The most commonly used treatments for warts involve destruction of the area of epidermis infected with the virus. Such treatments may involve application of topical preparations or surgical approaches. Other therapies aimed at modifying the growth of the epidermis or stimulating an immune response require either a topical or a systemic approach. Where treatment trials have been placebo-controlled, a 30% response rate is generally observed for placebo treatment.

Salicylic acid. The keratolytic effect of salicylic acid helps to reduce the thickness of warts and may stimulate an inflammatory response. A preparation containing 12–26% salicylic acid, possibly with additional lactic acid, in a quick-drying collodion or acrylate base, is the treatment of first choice for common and plantar warts. Daily use in a comparative study for 3 months achieved cure rates of 67% for hand warts, 84% for simple plantar warts and 45% for mosaic plantar warts, comparing favourably with other methods including liquid nitrogen [4]. A review of six placebo-controlled trials confirmed this impression, with 75% cured compared with 48% of placebo-treated patients [2]. Removal of surface keratin and the remnants of the previous application by gentle use of a pumice stone, emery board or foot file is a helpful preliminary in all warts and essential in very hyperkeratotic plantar warts. However, overenthusiastic abrasion is a common, if understandable, mistake that may enhance spread of the virus by inoculation into adjacent skin. It is conceivable that abrasion of warts may help to stimulate an immune response [5]. Accurate application of a salicyclic acid preparation, avoiding normal skin, may require a fine applicator such as a sharpened matchstick or a cocktail stick, and will minimize subsequent local discomfort. After drying, a whitish deposit remains. Penetration into thick keratin, as on the sole, is enhanced by adhesive plaster occlusion, which promotes maceration of the keratin layer and a reduction in barrier function. Occlusion can improve the response rate for treatment with salicylic acid [6].

These preparations are not suitable for anogenital warts. They can be particularly irritant on facial skin, though especially careful application or the use of weaker formulations, such as 4% salicylic acid in flexible collodion, may be successful.

Collodion contains colophony, which may cause allergic contact dermatitis. Long-standing warts have been observed to disappear if the patient perseveres with this inadvertent immunotherapy, but the discomfort is usually too great for this approach to be regularly useful.

Adhesive plaster containing 40% salicylic acid is useful for plantar warts. It is applied daily, cut to the shape of the wart or group of warts and held in place by plain adhesive plaster. The regular use of salicylic acid preparations on warts may need to be continued for at least 3 months and often longer.

Glutaraldehyde. The virucidal properties of glutaraldehyde can be used in wart treatment. Proprietary preparations contain 10% glutaraldehyde in aqueous ethanol [4] or in a gel formulation. Treated skin hardens and is coloured brown, which limits acceptability on the hands, but the fact that glutaraldehyde dries into the skin without a surface deposit (which may be rubbed off) makes it a useful application for warts on the feet. A preparation of 20% glutaraldehyde in aqueous solution produced a 72% cure rate for a variety of different cutaneous warts in 25 individuals [7]. Allergic contact dermatitis to the glutaraldehyde occurs occasionally and cutaneous necrosis is a rare complication of the strong solution.

Podophyllin and podophyllotoxin. Podophyllin is a plant-derived resin containing several cytotoxic compounds in unpredictable ratios. The most active of these is podophyllotoxin. Both the crude resin and purified podophyllotoxin are used in the treatment of anogenital warts, as

they are more effective on mucosal than keratinized surfaces. They act as antimitotics, disrupting the formation of the spindle on which chromosomes align at mitosis.

Purified podophyllotoxin 0.5% in ethanol applied twice daily for 3 days, extending treatment to 4 or 5 days if necessary and if tolerated, gives better results than podophyllin, with cure rates between 60 and 70% [8,9]. The same routine may be repeated after a week's break if lesions persist. Once-daily treatment is less effective. For both penile and vulval warts, self-application of podophyllotoxin in either solution or cream formulation can be performed by the patient and can give a higher remission rate than the use of podophyllin [10,11].

Podophyllin resin is not used so commonly now, but treatment should be under professional supervision. A solution of 10–25% in compound tincture of benzoin is applied accurately to the area and then allowed to dry for a few minutes. The resin should be thoroughly washed off after 4 h, though the time can be cautiously increased if the treatment is well tolerated. Applications are repeated weekly or more often. Of over 100 men treated weekly for 6 weeks, 22% were clear 6 weeks later and a 10% solution was as effective as a 25% solution [12].

Podophyllin should not be used on exceptionally large or bleeding areas, where its application has been followed by intrauterine death [13], vomiting, diarrhoea, liver damage, renal damage, coma, peripheral neuropathy [14], bone marrow suppression [15] and death [16], due to presumed systemic absorption. Oral ingestion has similar effects and can be fatal [17,18]. In animal studies, podophyllin is abortifacient but not teratogenic [19]. However, though its use in the usual small quantities appears safe, it is generally regarded as contraindicated in pregnancy [19]. The side-effect profile of podophyllotoxin appears to be safer, although the usual precautions for its use should be observed.

Some local irritation is expected especially with podophyllin and is usually greatest 1 or 2 days after application. Histologically, epidermal intracellular and intercellular oedema, mitoses and necrosis are seen, but no signs suggesting carcinogenicity [20].

Podophyllin and podophyllotoxin are generally ineffective if simply applied to warts of other types, due to the lack of penetration of the keratin layer. However, they can be used with caution under occlusion. A technique has been described for plantar warts [21] in which the keratin is pared down well and 25% podophyllin (in soft paraffin, liquid paraffin or a mixture of the two) is applied and occluded by plain adhesive plaster. The dressing is removed after a week, and the process repeated if the wart persists. Although success was achieved, acute pain can occur with intense local inflammation.

