesions in the anogenital area very commonly ulcerate, and this may result in dysuria or pain on defaecation. Other sites at which ulceration often occurs are the ears, nose and lips, where it may rapidly cause permanent loss of tissue, and mutilation (Fig. 15.9).

Bleeding is commonly the forerunner to ulceration, and may complicate it at any time. Such bleeding may be no more than a slow ooze, but it is occasionally brisk; it is however very uncommon for significant blood loss to occur. When bleeding has occurred, parents may become extremely anxious, fearing their child may exsanguinate when out of their sight, especially at night. Occasionally, an enuresis-warning blanket may provide reassurance in this situation [2]. Normally, compression will stop bleeding, but in an emergency, tissue adhesive sclerosis may be life saving [3].

Ulceration will almost certainly be followed by scarring.

Fig. 15.10 Small upper eyelid infantile haemangioma obstructing the line of vision and indicating immediate intervention.

Infection

Secondary infection may occur in an ulcerated haemangioma, or following surgical intervention. Occasionally, this may lead to septicaemia, with a potentially disastrous outcome [4–6]. Group A streptococci appear to be particularly dangerous in this situation.

Malignant change

Although malignant change may be a complication of hepatic haemangiomas [7], it almost certainly never complicates cutaneous infantile haemangiomas. However, true malignant vascular tumours in infants might conceivably be initially mistaken for infantile haemangiomas, particularly when they have a deep location. Such tumours include malignant haemangioendotheliomas [8] and malignant haemangiopericytomas [9].

Heart failure

Shunting of large volumes of blood through a large infantile haemangioma may lead to high-output heart failure [10].

Systemic haemangiomas

Visceral haemangiomas may occur with or without coexistent cutaneous infantile haemangiomas [11]. They are most often, but not exclusively, encountered in association with miliary haemangiomatosis.

Impairment of vision [12–17]

Infantile haemangiomas involving the eyelids and/or the orbit can interfere with vision in several ways (Fig. 15.10).

Firstly, obstructive amblyopia may result if the lesion directly obscures the line of vision. Currently available data suggest that closure of the eye for only a few days during the first year can result in obstructive amblyopia, so that obstruction of the line of vision by an eyelid infantile haemangioma should be regarded as an emergency.

Secondly, lesions in the eyelid or orbit may lead to astigmatism, even when the line of vision is not obstructed, probably due to a direct pressure effect on the cornea, and this can lead to astigmatic amblyopia. Eyelid lesions able to cause astigmatism may be only a few millimetres in diameter. The only clue to orbital involvement, other than an eyelid haemangioma, is proptosis.

Very marked proptosis may lead to exposure keratitis.

Whatever form of treatment is selected for the haemangioma, referral to an ophthalmologist who is familiar with these issues will be indicated, and it will probably be necessary to patch the unaffected eye, in order to minimize amblyopia and strabismus.

Airway obstruction

It is important to consider the possibility that any infant with a cutaneous infantile haemangioma may have a concurrent subglottic haemangioma [18–20]. This is most likely if the cutaneous lesion is in the lower part of the face, or the neck [20,21]. There may be direct extension into the subglottic airway from these sites. Symptoms most characteristically first develop between weeks 6 and 12, with progressive stridor which is most marked during feeding or crying. Cough, hoarseness and cyanosis may also be present. Acute airway obstruction may occur suddenly during a period of rapid enlargement, or as a result of haemorrhage within the tumour, and it has been estimated that untreated subglottic haemangiomas are associated with a mortality approaching 50% [19].

Any suspicion of subglottic angioma is an indication for X-rays of the area, followed, if necessary, by direct laryngoscopy.

Involvement of the nose in the neonatal period may also obstruct respiration, as neonates normally will not breathe through the mouth. However, the obstruction generally occurs slowly enough to allow the infant to adapt, although inability to breathe through the nose is likely to interfere with sucking and therefore with nutrition.

Interference with feeding

Feeding difficulties may complicate haemangiomas on the lips, particularly if ulcerated, and those that restrict nasal breathing.

Obstruction of the external auditory canal

Infantile haemangiomas that encroach on the ear, particularly those in the parotid area, may obstruct the external auditory canal. Although this will interfere with hearing

in the short term, it will generally not affect the development of normal ear function in the longer term. Bilateral obstruction after the age of about 1 year would, however, be likely to interfere with normal speech development, but must be very rare.

Deformation of bone

Deformation of bone occasionally results from direct pressure of an infantile haemangioma, and this is particularly likely to happen in the calvarium, the orbit or the mandible [22]. Very rarely, large infantile haemangiomas of the face may provoke overgrowth of the facial skeleton or of the auricular cartilage [23].

Spinal dysraphism and anogenital anomalies

Infantile haemangiomas in the lumbosacral area may be associated with underlying spinal dysraphism, tethered spinal cord, sacral anomalies, lipomeningocoele, imperforate anus, and genital and renal anomalies [24–27]. MRI is indicated if there appears to be a risk of such an association, which appears to be highest when the haemangioma is of plaque type, when it crosses the midline and when there is an underlying swelling, which is likely to indicate an associated lipoma, the presence of which may be suggested by deviation of the upper end of the gluteal cleft.

*PHACES syndrome (**p**osterior fossa malformations, **h**aemangioma, **a**rterial anomalies, **c**ardiac anomalies and coarctation of the aorta, **e**ye abnormalities, **s**ternal cleft and/or supraumbilical raphe)*

An association between posterior fossa brain abnormalities and large facial infantile haemangiomas is now well recognized [24,28–33], and there is evidence that the association may occur more commonly in female infants [34]. The facial haemangiomas most characteristically take the form of extensive plaques, that appear to occupy one or more facial dermatomes, and they may initially be mistaken for port-wine stains. They may be either unilateral or bilateral. Ulceration is common. The commonest posterior fossa abnormality is the Dandy–Walker syndrome, but other abnormalities have included arachnoid cyst, cerebellar atrophy with enlarged cisterna magna and fourth ventricle, cerebellar atrophy with vermis agenesis, and agenesis of the corpus callosum. These posterior fossa abnormalities may be reflected clinically by macrocephaly, enlarging head circumference, hemiparesis, developmental delay, or may be found on imaging in the absence of symptoms. Ipsilateral intracranial haemangiomas may also occur; they are generally asymptomatic and appear to regress spontaneously in parallel with associated extracranial lesions [35].

Such structural brain abnormalities are the most common extracutaneous manifestation. Next in frequency are intracranial and neck arterial anomalies [36,37]. These anomalies are associated with a risk of aneurysms and cerebral infarction [38].

These patients may also have cardiac anomalies, particularly coarctation of the aorta [29], pharyngeal or laryngeal haemangioma, a wide variety of eye abnormalities, including glaucoma [39], and ventral developmental defects, most characteristically sternal clefting or a supraumbilical raphe [40–44]. Affected children may show only one extracutaneous component of this syndrome, or combinations of several.

Congenital haemangiomas

It is now recognized that there is a distinctive type of haemangioma that is already fully developed at birth [1,2]. These tumours have been detected by ultrasound from the 12th week of gestation [1]. Pathologically they differ from other infantile haemangiomas by not expressing tissue-specific markers found in placental endothelium, in striking contrast to infantile haemangiomas [3].

Clinically, the feature that principally distinguishes them is their lack of a proliferative phase, and their tendency to involute very rapidly with the whole process generally being complete within the first year [1,3]. An occasional but highly characteristic finding has been the presence of hypertrichosis and/or milia-like lesions [2,4].

There is also a rare non-involuting type of congenital haemangioma [5]. These tumours have always been single, with an average diameter of 5 cm, enlarging in proportion to the child's growth. The overlying skin often shows coarse telangiectasia. The ideal treatment is excision.

Miliary haemangiomatosis of infancy

Occasionally, infants are born with very large numbers, generally many hundreds of small infantile haemangiomas of 'strawberry' type, or develop these within the first few weeks of life [1,2]. In such cases, the cutaneous lesions are characteristically relatively small, generally between 2 mm and 2 cm in diameter. The lesions may bleed, and quite often at least some are pedunculated. This condition, which is perhaps best termed *miliary haemangiomatosis of infancy* (Fig. 15.11), should not be confused with the relatively common situation in which a child develops a number of otherwise standard infantile haemangiomas. In these cases, appropriately termed *multiple infantile haemangiomas*, the number of lesions present will rarely number more than 10, in great contrast to miliary haemangiomatosis of infancy, in which lesions will generally number several hundreds, often thousands.

Fig. 15.11 Miliary haemangiomatosis causing cardiac failure in a 3-month-old infant.

Major complications may supervene, generally due to the presence of associated systemic haemangiomas, and these are responsible for a significant mortality, probably currently in the region of 25% [3,4]. The mean age of death in a large series was around 10 weeks [3]. The most serious of all complications is high-output cardiac failure, which is almost invariably due to shunting through one or more large hepatic angiomas [4–7], and which may be present at birth [8].

Apart from the liver, haemangiomas are also commonly present in the gastrointestinal tract, spleen, pancreas, salivary glands, adrenals, larynx, lungs, heart, skeletal muscle, kidneys, bladder, testes, thymus, thyroid, bone, meninges, brain and eyes [3,5,9–29].

Other potentially lethal complications include convulsions [12], intestinal haemorrhage [18] and obstructive liver disease [16,23].

The Kasabach–Merritt phenomenon has been reported frequently. However, while these cases may demonstrate low-grade thrombocytopenia, with platelet counts in excess of 50 000/mm^3 [3,11,12,30,31], the term Kasabach–Merritt syndrome is not warranted and the threat of severe coagulopathy is very low indeed.

In addition, individual haemangiomas may cause a wide variety of features due to local pressure. Convulsions and nerve palsies are particularly characteristic [32,33].

Intrauterine complications may occur, particularly hydrops fetalis and haemorrhage [8].

Certain investigations are therefore more or less mandatory in any infant with miliary haemangiomatosis, whether or not there is clinical evidence of systemic involvement. These include a full blood count including a platelet count, urinalysis to exclude bleeding, faecal occult blood testing, a chest X-ray to determine heart size and to seek lung lesions that might cause arteriovenous shunting, echocardiography to establish output status, and an abdominal ultrasound examination to examine the liver [34]. Where suspected on clinical grounds, lesions in other organs may be sought by appropriate investigations, including the use of technetium 99m-labelled red cells [6,35,36] and MRI.

The small haemangiomas that characterize miliary haemangiomatosis of infancy involute spontaneously, and typically do so more rapidly than in the case of standard infantile haemangiomas, the skin lesions often more or less disappearing by the age of 12 months [22].

Management is essentially as for single or multiple infantile haemangiomas. Treatment is not always indicated, and the need for intervention should be guided by careful evaluation of the risk of serious complications. It appears probable that prompt initiation of pharmacological treatment can reduce the risk of development of high-output cardiac failure where this is not yet established, and can be valuable when it is [6]. Where such complications are already present, systemic corticosteroid therapy is urgently indicated and the authors would recommend either pulsed intravenous methylprednisolone or prednisolone in a dose of 3–5 mg/kg/day, depending on the level of risk. If steroids are not rapidly effective, interferon-α (IFN-α) should be considered [7]. Anxieties have been raised concerning whether the combination of steroids and IFN-α is beneficial, and whether it might be associated with increased toxicity [37]. It is unclear therefore whether it is best to use the combination or to discontinue systemic steroid treatment when initiating IFN-α.

Where high-output failure is established and fails to respond to pharmacological therapy, selective arterial embolization of the responsible high-flow lesions in the liver will need to be considered urgently [7,38,39]. Resection may also be an option for single lesions [7].

Treatment of infantile haemangiomas

In the absence of complications or substantial aesthetic handicap, the most appropriate management of infantile haemangiomas is generally expectant. No treatment is indicated where a good aesthetic outcome can be predicted with reasonable confidence, and where complications appear unlikely to supervene. It can be helpful to show parents serial photographs illustrating the spontaneous resolution that has been observed in other cases.

It is very important to be aware of the speed with which these lesions can enlarge during their initial phase of growth. The progress of lesions that are still increasing in size should therefore be supervised, especially where they occur at or close to the special sites mentioned above. The need for therapeutic intervention should be kept under review until the situation has stabilized.

Despite the good prognosis for spontaneous resolution of most infantile haemangiomas, there is no justification for therapeutic nihilism. The need for treatment of individual lesions should be carefully and sympathetically considered, and procrastination should be avoided because delay may severely reduce the opportunities for successful treatment. Even small lesions may result in major aesthetic handicap at certain sites, such as the tip of the nose, the lip or the forehead, and, while a good result may ultimately be anticipated following spontaneous resolution, sufficient psychological harm may have been done in the meantime to justify earlier therapeutic intervention.

Where infantile haemangiomas are causing or threatening tissue loss secondary to ulceration (e.g. on the nose or ears), where airway obstruction is threatened or feeding is impeded, where there is interference with important structures such as the eyelids, or where the aesthetic handicap is significant, immediate treatment should be contemplated.

Treatment options include: (i) systemic corticosteroids; (ii) intralesional corticosteroids; (iii) topical corticosteroids under occlusion; (iv) laser therapy; (v) compression; (vi) surgical excision; (vii) embolization; (viii) vincristine; (ix) cryotherapy; (x) IFN-α-2a; (xi) sclerosant injection; and (xii) radiotherapy. Each case requires careful assessment and observation, knowledge of the advantages and disadvantages of the available therapeutic options, and familiarity with the natural history of this tumour at various sites.

Systemic corticosteroids

Systemic corticosteroids are the treatment of choice in most situations in which therapy is indicated (see Fig. 15.8) [1]. However, it is important to be aware that they are only effective during the proliferative phase [2–7]. For this reason, there is some urgency in making the decision to start treatment. Oral corticosteroid therapy should therefore be initiated at the first sign that the patient is developing a significant eyelid lesion, cardiac failure or upper airway obstruction.

Prednisolone should be given in a daily dose of 3–4 mg/kg body weight for 4–8 weeks, followed by gradual reduction of the dose over a period of several weeks. Alternate daily dosage regimens tend to be ineffective if used from the start of treatment. If no response is seen after 3–4 weeks, prednisolone therapy should be abandoned. A good response can be anticipated in the great majority of cases if treatment is started sufficiently early at a dose no less than 3 mg/kg/day. Treatment should also be contemplated when the integrity of the nose, ears or lips is threatened. Rebound increase in size may occur if treatment is discontinued too soon in rapidly proliferative lesions. Since such lesions can generally be expected to continue to proliferate during the first 6 months of life, it is usually unwise to discontinue therapy altogether until the seventh month.

The mechanism by which corticosteroids prevent further growth and reduce the bulk of infantile haemangiomas remains unclear. It has been shown that corticosteroids are able to increase microvascular sensitivity to endogen-

ous vasoconstrictor substances [8], and this effect may impede endothelial proliferation. It is perhaps more likely that corticosteroids modify endothelial proliferation more directly. Corticosteroids have been demonstrated to have an inhibitory effect on angiogenesis in the presence of heparin and heparin fragments [9,10]. Corticosteroid molecules bind to steroid receptors within proliferating haemangiomas, and may thereby inhibit the binding of 17β-oestradiol; corticosteroid administration in this situation also appears to result in a reduction in the levels of circulating 17β-oestradiol [11].

Infants tolerate this type of therapy remarkably well, and it is very unusual for adverse effects to occur that will not reverse within months of discontinuing therapy [12,13].

Intralesional corticosteroids

Intralesional injection of corticosteroids may effect rapid shrinkage, and is a very popular treatment for lesions of the eyelids [14–18]. In general, two or three treatments are required at approximately 6-week intervals. The failure rate is around 30%. It is important to bear in mind that substantial quantities of corticosteroid are being injected and that significant adrenal suppression may occur [19]. Local complications are unusual [15], but have included subcutaneous fat atrophy and eyelid necrosis, orbital fat atrophy, eyelid depigmentation and localized dystrophic calcification [20–24]. Retrobulbar haemorrhage may occur [15], and there have been several reports of central retinal artery occlusion and blindness [25–28]. The incidence of complications, which include accidental injection of the eye itself and damage to the optic nerve, is higher when retrobulbar lesions are treated.

This treatment has been used successfully to arrest proliferation and to shrink infantile haemangiomas at other sites [29,30]. Superficial haemangiomas have shown the best response, though overall results have not been as good as for eyelid lesions. Complications have included cushingoid appearance, cutaneous atrophy and anaphylaxis [30].

Combination therapy with systemic and intralesionally injected corticosteroids has also been advocated [31].

Topical corticosteroids

It has been suggested that potent topical steroids, with or without occlusion, can be an effective treatment approach for small haemangiomas of infancy [32,33].

Interferon-α [34]

Recombinant IFN-α-2a was originally developed as an antiviral agent. During trials in patients with the acquired immune deficiency syndrome (AIDS), it was found that IFN-α-2a had an inhibitory effect on Kaposi's sarcoma. IFN-α appears to inhibit endothelial cell proliferation [35].

Experience in complicated cutaneous haemangiomas of infancy has suggested, but not firmly established, a useful effect for both IFN-α-2a [36–40] and IFN-α-2b [41,42]. It is extremely difficult to evaluate the results of such treatment in open studies in a disorder in which spontaneous resolution is the norm [43], and lack of benefit has been reported [44]. For the present, therefore, the true value of IFN-α remains unestablished. Its benefit appears more slowly than that of systemic corticosteroids and this is certainly a limiting factor when rapid shrinkage of a proliferating haemangioma is required. Treatment with IFN-α will generally need to be prolonged [45].

There are theoretical reasons to worry that combination of systemic corticosteroids and IFN-α may be contraindicated [46], though the possibility of syngergism has also been suggested [41].

The cost of treatment is very substantial.

Increased serum transaminase levels are almost invariable; increases up to five times the upper limit of normal are not a cause for withdrawal of therapy. Prolonged treatment carries a risk of thyroid dysfunction. Neurotoxicity, in the form of spastic diplegia, is now thought to occur in as many as 20% of infants treated with IFN-α-2a, possibly less with IFN-α-2b [47–49].

Vincristine

There have been reports indicating the potential value of vincristine given orally as a single weekly dose of 2 mg/m^2 of body surface area in the treatment of life-threatening haemangiomas [50,51].

Laser therapy

The 585-nm flashlamp-pumped pulsed dye laser [1–5] has been used in an attempt to prevent enlargement of lesions at the macular or initial plaque stage during their early development. However, recent data suggest that it is unlikely to be effective [5–8].

The 585-nm flashlamp-pumped pulsed dye laser can be used to lighten any superficial haemangiomas and to flatten thin lesions (i.e. less than 4 mm), but flattening cannot be anticipated in thicker lesions [2] because the depth of penetration is limited to about 1 mm. This type of laser has been used to treat the very small haemangiomas that occur in miliary haemangiomatosis [9], but the excellent prognosis of this type of haemangioma would argue against such an intervention.

The flashlamp-pumped pulsed dye laser has proven valuable for reduction of pain and initiation of healing in ulcerated haemangiomas, where the ulceration has persisted despite good wound care techniques [10,11].

Excision using the carbon dioxide laser may be useful for the cosmetic therapy of lesions persisting into adult life, particularly lesions in the mouth, although a degree of scarring is inevitable [12–14].

Another laser that has been used for infantile haemangiomas is the neomydium : yttrium aluminium garnet (Nd : YAG) laser, which emits in the near infrared region and can produce photocoagulation to a depth of 1 cm [15]. Successful treatment of fully developed infantile haemangiomas has been reported, albeit with some post-treatment scarring, although this is probably less marked than with carbon dioxide laser excision [16,17]. In one report, treatment with this laser was followed by intralesional corticosteriod injection [18]. Improvements in the treatment of thick haemangiomas with the Nd : YAG laser may follow the introduction of special techniques such as skin surface cooling during irradiation or compression of

Fig. 15.12 Incompletely resolved infantile haemangioma in a 10-year-old, requiring surgical excision of residual sac.

lesions using cooled glass [19,20]. Intralesional radiation using light guides has also been described as having value in the shrinkage of large haemangiomas [21,22].

The development of the sapphire tip Nd : YAG laser scalpel permits excision with excellent haemostasis, and may prove a useful tool in the surgical treatment of infantile haemangiomas [23].

Compression

Another approach to the treatment of infantile haemangiomas that may be useful in individual cases is compression bandaging or intermittent pneumatic compression [24–30]. While it is not proven that this treatment can accelerate spontaneous resolution, compression bandaging can certainly provide temporary reduction of bulk that may allow a child with a giant infantile haemangioma on the trunk or a limb to wear normal clothes. Respiratory distress and/or cardiac failure are potential complications of overenthusiastic application of compression to large haemangiomas [31,32].

Surgical excision

Surgical excision is most often indicated for the redundant folds of atrophic skin that frequently persist after spontaneous involution of larger infantile haemangiomas (Fig. 15.12).

Surgical excision is also indicated in certain situations earlier in the evolution of infantile haemangiomas. This approach is particularly suitable for those lesions that are fairly spherical, particularly where these are of mixed type as this allows closure to be straightforward. Surgical excision should be considered for eyelid lesions, where it may sometimes be preferable to other techniques, similarly for disfiguring but small facial lesions, such as those that occur on the forehead [33].

A particular situation where surgery can be very successful is the nasal tip haemangioma [34–38], which can lead to significant cosmetic handicap, and which is notoriously reluctant to resolve spontaneously.

Extensive and complicated infantile haemangiomas affecting the head and neck may warrant surgical treatment in selected cases [39], and may be most appropriately treated by combining different treatment approaches [23].

Reconstructive surgery is indicated where tissue destruction has occurred during the proliferative phase of infantile haemangiomas. This is most commonly appropriate in relation to the face, when ulceration has led to the loss of parts of the nose, lips or ears.

Surgical excision may also be indicated for cosmetic reasons in lesions that prove unusually slow to regress or which fail to resolve completely. Sympathetic consideration is warranted for lesions on the face in school-age children, and occasionally in younger children, and the arguments for and against such intervention need to be carefully considered. A uniformly negative approach to treatment of infantile haemangiomas remains prevalent among dermatologists and paediatricians, and this may, in the authors' view, result in much unnecessary morbidity.

Embolization

Embolization techniques have been found to be useful in the treatment of hepatic haemangiomas, particularly in infants with high-output cardiac failure [40–42]. There has been considerable interest in the possible value of these techniques for the treatment of occasional complicated infantile haemangiomas in the skin, particularly those that threaten vision, for the relief of airway obstruction caused by oropharyngeal and subglottic haemangiomas [43,44], and for the treatment of high-output cardiac failure.

Cryotherapy

Excellent results have been claimed for cryotherapy in the treatment of superficial and deep infantile haemangiomas [45,46], although there is undoubtedly some risk of scarring [47].

Sclerosant injection

Where involution is incomplete and accurate serial measurements over a period of at least a year show no further involution, the injection of sclerosing solutions [48,49] may shrink deep infantile haemangiomas. The solutions preferred include sodium citrate 30%, mono-ethanolamine oleate 5%, glucose 30% and saturated saline. Using a small needle, 0.5–5.0 ml is injected at fortnightly or monthly intervals. Excellent results have been claimed.

Metallic magnesium is a powerful sclerosant, and its insertion into rapidly proliferating infantile haemangiomas has been reported to be an effective treatment approach [50,51].

Radiotherapy

Although radiotherapy is still sometimes employed [52], its use is difficult to justify in the case of cutaneous haemangiomas, though it may occasionally have a place in the therapy of certain systemic haemangiomas where these are causing problems, in bones, pituitary fossa or in the liver [41], for example, where other approaches have failed or are not feasible. The results of a controlled trial cast doubt on the effectiveness of radiotherapy for infantile haemangiomas [53]. Furthermore, there are a number of undesirable long-term sequelae. Such treatment carries the risk of carotid artery occlusion [54]. There is also a longer-term risk of disturbed bone growth and hypoplasia of soft tissues such as the breast [55,56] and larynx [57], and of cataract following therapy of eyelid lesions [58]. Although in one large survey, no evidence of an increased risk of malignancy was found [59], others have disagreed [60–62]; the CNS and thyroid gland appear particularly at risk in this respect [62]. In addition, there have been reports of development at the site of the irradiation of basal cell carcinomas [63], squamous carcinoma [64] or angiosarcoma [65,66], and in addition bone, thyroid, breast and soft tissue tumours [67–70].

Treatment of cardiac failure

Early therapy aimed at reduction of the shunt is essential, if life is to be saved once high-output cardiac failure becomes manifest, although medical treatment may occasionally be effective [71]. Systemic corticosteroids may lead to regression of hepatic haemangiomas and reversal of cardiac failure. If this approach fails, hepatic artery ligation [72–75], partial lobectomy [76] or transarterial embolization may be indicated [40,77,78].

Other haemangiomas of infancy

Tufted angioma

SYN. ANGIOBLASTOMA [1–4]

This is a rare type of angioma, which is seen most often in prepubertal children of either sex. Most cases have had an onset during early childhood, and lesions probably most commonly are present at birth or appear in the early weeks of life. Acquired cases have also been described in adults [5–8]. The initial appearance of tufted angioma during pregnancy has been reported [9], as has the eruption of multiple lesions in an immunocompromised adult liver transplant recipient [10].

It is also now clear that this tumour and kaposiform haemangioendothelioma are together responsible for the great majority of cases of the Kasabach–Merritt syndrome [11,12]. Cases of the Kasabach–Merritt syndrome presenting to dermatologists will almost always be due to tufted angiomas.

Histologically, there is a lobular proliferation of plump, oval cells surrounding tiny slit-like lumina [3]. These blood vessels are tightly packed and organized in rounded tufts, scattered in the dermis, and often described as resembling cannon-balls. The tufts may occur deeply in the dermis, and into the subcutis [13,14]. Thin-walled lymphatic channels may be seen at the periphery of the cellular masses or throughout the dermis.

MRI has demonstrated extension into muscle and fascia [15].

Clinically, tufted angioma takes the form of a rather poorly delineated, pinkish macule that evolves into a deep-red or purplish, indurated plaque or nodule, up to 20 cm in diameter. The lesion may be a fully developed plaque or mass at birth. They need to be distinguished particularly from port-wine stains, morphoea, lipogranuloma,

connective tissue naevus, smooth muscle hamartoma, lymphoma and sarcoma. Most lesions are tender or painful, and fine lanugo hair and/or hyperhidrosis are often apparent over the surface of the lesion. The lesion may extend deeply through the subcutis, fascia and into muscle [1,15].

Most tufted angiomas expand slowly for a period of months or years, after which they stabilize. Although they probably mostly remain unchanged unless treated, on occasions they may slowly resolve spontaneously [6,16]. These tumours generally appear to behave in a benign fashion, but may progressively worsen in some cases [17].

Generally, excision has been performed, although incomplete excision may result in recurrence. Soft X-ray therapy has also been reported to be successful [18]. There has been a single report of successful treatment with the pulsed dye laser, although the depth of these lesions would suggest that this treatment would be unlikely to be helpful [19]. Potent topical corticosteroids have been reported to reduce pain [1]. Successful or partly successful use of IFN-α-2a has been reported [15,20,21], but not all lesions respond [22]. High-dose systemic corticosteroids may be beneficial [22], and perhaps this treatment or IFN-α-2a should be tried before proceeding to excision, particularly where lesions are extensive.

Kaposiform haemangioendothelioma [1–3]

Kaposiform haemangioendothelioma is a rare vascular tumour occurring exclusively in childhood. It generally makes its appearance rather later than infantile haemangiomas, often months or years after birth, and is frequently a cause of the Kasabach–Merritt syndrome [2].

In the majority of cases, these tumours develop in the retroperitoneum, most often presenting around the age of 1 year [1,4]. Less commonly the presentation is cutaneous, either superficial or deep [1,5]. In the skin, kaposiform haemangioendothelioma tends to be a single lesion, which initially has the appearance of an innocuous vascular stain, but in other cases the lesion is subcutaneous and initially inapparent. After a variable interval, usually a few months, the lesion starts to grow rapidly to form a mass [6], which is generally complicated by development of the Kasabach–Merritt syndrome [5]. Congenital lesions have been reported occasionally [7]. Cases have also been reported in which there have been multiple cutaneous lesions [7].

Histologically, kaposiform haemangioendothelioma is composed of lobules or sheets of tightly packed spindled or more rounded endothelial cells and pericytes, with an infiltrative pattern in the dermis, subcutaneous fat and muscles. They contain few vascular lumina. Nuclear hyperchromasia and atypia are generally absent or minimal, and mitoses are rare [1]. As in tufted angioma, thin-walled bloodless vascular channels may be seen at the periphery of the cellular masses or throughout the dermis and subcutis; it is not clear whether these are an integral part of the tumour, or an associated lymphangiomatosis, or perhaps lymphatic hyperplasia secondary to obstruction of the lymphatics [1,2].

It is possible that tufted angioma and kaposiform haemangioendothelioma are the polar forms of a single pathological entity, and histological overlap has been observed [7].

Mortality in retroperitoneal kaposiform haemangioendothelioma appears to be high. These lesions are often large and frequently bleed locally. Skin lesions appear to have a much lower mortality [5]. Spontaneous regression of skin lesions has been reported, generally within the first 5 years of life [2].

Kasabach–Merritt phenomenon [1]

SYN. KASABACH–MERRITT SYNDROME; HAEMANGIOMA–HAEMORRHAGE SYNDROME

Consumption coagulopathy is an uncommon but highly characteristic complication of haemangiomas in infancy (Fig. 15.13). It is now clear that this complication almost exclusively occurs in association with tufted angiomas and kaposiform haemangioendotheliomas, occasionally with congenital haemangiopericytoma, but rarely if ever in association with the common type of infantile haemangioma [2–4].

An analogous bleeding diathesis has also been described as a complication of glomangiomas [5], in association with Gorham's disease [6–8], the blue rubber bleb naevus syndrome [9] and of angiosarcoma, both in an infant [10] and in an elderly adult [11].

A low-grade consumption coagulopathy may occur on a life-long basis in association with extensive lymphatic and venous vascular malformations. However, this coagulopathy is characterized more by reduced levels of circulating fibrinogen and clotting factor, and by increased levels of fibrin degradation products, whilst platelet counts remain reasonably high, usually over 70 000/mm^3. Cases of this type have occasionally inappropriately been termed Kasabach–Merritt syndrome [12].

Fig. 15.13 Kasabach–Merritt phenomenon: a deep angioma which has rapidly increased in size and became indurated and tender, with extensive subcutaneous bleeding.

A degree of thrombocytopenia may also be noted in children with miliary infantile haemangiomas, although it is very rare for significant coagulation defects to supervene in such cases [13,14]. The term Kasabach–Merritt phenomenon is inappropriate for such cases.

Haemorrhage in the Kasabach–Merritt syndrome appears to be a consequence principally of platelet sequestration, with associated consumption of clotting factors, within the vascular bed of the angioma, which has been demonstrated using chromium-51 or indium-111-labelled platelets [15,16], and more recently by an immunochemical method using monoclonal antibody to CD61 (platelet glycoprotein IIIa) [17]. The platelet count is very often extremely low, frequently less than 10 000/mm^3. Activation of the fibrinolytic system leads to the development of a continuing consumption coagulopathy in which increased consumption of platelets and clotting factors is balanced by their increased production [18]. Activation of the fibrinolytic system in this situation can be detected by the appearance of fibrin degradation products in the circulation. Under certain circumstances, for example surgical procedures, it is possible for acute disseminated intravascular coagulopathy to supervene with disastrous results [19]. Microangiopathic haemolytic anaemia has also been described [20].

Angiomas leading to the Kasabach–Merritt phenomenon may be cutaneous [2], intrathoracic, most often mediastinal, abdominal, especially retroperitoneal or intrahepatic [21,22], pelvic [23] or skeletal [7,8,24].

Cases of Kasabach–Merritt phenomenon presenting to dermatologists will almost all be due to tufted angiomas. Most of these cutaneous tumours are present at birth or appear during a period of months thereafter [25]. They are usually single lesions, taking the form either of an infiltrated reddish-blue plaque or a less defined deeper bluish tumour. They most commonly occur on the trunk, neck and proximal parts of the limbs, particularly the thighs and shoulders. The onset of Kasabach–Merritt phenomenon is signalled by a sudden and rapid increase in volume of the tumour, by a change in colour to a deeper violet, by the appearance of ecchymosis, which generally extends some way beyond the margins of the tumour, and often by tenderness. The rapid expansion of the angioma may cause potentially lethal compression of neighbouring vital structures, particularly when the lesion is in the cervicofacial area. In some case, the coagulation defect may already be present at birth [26], and it will become apparent in most cases within the first year of life. Occasionally, the onset of the coagulopathy is more delayed.

As a result of the coagulopathy, internal bleeding may occur at a great variety of sites, and is associated with a significant mortality, which reaches 40% of cases in some reported series [27].

If there is any doubt about the location of the angioma responsible for the Kasabach–Merritt phenomenon, an indium-111-labelled platelet scan may be invaluable [28,29].

Spontaneous resolution of the coagulopathy can be anticipated within a period of 1–6 years, and a mean of around 3 years [2]. Whereas the coagulopathy resolves, the causative tumour generally remains [3]. Where the responsible tumour is close to a joint, there may be residual limitation of joint mobility; this appears to be particularly common at the shoulder.

The Kasabach–Merritt phenomenon remains potentially lethal, particularly where the causative tumour is internal or where a more superficial tumour behaves in a rapidly infiltrative manner. However, treatment may itself have fatal complications. Because spontaneous resolution of the coagulopathy can be anticipated in the majority of cases [30,31], treatment is only absolutely indicated when it is likely that the patient's life is threatened. The choice of treatment will be determined by several factors, particularly the severity of the coagulation defect, the site of the causative tumour, and the presence or absence of associated mechanical compression of neighbouring viscera. Treatment of the Kasabach–Merritt phenomenon is characterized by highly variable responsiveness, and considerable versatility may be required in order to obtain control of the coagulopathy. Frequently multiple therapies are needed.

Systemic corticosteroid administration has been reported to have a directly beneficial effect on the disturbed coagulation–fibrinolysis system [32], and has occasionally proved valuable in the Kasabach–Merritt phenomenon [7,30,32]. Initial dosage should be between 2 and 4 mg/kg/day of prednisolone. Intravenous pulse therapy may be useful as a short-term measure [33,34]. General experience has been that prednisolone therapy is disappointingly ineffective when the coagulopathy is severe [35–37].

Benefit has been reported for injections of IFN-α-2a [38–40]. However, because the benefit is slow, this method is generally unlikely to be appropriate for the management of acute profound coagulopathy, but be worth considering when the coagulopathy is of relatively low grade.

Improved haemostasis can be accomplished by the use of platelet transfusions [41], although the effect tends to be abbreviated by rapid consumption of the platelets and clotting factors. In some cases, the coagulopathy may be worsened [42]. The principal use of this approach is in the preparation of the patient for surgical procedures including embolization.

Inhibitors of platelet function appear to have a limited role [43,44], although this has been disputed by reports of successful use of ticlopidine combined with aspirin [45,46], and of pentoxifylline [47]. There have been reports suggesting a role for inhibitors of fibrinolysis [31,48,49]. The concept of antifibrinolytic therapy, with agents such as tranexamic acid [50] or epsilon–aminocaproic acid [29], is that local thrombosis will be encouraged within the angioma vascular bed, reducing blood flow. Cryoprecipitate may also be required as a source of fibrinogen [49]. Recently, successful control of the coagulopathy has been reported with antithrombin III administration [22].

Although the spleen is often enlarged, splenectomy appears to be not only dangerous but also ineffective.

Limited experience suggests that continuous bandaging or intermittent pneumatic compression may be an effective treatment in controlling coagulopathy in the event that the lesion is appropriately sited, which is the exception [19,51].

Embolization can be an exceedingly valuable treatment [21,33,52–55], and can result in rapid and permanent reversal of severe acute coagulopathy.

Vincristine has proven very effective in the Kasabach–Merritt phenomenon, perhaps because it becomes bound to platelets and is therefore released preferentially at sites of platelet sequestration [2,25]. The recommended dose is 1.0–1.5 mg/m^2/week by slow intravenous infusion for at least 7 weeks, then with decreasing frequency, depending on response. This treatment appears to have a rapidly beneficial effect on the coagulopathy, and generally can also be expected to lead to shrinkage of the causative tumour over a period of months [25]. Successful combination treatment including vincristine has also been reported [56].

Surgical extirpation of tumours causing the Kasabach–Merritt phenomenon has been achieved in a number of cases with rapid relief of the coagulation defect [22,35,43,57], so long as adequate intraoperative haemostasis can be achieved. In the absence of adequate control of bleeding, surgical intervention may be catastrophic, and for this reason should not be contemplated unless embolization has been considered. On the other hand, surgical treatment may be more useful in the post-acute situation where the coagulopathy is controlled but the residual tumour is painful.

Radiotherapy may be effective in improving the coagulation defect [58], although the benefit may be rather delayed. Despite the risk of long-term complications [59], this approach has its advocates [27,60,61], and requires consideration in particularly difficult cases, although generally embolization should be preferred.

In general terms, the management of patients with the Kasabach–Merritt phenomenon should be as conservative as possible. Serial clotting studies and platelet counts should be undertaken, and the levels of fibrinogen and fibrin degradation products should be monitored. Oral corticosteroid therapy should be initiated early, and the

lesion should be compressed where this is possible. If the situation deteriorates, the relative merits of embolization, surgery, radiotherapy and infusions of vincristine should be weighed up. Frequently, the appropriate management will involve multiple therapies, used simultaneously or sequentially [62]. The likelihood of eventual spontaneous recovery of normal haemostasis and eventual regression of the angioma should be borne in mind at all times. It appears that vincristine and IFN-α may induce more long-term benefit in terms of tumour shrinkage.

Verrucous haemangioma [1–3]

This appears to be a distinctive entity. Although almost invariably present at birth, verrucous haemangiomas may appear later, even in adult life. Lesions are single or grouped, occurring on the legs in the great majority of cases. Small satellite lesions are commonly present. Sometimes lesions have a linear or serpiginous arrangement [1,4]. A variant has been described in which multiple lesions occurred in a more disseminated distribution, without evidence of systemic lesions [5]. Another variant has been termed digital verrucous fibroangioma [6].

They tend to start life as well-defined, dark-red, macular areas of vascular staining resembling port-wine stains, sometimes developing into soft, bluish red, vascular swellings. After a variable number of years, lesions start to take on their characteristic bluish black hue and an increasingly verrucous surface. Recurrent bleeding and infection often cause the patient to seek medical advice for the first time at this stage [7].

Histologically, verrucous haemangiomas are characterized by a hyperplastic epidermis showing orthohyperkeratosis, papillomatosis and irregular acanthosis with elongated rete pegs. The underlying dermis shows vascular spaces of variable size, which are congested with blood and which fill the rete pegs. There are lobules of capillaries in the subcutis interposed with fat cells and fibrous tissue [3,8]. The capillaries are lined by flat endothelium. The endothelium stains strongly with CD34, and the pericytes surrounding these vessels stain strongly with HHF-35 (anti-muscle specific actin).

Clinically, these lesions are frequently misdiagnosed, most commonly as infantile haemangioma or angiokeratoma, sometimes as lymphangioma circumscriptum or verrucous epidermal naevi.

They are best treated by excision [1,8,9]. Larger lesions will need grafting. There is a tendency for recurrence to occur unless excision is complete [3,7,10].

Digital verrucous fibroangioma

This lesion is regarded as a variant of verrucous haemangioma, based on its histological features [1]. It is however sufficiently distinctive clinically to warrant separate description. Lesions are generally single, and present from birth. They take the form of asymptomatic, soft to firm, domed nodules on the dorsum of a finger. Initially they are skin-coloured; with time they darken to a purplish brown colour.

Haemangiopericytoma

This vascular tumour is more fully considered in Chapter 53. However, it is a tumour that should be mentioned specifically in connection with infancy because about 3–5% of all haemangiopericytomas are congenital, with a pattern of behaviour that sets them apart from other haemangiopericytomas. In this subgroup, tumour growth may be very rapid and the histological features may suggest malignancy. Such tumours have mostly occurred subcutaneously on the head and neck, the trunk and limbs, and also internally. They generally have a dark red colour, suggesting a vascular origin. Despite the worrying

histological features, these tumours appear to be biologically benign; they may resolve spontaneously [1] or be cured by excision [2]. Local complications have included external haemorrhage. Recurrence may follow incomplete excision [3].

Fig. 15.14 Plaque-type glomangiomas on the back of a 14-year-old girl, which enlarged progressively.

Glomangiomas

SYN. MULTIPLE GLOMUS TUMOURS; GLOMANGIOMATOSIS

Although the commonest type of glomus tumour is the solitary form, which most frequently presents in young adult life, multiple forms are occasionally seen, predominantly in children, and these may cause substantial diagnostic difficulty.

Glomus cells are considered to be modified smooth muscle cells [1,2], which line the endothelial walls of structures known as *glomus bodies*. They are small cells which have eosinophilic cytoplasm and rounded, centrally placed nuclei [3]. They form structures termed glomus bodies which are found in the reticular dermis, and which are believed to function as temperature receptors. The solitary glomus tumour is an encapsulated proliferation of glomus cells lining small vascular lumina. In contrast, the childhood types are not encapsulated, and feature larger, more irregular vascular spaces, with fewer glomus cells; this type of lesion is considered hamartomatous and is now more usually termed *glomangioma*. Where a substantial proportion of the cells have the spindle appearance of conventional smooth muscle, the term *glomangiomyoma* has often been used [4].

Multiple glomus tumours generally have an earlier onset [2,5]. They are subdivided into three types:

1 disseminated multiple glomangiomas;
2 localized multiple glomangiomas;
3 plaque-like glomangiomas (glomangiomatosis).

Disseminated multiple glomangiomas. In the disseminated form, compressible red to blue papules or nodules, usually less than 1 cm in diameter, but occasionally larger, are widely distributed [6]. Their number is generally less than 10, but may occasionally be much greater [2,5]. Pain is less evident than it is in solitary glomus tumours [6].

Familial cases have been reported with what seems likely to be autosomal dominant transmission with variable penetrance and expression [2,4,7,8]. A mutation responsible for this condition has recently been identified and localized to chromosome 1p21–22 [9].

Localized multiple glomangiomas. The localized type of multiple glomangiomas features grouped blue nodules, which are usually limited to an area such as the hand or leg [3,10]. Mild pain may be present.

Congenital plaque-like glomangiomas. Plaque-like glomangiomas are extremely rare congenital lesions. They comprise numerous reddish blue compressible papules grouped in solitary or multiple plaques, each generally measuring between 10 and 20 cm across [11–14]. The lesions are soft, and the papules of which they are composed may be discreet or more confluent [15]. Such lesions may be painful. The centre of the plaque may be depressed [16]. The affected area may sag, and facial lesions may be very disfiguring [15]. Lesions affecting the lips tend to be spherical, soft, bright red nodules.

Some familial cases have been reported, suggesting an autosomal dominant transmission with variable expression [15,17,18].

Later onset has been described [19]. Partial involution has been described [20]. However, their normal behaviour is one of progressive growth with gradual enlargement of existing lesions and appearance of new lesions at previously unaffected sites (Fig. 15.14).

Deep infiltration into underlying muscles may occur [15].

Such lesions must be distinguished from tufted angioma, congenital plaque-like blue naevi [21], and from venous vascular malformations [11]. The latter distinction may be difficult, and can be simplified by the use of MRI [15].

Treatment has been disappointing, with poor response to pharmacological agents, to sclerotherapy and gradual recurrence after surgical resection [15].

Vascular malformations

Vascular malformations are structural defects of vascular development. They can be subdivided into high- (arterial malformations and single arteriovenous fistulas) and low-flow types (capillary, venous and lymphatic malformations), although mixed anomalies are common (particularly capillary–venous, capillary–lymphatic and arteriovenous) [1–4].

Some types of vascular malformation are liable to be confused with infantile haemangiomas, particularly some types of venous and lymphatic malformation, and the term cavernous haemangioma has often been, and often still is, applied to lesions that are not haemangiomas at all, but one of a variety of vascular malformation. Although there may sometimes be a degree of clinical overlap, such vascular malformations can be distinguished pathologically by their lack of endothelial cell proliferation, and clinically by their presence at birth and their lack of any tendency to spontaneous resolution. They will generally grow in proportion to the child, although they may gradually increase in size, sometimes rapidly as a reflection of thrombosis, sepsis or trauma.

Under this heading we will consider those types of vascular malformations that are of most concern to the dermatologist.

Capillary vascular malformations

SYN. TELANGIECTATIC NAEVI; VASCULAR STAINS

While this macular type of vascular anomaly has traditionally been separated into two principal types, the 'salmon patch' and the 'port-wine stain', the distinction is not always clear. Glabellar, forehead and upper eyelid salmon patches tend to fade very substantially, but similar lesions elsewhere, that are generally also called salmon patches, persist permanently. At several sites these lesions are called port-wine stains and salmon patches alternatively, for example those lesions on the upper lip or in the sacral area, and this can lead to substantial confusion. For this reason, there is a trend towards calling both types of lesion simply 'vascular stains'. In a recent review, the authors have called both types of lesion 'naevus flammeus', but have divided them into 'small' (salmon patch type) and 'large' (port-wine type) [1].

Salmon patch

SYN. NAEVUS SIMPLEX; NAEVUS FLAMMEUS SIMPLEX; ERYTHEMA NUCHAE; UNNA'S NAEVUS; 'STORK BITE'; 'ANGEL'S KISS'

Salmon patches are extremely common anomalies, which have been observed in the neonatal period in about 20–60% of children of all races [1–13]. The apparently greater

incidence in white neonates reported in some studies may simply relate to the greater ease with which subtle salmon patches can be seen in white skin.

Like port-wine stains, these lesions have in the past been called *naevus flammeus*; this term is therefore best avoided. There is evidence of a definite genetic influence in their aetiology, and both nuchal and facial salmon patches seem to be inherited in an autosomal dominant manner [14–16].

Histologically, no abnormality may be apparent in infancy, but persisting nuchal lesions in adults show dilatation of subpapillary capillaries [17].

Clinically, the lesions take the form of irregular, dull, pinkish red, macular areas, often featuring fine, linear telangiectasia. The nape of the neck and the occiput are by far the most commonly affected sites, but facial lesions (on the glabella, forehead, upper eyelids, tip of the nose or philtrum) are also frequent, as are lesions elsewhere in the scalp [4,8,12,18,19]. Less frequently, there may be lesions at sites on the posterior trunk and, occasionally, the limbs. In a recent survey, nearly 1% of neonates were found to have a lesion in the sacral area [19]. Lesions are often present at more than one of these sites. However, where lesions occur at sites other than the back of the neck and the occiput, there will almost invariably be a lesion present at these sites in addition.

Lesions on the face fade rapidly, and most will have more or less disappeared within a year [4,11]. However, they may become transiently visible again during crying or exertion, particularly in the case of forehead lesions. Lesions at other sites tend to be much more persistent, and probably remain unchanged into adult life in most cases [11,20]. A reasonable working estimate of the frequency of persistent nuchal salmon patches in adults is in the region of 20–30%. Although such lesions are generally covered in hair and therefore inconspicuous, they appear to be a predilection site for other dermatoses, such as psoriasis and seborrhoeic dermatitis [21].

Sacral lesions are of significance as they may occasionally be associated with spinal dysraphism [19,22,23]. These may be single or grouped, single lesions frequently being of triangular or rhomboidal shape, generally not exceeding 4 cm in diameter [19,24]. The presence of such a lesion in a neonate only warrants anxiety if it is associated with a second abnormality, particularly a lipomatous swelling, or a haemangioma, pit, dimple, sinus, localized hypertrichosis, cutis aplasia or a congenital melanocytic naevus. In the absence of such a lesion, further investigation is probably unwarranted [25].

Port-wine stain

SYN. NAEVUS FLAMMEUS

Definition. A port-wine stain is a vascular malformation of developmental origin characterized pathologically by ectasia of superficial dermal capillaries and clinically by persistent macular erythema.

Terminology. The port-wine stain is a less common but a more important lesion than the salmon patch. The term *naevus flammeus* has been applied to both, although most authorities would prefer to restrict its use to port-wine stains. In the past, port-wine stains have frequently been termed 'capillary haemangiomas', which they are not; unfortunately, this confusing practice still persists.

Aetiology and pathology. At birth, histological abnormalities are absent or minimal [1,2]. There is progressive

ectatic dilatation of mature dermal capillaries, which is initially most marked immediately below the epidermis [3]. The ectasia gradually involves increasingly deeply situated dermal blood vessels, although the number of affected vessels is always greatest in the upper dermis [1].

The endothelium is of normal appearance, and the total number of dermal blood vessels is probably not increased. It has been suggested that the lesion occurs as a result of a developmental weakness in the supporting elements of the blood vessel wall, although a recent study failed to demonstrate any gross quantitative or qualitative abnormality of distribution of immunofluorescent antibody-labelled type IV collagen, fibronectin or factor VIII [4].

The distribution of lesions on the face in areas roughly corresponding to those of sensory branches of the trigeminal nerve [5] has frequently been interpreted as suggesting that their pathogenesis may have a neurogenic basis, and in the past it was popular to ascribe them to neurological birth trauma [6]. It has now been demonstrated that the cutaneous superficial vascular plexus in port-wine stains has a greatly diminished density of perivascular nerves, suggesting that diminished neural influence on vascular tone may be the cause of port-wine stains [7–9].

Occasionally, lesions that appear to be identical to congenital port-wine stains have made their initial appearance later in childhood or in adult life [10–12], and may have followed trauma, possibly as a result of damage to the microvascular nerve supply.

Familial multiple telangiectatic naevi having the appearance of small port-wine stains have been reported on several occasions [13,14].

Clinical features. Port-wine stains are almost always present at birth, although they may initially be concealed by the normal hyperaemia of the neonatal skin. The reported incidence in the newborn has been from 0.1 to 2.0% [15–23]. They vary in colour from a fairly pale pink to a deep red or purple, and in size from a few millimetres to many centimetres in diameter. The face is the most frequently affected site, followed by the upper trunk, but lesions have occurred at almost any site including the mucosae. They are most often, but not invariably, unilateral with a fairly sharp midline cut-off. However, midline lesions are seen, and occasionally there is more or less symmetrical facial or limb involvement.

Port-wine stains are not infrequently associated with adjacent areas of naevus anaemicus [24,25], and it has been suggested that this phenomenon may be explained by somatic recombination [26].

Associated eye and brain abnormalities occur in 8–15% of patients with facial port-wine stains [5,27].

As a rule, the surface area affected remains unchanged relative to body size. On the face, the general rule is for port-wine stains to darken very slowly but progressively throughout life. At this site, it is also common for port-wine stains to become gradually raised and thickened, the thickening sometimes taking on a characteristic 'cobblestone' appearance [1,28]. Paradoxically, on the limbs and trunk, port-wine stains will often fade somewhat over the years.

A variety of venous and lymphatic abnormalities may be associated with port-wine stains [28,29], particularly when these occur on the limbs and trunk; such combinations are especially likely to occur in the Klippel–Trenaunay syndrome, but may also occur in the absence of limb hypertrophy.

Granuloma telangiectaticum is a relatively common complication of port-wine stains [30–33]. Other nodular angiomatous lesions may develop within or close to port-wine stains; a variety of histological appearances have been described in these lesions, including features of angiokeratoma, arteriovenous malformation and angiosarcoma [28,34,35].

Occasionally, the development of basal cell and/or squamous carcinomas has been reported as a long-term complication of port-wine stains, even in patients who had never been treated with radiotherapy [36–39].

Ocular problems associated with facial port-wine stains. Vascular anomalies may occur in any part of the ocular circulation in patients with facial port-wine stains. Dilated conjunctival vessels are common, especially when the eyelids are affected [1,2]. An abnormal plexus of episcleral vessels is frequently present, but may be hidden from view by overlying fascia. It is this type of malformation that is believed to play an important role in the pathogenesis of the glaucoma seen in a substantial proportion of patients with facial port-wine stains. Tortuous retinal vessels are commonly present, occasionally associated with arteriovenous communications [3]. However, the most characteristic ocular vascular malformation in patients with facial port-wine stains is the choroidal angioma [1,4,5], which has a different appearance from isolated solitary choroidal angiomas. This lesion produces increased redness of the fundus on ophthalmoscopic examination, sometimes subtle; an appearance that has been termed 'tomato catsup' fundus [6]. Choroidal angiomas push the retina forward producing a refractive abnormality termed *hyperopia*. If unrecognized and uncorrected, this can interfere with visual development, and can therefore result in amblyopia [7]. Although initially the retina is unharmed by choroidal angiomas, degenerative changes develop after about 10–20 years, which may result in discomfort and permanent loss of vision in the affected eye [1,5].

Of all the ocular problems associated with facial port-wine stains, the most significant is glaucoma. This complication of facial port-wine stains is not sufficiently appreciated. It is particularly important that dermatologists and paediatricians should be aware that glaucoma is not confined to patients with the Sturge–Weber syndrome. Approximately 10% of all patients with facial port-wine stains in the region of the eye have evidence of leptomeningeal involvement. Of these, 30–60% have glaucoma, whereas glaucoma is found in about 10% of patients with a facial port-wine stain without leptomeningeal involvement [8,9].

The precise aetiology of glaucoma in this situation remains the subject of debate, but it seems likely that there are several contributory factors [10–14]. Choroidal angiomas may increase the production of aqueous fluid. Anatomical anomalies of the anterior chamber angle may impair aqueous drainage, which may be further impaired by raised episcleral venous pressure due to arteriovenous communications.

Glaucoma in association with facial port-wine stains is almost always unilateral. While it is widely recognized that glaucoma is unlikely unless the upper eyelid is affected by the port-wine stain, both upper and lower eyelids are affected in most cases [2,8,9,15]. Indeed, if the face is affected both below and above the eye, the chance of detecting glaucoma is about 30–45% [9,15]. Increased conjunctival vascularity does not appear to be predictive of glaucoma.

The glaucoma is detectable in infancy in about 40% of cases [16]. Its onset has two later peaks, between the ages of 5 and 9 years in another 20% of cases, and after the age of 20 years in another 20%. In the early-onset type, the eye is frequently enlarged and the cornea may appear cloudy, whereas, in the later-onset type, the eye tends to become elongated with increasing myopia. It is important to be aware that glaucoma of either type is initially asymptomatic but untreated will cause progressive damage to the optic nerve, resulting in visual field loss and, ultimately, blindness.

Patients at risk should be seen by an ophthalmologist in infancy and at regular intervals thereafter throughout life (Fig. 15.15) [16]. Treatment is initially by goniotomy, followed, if unsuccessful, by trabeculotomy, and ultimately by cyclocryotherapy in refractory cases [13,17]. Choroidal effusion or haemorrhage is a particular and threatening complication of surgery for glaucoma [18].

A small number of cases have been described under the title *orbitofacial angiomatosis*, in which a facial port-wine stain has been associated with an orbital vascular

Fig. 15.15 Port-wine stain on the face of a 3-month-old child. Regular ophthalmological examination is imperative where a port-wine stain is close to the eye.

malformation causing proptosis, in addition to more common ocular complications such as glaucoma [19]. Whether this is a separate entity or not remains unclear, but it may be relevant that none of these patients had evidence of leptomeningeal angiomatosis.

Underlying soft-tissue swelling and/or bony overgrowth. Port-wine stains may be associated with angiomatous swelling and/or hypertrophy of underlying tissues at any site.

On the face, associated angiomatous swelling of the oral mucosa, lip, gingivae or eyelid is particularly characteristic.

On the limbs and trunk, soft-tissue swelling may occur with or without bony overgrowth.

The Sturge–Weber syndrome

SYN. ENCEPHALOFACIAL ANGIOMATOSIS

This term is applied where a facial port-wine stain is associated with an ipsilateral leptomeningeal vascular malformation [1]. Ocular involvement is not a *sine qua non* for this diagnosis.

The syndrome is a developmental malformation of the vasculature of the leptomeninges and facial skin, often also of the eye. Convincing evidence of a genetic factor is lacking [2], but there are reports of its occurrence in monozygotic twins [3], and of facial port-wine stains in first-degree relatives [4].

The cutaneous lesion shows histological changes identical to those seen in other port-wine stains.

Neuropathological examination shows an increase in vascularity of the leptomeninges within the subarachnoid space, which most typically affects the posterior cerebral hemisphere, particularly the occipital lobe, but which may affect the entire hemisphere; these changes are generally unilateral, but bilateral in about 15% of cases [5]. The altered blood flow leads to stasis and ischaemia [6]. With time, there may be progressive gliosis, demyelination, calcification and cerebral atrophy [7]. The adjacent superficial cortical veins may be absent, and there may be associated enlargement of the deep venous system and choroids plexus on the same side.

Leptomeningeal melanocytosis has been an associated finding in several patients with Sturge–Weber syndrome [8–10].

The usual cutaneous finding is a unilateral port-wine stain, involving roughly the areas served by the ophthalmic and maxillary divisions of the trigeminal nerve

Fig. 15.16 Port-wine stains on the face and trunk in a 3-year-old with Sturge–Weber syndrome.

[11,12]. The lesion may be only a few centimetres across, but it tends to be extensive, involving much of one side of the face, scalp, neck and sometimes other parts of the body in addition (Fig. 15.16). It is virtually a rule that at least part of the port-wine stain extends to the forehead and upper eyelid [11]. In practice, either the whole upper lid or the root of the nose are affected in the great majority of cases [13]. The oral and nasal mucosae may be involved and the lips may be greatly swollen [1]. While usually predominantly unilateral, some extension over the midline is frequent. The facial port-wine stain is bilateral in around 50%, although not necessarily symmetrical [2,14]. Port-wine stains are present on limbs or trunk in addition to the face in about 40% of cases [15]. There is no correlation between the extent of the port-wine stain and either the extent of leptomeningeal vascular malformation or the degree of neurological impairment. In particular, bilateral facial port-wine stains do not seem particularly likely to predict bilateral leptomeningeal vascular malformation [16].

There are no reliable data to indicate what proportion of children with a port-wine stain involving the upper eyelid or forehead will never develop the CNS manifestations of the Sturge–Weber syndrome.

From the neurological and ophthalmological points of view, Sturge–Weber syndrome is a progressive disorder that varies greatly in severity. In most cases, neurological symptoms have their onset during the first 2 years of life [4,17], and their first appearance after the age of 6 years is unusual. Some patients with extensive leptomeningeal vascular malformation remain asymptomatic throughout life.

Epilepsy occurs in 75–90% of cases [2,4,14] most often starting between the second and seventh month of life, but very occasionally seizures have first occurred in adulthood. Early onset generally appears to predict a more severe course. The initial trigger for seizures is frequently fever. Initially, focal motor seizures are the most common type, but other types of seizures may occur, including infantile spasms, and tonic, atonic or myoclonic seizures. Seizures may be of generalized type from the beginning, or they may progress from focal to generalized as the child gets older. There may be long intervals between seizures. It is not uncommon for seizures to be followed by episodes of encephalopathy with altered consciousness and/or transient postictal hemiplegia and homonymous hemianopia. Later, more permanent hemiplegia may occur. Double hemiplegia reflects bilateral intracranial disease.

The onset of seizures is frequently associated with the development of a hemiplegia and a homonymous hemianopia. Once seizures have started, children with the Sturge–Weber syndrome often experience rapid, sometimes catastrophic neurological deterioration [4,14,18]. In contrast, patients who do not have seizures generally show no evidence of mental retardation [16].

The eye is involved in 50–60% of all cases [2,11,15,19,20].

The ocular abnormalities occurring in patients with the Sturge–Weber syndrome differ in no way from those found in patients with facial port-wine stains without leptomeningeal vascular malformation, although they do occur more frequently. Hemianopia or cortical blindness may also occur, and reflect damage to the occipital cortex.

The Sturge–Weber syndrome is not infrequently associated with the Klippel–Trenaunay syndrome [21,22]. The combination of Sturge–Weber syndrome and Wyburn–Mason syndrome has also been reported [23]. In other cases, Sturge–Weber syndrome has been associated with oculocutaneous melanosis [24–26], a combination which some authorities regard as a distinct entity, *phakomatosis pigmentovascularis* [27]. There have also been several reports of coincidental leptomeningeal [8–10] or neurocutaneous melanosis [28].

The EEG shows suppression of cortical activity over the affected area, which may or may not be associated with focal epileptiform spike discharges [29].

Cortical calcifications can generally be seen radiologically as sinuous, double-contoured lines running with the cortical convolutions on the affected side, but this change is generally absent in infancy and, in a proportion or cases, throughout life. However, intracranial calcification is generally visible by CT scanning, especially when enhanced by contrast injection, within the first few months of life

[30,31]. Both CT scanning, particularly with enhancement by contrast injection, and MRI are able to identify and localize the leptomeningeal vascular malformation [32,33]. Gadolinium-enhanced MRI scans are now considered to be the superior technique for the detection of the leptomeningeal vascular malformation, definition of its extent and of associated vascular anomalies, assessment of the degree of parenchymal atrophy and of ischaemic damage [7,34]. It is now widely recommended that all infants with a facial port-wine stain affecting the eyelid and/or forehead should have early gadolinium-enhanced MRI scans to establish whether leptomeningeal vascular malformation is present.

From time to time, the question arises whether the Sturge–Weber syndrome can be diagnosed without a facial port-wine stain. This is largely a matter of semantics [35]. Strictly, the presence of the cutaneous lesion is essential to make this diagnosis. However, there is no doubt that analogous unilateral leptomeningeal vascular malformation occurs without the typical skin or eye changes [16,17,36,37]. Patients affected in this way are otherwise no different from those who have facial port-wine stains, although the authors are not aware of any case reported in which unilateral congenital glaucoma was associated with ipsilateral leptomeningeal vascular malformation in the absence of a facial port-wine stain.

Control of seizures is essential to minimize brain damage; this relies on anticonvulsants in the first place, but neurosurgical intervention should be considered early when medical treatment does not secure adequate control; this may allow more normal developmental progress [38–41]. It has been suggested that anticonvulsant therapy is indicated prophylactically where the distribution of a facial port-wine stain suggests a high risk of Sturge–Weber syndrome [13], but the view in the UK is that the potential toxicity associated with such treatment contraindicates its routine use for prophylaxis. If early MRI scanning indicates leptomeningeal angiomatosis, careful follow-up is required to detect the onset of seizures, which should be treated as soon as possible to try to prevent neurological deterioration.

The eyes require regular examination by an ophthalmologist to detect the earliest changes of glaucoma.

Phakomatosis pigmentovascularis. The word phakomatosis has come to imply simultaneous involvement by a developmental malformation syndrome of eye, skin and CNS. The rather clumsy term *phakomatosis pigmentovascularis* has been proposed for a syndrome combining vascular staining of port-wine stain type, oculocutaneous melanosis and CNS manifestations such as seizures and hemiplegia [1,2]. This disorder has also been reported under other titles, notably *Sturge–Weber syndrome with Klippel–Trenaunay syndrome, naevus of Ota and Ito* [3], *Sturge–Weber syndrome with oculocutaneous melanosis* [4,5] and '*oligosymptomatic form of Klippel–Trenaunay syndrome associated with giant nevus spilus*' [6].

This syndrome has much in common with the Sturge–Weber syndrome. However, it has been argued that it differs, firstly in the presence of widespread dermal, and usually scleral, melanocytosis, secondly in the generally more extensive port-wine staining, and thirdly in the presence of ultrastructural distinctions in the endothelial cell appearances [2].

It remains unclear whether there are yet good grounds for considering this disorder distinct from the Sturge–Weber syndrome. The situation has been complicated by the use of the term *phakomatosis pigmentovascularis* to describe a variety of other cases in which port-wine stains and pigmentary abnormalities of the skin were present. Cases showing such combinations of port-wine stains and cutaneous pigmentary abnormalities have been classified into several distinct subtypes, according to the skin lesions present [7]:

Type I: port-wine stain and linear epidermal naevus [1].
Type II: port-wine stain and dermal melanocytosis [3–5,7–10].
Type III: port-wine stain and naevus spilus [6,11–13]. Multiple granular cell tumours have been described in this subtype [11].
Type IV: port-wine stain, dermal melanocytosis and naevus spilus [7,14].

This classification includes cases in which there was evidence only of cutaneous disease, or of both cutaneous and extracutaneous disease; the subdivisions 'a' and 'b' have been used to denote, respectively, the absence or presence of extracutaneous involvement, particularly CNS, eye and skeletal abnormalities [15]. Many patients with intracranial involvement could be regarded as having Sturge–Weber syndrome [16]. This classification is perhaps too all-embracing, but it does serve to point out the wide variety of cases in which port-wine stains have been associated with congenital cutaneous pigmentary abnormalities.

Spinal dysraphism. A port-wine stain over the lower spine may be a marker of spina bifida occulta [1,2], and may therefore be associated with neurological abnormalities secondary to malformations or tethering of the spinal cord. It is probable, however, that lumbosacral haemangiomas are a commoner cutaneous vascular marker of such problems [3–5]. Symptoms of neurogenic bladder dysfunction or lower limb weakness may be present. A careful history and neurological examination are indicated in children who have a midline port-wine stain in the lumbosacral area, and the need for spinal radiography should be considered.

Cobb's syndrome (cutaneomeningospinal angiomatosis) [1–7]. This disorder comprises the very rare association of a port-wine stain in a segmental distribution and an arteriovenous malformation of the spinal cord within a segment or two of the involved dermatome. In practice, about 40% of patients with spinal arteriovenous malformations also have a port-wine stain, which is situated in the corresponding dermatome in about half of these [2]. There is no evidence of any genetic basis.

The port-wine stain may be rather faint [2], or, more rarely, may have a more verrucous appearance [8,9] in a segmental distribution on the trunk or limbs. This is associated with an arteriovenous malformation of the spinal cord, which generally will become symptomatic in childhood or adolescence, with fairly rapid onset of spastic paralysis of one or both lower limbs, and sensory loss below the level of the spinal lesion.

In many cases, the spinal vascular lesion is amenable to surgical treatment [10] and/or embolization [11].

Hereditary neurocutaneous angioma. An apparently distinctive familial disorder was described under this name in 1979 [1]. The disorder was transmitted as an autosomal dominant trait. All the affected individuals had one or more port-wine stains, at almost any site, associated with localized vascular malformations within the CNS. These CNS vascular lesions showed a marked tendency to bleed, resulting in a variety of neurological manifestations, and a high morbidity and mortality.

Treatment. Port-wine stains, particularly when they occur on the face, are liable to have a very profound effect on a child's psychological development and can cause substantial social disability [1–3]. Cosmetic camouflage has been used widely in an attempt to reduce their cosmetic impact, and, in the UK, a very satisfactory service is offered by the British Red Cross Society [4]. However, this approach appears to have limited appeal for patients in clinical practice.

Over the years, a great variety of treatments have been used to treat port-wine stains. These have included excision and grafting [5–7], tattooing [8–10], Grenz rays [11], thorium X [12], red phosphorus [13] and cryotherapy [14,15]. These techniques have largely proved unsatisfactory, and attention has more recently been focused on the therapeutic advances offered by infrared coagulation [16] and, more particularly, laser therapy [17].

The argon laser is capable of good results in treating port-wine stains [18–21]. However, initial optimism has been tempered by the occurrence of a variety of adverse effects, including hypopigmentation and scarring [22–25]. The incidence of these complications of argon laser therapy can be reduced by newer techniques, and this laser may continue to have a limited role in the treatment of port-wine stains, particularly dark or nodular lesions in adults. The argon laser has proved particularly unsuitable for the treatment of children because of the paler hue of their lesions, and the incidence of scarring in children is in the region of 40% [26].

Therapeutic results comparable to those achieved with the argon laser were reported with the much less costly, and simpler, non-laser infrared coagulator [16]. However, there is a substantial incidence of complications including hypertrophic scarring, post-inflammatory hyperpigmentation and atrophy. Although these make it a less satisfactory method for treating macular port-wine stains, it remains potentially valuable in the treatment of the more difficult nodular or plaque-like lesions [27].

Theoretically, the absorption spectrum of haemoglobin implies that yellow laser light at a wavelength of 577–578 nm should be optimal for the treatment of port-wine stains, rather than the blue-green argon light. These yellow wavelengths can currently be produced by three different laser systems: the argon-pumped tunable dye laser [28], the flashlamp-pulsed dye laser and the copper vapour laser [29]. Over recent years, the greatest interest

has focused on the flashlamp-pulsed dye laser. It is now clear that, in the hands of the skilled operator, this laser can substantially lighten the great majority of port-wine stains, particularly the lighter ones that are so common in children. Its wider availability over the past few years has revolutionized the treatment of facial port-wine stains [26,30–34]. In good hands, approximately 30% of patients with facial lesions will be discharged with complete or near-complete clearance, and over 60% will have a good or excellent result [35]. Adult patients tend to require more treatments than children [26,30–33]. Paler lesions tend to respond better than darker ones [33], and it has been recently demonstrated that this reflects a better response when the ectatic vessels are more superficial [36]. Location of the port-wine stain is also important in determining the likely response to treatment; lesions in the central area of the face (V2 distribution) and on the limbs often show a relatively poor response [37,38]. This appears to reflect the increased depth of the ecstatic vessels in these areas [39]. Smaller lesions tend to respond better than more extensive ones [40].

Results from the treatment of limb lesions have been relatively disappointing compared with those for facial lesions [33–35], and it has been found that distal limb lesions respond less well than more proximal lesions. However, there is some evidence that purple lesions may respond as well as lighter ones [35].

Unwanted effects of the flashlamp-pulsed dye laser include pain, bruising in almost every patient, oedema (70% of patients), occasional bullae (1%), crusting (25%), bleeding (12%), pyogenic granuloma (1%), transient hypopigmentation (1%) or hyperpigmentation (25%) [41,42]. Atrophic scarring occurs in 1–3% of cases [42,43], and hypertrophic scarring very rarely [42,44].

The treatment can be undertaken without general anaesthesia in adults. However, it does produce an unpleasant 'stinging' sensation and, for this reason, local anaesthesia is generally employed. In children, general anaesthesia should be used. To minimize the harmful effect of disfiguring facial port-wine stains on psychological development, it should be regarded as ideal to complete therapy before the age of about 5 years. Current pulsed dye laser equipment allows large areas to be treated much more rapidly than was the case in the past, but it remains the case that several treatments will be necessary to provide substantial improvements in most port-wine stains [26,30–32].

Other syndromes featuring macular telangiectatic vascular naevi

While authors of reports of the following conditions frequently use the term haemangioma to describe vascular stains, it is often unclear whether these lesions are true port-wine stains or 'salmon patches'; this is why we have preferred to call these lesions vascular stains where there is doubt. Many authorities would prefer to regard midline lesions as more likely to be 'salmon patches' and lesions situated away from the midline as more likely to be 'port-wine stains'.

Proteus syndrome

Definition. This syndrome was only recognized as a distinct entity as recently as 1983 [1], but is now firmly established and of considerable importance to dermatologists. The name was coined after Proteus, the mythological Greek sea god who could change his shape at will, in order to stress the variable nature of the clinical manifestations and the rather haphazard nature of the growth abnormalities that characterize the condition [1].

The Proteus syndrome comprises an association of asymmetrical overgrowth of almost any part of the body, verrucous epidermal naevi, vascular malformations and lipoma-like subcutaneous hamartomas. A wide variety of other abnormalities have been described, but minimal clinical criteria for diagnosis have not yet been established.

It is now regarded as almost certain that Joseph Merrick, the 'Elephant Man', had the Proteus syndrome, not von Recklinghausen neurofibromatosis, as originally believed [2].

Aetiology. Both sexes are affected with equal frequency and severity. The available data suggest that the Proteus syndrome is not genetically transmitted, but that it should probably be regarded as a complex developmental abnormality. It has been hypothesized that it reflects mosaicism for a genetic mutation that would be lethal in a non-mosaic state [3,4].

Pathology. Little has been published on the histological features of the skin lesions observed in patients with the Proteus syndrome. Although the soft subcutaneous masses that are such a characteristic element in the clinical presentation have generally been described as lipomas, they appear more often to be complex hamartomatous malformations containing mixtures in varying proportion of vascular, lymphatic and adipose tissue [5–7]. The linear verrucous epidermal naevi show typical histological features of this condition [8], but hypopigmented examples may show large vacuoles and aggregations of ribosome-like particles at the melanocyte–keratinocyte interface [9]. Biopsies from the cerebriform plantar lesions show increased amounts of normal collagen and reduced density of elastic fibres compatible with a collagenoma [10,11], but in one case it was reported that light and electron microscopy showed elongated, fine, cytoplasmic projections from some basal cells into the dermal–epidermal junction [8].

Clinical features [5–8,11–15]. Some manifestation of the disorder is almost invariably present from birth. Although the presenting problem may be one of the cutaneous abnormalities, more often it is an overgrowth phenomenon that first causes anxiety.

The most characteristic forms of overgrowth are assymetrical hypertrophy of the face, of part or the whole of one or both limbs, the trunk, or any combination of these, including hemihypertrophy of one side of the body. Macrodactyly has been regarded as particularly characteristic, but should not be considered absolutely necessary to the diagnosis. The rugose or cerebriform overgrowth of the plantar and/or palmar soft tissues on a hypertrophied foot and/or hand seems to be highly distinctive. Macrocephaly and/or an excessive linear growth rate are also common findings.

Three main types of skin lesion may be seen, none of which is in itself entirely diagnostic; it is the characteristic combinations in which they occur that should lead to the correct diagnosis. They are (i) epidermal naevi, (ii) vascular malformations and (iii) soft subcutaneous masses. Some cutaneous abnormality is present in the great majority of patients.

The epidermal naevi are generally of linear verrucous type, but may have the clinical features of sebaceous naevi [7]. They may show hyperpigmentation and/or hypopigmentation [5,6,8,11,12].

The vascular lesions that are found in the majority of these patients include extensive port-wine stains, both macrocystic and microcystic lymphatic malformations, and complex combined vascular malformations of the leg identical to the Klippel–Trenaunay syndrome [16]. Varicosity of superficial veins is also often described, but prominence of veins may quite often reflect a degree of lipodystrophy.

Soft subcutaneous masses are extremely common, and highly characteristic.

Other skin findings have included café-au-lait macules and macular hypopigmentation, which may be of a linear or whorled type [5,12,13]. Several thickened hypopigmented areas were described in a case that otherwise had the hallmarks of the Proteus syndrome [17]; these lesions were interpreted histologically as connective tissue naevi. Venous varicosities are often a prominent feature [6,14,17].

Non-cutaneous findings have included skeletal abnormalities, such as exostoses, kyphosis, scoliosis and spinal canal stenosis leading to spinal cord compression, ocular abnormalities including congenital blindness, epibulbar tumours, enlargement of the eye, cataract and strabismus, misshapen teeth, hypodontia and hypoplastic enamel, myopathy, pelvic lipomatosis, amastia, goitre, testicular tumours, craniosynostosis and complex congenital heart defects [5,6,8,14,18]. Spinal abnormalities have been the cause of some of the most serious functional problems experienced by these patients [19]. The great majority of patients are of normal intelligence, and although mental retardation and convulsions have been reported, they are rare.

Macrodactyly, hemihypertrophy and the multiple exostoses tend to progress throughout childhood and thereafter to stabilize. Ultimately, the prognosis depends upon severity, which varies dramatically from case to case [9,14].

Diagnosis. For many years, patients with the Proteus syndrome were diagnosed as Klippel–Trenaunay syndrome, 'congenital hypertrophy' or epidermal naevus syndrome. The principal differential diagnoses are other overgrowth disorders, particularly the Klippel–Trenaunay syndrome, macrocephaly with cutis marmorata, midline facial telangiectatic naevus, and syndactyly, Bannayan–Riley–Ruvalcaba syndrome [20], the congenital lipomatosis, in which macrodactyly has been reported [21], partial lipodystrophy [6,22], Maffucci's syndrome and von Recklinghausen neurofibromatosis [2], but the clinical features of these disorders generally allow them to be distinguished.

Treatment. The aims of treatment are the minimization of disability. Substantial contributions can be made by plastic and orthopaedic surgeons, ophthalmologists, orthodontic specialists and by physiotherapists. It is, for example, possible to stop the overgrowth of elongated fingers or toes during childhood by the destruction of the growth plate. Lipomatous swellings can sometimes be reduced by liposuction. Sadly, despite treatment efforts, this disorder may be responsible for major degrees of deformity and disability.

Cardiofaciocutaneous syndrome [1]

Vascular stains are a regular feature of this syndrome, a genetically determined disorder whose principal features include mental retardation, hypotonia, atrial septal defect,

pulmonary stenosis, eczema, hypotrichosis and a characteristic facial appearance [2]. It has been suggested that it may be a variant of Noonan's syndrome [3].

Roberts' syndrome [1–6]

SYN. HYPOMELIA–HYPOTRICHOSIS–FACIAL HAEMANGIOMA SYNDROME; PSEUDOTHALIDOMIDE SYNDROME

This is an extremely rare but distinctive disorder, transmitted by an autosomal recessive gene, which is characterized by five principal clinical features:
1 a mid-facial vascular stain
2 cleft lip with or without cleft palate
3 sparse, silvery-blond hair
4 tetraphocomelia
5 marked growth retardation.
There is considerable variability in severity [6,7].

The vascular naevus extends in the midline of the face from the forehead on to the nose and philtrum. The facial appearance is rather characteristic, with hypertelorism, shallow orbits, prominent eyes with bluish scleras, thin nares, micrognathia and malformed ears with hypoplastic lobules.

Cells derived from most patients exhibit abnormal cytogenetic and cellular phenotypes that include the premature separation of para- and pericentromeric heterochromatin visible on C-banded metaphase chromosomes, a phenomenon referred to as heterochromatic splaying [8].

Severely affected individuals are often stillborn or die in early infancy.

Thrombocytopenia–absent radii syndrome [1–5]

SYN. TAR SYNDROME; TETRAPHOCOMELIA–THROMBOCYTOPENIA SYNDROME

This disorder generally appears to be transmitted as an autosomal recessive trait, but parent-to-child transmission has been reported, also several cases in which an uncle or aunt and their niece or nephew have been affected, suggesting that the genetic situation may be more complex than it had appeared.

The principal findings are (i) congenital thrombocytopenia and (ii) absence or hypoplasia of the radius, which is usually bilateral.

Many patients also have vascular stains on the head and neck [1,3,4,5].

The thrombocytopenia may be very severe in infancy, with a mortality of about 40% from haemorrhage, but it generally improves considerably with time. The marrow shows absence or diminished numbers of megakaryocytes. Anaemia is also common.

Cow's milk allergic reactions seems to be unusually frequent in these infants, about 50% of whom have eosinophilia.

A single case report describes the failure of flashlamp-pumped pulsed dye laser to lighten the vascular naevus in this disorder, possibly because the platelet thrombi were not able to form in treated vessels [1].

Wyburn–Mason syndrome [1,2]

SYN. BONNET–DECHAUME–BLANC SYNDROME

This is an extremely rare disorder, probably not genetically transmitted. There may be some overlap with the Sturge–Weber syndrome [3].

The principal features are:
1 a unilateral retinal arteriovenous malformation, which may also involve the optic nerve, orbit, optic chiasm and tract;

2 an ipsilateral aneurysmal arteriovenous malformation of the brain, usually in the mid-brain, associated with a variety of neurological findings that may have a sudden onset precipitated by intracranial haemorrhage;
3 ipsilateral cutaneous vascular abnormalities.

The visual tract abnormalities may occur in the absence of the other features, and the cerebral abnormalities may less often occur without visual tract involvement.

Cutaneous abnormalities are not always apparent, and are generally subtle, taking the form of rather faint ipsilateral vascular staining or telangiectasia in the region of the affected eye, sometimes featuring punctate telangiectases [4–6]. More rarely, a more substantial cutaneous vascular malformation may be present [5,7].

The occurrence of a basal cell carcinoma has been reported in a young man with this condition; whether the association was fortuitous is impossible to determine [8].

Beckwith–Wiedemann syndrome [1–4]

SYN. EXOMPHALOS–MACROGLOSSIA–GIGANTISM SYNDROME

Although the majority of cases of this disorder have appeared to be sporadic, it is likely that this disorder is caused by an autosomal dominant gene with highly variable expression [5]. Genetic linkage studies have mapped the familial form to a specific region of chromosome 11, further supporting the underlying genetic aetiology of the Beckwith–Wiedemann syndrome [6]. Translocations and deletions of chromosome 11 have also been identified in some patients [7]. Prenatal diagnosis has been accomplished at 19 weeks gestation by ultrasound observation of abdominal enlargement and omphalocoele [8].

The major clinical feature of the syndrome is somatic and visceral overgrowth, resulting, most typically, in a baby that is large for gestational age with exomphalos, macroglossia and large kidneys. Hemihypertrophy occurs in approximately 13% of patients.

Vascular staining is present on the central forehead and upper eyelids in about 80% of cases, which often also extends to the nose and upper lip. It is reported that these naevi fade during the early years of life, sometimes becoming invisible later; this with their location suggests that they may behave more like salmon patches than classical port-wine stains. Linear indentations of the earlobe are also common and characteristic. These physical features are regularly associated with pancreatic hyperplasia, which may cause severe and refractory neonatal hypoglycaemia.

Hypoglycemia develops in the first few days of life in as many as one-third of affected infants, and it may result in neurological sequelae if it is not anticipated.

The ultimate prognosis of children who survive infancy is unknown. The excessive rate of growth appears to slow down, and the macroglossia, which initially may result in life-threatening respiratory obstruction, gradually becomes less prominent. There is an unexpectedly high incidence of a variety of malignancies, particularly Wilms' tumour, adrenal carcinoma, hepatoblastoma and rhabdomyosarcoma [9–11], and these tumours are commoner in those with hemihypertrophy.

Other associations with vascular stains

Vascular stains occur in at least a half of all cases of the *Rubinstein–Taybi syndrome* and in a similar proportion of children with *trisomy 13* [1]; in both cases the forehead is the commonest site.

The commonest cutaneous abnormality in *trisomy 18* [2] is a reticulate vascular naevus, but lesions resembling

port-wine stains have also been recorded. Vascular stains have been reported in *short-arm 4 deletion syndrome* [3], in *XXYY syndrome* and other *Klinefelter* variants [4,5].

Mid-facial vascular stains also occur occasionally in the *amyoplasia congenita disruptive sequence* [6] and in the *lethal multiple pterygium syndrome* [7].

Coats' disease is primarily a disorder of the eye, with retinal telangiectasia leading to exudation and retinal detachment. Cutaneous telangiectasia has been reported in several cases, and a macular telangiectatic naevus of the cheek in a single case [8].

Fig. 15.17 Port-wine stain on the right buttock and leg, typically combined with areas of naevus anaemicus.

Naevus anaemicus

Definition. Naevus anaemicus is a congenital anomaly of the skin, characterized by macular areas of pallor having a normal texture and normal melanin pigmentation, due to reduced blood flow. Such lesions were first recorded by Vörner in 1906 [1].

Aetiology and pathology. The prevalence of naevus anaemicus is not known, but it is not rare [2]. It is more frequent in females [3].

This lesion is a pharmacological anomaly rather than an anatomical one. Examination by light and electron microscopy reveals no abnormality [4]. Physical stimuli such as rubbing, intralesional injection of bradykinin, acetylcholine, 5-hydroxytryptamine, nicotine or histamine all fail to produce the anticipated vasodilatation [3,4], but erythema does follow axillary sympathetic block [4]. It is now considered probable that naevus anaemicus reflects locally increased vascular reactivity to catecholamines [3,4], a conclusion supported by autograft exchange transplantation studies [5], and by the finding that the pallor can be overcome by local injection of the α-adrenergic blocker phentolamine [5,6].

Areas of naevus anaemicus, frequently extensive, are often seen in close association with vascular stains of port-wine stain type (Fig. 15.17) [2,7,8]. It has been suggested that this phenomenon may be explained by somatic recombination [9].

Lesions of naevus anaemicus occur with increased frequency in patients with neurofibromatosis [3,8,10,11].

Clinical features [3,10–12]. The naevus anaemicus is a circumscribed, rounded, oval or linear area of pallor, having a normal texture. Lesions may be single or multiple (Fig. 15.18). Small blotches may be irregularly grouped. The margins of the lesion or lesions are frequently ill-defined. Under diascopic pressure, the naevus becomes indistinguishable from the blanched surrounding skin. Rubbing the skin causes reactive hyperaemia in the surrounding normal skin, but no change within the lesion itself. There is no loss of melanin pigmentation in the affected area. It may occur on any part of the body, but is most commonly seen on the trunk. It may be present at birth, or may appear in early childhood. Later onset has been reported, but as the lesion may be inconspicuous the history may be unreliable. Naevus anaemicus persists unchanged throughout life.

Diagnosis. Diascopy provides the most reliable method to distinguish naevus anaemicus from other causes of circumscribed pallor such as hypochromic naevi and vitiligo. Wood's lamp examination does not accentuate the lesion.

Fig. 15.18 Naevus anaemicus on the neck of a 12-year-old.

Treatment. Treatment is generally not required. Where there is a resulting cosmetic disability, the use of camouflage make-up is worth consideration.

Naevus oligaemicus

A case has been reported of an adult in whom a persistent fixed area of cyanotic erythema had been present for many years on the trunk [1]. Histology was normal. Careful studies demonstrated decreased blood flow through the lesion. There was evidence that the cause was relative stasis in the superficial microvasculature secondary to increased vasoconstrictor tone in the deeper thermoregulatory vessels.

Mixed vascular malformations

Cutis marmorata telangiectatica congenita

SYN. RETICULATE VASCULAR NAEVUS

Terminology. Though this disorder has most commonly been reported under the rather cumbersome term *cutis marmorata telangiectatica congenita* [1], it would in many ways be preferable to use a term such as *reticulate vascular naevus* [2]. This would have the additional advantage of emphasizing the distinction of the disorder from *cutis marmorata*, which is a cutaneous physiological response to cold.

Aetiology. This disorder is probably best considered as a combined capillary and venous vascular malformation. It is uncommon but not rare, occurring in about one in 3000 neonates [3].

Cutis marmorata telangiectatica congenita appears to be sporadic in the great majority of cases, but familial occurrence has occasionally been reported [4,5]. Taking into account the relatively high prevalence of associated problems in patients with the familial form [6,7], it has been suggested that it is the principal cutaneous manifestation of a syndrome inherited as an autosomal dominant trait but having highly variable expression [4]. It seems possible that the Adams–Oliver syndrome, believed to be transmitted as an autosomal dominant trait with variable penetrance and expression, may be a different manifestation of the same disorder [8].

Pathology [1,4,6,9]. The histopathology of this disorder remains ill-defined. Biopsies generally show dilated capillaries, capillary and venous lakes, and dilated veins throughout the dermis, and often also the subcutis. However, no abnormality has been apparent in some reported cases [10], implying that perhaps the problem is primarily functional rather than anatomical.

It was reported that the gestation of a fetus born with cutis marmorata telangiectatica congenita was associated with elevated maternal serum human chorionic gonadotrophin level and transitory fetal ascites [11].

Clinical features [6,12–14]. From birth there is reticulate

Fig. 15.19 Cutis marmorata telangiectatica congenita on the leg of an infant.

erythema of variable extent, producing a marbled effect (Fig. 15.19). The erythema varies in hue between patients and in different areas in the individual patient from a pale-red to a deep-purple colour. Telangiectasia is often visible within the hyperaemic areas and is sometimes prominent. The skin in these areas may be atrophic, and may be ulcerated at birth, resulting in linear or reticulate erosions [1,9,12–17]. The enclosed areas of skin may be of normal appearance or slightly erythematous.

Individual lesions sometimes measure only a few centimetres across. On other occasions, larger areas may be involved. Almost any area of the skin may be affected, but involvement of the limbs appears to be particularly common. The distribution may be segmental, and is generally asymmetrical if not strictly unilateral. Fairly sharp midline demarcation is common. In some cases, the condition has been very extensive, but it is very rarely generalized [18].

The face is often diffusely hyperaemic [19], and facial lesions may occur that are indistinguishable from typical port-wine stains [10,12,20,21]. Such patients are particularly at risk of congenital glaucoma [12,22,23], which may be bilateral if facial cutaneous involvement is diffuse [10,12]. In one of these cases, there was associated mental retardation, suggesting that the patient might have had Sturge–Weber syndrome [10]. Congenital glaucoma may also occur in the absence of a facial port-wine stain [12,22,24–26].

Underlying atrophy of the subcutaneous tissues appears to accompany the cutaneous lesions fairly regularly, resulting in associated facial hemiatrophy and reduced girth of affected limbs [6,14,26]. Reduced longitudinal limb growth has been reported [22], but is unusual. Hypoplasia of underlying bone has very occasionally been reported [27]. Hypertrophy of affected limbs rather than atrophy may rarely occur [6,13,20,21].

A wide variety of other congenital anomalies have been noted in reported cases. The frequency of these associated anomalies has varied from about 20% to 70% [7,12,18], but otherwise normal children with cutis marmorata telangiectatica congenita have almost certainly been relatively underreported. The most frequent have been transverse limb defects, cutis aplasia congenita, cleft palate and developmental delay. Cutis marmorata telangiectatica congenita has been reported in about 10% of cases of the Adams–Oliver syndrome [27,28]. Indeed, the clinical similarities between patients with cutis marmorata telangiectatica congenita and the Adams–Oliver syndrome are such that it has been suggested that they may be different expressions of the same disorder [8]. A family in whom congenital absence of the skin on the scalp was associated with cutis marmorata telangiectatica congenita may have had a limited expression of the Adams–Oliver syndrome [20].

More occasional associated abnormalities have included soft-tissue herniation [29], congenital generalized fibromatosis [26], macrocephaly [21,30], patent ductus arteriosus, scoliosis, spina bifida [13], double aortic arch [31], congenital retinal detachment [25], high myopia [32], congenital hypothyroidism [7], diabetes mellitus [33], chylothorax [27], neonatal ascites [11,33], renal artery stenosis [32], transient hepatic dysfunction [20,33,34] and dental anomalies [32].

The natural history of cutis marmorata telangiectatica congenita is usually one of gradual spontaneous improvement, although there may be some extension of the lesions during the first few days of life [7,9,13]. Ulcerations usually heal fairly rapidly. Generally the reticulate erythema fades, more rapidly in the first year, and slower thereafter. In patients with initially paler lesions, with limited telangiectasia and without ulceration, eventual complete disappearance is possible, but more prominent lesions will tend to be more persistent. Although even these will become less prominent over the years, a number of cases have been recorded where little significant improvement at all has occurred [4,7,15]. Limb circumference discrepancy becomes less prominent with time [14].

Diagnosis. Cutis marmorata telangiectatica congenita would appear to be a close relative of port-wine staining, clinically and pathologically, and vascular naevi of both types not infrequently occur together. The main differences are the better outlook for spontaneous improvement in cutis marmorata telangiectatica congenita, and their

more usual association with atrophy rather than hypertrophy of subcutaneous tissues. It is of particular importance to watch for development of glaucoma when the face is involved in either disorder.

There should be no confusion with cutis marmorata, a physiological cutaneous response to cold which is very prominent in the neonate, and which disappears with warming, also the more pronounced congenital livedo which may be seen in certain chromosomal and genetic disorders, most notably the de Lange syndrome, homocystinuria, the Divry–van Bogaert syndrome and trisomy 21.

It is important to be aware that congenital reticulate erythema with atrophy and telangiectasia may be a feature of neonatal lupus erythematosus [35,36]. The suspicion of neonatal lupus erythematosus should be greater where: (i) the head is affected; and (ii) the skin changes are bilaterally symmetrical. A clearly unilateral distribution would more or less rule out neonatal lupus erythematosus.

Treatment. Because of the natural tendency of these lesions to fade with time, active treatment should not be envisaged during the early years. Tunable dye laser therapy may help with persistent lesions, but it is often not very effective.

Macrocephaly–cutis marmorata telangiectatica congenita

SYN. MACROCEPHALY WITH CUTIS MARMORATA; HAEMANGIOMA AND SYNDACTYLY SYNDROME; MACROCEPHALY, CUTIS MARMORATA, MIDLINE TELANGIECTATIC NAEVUS AND SYNDACTYLY SYNDROME

This distinctive overgrowth syndrome was first recognized in 1996 [1,2]. The syndrome comprises combinations of macrocephaly, cutis marmorata telangiectatica congenita, macular vascular stain (commonly and incorrectly referred to as 'haemangioma') on the upper lip and/or philtrum, syndactyly, high birth weight (above 75th centile), hemihypertrophy, regional overgrowth, developmental delay, hypotonia, joint laxity, hyperelastic skin,

thick subcutaneous tissue, short stature, hydrocephalus and, less commonly, hemimegalencephaly, internal arteriovenous malformations and postaxial polydactyly [2–5]. Macular vascular stains have also been reported with a smaller frequency at other sites in these patients, and may be extensive [4,6,7]. Occasional cases have featured subcutaneous vascular swellings, which have probably been venous vascular malformations [6,8]. Otherwise typical cases have been described in which cutis marmorata telangiectatica congenita has been absent [6,9,10]. Macular linear hyperpigmentation has also been described, suggesting that the condition reflects mosaicism [4,7].

While this syndrome is now regarded as a well-established entity, there is substantial clinical overlap with Proteus syndrome, with Klippel–Trenaunay syndrome and with a condition described as *slowly progressive macrocephaly with hamartomas* [11].

Divry–van Bogaert syndrome [1–3]

SYN. CORTICO-MENINGEAL ANGIOMATOSIS

This extremely rare disorder appears to be transmitted as an autosomal recessive trait. The principal feature is diffuse non-calcifying leptomeningeal angiomatosis that is at least partly responsible for a variety of associated problems, which include epilepsy, visual field defects, progressive dementia and spastic paralysis. Congenital livedo has been a conspicuous feature in many patients. Affected individuals generally die during childhood.

Klippel–Trenaunay syndrome

Nomenclature and aetiology. The association of a port-wine stain on a limb with soft-tissue swelling, with or without bony overgrowth, is generally termed Klippel–Trenaunay syndrome. As originally defined, the syndrome comprised the triad of a port-wine stain extending the full length of a limb, venous varicosities of the same limb, either congenital or of onset in infancy, and overgrowth of all the tissues of the affected limb, particularly bone [1]. Today, the term is generally used for any case where there is an association of port-wine staining and increased limb size, whether or not bony overgrowth is present and whether or not venous varicosities are apparent.

A few years after Klippel and Trenaunay's paper, Parkes Weber described a syndrome which he called 'haemangiectatic hypertrophy' [2,3]. Although limb swelling is a feature, the syndrome described by Parkes Weber is distinct, as it reflects the presence of arteriovenous anastomoses in the affected limb, rather than the predominantly venous malformations that underlie the Klippel–Trenaunay syndrome. Thus, the term Klippel–Trenaunay–Weber syndrome is inappropriate, and should not be used. In fact, both of the described syndromes are just a part of a wider spectrum of vascular anomalies of the limb that result in limb enlargement. The term, *haemangiectatic hypertrophy*, as coined by Parkes Weber, can be usefully employed to embrace all those conditions in which this association is seen. Cutaneous abnormalities will be present in only a proportion of such cases.

Classification of these disorders has proved exceedingly difficult, and no really adequate system of classification has as yet been devised. However, from the clinical point of view, it is convenient to separate these conditions into three broad groups [4].

1 Predominantly venous malformations. Most of these patients will have the features of the Klippel–Trenaunay syndrome.

2 Predominantly arteriovenous fistulae. This is the disorder described by Parkes Weber [2,3].

3 Predominantly mixed venous–lymphatic malformations.

It appears that genetic factors lead to an increased risk of the Klippel–Trenaunay syndrome, at least in some families [5–7], and it has been suggested that the disorder may

Fig. 15.20 Klippel–Trenaunay syndrome: port-wine stain with increased limb size.

reflect autosomal dominant inheritance with variable expression [7], or perhaps paradominant inheritance [8].

The aetiology of the Klippel–Trenaunay syndrome is unknown, but it has been suggested that it reflects defective remodelling of the fetal vascular tree during embryogenesis [9].

Clinical features. In cases demonstrating the classical Klippel–Trenaunay triad, the most characteristic cutaneous lesion, both clinically and histologically, is a vascular stain of port-wine stain type (Fig. 15.20) [4,10–17]. One or several vascular stains are almost invariably present at birth, but in some cases such lesions make their first appearance during early childhood. These lesions are extremely variable both in extent and in colour, which may range from pale pink to deep purple. Most often, these vascular naevi occur on the affected limb, but more distant lesions may be a feature, and several limbs and/or the trunk may be affected simultaneously. A tendency for the naevus to be patchy is frequently commented upon, as is its general tendency to stop abruptly in the midline. It has been noted that the hypertrophied limb is affected in virtually every case, with the vascular staining more or less confined to this limb in about 75% [10,18]. In about 20% of cases, the whole of the ipsilateral side of the body is affected [10,18], usually with the exception of the face, and in about 15% the contralateral limb is also affected. Patients with otherwise typical Klippel–Trenaunay syndrome may lack such skin lesions. In one report, the proportion of patients without vascular staining was as high as 68% [19].

Fig. 15.21 Klippel–Trenaunay syndrome: port-wine stain on knee with numerous angiokeratomatous nodules.

It is not uncommon for other types of vascular malformation to be present (Fig. 15.21). Small angiokeratomas and lesions resembling granuloma telangiectaticum may occur as in other port-wine stains. Very occasionally, lesions of the type described as pseudo-Kaposi sarcoma or angiodermatitis have been reported in Klippel–Trenaunay syndrome [20]. These lesions have more often been reported in association with localized arteriovenous fistulae. It is in addition characteristic for other, often large or complex vascular malformations to coexist with the vascular staining. These quite often lie directly below areas of superficial vascular staining [18], and are likely to have been present since birth. Perhaps lymphangioma circumscriptum is the most typical of all, but lymphoedema is also common, and may be accompanied by recurrent bouts of cellulitis.

Very occasionally, patients have been prone to prolonged bleeding from telangiectatic areas of skin following trauma [21].

The legs are more often affected than arms. Many variations have been described, including facial involvement [22–24], often with features of the Sturge–Weber syndrome [23–25]. Hemihypertrophy may occur, in which the thorax is affected in addition to the arm and leg on the same side [15,26,27], as may bilateral involvement of two or all four limbs [27–30]. The affected part may be larger at birth or more rapid growth may only gradually become apparent. Increased length of limbs implies bony hypertrophy; increased girth implies soft-tissue overgrowth [10]. Rather rarely, there may be atrophy of the limb rather than hypertrophy [10,30,31]. Radiologically, the hypertrophic bone may show cortical thickening and osteoporosis may be a late feature [15,32].

Compensatory scoliosis is a complication of difference in leg length [10,33], and hip dislocation may occur [27].

Unilateral enlargement of the tongue has been described where the face is affected [26].

Venous varicosities of the affected limb are a frequent finding. Although these may appear early, more often they develop during later childhood or adolescence. The most common abnormality is a lateral venous anomaly [17]. Pain is a very common symptom [10]. About 25% of patients experience episodes of profound haemorrhage from ruptured varicosities [10], and about 5% have attacks of superficial thrombophlebitis.

Ulceration is said to be rare [11], but the real risk may have been underestimated [16,34]. The development of basal and squamous carcinomas has occasionally been reported [35], and is likely to be a greater risk in the presence of chronic ulceration [34].

There is a high rate of spontaneous deep-vein thrombosis and pulmonary embolism [10]. The deep venous system in the limb is frequently hypoplastic or absent [36,37].

Recurrent septicaemic episodes have complicated lower limb Klippel–Trenaunay syndrome [17].

Sympathetic overactivity in the affected limb may give rise to hyperhidrosis, which may be marked, or to vasoconstriction.

Entrapment syndromes, such as trigger finger and carpal tunnel syndrome, have been reported when the upper limb is affected, and are believed to be due to lymphatic obstruction [38].

Many associated developmental defects have been recorded. Occasional patients have had coincidental verrucous epidermal naevi [39,40]. Polydactyly, syndactyly and oligodactyly are relatively frequent [10,22,38]. Other associated abnormalities have included macrocephaly [24], blue naevi [23], pulmonary vein varicosities [41] and visceral venous malformations [10,29,42]. Lesions in the bladder causing haematuria appear to be present in as many as 5% of cases [10,29,42,43], and colonic and rectal lesions may be present in as many as 10% of patients [21,29,43], resulting in rectal bleeding and melaena.

Differential diagnosis. The principal problems in diagnosis are to differentiate between the Klippel–Trenaunay syndrome and (i) the Parkes Weber syndrome and (ii) the Proteus syndrome.

In the much rarer Parkes Weber syndrome, limb hypertrophy is caused by multiple arteriovenous fistulae. Vascular stains of port-wine-stain type may also occur, but appear to be less common and paler [13,17,44]. The affected limb is larger than the unaffected one, is warm and the superficial veins are conspicuous and may pulsate. A continuous bruit may be audible. Application of a tourniquet often results in slowing of the pulse (the Branham sign). The arm is more commonly affected than the leg [13,32]. The enlarged limb is not liable to be deformed, as is frequently the case in the Klippel–Trenaunay syndrome [12].

Confusion between the Klippel–Trenaunay and Proteus syndromes has been a major problem, and many cases of the Proteus syndrome were in the past reported under the title Klippel–Trenaunay syndrome. In the Proteus syndrome, limb hypertrophy and port-wine stains are associated with a variety of quite distinctive abnormalities, which serve to differentiate it clearly, at least in the majority of cases.

The syndrome of *diffuse phlebarteriectasis* appears to be an exceedingly rare but distinct condition in which the entire arterial and venous systems of a part or the whole of a limb is congenitally ectatic; bony hypertrophy may be a feature [32]. The existence of this syndrome has recently been questioned [17].

Patients with Maffucci's syndrome may have complex deep venous and lymphatic malformations in addition to the typical protuberant vascular swellings that may occur on the hands and feet in particular. In such cases, the clinical picture can resemble that of the Klippel–Trenaunay syndrome [17]. Other disorders featuring vascular malformations and overgrowth include the Bannayan–Riley–Ruvalcaba syndrome and the Beckwith–Weidemann syndrome.

Treatment. The majority of patients do well without treatment, or with elastic support alone [45]. Elastic support reduces symptoms of chronic venous insufficiency, decreases swelling caused by lymphatic stasis and protects the limb from minor external trauma that may provoke bleeding.

Few surgeons attempt more than ligation and stripping of superficial venous varicosities [10,45]. These procedures can relieve local symptoms, particularly pain. However, inadequate preoperative evaluation increases the risk of complications. In the 20% of patients with absence or hypoplasia of the deep venous system, this type of procedure is likely to make symptoms worse [13,32]. Both an MRI scan and contrast venography should be undertaken before any procedure on the superficial veins. Very occasionally, obstructions of the deep venous system can be relieved surgically with good results [19] and reconstructive procedures for deep-vein atresia or hypoplasia may occasionally be successful [45].

Gradual spontaneous fading of the naevus has been observed [10]. In selected cases, laser therapy may be appropriate on aesthetic grounds.

Patients with the Klippel–Trenaunay syndrome should probably be given thrombosis prophylaxis prior to any surgery because of the high rate of thromboembolic complications [10].

Bleeding from the lower gastrointestinal tract and the bladder may also require surgical treatment [43].

It is important to recognize the presence of any difference in leg length as this is likely to lead to scoliosis and early osteoarthrosis of knees and hips. During the early

years, the shoe on the shorter leg can be built up to compensate. Later, epiphyseal stapling (epiphysiodesis) or tibial osteotomy can be used to slow down growth in the longer leg. Amputation may be indicated if the enlarged limb, or part of it, is severely deformed [12,33,45].

Venous malformations

Blue rubber bleb naevus syndrome

This is a rare disorder comprising multiple venous malformations of the skin, gastrointestinal tract and, frequently, other sites [1–3]. Most cases have been sporadic, but there has been good evidence for autosomal dominant inheritance in a number of families [4–6]. However, two of these families had a disorder that was clinically atypical, and, in another family, only males appeared to be affected [7].

Histologically, the skin lesions comprise large, blood-filled, vascular lumina in the dermis and subcutaneous fat. More superficially, these lumina are often lined only with endothelial cells, whereas deeper lumina have a better developed vessel wall with smooth muscle [4,8]. The vascular channels are separated from one another by strands of connective tissue. Gastrointestinal lesions are histologically similar, with the vascular channels observed in the lamina propria and submucosa.

The most characteristic cutaneous lesions are compressible, blue or purple, soft, rubbery nodules with a wrinkled surface, which have often been likened to nipples. They are generally small and present in limited numbers, but they have on occasion been as large as 5 cm in diameter.

They have occurred as solitary lesions, but, in other cases, have been extremely numerous [7–12]. They may occur virtually anywhere on the body surface, and on the mucosa of the lips, the mouth and the glans penis. They may lie fairly deeply in the skin so that only bluish discoloration is visible at the surface. It is characteristic for them to be spontaneously painful, particularly at night, although this feature may be absent before puberty and may never occur in some patients. They may also be tender. In some cases, the lesions have demonstrated increased sweating, and an intimate relationship between the angiomatous vessels and sweat glands has been described histologically [9]. They may be present at birth, but more often appear progressively during early childhood. Occasionally, the onset may be in adult life [5,13,14], although it is possible that not all such cases have been genuine examples of the blue rubber bleb naevus syndrome.

Analogous lesions also occur in the gastrointestinal tract at all levels, but particularly in the small intestine, where they frequently bleed [4,15–19]. Rather characteristic nodular, blue, vascular lesions may be clearly visible on and under the tongue [20]. The resulting anaemia may be profound. They may also be the cause of intussusception [21]. There appears to be no correlation between the number of skin and gastrointestinal lesions. Lesions may less commonly occur in a variety of other sites, where they may provoke a wide spectrum of symptoms [8,9,12,14,20,22–26]. Reported examples include the nasopharynx, lungs, heart, liver, spleen, CNS [26], eye [27], urinary tract [2], muscle and joints. A single case has been reported in whom blue rubber bleb naevi were associated with multiple enchondromas, as found in Maffucci's syndrome [28]. A number of musculoskeletal problems have occurred in affected individuals [23], including gigantism of an arm requiring amputation in infancy [8].

Early-onset chronic consumption coagulopathy may occur [29].

It may require judgement to decide how deeply to investigate cases where this diagnosis is suspected and where the patient is asymptomatic. Where anaemia is present, or where internal bleeding has occurred, appropriate investigations may include gastrointestinal tract and bladder endoscopy, and head and spinal MRI.

Once developed, the vascular malformations of the blue rubber bleb naevus syndrome remain unchanged for life, with no tendency to spontaneous regression.

Blue rubber bleb naevi need to be distinguished from multiple infantile haemangiomas. They may also occasionally be confused with eccrine angiomatous hamartomas, glomangiomas, Maffucci's syndrome and angiokeratoma corporis diffusum. It is possible that is some cases at least, lesions reported as blue rubber bleb naevi would now be reclassified as glomangiomas of the disseminated multiple type.

Treatment of the blue rubber bleb naevus syndrome largely comprises symptomatic treatment of its complications. If anaemia cannot be controlled by iron supplements or intermittent transfusion, resection of heavily involved lengths of bowel may be indicated. Endoscopic cauterization may also be effective. Amputation may be indicated for skeletal deformity [1]. Successful carbon dioxide laser treatment of the skin lesions has been reported [18].

Maffucci's syndrome

SYN. DYSCHONDROPLASIA WITH HAEMANGIOMAS

Maffucci's syndrome comprises the association of cutaneous venous malformations with dyschondroplasia [1–8]. Familial occurrence does not appear to have been recorded.

Although few histological details have been published, it appears that the skin lesions comprise thick- and thin-walled dermal and subcutaneous vascular spaces, with a single endothelial lining. Although these lesions have frequently been called cavernous haemangiomas, they do not appear to be true haemangiomas but complex venous malformations.

Affected individuals are generally of normal appearance at birth, but multiple cutaneous vascular swellings generally start to appear in infancy. These lesions generally take the form of soft, bluish, occasionally tender subcutaneous protrusions. The skin lesions show no tendency to resolve, and grow proportionately with the child. Grotesque grape-like masses may develop on the hands and feet [6]. Cavernous lymphangiomas are also frequently seen [7], and may be the sole cutaneous manifestation [9].

Other cutaneous features reported have included pigmentary changes [1,3,5,10], particularly café-au-lait macules. Simultaneously with the appearance of the cutaneous vascular swellings, the patient develops hard nodules arising from the bones, especially those of the fingers and toes, and the metaphyses of the long bones of the arms and legs. Pathologically, these are enchondromas, which are radiologically translucent. These bone lesions may be unilateral or asymmetrical. The growth of affected bones is delayed and distorted due to interference with the epiphyseal cartilage, and slowly uniting pathological fractures are a common occurrence. Deformity may be gross, with hands and feet transformed into large and almost useless chondromatous masses [6].

A variety of other benign and malignant mesodermal tumours have been reported in Maffucci's syndrome, and the disease has a very high malignant potential [4]. The most common malignant tumour is the chondrosarcoma, which arises by malignant transformation in enchondromas, and probably occurs in some 15% of patients [4,11]. Other malignant mesodermal tumours have included fibrosarcoma [12], angiosarcoma [10], lymphangiosarcoma [13] and osteosarcoma [2]; various benign and malignant ovarian tumours have also been reported [4,10]. In addition, several non-mesodermal tumours have been described in these patients, including gliomas [3,4] and adenocarcinoma of the pancreas [12]. Multiple primary malignancies may occur [2,4,12].

Ollier's disease comprises dyschondroplasia without the cutaneous vascular malformations seen in Maffucci's syndrome; in other respects the two conditions are indistinguishable. Reports of internal vascular anomalies in Ollier's disease [14] add to the impression that the two conditions are extremely closely related.

A patient combining the features of Maffucci's syndrome and the blue rubber bleb naevus syndrome has been reported [15].

Clearly, these patients require careful follow-up, with a low threshold for obtaining radiological and histological examination of any lesions that enlarge rapidly or cause symptoms. Surgical excision of skin lesions may be justified to improve the patient's appearance. Radiotherapy is unhelpful.

Unilateral dermatomal haemangiomatosis [1,2]

Cases have been described in which vascular tumours, histologically similar to those reported in the blue rubber bleb naevus syndrome, developed during the second decade in a unilateral grouping suggesting a dermatomal distribution. The lesions have taken the form of purplish

hemispherical nodules, which may be tender, up to 1.5 cm in diameter. There has been no evidence of any associated bony or systemic lesions, and the affected limb has been of normal size. The lesions have shown no tendency to resolve spontaneously.

These lesions have closely resembled those encountered in Maffucci's syndrome, but the associated bone lesions seen in this disorder have been conspicuously absent.

Dermatomal vascular abnormalities are also a feature of Cobb's syndrome and unilateral dermatomal superficial telangiectasia (unilateral naevoid telangiectasia).

Gorham's disease [1–7]

SYN. HAEMANGIOMAS WITH OSTEOLYSIS; DISAPPEARING BONE DISEASE; OSTEOVASCULAR DYSPLASIA

In this condition, bone is replaced by vascular malformations comprising ectatic thin-walled sinusoidal blood vessels, and there may be associated cutaneous and soft-tissue vascular or lymphatic malformations. The osseous lesions cause osteolysis with fibrosis, and may lead to disappearance of entire bones. The skeletal lesions are usually unilateral and generally involve adjacent bones. There is a predilection for the bones of the shoulders and pelvic girdle [8].

Radiologically, there are lytic lesions of bone with little or no sclerosis. Associated coagulopathy has been described [9–11].

The condition appears to be self-limiting in many cases, but in some patients the disease may be aggressive and ultimately lethal [2,12].

Radiotherapy may be helpful, particularly for bone pain [1,6].

Other multiple vascular malformation syndromes

Bannayan–Riley–Ruvalcaba syndrome [1–11]

SYN. BANNAYAN–ZONANA SYNDROME; RILEY–SMITH SYNDROME; RUVALCABA–MYHRE–SMITH SYNDROME

This term is now used to encompass the disorders previously described separately as the Bannayan–Zonana, Riley–Smith and Ruvalcaba–Myhre–Smith syndromes [3,12].

Clinical features include macrocephaly, multiple subcutaneous and visceral lipomas and vascular malformations, and skeletal abnormalities. The disorder is transmitted as an autosomal dominant trait with variable expression. Clinical similarities with Cowden's syndrome have been recognized for many years [2]. It is now known that mutations in the *PTEN* gene, a tumour-suppressor gene located at 10q23.3, underlie both conditions. Indeed, families have been reported in which individuals with Cowden's syndrome and the Bannayan–Zonana syndrome have both been present, with identical *PTEN* gene mutations in each, suggesting that these two syndromes represent different phenotypic expressions of one disease [13,14]. It now seems probable that patients with Bannayan–Zonana syndrome are at increased risk of malignancy, as are those with Cowden's syndrome [15].

The predominant cutaneous lesions are usually soft, deeply situated lipomatous swellings, but lesions resembling lymphangioma circumscriptum or angiokeratomas have also been described [7]. The trunk and proximal limbs appear to be sites of predilection for these lesions, some of which clearly reach a considerable size. They have shown no tendency to spontaneous resolution. Other skin lesions, in order of decreasing frequency, have included:

1 lentigines on the glans and shaft of the penis;
2 multiple facial papules, showing histological features of both trichilemmomas and viral warts [2];
3 acanthosis nigricans;
4 multiple achordons.

The macrocephaly is not associated with hydrocephalus, and many of the patients show hypotonia, delayed psycho-

motor development, variable degrees of mental retardation and/or seizures.

Intracranial vascular malformations [9] or arteriovenous malformations [16] have been reported. Patients with Bannayan–Zonana syndrome may occasionally have hamartomatous lesions producing cord compression or intracerebral haemorrhage [15]. Additional features have included hamartomatous intestinal polyposis and retinal abnormalities.

Hereditary neurocutaneous vascular malformations [1–4]

SYN. HEREDITARY NEUROCUTANEOUS ANGIOMAS

Reports of this syndrome have been few in number, and it remains unclear whether it is a genuine entity. It appears to be transmitted by an autosomal dominant gene of highly variable expressivity. There are scattered cutaneous vascular anomalies, which are not well described, but are likely to be vascular malformations rather than haemangiomas. Some of the lesions in these families seem to have been macular [4], but others have been papular or nodular, occasionally large enough to warrant excision [2]. The importance of this disorder is the occurrence of intracranial arteriovenous malformations in several family members.

Angiokeratomas

The term angiokeratoma is applied to a number of quite distinct conditions that share a clinical presentation with asymptomatic hyperkeratotic vascular skin lesions and a histological combination of superficial dermal vascular ectasia and hyperkeratosis. The following varieties are generally recognized:

1 angiokeratoma circumscriptum;
2 angiokeratoma of Mibelli;
3 solitary papular angiokeratoma;
4 angiokeratoma of the scrotum and vulva;
5 angiokeratoma corporis diffusum.

Of these, only angiokeratoma circumscriptum is present at birth. The angiokeratomas should be regarded as capillary vascular malformations rather than haemangiomas [1]. Individual patients may occasionally have lesions of more than one of these types [2].

Angiokeratotic lesions may be a feature of the Klippel–Trenaunay syndrome and of Cobb's syndrome. In an isolated case report, a boy was described in whom multiple, widely distributed angiokeratomas were associated with a connective tissue naevus on the foot and a venous vascular malformation of the ankle, with decreased size of the affected leg [3].

Angiokeratoma circumscriptum

SYN. ANGIOKERATOMA CORPORIS CIRCUMSCRIPTUM NAEVIFORME

Aetiology and pathology [1–3]. Angiokeratoma circumscriptum is a vascular malformation of the vessels of the

papillary dermis. These vessels are ectatic histologically, and may be thrombosed. The overlying epidermis shows a variable degree of acanthosis, papillomatosis and compact hyperkeratosis. The elongated rete ridges may partially or completely envelop the dilated vessels. Transepidermal elimination of the dilated capillaries has been demonstrated [4,5]. Lesions in which deeper angiomatous elements have been reported were almost certainly verrucous haemangiomas.

Clinical features [1,5,6]. The condition is rare, and most characteristically takes the form of a fairly extensive hyperkeratotic vascular plaque, usually but not always present from birth. The lesions are typically situated unilaterally on a lower leg or foot, but can occur on thigh, buttock or occasionally elsewhere. They are deep red to blue–black in colour and tend to take on a streaky, banded or zosteriform configuration. The lesions become increasingly studded with warty keratotic papules or nodules, and they may bleed readily on trauma. There is no tendency to spontaneous improvement. Occasionally, they appear to extend during adolescence. Similar lesions have been a feature of the Klippel–Trenaunay syndrome [7], of other mixed vascular malformations [7,8] and of Cobb's syndrome [9].

Diagnosis. Angiokeratoma circumscriptum is distinguished from the other varieties of angiokeratoma principally by virtue of its very early onset and its clinical appearance as a plaque of aggregated papules. However, it may be virtually indistinguishable clinically from verrucous haemangioma; indeed, many of the lesions reported in the literature as angiokeratoma circumscriptum [10,11] were probably verrucous haemangiomas. The main distinction between these conditions is the presence of angiomatous capillary endothelial proliferation in the latter. Angiokeratoma circumscriptum may also be confused, both clinically and histologically, with lymphangioma circumscriptum; some lesions described in the literature as angiokeratoma circumscriptum have almost certainly been lymphangioma circumscriptum, for example several of those reported by Dammert [7]. When thrombosis occurs within the angiokeratoma, malignant melanoma may be mimicked clinically [3].

Angiokeratoma circumscriptum needs to be distinguished from acral pseudolymphomatous angiokeratoma of children, a distinctive entity that is a pseudolymphoma rather than an angiokeratoma [12].

Treatment. Small lesions may be treated by diathermy or by curettage and cautery, but larger lesions will require argon laser ablation [13,14] or surgical excision if treatment is contemplated.

Angiokeratoma of Mibelli

Aetiology and pathology. There is a definite familial predisposition to angiokeratoma of Mibelli, and it is considered probable that this rare condition is transmitted as an autosomal dominant trait with highly variable penetrance [1–3]. Girls appear to be affected predominantly. The distribution and the regular association with acrocyanosis and chilblains appear to implicate cold injury as a provocative factor.

The histopathological features are essentially the same as those of angiokeratoma circumscriptum, i.e. marked ectasia of vessels within the papillary dermis, with associated acanthosis, papillomatosis and hyperkeratosis of the overlying epidermis [3,4]. Elongated rete ridges tend to encircle and enclose the vascular lacunae.

Clinical features [3,5–7]. The lesions commonly develop between the ages of 10 and 15 years, but both earlier and later onset has been recorded. A history of recurrent chilblains is usual, but not invariable. The earliest lesions are minute, bright-red macules, which slowly increase in size and become elevated, warty and darker in colour. Many attain a diameter of about 5 mm, but some may be larger. The dorsal and lateral aspects of fingers and toes are most often affected, but lesions also occur on the dorsa

Fig. 15.22 Angiokeratoma of Mibelli in a 9-year-old child.

of hands and feet (Fig. 15.22) and occasionally on the knees and elbows. On the calves, lesions resembling erythema induratum may be present [2]. When climate and dress provide the right conditions, they may also develop on the buttocks. The lesions, which are often numerous, may be disfiguring but seldom cause symptoms; they have, however, been associated with ulceration of the fingertips [1,5]. There is little tendency to spontaneous resolution.

Treatment. The lesions can be treated, if desired, with liquid nitrogen, electrodesiccation, laser ablation or by local excision.

Solitary papular angiokeratoma [1]

This entity has been convincingly distinguished from the other angiokeratomas, particularly from angiokeratoma circumscriptum [2]. Both solitary papular angiokeratoma and angiokeratoma of Mibelli are almost certainly acquired disorders, probably arising as a response to trauma and cold injury, respectively, rather than being developmental anomalies, but both are considered in this chapter because of the clinical and histopathological similarities with the other angiokeratomas.

Histologically, solitary papular angiokeratomas are more or less indistinguishable both from angiokeratoma circumscriptum and angiokeratoma of Mibelli. Solitary angiokeratomas differ clinically mainly by their much later appearance, usually between the age of 10 and 40 years, often with a history of preceding trauma. They occur in both sexes and at more or less any site, although the legs are the site of predilection. Although usually single, multiple lesions may occur. The patient often presents with a history of sudden enlargement, darkening or bleeding in a long-standing lesions, leading to suspicion of a malignant melanoma [2]. The lesions have the appearance of warty papules, generally between 2 and 10 mm in diameter, and dark red to blue-black in colour.

Solitary papular angiokeratomas are frequently mistaken clinically for viral warts, melanocytic naevi, or more importantly, malignant melanoma. They should be removed by local excision if there is any anxiety about the diagnosis.

Angiokeratoma of the scrotum

SYN. ANGIOKERATOMA OF FORDYCE

Aetiology and pathology. The most common of the angiokeratomas, angiokeratoma of the scrotum, becomes more frequent with increasing age [1]. In a study in Japan, the prevalence was shown to increase from 0.6% in 16 year olds to 17% in those over 70 years of age [2]. It should probably be regarded as a degenerative disorder, and there is evidence that local venous hypertension plays a part in their development [1,3].

The histological features are similar to those observed in angiokeratoma of Mibelli and solitary papular angiokeratoma [4].

Clinical features [1,3,5,6]. Small, 1–4 mm, bright-red vascular papules may develop on the scrotum as early as late adolescence. With increasing age they become larger, darker and more numerous. Patients may occasionally complain of itching, soreness or bleeding [7]. Identical lesions may also occur on the glans or shaft of the penis, or even on the upper thighs and in the groins. Well-circumscribed, macular, telangiectatic lesions have been described on the oral mucosa in patients with angiokeratomas of the scrotum [8].

The diagnosis of angiokeratoma corporis diffusum

should be considered in any patient presenting with scrotal angiokeratomas.

Treatment. Liquid nitrogen cryotherapy, diathermy or laser ablation [9,10] can be used to treat symptomatic lesions. Evidence of associated disorders capable of increasing the scrotal venous pressure should be sought, particularly varicocoele, treatment of which may lead to regression of the angiokeratomas [3].

Other developmental defects

Complex defects of the first branchial arch

The complex disorders resulting from defective development of the first branchial arch [1] include the following of relevance to dermatologists:
1 mandibulofacial dysostosis (syn. Treacher Collins syndrome);
2 oculomandibulodyscephaly with hypotrichosis (syn. Hallermann–Streiff syndrome);
3 oculo-auriculovertebral dysplasia (syn. Goldenhar's syndrome) and hemifacial microsomia.
Defects in development of the other branchial arches do not result in cutaneous abnormalities, with the exception of thyroglossal cysts and fistulae, which are remnants of the thyroglossal duct, and branchial cysts and fistulae, which result from a failure to obliterate the cervical sinus.

Mandibulofacial dysostosis

SYN. TREACHER COLLINS SYNDROME; FRANCESCHETTI–KLEIN SYNDROME

Definition. An autosomal dominant disorder of craniofacial development resulting from defective development of the first branchial arch [1].

Aetiology. Treacher Collins syndrome is caused by mutations in the gene *TCOF1* at chromosomal locus 5q31.3 [2,3]. The gene product 'treacle' is a nucleolar trafficking protein, essential during craniofacial development, the mutational spectrum suggesting haplo-insufficiency during embryogenesis of the first and second branchial arches as the molecular mechanism [4]. Treacher Collins syndrome is a dominant trait, 60% of cases arising as new mutations [5]. Expression is highly variable with no apparent genotype–phenotype correlation, and in one study two of 28 families showed no mutation in *TCOF1* [6]. The abnormalities appear to result from arrested development of the first branchial arch at the 5–9-week stage. It will be of interest to dermatologists that the malformations observed in this disorder are similar to those produced in fetal mice by retinoids given at day 11.5 post-fertilization, corresponding to week 4 in humans [7,8]. Furthermore, Lungarotti *et al.* [9] described facial changes resembling mandibulofacial dysostosis in an infant whose mother took vitamin A during pregnancy. Mice deficient in endothelin-1 show strikingly similar craniofacial abnormalities to those seen in humans with the Treacher Collins syndrome [10].

Clinical features. The clinical presentation is highly variable with sometimes subtle manifestations. The facial anomalies are usually symmetrical and include antimongoloid slanting palpebral fissures, coloboma of the lower lid, absence of lower eyelid lashes, malformation of the pinnae with stenosis of the external auditory meati, micrognathia, hypoplastic zygomatic arches and extension of scalp hair on to the cheeks [2,3]. Blind fistulae and skin tags are sometimes present between the ear and the angle of the mouth. The mouth itself is unusually large, and the palate high and often cleft. Circumscribed scarring alopecia is an occasional finding. Most affected individuals are of normal intelligence but conductive-type deafness is a common problem.

Treatment. The facial appearance tends to improve as the child grows, and may be enhanced by surgery [1]. Early respiratory difficulties may develop as a result of a narrow airway, occasionally requiring tracheostomy [11]. Deafness requires early recognition and correction with hearing aids and, where possible, surgery.

Prenatal diagnosis by ultrasound may not be possible until the second trimester [12]. In some families a diagnosis can be made in the first trimester by linkage [13] or mutation [14] analysis. Ellis *et al*. [14] found mutations in *TCOF1* in 52 of 97 patients with Treacher Collins syndrome.

Hallermann–Streiff syndrome

SYN. OCULOMANDIBULODYSCEPHALY WITH HYPOTRICHOSIS; DYSENCEPHALIC SYNDROME OF FRANÇOIS

Definition. A craniofacial dysostosis comprising skeletal, ophthalmological and cutaneous defects.

Aetiology. Hallermann–Streiff syndrome is usually sporadic. The data from familial cases has been variably interpreted as indicating an autosomal dominant gene, with most cases reflecting new mutations [1], or autosomal recessive inheritance [2].

Pathology. Histologically, the skin shows a rather loose-weave arrangement of dermal collagen and fragmented elastic fibres [3]. Scanning electron microscopy of hairs demonstrates circumferential grooving or absence of the cuticle [4].

Clinical features [3–8]. The head is short (brachycephalic), the mandible hypoplastic and the nose beaked, producing a characteristic bird-like appearance. Ocular abnormalities are a major problem, particularly bilateral microphthalmia and cataracts. The mouth is small with a high-arched palate. Teeth are often present at birth; partial anodontia, hypoplasia and malimplantation of the teeth are also common [7]. There is proportionate dwarfism, and psychomotor retardation in 15–31% [5].

Cutaneous abnormalities are a striking feature. The scalp hair may be normal at birth, but soon becomes diffusely sparse and brittle, with lack of hair particularly along the sides and back of the head. A highly characteristic finding is alopecia along the lines of the cranial sutures. The eyebrows, eyelashes, and pubic and axillary hair are also scanty. The skin of the face is atrophic, particularly in the central part of the face, and telangiectasia may be prominent. Vitiligo and livedo have been reported [8].

Diagnosis. This condition must be differentiated from progeria, in which atrophy of the skin is more generalized, and alopecia both more pronounced and more diffuse.

Treatment. Airway compromise can be life-threatening and requires early intervention [8]. Affected children require expert ophthalmological and dental care. Reconstructive procedures are dealt with later and sometimes a wig is helpful. Aesthetic surgery is difficult because the skin is generally thin and prone to scarring [8].

Goldenhar syndrome and hemifacial microsomia

SYN. OCULO-AURICULOVERTEBRAL DYSPLASIA; FACIO-AURICULOVERTEBRAL SYNDROME; HEMIFACIAL MICROSOMIA

Definition. An association of defects arising in the first and second branchial arches.

Aetiology. Goldenhar syndrome is relatively common, with an incidence of about one in 5600 [1]. Genetic analysis has been hampered by phenotypic heterogeneity, particularly with regard to severity. The genetic data favours autosomal dominant inheritance although most cases are sporadic [2]. A minor related anomaly, such as pre-auricular skin tag, occurs in 8% of first-degree relatives [3]. Goldenhar syndrome appears to be the result of abnormal development of both the first and second branchial arches. Suggested causes include 'over-ripeness ovopathy' [4], haemorrhage involving the first and second branchial arches, and ectodermal non-disjunction and subsequent mesodermal tethering [5]. The last of these best explains the multisystem nature of this condition: involvement of the otic placode accounts for the ear anomaly and a similar process over the neuraxis explains the association with occult spinal dysraphism. Infants of diabetic mothers appear to be at increased risk [6]. Retinoic acid administered to rats on gestational days 10–12 produces similar anomalies [7].

Clinical features [3]. Much of the facial skeleton and musculature is hypoplastic. The pinna is small and deformed. Deafness may occur. Accessory auricles and pits are common, occurring along a line between the ear and the corner of the mouth. A low hairline on the forehead and temples has occasionally been reported. The facial, auricular and ocular abnormalities tend to be asymmetrical, occasionally more or less unilateral, when the term hemifacial microsomia is applied.

Ocular abnormalities are frequent and highly characteristic, particularly microphthalmia, upper eyelid coloboma, epibulbar dermoids and lipodermoids. Dermoids and lipodermoids present as yellow or white swellings at the limbus or corneal margin, dermoids usually in the lower outer quadrant and lipodermoids in the upper outer quadrant.

Vertebral anomalies are a constant feature, especially hypoplasia of vertebrae or hemivertebrae, most often in the cervical spine, and occult spinal dysraphism.

Diagnosis. There is phenotypic overlap with the oculocerebrocutaneous syndrome, in which ear anomalies are less common and focal skin defects more common than in Goldenhar anomaly [8].

Pre-auricular cysts, tags and sinuses

SYN. EAR PITS AND TAGS; CONGENITAL AURICULAR FISTULAE

Aetiology. The auricle is formed by the fusion of six small tubercles, three from each of the first two branchial arches. Imperfect fusion leads to entrapment of the epithelium to form pre-auricular cysts, which connect with the skin via pre-auricular sinuses. Such cysts and sinuses may occur as an isolated autosomal dominant trait [1]. Pre-auricular pits and sinuses also occur in the first and second branchial arch syndromes discussed above, i.e. Treacher Collins syndrome, Goldenhar's syndrome and retinoic acid embryopathy. They are frequent also in the following syndromes: cat eye [2], cervico-oculo-acoustic, 3p-, 4p-, Kabuki's, Nager's acrofacial dysostosis, Peters'-plus, Townes–Brocks [3] and branchio-oto-renal (BOR). BOR syndrome can be caused by mutations in the *EYA1* gene [4]. Posterior ear pits occur in the Beckwith–Wiedemann syndrome [5].

Clinical features. Asymptomatic pre-auricular cysts and sinuses are very common (Fig. 15.23), occurring in 6.2 per 1000 live births in Israel [6], more often in black populations, and in 2.5% of the Chinese population [7]. These congenital, often bilateral, lesions may go unnoticed until infection develops, when they present as an acutely tender swelling anterior to the ear, with pus draining through a small opening just in front of the ascending limb of the helix. In most cases infection is recurrent, and an asymptomatic sinus is present on the other side. Very

Fig. 15.23 Pre-auricular sinus.

occasionally, the patient may present with a granulomatous nodule at the mouth of the sinus.

Hearing impairment is found in 17% of neonates with isolated preauricular pits or tags [8]. Associated developmental anomalies of the branchial apparatus may coexist, particularly malformations of the auricle, accessory auricles, and branchial fistulae. CT scanning is more useful than MRI in the delineation of these anomalies [9]. Although preauricular sinuses coexist with renal anomalies in certain syndromes, e.g. the BOR syndrome [4,10], isolated pre-auricular tags or pits are not associated with renal anomalies [6,10].

Diagnosis. First branchial arch sinuses may discharge into the external auditory meatus (cervico-aural fistulae). Granulomatous lesions may be confused with lupus vulgaris [11].

Treatment. Hearing tests are indicated in neonates with isolated ear pits [8], but renal investigations are not [6]. Surgical excision is required when secondary infection has occurred, but should be delayed until the acute infection has been treated with systemic antibiotics. The lesion most typically comprises several cysts arranged along a longitudinal tract which blends with the periosteum of the auditory canal. Full visualization should be achieved before excision [12].

Accessory tragus

SYN. ACCESSORY AURICLE; CARTILAGE NAEVUS

Aetiology [1]. The tragus (the prominence anterior to the external auditory meatus) is derived from the dorsal portion of the mandibular (first) branchial arch. During embryonic life, the first arches grow ventrally to join in the midline, and accessory tragi may be found anywhere along this migratory course, from tragus to sternoclavicular joint.

Fig. 15.24 Accessory tragi.

Pathology. Numerous tiny hair follicles and eccrine sweat glands are conspicuous in the dermal core of accessory tragi, which are covered by normal epidermis. There is a prominent connective tissue framework in the subcutaneous fat [2]. Cartilage is almost always present. They may be difficult to differentiate from hair follicle naevi [3].

Clinical features. Accessory tragi take the form of small, skin-coloured tags or nodules, arising on or near the tragus, along a line drawn between the tragus and the corner of the mouth, or on the neck (*cervical auricles* or *wattles*) along the anterior edge of the sternomastoid muscle [4]. Vellus hairs often protrude from the surface. They may be unilateral or bilateral, single or multiple (Fig. 15.24), and either soft or cartilaginous in consistency. Like preauricular cysts and sinuses, they most commonly occur as a solitary abnormality, present in about 1% of neonates [5], sometimes showing autosomal dominant inheritance [6]. They also occur with other malformations and syndromes of the first branchial arch, such as Treacher Collins, Goldenhar, Nager's acrofacial dysostosis [7], 4p- [8], oculocerebrocutaneous and Townes' syndromes [9,10].

Similar lesions have very occasionally been described at other sites on the face such as the glabella [11].

Treatment. Accessory tragi are best removed surgically, with careful dissection and excision of any associated cartilage that may extend more deeply [4,12].

Cervical tab

SYN. CERVICAL AURICLE; WATTLE; CONGENITAL CARTILAGINOUS RESTS OF THE NECK [1–4]

Cervical tabs simply represent accessory tragi at the ventral end of the migratory path of the first branchial arch.

Histologically, they comprise lobules of mature cartilage embedded in dense collagen.

Clinically, cervical tabs take the form of an irregular, often pedunculated papule or nodule up to 15 mm in diameter, occurring on the neck along the line of the anterior border of the lower third of the sternomastoid muscle. They may be unilateral or bilateral, and are usually noted during infancy. Since these lesions are not associated with fistulous tracts or connections to deeper structures, excision is straightforward.

Branchial cysts, sinuses and fistulae

A 35-day-old human embryo has four gill-like branchial clefts on the sides of the neck, separating the branchial arches. The first cleft persists as the external auditory meatus, the others normally disappear by fusion. Incomplete fusion results in sinuses, fistulae and cysts. Sinuses (blind tracts) and fistulae (patent tracts) which open on to the side of the neck are visible at birth, and may become more prominent later because of mucous secretion, inflammation, infection or granulation tissue at the external opening. Typical sites for cutaneous openings are the parotid area and below the angle of the mandible (first branchial cleft), and along the anterior border of the sternomastoid muscle (second branchial cleft). Cysts usually present in the second or third decade as a painful swelling due to inflammation or infection.

Branchial cyst

SYN. BRANCHIAL CLEFT CYST; LATERAL CERVICAL CYST; LYMPHOEPITHELIAL CYST

Aetiology. The precise origin of branchial cysts remains unclear. The second branchial arch extends caudally during early embryonic life to fuse with the fifth arch, thus enclosing the second, third and fourth arches and their respective clefts to form an ectodermal pocket, termed the cervical sinus [1]. Branchial cysts may represent unobliterated remnants of either this cervical sinus or of the unenclosed first branchial cleft [2–4]. A previously popular but now discounted theory is that branchial cysts arise from remnants of the thymopharyngeal tract, the original connection between the thymus and the third pharyngeal pouch, from which it takes it origin, as is the case with cervical thymic cysts [5]. Many authorities now prefer the view that they arise by cystic degeneration of remnants of parotid glandular epithelium trapped within cervical lymph nodes, a theory that better explains their late clinical appearance and the frequent presence of lymphoid tissue in the walls of branchial cysts [1,6]. However, the similarities between the lining epithelium of branchial cysts and the tonsillar crypt epithelium have recently been stressed [7], raising yet further possibilities in relation to the origin of these anomalies.

Although these defects most commonly occur sporadically, familial cases have occasionally been reported [8].

Pathology [1,7]. Branchial cysts are usually lined by stratified squamous, less commonly by respiratory-type ciliated, columnar epithelium. Beneath the epithelium one can usually observe abundant lymphoid tissue, often with germinal centres and subcapsular lymph sinuses.

Squamous carcinomas arise very occasionally in the epithelial lining of the cyst [9].

Clinical features [1,10]. Branchial cysts present at any age, but most commonly during the second and third decades. The usual complaint is of a painless, stable swelling in the neck. In some cases, the swelling is painful, usually because of secondary infection, and in others the swelling is only intermittently apparent. Pressure symptoms may occur. These cysts vary from less than 1 cm to about 10 cm in diameter and are usually unilateral. On palpation they are generally obviously cystic, but in other cases they may appear solid. Work's classification [4] differentiates the rare type I lesions which lie superior to the facial nerve and parallel to the ear canal, sometimes postauricular [11], from type II lesions which may be closely associated with the facial nerve and occur in the parotid area or upper third of the neck.

Diagnosis. In the differential diagnosis of swellings at this site, one has to consider causes of unilateral lymph-node enlargement, particularly malignant and tuberculous lymphadenopathy [12], parotid and thyroid tumours, thymopharyngeal cyst [5], thyroglossal cyst, dermoid cyst, teratoma, carotid body tumour, infantile haemangioma and neurofibroma. Cystic hygroma occurs in the posterior triangle of the neck, i.e. posterior to the sternomastoid muscle, and is usually apparent from birth or shortly afterwards.

Treatment. Otological and MRI examination are important to exclude associated anomalies [11]. Branchial cysts are removed surgically, with superficial parotidectomy and facial nerve dissection if necessary [3,13].

Branchial sinuses and fistulae

SYN. CERVICAL SINUSES AND FISTULAE

Aetiology [1–3]. Branchial sinuses are believed to represent remnants of the branchial cleft depressions, particularly the second or cervical sinus. Familial occurrence has been recorded [4,5]. True branchial fistulae, opening into the pharynx, appear to be extremely rare, and must result from perforation of the second cleft membrane.

Pathology [3]. Branchial sinuses are lined by mucus-secreting columnar respiratory-type epithelium.

Clinical features [3]. Branchial sinuses are usually apparent from birth as pits or blind-ending tracts in the lower third of the neck, along the anterior border of the sternomastoid muscle. There is frequently a discharge, and infection may occur, although less frequently than in the case of branchial cysts. They are bilateral in about one-third of cases. A skin tag, sometimes containing cartilage, may mark the site of the opening. The tract itself may be palpable, running upwards in the neck from the cutaneous opening. Branchial fistulae share the same cutaneous distribution as branchial sinses, but open into either the pharynx or external auditory canal [6,7].

Branchial fistulae can occur as an isolated anomaly [7], but are also a characteristic component of the autosomal dominant BOR syndrome due to *EYA1* mutations, in which they are associated with pre-auricular pits, deafness and renal anomalies [8]. They also occur with pre-auricular pits, deafness, commissural lip pits and rib anomalies in the autosomal recessive branchio-oto-costal syndrome [9].

Treatment. Treatment is by surgical excision under general anaesthesia [10]. Injection of methylene blue into the cutaneous opening can be used to guide surgical removal [7]. Fistulae can be tackled by avulsion through the mouth using a varicose vein stripper [11].

Midline cervical cleft [1–5]

Aetiology. This anomaly probably results from imperfect first or second branchial arch fusion in the midline.

Clinical features. This lesion takes the form of a vertically orientated atrophic area, several centimetres in length, and several millimetres in width, in the lower anterior midline of the neck. There may be associated skin tags and the upper end and a sinus tract at the caudal end. Fibrous bands may connect the lesion with the underlying platysma, causing contractures of the neck and lower jaw. Traction on the growing mandible may produce a bony spur. It may be associated with thyroglossal and other branchial cleft anomalies.

Treatment. Treatment is surgical, via a series of Z-plasty incisions, ideally in the first year of life. Deep fibrous remnants should also be removed.

Thyroglossal cysts

Aetiology. Thyroglossal fistulae and cysts result from failure to obliterate the embryonic thyroglossal duct, and may occur anywhere along its length. Thyroglossal cyst is commoner in first-degree relatives of children with congenital hypothyroidism, segregation analysis supporting an autosomal dominant gene responsible for the different phenotypes [1].

Pathology. Thyroglossal cysts are lined by stratified squamous or mucus-secreting columnar epithelium.

Clinical features [2–5]. Thyroglossal cyst usually presents during the first 5 years of life but may not be diagnosed until adult life. It is the commonest cause of midline anterior neck swellings in children. It presents as a soft mass in the midline of the neck, 1–3 cm in diameter and close to the hyoid bone. It moves upwards on swallowing or on protrusion of the tongue. There may be an opening in the mouth at the foramen caecum, leading to fetor or an unpleasant taste. Occasionally, they drain externally, often as a result of previous surgical procedures. Recurrent infection may be a problem.

It is important to distinguish an ectopic thyroid from a thyroglossal cyst, because the former may be the patient's only functional thyroid tissue [6,7]. It is essential to undertake thyroid function tests and technetium-99m (^{99m}Tc) or iodine-123 (^{123}I) scintillation scanning to identify any possible ectopic thyroid tissue prior to surgical excision [8].

Malignant degeneration may occur in thyroglossal duct remnants, though generally this is associated with a good prognosis following excision [9].

Diagnosis. Enlarged lymph nodes and dermoid cysts are the main differential diagnosis [10]. Bronchogenic cysts may occur in the midline at the suprasternal notch, but are rare.

Treatment. Treatment is by dissection of the cyst and tract, and removal of the hyoid bone [10,11]. Ethanol sclerosis therapy has also been used [11].

Other defects of relevance to dermatology

Bronchogenic cyst

SYN. PRESTERNAL CILIATED CYST

Aetiology. These anomalies usually occur in the chest or

mediastinum, but are very occasionally found in the skin [1–15]. They are assumed to develop from tracheal buds at the time of division of the foregut into its tracheal and oesophageal components. At this stage, the right and left mesenchymal bars of the sternum are still unfused. How such cysts come to occur in an extrathoracic location is difficult to explain. The characteristic suprasternal site may reflect pinching off of bronchogenic tissue by the closing sternal plates. The other locations may be reached by migration of this tissue [3]. Alternative explanations for bronchogenic cysts include lymphatic or haematogenous spread of respiratory tissue and *in situ* anomalous tissue differentiation (heteroplasia) [8].

Pathology. The cysts occur in the dermis or subcutis. The mucosal lining comprises lamina propria and a pseudostratified columnar ciliated epithelium with goblet cells. The cyst wall frequently contains smooth muscle and mucous glands. Lymphoid tissue is occasionally present, particularly when secondary infection has occurred. Cartilage is occasionally seen, in keeping with the bronchogenic origin of this lesion. There is no connection to underlying structures.

Clinical features. Bronchogenic cysts are solitary and four times more common in males [9]. They are apparent at birth or shortly afterwards, usually as a pinpoint orifice, or a soft, asymptomatic mobile nodule that very slowly increases in size and may eventually discharge mucoid fluid through a small fistula. Other morphologies include a papillomatous nodule [5] and an area with the appearance of aplasia cutis, and linear, erythematous pruritic hyperkeratotic papules resembling ILVEN [9]. Cutaneous bronchogenic cysts are characteristically located close to the suprasternal notch or over the manubrium sterni [11]. Occasionally, they occur in the shoulder and scapular area [10], or in the thyroid gland. Lesions have also been reported on the chin [12,13] and abdominal wall [14]. Malignant transformation occurs in non-cutaneous bronchogenic cysts [9] but has not been reported in cutaneous bronchogenic cysts [9,13]. Tanita *et al*. [15] reported a malignant melanoma arising in a bronchogenic cyst on the scapular area of a middle-aged Japanese man.

Diagnosis. Differential diagnosis includes branchial cysts, sinuses and fistulae [16], thyroglossal cysts [17], teratomas and heterotopic salivary gland tissue [18].

Treatment. Treatment comprises surgical excision, which is advisable in view of the possibility of later malignancy [15].

Cutaneous associations with sternal clefts

Sternal clefts are rare congenital anomalies, which are, however, frequently associated with a variety of cutaneous abnormalities, including fistulae [1,2], an area of ulceration or scarring [3–5], supra-umbilical midline raphe [6] and facial haemangiomas. Congenital aortic aneurysm is one of the more serious extracutaneous associations. Recognized syndromes include the PHACE association [7] and the sternal malformation/vascular dysplasia association [8], which may overlap.

Congenital inclusion dermoid cysts

Aetiology and nomenclature [1–4]. Most cutaneous dermoid cysts probably develop from epithelium trapped along lines of embryonic fusion. They should not be confused with benign cystic *teratomas*, which are also sometimes termed dermoids. They are usually sporadic but there are several reports of familial dermoid cysts of the nose, midline dermoids have occurred in a mother and daughter, and external angular dermoids have been reported in siblings [5].

Pathology [1]. These cysts are located in the subcutis; they are often adherent to periosteum, and may invade or erode underlying bone. The cysts are lined by keratinizing stratified squamous epithelium, complete with hair follicles, sebaceous and sweat glands. The lumen contains lipid, keratin and hair. There may be an associated sinus tract extending superficially or deeply or both.

Clinical features [1,3,5]. About 40% of dermoid cysts are present at birth, and about 70% by the age of 5 years. They typically appear as subcutaneous 'doughy' spherical nodules varying from around 0.5 to 6.0 cm in diameter, largely depending on site. Many have a sinus opening, from which hairs may project. They tend to present at different sites in children and in adults [6]. In children, they are most often seen on the head and neck [3,6]. Predilection sites are the outer third of the eyebrow, the so-called *external angle dermoid* [7], the midline of the nose, usually near the bridge (Fig. 15.25) [2,4,8,9], the scalp, the submental area, the anterior neck, the anterior chest wall and the occipital area [10]. In adults, they are most commonly seen in the genital and postanal areas [6].

Periorbital lesions may displace the eyelid. Recurrent infection may be a problem, and osteomyelitis and meningitis are occasional complications [8,10,11]. Pressure erosion of bone may also occur [12].

Diagnosis [13]. In the neck, the dermoid cyst is only slightly less common than the thyroglossal cyst and may be clinically indistinguishable. It must likewise be differentiated preoperatively from ectopic thyroid gland.

Cysts at the bridge of the nose must particularly be distinguished from nasal gliomas, which present at birth as firm, reddish tumours at the side of the bridge, and meningoencephalocoeles which may pulsate and may be associated with an underlying skull defect [14].

It is essential to use MRI scanning [13,15] and/or high-resolution ultrasound [16] to evaluate midline facial masses, and thyroid function tests and ^{99m}Tc or ^{123}I scintillation scanning to identify any possible ectopic thyroid tissue prior to surgical excision of neck lesions [17].

Fig. 15.25 Midline dermoid cyst on the bridge of the nose.

Treatment [2,3,7]. Surgical excision may be complicated by the presence of deep tracts adherent to underlying periosteum, or the septum in the case of nasal lesions. Failure to excise these tracts leads to recurrence, and treatment of these lesions is therefore best undertaken under general anaesthesia by a plastic surgeon.

Nasal glioma

Nasal gliomas are rare childhood lesions [1–5], not true gliomas but rather encephalocoeles that have lost their intracranial connection. They comprise heterotopic neuroectoderm and probably develop from neuroectodermal tissue evaginated through the nasofrontal fontanelle, but subsequently not fully retracted by the dura, and amputated by closure of the craniofrontal sutures. Incomplete closure of these sutures may result in a stalk of fibroglial tissue attached to the neuroectodermal mass passing through the foramen caecum. Most are intranasal, but some appear externally.

Histology shows collections of astrocytes interspersed with dense connective tissue trabeculae, sometimes containing striated muscle fibres, within the dermis. In one case all three components of neural tissue were present, that is leptomeninges, glia and neurons, as well as sweat duct hyperplasia [5].

Nasal gliomas are generally present at birth, and thereafter grow in proportion to the child. They are asymptomatic and take the form of a firm, red or bluish, smooth, domed swelling to one side of the root of the nose. Unlike true encephalocoeles, they do not increase in size with the Valsalva manoeuvre. Intranasal gliomas take the form of a polypoid mass in the nose or pharynx, causing upper respiratory tract obstruction.

Differential diagnosis includes the true nasal encephalocoele and meningoencephalocoele [6], extracranial meningioma [7], other cutaneous neural heterotopias [8], congenital dermoid cyst, lacrimal duct cyst, neuroblastoma and rhabdomyosarcoma [9], but they are probably most often confused with infantile haemangioma [10,11].

Treatment is surgical. If preoperative imaging reveals an intracranial connection, collaboration is required between an ear, nose and throat surgeon and a neurosurgeon [4].

Transverse nasal groove

The appearance of this lesion may be explained by differential growth of the alar and septal cartilages of the nose during childhood [1] or as a residual embryonic groove in the frontonasal cartilage [2]. It is probably not rare, but is seldom noticed. It is often hereditary [2], possibly determined by an autosomal dominant gene [3].

This is probably the same lesion that has been considered to be associated with allergic rhinitis, thought to be caused by repeated manipulation of the nose, and usually termed a 'nasal crease' [4]. No studies have been reported that seek to determine whether this lesion is in fact more frequent in children with allergic rhinitis.

A reddish pink, transverse streak or a shallow groove appears at the junction of the middle and lower thirds of the nose, generally at about the age of 10 years and most often in girls. It is obliterated spontaneously during early adult life. The presence of milia and comedones along this nasal groove has been described [2,5–8].

Lip pits

There are three types of lip pits: commissural pits, sinuses of the upper lip and lower lip pits, also known as lip sinuses.

Commissural lip pits

These are the commonest type of lip pits, and are found in about 2% of neonates, the highest frequency being found in black neonates [1]. Pits are visible just within the oral cavity at the angle of the mouth. These pits are generally bilateral, and should be regarded as sinuses, ending blindly within a few millimetres of their openings. They probably arise as a result of locally incomplete fusion of the maxillary and mandibular prominences. Histologically, the sinuses comprise stratified squamous epithelium identical to that of the vermilion border. Ducts having a cuboidal epithelium have occasionally been noted to open into the main sinus lumen, but associated glands have not been identified. Commissural lip pits are frequently inherited as an autosomal dominant trait [2]. They may be associated with pre-auricular sinuses [3], and may rarely communicate with the parotid duct [4]. They have occasionally been reported in association with other defects particularly deafness, pre-auricular sinus, external ear anomaly [5–7], rib anomalies [8] and a variant of BOR syndrome without renal anomalies which mapped to 1q31 rather than to the established BOR gene (*EYA1*) locus at 8q13 [6,7,9]. Van der Woude's syndrome also features lip pits and maps to 1q31, but the two loci are distinct [9].

Sinuses of the upper lip

Congenital sinuses of the upper lip are extremely rare. One third are lateral, rarely symmetrical [10], while the rest occur in the midline above the vermilion border, between the philtrum and the frenulum [11–13]. The embryology of these sinuses is unclear. Lateral sinuses may represent a forme fruste of cleft lip due to failure of fusion of the maxillary processes, or aberrations in the normal mesodermal merging process [12]. However, cleft lip is more often lateral, whereas upper lip pit is more often medial [14]. The idea that upper lip sinuses arise from a burrowing process analogous to that which forms the nasal cavities [11] is supported by the facts that the upper lip and nasal cavities are formed at the same embryological stage, that both anterior nasal cavities and upper lip sinuses are lined by stratified squamous epithelium, and that the sinus never goes right through to the oral cavity [14].

Congenital midline sinus of the upper lip may present with recurrent swelling or cellulitis around the frenulum [14,15].

Occasionally, upper lip sinuses are associated with other developmental anomalies such as hypertelorism, nasal fistula and lip fistula [10,16,17].

Lower lip pits

SYN. CONGENITAL LIP SINUSES; CONGENITAL LIP FISTULAE

These take the form of bilateral openings in the vermilion border, at the peaks of the lower lip convexities, and may be associated with nipple-like protruberances [18]. Secretions may be expelled from these sinuses under the same conditions that stimulate secretion of saliva. Histologically, the pits are blind sinuses, about 2–15 mm in length, lined by stratified squamous epithelium identical to that of the lip [19]. At the blind end, mucous glands may be present.

Lower lip pits are a characteristic component of the Van der Woude syndrome, an autosomal dominant trait with very variable expression. When fully expressed, the syndrome comprises cleft lip, cleft palate and uvula, hypodontia and lower lip pits [20–24], but some patients and families have only lip pits [25]. Lower lip pits are also a characteristic feature of the popliteal pterygium syndrome, in which they are also associated with cleft lip and/or palate [26,27]. Van der Woude and popliteal pterygium syndromes share the facial phenotype and are in fact allelic variants, both caused by mutations in *IRF6* at 1q32 [28]. A variety of other anomalies have occasionally been reported in association with lower lip pits [29], including type I orofaciodigital syndrome [30].

Rudimentary polydactyly [1,2]

The commonest form of supernumerary digit is postaxial polydactyly (PAP), in which the additional digit, which may be well-formed (PAP-A) or rudimentary (PAP-B), arises from the ulnar border of the hand, at or near the base of the fifth digit.

Postaxial polydactyly is ten times more common in black people than in white people: the US estimates of incidence are 1/3300–1/630 live births in white people and 1/300–1/100 in black people. It is transmitted as an autosomal dominant trait, possibly modified by a sex-linked recessive modifier gene [1]. The prevalence is 44% in the offspring of affected black fathers and 31% in the offspring of black mothers. In the offspring of non-black fathers and mothers it is 34% and 33% respectively [1]. PAP occurs in 75% of patients with trisomy 13 (particularly those involving q31–q34) [2] suggesting a locus on chromosome 13. PAP-A can be caused by mutations in the *GLI3* gene at 7p13 and possibly another gene at 7p15–q11 [2], and other loci have been identified on chromosome 13 and at 19p13.1–13.2 [3].

The condition is often bilateral. The rudimentary lesion is a small, skin-coloured, sometimes pedunculated nodule, which may contain cartilage or be capped by a vestigial nail. Sometimes the lesion is soft and globular, in other cases warty.

The presence of numerous nerve bundles is a histological feature [4], which may also be seen at sites from which supernumerary digits have been amputated spontaneously, or traumatically, in early life [5].

Solitary ectopic nails have been reported on the palmar aspect of fingers, usually the little finger. These have been regarded as a separate abnormality from supernumerary digits [6]. In adults, such lesions must be distinguished from acquired digital fibrokeratomas [7].

Supernumerary digits may be excised on cosmetic grounds.

Supernumerary nipples

Supernunerary areolae and nipples are very common, occurring in about 6% of a German population [1]. There is some evidence that they are commoner in males than in females, and that they are commoner on the left side [1]. It is more frequent to have a supernumerary areola without a nipple, but supernumerary nipples do not occur without an areola. There appear to be a strong genetic predisposition, with the trait being transmitted on an autosomal dominant basis with incomplete penetrance. There is an unresolved debate as to whether there is [2–4], or is not [5,6], an association between supernumerary nipples and urinary tract malformations.

Developmental anomalies of the umbilicus

Clinically significant developmental anomalies in the region of the umbilicus are rare but present important diagnostic problems for the dermatologist [1]. The commonest

Fig. 15.26 Umbilical granuloma.

umbilical lesion in the neonate after detachment of the umbilical cord is umbilical granuloma (Fig. 15.26) [2,3], which has become less common since the routine application of talc to the umbilical stump was discontinued. A persistent umbilical lump or discharge requires investigation by ultrasonography or CT before considering surgical treatment [3,4].

Anomalies of the omphalomesenteric (vitelline) duct [3,5–8]

Very early in embryogenesis the omphalomesenteric (or vitelline) duct connects the yolk sac with the embryonic digestive tract via the umbilical cord. It is normally obliterated between the fourth and seventh weeks. Anomalies have been classified [7] as: (i) complete patency; (ii) partial patency (enteric, intermediate or peripheral); (iii) mucosal remnant at the umbilicus (umbilical polyp); or (iv) congenital band due to a fibrous remnant of either the vitelline duct or artery which can cause intestinal obstruction.

Completely patent omphalomesenteric duct [6,9,10]. Complete patency is clinically apparent soon after birth. The base of the cord separates to leave a sinus or a red nodule at the opening of an umbilical enteric fistula, the faecal discharge from which irritates the surrounding skin. Very rarely, ileum may prolapse through the fistula [6,11]. Treatment of these ducts requires excision of the umbilicus and tract.

Patency of the enteric portion of the duct [6]. Persisting patency of the proximal vitelline duct constitutes a Meckel's diverticulum. The duct may be patent throughout its length and closed peripherally only by skin or granulation tissue.

Patency of the mid-portion of the duct. A cyst along the course of a fibrosed vitelline cord presents as a periumbilical lump.

Patency of the peripheral portion of the duct [1,8,10,12]. This may present to dermatologists as a sinus 1.0–2.5 cm in depth intermittently discharging mucus, or a red, polypoid nodule (*umbilical polyp*) comprising ectopic gastrointestinal mucosa. Symptoms may be very slight, so that persistence of these lesions into adult life is not unusual. Occasionally the mucoid, serous or blood-stained discharge gives rise to troublesome dermatitis.

Omphalomesenteric umbilical polyp must be differentiated from umbilical granuloma (see above) and prolapsed urachal mucosa (see below). Fibrous umbilical polyp [13] presents in childhood, more commonly in boys, and is composed of fibrous tissue [13].

Treatment is by simple excision, having checked radiologically that there is no associated patent omphalomesenteric duct or urachus.

Anomalies of the urachus [4,5,14]

The elongation of the body stalk to form the umbilical cord obliterates the part of the allantoic cavity within it. The urachus is the residual intra-abdominal portion of the allantois, from the umbilicus to the vertex of the bladder. After birth it forms a fibrous cord, the median umbilical ligament. Persistence of epithelial remnants within the fibrous end is frequent. The urachus may remain patent throughout all or part of its length forming cysts, sinuses or fistulae leading from the umbilicus or bladder. Carcinoma may develop in a urachal remnant in adult life [15].

Complete patency of the urachus presents within days of birth by intermittent dribbling of urine from the umbilicus. The umbilicus may appear normal or the prolapsed distal portion of the urachal duct may form a globular nodule, covered partly by skin and partly by urachal epithelium. The surrounding skin may be irritated, but usually less severely than by a faecal fistula. The diagnosis may be confirmed radiologically. Surgical excision should be carried out as soon as possible, on account of the risk of urinary tract infection in the short term, and the risk of malignant change in adult life [15].

Partial patency of the urachus presents differently according to the site of the defect [4]. Peripheral patency (umbilical–urachal sinus) appears as a small opening or a granuloma-like lesion at the umbilicus. The lower portion of the urachus remains patent in about 33% of persons (vesico–urachal diverticulum). Urachal cysts may form at any point along the course of the urachus, and may communicate with the umbilicus, the bladder or with neither [16,17]. Unless they discharge their contents externally, they are seldom clinically evident unless large or infected. They present as tender midline swellings between the umbilicus and the symphysis pubis. If they communicated with the umbilicus, the discharged contents may consist of urine or mucus, pus or blood.

Congenital sinuses and cysts of the genitoperineal raphe

SYN. MUCOUS CYSTS OF THE PENILE SKIN; PARAMEATAL CYSTS

Median raphe cyst of the penis takes the form of a translucent or blue cyst, a tender nodule or an indurated cord at any site along the ventral midline between the urethral meatus and the anus usually near the glans [1–9]. Several theories have been proposed to explain their occurrence [9]. They may result from incomplete ventral fusion of the urethral or genital folds. Alternatively they may represent ectopic periurethral glands of Littre (*mucoid cysts*) [8,10], or separated outgrowths of urethral endoderm (*urethroid cysts*) [11].

Median raphe cysts of the penis are usually lined by pseudostratified columnar epithelium, except in the distal portion of the raphe where they are lined by squamous epithelium. Ciliated epithelium, similar to that of a bronchogenic cyst, was reported in one case [12], but not in others [13]. Melanocytes have also been reported in the lining of multiple median raphe cysts in two unrelated Japanese boys [14]. Apocrine cystadenoma of the penis is sometimes considered to be the same as median raphe cyst, but can be distinguished by positive expression of human milk fat globulin 1, a marker for breast and apocrine tissue [15].

In most cases, median raphe cysts of the penis remain asymptomatic until after puberty [9], and present only when they become the site of staphylococcal or gonococcal infections [16]. However, they may present incidentally as an asymptomatic papule at any age, in some cases as late as the seventh decade [7,13]. Surgery is indicated where infection is not controllable by antibiotics.

Mucous cysts occasionally develop in the retrorectal space and are probably derived from hind-gut remnants. These may discharge via a sinus along the posterior part of the raphe.

Anomalies of the anus

Anomalous anal papillae

Disturbance of the normal embryological development of the anus may rarely result in the appearance of one or more polypoid projections at the anus. These may be asymptomatic, but often become complicated by ulceration, faecal retention and constipation [1].

REFERENCE

Posterior midline cutaneous lesions associated with defects of the cranium, vertebrae and spinal cord

Aetiology. Failure of the caudal neuropore to close at the end of the fourth week of intrauterine life results in neural tube defects (*spinal dysraphism*), which may also involve tissues overlying the spinal cord, including the meninges, vertebral arch (*spina bifida*) and skin. Defective closure of the rostral neuropore, also during the fourth week, may result in analogous malformations in the occipital area.

Genetic factors are undoubtedly involved, and since the recurrence risk is less than 25%, a polygenic mechanism is likely. Spina bifida is commoner in infants of obese mothers, where obesity is defined as body mass index (BMI) > 29 kg/m^2 [1]. Environmental factors also play a part. Folic acid supplementation before and during pregnancy reduces the risk of open neural tube defects [2].

Classification. Neural tube defects can be classified according to whether they are open or closed, whether neural tissue protrudes externally, and whether their position is caudal or cranial.

Clinical features. An open defect of the caudal neural tube, with neural tissue widely exposed on the surface is termed a *myelomeningocoele*. This presents as a skin defect over the back, bordered laterally by the unfused dorsal portions of the vertebrae. The defect is generally covered by a transparent membrane, which initially leaks cerebrospinal fluid. It soon dries and ceases to leak, the fluid accumulation causing the membrane to bulge. Spinal cord function is variably impaired, and there may be associated defects of the brainstem and cerebellum, the *Arnold–Chiari malformation*, which result in hydrocephalus. *Meningocoeles* contain dura and arachnoid, but do not contain neural tissue. An open defect at the cranial end of the neural tube (*cranium bifidum*) may similarly be associated with protrusion of meninges (*meningocoele*) or brain tissue (*meningoencephalocoele* or *encephalocoele*).

Islands of ectopic neural tissue may persist externally as 'rests' overlying intact bone [3–5]. In the occipital and parietal areas of the scalp they are sometimes termed 'atretic' meningocoeles or meningoencephalocoeles [3] or 'meningiomas' [6]. Such lesions generally take the form of domed, hairless nodules with a collar of surrounding hypertrichosis (the 'hair collar' sign) [3,5,7,8], or sometimes just a tuft of hair [9], and are not necessarily confined to the midline. Ependymal rests may also be found in the sacrococcygeal area [10].

A *dorsal dermal sinus* is an open tract with no protrusion of neural or meningeal tissues. It appears as a deep dimple, the bottom of which cannot be seen. It may occur at any level from the occiput downwards, most commonly in the suboccipital and lumbosacral areas [11–15], only 1% and 10% occurring in the cervical and thoracic areas respectively [16]. The skin around the exit is often normal but may be dimpled, hairy or the site of a lipoma, abnormal pigmentation, port-wine stain or haemangioma [13,17]. Sometimes the cutaneous anomaly obscures the ostium of the sinus. In the occipital area, the exit site near the external protruberance of the occipital bone [15] is usually hidden by hair, which may be more luxuriant than elsewhere on the scalp. This insignificant dermatological anomaly is an important marker for serious associated complications including infection, underlying CNS anomaly and inclusion tumour [16]. Such sinuses are important as potential portals for the entry of infection into the subarachnoid space, leading to meningitis or a cerebellar abscess [18]. Spina bifida, spinal dysraphism or tethered cord may coexist with dorsal dermal sinus [16]. Congenital inclusion dermoid cysts are commonly associated [18] and may cause spinal cord compression [17,19].

In *spina bifida occulta* there is a defect in the vertebral arch, but the lesion is closed and not associated with protrusion of the spinal cord or meninges. The cord may be normal, malformed or hypoplastic, or it may be damaged by transfixation by a bony spicule or fibrous septum arising from a vertebra, usually in the lumbar spine (*diastematomyelia*). Occult spinal dysraphism may occur in as many as 20% of cases, but only a small percentage of these will have a significant associated neurological defect. While most common in the lumbosacral area, spina bifida occulta may occur at any level of the vertebral column [20]. Closed defects with overlying cutaneous malformations are of particular importance to dermatologists to whom they may present first [21]. In a series of 1449 healthy American neonates, 70 (4.8%) had dorsal cutaneous stigmata [22]. In 207 infants with midline dorsal cutaneous stigmata, there was associated occult spinal dysraphism in 16 (8%) diagnosed on ultrasonography [22]. In about 50% of cases of spina bifida occulta there is an overlying cutaneous abnormality [11,13,23–26]. Those reported include dermal dimple or sinus, lipoma [26,27], a tuft of long, soft, silky hair (often called a *faun-tail*) [28], pigmented macule, skin tag, tail-like protrusion [29], dermoid cyst, infantile haemangioma [30,31] macular vascular stain [32,33] and aplasia cutis congenita [34]. A *lipomyelomeningocoele* is a subcutaneous lipoma extending through the bony defect to the dura and attached to the cord. An association between cockade naevi at various body sites and spinal dysraphism has been suggested [35].

Even without any bony defect, a dorsal midline anomaly may overly a spinal abnormality, for example tethered cord with lumbosacral haemangioma, and vascular malformation of the spinal cord with an overlying port-wine stain (Cobb's syndrome).

A variety of other tumours and cysts, representing residual non-regressed distal cord and associated tissues, may occur in the retrorectal space, or subcutaneously over

the sacrum [36,37]. They include hamartomas [38], teratomas [39], lipomas [27], ependymomas [10,40] and vestigial tails largely composed of adipose tissue [41–44]. Non-neoplastic perirectal inflammatory conditions and giant cell tumours of the sacrum also occur. These may occasionally be associated with overlying cutaneous lesions such as skin tags and epidermal naevi [23].

The deep sacrococcygeal dimples and pits found in about 4% of all children are *formes frustes* of dorsal dermal sinuses, as probably also are *congenital pilonidal sinuses* [45,46]. In the absence of other cutaneous anomalies or neurological signs they require no investigation [22,47].

Diagnosis. The likelihood of a spinal defect underlying a posterior midline skin lesion depends firstly on age at presentation; a neurologically normal child or adult is unlikely to have a functionally significant spinal defect but might still have a sinus with risk of infection. Secondly it depends on the nature of the defect: simple postanal dimples are very common and usually uncomplicated; atypical dimples (> 5 mm diameter or > 2.5 cm from the anus), sinuses, masses, sacral hypertrichosis and multiple skin abnormalities are much less common, and warrant more intensive investigation [22,33,48]. Midline dorsal haemangioma, port-wine stain, and even sacral telangiectasia in an infant with an obvious naevus flammeus in the usual glabellar and occipital sites warrants investigation [33]. Ultrasound [49] or X-ray of the spine may be sufficient in the absence of a history of meningitis or neurological impairment. Ultrasound is most useful in neonates up to 3–4 months of age, before the posterior spinous elements ossify [49]. MRI is the investigation of choice for any suspicious lesions, allowing visualization of the tract and its termination as well as spinal anomalies and tumours compressing the cord [16,50].

Treatment. The treatment of large and open defects is beyond the scope of this book. Suspected dorsal dermal sinus should be investigated preoperatively with MRI to see whether it connects with the subarachnoid space [2]. Probing and sinography are inadvisable and may lead to meningitis. True sinuses are more likely above the lumbosacral area. Usually, no further action is required for asymptomatic lesions in the lumbosacral area noted in infancy if the plain spine X-ray is normal. However, any suggestion of neurological deficit should be investigated with a spinal MRI.

Congenital absence of skin

SYN. APLASIA CUTIS CONGENITA

The term 'aplasia cutis congenita' implies a failure of skin development, while the broader term 'congenital absence of skin' includes situations where the skin developed but has subsequently been lost. The appearance at birth is extremely variable, in terms of site, extent, depth, and degree of healing and scarring, and there are probably several different causes [1,2]. From careful review of the literature, a number of distinctive clinical disorders have emerged, many of which are genetic [2,3]. Frieden's classification has proved helpful [2] and a modified version will be used here.

Few histological descriptions are available [1,4]. The epidermis is absent, and usually the dermis. Where the dermis remains, the connective tissue lacks appendages and elastic fibres. The subcutaneous fat may also be partly or wholly missing and there may be an underlying skull and dural defect [5,6]. Where re-epithelialization has occurred the epidermis is flat, characteristically lacking appendages [7,8]; hypertrophic scarring may also occur [9].

Type 1: non-syndromic aplasia cutis congenita of the scalp

Non-syndromic aplasia cutis congenita of the scalp is the commonest pattern of congenital absence of skin. It sometimes shows autosomal dominant inheritance [1–8] with reports of concordant [9,10] and discordant [11] monozygotic twins. The usual position at or adjacent to the parietal hair whorl may be explained by this being the site of maximum scalp tension during the period of rapid brain growth from the 10th to the 18th week of gestation [7].

About 80% of all lesions of congenital absence of skin occur on the scalp [7,12–15]. Scalp lesions are single in about 70% of cases, double in about 20% and triple in about 5%. Lesions vary enormously in diameter (from 0.5 to over 10.0 cm), shape and depth. They may initially appear deeply ulcerated, superficially eroded, scarred or occasionally bullous [16], and sometimes heal with hypertrophic scarring [5,17]. A surrounding zone of hypertrichosis is frequently apparent, and it has been suggested that lesions demonstrating this feature are a *forme fruste* of a cranial closure defect [18]. The larger lesions are often the deeper ones, and may extend to the dura or even to the meninges [19–21]. Such deep lesions may be associated with haemorrhage, sagittal sinus thrombosis or meningitis [20,22–26]. Up to one-third of cases involve the underlying bone [6,9,21,27]. Locally dilated scalp veins reported in several cases [10,21,28,29] suggest that the scalp defect may result from a vascular developmental abnormality [29,30]. An isolated patch of congenital absence of scalp skin is often mistakenly attributed to birth trauma, particularly from fetal scalp electrodes [31].

Severe aplasia cutis congenita of the scalp regenerates spontaneously but has also been repaired with engineered skin [32] and bone grafts.

Type 2: congenital absence of skin on the scalp with limb reduction abnormalities

SYN. ADAMS–OLIVER SYNDROME

Adams–Oliver syndrome is characterized by congenital midline scalp defects and asymmetrical distal limb reduction anomalies. It is an autosomal dominant trait with highly variable penetrance and expression [1–8]. Several isolated cases have been reported [7,9–13].

Typically, the skin lesions are solitary or multiple bald scars near the vertex. They vary in diameter, from about 0.5 to 10.0 cm, larger lesions being disproportionately common [1,2,5,14–16]. The lesions also vary considerably in depth, sometimes penetrating the skull to the dura. Dilated scalp veins [5,6,10] are frequently associated, and may be the sole abnormality [17]. Intellect is normal.

Hypoplastic or absent distal phalanges are the most common limb anomalies, but defects range from hypoplastic nails [7,8] to absent hands or lower legs [1,18]. The lower limbs are generally more severely affected than the upper limbs.

Persistent cutis marmorata is reported in about 12% of cases [3,6,7,9,14,17,19,20] and was the sole feature in an obligate gene carrier [4]. In another family, cutis marmorata and scalp aplasia cutis congenita without limb defects may represent a limited expression of the Adams–Oliver syndrome [21]. Congenital heart disease affects about 8% of cases [19].

Adams–Oliver syndrome must be differentiated from focal dermal hypoplasia, trisomy 13 and the amniotic band sequence. Congenital absence of skin with split hand deformities [7,22], and congenital absence of skin with postaxial polydactyly [23,24] probably represent distinct genetic disorders.

Spontaneous osseous regeneration has been reported in a patient with a large skull and scalp defect due to the Adams–Oliver syndrome [25].

Type 3: congenital absence of skin on the scalp with epidermal naevi

Sebaceous naevi rarely occur in close proximity to areas of congenital absence of skin in the scalp [1–4]. Multiple areas of bullous congenital absence of skin have also been reported in a child with extensive unilateral verrucous epidermal naevi on the trunk and limbs [5].

Some of these cases have either had associated ophthalmological or neurological abnormalities identical to those seen in the epidermal naevus syndrome [2–4,6,7]. Happle and Konig [7] suggest that the co-occurrence of aplasia cutis congenita and nevus sebaceous is a twin spot phenomenon.

Type 4: congenital absence of skin overlying developmental malformations

Congenital absence of skin may overlie herniations of neural tissue. In the occipital and parietal areas of the scalp, heterotopic neural and/or meningeal tissue appears as a domed, hairless nodule with a collar of surrounding hypertrichosis (the 'hair collar' sign) [1–5]. The surface of the lesion is typically translucent and 'membranous' [6]. The lesion may be flat or depressed rather than raised, and will not always be sited in the midline. There may be an associated port-wine stain [2].

The skin is also characteristically absent or hypoplastic over a number of other developmental malformations, including spinal dysraphism [7], omphalocoele, gastroschisis and sternal clefts [8–10].

Congenital absence of skin has also been reported over other cranial [11] and intracranial developmental anomalies including arteriovenous fistula [12], leptomeningeal angiomatosis [13], congenital midline porencephaly [14] and cranial stenosis [15].

Type 5: congenital absence of skin associated with fetus papyraceus

Congenital absence of skin has been observed in a number of infants whose birth was accompanied by the delivery of a *fetus papyraceus*, that is a twin or triplet that had died *in utero* during the second trimester. [1–8]. In these cases, multiple, mostly symmetrical, linear or stellate areas of congenital absence of skin were present on the limbs and trunk (Fig. 15.27). Some also showed fibrous constriction bands on the limbs [1,3].

This type of congenital absence of skin may represent cutaneous infarction due to release of thromboplastin into

Fig. 15.27 Congenital absence of skin in an infant with a stillborn twin of fetus papyraceus type.

a shared placenta after an intrauterine death [9]. Symmetry of the skin lesions is hard to explain by this mechanism. Associated hyperechogenic areas diagnosed as haematomas in the liver of one patient were thought to support the idea of a vascular aetiology [7].

Similar skin lesions in one of surviving twins [10], and in singletons with no fetus papyraceus [11–16] might reflect *in utero* death of an unrecognized twin or triplet. In other similar cases without mention of a twin, placental infarction has occurred [17,18], or the placenta has been described as pale and large [18,19].

Type 6: congenital absence of skin as a feature of epidermolysis bullosa

SYN. BART'S SYNDROME

Bart *et al*. [1] reported a dominantly inherited disorder in 26 members of a large kindred, characterized by congenital absence of skin on the lower legs, widespread blistering of skin and mucous membranes, and nail dystrophy. Further ultrastructural and genetic studies of this family confirmed dominant dystrophic epidermolysis bullosa due to a glycine substitution in type VII collagen [2,3]. The original idea that this pattern of absent skin at birth indicates a specific form of epidermolysis bullosa [1] has given way to the view that it is a non-specific feature of epidermolysis bullosa, particularly the junctional and dystrophic types. In at least one family with dominant dystrophic epidermolysis bullosa, some affected members had 'Bart's syndrome' while others did not [4]. This pattern of congenital absence of skin has occasionally been reported without epidermolysis bullosa being diagnosed [5], but it is highly likely that all such patients have epidermolysis bullosa [6,7], perhaps with skin fragility less apparent after birth than before.

The lesions appear as extensive, well-defined, glistening, red ulcerations on the dorsum and medial aspect of the foot, often extending up the shin. They may be unilateral or, less frequently, bilateral and probably result from rubbing one shin and foot with the other heel, perhaps in response to pruritus. The idea that the lesions are determined by Blaschko's lines [8] seems less likely.

Type 7: congenital absence of skin caused by specific teratogens

Several cases have been reported of congenital absence of midline scalp skin in children whose mothers took methimazole or carbimazole for treatment of hyperthyroidism during pregnancy [1–6]. It is now regarded as highly likely that these drugs were responsible, although the risk appears to be low [6,7]. There have been isolated reports of scalp aplasia cutis congenita following first trimester intake of the prostaglandin misoprostol, and in one case benzodiazepines [8].

Type 8: congenital absence of skin as a feature of intrauterine infections

Congenital absence of skin may occur in neonates with intrauterine herpes simplex infection [1–3], but is a more characteristic finding in intrauterine varicella-zoster virus (VZV) infection [4–7], where it may be associated with other features of the 'congenital varicella syndrome'. The cutaneous ulceration or scarring is unilateral and linear, usually occurring in a zosteriform distribution. Such lesions are most often a sequel to maternal chickenpox during the first trimester. Confirmation of the diagnosis rests on the persistence of VZV IgG antibodies beyond 7 months of age when maternal antibodies [8] should have disappeared. Maternal chickenpox in the last trimester may also result in congenital ulcerations in the neonate, usually multiple and no larger than about 1 cm in diameter [9].

Type 9: congenital absence of skin as a feature of malformation syndromes

Congenital absence of the skin has been reported as a feature of several malformation syndromes, including the following.

Trisomy 13

SYN. PATAU'S SYNDROME

Congenital absence of skin in the parietal or occipital scalp is a regular feature of this chromosomal abnormality syndrome. Other characteristic findings include holoprosencephaly (a developmental anomaly of the forebrain), microphthalmia, iris colobomas, cleft lip and/or palate, polydactyly, narrow and excessively convex nails, and a port-wine stain on the forehead [1,2]. Infants with this syndrome rarely survive into the second year of life. Interestingly, patients with mosaic trisomy 13 may present as hypomelanosis of Ito with a rather characteristic 'phylloid' pattern of hypopigmentation [3], together with mental retardation and other features of trisomy 13 syndrome. Pigmentary reduction has not been reported in full-blown trisomy 13, but might not have been noticed in the presence of other serious defects.

Deletion of the short arm of chromosome 4 (the 4p- syndrome)

SYN. WOLF–HIRSCHHORN SYNDROME

Congenital absence of skin in the posterior midline scalp is also a frequent finding in this chromosomal abnormality syndrome [4,5]. Other typical features include ocular hypertelorism, a beaked or broad nose, microcephaly, low-set, simple ears and pre-auricular tags or pits. Affected individuals are profoundly mentally retarded and generally experience severe convulsions. Growth deficiency in weight relative to height is pronounced, and mortality in early childhood is high. Most patients have deletions involving large segments of 4p. Wolf–Hirschhorn syndrome is probably a contiguous gene syndrome, but exact genotype–phenotype correlations have not been established. A small critical region at 4p16.3 has been identified in a patient with growth retardation and minor facial features but no aplasia cutis [6].

Oculocerebrocutaneous syndrome

SYN. DELLEMAN–OORTHUYS SYNDROME

This distinctive malformation syndrome [7–14] occurs sporadically and in both sexes. The scattered, asymmetrical nature of the characteristic abnormalities suggests mosaicism for a mutant gene that would be lethal if the zygote were affected [15].

Typical non-cutaneous manifestations include orbital cysts, microphthalmia, eyelid colobomas, skull defects and cerebral malformations, particularly cystic spaces (porencephaly), and agenesis of the corpus callosum.

The cutaneous features comprise a highly characteristic combination of areas of cutis aplasia and skin tags. The skin tags may be up to about a centimetre in diameter and are usually on the face, around the eyes and the nose. Their histological features have not been reported. Well-defined areas of cutaneous hypoplasia occur mainly on the scalp, face, neck and lumbosacral area. Published details of these lesions are limited, but they are usually multiple, hypopigmented and sometimes appear 'punched-out' [14]. In one case, normal skin markings and lanugo hair within the lesions were regarded as evidence that these were not scars [14]. A ring of more profuse hair growth around scalp lesions has also been noted [10]. This syndrome overlaps with Goldenhar's syndrome (see above) [16].

Johanson–Blizzard syndrome

This rare autosomal recessive disorder is characterized by pre- and postnatal growth deficiency, microcephaly, variable intellectual impairment, deafness, thyroid dysfunction and rectourogenital abnormalities. Several features of ectodermal dysplasia make it of interest to dermatologists [17–21], including sparse hair with a marked frontal upsweep, absent eyebrows and eyelashes [20], hypodontia of both dentitions, peg-like deformity of remaining teeth [21] and hypoplastic nipples and areolae. Congenital absence of skin in the posterior midline scalp, and hypoplastic alae nasi also occur. Café-au-lait macules and dilated scalp veins may be observed.

Focal dermal hypoplasia syndrome

See Chapter 12.

*MIDAS syndrome (**m**icrophthalmia, **d**ermal **a**plasia, **s**clerocornea) (MLS syndrome [**m**icrophthalmia with **l**inear **s**kin defects])*

This syndrome was first described in 1990 [22]. A number of cases have been described since then [23–25]. This is an X-linked dominant condition, lethal in males, which is associated with heterozygous deletions on the X chromosome at Xp22.31. This region contains the gene *HCCS*, which encodes human holocytochrome *c*-type synthetase.

Girls with this syndrome have microphthalmia with linear skin defects of face and neck, sclerocornea, corpus callosum agenesis and other brain anomalies. The microphthalmia is usually but not invariably bilateral, as are the corneal opacities, though sclerocornea is not always present. The skin comprises erythematous atrophic lesions similar to those seen in focal dermal hypoplasia, but, in contrast to this condition, the skin lesions have in all cases so far been limited to the face, scalp, neck and upper trunk. They have also differed from those of focal dermal hypoplasia in not being accompanied by exophytic fatty protrusions. However, as in focal dermal hypoplasia, the lesions are asymmetrical and distributed in Blaschko's lines. Other, less regular manifestations have included congenital heart defects.

Focal facial dermal dysplasias

Symmetrical congenital atrophic lesions of the face resembling scars have been described under a number of different titles, including bitemporal aplasia cutis congenita, congenital ectodermal dysplasia of the face and hereditary symmetrical systemic aplastic naevi. The disorder may be isolated or associated with other facial anomalies. A review of published cases [26] suggested three distinct subgroups: (i) autosomal dominant focal facial dermal dysplasia without other facial anomalies; (ii) autosomal recessive focal facial dermal dysplasia without other facial anomalies; and (iii) focal facial dermal dysplasia with other facial anomalies (syn. Setleis' syndrome).

Autosomal dominant focal facial dermal dysplasia without other facial anomalies. A number of families have been reported in which the disorder is transmitted as an autosomal dominant trait [27–30]. The skin lesions appear to be the sole abnormality, and take the form of congenital, hairless, scarred areas on the face which are usually, but not always, oval in outline and symmetrical, and may be either hyper- or hypopigmented. These lesions may occur on the temple, or on the cheeks, where they tend to be disposed along a line that runs from the ear to the corners of the mouth. The size of the lesions is variable. There may be a surrounding rim of fine, lanugo-like hairs [31,32]. There may be a distinctly puckered appearance to the affected skin.

Histologically, there is atrophy of the dermis and subcutaneous fat, an absence of pilosebaceous follicles and eccrine glands but a normal epidermis. Striated muscle may be placed very close to the epidermis, and could be partly responsible for the occasionally reported puckering of the affected skin.

Autosomal recessive focal facial dermal dysplasia without other facial anomalies. Essentially identical skin lesions have been

reported in other families in which inheritance appeared to be of autosomal recessive type [26,28]. There have been reports of clinically indistinguishable but sporadic cases whose pattern of inheritance is uncertain [31,33].

Focal facial dermal dysplasia with other facial anomalies (Setleis' syndrome). Since the first report by Setleis *et al.* [34], several families have been reported in which children demonstrated a leonine, aged facies with absent or abnormal eyelashes and eyebrows, puckered periorbital skin, a rubbery feel to the nose and chin, and scar-like defects on each temple [35–39]. While most reported patients have been Puerto-Rican, other ethnic groups have been affected [39–41]. Both autosomal recessive [42] and autosomal dominant inheritance with variable penetrance and expressivity [38,40,43] have been reported.

Rare non-cutaneous manifestations include imperforate anus [39,44], megaureter [39], mental retardation [39] Fallot's tetralogy [34], iris coloboma, limb malformations and recurrent digital fibromas [44], and developmental delay [45].

Other disorders. Numerous other conditions have featured areas of absent skin at birth. Extensive symmetrical congenital erosions were reported in *congenital erosive and vesicular dermatosis healing with reticulate supple scarring* [46,47]. Aplasia cutis congenita can occur at any site in the amniotic band disruption sequence [48–50], and on the scalp in tricho-odonto-onychodermal ectodermal dysplasia [51]. Extensive congenital areas of absent skin resembling epidermolysis bullosa have been described in cases of ectodermal dysplasia with cleft lip and/or palate, in the EEC syndrome (*e*ctrodactyly, *e*ctodermal dysplasia, *c*lefting) [52], and in the AEC syndrome (*a*nkyloblepharon, *e*ctodermal defects, *c*left lip/palate) [53]. Areas of absent skin at birth have been recorded in a familial disorder featuring *lumpy scalp, odd ears and rudimentary nipples* [54]. Multiple scalp erosions at birth occurred in two phenotypic females with 46XY gonadal dysgenesis, associated with cleft lip and palate, ear deformity and pre-auricular pits [55].

Single families have been reported with conditions associated with congenital absence of skin. A disorder comprising congenital absence of skin, nipple and breast hypoplasia, nail dysplasia and delayed dental eruption has been described in a mother and her son [56]. Ear deformities and pre-auricular pits were also present in members of another family in association with unilateral facial paresis, dermal sinuses and congenital absence of skin [57]. Posterior midline scalp absence of skin and intestinal lymphangiectasia, leading to hypoproteinaemia and oedema, occurred in two siblings [58].

Single cases have been reported of a syndrome comprising bilateral scarring above the ears, linear submental scars, craniosynostosis, polydactyly, syndactyly, low-set, deformed ears, hypoplastic tibias and cardiac disease [59], and of a syndrome comprising extensive congenital erosions of the skin, anonychia and an atrophic lesion on the tongue [60]. Extensive aplasia cutis congenita occurred in a baby with an unbalanced translocation, being monosomic for distal 12q and trisomic for distal 1q [61]. In one fatal case with some features of very severe Johanson–Blizzard syndrome, almost complete congenital absence of skin was associated with absent ears, choanal atresia, syndactyly, imperforate anus, pulmonary hypoplasia and other anomalies [62].

Differential diagnosis. In the neonatal period parents sometimes mistake congenital absence of skin for obstetric trauma due to forceps or scalp electrodes [1,2], a confusion which may have significant medicolegal repercussions [3]. Congenital absence of skin may also resemble Volkmann's ischaemic contracture [4].

During childhood, congenital absence of scalp skin may be confused with sebaceous naevus, traumatic scarring, cicatricial alopecia, the linear scarring alopecia seen in *en coup de sabre* morphoea and the alopecia along scalp suture lines characteristic of the Hallermann–Streiff syndrome.

Cases have been described of congenital bald patches in the scalp with histologically normal skin apart from absent appendages [5]. These 'aplastic naevi' might represent the minimal end of the spectrum of congenital absence of skin.

Treatment. Most lesions will heal spontaneously from the margins, to leave a smooth, yellowish, hairless, papery scar. Underlying defects in the cranium generally resolve spontaneously during infancy [1–3]. Occasionally, hypertrophic scarring occurs [4], and linear lesions on the limbs may lead to joint contracture. In the vast majority of cases, the prognosis is excellent if attention is paid to the prevention of both secondary infection and further trauma.

Small lesions can be allowed to heal spontaneously, or treated by excision of the abnormal skin margins followed by primary closure [5]. Larger scalp defects are probably best treated by early grafting or flap rotation [6], as

delayed closure may be complicated by infection or haemorrhage from the sagittal sinus, which may be lethal [7–10]. Composite ('engineered') skin grafts have been used successfully, autologous fibroblasts being placed first, followed by keratinocytes a week later [11]. Bone grafts may be required to reconstruct large cranial defects [12,13]. However, some authors have recommended a conservative approach even for extensive lesions [2,14,15], with the opportunity for the scars of healed lesions to be excised later on if desired. Tissue expansion has proved very valuable for this type of procedure.

Amniotic bands and adhesions

SYN. CONGENITAL RING CONSTRICTIONS; INTRAUTERINE AMPUTATION; ADAM COMPLEX SYNDROME (*A*MNIOTIC *D*EFORMITIES *A*DHESIONS *M*UTILATION); RAISED LIMB BANDS

Definition. These are circumferential bands, occurring at birth or soon after, usually on limbs, and occasionally associated with other anomalies, particularly distal limb reductions.

Aetiology. Spontaneous amniotic rupture results in the formation of tough amniotic bands, which may encircle developing limbs, resulting in annular constrictions, secondary syndactyly and intrauterine amputations [1] in about one in 10 000 neonates. Some amniotic bands may be related to adhesion of amnion to abnormal areas on the fetal surface, particularly craniofacial defects [1] and cleft lip [2]. Occasional reports of congenital bands with an intact amnion, and appearance after birth suggest a localized abnormality in limb development rather than external constriction [3]. Aetiology and classification of these disorders is confused [3,4]. Both ring constrictions [5] and congenital amputations [6] are occasionally familial.

Pathology. Biopsies of raised bands showed no specific abnormalities [3].

Clinical features [1,3,7–10]. The most characteristic appearance is ring constrictions of digits, limbs, neck or trunk. The groove is usually about 1–3 mm wide and 2–4 mm deep. Beyond the constriction, there is often lymphoedema. Raised, narrow, scar-like bands can coexist with the more typical grooves [3]. Distal limb deformities, such as syndactyly, polydactyly, talipes and distal limb reduction, not necessarily of the same limb, are also frequent, as is peripheral nerve palsy [11]. *In utero* amputation may also occur. Neonatal herpes simplex has been reported localized to an area of ulceration at the site of amniotic band compression [12].

Diagnosis. In the Michelin tyre baby syndrome there is abnormal limb enlargement with folds, rather than primary constrictions. Histology of the folds may show diffuse smooth muscle hamartoma or lipomatous naevus.

Treatment. Plastic surgery is indicated for residual constrictive grooves in a limb or digit, where there is interference with vascular or lymphatic circulation.

Chapter 16

Pruritus

M.W. Greaves

Introduction and classification

Despite being the predominant symptom of skin disease and a frequent manifestation of systemic disease, pruritus (itching) has been largely neglected by investigators and consequently is poorly understood. The main difficulties have been lack of reproducible, standardized itch stimuli and a dearth of satisfactory methods for statistically analysable quantification. Itch can be defined subjectively as a poorly localized, non-adapting, usually unpleasant sensation which elicits a desire to scratch. Itch has recently been reclassified by Twycross *et al*. [1] as *pruritoceptive* (cutaneous, e.g. scabies), *neuropathic* (due to lesions of afferent pathways of the nervous system, e.g. peripheral neuritis, brain tumours), *neurogenic* (due to centrally acting mediators which do not damage the central nervous system, e.g. opioid peptides of cholestasis) and *psychogenic*.

Although itch and pain can readily be dissociated subjectively, they broadly share similar overall molecular mechanisms and neurophysiological pathways. However, new evidence indicates the existence of separate dedicated neurones for itch in both the peripheral and central pathways [2,3]. When itching is caused by a low-intensity mechanical stimulation involving weak activation of mechanoreceptors, the itch sensation is immediate, persists for no longer than the stimulus and is interpreted as a 'tickle'. In dry skin and skin of some atopics, mechanical stimulation may trigger a more persistent itching sensation (alloknesis) [4]. Prurigo is a term frequently incorrectly used to describe chronic itching of any cause. As originally defined by Hebra [5], prurigo denotes papules induced by scratching. On this basis, prurigo would include 'scratch prurigo', a rarely used synonym for symptomatic dermographism and, at the other end of the spectrum, chronic inflammatory and pigmented papules due to long-continued or repeated scratching (prurigo nodularis of Hyde) [6].

Itching as a symptom of skin disease is generally independent of external stimulation. The quality of itch varies greatly, ranging from burning, through pricking, to sensations of insects crawling over the skin. The psychophysiological basis of these differences remains unclear. Teleologically, itching, with resultant scratching, is of possible biological value in combating parasitic infestation. Although often publicly perceived as a trivial—even humorous—disability or even, with its associated scratching, as a pleasurable personal indulgence, it is more often socially disabling and a cause of serious impairment of quality of life. No effective and selective anti-itch drugs are available at the time of writing.

Measurement

There are no convincing animal models for pruritus. Methods used in humans include visual analogue scales (VAS) (statistical analysis is difficult) and recording of scratch movements [7] using fine glass electrodes

(microneurography) [8–10]. The 'Symtrack' computerized continuous itch-rating system, which is based on the VAS, or a variant of it, is the most widely used [11]. However, results obtained with a new method for quantifying scratching in which a piezoelectrical device is attached to the middle fingernail have been impressive [12].

Pathophysiology

Significant progress has recently been made in elucidating the neurophysiological pathways for itch. Although specialized nerve endings have been identified for a wide range of stimuli [13], no specific receptor has been identified for itch, and it is generally agreed that itch (and pain) are received by unspecialized free nerve endings [14] located close to the dermal–epidermal junction. Itch receptors are unmyelinated, confined to the skin and cornea, and are members of the polymodal nociceptor class. Recent immunohistochemical research utilizing protein gene product (PGP) 9.5 or neurone-specific enolase has supported, but not significantly extended, earlier light-microscope studies [15,16]. Itch-transmitting, polymodal, unmyelinated C fibres enter the dorsal horn of the grey matter of the spinal cord, synapse there with secondary neurones which cross over to the contralateral spinothalamic tract, and ascend to the thalamus. There, tertiary neurones relay itch to the level of conscious perception in the cerebral cortex.

That pain and itch are transmitted along the same nerve pathways was proposed by Rothman [17] and others and has been the prevailing view until recently. According to this interpretation, low-intensity stimulation of unmyelinated polymodal C fibres results in the sensation of itch, whereas high-intensity stimulation causes pain. However, a number of features of pain and itch argue against this interpretation. These include the difference in motor responses (itch induces scratching whereas pain evokes withdrawal); the differential effects of morphine, which relieves pain but makes itch worse; and the ability of itch and pain to be perceived independently at the same site. There is now convincing evidence that dedicated itch-transmitting neurones exist in both peripheral and central afferent pathways [2,3]. Microneurographic technology has enabled electrical recordings to be made from individual polymodal C fibres in peripheral cutaneous nerve fascicles. Stimulation of these neurones using histamine iontophoresis to cause itching has resulted in identification of a small (less than 5% of the total) subset of slowly conducting C fibres distinct from, and with a larger receptor field than, mechanosensitive polymodal neurones. Recently, the concept of dedicated itch neurones has been supported and extended by work demonstrating the presence of histamine-sensitive itch-specific secondary transmission neurones in the lateral spinothalamic tract of the cat [3]. That pruritus-specific C neurones are also temperature-sensitive is of clinical significance, since it offers an explanation for the everyday observation that itching is worse in a warm environment, e.g. in bed.

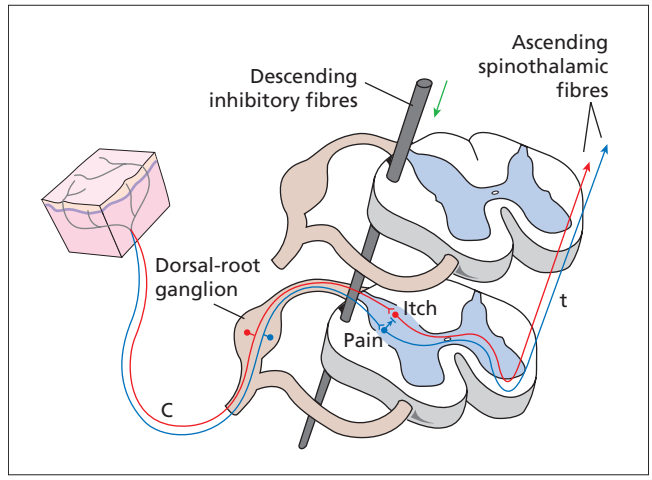

Fig. 16.1 Ascending and descending pathways modulating itch. C, unmyelinated slow-conducting C fibres; t, transmission neurone. (Reproduced with permission from Elsevier Science Ltd, *The Lancet* 2003; **361**: 690–4.)

Recent studies, using functional positron-emission tomography to measure changes in cerebral blood flow, suggest the involvement of the anterior cingulate cortex (Brodmann area 24) in the recognition of itch sensation at conscious levels [18], whilst the premotor cortical areas participate in intention to scratch. Ascending and descending pathways are represented in a simplified form in Fig. 16.1.

Central itch

Psychoneurophysiological aspects of itching are complex and poorly understood. They have led to the important concept of 'central itch', i.e. itching which is perceived as occurring in the skin, but which actually originates in the central nervous system due to dysfunctional processing of sensory information in the central pathways. Melzack and Wall [19] proposed the involvement of large, fast-conducting, myelinated sensory fibres in modulation of the discharge of the unmyelinated itch- or pain-transmitting fibres via the substantia gelatinosa ('gate' control of pain). According to this proposal, itch is due to a combination of peripheral excitation and central disinhibition. Scratching, by activating inhibitory fast-conducting myelinated fibres, closes the 'gate' by activation of suppressor neurones of the substantia gelatinosa and reduces the itch. Alloknesis (slight mechanical stimulation of skin causes intense itching) characteristically occurs in some patients with atopic eczema. It is thought to be due to excitation of central itch-transmission neurones due to reduced gating [4,19]. However, the recent suggestion that endogenous

opioid peptides of the central nervous system also play a crucial role in regulation of itch and pain traffic has complicated the picture. Opioid peptides have important peripheral actions, but also have an even more crucial central role. Morphine, administered spinally or epidurally, frequently causes intense itching [20–23], especially of the face, without visible inflammatory changes, and this symptom is rapidly relieved by intravenous naloxone or other opioid peptide μ-receptor antagonists [21,23]. Thus, the presence of opioid peptides and their μ-specific receptors, which modulate function of calcium channels specifically on unmyelinated C fibres in the central nervous system [24], provides a central itch- and pain-regulatory mechanism which is capable of therapeutic manipulation. Recent observations on the ability of serotonin (5-HT_3 receptor) antagonists to reduce itching, including that due to opioid peptide-induced pruritus, raise the possibility of an additional molecular mechanism to modulate itch centrally [25], and it is of interest that odansetron, a 5-HT_3 antagonist, has been reported to reduce morphine-induced pruritus [26]).

Peripheral mediators of itching in skin diseases

Itch can be evoked or augmented by a variety of stimuli, both physical and chemical (Table 16.1). That peripheral pharmacological mediators play a key role in the production of itching in inflammatory skin disease, originally proposed by Lewis as his 'H-substances', is supported by several lines of evidence. These include the ability of a wide range of naturally occurring pharmacological agents, including histamine and proteases, to reproduce the sensation of itch on injection into skin, the ability of antagonists of these agents to reduce itching and the regular experimental recovery of mediators known to be capable of causing or enhancing itching from inflamed pruritic skin. However, it must be appreciated that not all forms of itching involve release of peripheral mediators. Low-grade mechanical and electrical stimuli (Table 16.1) and the 'dry itch' of senescent skin may not involve peripheral mediators, although in these cases pruritus is likely to be peripheral rather than central. Nevertheless, it is a reasonable assumption that peripheral mediators cause itching in the majority of inflammatory dermatoses.

Histamine and its receptors

Histamine causes severe itching if injected or iontophoresed into skin, or if it is applied to superficially abraded skin, although it produces pain if injected more deeply into skin [27]. At least three subclasses of histamine receptors are recognized. The recently described histamine H_3 subclass behave as autoreceptors, regulating release and biosynthesis of histamine in brain slices and certain other tissues, but they have yet to be positively identified in skin [28]. Both H_1 and H_2 receptors have been characterized in human skin using specific H_1- and H_2-receptor agonists and antagonists, and these studies have consistently implicated histamine H_1 but not H_2 receptors in histamine-induced itching [27]. Thus, there is no theoretical basis for use of H_2 antagonists (cimetidine, ranitidine) in the suppression of itching caused by histamine. A recently proposed fourth class of intracellular histamine receptors (H_{ic}) [29,30] may be involved in the ability of histamine to regulate cell proliferation and is not proposed to be involved in itching. Cutaneous responses to histamine may not be due solely to the direct actions of histamine. Recent work on the kinetics of the inflammatory responses of skin to histamine raises the possibility that some of these may be mediated indirectly by hitherto unrecognized substances whose release or formation is evoked by histamine [31]. The majority of histamine released in skin as a consequence of injury originates from the dermal mast cells. Evoked release of histamine and

other mast cell mediators is a consequence of an energy-dependent signal-transduction process. That alternative sources of histamine-evoked itching may exist in skin cannot be ruled out. A recent immunohistochemical study in rat skin [32] has clearly demonstrated immunoreactive histaminergic nerves, although this phenomenon has yet to be reported in human skin.

Histamine has been recovered directly from involved skin in a number of inflammatory dermatoses. In cold urticaria, release of histamine into the venous blood effluent from the cold-challenged limb consistently reflects the onset, development and regression of itching and other local changes occurring following cold exposure. Suppression of evoked histamine release by oral doxantrazole treatment also suppressed itching, but not wealing, in patients with cold urticaria [33]. Histamine has also been recovered from affected skin in ultraviolet-induced inflammation [34] and atopic eczema [35]. Further evidence of the involvement of histamine in inflammatory dermatoses derives from the well-known symptomatic relief obtained in many of these by systemic H_1 antihistamine treatment, although the sedative effect of the traditional H_1 antihistamines has been claimed to be at least as important as the antihistaminic action in atopic eczema [36].

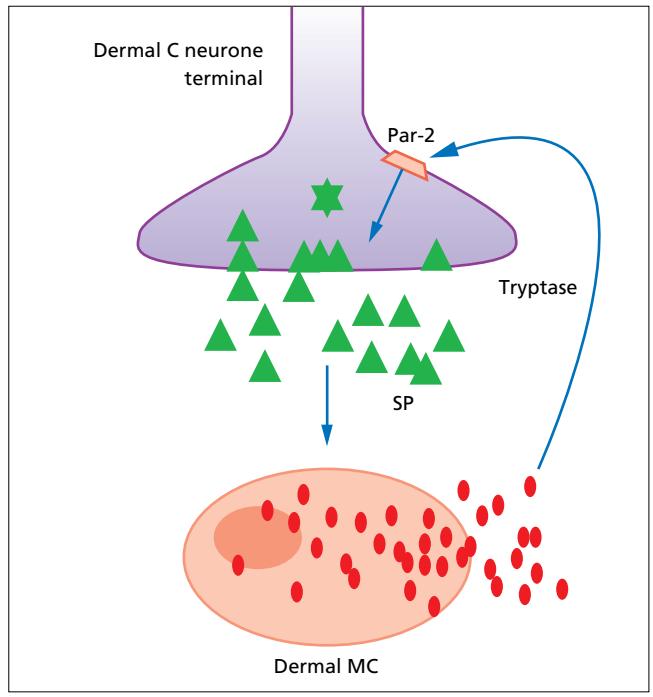

Fig. 16.2 Functional links between C neurone terminals and dermal mast cells: role of protein-activated receptor 2 (Par-2). SP, substance P; MC, mast cell.

Tachykinins

In view of their location in unmyelinated sensory nerve fibres in skin, neuropeptides are candidate mediators of itching in inflammatory dermatoses. Substance P, an 11-amino-acid neuropeptide, causes redness, wealing and itching [37,38]. Immunoreactive substance P is present in normal skin and in increased amounts in inflamed itchy skin [39]. To what extent substance P-induced itching is due to an indirect action via mast cell degranulation and histamine release is uncertain [37]. Of special interest is the fact that—unlike anti-IgE, compound 48/80 and other mast cell degranulators—substance P selectively and rapidly releases histamine but little or no prostaglandin D_2 or other cutaneous mast cell products from human isolated cutaneous mast cells *in vitro* [40]. Since the concentrations of substance P which degranulate mast cells tend to be unphysiologically high, it seems more likely that this neuropeptide has a priming function on histamine release evoked by other mast cell activators, including specific antigen–IgE interaction [41]. Recent work [42] has shed further light on links between dermal mast cells and afferent C neurones (Fig. 16.2). It has emerged that tryptase released by activated mast cells acts on a substrate called Par-2 (proteinase activated receptor 2) located in C neurone terminals. This results in release of vasoactive peptides including substance P. As already indicated, substance P can activate mast cells, thus closing the loop. Topical capsaicin application, which is known to deplete substance P from sensory nerve endings, abolishes pain and itch [43]. Substance P is colocalized with other neuropeptides, including calcitonin gene-related peptide (CGRP) and vasoactive intestinal peptide (VIP), in cutaneous human sensory nerve endings, but the involvement of CGRP and VIP in itch has not been fully explored. Substance P is synthesized in the dorsal root ganglion of nociceptor C fibres and transmitted peripherally in granules.

Opioid peptides

The opioid receptors consist of three classes: μ, δ and κ. The pruritic action of opoids is antagonized by naloxone and therefore belongs to the μ category.

The regulatory role of opioid peptides in the central nervous system has already been discussed above. Opioid peptides injected intradermally cause wealing and itching, probably at least partly through histamine release. However, more interestingly, low doses of opioid peptides, insufficient by themselves to cause itching, could strikingly enhance itching due to intradermal injection of histamine and this effect could not be antagonized by naloxone, indicating that this response does not involve μ-receptors [44,45]. Since the phenomenon also could not be inhibited by H_1 antihistamines or by prior depletion of cutaneous stores of histamine with compound 48/80 injections, or by indomethacin, it seems unlikely to be mediated by histamine release or prostaglandin synthesis [44]. Thus, opioid peptides may have an important peri-

pheral augmenting action on histamine itch, in addition to their pruritic central action. However, the former is not a class-specific action, since fentanyl and oxymorphone do not cause degranulation of human skin mast cells [46].

Other vasoactive peptide products of proteases

The use of the fine spicules of *Mucuna pruriens* (cowage) as probes enabled Shelley and Arthur [47] to carry out simple pathophysiological studies of itching in human volunteers, which led them to propose the involvement of peptide products of proteases as mediators of itching. The protease of cowage (mucunain) proved to be more active than histamine on a molar basis in inducing itching. However, no potent itch-producing peptide released by protease activity *in situ* has yet been recovered from human skin. The protease kallikrein is pruritogenic in human skin [48], but bradykinin produced by the action of kallikrein has little or no pruritic activity, although it causes pain [48]. Other proteases besides kallikrein cause itching, including chymotrypsin [49].

Cytokines

Cytokines are low-molecular-weight proteins produced by almost all eukaryotic cells, and they act on specific cell-surface receptors. They include the interleukins, chemokines, interferons and colony-stimulating factors. The first to be studied, interleukin-1 (IL-1), although powerfully pro-inflammatory in human skin [50], does not cause itching. Likewise, the chemokine IL-8, which causes leukocyte chemoattraction, causes no perceptible itch. Few others have been systematically studied from this standpoint. However, human recombinant IL-2 given intravenously to cancer patients for therapeutic reasons was noted regularly to cause intense itching, associated with redness and a blood eosinophilia [51]. Human recombinant IL-2 injected intradermally caused intense itching in skin of atopic and non-atopic human volunteers alike [52]. Since activated T lymphocytes, an important source of IL-2, are a feature of the dermal infiltrate of atopic dermatitis, a role for IL-2 in the characteristic itching of this disorder has been proposed. That ciclosporin (cyclosporin), a potent inhibitor of IL-2 production by T lymphocytes, causes relief of itching in atopic dermatitis lends further support to a proposed role for IL-2 in the itching of atopic dermatitis [53]. Leukocytes from atopic patients, but not those of control subjects, released increased amounts of IL-8 upon challenge by specific antigen, although this cytokine is not recognized as a direct cause of pruritus [54].

Prostaglandins and other eicosanoids

Increased cutaneous levels of arachidonate metabolites are found in a wide range of inflammatory skin diseases, including physical urticarias, ultraviolet inflammation, psoriasis and eczema [33,55]. The lipoxygenase metabolites most frequently identified in these conditions—leukotrienes B_4, C_4, D_4 and E_4, and 12- and 15-hydroxyeicosatetraenoic acid—cause little or no pruritus, despite being potent pro-inflammatory agents in human skin. Prostaglandin E also shows little or no pruritic activity in human skin, even when applied in a wide range of doses. However, it has the striking property of potentiating itching due to other mediators in concentrations which by themselves have no visible pro-inflammatory activity. By applying a range of concentrations of histamine to scarified human skin pretreated with doses of prostaglandin E_1 insufficient to cause visible reddening of the skin, it was possible to demonstrate a doubling of the sensitivity of the skin to histamine-induced itching [56]. Similar results were subsequently reported by others who have also shown potentiation by prostaglandin E_2 of itch due to other substances [57], and a study in which the H_1 antihistamine clemastine failed to antagonize the prostaglandin E enhancement of itching [58] suggests that this prostaglandin enhances itching due to other mediators. Increased skin concentrations of E prostaglandins have been reported in eczema and ultraviolet B inflammation, both of which are associated with pruritus [33]. Although aspirin, a prostaglandin synthetase inhibitor, has little or no effect as an anti-pruritic [59], non-steroid anti-inflammatory drugs have been demonstrated to reduce pruritus associated with morphine-induced spinal analgesia [60].

Factors modulating itching

Central mechanisms for regulation of itch traffic have already been referred to earlier. Psychological factors, including emotion, inattention and a variety of auditory, visual and other sensory inputs may act through these central pathways, resulting in modification of perception of itching. That warmth exacerbates itching is a familiar experience which has a physiological basis, conferring a rationale on cooling as a method of controlling itching. Cooling acts directly on sensory receptors, whereas heating stimuli appear to act centrally [61].

Scratching

Scratching is a reflex functioning at a spinal level, although modified greatly by higher centres. Scratching relieves itching for several minutes after scratching has ceased. Since the sensation of itching is reinforced by facilitating circuits in the relay synapses of the spinal cord, the prolonged scratch-induced relief could be due to temporary suppression of these circuits [19]. Stimulation of fast-conducting myelinated afferents inhibits these circuits via pre- and postsynaptic mechanisms. These afferents could

be activated by vibration, transepidermal electrical nerve stimulation (used therapeutically to allay itching) or more simply by scratching. Alternatively, scratching could simply damage sensory nerve endings, repair occupying several minutes. Why some itches evoke scratching and excoriation (as in scabies) whereas others prompt rubbing (as in lichen planus) is unknown. Scratching has been ingeniously utilized as an indirect, objective method of quantifying itch and as such has been utilized in the evaluation of treatment of itching [7,12].

Itching in non-inflamed skin

The molecular and physiological basis of pruritus associated with clinically normal skin in the absence of underlying systemic disease is in most instances uncertain, although clues are beginning to emerge. The problem of itch in ostensibly healthy skin is likely to become more pressing, with the increasing emergence of pruritus in senescent but visibly normal skin as a challenging therapeutic problem. Initially, careful examination of the skin must be made to exclude visible signs of skin disease. Patients with symptomatic dermographism who have the will to forbear scratching may have a normal-looking skin at the time of examination. It is also conceivable that localized or widespread itching without physical signs may be a manifestation of mild urticaria ('weal-less urticaria'). In such cases, levels of histamine and other mediators could be subthreshold with regard to vascular, but not sensory, effects. This phenomenon is recognized in aquagenic pruritus, contact urticaria, dermographic pruritus and cholinergic urticaria [62–65].

A detailed history is of paramount importance, including the quality, distribution and periodicity of itching. Itching, likened by the patient to insects crawling over the skin, is often psychoneurotic in origin—or occasionally due to insects actually crawling over the skin! Itch, which is migratory in timing and distribution, may be secondary to internal malignancy. Most patients with itching are especially uncomfortable in bed, probably because of warmth and little to distract their attention. Localized, fixed itching may be due to organic neurological disease—for example, in segmental neurofibromatosis [66].

Itching in disease states

Chronic renal disease

Itching occurs in chronic, but not acute, renal failure. The majority of patients with chronic renal insufficiency experience pruritus at some stage in the progress of their disease, but it is severe in only a few. Estimates of the overall frequency of pruritus in patients with renal failure varies widely in different series, as does its relationship to haemodialysis, including maintenance dialysis. On maintenance dialysis, about 80% are affected [1,2], but it rarely improves with dialysis alone. Recent work suggests that patients dialysed using less permeable (cuprophane) membranes suffer pruritus more frequently than those using more permeable (polysulphone) membranes [3]. Although the skin of some patients may appear dry, frequently it is essentially normal in appearance. Itching may be persistent, extensive and intractable, but in other patients it may be transitory and localized [1,2]. Histologically, the clinically normal skin may show attenuation of sweat and sebaceous glands, and increased population densities of cutaneous mast cells have been described [4]. However, no correlation between mast cell population densities and pruritus has been established. There may be an angiopathy [5]. Abnormal sprouting of neurone-specific enolase-positive unmyelinated nerve fibres in skin of uraemic patients has also been reported [6]. Other suggested factors in the pathogenesis include raised serum parathyroid hormone levels due to secondary hyperparathyroidism [7], and it is of interest that parathormone is known to cause increased populations of tissue mast cells [8]. However, although parathyroidectomy has relieved pruritus in some patients [9], no convincing correlation between parathormone levels and pruritus has been demonstrated in renal failure patients [7]. Stahle-Backdahl has proposed a correlation between sequences in the mid-region of the parathyroid hormone, rather than the intact molecule [3]. Renal pruritus has been proposed to be related to aluminium overload during haemodialysis [10] (treatable by administration of desferrioxamine mesylate), but this has not been confirmed.

Pharmacological mediators have been proposed to be responsible for renal pruritus. Histamine is an improbable candidate, since treatment by antihistamines is ineffective. Skin biopsies from patients with chronic renal failure show increased numbers of intraepidermal $CD1^+$ T cells, raising the possibility that T-cell-derived cytokines could be implicated in pruritus [11,12]. Opioid peptides have also recently been implicated, elevated plasma met-enkephalin levels having been reported in haemodialysis patients [13], although a correlation has yet to be established [14]. The pathophysiology of uraemic itching has been usefully reviewed by Murphy and Carmichael [15].

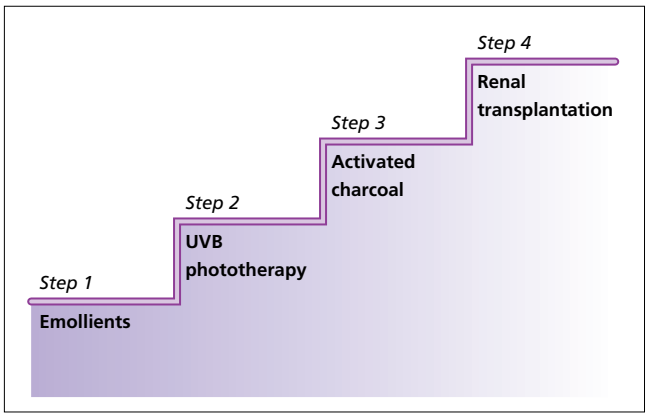

Fig. 16.3 Treatment ladder: pruritus of chronic renal failure.

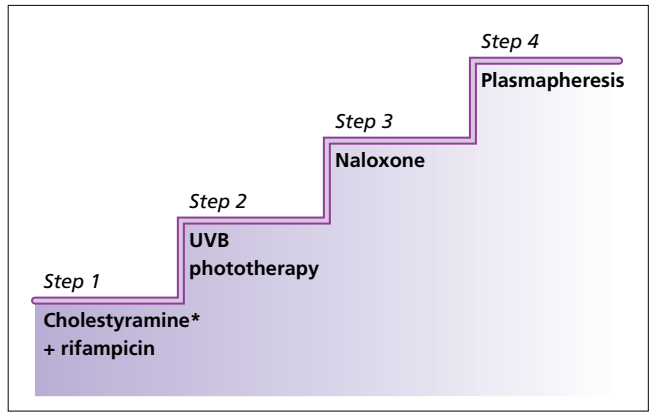

Fig. 16.4 Treatment ladder: pruritus of cholestasis. *Ineffective in total biliary obstruction.

The only treatment for renal pruritus (Fig. 16.3) which is reliably effective is renal transplantation. Parathyroidectomy may be followed by remission of pruritus in patients with secondary hyperparathyroidism [9]. Phototherapy with ultraviolet B (UVB) is frequently effective and may act systemically as well as locally [16]. That ultraviolet therapy depletes the vitamin A content of the skin has been proposed as a mode of action [17]. Only UVB phototherapy and possibly activated charcoal have an established track record for this indication [18,19]. Other treatments, including heparin, mexiletine, ion-exchange resin and intravenous lidocaine (lignocaine) have been advocated [16], but are of uncertain effectiveness and usually impractical to use. A 1996 report of a placebo-controlled trial of an orally administered opioid antagonist, naltrexone, attracted much attention, but the apparent effectiveness of this treatment remains to be independently confirmed [20]. Antihistamines and topical steroids are generally unhelpful in uraemic itching, but emollients may provide relief in those with a dry skin. Since itching may be restricted to certain areas, topical capsaicin 0.025% has been reported to be effective in localized uraemic pruritus [21]. In the longer term, only expansion of the renal transplant programme is likely to bring sustained relief to these greatly distressed patients.

Cholestasis

Pruritus, which may be generalized or localized, for example to the hands and feet, is a frequent and distressing symptom of cholestasis, and its molecular basis is still debated. Hepatitis C is an important cause of intense cholestatic pruritus, and should be considered as part of the work-up of patients with severe pruritus. Cholestatic pruritus is associated with elevated plasma levels of bile salts [22], but evidence of a direct correlation has been lacking. Measurements of skin-tissue levels of bile salts and their relationship to serum levels, and to intensity of itching, gave inconclusive results and the bile-salt levels did not differ from corresponding values in control subjects [23]. Bile salts applied to blister bases in human skin, although causing pruritus, do so at minimal effective concentrations far exceeding those achieved in cholestatic jaundice [24]. Analysis of individual bile acids in skin and serum, including quantitatively minor components of the bile-acid family, also failed to show a quantitative relationship with pruritus [23]. Lack of demonstrable quantitative relationships has not, however, discouraged a number of investigators from exploring methods for lowering serum and skin bile-salt levels in the management of itching due to cholestasis. For example, plasma perfusion through charcoal-coated glass beads was associated with a marked improvement in cholestatic pruritus, although a relationship between clinical response and fall in bile-salt level was not demonstrated. Similar results have been achieved with ion-exchange resins, including cholestyramine [25,26]. These reports raise the possibility that observed clinical improvements may be a consequence of removal of pruritogenic factors other than bile salts following such procedures.

Treatments for pruritus of cholestasis are summarized in Fig. 16.4. In a randomized cross-over trial comparing cholestyramine, terfenadine (a low-sedation H_1 antihistamine now withdrawn by the manufacturer owing to cardiac side effects) and chlorpheniramine with placebo in pruritus due to obstructive liver disease, only terfenadine and cholestyramine showed evidence of significant suppression of pruritus, but cholestyramine was associated with a high incidence of side effects [25]. Other methods advocated for the relief of itching of cholestasis include phenobarbital and rifampicin [27,28], plasmapheresis [29], phototherapy [26] and, more recently, ondansetron [30]. Effective treatments of hepatobiliary pruritus have recently been reviewed [31].

Earlier work highlighted the importance of dysregulation of central opioid peptides in patients with cholestatic pruritus [32]. The evidence can be summarized as follows.

Plasma levels of opioid peptides are elevated in human [32] and rat [33] cholestasis. Furthermore, plasma from patients suffering from pruritus of cholestasis induces facial scratching, reversed by naloxone, when injected into the medullary dorsal horn of the monkey [34]. Most importantly, carefully controlled trials established the effectiveness of systemic and oral opioid antagonists in the treatment of cholestatic pruritus [35,36]. Thus, the conclusion that opioid antagonists are of value in treatment of the pruritus of cholestasis is based upon evidence of increased opioidergic tone in chronic cholestasis patients, and the impressive response to naloxone (a specific opioid μ-receptor antagonist). This response can be associated with opioid withdrawal symptoms [35–37].

Apart from biliary disease, cholestatic pruritus may also occur in pregnancy [38] and premenstrually [39]. However, the role of opioid peptides in these contexts has yet to be established.

Iron deficiency

Iron deficiency has been implicated as a cause of intractable pruritus in the absence of visible skin disease, or even in the absence of anaemia [40]. Of special interest is a report by Salem *et al*. [41] of pruritus and severe iron deficiency in polycythaemia vera. In these patients, correction of iron deficiency apparently correlated with improvement in pruritus. However, a study of iatrogenic venesection-induced iron deficiency over a 60-month period revealed no instance of pruritus in 21 patients [42]. That patients with iron deficiency complain of troublesome pruritus is evident, but present data suggest that the itch is likely due to factors other than the iron deficiency itself.

Polycythaemia vera

As many as 50% of untreated patients with polycythaemia develop a severe, prickly and distressing discomfort within minutes of water contact, lasting 15–60 min [43]. As it frequently occurs after the patient emerges from bathing, it is often referred to as 'bath itch'. No visible changes are present in the skin, and the symptom may be associated with elevated serum and urinary histamine levels [43]. Platelet aggregation has been suggested as a possible mechanism and source of pruritogenic factors, including histamine [44]. Water-induced itching may precede development of polycythaemia vera by several years [45]. Bathing by regional sponging may mitigate the itch. Successful treatment of the underlying polycythaemia may not relieve the itching and although correction of venesection-induced iron deficiency may give relief, it may be at the expense of exacerbating the polycythaemia [41]. Antihistamines are generally ineffective. Psoralen ultraviolet A (PUVA) photo-chemotherapy, with 8-methoxypsoralen and UVA, has been successful in some patients [46]. One report cites the use of long-term treatment with interferon alfa-2b for severe pruritus of polycythaemia vera [47].

Spontaneous itching as a manifestation of endocrine and malignant disease

Thyrotoxicosis

Intractable itching, associated with a warm, moist skin, is a recognized accompaniment of thyrotoxicosis and may be the presenting symptom [48]. The cause is uncertain. Localized pruritus may result from mucocutaneous candidiasis. Cutaneous vasodilatation, a regular feature of the disease, leads to increased skin surface temperature, which lowers the itch threshold [49]. Myxoedema may also cause troublesome itching, but in this case the cause is usually excessive drying of the skin, which feels cool, and which responds to application of moisturizing creams.

Diabetes mellitus

Contrary to popular wisdom, generalized pruritus is not a manifestation of diabetic mellitus, the erroneous belief having originated from a 1927 report of a 3% prevalence in 500 patients [50], which coincides with the expected frequency in the general population. A more recent study [51] reported generalized pruritus in eight of 300 diabetic patients, which was not more common than in non-diabetic patients. However, intractable anogenital itching may occur due to mucocutaneous candidiasis. Localized pruritus of the scalp is also a recognized manifestation of diabetes and is usually resistant to antipruritic measures [52].

Pruritus and malignancy

The problem of pruritus as a manifestation of malignant diseases has been the subject of numerous publications reviewed by Lober [53] and Paul *et al*. [54]. Paul *et al*. followed up 125 patients with generalized pruritus for 6 years [54]. Of these, 66% still had pruritus at the end of the study. Although four proved to have a malignant condition at the onset of the study, only four others developed malignancy during the follow-up period. This is no different from the expected frequency in the general population. However, pruritus, often induced by contact with water, is a recognized presenting symptom of polycythaemia vera [45]. Pruritus is intense in Sézary syndrome, but the skin is inflamed in this malignancy. The practical issue of the extent to which patients with generalized pruritus in the presence of a normal skin should be investigated cannot be separated from economic considerations [55].

Aquagenic pruritus

This term was first used by Shelley [56] to describe what was considered to be a variant of aquagenic urticaria. Three cases of aquagenic pruritus were subsequently reported in detail and shown to be distinct from aquagenic urticaria [57]. The condition was subsequently extensively reviewed [58,59]. Typically, contact with water at any temperature leads to an intense pricking itch in the exposed skin, without visible change in the appearance of the skin. The same symptoms may be evoked by a sudden drop in temperature of the skin. The condition is very chronic and intractable, and sufferers frequently are wrongly considered to be psychoneurotic. The condition, which closely resembles the pruritus of polycythaemia vera, responds poorly to antihistamine treatment but may respond to UVB phototherapy or PUVA [46,60]. It may be a premonitory symptom of polycythaemia vera [45]. Other underlying causes recently reported include metastatic carcinoma of the cervix [61], hypereosinophilic syndrome [62], juvenile xanthogranuloma [63] and the myelodysplastic syndrome [64]. The molecular basis of the pruritus is uncertain. Investigation of affected skin has shown elevated histamine concentrations and increased cutaneous mast cell degranulation, and the serum histamine concentration has also been shown to be raised [43,57]. The lack of visible evidence of histamine release can be explained by its slow rate of release, leading to skin concentrations sufficient to cause itching but below the threshold for visible vascular changes. However, histamine is unlikely to be the sole mediator, since antihistamine treatment is generally ineffective, and there is also evidence of the involvement of acetylcholine, since topical hyoscine treatment rendered skin unresponsive to water contact [57]. Further evidence for acetylcholine as a mediator derives from a recent report of increased acetyl cholinesterase activity localized to nerve fibres investing eccrine sweat glands in patients with aquagenic pruritus [65]. There has also been a report of increased tissue fibrinolytic activity in affected skin of patients with aquagenic pruritus [66], which could be a response to increased local concentrations of histamine or acetylcholine.

Pruritus as a symptom of senescence

Persistent and widespread itching, often associated with extensive excoriation, is experienced by at least 50% of those in the seventh decade of life or beyond. Because of the gradually increasing proportion of elderly persons in the population, it is also a burgeoning problem. In women, the itching may be a manifestation of the postmenopausal syndrome. Pruritus of elderly people may be a symptom of subtle skin disease, a manifestation of underlying systemic disorder, including renal, hepatic or malignant disease, or it may be a skin manifestation of an adverse drug reaction. However, in most instances, itching is a result of excessive dryness (xerosis) of the skin. In a recent study of 149 elderly men and women, 39% had pruritus due to xerosis [67]. There is evidence of slow reduction of sebum production by skin in association with ageing, and its composition also alters [68,69]; however, this is not thought to be a major factor in xerosis of the elderly. Senescence in the skin is frequently associated with failure of the skin to retain water. The resulting dryness and fine cracking of the skin is associated with troublesome itching, which in most instances responds to emollient treatment. Water-induced itching in elderly people [59] is a variant of senescent pruritus, being particularly common in institutionalized elderly people who may be exposed to an overheated, dry environment, resulting in skin desiccation, and both it and the common spontaneous variety respond to emollient treatment. Analysis of senescent stratum corneum has shown a greatly reduced water content [70]. It is usually most expedient to prescribe several different emollients and encourage the patient to experiment with these, since it is not possible to predict with confidence individual responses. Soft white paraffin ointment is cheap, occlusive and has been shown to accelerate recovery of barrier function in damaged skin [71]. The patient must be encouraged to apply emollients at least four times daily and, if necessary, ambient temperature and humidity should be modified. Corticosteroids, antihistamines and cooling lotions are not indicated in itching due to xerosis.

Psychogenic pruritus

Itching, either localized or generalized, can be a skin manifestation of psychological disturbance. There are no satisfactory 'rule in, rule out' diagnostic paradigms; therefore, in practice the conclusion that local or generalized itch is psychogenic in origin is arrived at by a process of exclusion of cutaneous or systemic causes.

Perianal and, in women, vulval itching are the commonest manifestations of local psychogenic pruritus, although in these instances great care must be taken to rule out occult remediable causes, including threadworms (pinworms), dermatitis medicamentosa, diabetes-induced candidiasis and local inflammatory or neoplastic disease. Widespread psychogenic pruritus may result in extensive and disfiguring excoriations and even scarring to the extent of self-mutilation. Parasitophobia (delusions of parasitic infestation of the skin) is normally readily recognizable, because of the patient's description of the itch and even the presentation by the patient of particulate material considered by the sufferer to represent the supposed insects or their products. Of two recent patients of the author's, one brought along a small portable micro-

scope to aid viewing of the 'insects', and the other brought textbooks of dermatology and parasitology to the clinic to support her case! Although rarely successful, psychiatric advice should be sought, and antidepressant and anxiolytic drugs, including doxepin and hydroxyzine, should be tried. Treatment options for these patients have been well reviewed [72]. Pimozide (phenylbutylpiperidine), a phenothiazine, has been advocated for treatment of delusions of parasitosis [73]. It is also self-evident that patients experiencing severe persistent pruritus become secondarily depressed, and that this may itself lower the threshold for pruritus, thus completing a 'vicious circle' of itch, depression and more itch [74].

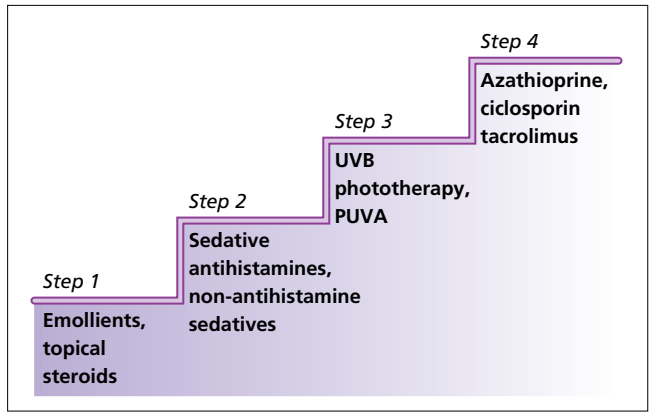

Fig. 16.5 Treatment ladder: pruritus of atopic eczema.

Postmenopausal pruritus

Persistent or episodic widespread itching is a frequent association with the postmenopausal syndrome. The itching characteristically evokes rubbing, rather than heavy excoriation, and is frequently associated with hot flushes. It is especially troublesome at night, and is usually associated with raised plasma levels of pituitary follicular and luteal stimulating hormones. These hormones are unlikely, however, to be the direct cause of the itching and associated flushing, which are probably attributable to local tissue mediators. Hormone-replacement therapy with ethinyl oestradiol is usually sufficient to control postmenopausal pruritus due to this cause [75], but since systemic oestrogen therapy can be hazardous, expert endocrinological advice should be sought. Localized genital pruritus may also be a postmenopausal manifestation of oestrogen deficiency and may be associated with mucocutaneous candidiasis. It should respond to corrective hormone therapy, combined if necessary with nystatin or other anti-*Candida* therapy.

Pruritus of atopic eczema

The itch of atopic dermatitis is aggravated by scratch damage, which causes enhanced inflammation (itch–scratch cycle). Itching is usually worse at night, and is aggravated by contact with wool, sweat, spicy foods and alcohol. Considerable sleep loss and incapacity ensues. No aspect of pruritus has provoked more debate than the pathophysiology of itching in atopic eczema and its management. Pruritus in atopic dermatitis involves pruritoceptive neurogenic and probably psychogenic mechanisms. Several studies, reviewed by Rajka [76], have reported an enhanced and abnormally prolonged response to application of pruritic pharmacological stimuli in unaffected skin in atopic patients. Studies of the itching response of atopic dermatitis patients to histamine iontophoresis suggest a decreased response of afferent cutaneous fibres to high doses, but an increased sensitivity to low concentrations—possibly because of increased permeability of clinically normal-looking skin of these atopic patients [77]. There is also an increased population density of sensory nerve fibres in the affected lichenified pruriginous skin [78], although this is probably non-specific. It is important to distinguish itching associated with inflammatory changes or chronic lichenification from that simply due to excessive drying of the skin in patients with atopic eczema, since emollients, which may be all that is required for the management of xerosis, will be inadequate where inflammatory changes are responsible for the itching. Recent dermal microdialysis studies have demonstrated the involvement of mast cell mediators other than histamine in lesional skin of atopic eczema patients [79]. In the latter situation, a combination of antihistamines with topical treatment may or may not be helpful, depending upon the importance of histamine as a pruritogen. Treatment approaches to itching in atopic eczema are summarized in Fig. 16.5. The role of sedative versus low-sedation antihistamines is controversial. On the basis of a comparison of itching in atopic eczema patients receiving successively terfenadine (now withdrawn by the manufacturers due to adverse cardiac side effects) or astemizole (low-sedation antihistamines), trimeprazine (sedative antihistamine) and nitrazepam (non-antihistamine sedative), one study [80] concluded that sedation was a required component of successful systemic treatment of itching in atopics, and that, moreover, itching in atopic eczema involved a central component. However, numbers of patients were small and subsequent studies have yielded conflicting results [81]. However, the itching of atopic eczema is multifactorial, being due to dryness, inflammation and probably to disturbed regulation of itch traffic in the central nervous system. In this context, alloknesis (itchy skin; see above) forms a major component of the itch suffered by the atopic eczema patient—explaining, for example, the paroxysms of itching experienced by patients in response to sudden

changes of temperature, humidity, undressing or dressing, etc. These multiple and distinct mechanisms may explain seemingly conflicting views on the nature and causation of pruritus in atopic eczema. Evening primrose oil, which contains essential fatty acids, including dihomo-γ-linolenic acid, has been proposed to be effective in relieving pruritus of atopic eczema [82], but other studies [83,84] have challenged this finding, and the use of this preparation in itching of atopic eczema is controversial. However, immunosuppressives—including systemic azathioprine and ciclosporin—are highly effective in relieving the itching (and other signs and symptoms) of chronic atopic eczema [85,86], probably due to an action on activated $CD4^+$ T-helper lymphocytes. Recently, a topical T-cell-suppressing immunosuppressant with an action closely resembling that of ciclosporin, called tacrolimus, which is highly effective in relieving the symptoms and signs of atopic eczema, including pruritus, has been introduced [87], but its long-term safety needs to be established, and it remains to be seen to what extent tacrolimus will form a practical replacement for topical steroids. Aspirin, contrary to reports in some textbooks, is ineffective in the suppression of itching in atopic eczema [88].

Acquired immune deficiency syndrome

Itching is an important symptom of acquired immune deficiency syndrome (AIDS) [89]. Whilst this may be associated with numerous causes, including cholestasis, seborrhoeic dermatitis, scabies or candidiasis (Table 16.2), it also occurs as a characteristic generalized papular and excoriated pigmented eruption resistant to topical steroid treatment. Histologically, affected skin shows follicular damage associated with an eosinophilic infiltrate [90]. Although the histological features are not dissimilar from those of Ofuji's eosinophilic pustular folliculitis, the clinical picture in the latter, which features polycyclic plaques, is different. Treatments reported to be effective include dapsone, pentoxifylline, UVB phototherapy and PUVA [91–93].

Photosensitivity
Systemic causes of pruritus (renal, hepatic, endocrine)

Important miscellaneous causes of intense itching

Hydroxyethyl starch-induced pruritus [94]

Hydroxyethyl starch (HES) is used widely as a plasma substitute, especially on the continent of Europe. It is also used to improve the function of the microcirculation. Generalized pruritus has been reported as a rare but well-recognized complication. It results from deposits of HES in the skin, and may be associated with erythema [94,95]. It is poorly responsive to antihistamines, but may respond to topical capsaicin [96].

Pemphigoid nodularis

Bullous pemphigoid can present with non-specific pruritus. There have also been reports from several centres [97–99] of patients presenting with a chronic prurigo nodularis-like eruption who subsequently proved—by histological examination, direct immunofluorescence and clinical follow-up—to have bullous pemphigoid; blisters eventually developed in most reported cases. It is important to carry out a skin biopsy for histological examination and direct immunofluorescence for immunoreactants on all patients with what appears to be prurigo nodularis.

Notalgia paraesthetica

This is a fairly common cause of localized persistent pruritus. Characteristically, patients complain of persistent burning pruritus localized to the mid-scapular area, but often extending from there to a more widespread distribution, including the scalp. Apart from mild lichenification and pigmentation with or without macular amyloidosis, there is usually little to see. Reports of increased cutaneous innervation are probably correct, but may represent a non-specific change [100]. Recent reports stress the importance of nerve root entrapment [101,102]. Capsaicin cream appears to be effective in some patients, and the current view is that it is a type of localized sensory neuropathy [103].

Brachioradial pruritus

This increasingly common sunlight-induced chronic pruritus is localized to the outer aspect of the elbow, and adjacent lower and upper arms [104]. The increased popularity of prolonged and frequent outdoor holidays in areas of high insolation amongst middle-aged and elderly fair-skinned people probably accounts for its increased frequency. A typical patient of the author's with this diagnosis had spent much of the year sailing and golfing in the Caribbean region. She responded to treatment with capsaicin cream [105]. However, it can be unresponsive to

treatment. Gabapentin has been reported to be effective in such cases [106]. Pruritus and prurigo due to chronic sun exposure may occasionally be much more widespread and has been termed 'solar pruritus'. They are probably identical to brachioradial pruritus [107].

Pruritus and anorexia nervosa

That generalized pruritus is one of several skin manifestations of anorexia nervosa is well recognized [108]. Itching is associated with low body weight and resolves with weight restoration. The itching is independent of underlying disease, including endocrine factors, renal or hepatic complications, or excessive washing. The skin may be excoriated and present a prurigo-like appearance. The itching could be central (neurogenic) in origin, but further evidence is awaited [109].

Investigation of generalized pruritus

History taking is important and can save time in the long run. The onset, quality, severity and timing of the itching should be established. The location and fixed or ephemeral nature of bouts of itching should be determined, together with relationship to activities, provoking factors, medications, recreational, social and ablutional habits. Use of a questionnaire, e.g. the Eppendorf Itch Questionnaire [110], enables elicitation of standardized historical information.

In the absence of obvious localizing symptoms or signs indicating systemic disease, it is essential to carry out a full physical examination, including rectal and pelvic examination. This should be followed by full blood counts, chest X-ray and thyroid, renal and liver-screening tests. Routine imaging investigations and endoscopy are probably not justified in the absence of localizing symptoms or signs, although examination of the stool for occult blood is a useful and cheap investigation. The possibility that persistent, generalized pruritus in the absence of skin signs can be an adverse reaction to a systemic drug should never be overlooked. All patients with generalized pruritus of unrecognized cause should be followed up regularly as long as the symptom persists.

Management of itching

Obviously, the most important step is to identify and treat the fundamental cause of the itch, whether it is primarily in the skin or of a systemic origin. At the same time, patients require symptomatic relief. Pruritus is temperature-dependent [49], and therefore wearing light clothes, keeping the bedroom cool, using light bedclothes and keeping the working environment as cool as possible are all helpful measures. A cool shower before retiring may allow sleep. Pruritus due to dry skin, especially prevalent in elderly people, may respond to emollients such as soft yellow paraffin and aqueous cream. Water-induced itching in elderly people, which is distinguished from aquagenic pruritus by the presence of clinical evidence of dry skin, is especially responsive to treatment by moisturizing preparations. H_1 antihistamines and topical corticosteroids should not be used in the absence of visible inflammatory changes in the skin. Topical antihistamines carry a small risk of contact sensitization, although the topical tricyclic compound 5% doxepin cream has been shown to be safe and effective for treatment of itch due to eczema [111]. However, it does cause sedation due to percutaneous absorption. Low-sedation antihistamines are of controversial value in the itch of atopic eczema, but are the treatment of choice for itching in patients with urticaria. There are no available effective and specific antipruritic drugs. Topical phenol and crotamiton [112], though widely used for this purpose, are of unproven value. A carefully controlled study suggests that topical 1% menthol in 90% ethanol is of significant value in the symptomatic relief of histamine-induced pruritus [113], probably due to activation of cold-sensitive Aδ nerve fibres. Capsaicin is being used topically with apparent success in several localized chronic pruritic disorders [114]. Systemic tricyclic antidepressants may be of help in some patients with intractable itching. Other suggested measures of uncertain efficacy include transcutaneous nerve stimulation [115] and acupuncture [116]. Use of opioid-receptor antagonists, including naloxone, shows early promise in the management of otherwise intractable pruritus [117]. Paroxetine, a selective serotonin reuptake inhibitor, may have a place in the treatment of intractable pruritus, including the pruritus of advanced cancer [118].

Chapter 17

Eczema, Lichenification, Prurigo and Erythroderma

C.A. Holden & J. Berth-Jones

Eczema

Definition. Eczema is an inflammatory skin reaction characterized histologically by spongiosis with varying degrees of acanthosis, and a superficial perivascular lymphohistiocytic infiltrate. The clinical features of eczema include itching, redness, scaling and clustered papulovesicles. A wide range of external and internal factors acting singly or in combination can induce the condition.

The terms 'dermatitis' and 'eczema' are nowadays generally regarded as synonymous, although some authors still use the term 'dermatitis' to include all types of cutaneous inflammation, so that all eczema is dermatitis, but not all dermatitis is eczema. The term 'dermatitis', however, should be used with care, as some patients regard it as implying an occupational cause. Unfortunately, there is still no international agreement on the use of these terms [1,2].

Ackerman [1] has argued that, as the term eczema cannot be defined in a way that meets with universal approval, it should be dropped from dermatological parlance, but there seems to be a consensus that the term still serves a useful purpose for the clinician.

Classification. Eczema accounts for a large proportion of all skin disease. The classification of the many clinical forms is difficult, not only because nomenclature is controversial [3], but also because in many cases the precise cause is unknown. Multiple factors may be implicated, and two or more forms of eczema may be present in the same patient simultaneously or consecutively. The classification shown in Table 17.1 divides eczema into two groups. The first, exogenous eczemas, are related to clearly defined external trigger factors, although inherited tendencies can also play a part. The term endogenous

eczema implies that the eczematous condition is not a result of exogenous or external environmental factors, but is mediated by processes originating within the body. In some conditions, however, there are both external and internal precipitating factors. Hand eczema, for example, even when primarily endogenous, is often aggravated by contact with irritants such as detergents or solvents. Discoid and asteatotic eczemas (both regarded as endogenous) can be adversely affected, if not caused, by excessive dehydration of the stratum corneum by low ambient humidity. There remain some cases of eczema that do not fit the described patterns [4]. However, it is convenient to continue to classify eczema as of endogenous or exogenous type. The classification includes the principal forms of eczema, although these conditions do not necessarily show the histological changes of eczema at all stages.

Some forms of eczema are altered by regional variations in structure and function of the skin, and these may modify its appearance in regions such as the hands (see p. 17.20) and the lower leg. Other forms occur only in special environments, in certain racial groups (see Chapter 69) or at certain ages (see below).

Prevalence. There have been numerous studies of the prevalence of atopic dermatitis (see Chapter 18), but fewer in other types of eczema. An important survey of the prevalence of skin disease was carried out in the USA on a sample of over 20 000 people who were representative of the whole population, and who were examined meticulously by trained observers [1]. Nearly one-third had significant skin pathology. The prevalence of all forms of eczema was 18 per 1000, seven of whom had atopic dermatitis. Hand eczema, dyshidrotic eczema and nummular eczema each accounted for about 2 per 1000. In a recent population-based survey of public health issues in Stockholm, Sweden, a postal questionnaire was sent to 15 000 adult inhabitants. Fifteen per cent of respondents reported a history of childhood eczema. The 1-year prevalence of hand eczema was 8%, skin symptoms on the face occurred in 14% and allergy to nickel was reported in 15% of females [2]. Population-based studies of contact allergic dermatitis suggest 40% of subjects demonstrate at least one contact allergic reaction [3].

Consultations for eczema are common in primary care. Horn [4] recorded the details of 6819 dermatological consultations in a UK general practice of around 3000–4000 patients from 1958 to 1985. Eczema patients formed the largest group (19% of the consultations; see Table 17.2 for details).

Table 17.2 Incidence of various types of eczema seen in a single general practice over 27 years in Ipswich, UK. (From Horn [4].)

Eczema type	Incidence (%)
Hand eczema	15
Contact dermatitis	12
Seborrhoeic	11
Discoid	7
Lichen simplex	6
Atopic	5
Gravitational	4
Other (mainly unspecified)	40

In a general practice in Belfast, 8% of patients seen during an 8-week period had a dermatological condition. Dermatitis accounted for 25% of these, of which 63% were considered to be exogenous in origin [5].

In addition, many cases are referred to hospital, and in one series represented 17% of all new dermatological cases [6]. A national tertiary referral centre in Singapore has described the profile of eczema referred between 1989 and 1990 [7]; 25 448 new cases were analysed. These represented 34% of new cases seen at the centre. Sixty-seven per cent of eczema cases were classified as endogenous and 13.7% were contact dermatitis. Exfoliative dermatitis comprised 0.5% of all eczemas. The authors commented on the increase in the proportion of endogenous eczema seen in 1989–90 compared with that reported in 1973.

The uncertainty and variation in the nomenclature of endogenous eczema makes interpretation of statistics tentative. Atopic eczema is reasonably well defined, and there have been several recent studies suggesting an increased prevalence of atopic dermatitis (see Chapter 18), but prevalence of other forms of eczema may be decreasing [8].

Eczema and age

Certain patterns of eczema can be seen more commonly in particular age groups. Most cases of eczema in infants and young children are atopic. In the HANES epidemiological survey in the USA [1], atopic dermatitis was by far the most common form found up to the age of 11 years; discoid and 'dyshidrotic' eczema were recorded, but were far less frequent. Perioral eczema or lick eczema around the mouth is common in children with atopic eczema (see Chapter 18), but it can also occur in non-atopic children. Hand eczema is common in atopic children, but uncommon in non-atopic children. Other specific patterns of eczematous change are almost restricted to children; for example, lichen striatus (see p. 17.43), juvenile plantar dermatosis (see p. 17.33), seborrhoeic dermatitis of infancy and napkin dermatitis (see Chapter 14).

Pompholyx and atopic eczema are less common in elderly people, but other forms of eczema assume greater importance. Discoid eczema occurs particularly in elderly males in winter, and asteatotic eczema of the legs is also common. In elderly factory workers, irritant hand eczema can be very troublesome, although contact dermatitis becomes less common with advancing age. The subject is discussed more fully in Chapter 70.

Histopathology [1–4]. The histopathological features of eczema reflect a dynamic sequence of changes resulting from inflammation of the epidermis and the underlying dermal structures. These vary with the intensity and stage of the eczematous process, and are frequently modified by secondary events such as trauma and infection.

Spongiosis is an intercellular epidermal oedema that leads to stretching and eventual rupture of the intercellular attachments, with the formation of vesicles. The epidermal vesicles commonly occur in discrete foci, but on the palms and soles they tend to become large by coalescence. There is variable infiltration of the epidermis by lymphocytes. Increased epidermal mitotic activity leads to acanthosis, but if spongiosis is intense, disintegration of the suprapapillary epidermis may cause clefts to form, exposing the underlying dermis.

In the subacute stage, spongiosis diminishes, and increasing acanthosis is associated with formation of a parakeratotic horny layer. This often contains layers of coagulated plasma and pyknotic nuclei of inflammatory cells. Later, the rete ridges become elongated and broadened, and hyperkeratosis replaces parakeratosis. The changes are then those of lichenification.

Vascular dilatation in the dermis is marked in all stages. The papillary vessels are particularly involved, and in lichenification they may become tortuous. The infiltrate is predominantly lymphohistiocytic, although polymorphs and eosinophils may be present in very acute eczema, and eosinophils are particularly common in eczematous drug eruptions. In the presence of infection, polymorphs may invade the epidermis. In grossly lichenified eczema, prurigo and exfoliative dermatitis, the infiltrate is mixed, and may be so dense that it simulates a granuloma.

Secondary changes. The trauma of rubbing or scratching may cause superficial erosions, haemorrhage or subepidermal fibrinoid changes. Although some degree of lichenification is always present during a prolonged attack of eczema, it is particularly prominent in atopic dermatitis. At times, extreme hyperkeratosis and papillomatosis develop.

With secondary infection, the formation of follicular or subcorneal pustules can simulate the appearance of impetigo, although typical eczematous changes are still visible at the edges of the lesion. Other modifications of the histopathological pattern are mentioned below in relation to different clinical varieties of eczema.

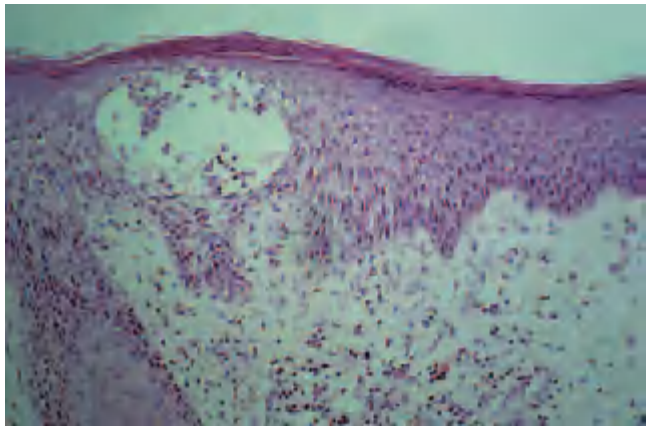
Differential diagnosis. Spongiosis and a dermal lymphohistiocytic infiltrate are always present at some stage in eczema, but the dynamic nature of the changes and their modification by secondary events may make histological diagnosis difficult. All the changes mentioned, with the exception of the spongiotic vesicle, may be found in burns or simple traumatic lesions of the skin.

The distinction between eczema and psoriasis can be especially difficult, particularly on the palms and soles. Seborrhoeic dermatitis (see p. 17.10) is particularly difficult to distinguish from psoriasis, but the finding of Munro's microabscesses is suggestive of the latter. It is generally true that cases that cause diagnostic difficulty clinically often have an equivocal histological appearance.

The histological features of pityriasis rosea are those of eczema, but the clinical features, particularly the distribution, are characteristic.

Changes in the various stages of eczema

1 *Acute* (Fig. 17.1). The histological picture is dominated by spongiosis and vesicle formation. The intercellular oedema may be diffuse, but more commonly occurs in discrete foci, and is most intense in the mid-epidermal region. Loosening and disruption of the individual Malpighian cells occur, and some intracellular vacuolation may be found, with displacement of the nucleus from the centre of the cell. Loose, shrunken epidermal cells may resemble histiocytes. Vesiculation occurs as a result of further fluid accumulation and detachment of cells. When



(a)

(b)

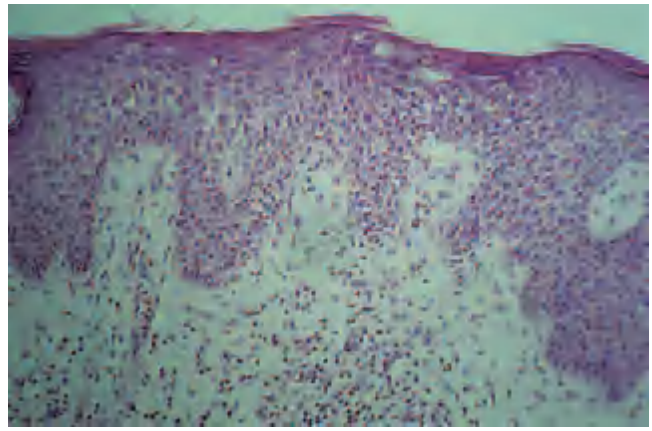
Fig. 17.1 (a) Acute vesicular eczema. The epidermis shows distinct vesicle formation. The vesicle contains serum, and a moderate number of inflammatory cells. H&E, × 100. (Courtesy of Dr M.G. Cook, Royal Surrey County Hospital, Guildford, Surrey, UK.) (b) Acute eczema of the arm, with redness, scaling and weeping.

this is intense, the appearances are those of reticular degeneration. The vesicles and the oedematous epidermis may be permeated by mononuclear cells, chiefly monocytes.

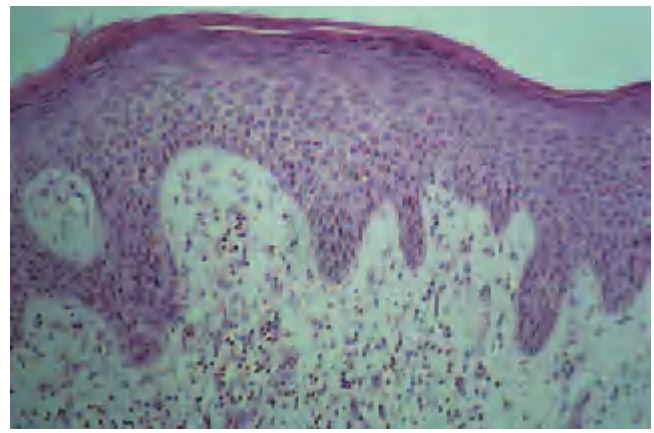
On the palms and soles, the resistance of the thick stratum corneum delays the rupture of the vesicles, which tend, in consequence, to become large and bullous by coalescence. In the weeping stage, thinning or destruction of the suprapapillary epidermis causes clefts, which may reach the underlying dermis.

2 *Subacute* (Fig. 17.2a). Spongiosis and vesiculation diminish and acanthosis increases. A parakeratotic stratum corneum forms, which contains coagulated plasma and the pyknotic nuclei of inflammatory cells. Later, the epidermal thickening becomes more marked, and the rete ridges more elongated and broadened. The appearances merge into those of lichenification.

3 *Chronic* (Fig. 17.2b,c). Hyperkeratosis coexists with areas of parakeratosis. Spongiosis and vesiculation give rise to acanthosis. Cells no longer invade the epidermis, but dermal changes (see below) become more prominent.



(a)



(b)

(c)

Fig. 17.2 (a) Subacute eczema. There is irregular acanthosis and patchy spongiosis, with the formation of incipient microvesicles. A few lymphocytes are migrating up from the dermis into the epidermis. H&E, × 100. (Courtesy of Dr M.G. Cook, Guildford, Surrey, UK.) (b) Chronic lichenified eczema. There is compact hyperkeratosis, some patchy parakeratosis and irregular acanthosis. Mild spongiosis is seen throughout much of the epidermis, and there is a lymphocytic infiltrate in the upper dermis. H&E, × 100. (Courtesy of Dr M.G. Cook, Guildford, Surrey, UK.) (c) Chronic eczema of the arm.

4 *Recovery*. In uncomplicated eczema, where no secondary changes or fresh attacks occur, the changes gradually revert to normal. Infection, or the trauma of rubbing or scratching, obviously modify this process.

Pathogenesis. There has been considerable research on the pathogenesis of some types of eczema, particularly allergic contact dermatitis, primary irritant dermatitis and atopic dermatitis (see Chapter 18). A difficulty in the research has been distinguishing non-specific common pathways from specific mechanisms. The interaction of trigger factors, keratinocytes and T lymphocytes seems particularly important in most eczema types.

Allergic contact dermatitis represents a reproducible model of eczema development [5]. The condition is an immune reaction to small molecules (haptens). On first exposure to the hapten, Langerhans' cells and dermal dendritic cells bearing the antigen migrate to the regional lymph node and encounter naïve T cells. Interaction with the antigen-bearing dendritic cells causes T-lymphocyte differentiation into a variety of subtypes secreting different cytokine patterns (Th1 and Th2) and specialized $CD4^+$ T lymphocytes with regulatory functions to modulate allergic contact dermatitis. The T cells also acquire tissue-homing antigens such as cutaneous lymphocyte-associated antigen (CLA) along with receptors permitting adhesion to skin endothelium and response to cytokines promoting specific binding to keratinocytes.

On subsequent exposure to the contact allergen, $CD8^+$ T cells display a Th1 cytokine profile that is interferon-γ (IFN-γ) predominant. The hapten in the skin may be presented to the T cells by Langerhans' cells, keratinocytes or other T cells. T-cell activation ensues, with cytokine release and up-regulation of killer molecules such as perforin, granzyme-B and Fas ligand. IFN-γ promotes expression of major histocompatibility complex (MHC) class II, the intracellular adhesion molecule 1 (ICAM-1), and increases Fas expression on the keratinocytes. In addition, IFN-γ stimulates keratinocyte production of cytokines and chemokines that are responsible for the epidermal influx of lymphocytes. Chemokine release from infiltrating cells also modifies the reaction.

Epidermal damage and the characteristic feature of spongiosis seem to result from T-cell-mediated cytotoxicity, in particular Fas-induced keratinocyte apoptosis, which may be a final common pathway in many types of eczema [6].

Eczema may be provoked in a non-allergic manner, as in irritant contact dermatitis. The three predominant processes that occur in irritant dermatitis are disturbed barrier function, epidermal cell change, and release of inflammatory mediators and cytokines.

Certain irritants may provoke a chronic reaction in which an effect on epidermal cell turnover predominates, leading to lichenification, whereas in acute irritant reactions inflammatory mediator and cytokine release is similar to that seen in acute allergic contact dermatitis [7]. There is debate as to whether the cytokine profiles of the two reactions differ [7–9]. Indeed, it has been proposed that irritant reactions to haptens may be required to facilitate contact sensitization [10].

Following activation of the immune pathway by cytokine release, the accumulation of inflammatory cells progresses, leading to the morphological changes apparent histologically and clinically. In allergic contact dermatitis, the earliest changes seen by light microscopy occur some 3–6 h after the application of the allergen to the skin. Vasodilatation occurs, with extravasation of monocytes into the upper dermis [1]. After 8 h, the mononuclear cells enter the epidermis and spongiosis is seen, and by 72 h vesicles are present. The histological changes of primary irritant dermatitis are similar, but they appear to proceed more quickly, depending on the concentration of the irritant used. Both intracellular and intercellular oedema are visible throughout the epidermis at 3–6 h, and within 24 h there may be epidermal necrosis, with cellular vacuolation and nuclear pyknosis. In severe forms, the primary epidermal damage may progress to subepidermal blister formation.

Electron microscopy has shown that the earliest epidermal changes in allergic dermatitis start in the basal and Malpighian layers, where cytoplasmic vacuoles and dilated endoplasmic reticulum are seen. The keratinocytes then lose contact by breakage of their microvilli and retraction of desmosomes [11,12].

Secondary dissemination

A very characteristic feature of eczema is its tendency to spread far from its point of origin [1]. This is especially likely when the primary site of the eczema is on the legs or the feet. The eczema may have been present for only a few days, or for many years, before dissemination occurs. The dissemination, which is often preceded by an exacerbation at the primary site, usually occurs explosively. The secondary eruption may at first consist of small oedematous papules, but these soon become obviously eczematous, and grouped papulovesicles may become confluent in small plaques. Occasionally, the lesions take the form of red macules, or weals. The distribution is usually symmetrical.

The course of the secondary eruption depends largely on the progress of the primary lesion. If the primary lesion remains acutely inflamed, the eruption increases in severity and may become generalized. If the patient is rested and the local lesion allowed to settle, the secondary eruption will subside, but will often recur very readily if the local lesion relapses. In a small proportion of patients, the generalized secondary eruption evolves into an erythroderma, which may become self-perpetuating.

Mechanisms of dissemination

There are four main mechanisms:
1 Spread by contact with an external allergen
2 Spread by ingestion or injection of an allergen
3 'Conditioned hyperirritability'
4 Bacterial hypersensitivity.

External contact

In many cases the extension is merely the result of continued contact of new areas of the skin with a specific external allergen. With increasing degrees of allergic sensitivity, minimal contact may provoke an eczematous response. The pattern of extension in such cases is asymmetrical and its progress is irregular. For example, a contact dermatitis of the lower leg induced by lanolin sensitivity may spread to the hand applying the offending ointment, whence, as a result of casual contact, it may appear on the face.

In chronic venous eczema of the lower leg without secondary dissemination, allergy to one or more topical medicaments can be demonstrated by patch testing in approximately 50% of cases. In chronic venous eczema with dissemination, however, positive patch tests to medicaments are demonstrated in over 90% of cases. It has been suggested that dissemination follows the percutaneous absorption of the medicament in such highly sensitized individuals.

Ingestion or injection

In other cases, an eruption originally induced by sensitivity to a topical allergen may relapse after ingestion or injection of the same chemical (e.g. a medication that can be used topically or systemically). The eruption tends to be widespread and more or less symmetrical, and is usually of sudden onset. Previously affected sites may be preferentially affected, and traumatized sites may also be involved. The diagnosis may be suspected in a widespread recurrent eczema that does not conform to the recognized pattern of endogenous eczema, yet cannot be related to external contact or to dissemination from a primary focus.

'Conditioned hyperirritability'

This term refers to the phenomenon whereby an area of inflamed skin on one part of the body results in a generalized hyperirritability of the skin at sites that are distant from the primary site of inflammation. There is considerable evidence that eczematous patients are more vulnerable to mild primary irritants than normal people, but the increased reactivity does not persist after the eczema subsides.

Conditioned hyperirritability seems to be associated with any focal inflammation of the skin, and it may explain some clinical phenomena such as the 'angry back' syndrome, in which a strongly positive patch-test response can increase the percentage of false-positive reactions on the back at the same time.

In the past, some clinicians have used the term 'autosensitization', for secondary dissemination of eczema when the cause of the dissemination is unknown [2]. Although it has long been suspected that autoallergy has a role in this dissemination, autoantibodies have been demonstrated convincingly in only a few cases [3]. Roper and Jones [4] reviewed the evidence, and concluded that autoantibodies are unlikely to play a significant part in the production of conditioned hyperirritability.

Circulating activated T lymphocytes are increased in number in autosensitization [5,6]. In addition, peripheral blood mononuclear cells show increased proliferation in the presence of an autologous skin homogenate compared with control subjects. This suggests that an abnormal cell-mediated immune response against autologous skin antigens could be occurring [7,8]. The role of cytokines in this phenomenon has yet to be elucidated, and the possibility of a non-immune process such as a neurological mechanism has not been completely excluded.

Bacterial hypersensitivity

Heavily infected eczema will sometimes disseminate in the absence of demonstrable allergic sensitivity to topical

medicaments. It is probable that allergy to bacteria or their products is sometimes a factor in the dissemination. The evaluation of patch tests or prick tests with bacterial filtrates is difficult, however, as some normal subjects and many with chronic localized eczemas give strongly positive reactions.

Clinical features. Most of the exogenous types of eczema are discussed elsewhere (see Table 17.1). In view of the degree of overlap between infective eczema (generally regarded as exogenous) and seborrhoeic dermatitis (generally regarded as endogenous), infective eczema is discussed below with other types of endogenous eczema. Eczematous drug eruptions are also mentioned here, as there is an endogenous component, even though the drug is exogenous in origin. The most important example of endogenous eczema is atopic dermatitis. This is dealt with fully in Chapter 18. Other examples of endogenous eczema are discussed below.

Infective dermatitis

SYN. MICROBIAL ECZEMA

Definition. Infective eczema (Fig. 17.3) is eczema that is caused by microorganisms or their products, and which clears when the organisms are eradicated. This should be distinguished from infected eczema (Fig. 17.4) in which eczema resulting from some other cause is complicated by secondary bacterial or viral invasion of the broken skin. In practice, however, the two conditions can coexist, and the distinction can be difficult. Moreover, the bacterial flora of an eczematous lesion differs quantitatively from that of normal skin [1], and the demonstration that organisms are present does not establish that they are modifying the lesion. The distinction between colonization and infection can be very difficult, but the presence of an increased level of C-reactive protein in the blood may offer a useful clue [2].

Fig. 17.3 Infective eczema in a non-atopic man. Histology of this localized rash showed eczema, and *Staphylococcus aureus* was repeatedly isolated. There was no response to topical steroid therapy, but the condition cleared rapidly with oral flucloxacillin.

Fig. 17.4 Infected dermatitis. This man had a patch of discoid eczema that became secondarily infected with *Staphylococcus aureus*.

Infective dermatitis therefore is a controversial entity, and some dermatologists never make this diagnosis. Nevertheless, cases are seen occasionally in which bacterial or viral invasion of the skin seems to occur as the primary event, and is followed by secondary eczematization which can spread for some centimetres beyond the obvious infection. The patches of eczema that occasionally develop around lesions of molluscum contagiosum provide a good example (Fig. 17.5), because the pearly papules are

Fig. 17.5 An area of eczematization developing around lesions of molluscum contagiosum. The skin had previously appeared normal, and it returned to normal when the molluscum infection cleared. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

the initiating event, and eczema can develop in the surrounding skin some days later, even when the lesions have not been scratched or traumatized. The eczema generally clears when the molluscum lesions subside. Similarly, one occasionally sees eczematous skin around infected wounds, and the eczema clears with antibiotic treatment alone.

Some experts would include seborrhoeic dermatitis as a form of infective dermatitis, on the grounds that the levels of *Malassezia* yeasts in the skin are increased, and the eczema may clear following anti-yeast therapy. However, the exact role of these yeasts in the pathogenesis of seborrhoeic dermatitis is still uncertain, and some authorities do not accept seborrhoeic dermatitis as infective.

Pityriasis rosea is not usually considered to be a form of eczema, although the histology may show spongiosis (see Chapter 25).

Pathology. The histological picture of infective eczema is in general that of subacute or chronic eczema, in which spongiosis is combined with acanthosis, hyperkeratosis and patchy parakeratosis. The dermis shows inflammatory changes, with polymorphonuclear and lymphocytic infiltration that invades the epidermis to a variable extent. In some stages, subcorneal pustulation may be conspicuous.

Pathogenesis. The mechanism by which microorganisms cause eczema is not understood. Bacterial antigens can promote a cytotoxic reaction in the skin, but such a reaction is perhaps more likely to aggravate or perpetuate than to initiate the eczematous process [3–6]. Bacterial superantigens such as staphylococcal protein A and enterotoxin B [7] may be profound immune stimulants and may aggravate atopic dermatitis (see Chapter 18). Bacterial antigens may play this part in a variety of syndromes, including discoid eczema, and not merely in infective dermatitis. Cultured staphylococci applied topically can also provoke an eczematous delayed hypersensitivity reaction [7,8].

The possibility that bacterial antigens from systemic foci of infection can cause eczema has not been fully established. It does seem to be accepted, however, that eczematous reactions can occur as an allergic reaction to a fungal infection elsewhere in the skin (see p. 17.9).

Clinical features. The distinction between infective and infected eczema can be difficult.

Infected eczema. Infected eczema shows erythema, exudation and crusting. The exudation may be profuse with crusting, or slight, with the accumulation of layers of somewhat greasy, moist scale, beneath which the surface is raw and red. The margin is characteristically sharply defined, and the horny layer often splits to form an encircling collarette. There may be small pustules in the advancing edge and, where a flexure is involved, it is often the site of a deep and persistent fissure.

Infective eczema. Infective eczema usually presents as an area of advancing erythema, sometimes with microvesicles. It is seen predominantly around discharging wounds or ulcers, or moist skin lesions of other types. Infective dermatitis is relatively common in patients with venous leg ulcers, but care must be taken to distinguish it from contact dermatitis caused by the application of topical medicaments.

Microbial eczema of the feet. This is a distinctive pattern of eczema that mainly affects the interdigital spaces on the dorsum of the medial toes. Staphylococci or streptococci can be cultured, and the lesions respond to antiseptic or antibiotic therapy [9]. This condition seems to occur particularly in patients with poor standards of hygiene, and it is favoured by hyperhidrosis and heavy footwear. In children, the condition must be distinguished from juvenile plantar dermatosis.

Tinea pedis. This may also become eczematous because of the overgrowth of Gram-negative organisms [10]. Infective dermatitis may also complicate chronic threadworm infestation, pediculosis or scabies. It is not always clear how much of the eczematous change is caused by repeated

scratching, how much is caused by secondary impetigo and how much, if any, is a direct response to the infestation.

Treatment. Factors predisposing to infection should be sought, and when possible eliminated. Although topical antibacterial agents are effective in mild forms of infective eczema resulting from bacteria, systemic antibiotics should not be withheld, especially in severe or widespread infections. In acute exudative lesions, potassium permanganate soaks are helpful for the first 2 or 3 days, in combination with a systemic antibiotic.

Infective dermatitis of children associated with human T-cell leukaemia virus 1 (HTLV-1) infection

SYN. INFECTIVE DERMATITIS OF JAMAICAN CHILDREN

Sweet, in 1966 [1], used the term infective dermatitis to describe a pattern of dermatitis observed in Jamaican children. Subsequently, Walshe [2] documented the clinical features in 25 Jamaican children. They included severe exudative eczema with crusting involving the scalp, eyelid margins, perinasal skin, retro-auricular areas, axillae and groins. There was a generalized fine papular rash, a chronic nasal discharge, and positive cultures for *Staphylococcus aureus* or β-haemolytic streptococci from nose and/or skin. The rash responded to oral antibiotic therapy, but relapsed on its cessation.

LaGrenade *et al*. [3], in 1990, found HTLV-1 infection in all of 14 children with this pattern of dermatitis. A later case report identified one of the children originally described by Sweet and Walshe who, 17 years later, had developed adult T-cell leukaemia [4]. Some of these children may also go on to develop tropical spastic paraparesis [5]. This pattern of dermatitis may be an important early marker of HTLV-1 infection [6].

Dermatophytide

Eczematous reactions can occur as an allergic response to a dermatophyte infection elsewhere on the skin (a dermatophytide) [1–3]. The following criteria must be fulfilled to confirm this diagnosis:

1 A proven focus of dermatophyte infection
2 A positive skin test to a group-specific trichophytin antigen
3 Absence of fungi in the dermatophytide lesions
4 Clearing of the dermatophytide after the fungus has been eradicated.

A dermatophytide is thus a secondary distant aseptic skin lesion, analogous to the cutaneous tuberculide of tuberculosis [1].

One study indicated that this condition is rare, as only 10 cases were confirmed in 1500 dermatophyte infections [2]. Other studies have suggested that dermatophytide may be more common. In one retrospective review of dermatophytide, 37 cases were seen in a dermatology department in a 2-year period. However, the patients were not skin tested to dermatophyte antigen [4].

Various clinical patterns of dermatophytide can occur. Eczematous vesicles on the hands or feet are the most common pattern. On the hands, the lesions occur symmetrically on the sides of the fingers, usually as a reaction to tinea pedis. An eczematous dermatophytide can also mimic pityriasis rosea [1].

Other dermatophytides have been described, often as single-case reports, including erysipelas-like dermatitis, erythema nodosum, erythema annulare centrifugum, urticaria and erythroderma.

A dermatophytide is probably more likely to develop with inflammatory dermatophytes, such as *Trichophyton mentagrophytes* of the zoophilic type [2].

A similar allergic reaction to a yeast infection may be termed a candidide (levuride). In this case the eczematous reaction may be localized to the hands or groin [1].

A dermatophytide can be mimicked by bacterial infection. In one study, *Staphylococcus aureus* and β-haemolytic streptococci were commonly isolated from lesions that were clinically thought to be examples of a dermatophytide [2].

Post-traumatic eczema

There have been several case reports of dermatitis occurring in the saphenous vein graft donor site for coronary artery bypass surgery [1,2]. The rash is composed of reddish brown, slightly crusted and scaly patches, with occasional papulovesicles. Histology shows subacute spongiotic dermatitis. The condition responds to topical corticosteroids, but tends to relapse when the treatment is stopped.

Initially, postoperative venous stasis was suggested as the cause. Subsequently, two cases have been reported associated with sensory neuropathy in the distribution of the saphenous nerve [3]. The dermatitis was located in the same area. Otherwise, the cases were identical to those previously reported. The dermatitis and the sensory neuropathy resolved in tandem over a 2-year period.

Seborrhoeic dermatitis

SYN. PITYROSPORAL DERMATITIS; DERMATITIS OF THE SEBACEOUS AREAS

Definition. This is a chronic dermatitis that is difficult to define exactly, but it has a distinctive morphology (red, sharply marginated lesions covered with greasy-looking scales) and a distinctive distribution in areas with a rich supply of sebaceous glands, namely the scalp, face and upper trunk. In some cases the flexures are also involved, but this is not an essential diagnostic criterion.

Dandruff (visible desquamation from the scalp surface) appears to be the precursor of seborrhoeic dermatitis, and this may gradually progress through redness, irritation and increasing scaling of the scalp to true seborrhoeic dermatitis.

Incidence. The prevalence of seborrhoeic dermatitis is approximately 1–3% in the general population of the USA, and 3–5% in young adults, although mild degrees of dandruff are much more common [1]. The figure is much higher, however, in patients with early human immunodeficiency virus (HIV) infection. Of 155 patients in the WR1A–2A stage of infection (with normal helper T-cell count and delayed hypersensitivity), 36% had seborrhoeic dermatitis [2].

Aetiology [3,4]. Yeast of the genus *Malassezia* is increased in the scaly epidermis of dandruff and seborrhoeic dermatitis [5,6]. Although it has been suggested that this is secondary to the increase in size of the habitat provided by the scaling [7], it is generally accepted that the presence of yeast of the genus *Malassezia* causes the condition [3,4,8].

The way in which *Malassezia* spp. induce inflammation and desquamation is not clear. Although patients with dandruff have high antibody titres to *Malassezia* compared with control subjects, and patients with seborrhoeic dermatitis have altered cell-mediated responses, the immunological reaction is variable [8–10]. Some of the histological features of seborrhoeic dermatitis can be reproduced by inoculating animal skin with killed yeasts [11], and the wide variety of cytokines expressed in the inflammation are similar to those in other yeast infections [12]. However, the principal evidence of a role for *Malassezia* spp. is the response of the condition to treatments that reduce the yeast numbers [4].

The sebaceous glands are active at birth, but when stimulation by maternal androgen ceases they become inactive for 9–12 years. This observation has been regarded as significant in relation to the age incidence of seborrhoeic dermatitis. The condition known as seborrhoeic dermatitis of infancy (see Chapter 14) is normally confined to the first months of life, but it is not established that it is the same condition as seborrhoeic dermatitis of adolescence and adult life. The latter is rare before puberty, and reaches its peak between 18 and 40 years of age; occasional cases are seen in old age. At all ages, seborrhoeic dermatitis is more common in males than in females.

Although maturation of the sebaceous glands may be a permissive factor for the development of seborrhoeic dermatitis, the role of seborrhoea in the pathogenesis of the condition is debatable. Many young adults with the condition appear to have a greasy skin, but when the sebum excretion rate from forehead skin was measured in patients with classical seborrhoeic dermatitis, it was normal in males and significantly reduced in females [13]. On the basis of this finding, it was suggested that 'dermatitis of the sebaceous areas' might be a more accurate term than 'seborrhoeic dermatitis'. Some clinicians believe that there is an increased prevalence of seborrhoeic dermatitis among patients with acne vulgaris and rosacea, but there are no data to support this.

Seborrhoeic dermatitis may also be a complication of parkinsonism, which is associated with seborrhoea. Treatment of parkinsonism with levodopa reduced sebum excretion when seborrhoea was initially present, but had no effect on the normal sebum excretion rate [14]. Treatment of parkinsonism with levodopa can also sometimes improve seborrhoeic dermatitis in these patients [15]. Seborrhoeic dermatitis has also been reported in a patient in whom unilateral seborrhoea and seborrhoeic dermatitis developed on the face after facial nerve paralysis [16], and also in patients with paralysis of the trunk [17]. The increase in the pool of sebum in immobile skin may be important in these cases, and in parkinsonism [18].

Qualitative abnormalities in the composition of sebum have not been demonstrated. Mild abnormalities in the surface lipids [19,20] could well result from the ineffective keratinization that is often demonstrable histologically.

The heightened susceptibility of the seborrhoeic skin to bacterial infection and to physical and chemical injury results in a high incidence of contact dermatitis and skin infection. Some authors confuse exogenous dermatitis in a seborrhoeic subject with the morphologically distinctive seborrhoeic dermatitis.

Seborrhoeic dermatitis is now established as a possible marker of early HIV infection [2,21], and exacerbations may be seen with progression of the HIV infection, presumably caused by the enhanced growth of yeasts secondary to immunosuppression [22]. It is also suggested that local cutaneous immunosuppression may increase the prevalence of seborrhoeic dermatitis [23].

It has also been claimed that seborrhoeic dermatitis is more common in a variety of general medical disorders, including myocardial ischaemia [24], malabsorption, epilepsy, obesity and alcoholism, especially alcoholic pancreatitis [25]. However, the evidence is far from convincing, and poor hygiene associated with hospitalization and severe illness may play a part in some of these cases.

Seborrhoeic dermatitis involving the usual sites on the face was observed to occur in 28 of 402 patients undergoing psoralen and UVA (PUVA) therapy for psoriasis, but not in 55 patients being treated with PUVA for other conditions [26]. Spongiosis was present in the three patients biopsied.

Pathology. The histology is not diagnostic, but generally shows features of both psoriasis and chronic dermatitis. Much of the stratum corneum is often lost in the process of fixation, and most of its cells are parakeratotic. There is slight to moderate acanthosis, with slight spongiosis. Spongiosis is the major feature which distinguishes it from psoriasis. The dermis shows a mild chronic inflammatory infiltrate.

It seems likely that the initial event is the 'squirting papilla' described by Pinkus and Mehregan [27]. Capillary dilatation in the papillae is followed by migration of inflammatory cells through the vessel walls and into the epidermis, where they incite spongiosis. This is similar to the burst of inflammation that sometimes occurs in psoriasis.

As the inflammation subsides there is an increase in production of keratinocytes. Epidermal proliferation, as measured by the mitotic and labelling indices, is increased, and desquamation is increased [28].

Ultrastructural studies show a closer resemblance to discoid eczema than to allergic or irritant contact dermatitis.

The histology of seborrhoeic dermatitis in patients with acquired immune deficiency syndrome (AIDS) tends to show more follicular involvement, and more plasma cells. Neutrophils and nuclear dust may be present focally among the epidermal parakeratotic cells [21]. *Malassezia* yeasts are prominent in the skin of AIDS patients with seborrhoeic dermatitis compared with seborrhoeic dermatitis patients without AIDS [29].

Table 17.3 Clinical patterns of seborrhoeic dermatitis.

Infantile (Chapter 14)
Scalp (cradle cap)
Trunk (including flexures and napkin area)
Leiner's disease
Non-familial
Familial C5 dysfunction
Adult
Scalp
Dandruff
Inflammatory—may extend onto non-hairy areas (e.g. postauricular)
Face (may include blepharitis and conjunctivitis)
Trunk
Petaloid
Pityriasiform
Flexural
Eczematous plaques
Follicular
Generalized (may be erythroderma)

Clinical features. Most forms of seborrhoeic dermatitis share certain distinctive characteristics. They commonly originate in hairy skin, and involve the scalp, face, presternal and interscapular regions, and the flexures. The lesions tend to be dull or yellowish red in colour and covered with greasy scales.

Morphological variants. There are several morphological variants of seborrhoeic dermatitis, which in the adult form occur in various combinations and degrees of severity (Table 17.3).

Scalp. Dandruff is usually the earliest manifestation of seborrhoeic dermatitis. At a later stage, perifollicular redness and scaling gradually extend to form sharply

Fig. 17.6 This type of seborrhoeic dermatitis around the ears readily develops secondary bacterial infection.

marginated patches that may remain discrete, or coalesce to involve the greater part of the scalp and extend beyond the frontal hairline as the 'corona seborrhoeica'.

In chronic cases there may be some degree of hair loss, which is reversible when the inflammation is suppressed. It has not been established whether seborrhoeic dermatitis of the scalp accelerates the onset of male-pattern (androgenic) alopecia.

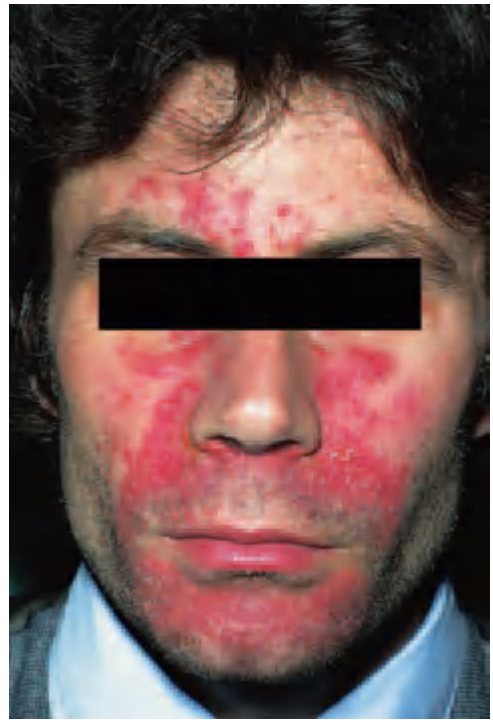
Behind the ears there may be redness and greasy scaling, and a crusted fissure often develops in the fold (Fig. 17.6). Adherent masses of sticky scale and crusts may extend into the adjacent scalp. Both sides of the pinna, the periauricular region and the sides of the neck may be involved. Otitis externa, irritable and intractable, may accompany seborrhoeic dermatitis in other sites, or may occur alone.

Face. On the face, seborrhoeic dermatitis characteristically involves the medial part of the eyebrows, the glabella and the nasolabial folds (Fig. 17.7). Areas of erythema and scaling occur, usually in association with involvement of the scalp.

Blepharitis is common. The margins of the lids are red and covered by small white scales. Yellow crusts may form, and separate to leave small ulcers, healing to form scars, with destruction of lash follicles.

Episodic variation in intensity is common, often being precipitated by tiredness or stress. Exposure to sunlight

(a)



(b)

Fig. 17.7 (a) Seborrhoeic dermatitis of the forehead. (b) Severe seborrhoeic dermatitis of the face with prominent involvement of the nasolabial groove.

produces a temporary exacerbation, followed by improvement as the tan develops.

A superficial form of seborrhoeic dermatitis of the chin is common in men in the early stages of growing a beard, but is cured when the beard is shaved off.

Young women sometimes have paranasal erythema associated with a tendency to flushing. It is not always clear whether this is rosacea or mild seborrhoeic dermatitis, but overtreatment with strong topical corticosteroids may convert this into perioral dermatitis.

Trunk. On the trunk, several forms of seborrhoeic dermatitis occur. Most common is the petaloid form (so-called

Fig. 17.8 Seborrhoeic dermatitis of the presternal region. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

because the lesions are petal-shaped). This is often seen in men on the front of the chest and in the interscapular region (Fig. 17.8). The initial lesion is a small red-brown follicular papule, covered by a greasy scale. Some patients have a widespread eruption of lesions that do not progress beyond this stage. More often, extension and confluence of the follicular papules gives rise to a figured eruption, consisting of multiple circinate patches, with a fine branny scaling in their centres, and with dark-red papules with larger greasy scales at their margin.

A rarer form, involving the trunk and limbs, is the so-called pityriasiform type. This is a generalized erythematosquamous eruption, somewhat similar to, but more extensive than, pityriasis rosea. In particular it involves the neck up to the hair margin. It is not particularly pruritic, and it resolves spontaneously, although somewhat more slowly than does pityriasis rosea. In some patients the lesions may become psoriasiform.

Flexures. In the flexures, notably in the axillae (Fig. 17.9), the groins, the anogenital and submammary regions, and the umbilicus, seborrhoeic dermatitis presents as an intertrigo, with diffuse, sharply marginated erythema and greasy scaling. Crusted fissures develop in the folds, and with sweating, secondary infection and inappropriate treatment, a weeping dermatitis may extend far beyond them. The genitalia of both sexes may be involved, and the lesions show the usual range from minimal erythema and scaling to severe crusted dermatitis. In this site, and occasionally elsewhere, the chronic, thickened, dull-red scaly patches of the psoriasiform variety of seborrhoeic dermatitis may develop.

The severity and course of seborrhoeic eruptions are very variable. All show a tendency to chronicity and recurrence.

Severe and extensive forms may be complicated by eczematous reactions remote from the sites initially involved, especially by pompholyx and discoid eczema.

Fig. 17.9 Seborrhoeic dermatitis of the axilla; flexural areas often become secondarily infected. (Courtesy of Dr A. Marsden, St George's Hospital, London, UK.)

Such eruptions are discussed separately below. The pattern and course of the disease may also be modified by contact dermatitis and provoked by medicaments, by pyoderma or by an infective bacterial dermatitis. Occasionally, seborrhoeic dermatitis may become generalized, resulting in erythroderma.

Modifications in the clinical features and course may be seen when seborrhoeic dermatitis occurs in association with atopy, or with psoriasis, and in the latter case the diagnosis can be extremely difficult, because both the clinical and histological features can be equivocal. Some dermatologists use the term *sebopsoriasis* for this overlap condition.

Diagnosis (Fig. 17.10). In a classical case the diagnosis is easy, but in some cases the diagnosis can be difficult, partly because of the lack of well-defined diagnostic criteria. The diagnosis is often made too freely. Nowadays it is very important to consider the possibility of HIV infection in any patient with severe seborrhoeic dermatitis, particularly in a patient involved in high-risk activities.

The differential diagnosis covers an enormous range of conditions. Psoriasis, when confined to the scalp, may be confused with seborrhoeic dermatitis. The lesions are usually palpably thickened in psoriasis, and brighter pink in colour, with a silvery scale. The rest of the body must be examined, especially the nails, and there may be a family history of psoriasis.

Lichen simplex of the nape of the neck occurs in females, and can mimic seborrhoeic dermatitis. The thickened plaques in this condition are, however, intensely irritable.

Fig. 17.10 Slight redness and scaling at the medial ends of the eyebrows may provide a diagnostic pointer to seborrhoeic dermatitis.

Infective dermatitis complicating pediculosis can also be confused with seborrhoeic dermatitis.

Contact allergy [30] and *Trichophyton tonsurans* infection [31] may mimic seborrhoeic dermatitis of the scalp.

Pityriasis rosea must be distinguished from the pityriasiform type of seborrhoeic dermatitis, in which the lesions are more widely distributed, and in which there is no herald patch. In the flexures, microscopic examination of scrapings from the advancing margin and examination under Wood's light will exclude ringworm infections, candidiasis and erythrasma. Acute flexural dermatitis may also suggest the possibility of allergic sensitization to a chemical in clothing, and patch tests may be needed. Moist crusting of the face or of the midline of the chest or back occurs in pemphigus erythematosus and in pemphigus foliaceus. Biopsy is required if these conditions are suspected. Axillary and sometimes interscapular crusting, tending to relapse in the warmer weather, occurs in benign familial pemphigus.

The brown scaly lesions of pityriasis versicolor are flatter, more extensive and less symmetrical than the lesions of petaloid seborrhoeic dermatitis of the trunk. Microscopy of scrapings quickly establishes the diagnosis.

Follicular seborrhoeic dermatitis of the trunk must be differentiated from Darier's disease, in which the papules are brown, greasy and dome-shaped, and tend to be clustered. Biopsy is diagnostic. Lesions resembling seborrhoeic dermatitis can occur in zinc deficiency and acrodermatitis enteropathica [32].

Drug eruptions, particularly those resulting from methyldopa, chlorpromazine or cimetidine may mimic seborrhoeic dermatitis.

Despite the non-specific nature of the histological appearances of seborrhoeic dermatitis, biopsy will often reliably differentiate it from many of the conditions with which it may be confused.

Treatment. It should be emphasized to the patient at the outset that, although seborrhoeic dermatitis can generally be suppressed, there is no permanent cure. The condition may require regular treatment for many years.

Dandruff is usually treated by the frequent and regular use of medicated shampoos which act against *Malassezia* yeasts, including selenium sulphide, ketoconazole [33] and various tar shampoos. One per cent terbinafine solution has also been shown to be effective [34]. Alcohol-based preparations and hair tonics should be avoided. For severe dandruff with persistent scaling or crusting, 5% salicyclic acid ointment may be useful. If secondary bacterial infection is present or suspected, oral erythromycin or flucloxacillin may be used.

Acute forms of seborrhoeic dermatitis on the face and trunk usually respond to mild steroid ointments. Hydrocortisone ointment (0.5%) is often effective, particularly if combined with sulphur (0.5%). Ketoconazole cream (2%) is possibly a more logical therapy, which has been shown to be equally effective [35–39]. In many situations, the acute inflammatory changes can be suppressed with mild topical corticosteroid creams or steroid and imidazole combination creams, which can then be changed to ketoconazole cream for long-term control. Topical metronidazole, ciclopiroxolamine and tacalcitol have also been reported to be helpful [40–42]. Frequent washing with soap and water is helpful, because removal of lipid removes the substrate for the yeasts.

For unresponsive cases, a course of UVB therapy may be helpful [43], or even a short course of oral ketoconazole (200 mg/day for 14 days). Oral itraconazole (100 mg/day for up to 21 days) is also effective, as is oral terbinafine [44]. Other topical preparations that have been shown to be effective include benzoyl peroxide [45] and 5% lithium succinate ointment [46].

Generalized seborrhoeic dermatitis usually responds to the medications listed above, but in recalcitrant cases systemic steroids may be required. Prednisolone 30 mg/day usually produces a rapid response. Isotretinoin may also be helpful [18].

Flexural seborrhoeic dermatitis is treated in the same way as intertrigo (see Chapter 68).

Infantile seborrhoeic dermatitis

There is still some debate as to whether this condition occurs as a separate entity, or is merely a variant of atopic dermatitis (see Chapter 14 for discussion).

Malassezia folliculitis

SYN. SEBORRHOEIC FOLLICULITIS; PITYROSPORAL FOLLICULITIS

Definition. Folliculitis caused by *Malassezia* yeasts (e.g. *Malassezia furfur*). Although not an eczema, *Malassezia* folliculitis is included here because of its association with seborrhoeic dermatitis.

Aetiology. *Malassezia* yeasts can hydrolyse triglycerides into free fatty acids, and it has been postulated that an overgrowth of the yeast in a follicle produces folliculitis by a combination of fatty acid production and blockage of the follicular ostium by scale [1,2]. The ability of the yeasts to activate the alternative complement pathway may also be implicated in the inflammatory process.

Pathology. There is folliculitis, with a perifollicular mononuclear infiltrate, predominantly around the infundibular region of the follicle. Sparse *Malassezia* yeasts can be identified in the affected follicles, but mycelial forms are usually absent. *Malassezia* yeasts can also be identified in skin scrapings.

Clinical features [3,4]. The condition most commonly affects adult males, and is associated with a tendency to seborrhoeic dermatitis or severe dandruff. It has been reported in 12 of 42 patients with Down's syndrome [5]. The rash is dimorphic, with erythematous follicular papules and follicular pustules. Lesions occur mainly on

Fig. 17.11 *Malassezia* folliculitis. (Courtesy of Dr F.A. Ive, Dryburn Hospital, Durham, UK.)

the upper trunk and shoulders, and are usually pruritic (Fig. 17.11).

Differential diagnosis. Acne vulgaris may be distinguished by the presence of comedones, cysts and scars, which do not occur in *Malassezia* folliculitis. Similar lesions can occur in immunocompromised individuals such as those with AIDS and organ transplant recipients [6]. The condition should be considered in the differential diagnosis of steroid-induced folliculitis [7]. Transmission of the condition between individuals has been suggested [8].

Treatment. Patients should be advised to avoid occlusive clothing, and broad-spectrum antibiotic therapy should be stopped whenever possible. The condition responds well to 2% ketoconazole cream [9]. However, the eruption often relapses, and intermittent prophylactic treatment once or twice weekly may be indicated [10]. Systemic treatment with oral itraconazole may occasionally be helpful. In Down's syndrome patients the condition improved with oral itraconazole but relapsed when the medication was stopped [5].

Asteatotic eczema

SYN. WINTER ECZEMA; ECZÉMA CRAQUELÉ

Definition. Eczema associated with a decrease in skin surface lipid. Senile eczema and asteatotic eczema are often regarded as synonymous, but it is not certain that all eczema without demonstrable cause, occurring in elderly people, is in fact of the asteatotic type.

Aetiology. Although the condition is thought to be caused by a decrease in skin surface lipid, the exact pathogenesis of the skin changes is obscure. The amino acid content of the skin is lower in the more severe cases [1]. A decrease in the keratohyaline-derived natural moisturizers may also be important [2].

Hyposteatosis occurs in many conditions of maldevelopment, malnutrition and atrophy of the skin, but does not necessarily lead to eczema. The part played by loss of fluid from the skin has been underrated in the past. The relationship between the transpiration rate and the lipid layer has been the subject of many studies [3]. Using excised skin it was shown that removal of lipid increased water loss 75-fold, and that this returned to normal when lipid was restored. The implications for treatment are obvious. At present the relevant factors in the production of asteatotic eczema can be considered to be a naturally 'dry' skin and a lifelong tendency to chapping; a further reduction in lipid with age, illness, malnutrition or hormonal decline; increased transpiration relative to the environmental water content; loss of integrity of the water reservoir of the horny layer; chapping and degreasing (and perhaps cell damage) by industrial or domestic cleansers or solvents; low environmental humidity and dry, cold winds increasing convection loss; or repeated minor trauma leading to inflammation and further disorganization of the surface aqueous–lipid balance. Percutaneous absorption through the degreased and damaged epidermis is increased, and contact irritants and sensitizers may further damage and irritate the skin.

A patient will often ascribe the onset to an event or change in life that is quite trivial, for example the installation of central heating or a particularly cold dry winter [4]. In industry, years of contact with degreasing agents may be tolerated until, usually in the 50–60 age group, some small additional hazard precipitates a disabling dermatitis.

Fig. 17.12 Eczéma craquelé (winter eczema). (Courtesy of Dr W.A.D. Griffiths, St Thomas' Hospital, London, UK.)

Diuretics sometimes appear to be an important contributory factor in elderly people [5]. Asteatotic eczema may be a presenting sign of myxoedema [6]. It can also be caused by zinc deficiency [7]. Cimetidine has also been reported to cause asteatotic dermatitis [8], as have topical corticosteroids [9].

Histopathology. The features are those of a mild subacute eczema, with a varying amount of dermal infiltrate. When vesicular or nummular eczema supervenes, the changes are more marked, and are as seen in the latter disease.

Clinical features (Fig. 17.12). The condition occurs particularly on the legs, arms and hands. It tends to be more marked in the winter and in elderly people. The asteatotic skin is dry and slightly scaly. The surface of the backs of the hands is marked in a criss-cross fashion, as though the continuity and flexibility of the keratin had been disturbed. The finger pulps are dry and cracked, producing distorted prints and retaining a prolonged depression after pressure ('parchment pulps'). On the legs the pattern of superficial markings is more marked and deeper ('crazy-paving' pattern or eczéma craquelé). In some patients the fissures may become haemorrhagic. The borders of this irregular reticulation become erythematous and slightly raised, and frank eczematous changes finally develop. Similarly, on the hands, localized areas become 'chapped' or itchy, and eventually form eczematous patches.

The condition can remain in this state for months, relapsing each winter and clearing in the summer, but eventually becoming permanent. Scratching, rubbing or contact irritants and sensitizers cause further eczematous changes or spread; or a more diffuse vesiculosquamous eruption occurs.

Nummular eczema can also occur on this background, although the relationship between the two conditions is uncertain.

Irritation in this form of eczema is often intense, and worse with changes of temperature, particularly on undressing at night.

Treatment. The patient's immediate environment may need to be adjusted. Central heating should be humidified where possible, and abrupt temperature changes should be avoided. Wool is usually poorly tolerated and possibly damaging by irritation. Baths are best restricted and should not be hot. Bath oils or oatmeal packs are helpful. Emollients should be used after bathing or daily. Creams based on lanolin or mixtures of lanolin and paraffins are generally helpful.

Weak topical corticosteroids are often prescribed, and those contained in a urea base (see Chapter 75) are very appropriate in this situation as urea encourages hydration. Among the older remedies, ichthammol is of value.

This is one of the forms of eczema in which soaps and detergent cleansers can be seen by the physician and felt by the patient to be deleterious. Emulsifying Ointment BP (hydrophilic ointment) or oatmeal or bran can be substituted.

Generalized eczéma craquelé

Extensive or generalized forms involving the trunk as well as the legs are rare but should raise the suspicion of malignancy. Cases have been reported in association with malignant lymphoma [1], angioimmunoblastic lymphadenopathy [2], anaplastic gastric adenocarcinoma [3] and spheroidal cell carcinoma of the breast [4].

Discoid eczema

SYN. NUMMULAR ECZEMA

Definition. Discoid eczema is characterized by a single, non-specific morphological feature, namely circular or oval plaques of eczema with a clearly demarcated edge. It is to be distinguished from an irregular patchy form of eczema in which the lesions do not have recognizable clear margins. The condition is poorly defined, however, because many eczema patients have one or two circular or oval lesions and few patients with discoid eczema have only circular lesions [1,2].

Aetiology. In most cases the cause is unknown. Some authors have found a high incidence of atopy in their patients [3], but others have not [4], and the levels of IgE are within the normal range [5].

Many authors have stressed the role of infection [6,7]. As in other forms of eczema, heavy colonization of the lesions by staphylococci may increase their severity, even in the absence of clinical evidence of infection [6,7]. However, allergic sensitivity to staphylococci or micrococci may be responsible at least for secondary dissemination [8].

Local physical or chemical trauma plays a part in some cases, and discoid eczema sometimes develops at the site of an old injury or scar.

Specific allergy is uncommon, but may be overlooked in severe or persistent cases if patch tests are not performed [9].

Dry skin caused by low environmental humidity is sometimes associated with discoid eczema [2,10], particularly in the elderly [11]. An association between excessive alcohol intake and discoid eczema has been reported [12].

Discoid eczema has occurred rarely as a result of sensitivity to aloe [13], depilating creams [14], mercury [15] and in patients taking methyldopa [16] or gold [17].

Emotional stress may have a role in some cases, but it is unlikely to be the primary cause.

Discoid eczema is relatively rare in children [18].

Histopathology [19,20]. There is a subacute dermatitis indistinguishable from other forms of eczema, with spongiotic vesicles and a predominantly lymphohistiocytic infiltrate. Eosinophils may also be present in the upper dermis.

Electron microscopic studies have shown that the intense intercellular oedema leads to a reduction in the number of desmosomes between the cells of the basal layer, whereas those in the stratum spinosum are mostly preserved.

Clinical features. The diagnostic lesion of discoid eczema is a coin-shaped plaque of closely set, thin-walled vesicles on an erythematous base. This arises, quite rapidly, from the confluence of tiny papules and papulovesicles. These

Fig. 17.13 Discoid eczema of the lower leg. (Courtesy of Dr W.A.D. Griffiths, Epsom Hospital, Surrey, UK.)

may occur, in the phase of very acute dissemination, as individual lesions on the trunk or limbs at the same time as localized plaques are being formed. In the acute phase the lesions are dull red, oozy, crusted and highly irritable (Fig. 17.13). They progress towards a less vesicular and more scaly stage, often with central clearing and peripheral extension, causing ring-shaped or annular lesions. As they fade, they leave dry scaly patches.

After any period between 10 days and several months, secondary lesions occur, often in a mirror-image configuration on the opposite side of the body. It is very characteristic of this disease that patches which have apparently become dormant may become active again, particularly if treatment is discontinued prematurely.

It may be convenient to recognize the following patterns:

1 Discoid eczema of the hands and forearms
2 Discoid eczema of the limbs and trunk
3 'Dry' discoid eczema.

Discoid eczema of the hands affects the dorsa of the hands or the backs or sides of individual fingers. It often develops as a single plaque, which may occur at the site of a burn or a local chemical or irritant reaction. Secondary lesions may occur on the hands, fingers or forearms, but generalized spread is uncommon. It is a not uncommon form of irritant occupational dermatitis, but may also occur in housewives or secretaries in whom the provoking factors are less clear. An atopic history appears to be more frequent in young women with discoid hand eczema than in other forms of the disease.

The more usual form of discoid eczema affects the limbs and trunk. It appears to be particularly prevalent among managerial or professional classes. It is also seen in elderly people, often with dry skin exacerbated by low humidity, central heating, car heating, etc.

The initial patch usually occurs on the lower leg, and secondary lesions spread to the other leg, the arms and often the trunk. In the course of their evolution, the lesions

Table 17.4 Diagnosis of some discoid lesions.

Disease	Distribution	Features	Histology	Course and evolution
Prelymphomatous eruption	Flank, trunk, proximal limbs	Angular, bizarre, infiltrated, itchy	Dermal primary	Persistent, may change to lymphoma
Chronic superficial dermatitis	Limbs more than trunk	Oval or round, no infiltration	Epidermal eczematous	Very chronic, benign, no fluctuations
Pityriasis alba	Face, proximal limbs	Depigmentation	Very mild eczema	Spontaneous remission after 1 or more years
Discoid (nummular) eczema	Limbs more than trunk	Oval or round, very itchy	Eczema, often intense changes	Variable, fluctuant or intermittent
Tinea corporis	Limbs or trunk	Oval or round, itchy Scraping produces scale for mycology	PAS stain shows fungus	Progresses and spreads steadily until treated

may become increasingly oedematous and crusted, possibly because of secondary infection. Extension then becomes rapid and, in severe cases, much of the trunk and limbs will be involved. Scattered papulovesicles may then be interspersed with large and small plaques.

All forms of discoid eczema are chronic, with partial remission during which plaques tend to clear in their centres. Most forms tend to relapse at long or short intervals, and most are worse during the colder months of the year. A review of 325 cases showed that most either cleared within a year or persisted for many years [21].

'Dry' discoid eczema is an uncommon variant, consisting of multiple dry, scaly, round or oval discs on the arms or legs, but also with scattered microvesicles on an erythematous base on the palms and soles [22]. Itching is minimal, in contrast with other forms of discoid eczema, and the condition persists for several years, with fluctuation or remission. It is notably resistant to treatment.

Diagnosis (Table 17.4). Discoid eczema may simulate ringworm, but even when the lesion of discoid eczema clears in the centre, the edge is broader, more vesicular and more vivid in colour than lesions caused by *Trichophyton* infection, where scaling of the edge is a more conspicuous feature. If there is any doubt, scrapings should be examined for the presence of mycelia.

Exogenous contact dermatitis should be suspected if the condition is unusually severe and persistent or if patches are few, asymmetrical or of unusual configuration. Irritants, and occasionally sensitizers, may provoke this discoid type of response; when the patient's occupation suggests this, patch tests should be carried out [9].

In psoriasis, the lesions are dry, the scaling is more prominent and the irritation milder.

The features of exudative discoid lichenoid dermatitis and chronic superficial scaly dermatitis are discussed below.

Treatment. Emollients and topical corticosteroids, perhaps with added clioquinol or antibiotic, are useful. In the early stages, a potent steroid may be needed, dilute forms often being relatively ineffective. Coal-tar pastes or ointments may be added in the less acute stages, and sometimes a combination of tar and dilute corticosteroids will be most effective for long-term management. Ambient conditions of low humidity should be corrected, and bath oils are soothing.

A course of a broad-spectrum systemic antibiotic such as oxytetracycline or erythromycin is often helpful in severe exudative cases. In severe cases, bed rest and removal from a stressful environment are advised, and oral steroids may occasionally be required.

General considerations such as the avoidance of irritants apply, as with other forms of eczema.

Hand eczema

Hand eczema is such a common and distressing condition, and poses such difficult problems for the dermatologist, that it deserves separate consideration [1]. Up to 30% of occupational medical practice relates to hand eczema, with important issues regarding medical litigation, worker's compensation and disability. One-quarter of the patients referred to a specialized contact dermatitis clinic suffered from hand dermatitis [2].

Definition and nomenclature. The term hand eczema implies that the dermatitis is largely confined to the hands. If the eczema is widespread and the hands appear to be involved only coincidentally, it is preferable to speak of hand involvement.

Classification. No single classification of hand eczema is completely satisfactory. Although several different morphological forms exist as fairly consistent entities, some of these entities can have several different causes, and conversely a single cause can sometimes produce several different morphological patterns. This has led to considerable confusion in previous classifications.

An *aetiological classification* is shown in Table 17.5, and this may be useful to the clinician as a checklist in an individual case, although the list does not exhaust the aetiological possibilities. Other rare causes have been reported (e.g. gravitational eczema secondary to arteriovenous shunts in the forearm). There are probably other causative agents which have yet to be identified.

Most cases of hand eczema have a multifactorial aetiology. This not only makes treatment difficult, but it can also cause considerable problems in medicolegal cases (e.g. occupational dermatitis in which negligence is alleged against an employer).

Atopy, a naturally dry skin, a tendency to seborrhoeic dermatitis, a superadded contact allergic or irritant dermatitis, or even the effect of rubbing or scratching may all obscure or potentiate the original cause. Even the daily mild trauma of normal life and climatic influences may play some part [3], and litigation itself may cause an exacerbation of the condition. The role of stress in aggravating hand eczema is difficult to evaluate, and the disease itself is of course very stressful [4]. Many patients give a convincing account of exacerbations at times of acute anxiety, frustration or grief.

Table 17.5 Hand eczema: aetiological possibilities to be considered.

Exogenous
Contact irritants
Chemical (e.g. soap, detergents, solvents)
Physical (e.g. friction, minor trauma, cold dry air)
Contact allergens
Delayed hypersensitivity (type IV) (e.g. chromium, rubber)
Immediate hypersensitivity (type I) (e.g. seafood)
Ingested allergens (e.g. drugs, possibly nickel, chromium)
Infection (e.g. following bacterial infection of hand wounds)
Secondary dissemination (e.g. dermatophytide reaction to tinea pedis)
Endogenous
Idiopathic (e.g. discoid, hyperkeratotic palmar dermatitis)
Immunological or metabolic defect (e.g. atopic)
Psychosomatic: stress aggravates, but may not be causative
Dyshidrosis: increased sweating aggravates, but may not be causative

The role of hormonal factors is also difficult to assess. Occasionally, there is a history of premenstrual exacerbation or deterioration during pregnancy.

Exogenous causes. Contact irritants are the most common exogenous cause of hand eczema [5], but contact allergens such as chromium, epoxy glues and rubber are also important (see Chapter 20). All patterns of hand eczema are possible in contact allergy. Rubber dermatitis usually affects the dorsa of the hands (Fig. 17.14), but so can contact irritant and atopic dermatitis [6]. Certain occupations are particularly likely to provoke hand eczema. The problem of occupational eczema in hairdressers, fish industry workers, farmers, construction workers, dental and medical personnel, metal workers and caterers has provoked many studies to determine its prevalence and to develop programmes for prevention of hand dermatitis [7–9]. This topic is discussed in more detail in Chapters 19 and 20.

Mention must also be made of the possibility of type 1 allergic reactions to certain proteins. In mild cases they provoke a vesicular eczema of the fingers in certain individuals, particularly those who prepare seafood. In one Scandinavian study, no less than one-third of restaurant food handlers with hand dermatitis had such a contact urticaria [10]. Greater concern has arisen in recent years because of the increasing frequency of reactions to natural rubber latex protein found in latex gloves. The reactions range from contact urticaria to rhinitis, asthma and anaphylaxis [11]. Particular attention has been paid to hospital employees, and 7% of staff reported symptoms suggestive of latex sensitivity in a study conducted in the north-west of England [12].

Fig. 17.14 Bullous eczema caused by contact allergy to rubber gloves.

Oral ingestion of allergens such as nickel, chromium or balsam of Peru is reported to provoke or aggravate hand eczema in sensitized individuals [13–17], although the subject remains controversial [18].

Endogenous causes. Twin studies suggest hereditary factors play a part in the development of hand eczema [19], with the atopic diathesis as the most common endogenous cause [20]. Hand eczema is more common in people with a previous history of atopic dermatitis elsewhere [21]. The most common site of atopic dermatitis in the adult is the hands, and in some patients the hands alone may be involved. Indeed, the atopic state may first become apparent by the development of hand eczema in an adolescent or young adult when they are exposed to school, hobby or occupational irritants. The eruption is often patchy and always very irritable, but there is no specific topographical pattern [22,23]. Lichenification may be evident at an early stage, and pompholyx may or may not be present. The atopic diathesis may also predispose to a discoid pattern of hand eczema in young adults. Atopic hand eczema probably has the worst prognosis of all types of hand eczema [5].

A morphological classification of hand eczema is often suggested. Although most cases are of a patchy vesiculosquamous nature without any special characteristics, about one-third of cases present particular patterns that deserve recognition (Table 17.6). The various patterns are discussed below. However, there are no hard and fast divisions; the morphology frequently changes in an individual case, so that the diagnosis may have to be revised.

Histopathology. In general, the differences between the various forms of hand eczema are clinical rather than histological, but the considerably thickened horny layer and the presence of numerous sweat glands modify the histological features of eczema on the hands.

Table 17.6 Morphological patterns of hand eczema.

Pompholyx
Recurrent focal palmar peeling
Hyperkeratotic palmar eczema
Ring eczema
'Wear and tear' dermatitis (dry palmar eczema)
Fingertip eczema
Apron eczema
Discoid eczema
Chronic acral dermatitis
'Gut' eczema
Other patterns (e.g. patchy vesiculosquamous)

Prevalence. Minor degrees of hand eczema are very common, and virtually everyone suffers from mild dryness and chapping at some time or another. The perception of whether these changes amount to hand dermatitis can influence the findings of epidemiological studies [24].

In most surveys, hand eczema is more common in females, in a ratio of approximately 2 : 1 [5], and in adolescents with hand eczema the prevalence increases in girls as they age whereas it decreases in boys [25]. Agrup [26] found that about 2% of people in one county in southern Sweden had active hand eczema, but only 25% of them had consulted their doctor about it in the previous year, and 25% had never sought medical advice. A study of prevalence in Sweden in 1984–8 by questionnaire of 16 584 individuals showed that 11% had suffered from hand eczema within the year, with a point prevalence of 5% [27].

In high-risk groups the figures are even higher. In Finland, 44% of 617 hospital personnel engaged in 'wet work' (e.g. nurses, cleaners, kitchen staff) had a past or present history of hand eczema, and 28% had at least two attacks [28]. This is confirmed by a study demonstrating significantly greater risk of hand dermatitis among hairdressers compared with office workers [29].

Eczema of the hands accounted for 34% of all cases of eczema seen in Singapore [30].

Morphological types of hand eczema

Pompholyx

SYN. VESICULAR ECZEMA OF PALMS AND SOLES; DYSHIDROTIC ECZEMA

Definition and nomenclature. Pompholyx is a form of eczema of the palms and soles in which oedema fluid accumulates to form visible vesicles or bullae. Because of the thick epidermis in these sites, the blisters tend to become larger than in other body areas before they burst. When pompholyx occurs on the palms, it may be called cheiropompholyx, and when on the soles, podopompholyx. The alternative name, dyshidrotic eczema, refers to a supposed connection with sweat gland activity, as the condition is worse in hot weather. However, most authors feel that this term should be abandoned, as no causal relationship with the sweat glands or sweating has been demonstrated.

Incidence. Few figures are available, but pompholyx probably accounts for about 5–20% of all cases of hand eczema [1,2].

Aetiology. The cause remains obscure. In most cases no exogenous cause is found. Monozygotic twins have been affected simultaneously [3], suggesting that hereditary predisposition may be important, but in a study of nickel allergy in twins, only one pair out of 14 was concordant with pompholyx. In seven other pairs, pompholyx occurred only in the nickel-sensitive twin [4].

The role of the sweat glands has been disputed. Although the distribution of the lesions corresponds to that of emotionally activated palmoplantar sweating and the condition is worse in hot weather, hyperhidrosis is by no means a constant feature. Indeed, eczematous changes have been both induced and relieved by sympathectomy reducing hyperhidrosis [5,6]. A thorough examination of serial sections of pompholyx vesicles [7] showed that sweat ducts were often pushed aside by the tense vesicles or passed between them. The contents and pH of the vesicular fluid suggested that vesicles ruptured the sweat ducts rather than the reverse. In one study, biofeedback training aimed at reducing sweating produced slight improvement [8].

The role of atopy is also difficult to assess, partly because of the paucity of controlled studies [9]. In one study a family or personal history of atopy was obtained in 54 out of 131 patients with pompholyx [10]. Lodi *et al*. [11] found personal and family atopy in 50% of their patients with pompholyx compared with 12% of control patients, but other studies have found no correlation between atopy and pompholyx [12,13]. Schwanitz [9] reviewed the evidence relating to the causes of pompholyx in some detail, and concluded that atopy is probably the most important factor and the role of dyshidrosis has been overemphasized in the past.

Primary irritants can cause pompholyx; for example, in metal workers exposed to soluble oils [12].

Direct-contact allergens may sometimes evoke a palmar vesicular reaction instead of the more common dorsal pattern [14]. Responsible allergens include primin, isopropyl *para*-phenylenediamine, benzoisothiazolones and dichromates [15]. Perfumes, fragrances and balsam ingredients must also be considered as potential allergens [16]. Patch tests of nickel sulphate applied to the palms or fingers of nickel-sensitive subjects may produce a vesicular pompholyx-like reaction, but contact sensitivities found on patch testing may be secondary phenomena [17].

The role of ingested metals in provoking exacerbations of vesicular palmar hand eczema has been studied. Some authors [17–20] found that many nickel-sensitive patients have this pattern of hand eczema, and produced flares by giving oral nickel sulphate—although usually in doses far greater than the natural daily intake. Others have been unable to confirm this [21,22]. Chromium and cobalt allergy may also occasionally be implicated [16,23]. Oral neomycin provoked pompholyx in three of 10 neomycin-sensitive patients with leg ulcers [24].

Other haptens may give rise to pompholyx. These are difficult to detect, but a careful history, supplemented by 'feedback' tests, may occasionally pinpoint an offending allergen. Patch tests, although producing a low yield of positive results, should be performed in all cases of pompholyx.

Fungal infection elsewhere on the body, usually the feet, can provoke eczema of the palms. In the past this pompholyx *dermatophytide* [16] was diagnosed more frequently than it is now, and it has been regarded as a rare association in other studies [15,25]. The clinical picture is usually of a unilateral inflammatory fungal infection of the foot, followed by development of a bilateral vesiculobullous eruption on the palms. It is necessary to prove the presence of the fungus by examination of skin scrapings from the foot. Coexistence of pompholyx on the hands and feet is not uncommon, but in these cases involvement is bilateral and symmetrical.

Irritant or allergic dermatitis resulting from treatment of a fungal infection of the foot may also precipitate a palmar pompholyx. Primary allergic contact dermatitis of the feet (e.g. from rubber shoe chemicals) may induce a sympathetic palmar eruption.

The role of *bacterial foci* cannot be dismissed. Some reported cases may have been examples of a true pustular bacteride affecting the palms or soles.

The role of *stress* is, as usual, difficult to define. In some patients, recurrences can convincingly be related to stressful episodes, but in many others there is no such correlation. It has been suggested that patients with pompholyx are unduly susceptible to stress, but it should be remembered that pompholyx itself causes stress, particularly if there are financial problems because of loss of work.

Pompholyx may rarely follow a *drug eruption*. Aspirin ingestion, oral contraceptives and cigarette smoking also increase the risk of pompholyx [13].

Histopathology. The early features have not been sufficiently well studied. Fully formed lesions show the changes of acute eczema modified by the thick overlying epidermis. The subsequent course is that of a subsiding eczema, with hyperkeratosis and epidermal shedding.

Clinical features (Fig. 17.15). Pompholyx may occur at any age, but it is more common before the age of 40 years.

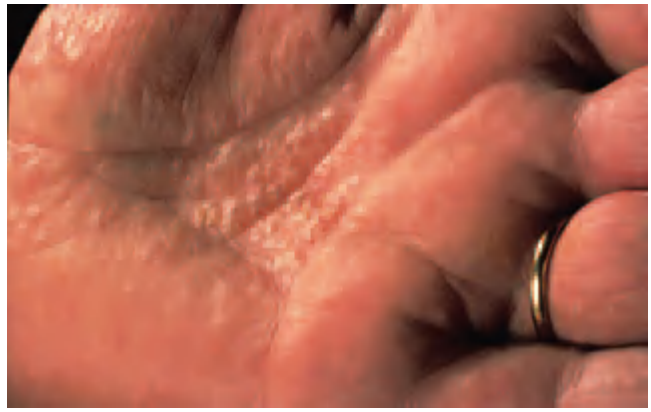

Fig. 17.15 Pompholyx, showing confluent vesicles of the palm.

Onset before 10 years is unusual. An attack of pompholyx is characterized by the sudden onset of crops of clear vesicles, which appear deeply seated and 'sago-like'. There is no erythema, but a sensation of heat and prickling of the palms may precede attacks. Vesicles may become confluent and present as large bullae, especially on the feet. Itching may be severe, preceding the eruption of vesicles. The attack subsides spontaneously, and resolution with desquamation occurs in 2–3 weeks in most cases, but recurrent attacks in this period may cause a wave-like continuation of symptoms in a minority of cases. In mild cases, only the sides of the fingers may be affected, but in a typical case the vesicles develop symmetrically on the palms and/or soles. Unilateral or asymmetrical patterns occur, but this should alert the dermatologist to look for contact causes of the eruption. In 80% of patients only the hands are involved. The hands and feet, and the feet alone each account for approximately 10% of patients. Secondary infection with pustule formation and lymphangitis is not uncommon, and may complicate each attack in certain patients. Rubbing and inappropriate treatment may produce secondary eczematous changes extending beyond the volar surfaces. After recurrent attacks spreading to the dorsa of the fingers, the nails may develop dystrophic changes, irregular transverse ridging and pitting, thickening and discoloration. Such changes can follow even mild attacks, and may be the patient's presenting complaint.

In cases in which no cause can be demonstrated (the majority) recurrences are usual. They may occur at intervals of 3 or 4 weeks for months or years, or at long irregular intervals. Pompholyx is more common in warm weather, and in some patients attacks occur annually each summer.

Diagnosis. There is some debate whether the term pompholyx should be reserved for typical cases in which the attacks resolve and recur. Chronic recurrent vesiculation without periods of remission may be termed chronic vesicular dermatitis.

A circumscribed and asymmetrical area of scaling and vesiculation of the palm or sole should suggest the possibility of dermatophytosis, and scrapings should be examined for fungus. If the erythema is limited to one or two interdigital clefts, is asymmetrical or involves the dorsal skin to any extent, the possibility of a contact dermatitis must be considered, and excluded by a careful history and by patch testing. In pustular psoriasis of the palms and soles there are usually no clear vesicles, although this is not invariably so [26]. The pustules are sterile on culture, and leave characteristic brown marks as they resolve. Occasionally, secondary bacterial infection of pompholyx may occur, with pustule formation, but in these cases the lesions tend to be painful, with surrounding erythema, and culture of the pus yields the causative organism. A pustular bacteride secondary to bacteria elsewhere in the body may also lead to confusion.

Repeated attacks of pompholyx may produce hyperkeratotic lesions that mimic psoriasis vulgaris.

Pemphigoid, linear IgA disease and pemphigoid gestationis occasionally present with blisters on the palms that mimic pompholyx [27,28].

Treatment. Any obvious cause of the eruption should be eliminated, but in most cases one will have to rely on non-specific measures. In the acute phase, rest and bland applications are indicated. Involvement of the feet may require the patient to be treated in bed. The hands or feet should be soaked three or four times a day in either Burow's solution (aluminium acetate 1%) or potassium permanganate solution (diluted 1 : 8000). Large bullae may be aspirated using a sterile syringe. Systemic antibiotics will be required if secondary bacterial infection develops. This is most likely to be staphylococcal, and flucloxacillin is usually effective.

As the eruption subsides the soaks should be discontinued, and zinc cream or oily calamine lotion can be substituted. Topical steroids are useful in the subacute and chronic phases. In a few severe cases, a course of oral steroids may be justified.

For chronic pompholyx that has entered the hyperkeratotic phase, tar preparations such as 2–5% crude coal tar may be used, or a steroid preparation may be combined with a coal tar solution. Low-dose methotrexate and radiation therapy have both been used with success in refractory cases [29,30].

Recurrent focal palmar peeling

SYN. DESQUAMATION EN AIRES

In the past this condition was called keratolysis exfoliativa, but the term is best avoided because of confusion with another condition of the same name (see Chapter 34).

The condition is probably a mild form of pompholyx. During the summer months, small areas of superficial

(a) (b)

Fig. 17.16 Recurrent focal palmar peeling. Well-established lesions on: (a) hands (courtesy of Dr A. Marsden, St George's Hospital, London, UK); and (b) feet.

white desquamation develop on the sides of the fingers and on the palms or on the feet (Fig. 17.16). They appear abruptly, and expand before peeling off. There is little or no irritation, and vesicles as such are not seen. The condition is probably not rare, but because it is relatively asymptomatic it often does not reach the dermatologist. Some patients subsequently develop true pompholyx.

Hyperkeratotic palmar eczema

SYN. TYLOTIC ECZEMA

This condition is a distinct form of hand eczema which is characterized by highly irritable, scaly, fissured, hyperkeratotic patches on the palms and palmar surfaces of the fingers [1,2] (Fig. 17.17). It is a common condition, and 2–5% of all applications for permanent disability pensions in some western European countries are a result of hyperkeratotic hand eczema.

The aetiology is unknown. Patch tests are usually negative, and the incidence of atopy and psoriasis is no greater than in a normal control population. The distinction from localized psoriasis of the hands can, however, be very difficult. It is most frequent in men of middle age or over, and is extremely refractory to treatment, although PUVA may be helpful [3]. Steroid ointments, crude coal tar, salicylic acid and Grenz rays may be tried. A review of 32 patients re-examined 10 years after initial presentation showed that in 29 the condition had remained more or less unchanged [1,3]. Oral retinoid tablets such as etretinate may be helpful [4].

Ring eczema

This characteristic pattern particularly affects young women, rarely men. The condition usually starts soon after marriage or childbirth. An irritable patch of eczema begins under a ring—usually a broad wedding ring—and typically spreads to involve the adjacent side of the middle finger and the adjacent area of the palm. It may remain confined to these sites, but is occasionally followed by the appearance of discoid patches elsewhere; or a more diffuse vesicular eczema may develop. Despite the clearly defined demarcation of the initial eruption, these patients cannot be shown to be sensitive to gold or copper although, curiously, nickel, cobalt and even chromium sensitivity are more commonly found on patch testing than might be expected; only rarely can 'white gold' alloys be implicated. Ring dermatitis has been described as the clinical presentation of fragrance sensitization [1]. Transference of the ring to the other hand is often rapidly followed by the appearance of eczema at the new site and, once affected, patients may aver that wearing of the ring for only a few minutes, even without washing, causes irritation. This type of hand eczema is probably caused primarily by concentrations of soap and detergent beneath rings (which may tighten on fingers immersed in hot water), but microtrauma, especially friction, may also have a role.

Very rarely, radioactive gold in a ring may cause radiation dermatitis, which mimics this type of wedding ring eczema [2].

'Wear and tear' dermatitis

SYN. ASTEATOTIC HAND ECZEMA; HOUSEWIVES' DERMATITIS; DRY PALMAR ECZEMA; DERMATITIS PALMARIS SICCA

This condition affects housewives and cleaners who frequently immerse their hands in water and detergents, and is presumably caused by a combination of asteatosis, exposure to mild irritants such as soap, and mild trauma (e.g. from wringing out dishcloths). The skin feels dry, it becomes criss-crossed with superficial cracks associated with a damaged horny layer, and it is unable to respond with its normal pliability to hand and finger movement (Fig. 17.18). These cracks often stand out white against an erythematous background. In addition to palmar involvement there may be dryness and chapping of the skin over the dorsa of the knuckle joints. The condition may also be associated with fingertip eczema (Fig. 17.19) or with ring dermatitis.

Fig. 17.18 Dry palmar eczema.

Fig. 17.19 Fingertip eczema in a patient with wear and tear dermatitis. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

Some patients with juvenile plantar dermatosis also have hand involvement, and some patients have the distinctive palmar dermatitis alone. This is a dry, glazed, erythematous, fissured and only mildly pruritic condition, which has been called dermatitis palmaris sicca [3]. Exudation and weeping do not occur in this condition. There seems to be little or no clear morphological distinction between this condition and 'wear and tear' dermatitis.

Fingertip eczema

This condition also presents a very characteristic pattern, involving the palmar surface of the tips of some or all the

Fig. 17.20 Fingertip eczema resulting from allergy to plant bulbs. (Courtesy of Dr F.A. Ive, Dryburn Hospital, Durham, UK.)

fingers. The skin is dry, cracked and sometimes breaks down into painful fissures. Usually remaining localized, it may occasionally extend along the palmar surfaces of the fingers to merge with palmar eczema (Fig. 17.20).

Two patterns may be distinguished. The first and most common involves most or all of the fingers, mainly those of the dominant hand, and particularly the thumb and forefinger. The condition is usually worse in the winter and generally improves on holiday. Patch tests are negative or not relevant; it is a cumulative irritant dermatitis in which degreasing agents combine with trauma as causative factors. The second pattern involves preferentially the thumb, forefinger and third finger of one hand. This is usually occupational (whether in factory, market garden or house). It may be either irritant (e.g. in newspaper delivery employees) or allergic (e.g. to colophony in polish, or to tulip bulbs or stems [4,5]). The condition usually involves the dominant hand, but there may be allergy to onions, garlic and other kitchen products held in the serving hand. In these cases, patch testing (and 20-min contact tests) may be rewarding [6].

Apron eczema

This condition is a type of hand eczema that involves the proximal palmar aspect of two or more adjacent fingers and the contiguous palmar skin over the metacarpophalangeal joints, thus resembling an apron (Fig. 17.21). This

Fig. 17.21 'Apron' eczema, showing the characteristic distribution.

pattern of hand eczema is rarely caused by contact allergic dermatitis but may reflect the effect of irritants [7].

Discoid eczema

See page 17.18.

Chronic acral dermatitis

This is a distinctive syndrome affecting patients in middle age. A chronic hyperkeratotic papulovesicular eczema of the hands and feet, intensely pruritic, is associated with grossly elevated IgE levels in subjects with no personal or family history of atopy. The condition responds to oral corticosteroids, but the response to topical therapy is poor [8].

'Gut' eczema

SYN. SLAUGHTERHOUSE ECZEMA

Workers who eviscerate and clean pig carcasses are at risk of developing vesicular eczema, which starts in the finger webs and spreads to the sides of the fingers. This is a mild, self-limiting condition, which clears in a week or two, even if the patient remains at work, but it can recur at intervals. Workers in Danish bacon factories call this 'fat eczema', although there is little evidence that it is caused by fat and prick tests to pig fat extracts are negative [9]. The pathogenesis is unknown, but some slaughtermen have developed contact urticaria from exposure to animal blood [10].

Patchy vesiculosquamous eczema

There remains a large group of cases in which a mixture of irregular, patchy, vesiculosquamous lesions occur on both hands, usually asymmetrically. In contrast to the lesions of discoid hand eczema, the degree of activity and

distribution of the lesions vary, appearing now at one site, now at another. Nail changes are common if the nail folds are affected.

The above list by no means exhausts the possible morphological patterns of hand eczema. Some patients, for example, have dry, scaly eczema confined to a small area on the thenar or hypothenar eminence, and this is almost always endogenous. Others may have vesicular eczema confined to the edge of the hand in a very persistent form.

Differential diagnosis. The diagnosis of hand eczema is usually self-evident, but the distinction from psoriasis can be very difficult. Most experienced dermatologists have seen cases they have confidently labelled as hand eczema, which have later developed typical psoriasis in other areas [1]. In some cases even biopsy does not allow a clear distinction to be made. In most cases of psoriasis on the hands, however, the silvery nature of the scale, involvement of the knuckles, sharply demarcated 'scalloped' edges to the erythema along the borders of the hands and fingers, and the relative absence of pruritus are helpful pointers. A family history of psoriasis and the presence of nail pits in the absence of nail fold lesions are also suggestive.

Tinea can also be missed, especially when it is extensive and irritable (Fig. 17.22), or secondarily infected. Unilateral scaling of the palm should always suggest a possible *Trichophyton* infection and a discoid plaque resulting from *T. verrucosum* is sometimes seen in farmers.

The special characteristics of palmar pustulosis are usually evident, and lichen planus (Fig. 17.23) and pityriasis rubra pilaris usually pose no difficulties.

It must be emphasized that the whole skin should be examined in any case of hand eczema in which the diagnosis is in doubt. There may, for example, be evidence of nickel allergy or tinea pedis, or small patches of psoriasis of which the patient is unaware.

Fig. 17.22 *Trichophyton* infection of the hands, which had failed to respond to topical steroids. Note the nail involvement.

Fig. 17.23 Lichen planus mimicking hyperkeratotic hand eczema, but the margins are well demarcated, and the lesions on the left wrist are characteristic of lichen planus.

Prognosis. Unless a responsible allergen can be identified and removed, the prognosis of hand eczema is always uncertain. Some allergens such as nickel, rubber chemicals and fragrances are ubiquitous, however, and complete avoidance in the home environment is difficult to achieve [2–5]. In general, eczema on the dorsa of the hands clears more readily, and is less likely to recur than palmar eczema. Acute attacks of pompholyx will usually settle down and in one-third of the cases will not recur. In another third, recurrences will take place, and in the remainder the condition will pass into a chronic, possibly hyperkeratotic stage. Those forms of hand eczema that are caused in part or wholly by the effects of irritants carry a particularly poor prognosis unless these irritants can be

completely removed. Interdigital dermatitis has been shown to be a potential precursor of more severe hand dermatitis in hairdressers. Recognition of this sign by the patient may allow early intervention to prevent progression of the disease [6].

A prolonged period of rest for the skin is usually necessary for complete restoration of the protective function of the stratum corneum [7]. Patients who have suffered from severe hand eczema will often remain vulnerable to mild irritants for several months after the eczema has apparently cleared.

There are few figures available for assessing the prognosis of non-occupational hand eczema. Many patients learn to 'live with' their condition, and cease to attend doctors—a poor reflection of our capabilities in this field. The prognosis is worse in patients with atopic eczema [8,9].

In one study, one-quarter of patients were symptom-free, and a further half had improved after a follow-up period of 6–22 months [10]. In a longer follow-up of 213 cases, less than one-third had entered complete remission [11]. Change of occupation did not affect the prognosis.

The behaviour of hand eczema in pregnancy is variable.

Treatment. Treatment of acute hand eczema is as for pompholyx (see p. 17.22). For *chronic* eczema, particular attention must be paid to possible causative factors, and a full occupational and social history, with details of hobbies and spare time activities, is essential. Patients must be asked exactly what their job involves and how they protect their hands. Patch tests are advisable (see Chapter 20).

The same general principles of treatment apply as for chronic eczema on other parts of the body (see p. 17.39). The three most useful measures are:

1 Avoidance of irritants
2 Frequent application of emollients
3 Sparing use of topical steroids [12].

Avoidance of irritants. This is particularly difficult for patients with hand eczema, as irritants are so ubiquitous. Education of the patient to the possible dangers is of paramount importance, and printed advice sheets are useful, as patients often have a poor recollection of oral instructions. Examples of suitable instruction sheets have been provided by Epstein [12].

Cleanliness is important, but too much soap and water can be harmful. A wide variety of soap substitutes are now available. Older remedies such as a tablespoon of emulsifying ointment mixed in a cup of hot water are often helpful. Very brief exposure to soap followed by immediate application of a topical lipid is unlikely to be harmful, and may be beneficial by removing bacteria and debris [13].

Barrier creams are usually ineffective for hand eczema of occupational origin, although new products are frequently being reported as showing some promise [14,15]. In practice they may not be applied effectively [16] and the debate continues about their actual benefit [17]. Gloves usually provide the best protection, and time should be spent discussing with the patient the details of the material, size and weight of the gloves to be used, so that they can be tailored to the individual's particular need. Gloves with holes in them may be worse than no gloves at all, but gloves that are too thick may make it impossible to perform a particular task. It should also be remembered that some allergens such as acrylates and epoxy resins can penetrate vinyl or rubber gloves [18]. Rubber gloves generally give good protection for housework. In patients with rubber allergy, polyvinyl chloride household gloves should be worn instead. If sweating makes the condition worse, it may be helpful to wear cotton gloves beneath the protective gloves. Gloves should also be used for dry work, to prevent soiling and trauma, especially for gardening in cold dry air. Thin leather is usually better than cotton for this purpose.

Emollients. Emollients should be applied frequently as a thin smear rubbed gently into the skin, and several jars should be left at convenient locations such as near sinks, so that they are readily available. The choice of emollient will vary with the patient. Some people will benefit from a greasy preparation such as emulsifying ointment, and others will prefer a more cosmetically acceptable cream such as aqueous cream, which sinks into the skin more readily, and is less likely to stain. Numerous commercial preparations are now available. Patients should be warned that some topical preparations sold over the counter by pharmacists as antipruritics or emollients can contain irritants such as alcohol or propylene glycol, and they should use only what the dermatologist recommends.

Topical steroids. These are used in all but the mildest cases, but as always they should be used sparingly, and in the weakest potency that is effective. Hydrocortisone in a concentration of 1% is perfectly safe, but stronger steroids are often required and these can cause atrophy. Even though the palms are thick, the epidermis can be rendered thin and fragile by potent topical steroids. This is not a major problem in hyperkeratotic eczema, but in these cases steroids are relatively ineffective. If bacterial infection is present, a systemic antibiotic may be needed, and the use of a combined steroid–antiseptic or steroid–antibiotic preparation may help to lessen the risk of infection and improve the response. The risk of bacterial overgrowth resulting from steroids, however, is probably less than one might expect. It has been shown that a potent steroid used alone can reduce or even eliminate *Staphylococcus aureus* colonization in hand eczema [19].

In difficult, unresponsive cases the use of a potent steroid under occlusion may be considered. The steroid is

applied at bedtime, and polythene gloves are worn overnight, sealed at the wrist with sticky tape. This is an effective treatment, but it greatly increases the risk of atrophy and secondary bacterial infection, and should be discontinued as soon as the eczema shows satisfactory improvement.

If hand eczema does not respond to topical steroid therapy, the diagnosis should be reviewed, particularly with regard to the possibility of tinea. The patient should be quizzed again about exposure to irritants or allergens, and the possibility of sensitization to medicament bases or preservatives or even the corticosteroid itself should also be considered, with patch tests if necessary.

After improvement of the dermatitis with daily corticosteroid use, the intermittent use of a potent corticosteroid cream may safely prevent relapse [20].

Epstein [12] recommends intradermal injection of triamcinolone (10 mg/mL) into recalcitrant localized patches of hand eczema.

Other measures. Tar pastes are often useful for chronic unresponsive cases. Generally speaking, the messier preparations such as 5% crude coal tar tend to be more effective than the cosmetically more acceptable preparations.

Salicylic acid ointment is also sometimes helpful for hyperkeratosis and persistent scaling [21]. Various combinations of tar, steroids and salicylic acid may be tried, and Baden [22] has recommended the application of a keratolytic gel of salicylic acid and propylene glycol under occlusion for 2–4 h before the application of steroid ointments at night.

Oral PUVA chemotherapy and UVB therapy have proved useful for several types of hand eczema, including allergic contact dermatitis, dyshidrotic eczema and hyperkeratotic palmar eczema [3,23–29]. Topical PUVA soaks have also been shown to be effective and safe, although patient compliance is crucial to success [30]. A PUVA cream therapy may be more useful [31].

Radiotherapy is also effective for stubborn hand eczema. Grenz rays were widely used in the past, as these were thought to be safer than X-rays. Fairris *et al*. [32] have shown that superficial X-rays give a better result, and they advise that patients can safely receive three courses of 3 Gy of superficial X-ray therapy during a lifetime.

Etretinate is sometimes effective for hyperkeratotic eczema, but there is a high incidence of side effects [33]. Ciclosporin has been reported to be useful in recalcitrant cases of chronic vesicular hand eczema, and appears to be as effective as a potent topical corticosteroid, although side effects may be a concern [34,35]. Ranitidine was shown to have adjuvant benefits to topical steroid treatment of atopic hand dermatitis, without any side effects [36]. A pilot study of 9-*cis*-retinoic acid showed a good response to the drug in over half the cases [37].

Painful fissures of the fingertips are a therapeutic problem. The main requirement is to keep the keratin as pliable as possible by the use of greasy preparations, and it often helps to use polythene occlusion at night, with thin leather gloves during the day. Once formed, fissures are slow to heal, but they can sometimes be rendered painless by sealing them with a product such as compound benzoin tincture. Recurrent infection of fissured hand eczema can give rise to lymphoedema, and long-term low-dose antibiotic prophylaxis with penicillin may be required [38].

In indolent cases in which metal allergy of dietary origin is thought to be playing a part [39], the use of an oral chelating agent may be considered. Disulfiram 200 mg/day for 8 weeks produced good results in an open study, but this treatment carries a risk of liver dysfunction [40].

Venous eczema

SYN. GRAVITATIONAL ECZEMA

Definition. Eczema secondary to venous hypertension.

Nomenclature. This condition is also called stasis eczema or varicose eczema. It is increased venous pressure rather than stasis that seems to be the prerequisite. Although it is often associated with varicose veins, these are not always present.

Pathogenesis [1–4]. The oxygen content in the femoral venous blood of the leg affected by venous hypertension is increased, and the venous blood in such limbs has a faster circulation time than normal [5,6]. These observations could be explained by the development of arteriovenous shunts in the affected areas, but the use of radioactively labelled macroaggregates or microspheres has failed to provide any evidence for such shunts.

An alternative explanation for these findings has been provided by Browse and Burnand [2], who suggested that the high ambulatory venous pressure within the calf muscle pump is transmitted to the capillary circulation in the skin and subcutaneous tissues of the calf. This distends the local capillary bed and widens the endothelial pores, thus allowing fibrinogen molecules to escape into the interstitial fluid, where they form a fibrin sheath around the capillaries. This layer of fibrin presumably forms a pericapillary barrier to the diffusion of oxygen and other nutrients that are essential for the normal vitality of the skin. The hypothesis that pericapillary fibrin impedes oxygen diffusion has been supported by a study using positron emission tomography [7].

It has also been suggested that cutaneous inflammation in venous hypertension may result from increased sequestration of white cells in the venules, with consequent release of proteolytic enzymes and free radicals which produce tissue damage [3]. In normal subjects, white cells are sequestered in the limb when venous pressure is elevated, and in patients with venous insufficiency the effect is enhanced, with increased endothelial contact and adhesion of white cells [8]. This effect may be related to an increase in expression of adhesion molecules ICAM-1 and VCAM-1 on the vascular endothelium in affected skin [9].

Clinical features. Venous eczema is an erythematous, scaly and often exudative eruption usually seen around the ankle and lower leg (Fig. 17.24). It often occurs as a late result of deep-vein thrombosis. On occasions, similar changes occur at other sites of venous hypertension such as the pendulous skin over an obese abdomen or in association with an arteriovenous fistula in the upper limb [10]. The eczema may develop suddenly or insidiously. The patients are usually middle-aged or elderly and most often female. The increased incidence in females is presumably a result of hormonal effects and the tendency for deep-vein thrombosis to occur during pregnancy.

The eczema is often accompanied by other manifestations of venous hypertension, including dilatation or varicosity of the superficial veins, oedema, purpura, haemosiderosis, ulceration or small patches of white atrophic telangiectatic scarring (atrophie blanche). These changes, which occur in various combinations, are discussed in more detail in Chapter 50. Leashes of dilated venules around the dorsum of the foot or the ankle are particularly common. There may be a subepidermal vascular proliferation producing purple papules around the ankle, which may resemble Kaposi's sarcoma [11]. Secondary patches of eczema may develop on the other leg, even when it is not affected by obvious venous insufficiency. Generalized secondary dissemination may occur and on occasions this can progress to erythroderma.

These changes are often modified by secondary contact dermatitis, infection and rubbing. Allergic contact

Fig. 17.24 Venous (gravitational) eczema.

dermatitis is a common complication of venous eczema, possibly because of the large numbers of antigen-presenting cells in the inflamed skin [12].

Differential diagnosis. Although most cases of eczema of the lower leg are secondary to venous hypertension, it must be remembered that many other types of eczema can affect this region, and in many cases there are multiple causative factors. In children or young adults, atopic dermatitis can manifest as lichenified patches around the ankle or behind the knees. Allergic contact dermatitis of the lower legs is usually caused by topical medicaments (Fig. 17.25). Patch testing is often indicated. An infected ulcer may be complicated by infective eczema spreading from the edge of the ulcer, and responding to appropriate antibiotic therapy (see p. 17.7). Discoid eczema is common on the lower leg, usually on the anterior or anterolateral aspect. Asteatotic eczema commonly affects the legs of elderly patients.

Although the exact cause of eczema on the lower legs can be difficult to elucidate, other conditions can usually be readily identified. Psoriasis may present as a single, irritable plaque on the leg, but is usually more scaly and clearly marginated. Hypertrophic lichen planus of the lower leg may occasionally be mistaken for eczema if there are no characteristic lesions elsewhere. Dermatophyte infection may present as diffuse erythema and scaling, and can be difficult to recognize, particularly if it has been treated with topical steroids. Profuse actinic keratoses may cause red, irritable patches on the lower legs in sunny climates. In the late stage of borreliosis the leg can feel heavy, with thick cyanotic itchy skin which may mimic the changes of venous hypertension [13].

Treatment. The underlying venous hypertension should be controlled. Obese patients should be urged to lose weight. Well-fitted support stockings or firm bandages can be helpful if worn regularly. The legs should be elevated when the patient is recumbent.

Fig. 17.25 Contact dermatitis of the lower legs caused by allergy to paste bandages.

Mild topical steroids may be used to relieve irritation, but the use of potent steroids should be limited to short periods of a few days as they may cause cutaneous atrophy and increase the risk of ulceration. Bacterial infection must be treated where appropriate, but the risk of sensitization to topical antibiotics and antiseptics should be borne in mind, and systemic antibiotics may be preferable. Bacteria cultured from a swab are not necessarily playing a pathogenic part. If trauma is thought to be playing a part, and the patient cannot resist scratching, a paste bandage may be helpful.

Juvenile plantar dermatosis

SYN. FOREFOOT ECZEMA; PERIDIGITAL DERMATOSIS; DERMATITIS PLANTARIS SICCA; ATOPIC WINTER FEET

Definition. This condition is characterized by shiny dry fissured dermatitis of the plantar surface of the forefoot. It occurs mainly in children aged 3–14 years.

Nomenclature. The first record of this condition appeared in 1968, and since then it has been described under a variety of names depending on the author's beliefs concerning pathogenesis and the possible association with atopy. The name 'juvenile plantar dermatosis' has the merit of making no presumptions about cause.

Aetiology [1–4]. It is thought that changes in the composition of children's socks and shoes in the last 30 years or so may be responsible for the emergence of this disease. Biological materials such as cotton, wool and leather have gradually been replaced by various synthetic materials (nylon, plastics), and these are generally less porous than the natural materials they have replaced. This loss of permeability is enhanced by various repellent coatings designed to improve the durability of the shoe surface. The feet are thus subjected to hot humid conditions that encourage mild maceration, particularly in children who may wear trainer shoes throughout their waking hours. The maceration probably causes sweat retention and, although the exact mechanism is uncertain, this may aggravate the condition [3]. This is not the whole story, however, for occasional cases have occurred in children wearing open leather sandals and cotton socks. Many of the affected children are keen on sports, and this suggests that friction and enhanced sweating may be playing some part.

An association with atopy has been proposed but the evidence for this is not convincing. In a controlled study, a personal or family history of eczema or other atopic illness was not more common in cases than in controls [1].

Fig. 17.26 Juvenile plantar dermatosis, showing the characteristic glazed appearance of the forefoot skin.

Juvenile plantar dermatosis has been seen in identical twins [5].

Pathology [2,6]. The histology shows a mild, non-specific eczema. Blockage of sweat ducts can sometimes be identified.

Clinical features. Few cases have been reported in adults or infants. There is a slight preponderance of male patients. The presenting features are redness and soreness on the plantar surface of the forefoot, which assumes a shiny, 'glazed' and cracked appearance (Fig. 17.26). The condition is most severe on the ball of the foot and toe pads, and tends to spare the non-weight-bearing instep. The toe clefts are normal, and this helps to distinguish the condition from tinea pedis. The symmetry of the lesions is a striking feature. Occasionally, the disease can affect the hands, resulting in sore, shiny, fissured palms or fingertips. This is more likely in atopic subjects [7].

Diagnosis. This is a clinical diagnosis, although skin scrapings to exclude fungus and patch tests to exclude footwear allergy may be helpful if there is any doubt. Consultation with the manufacturer of the shoes may help to identify potential allergens.

Treatment. Most cases will clear spontaneously during childhood or adolescence, but the condition may persist into adulthood [8]. Patients are usually advised to change from non-porous footwear to 100% cotton socks, and leather shoes or sandals, although the majority report that these changes in footwear do not help significantly [1,8–10].

In severe cases, with cracking and exudation, bed rest may be needed. A variety of topical preparations may help, including urea preparations, Lassar's paste, white soft paraffin or tar, but no single preparation is always effective [2,11,12].

'Metabolic' eczema and eczema associated with systemic disease

Eczema associated with malabsorption

The possible interrelation of eczema and disordered intestinal absorption is not fully understood but it seems that widespread eczema can occasionally be either the cause or the result of intestinal malabsorption [1,2].

Severe inflammatory skin disease often seems to cause a degree of malabsorption—a condition known as dermatogenic enteropathy [1,3]. This is usually asymptomatic. The mechanism is not known, but the malabsorption improves rapidly as the skin is treated.

Many of the cases of eczema reportedly caused by malabsorption may, in reality, have been dermatitis herpetiformis, as they mostly predate the establishment of modern histological and immunological criteria for this disease [4,5]. However, the response of the eczema in some cases to correction of the serum calcium suggests that there may be other mechanisms involved [6]. A case of dermatitis associated with lactose intolerance and apparently improving in response to a lactose-free diet is also difficult to explain [7].

Wiskott–Aldrich syndrome

This syndrome is fully described in Chapter 14.

Hypogammaglobulinaemia

A form of eczema, clinically very similar to atopic eczema, has been described in boys with hypogammaglobulinaemia [1,2].

Hyper-IgE recurrent infection syndrome

SYN. JOB'S SYNDROME

This rare disorder is characterized by recurrent bacterial infections of the skin, nasal sinuses and respiratory tract, commencing in early childhood, in the presence of serum levels of IgE which are around 10 times greater than normal (more than 2000 i.u./mL). Chronic eczema, often impetiginized, is a common feature (see Chapter 14).

Pyoderma, folliculitis and atopy, with defective leukocyte and lymphocyte function

SYN. JUNG'S DISEASE

A familial immunodeficiency disease characterized by atopic dermatitis, recurrent and persistent pyoderma and folliculitis has been described in a father and son [1]. It was accompanied by abnormalities of lymphocyte function and defective leukocyte chemiluminescence responses, which were associated with defective intracellular killing of microbial organisms. The abnormalities of lymphocyte and leukocyte function and the clinical manifestations responded dramatically to treatment with the H_1 antagonist chlorphenamine (chlorpheniramine), suggesting that the underlying defect in this disease may be related to defective histamine metabolism or abnormal expression of histamine receptors on lymphocytes and leukocytes.

Pellagra

Photosensitive dermatitis is a feature of pellagra. Hartnup disease, with massive aminoaciduria, may also be asso-

ciated with a pellagra-like rash after exposure to the sun, presumably because nicotinamide synthesis from tryptophan is decreased. A similar phenomenon can occur as part of the carcinoid syndrome.

Phenylketonuria

Eczema occurs in 25% of untreated patients with phenylketonuria in the early years of life. It responds to dietary treatment by exclusion of phenylalanine and recurs when the treatment is stopped [1–3].

Eczematous drug eruptions

Eczematous drug reactions may be localized (e.g. resembling seborrhoeic or discoid eczema) or generalized. A carbamazepine reaction initially involving the flexures and resembling atopic dermatitis was reported recently [1]. Eczematous eruptions, including cheiropompholyx, may follow infusion of human immunoglobulin [2]. Severe reactions can rapidly progress to erythroderma.

Drug reactions are more fully described in Chapter 73.

Exudative discoid and lichenoid chronic dermatosis [1]

SYN. SULZBERGER–GARBE DISEASE

Definition. This disease has no rigid criteria, but it is a widespread, extremely pruritic eruption, characterized by discoid, lichenoid and exudative phases, which either coexist or alternate rapidly with each other. After a chronic course of months or years, the condition ends in spontaneous cure. It occurs predominantly in adult male Jews, usually between the ages of 40 and 60 years. More than 100 cases have been reported [2], but some authors deny its existence as a distinct entity [3].

Aetiology. The cause is unknown.

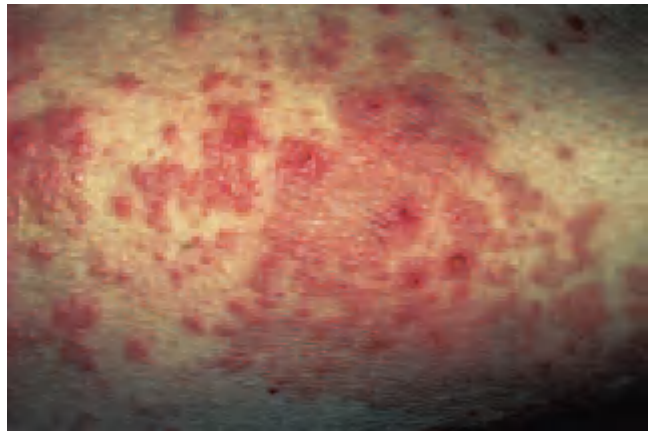

Fig. 17.27 Sulzberger–Garbe disease. (Courtesy of Dr A. Warin, Royal Devon and Exeter Hospital, Exeter, UK.)

Pathology. The histology is non-specific, and can mimic discoid eczema, allergic contact dermatitis or lichen simplex. There may be a characteristic swelling of the endothelial cells of the small vessels, which are surrounded by a 'cloudy' oedema. An infiltrate of mixed cells, including plasma cells and eosinophils, may form a mantle around the arterioles.

Clinical features. The eruption, which is exceedingly pruritic, has discoid, lichenoid and exudative phases, present together or alternately. The plaques are widely distributed (Fig. 17.27). In addition, there may be showers of round urticated lesions which appear as the discoid eczematous lesions wane.

Penile and scrotal lesions are common, and are almost pathognomonic. They are also the most persistent feature. Gynaecomastia is present in some patients [2], and blood eosinophilia is frequent.

Differential diagnosis. The differential diagnosis is wide, and includes mycosis fungoides, contact dermatitis, dermatitis herpetiformis, discoid eczema and lichen planus.

Treatment. Treatment is with systemic steroids, which may have to be continued until spontaneous resolution occurs. A rapid response to azathioprine was observed in two cases [4].

Table 17.7 Features which distinguish between prelymphomatous (prereticulotic) eruption and persistent superficial scaly dermatitis.

Prelymphomatous eruption	Persistent superficial dermatitis
Bizarre or angulated shape	Regular, round or oval shape
Fine scale	Coarser scale
May be irritable	Little or no irritation
Progresses to cutaneous lymphoma	Does not become malignant
Histology	
Absence of epidermal eczema	May be eczematous changes
Dermal infiltrate	Little or no dermal infiltrate

Fig. 17.28 Chronic superficial scaly dermatitis.

Chronic superficial scaly dermatitis

SYN. PERSISTENT SUPERFICIAL DERMATITIS; CHRONIC SUPERFICIAL DERMATITIS; SMALL PLAQUE PARAPSORIASIS; BENIGN FORM OF PARAPSORIASIS-EN-PLAQUES; DIGITATE DERMATOSIS; XANTHOERYTHRODERMIA PERSTANS OF RADCLIFFE-CROCKER

Definition. A chronic condition characterized by the presence of round or oval erythematous, slightly scaly patches on the limbs and trunk, which histologically show mild eczematous changes with little or no dermal infiltrate.

The condition is clinically benign by definition [1]. However, in some cases, clonality of the lymphocytic infiltrate can be demonstrated [2]—a feature suggesting that this may be regarded as an abortive form of cutaneous T-cell lymphoma [3]. Ackerman [4] has taken this argument further and expressed the view that even an abortive T-cell lymphoma is still a T-cell lymphoma so this condition is a clinical presentation of mycosis fungoides.

Nomenclature. This condition was formerly included with various potentially prelymphomatous eruptions under the general term of parapsoriasis [5–7]. The term chronic superficial scaly dermatitis was introduced by Calnan and Meara [1] to distinguish a subgroup of patients who did not progress to frank lymphoma, and the features that they used to distinguish this subgroup are shown in Table 17.7.

The nomenclature has been discussed in detail by Lambert and Everett [6].

Aetiology. The cause is unknown.

Pathology. The histology is not characteristic. It usually shows the changes of a very mild eczematous eruption, consisting of patchy parakeratosis, mild spongiosis and a slight, mainly perivascular infiltrate in the dermis, chiefly composed of lymphocytes [7].

Clinical features. The disease occurs in all races, although it is probably rare in dark-skinned people. Its geographical distribution varies considerably; for example, it is more common in the south than in the north of England, and appears to be uncommon in America. In most cases the onset is in middle life, and the disease persists indefinitely, with or without remission. It is much more common in men than in women.

The disease begins insidiously with one or more erythematous, slightly scaly patches. The legs, trunk and arms are most often affected (Fig. 17.28). It seldom involves the face, palms or soles. The patches are generally round or oval, but finger-like processes are also common, especially on the trunk, giving rise to the alternative name 'digitate dermatosis'. The patches are usually about 2.5 cm across, although much larger areas occur at times, especially on the legs. The colour is pink, brown or slightly yellow. The individual patches are often slightly wrinkled, resembling cigarette paper.

Symptoms are usually minimal, but some itching may occur. The patches are more prominent in winter than in summer, and may clear temporarily with natural or artificial sunlight. They will also clear for a time with suitable topical medications, but recur in the same—or adjacent—areas when treatment is stopped. After extending for a time, in most cases they then remain static and, with minor fluctuations, persist throughout life. In a few patients the condition clears permanently.

Some cases originally diagnosed as chronic superficial scaly dermatitis later develop reticulate pigmentation or atrophy, and these cases may then need to be reclassified as prelymphomatous poikiloderma.

Differential diagnosis. The main diagnostic problems are discoid eczema, eczematides, poikiloderma in its early phase and the early stages of the classical (Alibert) form of mycosis fungoides (Chapter 54 and Table 17.4).

The history, clinical appearance, response to treatment and histology will usually establish the diagnosis.

Treatment. Only symptomatic treatment is required to allay irritation. Mild steroid ointments are generally beneficial. Natural sunlight, broad-band UVB and PUVA can be helpful when required but relapse often occurs soon. Narrow-band UVB may also be effective in inducing remission, which can last from a few weeks to many months [8].

Pityriasis alba

Definition. This is a pattern of dermatitis in which hypopigmentation is the most conspicuous feature. Some erythema and scaling usually precede the development of hypopigmentation but these are often relatively mild.

Aetiology. Pityriasis alba is sometimes a manifestation of atopic dermatitis but it is certainly not confined to atopic individuals.

Pathology. The histological changes are unimpressive—acanthosis and mild spongiosis, with moderate hyperkeratosis and patchy parakeratosis. There may be follicular plugging, spongiosis and sebaceous gland atrophy [1–4]. On electron microscopy there are reduced numbers of active melanocytes and a decrease in number and size of melanosomes in affected skin [3].

Clinical features [2,5,6]. Pityriasis alba occurs predominantly in children between the ages of 3 and 16 years. The sexes are equally susceptible. The individual lesion is a rounded, oval or irregular plaque, which is red, pink or skin-coloured and has fine lamellar or branny scaling. Initially, the erythema may be conspicuous and there may even be minimal serous crusting. Later, the erythema subsides completely, and at the stage at which the lesions are commonly seen by a physician they show only persistent fine scaling and hypopigmentation. It is this that commonly induces the patient to seek advice. The hypopigmentation is most conspicuous in pigmented skin, and in lighter skins may become more evident after sun-tanning (Fig. 17.29).

Fig. 17.29 Pityriasis alba: the failure of the affected patches to tan may first bring them to the patient's notice. (Courtesy of Dr A. Marsden, St George's Hospital, London, UK.)

There are usually several patches ranging from 0.5 to 2 cm in diameter, but they may be larger, especially on the trunk. In children, the lesions are often confined to the face, and are most common around the mouth, chin and cheeks. In 20% of affected children the neck, arms and shoulders are involved as well as the face. Less commonly, the face is spared and there are scattered lesions on the trunk and limbs.

The course is extremely variable. Most cases persist for some months, and some may still show hypopigmentation for a year or more after all scaling subsides. Recurrent crops of new lesions may develop at intervals. The average duration of the common facial form in childhood is a year or more.

Diagnosis. The age incidence, fine scaling and distribution of the lesions usually suggest the diagnosis. Conspicuous hypopigmentation may lead to a misdiagnosis of vitiligo. Discoid eczema in an atopic child is intensely pruritic, and the lesions are larger and more oedematous.

In older children and adults, the lesions on the trunk, during their early erythematous phase, may be mistaken for psoriasis but the distribution and the relatively mild scaling should exclude this diagnosis. Mycosis fungoides, although relatively rare, may present with lesions clinically resembling pityriasis alba [7]. This condition can

also be difficult to distinguish histologically, so follow-up and repeat biopsy are sometimes required.

Treatment. Response to treatment is often disappointing, mainly because the pigmentation takes a long time to recover. The scaling can be reduced by a bland emollient cream, and for chronic lesions on the trunk a mild tar paste may be helpful. Mild topical corticosteroids are helpful if inflammation persists. Topical tacrolimus and pimecrolimus are effective and well tolerated in facial atopic eczema and seem likely to prove helpful, if required, in pityriasis alba.

Halo dermatitis

SYN. MEYERSON'S NAEVUS; MEYERSON PHENOMENON

Meyerson [1] described two patients with multiple pruritic, papulosquamous lesions surrounding melanocytic naevi (Fig. 17.30). More than 20 similar cases have since been described [2–4], mainly in young adults. Histology shows a benign naevus surrounded by a dermal lymphocytic and eosinophilic infiltrate, with overlying acanthosis, spongiosis and parakeratosis. One case developed during treatment with IFN-α2b in a patient with dysplastic naevus syndrome and Behçet's disease [5]. The condition usually resolves spontaneously within a few months, without involution of the naevus. It differs from Sutton's halo depigmentation, although the two conditions have been reported to coexist in the same patient and in one case progression to Sutton's naevus occurred [6]. Similar changes have been seen around seborrhoeic warts [7], and other elevated skin lesions [8], and termed the Meyerson phenomenon.

Diagnostic tests for eczema

Most cases of eczema can be diagnosed clinically. It can sometimes be helpful to measure the total IgE level in order to determine whether an individual is atopic, particularly when the distribution of eczema is atypical and there is no background of other atopic illness. Secondary infection can be confirmed by taking swabs for culture and sensitivity to identify any bacterial resistance, such as methicillin-resistant staphylococci. When dermatophyte infection is suspected, scrapings should be taken for microscopy and culture. Microscopy can also be invaluable to confirm a diagnosis of scabies, which is easy to miss in a patient with pre-existing eczema. Biopsy can occasionally be helpful in confirming the eczematous nature of the eruption, and immunofluorescence can help identify less common conditions such as dermatitis herpetiformis or, in older patients, a non-bullous presentation of bullous pemphigoid.

Patch testing in eczema [1–3]

Routine use of patch testing is not indicated for typical presentations of endogenous eczema such as atopic dermatitis, pityriasis alba and seborrhoeic eczema. This investigation is much more important in atypical or asymmetrical eruptions and especially in dermatitis affecting the face, hands and feet [3].

Even in apparently endogenous eczema, the threshold for patch testing should be low. Sensitization commonly develops to topical medicaments, prescribed or self-administered, and this may exacerbate the eruption. Sometimes topical remedies are concealed or forgotten by the patient, or the reaction they cause is partially suppressed by the concomitant use of topical corticosteroids. Sometimes an unexpected positive test points to a 'hidden' or obscure cause (e.g. fragrances, preservatives, vehicles, epoxy or rubber chemicals). Such substances are commonly encountered in the environment and in topical medication.

When a strong suspicion of a contact allergic cause for the eczema exists, it may be important to test with other potential allergens in addition to the routine battery (e.g. household plants, material extracted from footwear, phosphorus sesquisulphide, acrylates). The observer must be wary of false-positive irritant reactions, especially in an 'excited' eczematous skin [4]. For this reason it is always wise to allow the acute phase of an eczema to subside before patch testing is carried out, or to repeat any positive tests when it has done so. If a contact urticaria is thought to be occurring, the patch tests should be read 1 h after application [5].

Even if a positive patch test is judged to be relevant (the patient comes into contact with that substance), it does not necessarily follow that the exclusion of that substance from the environment of the patient will result in a cure. The allergen may be only one of several contributory factors.

Although patch tests are designed to detect allergens, many substances give an irritant reaction when tested, and it is often difficult to be sure of the relevance of such a reaction to the patient's eczema. It must also be borne in mind that many topical medicaments can produce an irritant reaction (e.g. alcohol-based preparations and propylene glycol). The choice of concentration of test substance and suitable vehicle are vitally important (see also Chapter 20 for details of patch testing) [2].

The management of eczema

A wide range of dermatoses are encompassed by the term eczema. Specific aspects of their treatment are described under their respective headings. Some fundamental principles of management shared by all eczematous dermatoses are described here.

Table 17.8 Indications for therapeutic agents in eczema.

Therapeutic agent	Acute	Subacute	Chronic
Rest, sedation	++	+	±
Wet dressings and soaks	++	±	–
Wet wrap bandaging	++	+	±
Paste bandages	±	+	++
Sedative antihistamines	++	++	+
Emollients	++	++	++
Corticosteroids, local	+	++	+
Pimecrolimus (topical)	+	++	++
Tacrolimus (topical)	+	++	++
Tar, ichthammol, etc.	±	+	++
Polythene occlusion	±	+	+
Intralesional steroids	–	±	+
Habit reversal therapy	–	±	+
X-ray therapy	–	–	±
Systemic corticosteroids	+	+	±
Ciclosporin	+	+	±
Azathioprine	–	+	+

In order to establish the underlying diagnosis, a careful history and examination are required. These will also help to identify additional aggravating factors (such as exposure to irritants) or complicating factors (such as infections or allergies to medications) that are playing a part in the pathogenesis. In order to optimize management, the dermatologist needs to be familiar with the patient's occupation, domestic circumstances and personality. It is also important to determine how the patient is affected by the disease. Which symptoms are most troublesome? How much embarrassment is experienced? Which aspects of the patient's work and social life are disrupted?

Previous treatment experience must be explored. It is necessary to assess how much time and effort a patient (or parent) is willing and able to devote to the care of their or their child's skin. An additional issue that must be addressed is the attitude of the patient to the risks and side effects associated with any treatment that may be required. A particularly common problem is an inappropriate level of anxiety about the use of topical corticosteroids. Only when all this information is available can the optimal treatment strategy be determined.

A considerable range of effective treatment modalities is available. These include conservative and extremely safe approaches such as rest and the application of emollients, and 'aggressive', more hazardous treatments such as phototherapy, systemic immunosuppressants or radiotherapy. Some frequently used treatments are listed in Table 17.8. When an extrinsic cause is identified or suspected this should be removed. In all cases, exposure to irritants should be carefully avoided and the skin should be protected using emollients and appropriate dressings.

Psychological support is an important aspect of management at all stages.

Acute eczema

Acute eruptions and exacerbations of eczema cause great alarm and anxiety, and the stress of the situation is usually aggravated by loss of sleep caused by intense pruritus and soreness. Patients should be reassured that the eruption will be brought under control. Adequate rest is essential, and on occasions this is best provided in a hospital bed. An affected leg should be elevated or well supported, and affected hands should be used as little as is practicable. In extremely acute hand eczema a sling is useful.

Highly oedematous, vesicular and exudative eruptions such as pompholyx benefit from soaks in an astringent such as a 1 : 10 000 solution of potassium permanganate. An alternative is Burow's solution BP, which contains the astringent aluminium acetate and is less messy than potassium permanganate. Liberal applications of aqueous cream and other bland emollients are soothing. Moderately potent or potent topical steroids are generally used, at least for a few days, to speed resolution of acute episodes. Topical immunomodulators such as tacrolimus and pimecrolimus seem likely to be beneficial in most forms of eczema and especially in atopic dermatitis [1]. Tacrolimus ointment 0.1% seems to be equivalent in potency to potent topical corticosteroids such as betamethasone valerate [2] and hydrocortisone butyrate [3]. When practical, tubular bandaging can be used to help keep topical medications in place. The wet wrapping technique, in which a layer of wet tubular bandage (e.g. Tubifast®) is covered with a dry layer, can be particularly useful. Hazards include a risk of hypothermia, although—in moderation—the cooling effect is highly beneficial. Emollients and other medications can be applied under the bandaging as required. Penetration of topical corticosteroids can be significantly increased by this form of occlusion, enhancing both beneficial and adverse effects. Mild or moderate potency corticosteroids should be used for the face and genital areas. Potent or very potent steroids are required, at least initially, for acute pompholyx on the hands or feet.

When secondary infection is present or staphylococcal contamination of the skin is thought to be an aggravating factor, oral antibiotics are often used. Topical preparations containing antibiotics or antiseptics in combination with steroids can also be helpful. These compound formulations should only be used when there is an indication for each constituent, in order to avoid unnecessary exposure to the risks of sensitization and emergence of bacterial resistance.

Excoriation can be reduced further by a sedative antihistamine such as hydroxyzine or alimemazine (trimeprazine), and additional hypnotics may be needed for a few days to ensure sleep.

Subacute eczema

If an acute eczema has failed to clear almost completely in 3–4 weeks, any perpetuating factors should be carefully sought. Has exposure to a sensitizing agent been overlooked? Has the patient become intolerant of the treatment prescribed? Has the treatment been effectively carried out?

Admission to hospital can often be helpful in these circumstances to ensure that the aetiological factors have been fully explored and that treatment will be regularly and effectively carried out. Rapid resolution usually follows admission and a period of rest. A prompt relapse on discharge may indicate photosensitivity or an allergic cause in the patient's home environment. Rapid deterioration after the arrival at the bedside of a generous bunch of flowers sometimes helps to establish the diagnosis of chrysanthemum sensitivity.

Paste bandages are of special value in occluding areas that are frequently excoriated, as in many lower leg eczemas. These must be applied skilfully to ensure that they are firm but not tight enough to cause discomfort or to restrict arterial or venous blood flow. Corticosteroids under polythene occlusion may be helpful at this stage, if only for a few days, to lessen itching. Topical immunomodulators such as tacrolimus and pimecrolimus are effective. Cleaning and bathing need not be routinely forbidden, and may be comforting, but long hot soaks and the use of soap should be discouraged. In some cases of asteatotic and discoid eczema, baths may be poorly tolerated and should be restricted. Liberal applications of emollients after bathing are helpful. Bath oils can be beneficial but are best avoided for elderly patients as they make the bath more slippery.

Chronic eczema

In chronic eczema, oedema, vesiculation and exudation give way to a more stable picture of erythema, scaling, excoriation and lichenification. Pruritus often remains troublesome, especially in atopic dermatitis. It is important to reconsider regularly whether complications such as sensitization to medicaments or superinfection are playing a part.

Emollients should be applied frequently. Soaps and other potential irritants, and sensitizers such as perfumes should be avoided. Mild, moderate or potent topical corticosteroids and topical immunomodulators are helpful [1–3]. In seborrhoeic dermatitis, and most cases of discoid eczema and atopic dermatitis, mild or moderate potency steroids are usually adequate. In severe atopic dermatitis and endogenous hand eczema, more potent steroids may be required. Long-term use of potent corticosteroids requires particular caution to minimize atrophy of the treated skin. For patients prone to frequent flares of eczema, a recently developed strategy that may prove

useful to limit steroid requirement is to induce remission with once or twice daily application of a potent topical steroid and then apply the steroid only for 2 days each week to maintain remission [4]. The use of topical immunomodulators such as tacrolimus and pimecrolimus provides a useful alternative, and these will also help in reducing cumulative exposure to steroids. This is particularly beneficial when prolonged treatment is required for eczema involving the face—a common situation in atopic dermatitis. Coal tar or shale tar (ichthammol), usually applied as creams containing tar extracts or bandages impregnated with tar paste, can be soothing and reduce pruritus. Occlusive dressings and bandages may be useful.

In the most severe cases, systemic steroids may be required. These act rapidly, improving symptoms within a day or two, but they should be discontinued as soon as possible. Alternatives to steroids include ciclosporin, which also acts rapidly [5], and azathioprine, which has a more gradual onset of action [6]. Cytotoxic immunosuppressants such as mycophenolate mofetil, methotrexate and cyclophosphamide have also occasionally been used. All these systemic modalities require careful monitoring. Various modalities of phototherapy have been successfully used in chronic eczema, especially in atopic dermatitis. These include UVB and, more recently, narrow-band UVB [7,8], PUVA [9] and UVA1 [10]. PUVA is also used for hand and foot eczema, often with topical application of 8-methoxypsoralen. However, phototherapy is potentially carcinogenic. In carefully selected cases of severe hand or foot eczema, superficial radiotherapy (Grenz rays) is effective. This is also potentially carcinogenic and is probably best reserved for older patients.

Murray Williams' warts

Multiple seborrhoeic warts occurring in areas of resolved eczema have only occasionally been reported since the phenomenon was described by Williams in 1956 [1,2]. Multiple warts arise in the few months following resolution of the eczema and tend to gradually resolve by 5–6 months.

Lichenification

Lichen simplex

SYN. CIRCUMSCRIBED NEURODERMATITIS

Definition. Lichenification is a pattern of cutaneous response to repeated rubbing or scratching. It is characterized histologically by acanthosis and hyperkeratosis, and clinically by a thickened appearance of the skin, with accentuation of the surface markings so that the affected skin surface resembles tree bark (Fig. 17.31). It is common in patients with atopic eczema, but may also be secondary to other irritant dermatoses.

The term *lichen simplex* is used where there is no known predisposing skin disorder, whereas if the excoriation is initiated by a pruritic dermatosis, the term *secondary lichenification* is applied. In some patients, the lichenification may become self-perpetuating after the initial dermatosis has subsided, and so the distinction between

Fig. 17.31 Lichenification of the arm in a patient with atopic eczema.

primary and secondary lichenification is sometimes blurred.

Not all individuals are capable of developing lichenification. Patients with lichen simplex are more readily conditioned to scratch following an itch stimulus than control subjects [1]. Lichenification is a characteristic feature of the atopic state [2], but not all atopics lichenify, and lichenification is seen in many individuals who show no stigmata of atopy. There appears to be well-marked racial variation in the capacity of the skin to lichenify; the high incidence of lichenification in oriental people has often been emphasized.

In the predisposed subject, emotional tensions play an important part in favouring the development of lichenification and ensuring its perpetuation [3].

The borderline between lichenification and some prurigos is tenuous, both in nomenclature and in practice. Prurigo nodularis could also be called nodular lichenification.

Pathology [4,5]. The histological changes of lichenification vary with site and duration. Acanthosis and variable degrees of hyperkeratosis are usually observed. The rete ridges are lengthened. Spongiosis is sometimes present, and small areas of parakeratosis are occasionally seen. There is hyperplasia of all components of the epidermis [6]. The labelling index has been shown autoradiographically to be over 25%, but the transit time is longer than in psoriasis [7].

The dermis contains a chronic inflammatory infiltrate, and in very chronic lesions there may be some fibrosis. Silver impregnation techniques show proliferation of the Schwann cells, which may make up an appreciable proportion of the cellular infiltrate.

In very chronic lesions, especially in giant lichenification, the acanthosis and hyperkeratosis are gross, and the rete ridges are irregularly but strikingly elongated and widened.

Clinical features [5]. In all forms of lichenification, pruritus is the predominant symptom, and is often out of proportion to the extent of the objective changes. It may develop in paroxysms of great intensity. Scratching tends to give great satisfaction initially, but is then continued with violence until the skin is sore. There is then a refractory period of some hours until the itch recurs. During the early stages the skin is reddened and slightly oedematous, and the normal markings are exaggerated. The redness and oedema subside, and the central area becomes scaly, thickened and sometimes pigmented. Surrounding this central plaque is a zone of lichenoid papules, and beyond this an indefinite zone of slight thickening and pigmentation merges with normal skin. These features may be greatly modified by the site and duration of the lesion. In mild cases, follicular eczematous papules may be seen,

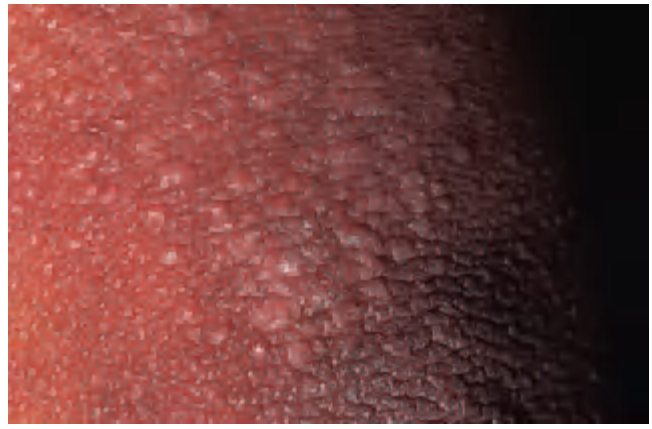

Fig. 17.32 Follicular papules of lichenification adjacent to the elbow.

Fig. 17.33 Lichen simplex. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

particularly on the forearms and elbow regions of children (Fig. 17.32).

Lichen simplex is uncommon in childhood. The peak incidence is between 30 and 50 years of age, but it is seen at any age from adolescence onwards. Women are affected more often than men. Single and multiple sites are involved with approximately equal frequency. Almost any area may be affected, but the most common sites are those that are conveniently reached. The usual sites are the nape of the neck, the lower legs (Fig. 17.33) and ankles, the sides of the neck, the scalp, the upper thighs, the vulva, pubis or scrotum, and the extensor forearms.

Lichen simplex of the nape of the neck, *lichen nuchae*, is almost confined to women. The plaque may be limited to a small area around the midline of the nape or may extend some distance into the scalp. Scaling is often profuse and psoriasiform, and episodes of secondary infection are frequent. The fold behind the ear may also be involved. Scaling, crusting and fissuring are more evident than the usual changes of lichenification. Other regions of the scalp are less often affected. The presenting manifestation is an area of scaling, with twisted broken hairs. The epidermal thickening may be great enough to form a nodule.

In other sites, the typical features of lichenification are usually retained, but if the subcutaneous tissues are lax, and excoriation continues for many years, solid tumour-like plaques may be formed, with a warty cribriform surface. This, the so-called *giant lichenification of Pautrier* [8], occurs mainly in the genitocrural region.

A localized patch of lichenification, *notalgia paraesthetica*, is described as a small patch of itchy lichenified skin most often observed at the inferior tip of the scapula.

The descriptive term *pebbly lichenification* has been applied to a distinctive clinical variant, consisting of discrete, smooth nodules, seen occasionally in atopic and seborrhoeic subjects, and in photodermatitis. Clinically it may simulate lichen planus.

A dermatomal pattern of lichen simplex chronicus has been described as the initial presentation of an intramedullary neoplasm with syringomyelia [9].

Secondary lichenification complicates persistent skin lesions of many types. It occurs on the lower leg in the presence of venous insufficiency, in atopic dermatitis, in asteatotic eczema, in low-grade chronic contact dermatitis and in some chronic infections with *Trichophyton rubrum*.

Diagnosis. The morphological diagnosis of lichenification is not usually difficult—lichen planus, lichen amyloidosus and psoriasis have to be excluded, and typical lesions should be sought in other sites. Sometimes, however, no conclusive diagnosis is possible on either clinical or histological grounds. A patient with psoriasis may occasionally develop lichen simplex that combines the histological features of both conditions.

Once the diagnosis of lichenification has been established, its causation must be carefully investigated. Symmetrical lesions in particular should suggest secondary lichenification of a contact dermatitis. More than one woman with formalin dermatitis of the base of the neck has been referred to a psychiatrist, when she should have been patch tested and advised merely to discard the offending article of clothing. Similarly, a chronic *T. rubrum* infection of the thighs or feet, with secondary lichenification, responds better to griseofulvin than to tranquillizers.

Treatment. If the lichenification is considered to be primary, a careful psychological history should be taken, and the patient given some assistance in reducing their tensions. The nature of lichen simplex and the need to break the scratching habit must be explained. Sedation is often needed, and sedative antihistamines may be helpful. A topical antibiotic may be prescribed for a few days if secondary infection is present. In most cases, a steroid cream is the treatment of choice.

On an arm or leg it is useful to apply an occlusive bandage that prevents scratching. For very chronic lesions the authors find tar paste medicated bandages very helpful. They should be renewed at intervals of 5–7 days. Self-adhesive steroid-impregnated tape (e.g. Haelan® tape) can often be effective. Alternatively, a potent steroid ointment under polythene occlusion, for short periods, may also be useful. Modest improvement has also been shown with 5% doxepin cream [10].

Circumscribed chronic lesions are often most effectively treated by dermal infiltration with triamcinolone (10 mg/mL).

Lichen striatus

SYN. LINEAR LICHENOID DERMATOSIS

Definition and aetiology. Lichen striatus is a self-limiting, inflammatory, linear dermatitis of unknown origin. The factors determining the linear distribution are unknown, as none of the proposed embryological, neurological and vascular hypotheses is applicable to all cases. It has been suggested that the lesions develop in the lines of Blaschko [1], which are thought to be caused by a form of human 'mosaicism' in which different groups of cells behave differently for reasons that are not yet clear. In a series of 26 patients, 80% were atopic [2].

Pathology [3–5]. The histological appearances are variable, but may be distinctive. They often resemble lichen planus, with a band-like infiltrate in the dermis and overlying epidermal changes. The earliest change is intercellular oedema stretching the tonofilament–desmosome complexes and separating the epidermal cells. Like the spongiosis, acanthosis is variable in degree. Dyskeratotic keratinocytes, like the 'corps ronds' of Darier's disease, are seen in approximately 50% of cases. There is focal liquefactive degeneration of the basal layer. The dermis is oedematous, and the vessels and appendages are surrounded by an infiltrate of lymphocytes and histiocytes, which may be quite dense and extend deeply. Scattered cells often penetrate the epidermis.

Clinical features [2,6]. Over 50% of cases occur in children, usually between the ages of 5 and 15 years, but onset in early infancy and in old age has been reported. Females are affected two or three times as frequently as males. Small pink lichenoid papules, discrete at first but rapidly coalescing, appear suddenly and extend over the course of a week or more to form a dull red, slightly scaly linear band, usually 2 mm to 2 cm in width, and often irregular. Occasionally, the bands broaden into plaques, especially on the buttocks. The lesion may be only a few centimetres in length or may extend the entire length of the limb, and may be continuous or interrupted (Fig. 17.34). Parallel linear bands or zosteriform patterns have been recorded.

The initial lichenoid papules are pink and not violaceous, and show no umbilication or Wickham's striae. The papules may be hypopigmented in dark-skinned people.

The lesions occur most commonly on one arm or leg, or on the neck, but may develop on the trunk. The abdomen, buttocks and thighs may be involved in single extensive lesions, but multiple lesions are rare, and bilateral involvement is exceptional. Involvement of the nails may result in longitudinal ridging, splitting, onycholysis or nail loss [7,8].

There are usually no symptoms, but pruritus may occasionally occur. The course is variable. The lesion usually reaches its maximum extent within 2 or 3 weeks, but gradual extension can continue for several months. Spontaneous resolution can be expected within 3–6 months in most cases, but some lesions may persist for over a year. Resolution may be followed by temporary hypopigmentation.

Diagnosis. Epidermal naevi, linear or zosteriform, may first appear in childhood or later, and the inflammatory linear epidermal naevus (see Chapter 15) in particular has many clinical and histological features in common with lichen striatus, but the naevi persist indefinitely. Linear forms of lichen planus and psoriasis can usually be differentiated clinically, even in the absence of typical lesions in other sites, which should always be sought. Linear porokeratosis must also be considered [9]. Biopsy may be helpful.

Fig. 17.34 Lichen striatus of the inner thigh in a girl aged 16 years. The histological changes were those of chronic eczema. (Courtesy of Dr R.A. Marsden, St George's Hospital, London, UK.)

Treatment. Usually none is necessary. In the unusual persistent case, infiltration with steroids may be effective. Nail involvement may respond to a potent steroid cream under occlusion.

Prurigo

Definition. This term is best used to denote a group of skin

diseases characterized by intensely pruritic papules or nodules.

The definition has been the subject of much debate. Some authors have stressed the intense pruritus, others have emphasized visible excoriations, and yet others have suggested that there should be no identifiable local cause for the scratched lesions.

The term was originally introduced by Hebra [1] to denote papules induced by scratching. This definition allows the inclusion of entities such as the papular urticaria caused by insect bites, where dermographism may also be present. Many of the original cases of *Hebra's prurigo*, described in Vienna in the 19th century, were probably atopic patients in poor social conditions. Flea bites may well have played a part in producing the papular lesions.

The archaic term *Besnier's prurigo* has been applied to the chronic lichenified flexural form of atopic eczema.

Nodular prurigo

SYN. HYDE'S PRURIGO

Definition. Nodular prurigo is characterized clinically by chronic, intensely itchy nodules and histologically by marked hyperkeratosis and acanthosis with downward projections of the epidermis. It is generally regarded as a variety of eczema. In many cases there is a history of atopic dermatitis or another form of eczema.

Aetiology [1]. The cause is unknown. Emotional stress seems to be a contributory factor in some cases and it can be difficult to determine whether this is the cause or a result of the prurigo. Approximately 65–80% of patients are atopic. In these patients, the age of onset may be earlier [2], even if no eczematous eruption is present. In 20% the condition starts after an insect bite [3].

Pathology [4,5]. The changes somewhat resemble those of lichen simplex, but the hyperkeratosis may be even greater, and the downward projections of the epidermis so marked as to suggest pseudoepitheliomatous hyperplasia (Fig. 17.35). The dermal infiltrate is dense, and there may be neural and vascular hyperplasia. These changes may arise, in part, as a non-specific reaction to repeated scratching [6]. In some cases the histology is that of chronic eczema. Mast cells are prominent, and there may be striking extracellular deposits of eosinophilic granule proteins such as major basic protein and eosinophil-derived neurotoxin [7], suggesting that mast cells and eosinophils may play a major part.

In the early literature, Pautrier described 'neuromas' in this condition, but these have not been seen in recent large series of patients [3,8]. However, there are increased numbers of calcitonin gene-related peptide and substance P immunoreactive nerve fibre bundles in the skin of the nodular lesions, and neuropeptides may play a part in causing the intense itching [9,10]. In 75% of cases an increase in the number of Merkel cells is also seen [11]. Such changes do not occur in the lesions of lichen simplex.

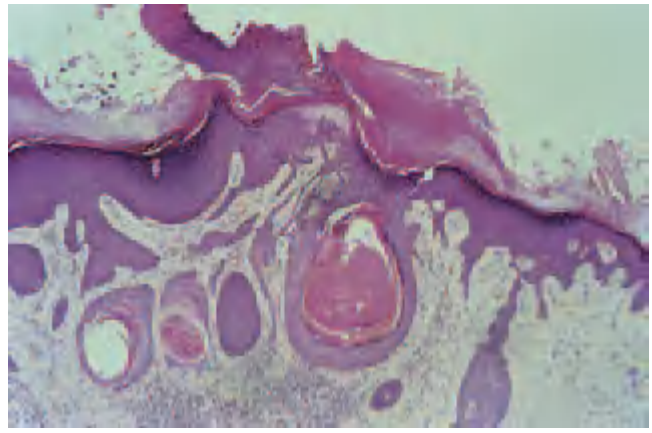

Fig. 17.35 Nodular prurigo. This shows gross accentuation of the changes found in lichenification. The epidermal downgrowth is pseudoepitheliomatous in extent. There is a mixed inflammatory cell infiltrate in the dermis and some sclerosis of the dermal collagen. H&E, × 40. (Courtesy of Dr M.G. Cook, Royal Surrey County Hospital, Guildford, Surrey, UK.)

Clinical features. Cases occur at all ages, but mainly from 20 to 60 years. Both sexes are equally affected. The individual lesions range from small papules to hard globular nodules, 1–3 cm in diameter, with a raised warty surface. The early lesion is red, and may show a variable urticarial component. Pigmentary changes are common. Crust and scale may cover recently excoriated lesions. The intervening skin often shows slight xeroderma, and there is often an irregular ring of hyperpigmentation immediately around the nodules. The number of lesions varies greatly and may be very large. The nodules may be arranged in groups. They usually develop initially on the distal parts of the limbs, and are worse on the extensor surfaces (Fig. 17.36). The trunk, face and even the palms can be affected.

The patient is tormented by crises of intense pruritus. New nodules develop from time to time, and existing nodules may remain pruritic indefinitely, although some may regress spontaneously to leave scars. The disease runs a very protracted course.

Diagnosis. The large, more-or-less symmetrical nodules, and the intense, often distressing pruritus are the key clinical features. These may also arise as a secondary event in a wide range of cutaneous and systemic diseases, which must be considered carefully before arriving at a diagnosis of idiopathic nodular prurigo.

Fig. 17.36 Nodular prurigo of the arm. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

Skin diseases that may mimic nodular prurigo include hypertrophic lichen planus, especially on the lower legs. The lesions are usually violaceous, and may be associated with more typical lichen planus lesions elsewhere. A variant of bullous pemphigoid called pemphigoid nodularis may present as nodular prurigo for some time before the typical urticated plaques and blisters supervene [12,13]. Immunofluorescence findings are those of pemphigoid, and the disease can be treated as pemphigoid with immunosuppressive therapy. Most cases occur in elderly women, but a juvenile form has been reported [14].

An unusual case of porokeratosis has been described in which some lesions, histologically demonstrating features of porokeratosis, clinically resembled prurigo nodules [15]. Cases are also described in association with oncocerciasis, leech bites, reactive perforating collagenosis and multiple granular cell tumours [1]. Allergic contact dermatitis may also result in a papulonodular eruption, and patch testing can sometimes be helpful [16].

Systemic causes of pruritus that can give rise to lesions resembling nodular prurigo include renal failure [17], liver disease [18], lymphoma [19] and HIV infection (see Chapter 26) [20]. Gluten-sensitive enteropathy has been found in some patients [21,22], but is not present in the majority [3,23].

Treatment. Measures used to reduce excoriation include cutting the nails very short, wearing gloves at night and occlusion of the involved regions of skin with bandages, dressings or steroid-impregnated tape. Sedative antihistamines are often used and are most helpful at night. Emollients may be helpful when xerosis is present. Topical steroids are not usually effective, but intralesional injection of triamcinolone can be beneficial. Topical capsaicin [24] has been used with success in some cases. Cryotherapy can be helpful but may result in pigmentary changes, especially in pigmented skin. Application of the sensitizer dinitrochlorobenzene (DNCB) improved nodular prurigo in one case [25].

Systemic agents, which can be highly effective, include thalidomide, although this is hazardous in fertile female patients because of teratogenicity. This drug can also induce a painful peripheral neuropathy [26,27]. Ciclosporin [28] and azathioprine [29] can also be highly effective, although the disease tends to relapse after the drugs are discontinued. Interestingly, ciclosporin also proved effective in a case associated with uraemia [30].

Nodular prurigo can respond well to PUVA, using local application of psoralen [31]. Oral PUVA is also used on occasions. A pleasing response has been reported to UVB [32], and narrow-band UVB may be effective alone and in combination with thalidomide [33].

Assessment of the patient's emotional state is desirable; antidepressants and tranquillizers can prove useful in selected cases [34].

Chronic prurigo of adults

SYN. CHRONIC PAPULAR URTICARIA; SUBACUTE PRURIGO; PAPULAR DERMATITIS

These terms are used to denote pruritic papular eruptions, which often appear rather similar to nodular prurigo except that the lesions are smaller and less elevated. Chronic prurigo is regarded as eczematous in nature although, as in the case of nodular prurigo, a similar clinical picture can arise in patients with systemic causes of pruritus. Another similarity with nodular prurigo is the association with stress and other psychological factors in some cases. Neurotic excoriation has previously been included as synonymous with subacute prurigo (see below).

Biopsy shows a non-specific dermatitis.

Treatment is similar to that of nodular prurigo and tends to be difficult. Soothing topical applications such as crotamiton or 0.5% menthol in aqueous cream are often used. Some patients respond well to a course of UVB or PUVA [1].

Prurigo pigmentosa [1–6]

Definition. Irritable red papules on the trunk and neck that fade to leave reticular hyperpigmentation.

Aetiology. The cause is unknown. Some cases have occurred in patients who were diabetic, dieting or anorexic, and it has been suggested that the associated metabolic changes, including ketosis, may have a role [7].

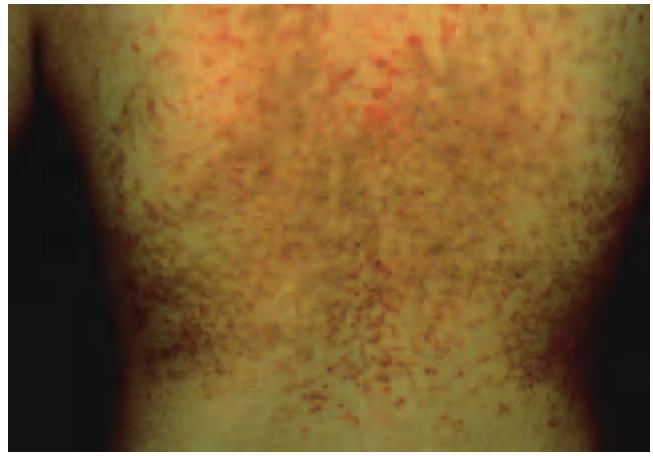

Fig. 17.37 Prurigo pigmentosa. (Courtesy of Dr M. Aso, Tottori University School of Medicine, Tottori, Japan.)

Pathology. The histology is non-specific, but often somewhat lichenoid. Immunofluorescence is negative. Occasional blood eosinophilia occurs.

Clinical features. The condition is rare in the Western world, but many cases have been described in Japan. The disorder is more common in adult females, with an onset in the spring and summer months. The characteristic lesions are found on the trunk and neck, and present as itchy red papules, sometimes with vesicles, which coalesce to produce a reticular pattern (Fig. 17.37). Later they are replaced by a reticular hyperpigmentation.

Diagnosis. This is based on the clinical and histological features. Patch testing may be helpful in excluding allergic contact dermatitis.

Treatment. Minocycline 200 mg/day appears to be the treatment of choice [1], as the pruritus and rash disappear within a week in most cases. About one-third of patients respond dramatically to dapsone. A prompt response to macrolide antibiotics has been reported [8]. Neither the rash nor the itching respond to oral antihistamines or topical steroids.

Prurigo of pregnancy [1,2]

This is regarded as a specific dermatosis of pregnancy (see Chapter 70). It occurs in about 1 in 300 pregnancies. In some cases it appears to be a manifestation of atopy. Pruritic papules and nodules develop on the abdomen and/or limbs, usually at 25–30 weeks of gestation. These may persist for several weeks after delivery. Skin biopsy reveals non-specific epidermal thickening, parakeratosis and a lymphocytic infiltrate in the upper dermis. Immunofluorescence is negative. The itch is usually improved by potent topical steroids and sedative antihistamines. The condition is not associated with any risk to the pregnancy.

Dermographic prurigo

This is a severe form of symptomatic dermographism in which urticarial weals and excoriations occur at sites of clothing pressure, especially around the edges of a brassiere or belt. There may eventually be some pigmentation.

Actinic prurigo

SYN. HUTCHINSON'S SUMMER PRURIGO

This is an uncommon photodermatosis (see Chapter 24).

Neurotic excoriation

This disorder, which predominantly affects middle-aged women who appear to be under emotional stress, has also been called subacute prurigo. This latter term is now more appropriately used synonymously with chronic prurigo of adults. It is not a satisfactory description of neurotic excoriation, as the lesions are excoriated erosions or ulcers rather than papules. This term should be reserved for cases where psychological factors are the primary cause of repeated excoriation. Neurotic excoriation is described further in Chapter 61.

Erythroderma

Definition. Erythroderma is the term applied to any inflammatory skin disease that affects more than 90% of the body surface. The term exfoliative dermatitis is used synonymously, although the degree of exfoliation is sometimes quite mild.

Table 17.9 Relative prevalence of erythroderma in adults.

Condition	Prevalence (%)
Hereditary disorders	
Ichthyosiform erythroderma	1.0
Pityriasis rubra pilaris	
Psoriasis	25.0
Eczema of various types	40.0
Drugs	
Especially organic arsenic, gold, mercury	10.0
Occasionally, penicillin, barbiturates, etc.	
Pemphigus foliaceus	0.5
Lymphoma and leukaemias	15.0
Other skin diseases	
Lichen planus	
Dermatophytosis	0.5
Crusted scabies	
Dermatomyositis	
Unknown	8.0

Incidence. A recent study from the Netherlands estimated the annual incidence at 0.9 per 100 000 population [1].

Aetiology [2–6]. The main causes of erythroderma in adults are listed in Table 17.9. The figures vary somewhat with the age of the population, and are based on several published studies. In younger people (e.g. military personnel) there will be a larger proportion resulting from drug allergies [6]. Drugs commonly causing erythroderma are listed in Chapter 73. In some communities the incidence of erythroderma may be higher because of self-medication and use of traditional remedies [7]. The use of herbal remedies such as St John's wort [8] may trigger this reaction.

The causes of erythroderma in the newborn are considered in Chapter 14. Other, rare causes of erythroderma include sarcoidosis [9], Hailey–Hailey disease [10], pemphigoid [11], toxic shock syndrome [12], lupus erythematosus [13], angioimmunoblastic lymphadenopathy [14] and dermatomyositis [15]. Graft-versus-host disease may progress to erythroderma in some cases. A related disorder was reported in Japan, where cases of fatal erythroderma occurred following major surgery. It was suggested that these cases were examples of post-transfusion graft-versus-host disease [16].

Erythroderma has rarely been reported with seroconversion following HIV infection [17]. In established AIDS, erythroderma can arise from a variety of causes. Some are examples of severe seborrhoeic dermatitis, others are associated with lymphoma, and some are of unknown cause [18]. However, it should be noted that $CD4^+$ T lymphocytopenia has been caused by erythroderma in the absence of HIV infection [19].

Males are affected between two and three times more frequently than females and, if the hereditary disorders and atopic dermatitis are excluded, most are over 45 years old.

Pathology. Histopathology can help identify the cause of erythroderma in up to 50% of cases, particularly if multiple skin biopsies are examined [20]. The histological appearances vary, depending upon the severity and duration of the inflammatory process. In the acute stage, spongiosis and parakeratosis are prominent, and a non-specific inflammatory infiltrate permeates, to a variable depth, a grossly oedematous dermis. In the chronic stage, acanthosis and elongation of the rete ridges become more prominent.

In erythroderma resulting from lymphoma, the infiltrate may become increasingly pleomorphic, and it may eventually acquire specific diagnostic features, such as a band-like lymphoid infiltrate at the dermal–epidermal junction, with atypical cerebriform mononuclear cells and Pautrier's microabscesses [21]. In other cases, however, it remains non-specific throughout its course, and the distinction can be difficult. Patients with Sézary syndrome often show some features of chronic dermatitis, and benign erythroderma may occasionally show some features suggestive of lymphoma.

Immunophenotyping of the lymphoid infiltrate may not solve the problem, as it generally shows features of mature T cells in both benign and malignant erythroderma [22].

In psoriasis, papillomatosis and clubbing of the papillary zones may be seen, and in pemphigus foliaceus, superficial acantholysis will be present. In ichthyosiform erythroderma and pityriasis rubra pilaris, repeated biopsies from carefully selected sites may reveal their characteristic features.

Clinical features. Erythroderma developing in primary eczema or associated with a lymphoma is often of sudden onset. Patchy erythema, which rapidly generalizes, may be accompanied by fever, shivering and malaise. Hypothermia may develop and a low-reading thermometer should be used to take the temperature.

The erythema extends rapidly and may be universal in 12–48 h. Scaling appears after 2–6 days, often first in the flexures, but it varies greatly in degree and character from case to case. The scales may be large, or fine and bran-like. At this stage the skin is bright red, hot and dry and palpably thickened. The intensity of the erythema may fluctuate over periods of a few days or even a few hours. Irritation is sometimes severe, but a sensation of tightness is more characteristic. Many patients complain of feeling cold, especially when the erythema is increasing.

When the erythroderma has been present for some weeks, the scalp and body hair may be shed and the nails become ridged and thickened, and may also be shed. The periorbital skin is inflamed and oedematous, resulting in ectropion, with consequent epiphora. In very chronic cases there may be pigmentary disturbances, especially in black people, in whom patchy or widespread loss of pigment is often seen.

The degree of enlargement of the lymph nodes in the absence of an underlying malignant lymphoma is variable. They are usually slightly or moderately enlarged and of rubbery consistency, but in some cases the enlargement may be gross. It is important that this dermatopathic lymphadenopathy is not mistaken for lymphoma. In difficult cases, lymph node biopsy may be advisable, but the pathologist must be told that the patient is erythrodermic for a reliable histological interpretation to be made.

The general picture is modified according to the nature of any underlying disease and the patient's age and general physical condition.

Eczemas. Generalization of an eczema occurs most frequently in the sixth and seventh decades when venous eczema is a common precedent. However, atopic erythroderma may occur at any age. Exacerbation of existing lesions usually precedes the generalization, which follows the usual pattern. Pruritus is often intense. Some elderly patients have increased serum IgE and lactic dehydrogenase levels, with eosinophilia [23].

Psoriasis. In generalized psoriasis, the clinical picture may also conform to the usual pattern, and when the exfoliative stage is fully developed the specific features of psoriasis are lost. In some cases, crops of miliary pustules may develop at intervals, and transition to generalized pustular psoriasis may occur, especially in cases treated with potent topical steroids or systemic steroids [24]. Emotional stress, intercurrent illness and phototherapy overdosage can also precipitate erythroderma.

Drugs. A wide range of drugs can cause erythroderma. Among the more commonly implicated are pyrazalone derivatives such as phenylbutazone, hydantoin derivatives, carbamazepine, cimetidine, gold salts and lithium [25]. The eruption may start as a generalized eczema, or scarlatiniform or morbilliform erythema, often accompanied by some irritation, which increases steadily in severity. Erythema may first appear in the flexures or over the whole skin (Fig. 17.38). This group has the best prognosis of all the causes of erythroderma [2,26], often resolving in 2–6 weeks [27].

Lymphoma, leukaemia and other malignancy. Cutaneous T-cell lymphoma is the most common malignancy to cause erythroderma, followed by Hodgkin's disease. Non-Hodgkin's lymphoma, leukaemias and myelodysplasia

Fig. 17.38 Widespread drug rash. This will rapidly progress to erythroderma if the drug is continued.

have also been reported. Association with other internal malignancies has been observed less often [5].

The clinical picture follows the pattern already described, but the accentuation of certain features should arouse suspicion that a lymphoma is associated, even if repeated investigations over a period of months fail to provide convincing confirmatory evidence. In many such cases, the underlying disease will eventually be detected. Pruritus is often very severe. The erythroderma is universal, and the infiltration of the skin may be so severe that the patient's features are deformed. Rubbing and scratching may produce secondary lichenification. Enlargement of the lymph nodes may be considerable, even if they are histologically not involved by the lymphoma.

Biopsy of involved skin may show only non-specific features initially and may need to be repeated several times before infiltration with atypical lymphocytes becomes evident. The use of a skin biopsy for analysis of T-cell receptor genes to determine whether clonality is present in the infiltrate may prove to be a useful investigation in these circumstances [28,29]. Lymph node biopsy may be diagnostic of lymphoma but often shows only the features of dermatopathic lymphadenopathy. There may be hepatosplenomegaly. A differential white blood cell count should be performed and the blood examined for abnormal cells. Eosinophilia may suggest Hodgkin's disease. Atypical lymphocytes with cerebriform nuclei, *Sézary cells*, are often observed in erythroderma regardless of cause. When they constitute more than 20% of the circulating peripheral blood mononuclear cells they become diagnostic of the leukaemic variant of cutaneous T-cell lymphoma known as the Sézary syndrome. Large Sézary cells (15–20 μm in diameter) are diagnostic even in small numbers [30]. The demonstration of a clonal T-cell population in the peripheral blood by analysis of T-cell receptor genes, using polymerase chain reaction (PCR), appears to offer high diagnostic specificity for Sézary syndrome. The sensitivity also appears high but on occasions the test may need to be repeated if initial results are negative and this diagnosis is still suspected [30].

Pemphigus foliaceus. Moist, crusted lesions on the face and upper trunk often precede the development of the erythroderma. Scaling is conspicuous, moist and adherent. Crops of thin-walled bullae may erupt, especially on the limbs.

Ichthyosiform erythroderma. This condition is usually present from birth or early infancy.

Pityriasis rubra pilaris. The erythrodermic forms can begin in childhood or adult life. The presence of follicular horny plugs on the knees and elbows and on the backs of the fingers and toes is distinctive. In many cases, islands of normal skin persist in the erythrodermic regions, and horny plugs may be evident around their margins. These normal pale 'islands' are very suggestive of the diagnosis, and the skin on the palms and soles often has an orange discoloration.

Lichen planus. Erythrodermic lichen planus is very rare, but lichenoid reactions to gold, quinine and other drugs are not uncommon. As the initial erythema and oedema subside, individual violaceous papules may be revealed. The buccal mucous membrane may show typical lacy, bluish white streaks.

Dermatophytosis. Generalized erythroderma has very rarely resulted from chronic infection with organisms such as *Trichophyton violaceum*.

Norwegian scabies. The heavily crusted hands and feet, with thickened nails, so characteristic of Norwegian scabies, may occasionally be accompanied by generalized erythema and scaling. The condition is often mistaken for erythrodermic psoriasis. The occurrence of scabies in others in the same environment, or in the medical or nursing staff caring for the patient, will soon make the diagnosis clear.

Erythroderma of unknown origin. The percentage of cases in which no underlying disease is demonstrable diminishes with the thoroughness of investigation and the duration of observation, but in any series of cases it is rarely below 10% [3,4,27]. The cutaneous changes may precede any other evidence of a lymphoma by many months or years. If these cases are excluded, the hard core of chronic erythrodermas of unknown origin consists mainly of elderly men, in whom the condition runs a very long course with partial and temporary remissions. These have been

labelled the 'red-man syndrome'. It is characterized by marked palmoplantar keratoderma, dermatopathic lymphadenopathy and a raised serum IgE [23,31]. It is important to note that this condition is not established erythrodermic cutaneous T-cell lymphoma, which is occasionally referred to as 'l'homme rouge'.

The three most common causes of idiopathic protracted erythroderma are probably atopic dermatitis of the elderly, intake of drugs overlooked by the patient and prelymphomatous eruptions [3].

Secondary haemodynamic and metabolic disturbances. Chronic generalized erythroderma is associated with profound metabolic disturbances [11,32–34]. The blood flow through the skin is markedly increased, and this can result in high-output cardiac failure, especially in elderly patients [35,36]. The increased skin perfusion may lead to hypothermia [37]. When the body temperature is raised, heat loss is further increased. The regulation of temperature is grossly disturbed, and the patient behaves like a poikilothermic animal, tending to adopt the environmental temperature. The excessive loss of heat leads to compensatory hypermetabolism and a raised basal metabolic rate.

Fluid loss by transpiration is much increased and is roughly proportional to the basal metabolic rate. The loss of exfoliated scale may reach 9 g/m^2 of body surface or more each day [38].

Hypoalbuminaemia is common, and probably has several causes. Dilution by increased plasma volume may be one cause [39], but is likely to be less important than a lowered total albumin mass caused either by a decrease in synthesis or an increase in metabolism [40,41]. There is also an increased protein loss via scaling and exudation. Oedema is common. Occasionally, the increased capillary permeability is severe enough to justify plasma infusions as well as parenteral steroids.

Immune responses may become altered, reflected by an increase in gammaglobulins; occasional patients have been described with very high levels of serum IgE [42], and $CD4^+$ T lymphocytopenia may occur in the absence of HIV infection [19].

Elderly patients living alone may already be malnourished prior to developing erythroderma. Any exudative or extensive scaling condition will intensify this.

Prognosis and complications. Erythroderma is a serious condition in itself, quite apart from hazards associated with the underlying disease, and is sometimes fatal despite skilled management. It is particularly dangerous in elderly people. Reported death rates have varied from 18 to 64% [2,4,6], but with modern therapy the rate is probably lower.

The more common forms of erythroderma—eczematous, psoriatic or of unknown origin—may continue for months or years, and tend readily to relapse [24]. As the patients are often elderly, the prognosis must always be guarded. The metabolic disturbances involve a serious risk of hypothermia, cardiac decompensation, peripheral circulatory failure and thrombophlebitis. Cutaneous, subcutaneous and respiratory infections are common, and the majority of patients who die do so from pneumonia [24].

The treatment can also be hazardous, especially when systemic steroids and immunosuppressants are required.

Diagnosis. The recognition of erythroderma is easy, but the diagnosis of the underlying cause may be very difficult. The difficulty of exact classification of some of these cases is illustrated by the report of seven patients with erythroderma who were followed for 3–16 years before they developed the Sézary syndrome (cutaneous T-cell lymphoma). Four of these patients had multiple contact allergies or drug reactions, and one had severe atopic dermatitis [43].

The history is often helpful in identifying the hereditary disorders, drug reactions and psoriasis, but in some cases the erythroderma is of sudden onset and the history may not be helpful. Multiple biopsies are usually, but not invariably helpful [44], and the eczematous erythrodermas and those associated with lymphoma may not show any distinctive histological features.

Treatment. Treatment in hospital is advisable, because some patients can develop serious general medical problems. In these cases, the protein and electrolyte balance, circulatory status and body temperature require continual surveillance. The environmental temperature must be carefully regulated. Cooling and overheating must both be avoided by the use of extra blankets or fans, respectively.

Urea and electrolyte levels and fluid balance should be monitored. Adequate fluid intake must be maintained, but if there is oedema, diuretics and/or plasma infusion should be considered. Cardiac failure must be treated if it develops.

The possibility that the erythroderma is caused by a drug reaction should be considered in every case, and all non-essential drugs should be withdrawn.

The cutaneous inflammation should be treated in the first instance with soothing emollient creams, or a mild topical steroid. The majority of patients will improve over a week or two on this regimen, during which time the diagnosis of the underlying condition will probably be established.

If active topical medication is applied it must be remembered that the barrier function of erythrodermic skin is greatly reduced. This is potentially hazardous because topical application of medications such as salicylic acid, corticosteroids or vitamin D analogues will result in much higher systemic exposure than might be expected in other circumstances.

Many dermatologists prefer to avoid systemic steroids if possible, because of the dangers of fluid retention, secondary infection and diabetes, but in severe persistent cases they may become necessary. There is some evidence that the use of systemic steroids or potent topical steroids in psoriatic erythroderma can provoke the development of pustule formation [24]. In such cases, low-dose methotrexate, acitretin or ciclosporin [33] may be safer alternatives. Topical tar and UV therapy should also be avoided on erythrodermic psoriasis.

Antibiotics are required to control secondary infection. Heng [45] has suggested that colonization of the skin by *Staphylococcus aureus* may actually cause erythroderma, which will clear with appropriate antibiotic therapy.

The optimum treatment of erythrodermic cutaneous lymphoma is still debated. Options include systemic steroids, PUVA, total body electron beam irradiation, topical nitrogen mustard and systemic chemotherapy [46]. The use of methotrexate has appeared beneficial in a retrospective study of 29 patients [47]. However, diagnostic histology was only obtained in 13 of these cases so they may have been a somewhat heterogeneous group. Extracorporeal photopheresis has been advocated [48], but it is not yet clear whether this prolongs survival.

Papuloerythroderma of Ofuji [1–5]

This distinctive pattern of erythroderma was described by Ofuji *et al*. in 1984 [1]. It differs from ordinary erythroderma in that papulation is prominent, it tends to spare the face and flexures, and it is consistently and often intensely pruritic.

It is not yet clear whether this represents a distinct disease or a reaction pattern. Although most cases have been seemingly idiopathic, several have been reported in association with other diseases.

Pathology. Histological features are usually non-specific. In the epidermis there are variable, but most often mild degrees of acanthosis, spongiosis, hyperkeratosis and focal parakeratosis. There is marked lymphohistiocytic infiltration of the dermis, predominantly perivascular in distribution, with a variable and often conspicuous number of eosinophils. A mild degree of epidermotropism has occasionally been observed and, rarely, plasma cells and multinucleate giant cells. Immunofluorescence is negative.

Clinical features. Papuloerythroderma has been observed entirely in an elderly population with ages at diagnosis ranging from 57 to 100 years. Many cases occur in the eighth or ninth decades. Males are predominantly affected, the male : female ratio being estimated at 4.7 : 1 [2].

The erythroderma typically begins with an eruption of brownish red, flat-topped papules, which become confluent (Fig. 17.39a). The limbs and trunk are affected but the face and flexures, especially axillary and inguinal regions, tend to be spared. A characteristic and distinctive pattern of sparing of the abdominal flexures has been termed the 'deck chair sign' [3], indicating the similarity to the distribution of sunburn in one who has been sitting out in a deck chair for too long (Fig. 17.39b). The lesions sometimes develop along scratch marks. Pruritus is a consistent feature and ranges from moderate to extremely severe. Additional features often observed include hyperkeratosis and fissuring of the palms and soles and benign lymphadenopathy.

There is usually circulating eosinophilia and a raised IgE. There is often a mild degree of absolute or relative lymphocytopenia.

Reports of papuloerythroderma occurring in association with malignancies, which have included T-cell [4,5] and B-cell lymphomas [5], gastric [5], lung [5], colon [6] prostate [2] and hepatocellular carcinomas [7], would suggest that this eruption may sometimes occur as a paraneoplastic phenomenon. There are also several reports that papuloerythroderma may progress to mycosis fungoides [2,8,9], in one case 11 years after the onset of symptoms [10]. In some cases, papuloerythroderma therefore seems to be a presentation of cutaneous T-cell lymphoma. One case developed into psoriasis [2]. Papuloerythroderma has also been reported in association with HIV infection [11,12] and, in one case, biliary sepsis [13].

Fig. 17.39 Papuloerythroderma of Ofuji. (a) The papules. (b) The 'deck-chair' sign (sparing of the body folds). (Courtesy of Dr M.J. Tidman, Edinburgh Royal Infirmary, Edinburgh, UK.)

Treatment. Emollients, topical corticosteroids and antihistamines have produced a slow response in some cases. The condition can respond well to oral prednisolone, although high doses are sometimes required. PUVA, including bath PUVA, has proved effective in several reports. Azathioprine [14], ciclosporin [15] and etretinate [16] may be effective. In view of the possible associations with malignancy and HIV infection, and as some cases progress to cutaneous T-cell lymphoma, the use of retinoids or PUVA would seem preferable to immunosuppressant drugs. However, papuloerythroderma is sometimes very refractory to treatment. It typically persists for many years but some cases have remitted.

Eosinophilic pustular folliculitis

The term eosinophilic pustular folliculitis has been used to describe several conditions characterized histologically by follicular and perifollicular inflammation containing numerous eosinophils. The original cases were described by Ofuji in immunocompetent Japanese patients [1]. Subsequently, the term was used for a rash with a different appearance in infants [2,3] and in immunocompromised patients on chemotherapy or with AIDS [4,5], or in patients who had received a bone marrow transplant [6]. These latter conditions are discussed elsewhere (see Chapters 26 and 59). Ofuji's variant is discussed here although its nosology is uncertain at present. Morphologically it is more like pustular psoriasis and subcorneal pustular dermatosis than eczema. The plaques in the Ofuji variant tend to be larger and more florid than the skin lesions in the immunocompromised patients.

Eosinophilic pustular folliculitis of Ofuji

Definition. This is an inflammatory disease characterized by the presence of plaques studded with numerous papules and sterile pustules in the seborrhoeic areas of the skin [1,7–10].

Aetiology. The cause is unknown.

Pathology. The inflammation is mainly centred on the hair follicles, which are infiltrated by eosinophils, with some neutrophils and mononuclear cells. There may be some degree of spongiosis and even destruction of the upper part of the follicle, to form a sterile eosinophilic pustule. The condition also affects the epidermis outside the follicles, where there is spongiosis and a tendency to form intraepidermal eosinophilic abscesses. There is a perivascular dermal infiltrate. Immunohistochemical analysis shows expression of adhesion molecules predominantly on follicular epithelium and perifollicular vascular endothelium. The authors suggested that these findings could explain the predominantly follicular distribution of the inflammation [11]. Chemotactic factors for eosinophils and neutrophils have been found in lesional stratum corneum extracts [12].

Clinical features. More than 90% of cases reported are from Japan and it is rare in other countries. Most non-Japanese patients have had the type associated with immunodeficiency or the infantile type, but some appear to have the Ofuji variant [10].

This disorder usually starts in adult life with pruritic circinate or serpiginous plaques, which are studded with follicular papules and pustules. There is a tendency to peripheral spread and central clearing. The lesions are located mainly on the face, trunk and extensor surfaces of the upper arms. Much less commonly, there is involvement of the palms and soles [13], and the term pustular folliculitis is then inappropriate. In severe cases, there may be scarring alopecia of the scalp [14]. There is a tendency for the disease to go into remission, followed by periodic exacerbations, which are accompanied by circulating leukocytosis and eosinophilia. When the inflamed plaques have reached a certain size, they tend to subside, leaving slight pigmentation.

Diagnosis. The condition can be confused clinically with other forms of folliculitis, follicular eczema, subcorneal pustular dermatosis or pustular psoriasis. The histology, however, is characteristic.

Treatment. The cases originally described by Ofuji [1] responded well to treatment with prednisolone, but this has not been true for all subsequent cases. Some patients have responded to dapsone [15], and others have responded to topical steroids, minocycline, oxyphenbutazone or IFN-γ [16]. In the AIDS-associated variant, some patients respond to permethrin cream [17] or oral itraconazole [18], but a few do not respond well to any treatment.

Chapter 18

Atopic Dermatitis

P.S. Friedmann & C.A. Holden

Definition

Atopic dermatitis is a difficult condition to define, because it lacks a diagnostic test and shows variable clinical features. The following definition seems to be in accord with most consensus groups. Atopic dermatitis (which is synonymous with atopic eczema) is an itchy, chronic or chronically relapsing, inflammatory skin condition. The rash is characterized by itchy papules (occasionally vesicles in infants), which become excoriated and lichenified, and typically have a flexural distribution. The eruption is frequently associated with other atopic conditions in the individual or other family members [1–3].

Atopy

One of the difficulties in defining atopic dermatitis arises from the impreciseness of its association with atopy and the nature of atopy itself. The word 'atopy' was introduced by Coca [4] in 1923 as a convenient collective term for a group of diseases, chief among which are asthma and hay fever, which occur spontaneously in individuals who have a family history of susceptibility. Later [5], reagin (IgE) antibodies were detected in these individuals, and could be transferred to normal individuals by the Prausnitz–Küstner (PK) test. The atopic diseases were once considered to be peculiar to humans, but it is now recognized that several species are susceptible. Atopic dermatitis and disorders resulting from anaphylaxis, for example those resulting from insect stings and food allergies, were found to be associated with IgE antibodies and therefore grouped with the atopic diseases. Such grouping is not completely acceptable, as 20–40% of individuals with atopic dermatitis can have a normal total or specific IgE level [6], and it is rarely attributable to a specific allergic reaction; the IgE antibodies present in the blood often appear to be incidental to the condition.

Recently, it has been debated whether the group with dermatitis and normal IgE levels can be distinguished clinically, immunologically and prognostically [7]. This subgroup has been variably termed intrinsic, non-atopic infantile eczema or atopiform dermatitis [8].

Terminology

This debate has added to the already wide variety of historical names for the condition. Currently, 'atopic dermatitis' and 'atopic eczema' are the most widely used. 'Besnier's prurigo' was used in continental Europe. Previously used terms include 'disseminated neurodermatitis',

spätexudatives Ekzem and *prurigo diathésique*. We suggest maintaining the use of the term 'atopic dermatitis' until the clinical relevance of dividing the disease into subgroups is confirmed.

Diagnostic criteria

Hanifin and Rajka [1] proposed major and minor diagnostic criteria based on their clinical experience. These criteria allow a uniformity of diagnosis for hospital-based and experimental studies but are not helpful for population-based studies [2]. The major criteria are found consistently in cases of atopic dermatitis, but the minor criteria are commonly found in control groups [3]. In addition, the criteria have not been validated against a physician's diagnosis or tested for repeatability.

In order to address these issues, Williams coordinated a UK working party to attempt to refine the criteria of Hanifin and Rajka into a repeatable and validated set of diagnostic criteria for atopic dermatitis [4–6] (Table 18.1).

These diagnostic guidelines appear to be valid for adults, children and non-white ethnic groups suffering from atopic dermatitis [6], and have been validated in a population setting [7]. They were primarily developed for epidemiological studies and, of necessity, exclude some signs that could be useful for diagnosis in individuals but are not common enough for use when assessing large populations.

More recently, other modifications of the diagnostic criteria have been proposed, but these have been less rigorously validated [8].

Table 18.1 The UK refinement of Hanifin and Rajka's diagnostic criteria for atopic dermatitis. (From Williams *et al*. [6].) Scabies should be excluded.

In order to qualify as a patient with atopic dermatitis with the UK diagnostic criteria, the child must have:
- An itchy skin condition (or parental report of scratching or rubbing in a child)

Plus three or more of the following:
1 Onset below age 2 years (not used if child is under 4 years)
2 History of skin crease involvement (including cheeks in children under 10 years)
3 History of a generally dry skin
4 Personal history of other atopic disease (or history of any atopic disease in a first-degree relative in children under 4 years)
5 Visible flexural dermatitis (or dermatitis of cheeks/forehead and outer limbs in children under 4 years)

Prevalence

Although it is accepted that atopic dermatitis is a common disease, precise measurement of its frequency is difficult, because different methods of assessment have been used. For example, some studies have based information purely on questionnaire results without objective validation of the quality of responses. Other studies have used clinical examination by dermatologists to supplement and confirm data from interview and questionnaire. Detailed reviews of the prevalence studies are to be found in McNally and Phillips [1] and Williams [2]. The International Study of Asthma and Allergies in Childhood (ISAAC) used cross-sectional questionnaires to sample school children of 6–7 years and 13–14 years in 56 centres throughout the world. A history of an itchy relapsing rash affecting skin creases in the previous 12 months was a main outcome measure.

Overall, from the ISAAC study data and many other studies, a pattern emerges that atopic eczema is most prevalent in the most developed 'Westernized' countries, and least prevalent in the most non-Westernized and underdeveloped countries. Thus, in Norwegian children from 7 to 13 years of age, the cross-sectional prevalence was 19.7% [3]. In Danish children up to 7 years of age, the lifetime prevalence was 22.9%, whereas in Germany and Sweden 13.1% and 15.5%, respectively, were reported [4].

In England, the point prevalence in 3–11-year-old children was found to be 11.5–14% [5], and the 1-year period prevalence was reported as 11.5% [6]. In Japan, figures of 9.5% and 20% have been reported for elementary school children and 3-year-olds, respectively [7,8]. By contrast, in Tanzania, the point prevalence in 7–8 year olds was found to be only 0.7% [9].

Studies of migrants show some interesting patterns. There are reports comparing the frequencies of atopic eczema in particular ethnic/genetic groups in their homeland with those in their adopted new homeland. For example, children who migrated to New Zealand from Tokelau have a much greater prevalence of atopic eczema than those in their country of origin [10]. Immigrant populations appear to develop a prevalence of atopic eczema even greater than that of the indigenous population of their adopted homeland. Thus, black Afro-Caribbean children residing in London were shown to have twice the prevalence (16.3%) of atopic eczema of their Caucasian counterparts (8.7%) [5]. A study from Sweden showed that immigrant Turkish children had a significantly higher prevalence of atopic disease (32.4%) than Swedish children (6%) [11].

These observations clearly reflect the fact that environmental factors play a large part in determining the expression of atopic diseases. The tantalizing question is whether the Westernized countries have an environment that actively promotes the atopic phenotype, or whether the underdeveloped world has factors that actively suppress the expression of the atopic phenotype.

There is accumulating evidence that the prevalence of atopic diseases in general and atopic eczema in particular have been increasing over the last three or four decades. Among the epidemiological experts, there is concern that changing methods of assessment and methodological errors may have distorted the true picture [12]. However, a composite picture from many studies suggests that the cumulative incidence in children up to 7 years of age was less than 3% if they were born before 1960, 4–8% for those born between 1960 and 1970, and 8–12% for those born after 1970.

In the elegant twin studies by Schultz Larsen, the cumulative incidence was shown to rise progressively from about 3% for twins born between 1960 and 1964, to 12% for those born between 1975 and 1979 [13,14]. Selnes *et al*. surveyed large numbers of Norwegian children (7–13 years of age) in 1985 and 1995, and found the cumulative incidence of atopic eczema had risen from 13.2% to 19.7% over the intervening 10 years [3]. The reasons for this steady rise in the prevalence of atopic diseases is not clear, but there are a number of possible environmental candidates (see below).

The consequence of the rising prevalence of atopic eczema is a heavy burden on medical services and budgets. In Britain, it has been estimated that the annual cost of atopic dermatitis is about £465 million [15], and in the USA, insurance payouts to cover the costs of atopic eczema have been estimated at between $0.9 and $3.8 billion [16].

Aetiology

Genetic factors

The importance of genetic factors in determining the expression of the atopic phenotype is reflected in data from twin studies. Thus, monozygotic twins have a concordance rate of 0.72, whereas dizygotic twins have a concordance rate of only 0.23 [1–3].

Recently, studies of genetic linkage have identified a number of genes related to the expression of different atopic syndromes, IgE levels, and cytokines relevant to the regulation of IgE levels. However, no gene of causal significance has yet been identified for atopic eczema. A gene predisposing to atopy, as defined by hyper-IgE responsiveness, was found on chromosome 11q13 [4,5], and it may encode the β chain of the high-affinity IgE receptor FCεR1β [6]. However, there appears to be no linkage of atopic eczema to this gene [7,8]. Genes on

chromosome 5q encoding the interleukin-4 (IL-4) gene cluster have been linked to atopic mucosal syndromes [9], but this linkage has also not been confirmed [10]. A gene at 16p11.2–12 encoding the α chain of the IL-4 receptor has been linked to atopy [11–13]. The gene encoding mast cell chymase has been linked to atopic eczema [14,15], but this association has not been confirmed [16]. Variants in the RANTES gene promoter-region have been reported to be associated with atopic eczema [17].

Maternal factors and inheritance

There is accumulating evidence that atopic disorders are more frequently transmitted by mothers than by fathers. A number of population-based surveys have shown that the risk of children developing atopy is significantly greater with an atopic mother than with an atopic father [1,2]. Cord blood IgE is high in babies whose mothers are atopic or have high IgE, whereas paternal atopy or raised IgE were not associated with raised cord blood IgE.

Genes encoding IgE responsiveness, located on chromosome 11q13, are more frequently inherited from the maternal side [3,4]. Thus, of 203 sib pairs analysed, 62% shared the maternal allele and 38% did not. Of the alleles that were paternal, the proportion shared with the offspring was close to 50%.

Pregnancy/intrauterine factors

The question arises of how maternal factors can modify the expression of atopy. One possible mechanism is through so-called genetic imprinting—in which paternal genomic effects are suppressed. Another possible mechanism is intrauterine programming—a major factor of which is the balance between fetal nutrition and growth rate. A number of non-dermatological conditions are programmed in fetal life. For example, death rates from coronary heart disease fell progressively between those who were less than 5.5 lb (2.5 kg) at birth and those who were more than 9.5 lb (4.3 kg) [5]. For atopy, there is a positive correlation between increasing birth weight and prevalence of atopic eczema [6–8]. A third possible factor is the onset of immunological sensitization through intrauterine exposure to food and environmental allergens. Cord blood IgE levels and the presence of antigen-specific T lymphocytes in cord blood indicate that immune sensitization occurs in fetal life. The concentration of IgE in cord blood is a predictor for subsequent development of atopy [9]. Maternal exposure to a number of agents, including antigens, alcohol, cigarettes and other pollutants, has attracted attention, but none has emerged as a major regulatory factor.

Environmental factors

The rate of increase in the prevalence of atopic eczema is too rapid to be accounted for by changes in population genetics. Therefore, environmental factors are the most likely modulating influences. The two principal aspects that have attracted attention are 'pollution' and microbes.

The fall of the Berlin Wall separating East and West Germany provided an opportunity to examine the role of industrial pollution by comparing the 'dirty' East with the 'clean' West. Cohorts of preschool children from comparable cities in the East (Halle) and West (Duisburg) and a rural area (Borken), were recruited in one study [1]. Questionnaires assessed the personal and family history of atopic disease, as well as many of the relevant factors such as socio-economic status. All of the children were examined by dermatologists. The levels of airborne pollutants were compared, and sulphur dioxide was fourfold higher in Halle, whereas dust and nitrogen oxides were comparable between the cities. The prevalence of atopic eczema was 17.5% in Halle, but only 5.7–7.3% in Duisburg. However, conflicting findings emerged in a study comparing the prevalence of atopic disease in Leipzig (East Germany) and Munich (West Germany). A slightly lower prevalence was observed in Leipzig compared with Munich [2]. The identification of relevant pollutants that might contribute to the expression of the atopic phenotype is still confused. Indoor pollution levels from cigarette smoke or nitrogen oxides in the gas exhaust from cookers and heaters are difficult to quantify.

Environmental microbes—the hygiene hypothesis [3,4]

Interaction with environmental microbes may be important in the causation of atopic eczema in a number of ways. Early-life exposure may condition the maturation of the immune system so that the apparent dysregulation associated with production of IgE antibody and formation of allergies does not occur. In individuals with the atopic phenotype, eczema may be induced or exacerbated by staphylococcal toxins or by the presence on the skin of *Malassezia* yeasts. The possible role of microbes in the early maturation of the immune system may be the major factor that could explain the differences between the Western world and the developing world regarding the incidence of atopy and allergic diseases. This idea was initially proposed as the 'hygiene hypothesis' [4]. Indirect support for this hypothesis derives from the observations that allergic sensitization is greatest in first-born and is less frequent in children from large families [4].

Many studies have examined the effects of particular organisms or routes of infection, and a preponderance of findings suggest that microbes entering via the faecal–oral route have a greater protective effect against the development of atopic allergic diseases than those entering via respiratory routes. Thus, early exposure to hepatitis A virus, *Helicobacter pylori* or *Toxoplasma gondii* is reported to reduce the risk of atopy by more than 60% [5]. By contrast, it seems that exposure to respiratory pathogens is not associated with this effect [5].

Significant differences have been observed in the prevalence of allergies between rural and urban areas within one country, which could also reflect different levels of exposure to microbes. Moreover, there are differences in the prevalence of allergic diseases among children living on farms and those living in the same rural environment, but not on farms [6–9]. This difference suggests that contact with livestock and poultry is a key factor, and although the levels of aeroallergens are likely to be higher in the farm environment, the levels of bacterial endotoxin are also much higher in the household dust from farms [8,10].

The potential importance of endotoxins lies in the powerful effects they can have in regulating the responses developed by the immune system (see below). The possibility that microbial endotoxins play a major role in driving the immune system towards 'productive'/protective responses and away from non-productive/nuisance responses associated with allergy, suggests that what matters is the total microbial burden to which the immature immune system is exposed, rather than particular infections. The effects of bacterial endotoxins on immune function will be discussed below in the section on immune dysregulation.

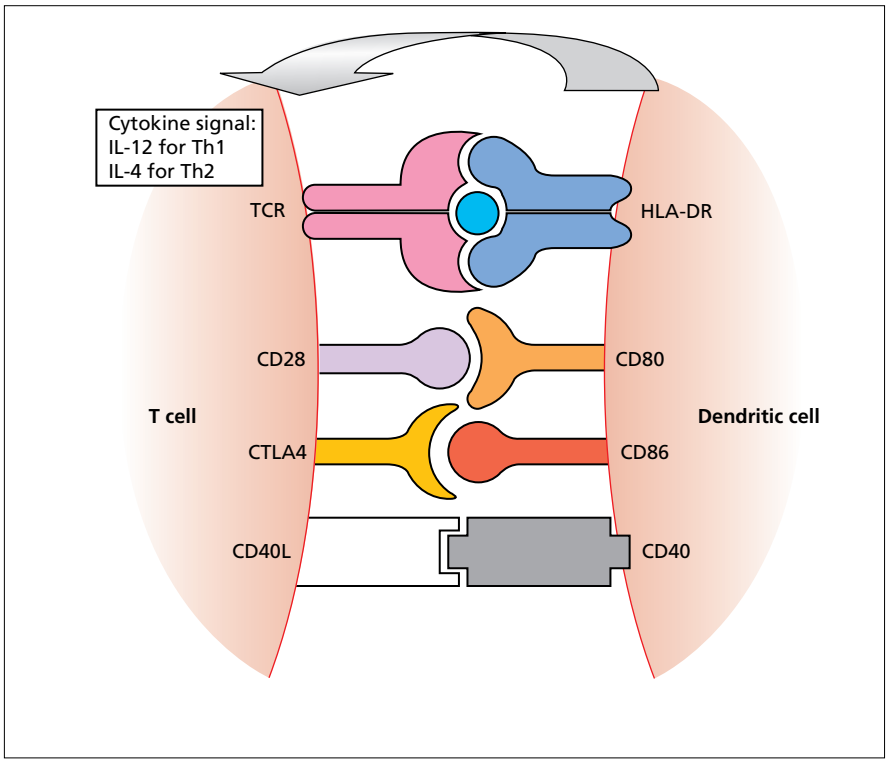

Fig. 18.1 Activation of naive T lymphocyte by interaction with dendritic antigen-presenting cell. Signal 1 comes from interaction of the T-cell receptor (TCR) with the complex of MHC class II and the antigenic peptide (blue circle) lying within its groove, on the surface of the dendritic cell. Signal 2 results from the interaction of co-stimulatory molecules (CD80, 86 and 40) on the dendritic cell with their counter receptors. CD28 is thought to give positive signals whereas CTLA-4 appears to give negative or inhibitory signals. Signal 3 is given by soluble cytokines including IL-1β and IL-12 which drive T-cell differentiation towards a Th1 phenotype, and IL-4 which favours differentiation towards the Th2 type.

Immune dysregulation

The defining characteristic of the atopic immune system is the capacity to generate IgE antibodies in response to allergens. The key disturbance to immune regulation that results in this IgE production appears to be the differentiation pathway followed by $CD4^+$ helper T lymphocytes. Naive precursor Th0 cells are induced to differentiate into Th2 cells, characterized by the production of interleukins (IL) -4, -5 and -13. Th2 cells 'help' or control the type of immunoglobulin (Ig) that B lymphocytes make, inducing synthesis of IgE.

Cellular mechanisms

The regulatory mechanisms that underlie the preferential development of Th2 cells appear to involve the interaction between dendritic antigen-presenting cells and $CD4^+$ helper T lymphocytes. The question arises of whether there is something different about the dendritic cells (DCs) of atopic individuals and the signals they give to T cells, or whether there is a defect in the T cells themselves.

Dendritic cells. Much work has gone into examining the mechanisms by which DCs regulate the differentiation of Th cells, and there is accumulating evidence that DCs may also subdivide into DC1, preferentially inducing Th1 cells, and DC2, inducing Th2 cells [1]. The critical stimulus, 'signal 1', is given during the presentation of antigenic peptides held in the groove of major histocompatibility complex (MHC) class II molecules (Fig. 18.1). Secondary signals ('signal 2') come via interactions of 'co-stimulatory' surface molecules such as CD80 and 86 on the DCs with their counter receptors CD28 and CTLA4 on the T cells. In murine systems, signalling via CD80 can preferentially induce Th1 differentiation, and CD86 can induce Th2 differentiation [2]. There is evidence that signalling through CD28 gives a positive activation signal, whereas signalling through CTLA4 may either give an inhibitory signal or activate T-regulatory cells which have inhibitory (suppressor) activities [3]. In addition, binding of CD40 ligand on T cells interacting with CD40 on the DC is one of the strongest signals for the T cell to produce interferon-γ (IFN-γ) and to differentiate towards a Th1 phenotype [4,5]. Cytokines released from the DCs give 'signal 3', which is also important in determining the final differentiation into Th1 or Th2 cells. IL-12 drives a Th1 response and IL-4 drives a Th2 response (Figs 18.1 & 18.2) [6–8].

There is little direct evidence that DC function is altered in atopic individuals. However, it has been observed that monocytes from atopic donors produce greater quantities of prostaglandin E_2 (PGE_2) and IL-10 than cells from non-atopic individuals [9,10]. PGE_2 can suppress production of IFN-γ, a cytokine which is not only produced by Th1 lymphocytes but which also favours the differentiation of naive Th0 cells towards the Th1 phenotype. Similarly, IL-10 is both a suppressive/regulatory cytokine and also drives Th0 cells towards a Th2 phenotype [11]. DCs from atopic individuals have yet to be shown to behave similarly.

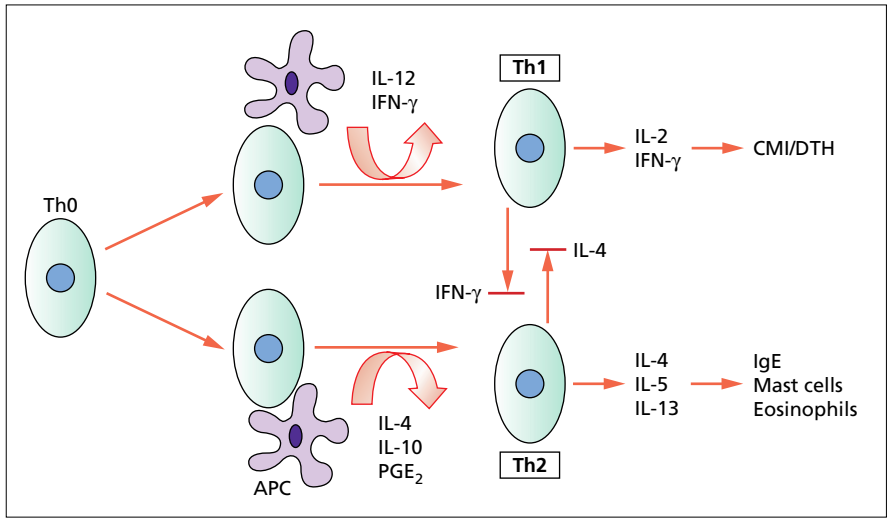

Fig. 18.2 Differentiation of helper T lymphocytes. Precursor Th0 cells have the potential to differentiate into either Th1 or Th2 type cells, depending upon the signals they receive during the interaction with dendritic antigen-presenting cells (APC) (see also Fig. 18.1). Depending upon the cell surface co-stimulatory molecule interactions and the presence of particular cytokines, the differentiation is directed. IL-12 is the critical determinant of Th1 generation, IL-4 and possibly IL-10 drive Th2 formation. Atopic monocytes (and hence possible dendritic cells) produce increased amounts of prostaglandin E_2 (PGE_2), which helps drive T-cell differentiation towards the Th2 phenotype.

A property of DCs in atopic individuals that has attracted much interest is the finding that they bear antigen-specific IgE on their surface [12,13]. The IgE is bound to the high-affinity receptor for IgE, FcεR1, normally found on mast cells and basophils [14–16]. There is controversy as to whether FcεR1 is expressed exclusively on DCs from people with atopic eczema, or whether it can be expressed in atopic individuals without eczema but with active 'allergic' disease such as asthma [16,17]. FcεR1 on DCs differs from that on mast cells and basophils in that it comprises the alpha and gamma chains, but lacks the beta chain [18]. This may alter its capacity either for expression on the cell surface or for activating intracellular signals [18]. FcεR1 is induced on DCs by IL-4 and possibly also by high levels of IgE. The surface-bound IgE on DCs has been shown *in vitro* to perform the function of 'antigen focusing' to allow DCs to present antigens to T cells much more efficiently. Thus, T cells can be activated to respond to one-hundredth to one-thousandth the amount of antigen [19]. However, it is not clear whether or how this is important in the pathogenesis of atopic eczema.

T lymphocytes. The fetal immune system is normally weighted towards generating Th2 responses, which is necessary to reduce the chance of the fetus and mother reacting against each other with subsequent spontaneous abortion. This is reflected by production of low basal levels of IFN-γ. In the postnatal period, the immune system appears to 'mature', and production of IFN-γ increases. However, in infants destined to develop infantile atopic

eczema, the basal production of IFN-γ is particularly low [1]. This could reflect an intrinsic defect in T-cell function.

There is evidence that activation signalling in T cells may be different in atopic individuals (see below). Thus, constitutional over-activity of cyclic adenosine monophosphate (AMP) phosphodiesterase is associated with blunted or attenuated cAMP-mediated signalling. This has been shown to tie in with differentiation of atopic T cells towards a Th2 phenotype [2]. In addition, T cells from atopic donors respond to allergens such as Der p1 from dust mites with an increased production of Th2-type cytokines and IL-13 in particular [3]. This could be blocked with an inhibitor of adenylate cyclase—the kinase which transduces cAMP-induced signals to more downstream targets. Paradoxically, it is also blocked by rolipram, an inhibitor of type IV cAMP phosphodiesterase, which, by inhibiting breakdown of cAMP, augments intracellular cAMP levels and therefore has the exact opposite effect of inhibiting cAMP breakdown.

The reasons why the atopic immune system responds with ready generation of Th2 lymphocytes are not clear, but a hypothesis attracting much attention is the so-called 'hygiene hypothesis' (see above). This proposes that exposure in early life to microbes of various types, but especially those possessing lipopolysaccharide (LPS) endotoxin, such as *E. coli* and other enteropathogens, is critical in pushing immune responses towards a Th1 type. The LPS activates production of IL-12 by DCs, which promotes production of IFN-γ and hence can deviate T-cell activation induced by any other antigen present at the same time towards a Th1 response.

Apart from alterations in immune regulatory mechanisms, the allergens themselves seem to evoke different responses in atopic individuals. Thus, both atopic and non-atopic people make IgG antibodies against *Candida albicans*, whereas house-dust mite antigen Der p1 evokes IgE antibodies in atopics but IgG antibodies in non-atopics [4,5]. It has been suggested that this property is related to the natural function of many allergens as proteases.

Immunoglobulins

IgE. The main immunoglobulin abnormality is increased production of IgE. This results in the presence of many antigen-specific IgE species to ingested or inhaled antigens and, frequently, an increase in total serum IgE. About 80% of patients with atopic dermatitis have increased amounts of total IgE. If dermatitis is the only clinical manifestation of atopy, the amounts of total IgE may be little above the normal range [1–3] and the patients show no anaphylactic sensitivity to environmental antigens [4,5]. However, even though total IgE levels may be normal, there are almost always specific IgEs directed at environmental aero- and/or food allergens. If there is concomitant asthma or allergic rhinitis, the concentrations of IgE may be very much above normal [2,3]. IgE also increases in amount with increasing severity and extent of the dermatitis, even without respiratory allergy, and patients with high levels are likely to have a poorer prognosis. The converse has also been demonstrated, in that persons who were free of classical signs of atopic dermatitis for a year had normal amounts of IgE, even if they had persistent or recurrent eczema of the hands, or discoid eczema [6].

The production of very large amounts of IgE equivalent to levels encountered in the hyper-IgE syndrome, may be induced by *Staphylococcus aureus* antigens [7]. Some staphylococcal exotoxins are superantigens [8], which activate a greater number of lymphocytes than those stimulated by specific antigen, resulting in a 'superstimulation' (Chapter 10). One manifestation is an excessive synthesis of IgE. Staphylococci colonize the skin of atopic dermatitis patients, and exotoxins with superantigen properties have been isolated from them [9,10]. One such exotoxin, the toxic shock syndrome toxin I, although inhibiting *in vitro* IgE synthesis by blood mononuclear cells at high concentration, was found to stimulate synthesis of IgE by the mononuclear cells of atopic dermatitis patients at low concentration. This pathway may have contributed to the increased IgE synthesis in this disorder [10].

IgE is involved in autoimmune reactivity in two ways. Firstly, it is an antigenic target for IgG anti-IgE antibodies, and secondly it can also be autoreactive, with specificity for self proteins. IgE occurs in serum in the form of immune complexes with IgG and C3, but the amounts of precipitable complexes are not related to the concentrations of serum IgE or to the severity of the skin condition [11,12]. As much as 32% of the serum IgE may be in the high-molecular-weight complexes [13], which should therefore influence the interpretation of serum IgE assays. IgE–anti-IgE complexes also occur, with antibody specificity to the CH_3 and the CH_4 IgE epitopes [12]. The ability of the free IgG anti-IgE antibodies to release histamine and other mediators from mast cells and basophils *in vitro*

varies. In some tests, no histamine was released [14,15], whereas in others histamine release occurred [16,17]. Similar autoantibody complexes occur in other atopic disorders.

Autoreactive IgE antibodies have been reported to be directed against self proteins, some of which may be skin-derived [18,19]. This autoreactivity probably develops secondary to the chronic exposure to skin-derived antigens. However, it is thought that once present, the autoreactivity may contribute to the chronicity and severity of the dermatitis.

Other immunoglobulins. The amounts of IgG, IgA and IgM in atopic dermatitis are usually normal, but increases have been reported, particularly in severely affected persons. However, in patients with severe eczema complicated by cutaneous infection, an increase in IgG appears to be due to antibodies to bacteria. In other cases, the increase is due to antibodies to food antigens. Any change in total IgG is considered to be a secondary or unrelated phenomenon, and not contributory. Furthermore, *in vitro* synthesis of IgG by blood mononuclear leukocytes was less than in cells from normal persons, and attributed to decreased responsiveness of atopic B cells [1].

Although total IgG usually remains within normal limits, some patients show an increase in the subclass IgG4 [2,3]. However, because this subclass is quantitatively the smallest of the four subclasses, the increase in IgG4 is unlikely to make a significant difference to the total IgG. IgG4 antibodies were specific for β-lactoglobulin [4] and for egg [5]. No clinical relevance was found on comparison of the amounts of IgG4 antibody with those of IgE, or with skin-test results [5]. In children with eczema complicated by asthma, IgG4 was much increased, usually with increases in total IgE [6,7]. Those who had an increase only in IgE or IgG4 did not have eczema, but asthma alone [6]. There is no clear evidence that IgG4 is anaphylactic—i.e. mediating mast cell responses on challenge with antigens—or that it contributes to the clinical changes of atopic dermatitis. It may be protective, because it has been shown *in vitro* that IgG4 will impede sensitization of basophils by IgE [8]—a conclusion supported by the finding of increased amounts of IgG4 and relatively small amounts of IgE anti-ovalbumin in children with atopic dermatitis [9].

It has been proposed that atopic subjects have an IgA deficiency which permits excessive absorption of allergen through mucosae, resulting in increased production of IgE. A modification of this theory is that the IgA deficiency may be transient, occurring for a few months early in infancy, and that the increased allergen absorption primes the individual to excessive production of IgE later in life.

The contention that a transient IgA deficiency in infants, particularly those born of atopic parents, predisposes the infants to increased production of IgE antibodies and atopic eczema later in life, led to the proposition that the atopic state could be avoided if the infants were not exposed to potent allergens during the susceptible period. The most common allergens are foods, for example milk and eggs, and elimination of potent food allergens for the first 6 months of life in high-risk infants is reported to reduce the incidence of eczema. However, allergen avoidance by breastfeeding and soya preparations has not been associated consistently with a decreased incidence of atopy, although in these reports complete avoidance is not evidenced during the critical period. Likewise, allergen avoidance by the mother during pregnancy and during breastfeeding has led to modest or equivocal benefit.

Pathogenesis of eczema—the role of allergy

There are many factors, including allergies, infections, emotional, climatic and other environmental influences that contribute to the causation of atopic dermatitis. In early life, atopic infants develop eczema as the first of the possible atopic syndromes, which include eczema, asthma and rhinitis. There is evidence that immune sensitization occurs to food-derived allergens as well as aeroallergens [1–3]. The infantile intestine shows increased permeability to macromolecules and this is greater in atopic infants. This may be due to inherent 'leakiness' and also, because of the transient deficiency of IgA, the IgA-mediated clearance mechanisms are less effective, allowing greater entry of food-derived macromolecules into the systemic circulation, where they may induce immunological sensitization. It is completely unclear why circulating T cells reactive with food antigens should home to the skin and generate an eczematous process rather than producing a gut-centred pathology. It may be hypothesized either that food-derived antigens somehow activate immature T cells to become skin-homing, or that skin-homing lymphocytes are stimulated as a result of their target antigens reaching the skin via the circulation. Perhaps because the epidermal permeability barrier is disrupted by the eczema, allowing penetration of environmental aeroallergens, during the first few years of life there is progressive development of immune reactivity to aeroallergens, reflected by the presence of specific IgE and T-cell responses [4].

The role of airborne environmental allergens both in the initial sensitization of atopic individuals and the subsequent elicitation of the clinical features is becoming clear. Environmental allergen levels are probably the major determinant of whether sensitization of genetically predisposed individuals occurs. Thus, children born just before the birch pollen season in Scandinavia have a higher risk of sensitization to birch pollen than those born after the season [5]. Babies born in autumn, when house-dust mite (HDM) numbers are highest, have a greater risk of sensitization by HDM [6], and avoidance of exposure to HDM and food allergens for the first year of life was associated with significant diminution in the proportions of clinically detectable eczema and asthma [7]. A recent Japanese study showed that if atopic babies (with detectable IgE antibodies to various foods but not HDM) were protected from contact with HDM by encasing their bedding in dust-proof bags, there was significantly less sensitization to HDM, reflected by IgE and prick test response [8]. However, it was not followed through to see whether there was a reduction in associated clinical problems. It has been proposed that the risk of becoming sensitized to HDM is greatly increased by exposure to dust containing 10 μg/g of Der p1, and that even 2 μg/g confers a significant risk [9]. It appears that, in some individuals, priming of immune responses to a range of allergens may happen during intrauterine development [10,11]. In others, the induction of sensitization appears to occur postnatally and during childhood. The sensitization is reflected by the presence of antigen-specific helper T lymphocytes and specific antibodies of IgE class.

The role of aeroallergens such as HDM in provoking or maintaining atopic dermatitis has been the subject of controversy and uncertainty. The presence of immune sensitization and allergic reactivity, reflected by the presence of positive responses to skin challenge administered in different ways, can be detected in the large majority of patients with atopic dermatitis. Prick testing with aeroallergens such as Der p1 or extracts of animal fur or pollens elicits a weal and flare response after 10–15 min. This is mediated by specific IgE antibodies on the surface of skin mast cells. When the IgE binds antigen, the mast cells are triggered to degranulate, releasing histamine and other mediators. Intradermal or epicutaneous patch challenge on tape-stripped skin elicits a triphasic allergic response [12,13] (Fig. 18.3). There is a 15-min immediate weal and flare due to histamine release from skin mast cells. There is a 'late-phase response' consisting of erythema and a deeper oedematous reaction between 6 and 24 h, and there is a delayed response at 48 h. After intradermal challenge, this is an erythematous papular reaction similar to a tuberculin test, but after patch challenge a classical eczematous reaction develops. The proportion of positive responses can be varied by more or less aggressive tape-stripping to disrupt the stratum corneum permeability barrier and by using higher concentrations of allergen [14]. This author (PSF) detected positive patch tests to HDM extract in up to 88% of adults and 60% of children older than 5 years. Others have used the so-called 'atopy

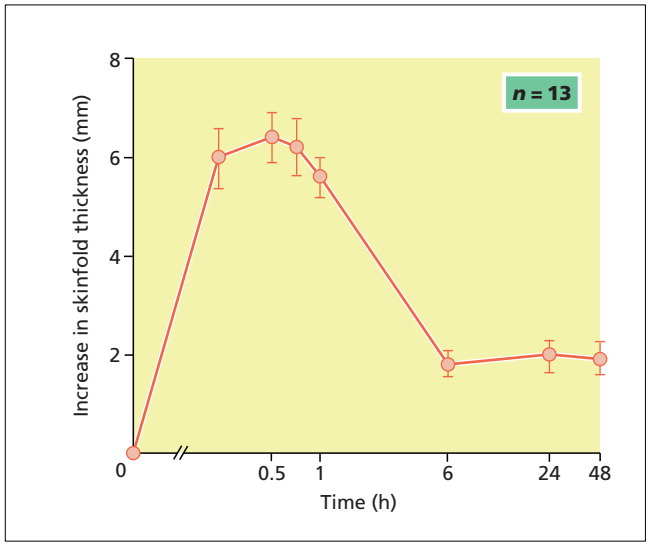

Fig. 18.3 Response elicited by intradermal inoculation of allergen (house-dust mite extract) in individuals with atopic dermatitis. A triphasic allergic response is seen, consisting of an immediate (15-min) weal and flare, a 6-h late-phase response and a 24–48-h delayed-type response. (Reproduced with permission from [12].)

patch test' without tape stripping and obtained positive responses to aeroallergens in about one-third of atopic eczema sufferers [15].

Patch test responses can be elicited in atopic eczema sufferers with a range of other allergens, including foods [16] and the ubiquitous skin surface *Malassezia* yeasts [17–19].

The eczematous response developing in allergen-induced patch test reactions has been used to model naturally occurring eczema for investigation of the role of T lymphocytes. From 8 h onwards, there is infiltration of $CD4^+$ T cells, 10–20% of which express $CD25^+$, the p55 chain of the IL-2 receptor, indicating that they have been activated through the T-cell receptor by contact with specific antigen. A number of workers have cloned the T cells in the first 12–24 h of such reactions and shown that they are predominantly of the Th2 type, producing IL-4 and IL-5 [20–22]. Also, up to 24 h after intradermal challenge with HDM, IL-4 and IL-5 production has been detected after amplification by polymerase chain reaction (PCR), but at later time points Th1 cells and their cytokines predominate [23–25]. In addition to the lymphocyte infiltration, there is heavy infiltration with eosinophils during the first 6–24 h of patch test challenge in atopic eczema sufferers.

The crucial question is whether allergic reactions induced by any allergen—aero or food—are of pathogenic importance in the causation of lesions of atopic eczema. The strongest evidence that this can be the case derives from studies of the effects of avoidance of house-dust allergens in the domestic environment. A placebo-controlled, double-blind study by Tan *et al*. [26] examined a combination of dust-mite eradication measures (sealed containment bags for the mattress, pillows and bedding top covers, a high-power vacuum cleaner and a spray containing agents to kill mites and denature their allergens). It was shown that highly significant reductions in Der p1 load in carpets and beds occurred. This was associated with great clinical benefits in both adults and children (over 6 years old) with severe atopic eczema. For unidentifiable reasons, these findings were not reproduced in a German study which used an essentially similar design [27].

The clinical relevance of allergy to *Malassezia* yeasts is indicated by studies showing that treatment with itraconazole to eradicate the yeast resulted in improvement of the eczema comparable with that obtained with betamethasone valerate [19]. Hence, there is some compelling evidence that allergic reactions to common allergens may play an important part in the pathogenesis of atopic eczema in many people. However, such reactions do not appear to account for the entire process, and the whole approach suffers from a lack of robustness in the tests to identify those individuals who would benefit from avoiding any particular allergen.

Pharmacological and vascular abnormalities

The small blood vessels in atopic dermatitis show a tendency to vasoconstriction responses:

1 Pallor of the skin after stroking—white dermographism
2 Delayed blanch with acetylcholine
3 White reaction to nicotinic acid esters
4 Abnormal reactions to histamine in affected skin
5 Low finger temperature
6 Pronounced vasoconstriction on exposure to cold.

None of these findings is pathognomonic. The delayed blanch phenomenon with acetylcholine [1–3] and related drugs is characteristic for atopic dermatitis, and occurs less regularly with other atopic disorders. Whether these pharmacological changes in atopic dermatitis are secondary to cutaneous inflammation, or whether the deranged pharmacology and the immune abnormalities are both secondary to a common defect, is not known. However, these patterns in vascular responses led to the so-called β-adrenergic blockade theory proposed by Szentivanyi [4]. Although this theory no longer remains tenable, it has led to observations of abnormalities in a range of intracellular second messenger signalling pathways. In atopic individuals, attenuated cAMP signalling results from overactive cAMP-phosphodiesterase, which is associated with several of the phenotypic features. The principal observations summarized by Hanifin and Chan [5] follow from the well-known increased IgE synthesis that characterizes atopic individuals. *In vitro*, this appears linked to reduced IFN-γ production by mixed peripheral blood mononuclear cells (PBMCs) from patients with atopic dermatitis. However, atopic T cells actually show increased production of IFN-γ *in vitro*; hence, it was concluded that the monocytes produce an inhibitor of IFN-γ synthesis. Atopic PBMCs produce increased amounts of PGE_2 and it is the monocytes which are the source [6]. It was shown by Betz and Fox that PGE_2 inhibits IFN-γ production [7], and Chan *et al*. showed that inhibition of PGE_2 with indomethacin results in increased IFN-γ production by atopic PBMCs [6]. Atopic monocytes also produce increased amounts of IL-10, which also inhibits production of IFN-γ [8].

Hanifin had previously shown that PBMCs from atopic subjects have blunted cAMP responses to agents acting on adenylate cyclase such as histamine, isoprenaline or prostaglandins [9]. This was found to be a result of elevated cAMP-phosphodiesterase (PDE) activity [10], so the cAMP was hydrolysed more completely. These abnormalities were also present in people with respiratory atopic disease. Sawai *et al*. [11] showed that there was no correlation between cAMP-PDE activity and severity of eczema. The abnormality has also been shown to be present in cord blood from babies with atopic parents [12,13].

The elevated cAMP-PDE activity was shown to be located predominantly in monocytes [14]. Chan and colleagues went on to type the PDEs in atopic leukocytes [15]. They found that three isoforms were common to both monocytes and lymphocytes, and all were more active than in cells from non-atopics. However, the atopic monocytes had an additional isoform which was specific for cAMP and was calcium/calmodulin-dependent. Also, the PDE was more susceptible than control PDE to inhibition by Ro20-1724—an inhibitor of PDE type 4 [15,16]. It should be noted that Gantner *et al*. found no differences between PDE expression or activity in cells from healthy and atopic blood donors [17].

One aspect which makes interpretation of data about levels of PDE activity difficult is that PDE activity is subject to modulation by various factors. Thus, PDE activity is induced by stimuli which increase cAMP, such as long-term administration of β-adrenergic agonists. This has clouded the question of whether elevated PDE is found in atopic asthma, as most patients receive chronic therapy with these agents. In monocytes from healthy subjects PDE activity is increased by cytokines IL-4 and IFN-γ [18]. However, in monocytes from atopic dermatitis patients, IFN-γ at low concentrations was without effect and at higher concentrations it reduced PDE activity [18]. This difference may be because in atopic cells PDE activity is already maximally induced.

The PDEs form a family of at least seven groups [19]. The different types vary in their affinity for cAMP or cyclic guanosine monophasphate (cGMP), their susceptibility to

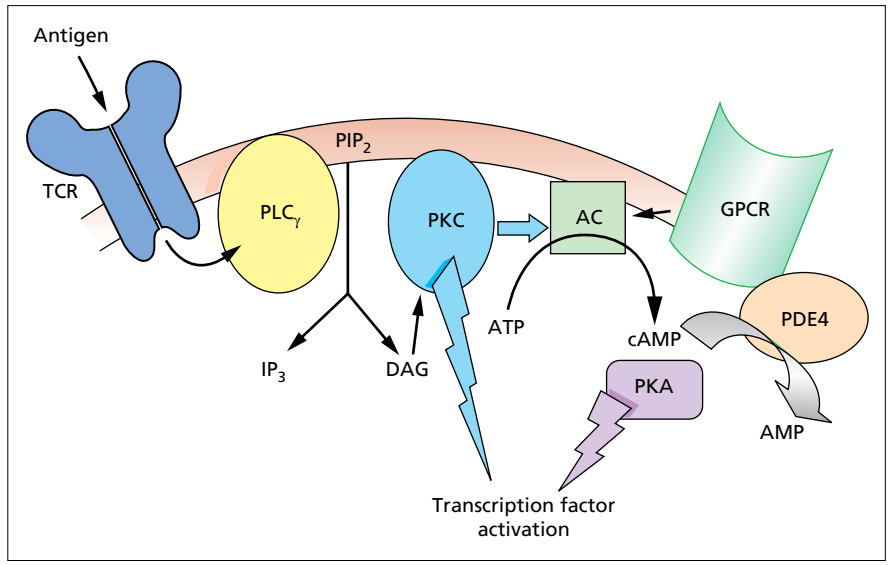

Fig. 18.4 Intracellular signalling that interacts with cAMP in T cells. The T-cell receptor (TCR) receives activating signals from the dendritic antigen-presenting cell. It activates phospholipase Cγ (PLCγ) which cleaves membrane phosphatidyl inositol bis-phosphate (PIP_2) to diacylglycerol (DAG) and inositol triphosphate (IP_3). The DAG activates protein kinase C (PKC), which activates a variety of targets, including transcription factors. It can also activate adenylate cyclase (AC), which generates cAMP. Membrane receptors that are coupled to G proteins (G protein-coupled receptors, GPCR) activated by their ligands signal via generation of cAMP which in turn activates protein kinase A (PKA). cAMP is degraded by the actions of cAMP phosphodiesterase type 4 (PDE 4), which is constitutively overactive in atopic cells. This attenuates or switches off cAMP signalling which may alter the balance of 'cross-talk' between different signalling pathways.

different inhibitors and, in some cases, in their cell/tissue distribution. Type 4 PDE (PDE 4) is cAMP-specific and was characterized by inhibition by rolipram and Ro20-1724. PDE type 4 is present in inflammatory cells—mast cells, eosinophils, monocytes, macrophages and lymphocytes.

Several activities of mononuclear cells are mediated via cAMP and can be reduced by inhibitors of PDE 4: increased PGE_2 production [8]; spontaneous IgE production by B cells [20] and release of histamine from basophils [8]; increased spontaneous production of IL-10 is reduced, as is the anti-CD3-induced increase in IL-4 production [8,21]; migration of eosinophils [22]; *in vitro* transmigration of lymphocytes, but not monocytes, through a monolayer of endothelial cells [23]; allergen-induced release of IL-5 [24].

cAMP is a second messenger that lies in the midst of a network of pathways (Fig. 18.4). Different signalling mechanisms are involved, depending on which cell surface receptors are activated. The T-cell receptor activates phospholipase Cγ, which in turn cleaves phosphatidyl inositol bis-phosphate to release diacylglycerol (DAG) and inositol tris-phosphate (IP_3). These moieties can both act as further signals in different directions; IP_3 activates release of calcium from intracellular stores, DAG activates protein kinase C (PKC). PKC can activate adenylate cyclase, generating cAMP which activates protein kinase A (PKA). The intensity of the effects of cAMP are blunted through the overactivity of PDE 4 (see above). The inositol pathway of peripheral blood mononuclear cells shows evidence of chronic activation and hyporesponsiveness to subsequent stimulation [25,26]. Apart from the clear evidence of the effects of the altered second messenger signalling in T lymphocyte differentiation towards a Th2 type (see above and [27]), the further importance of these processes in the wide range of vascular, neural and immune alterations in atopic eczema has yet to be elucidated.

Neuropeptides

Neuropeptides mediate vasodilatation, oedema, itch and pain, the axon-reflex flare, sweat gland secretion, and have some, probably minor, ability to regulate T-cell activation [1]. Vasoactive and proinflammatory neuropeptides mediate tissue change and sensory stimuli in perturbed skin (Chapter 9). Theoretically, neuropeptides could have a significant role in many of the features of atopic dermatitis, including the vascular changes, the itch, the symptoms associated with sweating and the leukocyte infiltration. The neuropeptides which have been studied in the lesions are substance P (SP) and calcitonin gene-related peptide (CGRP), often present together in unmyelinated C sensory fibres, somatostatin (SOM), vasoactive intestinal polypeptide (VIP), which coexists with acetylcholine in postganglionic sympathetic fibres, and neuropeptide Y (NPY) in adrenergic fibres. Assays of skin extracts have shown greatly increased amounts of VIP in atopic lesions [2–4], and reduced amounts of SP [3,5], although SP has also been reported to be unchanged in comparison with normal controls in one study [2].

Immunohistochemical examination has revealed NPY-positive dendritic epidermal cells in lichenified atopic dermatitis lesions, but no somatostatin fibres. Healthy normal control skin showed the opposite—no NPY dendritic cells, but a normal network of somatostatin fibrils [6]. Elsewhere, it has been reported that NPY fibres (adrenergic) are fewer than normal, but CGRP and SP (sensory) fibres are increased in number [7].

The skin of atopic dermatitis patients shows altered reactivity to injections of neuropeptides. Intradermal injection of SP induces a weal and flare response—at low doses, this is the result of direct effects on vasculature, whereas at higher doses, SP induces degranulation of mast cells with histamine-mediated weal and flare. Contradictory findings have been reported regarding cutaneous responses to injection of SP in atopic individuals. Coulson and Holden [8] observed greater weal volumes in atopics than in non-atopics, with no difference in the area of flare. In another study, although injection of SP elicited weals of similar size, there was less flare in atopic dermatitis skin than in controls [9]. Injection of neuropeptides was also reported to induce less than normal weal and flare responses [10].

Apart from effects on vascular reactivity and pruritus, neuropeptides can play a part in recruitment of granulocytes by up-regulating expression of adhesion molecules, including VCAM-1 on endothelial cells [11]. They can also modulate lymphocyte function *in vitro*. Thus, SP augments production of IFN-γ and IL-4 by lymphocytes from atopic donors but has little effect on cells from non-atopic donors [1,12]. VIP had no effect on lymphocyte cytokine production [12]. Hence, neuropeptides may contribute to the complex mix of factors regulating lymphocytes in atopic dermatitis.

Pruritus

The major symptom that accompanies the rash of atopic eczema is pruritus. The mediators and mechanisms responsible for this symptom are still totally obscure. Symptoms of itching are induced in patients with atopic eczema by stimuli that induce sweating, both thermal and emotional, as well as contact with fibres, especially wool. Clues regarding mediators come from the effects of therapeutic agents with defined mechanisms of action. Thus, despite the general presumption that mast cell degranulation via IgE-mediated allergen-specific mechanisms is important in atopic eczema, antihistamines generally have little effect on the pruritus of atopic eczema [1]. The older, sedating H_1 antagonists may improve the subjective comfort through sedation and deeper sleep. Ciclosporin (cyclosporin) causes very rapid cessation of the pruritus—which might indicate the involvement of T-lymphocyte products such as cytokines. However, ciclosporin has effects on cells other than lymphocytes, and may inhibit formation of prostaglandins [2]. As described above, responses to neuropeptides appear altered in atopic eczema. Neuropeptides such as SP, VIP, SoM and neurotensin provoke itch together with neurogenic inflammation in the form of erythema and weal and flare [3]. Capsaicin depletes nociceptive nerve endings of CGRP and SP and is reported to reduce pruritus in atopic eczema [4]. Acetylcholine (ACh), the archetypal neurotransmitter, activates both vasodilatation and sweating. ACh is also produced *in vitro* by keratinocytes [5]. ACh levels are raised in lesional skin of atopic eczema, and intradermal injection of ACh elicits pruritus rather than pain in patients with atopic eczema [6]. However, use of anticholinergic agents for treatment of the pruritus of atopic eczema has not become a useful therapeutic measure.

It has been suggested that opioids may play a part in the pruritus of atopic eczema; indirect evidence for this comes from the observation that opioid receptor antagonists such as naloxone or nalmefene can reduce pruritus [7]. However, others have failed to reproduce this observation [8].

Proteases, including tryptase and chymotryptase, are released by mast cells, and it has been proposed that they play a part in causing pruritus. Intradermal injection of mast cell tryptase elicits pruritus, erythema, leukocyte infiltration and oedema [9]. Proteases exert a range of effects through activation of protease-activated receptors (PARs), including PAR-2 in particular [10]. PAR-2 receptors are found on endothelial cells, sensory nerves and keratinocytes, and play a part in the inflammatory process resulting from mast cell degranulation. With greater availability of PAR-2 antagonists for use in clinical situations, it will be easier to assess the functional importance of these receptors.

There has been speculation that cytokines may contribute to the pruritus of atopic eczema. Cytokine-rich supernatants from mitogen-stimulated lymphocytes can induce pruritus when injected into atopic eczema sufferers but not healthy controls [11,12]. A wide range of cytokines are released in atopic eczema. They include IL-2, 4, 5, 6, 8, 10, 13, IFN-γ and tumour necrosis factor-α (TNF-α). Most of these have been injected into human skin without producing significant pruritus. The exception is IL-2 which can produce redness and itching when used in therapy of malignancy [13]. A possibility that has not been explored is that of synergism between some of the above mediators—say cytokines and neuropeptides.

Sweating

Many patients are aware that sweating induces itching and aggravates their condition. This may reflect altered sensations associated with the neuropeptides released in the neurogenic control of sweat glands. Altered inflammatory responses to ACh are described above, and increased numbers of nerve fibres have been described around the sweat glands in atopic non-lesional skin compared with lesional and healthy control skin [1]. Sweating responses to neurogenic stimuli are altered in atopic eczema sufferers, although there is some lack of agreement between findings, and diverse methods have been used to quantify sweat production. Sweating in response to cholinergic stimulation was found to be reduced in volume by one group [2,3], but normal in volume, although of more prolonged duration, by another group [4]. A possible explanation for differences comes from the study of Eishi *et al*. [5], who measured both direct cholinergic effects on sweat glands and distant effects mediated via the axon reflex. They found that directly induced sweat production hardly differed from that in healthy controls, whereas axon reflex-induced sweating was of lower volume with a longer latency. In a study of the response to adrenergic stimulation, sweating was similar between atopic eczema patients and non-atopic controls at low concentrations of epinephrine (adrenaline), but at higher concentrations sweating in non-atopic individuals was increased, whereas in atopic eczema patients it was decreased [6]. Sweating in response to the thermal stress of sitting in a heated room was found to be reduced in atopic eczema patients [7]. However, there was no difference in sweating responses induced by hard cycling on a bicycle ergometer between atopic eczema sufferers and healthy controls [8].

Another way in which sweating may induce itching and aggravate the eczema is related to the observation that there seems to be an IgE-mediated allergic reactivity to components of sweat [9]. Thus, skin challenges with autologous sweat induced positive responses in 56 of 66 (84%) patients, compared with three of 27 (11%) healthy controls. Also, basophils were induced to release histamine in an IgE-dependent process [9]. The nature of the reaction-inducing substances is completely obscure.

Psychological factors

It is a common clinical experience that patients with atopic dermatitis complain that their condition is exacerbated by episodes of psychological stress. This is also found in many inflammatory dermatological conditions. One demonstration that psychological stress modulates immune/inflammatory processes is by Buske-Kirschbaum *et al*. [1]. They showed that formal stressing of people who experience recurrent herpes simplex lesions could significantly increase the recurrence rate of cold sores, and there was also a rise in plasma levels of TNF-α. The role and mechanisms of psychosocial stress on the clinical course of atopic dermatitis still remain to be elucidated. When volunteers are subjected to formal stress tests in the form of public speaking and performance of mental arithmetic, a wide range of endocrinological changes occur. These include increased production of epinephrine, adrenocorticotrophic hormone (ACTH), corticotrophin-releasing factor (CRF) and cortisol, and reduced production of growth hormone, prolactin and progesterone [2]. The stress-induced rise in free cortisol is reportedly lower in patients with atopic dermatitis [3]. White blood cells and various cytokines also change in response to stress tests: increases in lymphocyte, monocyte, neutrophil and basophil numbers were seen 10 min after the stress provocation test, and were equal in atopic individuals and healthy controls [4]. Also, although IFN-γ increased and IL-4 decreased in both control and atopic groups, atopic individuals showed a significant increase in eosinophils and IgE in response to stress [4]. Fjellner *et al*. examined itch in response to intradermal inoculation of histamine, but found there was no demonstrable effect of stress [5].

Another humoral influence that appears to modulate atopic dermatitis is mediated by the sex steroids. One-third of 133 patients questioned claimed there was a significant premenstrual flare of atopic eczema [6]. Pregnancy exacerbated eczema in 52% of women, whereas it ameliorated eczema in 24% [6]. It has been proposed that a possible mechanism by which sex steroids alter susceptibility to inflammatory skin diseases is by modification of sensitivity to anti-inflammatory effects of glucocorticoids. In a comparison of differences in susceptibility between men and women, Rohleder *et al*. [7] stressed volunteers as

above; women were tested in the luteal phase of the menstrual cycle. Sensitivity to glucocorticoids was assessed *in vitro* by measurement of dexamethasone inhibition of LPS-stimulated production of IL-6 and TNF-α. Salivary cortisol levels increased equally between the sexes. However, in men, glucocorticoid sensitivity was markedly increased 1 h after stress, whereas it decreased significantly in women. Similarly, LPS-induced cytokine production decreased in response to stress in men, but increased in women. It is not clear whether this is the result of the increased cortisol production suppressing cytokine production in men or of a change in responsiveness to LPS itself. Hence, the premenstrual flares of atopic eczema could reflect the reduced sensitivity to the anti-inflammatory effects of endogenous cortisol.