Formalin. Soaks or compresses of 2–3% formalin in water (formalin is about 37% formaldehyde in water) may be effective for plantar warts [22], but is time-consuming and difficult to limit to affected skin. The affected area must be soaked in the solution for 15–20 min daily, using soft paraffin as a barrier application to protect more sensitive skin. The formalin is virucidal but also dries and hardens the skin, facilitating paring. A comparative study of formalin soaks with either water soaks or oral saccharose showed no difference in clearance [23].

Topical 5-fluorouracil. A 5% solution of 5-fluorouracil (5-FU) carefully applied daily under occlusion for a month is more effective than placebo [24], but if used periungually may cause onycholysis. A paint containing 5% 5-FU and 10% salicylic acid cleared 50% of hand warts in poultry workers, compared with 4% with the salicylic acid alone [25]. An ointment containing 5% 5-FU was effective for plane warts, although its value was limited by a high incidence of hyperpigmentation as well as erythema and erosion [26]. Application of a solution containing 0.5% 5-FU, 10% salicylic acid and 8% dimethylsulfoxide three times daily for 5 days immediately followed by curettage was successful in six patients with widespread warts [27]. A newer formulation of 5-FU may soon permit slow-release of the compound within warts following intralesional injection.

Caustics. Monochloracetic acid, trichloracetic acid, silver nitrate [28] and other highly irritant chemicals can be used with effect but may cause painful reactions. In treatment of genital warts, cryotherapy is slightly more effective than trichloracetic acid alone [29].

Retinoic acid. This may be applied topically in plane warts, although the best results are claimed for higher than usual concentrations and irritation is common [30]. Of 25 children with plane warts treated with 0.05% tretinoin cream, 85% cleared their warts compared with 32% of controls [31].

Photodynamic therapy. Systemic or topical aminolaevulinic acid can be taken up by dividing cells, metabolized to protoporphyrin and then photoactivated to produce a damaging effect on the cell. The use of this method to treat common warts has so far been limited but has shown some useful effect in hand and foot warts [32] and also in laryngeal papillomatosis [33].

Surgical methods. Excision is usually to be avoided since scarring is inevitable and recurrences of the wart in the scar are frequent. However, good results have been obtained by snipping out perianal warts after subcutaneous injection of 1 in 300 000 epinephrine (adrenaline) in physiological saline under general or local anaesthesia [34]. Curettage can also be effective as treatment for filiform warts.

Curettage and cautery/electrocoagulation, usually in combination, may be used for painful or resistant warts, but carry a risk of scarring. Topical application of eutectic mixture of local anaesthetics (EMLA cream) to the vulva for 10 min numbed the area in over 90% of cases [35]; otherwise, and for keratinized skin, local anaesthetic injection or even general anaesthesia would be required.

A technique of blunt dissection has been advocated for plantar warts [36].

Cryotherapy. Liquid nitrogen is commonly used in hospital practice. Sophisticated instruments are available for producing a thin stream of the liquid to be directed at the lesion, but very satisfactory results are obtained by application of a cotton bud dipped in the fluid. This is made by twirling loose wisps of cotton wool by hand around one end of an orange stick; proprietary buds are too small and too tightly packed. This simple method can be surprisingly versatile: the rate of discharge of the fluid onto the skin is affected by the overall size of the bud, the amount of fluid with which it is charged, the size of the end (a fine point can be fashioned for treating very small warts), the angle at which it is held (holding away from the vertical lessens the discharge rate) and the tightness of packing of the cotton wool, which may be increased temporarily by local pressure.

Any thick keratin should be pared off. This will improve the cure rate in plantar warts [37]. Mucosal surfaces should be dry to avoid the formation of surface ice, which sticks to the bud. The end of the bud should not overhang the wart surface. In standard treatment, the application is continued until a rim of iced tissue (easily seen as a white discoloration) about 1 mm in width develops in the normal skin surrounding the wart. This may stimulate the development of an immune response [38]. After thawing, a second freeze cycle will improve the cure rate in plantar warts, although the benefit is less marked in hand warts [39].

The response to treatment with cryotherapy is comparable to that achieved with salicylic acid [4,40]. Treatment repeated every 3 weeks gives a 30–70% cure rate for hand warts after 3 months [2,4,41]. More frequent treatments may improve responses [41] but will induce more pain, and longer intervals are less effective [4]. If this fails or when a wart is particularly painful or deep, or both, as may occur over a bony prominence on the foot, more prolonged application, typically up to 30 s, perhaps repeated after thawing, may be used to achieve a greater destructive effect at the cost of significantly greater blistering and pain. For such treatment, local or even general [42] anaesthesia may be considered. The common practice of dipping cotton buds for different patients into a common flask containing the liquid nitrogen may carry a risk of cross-infection (see p. 25.40).

Carbon dioxide snow can be used similarly, but the temperature is higher than that of liquid nitrogen and freezing takes about three times as long. The snow is made by allowing the gas to expand rapidly, as by discharging it into a chamois leather bag tied over the gas cylinder outlet. It can be kept in a vacuum flask for several hours. 'Pencils' of the snow can be made by packing it into hollow metal cylinders. Alternatively, the snow can be mixed with acetone to form a slush that can be applied with a cotton bud.

The main disadvantage of freezing is pain. This is unpredictable and surprisingly variable between patients, but in some cases, especially with longer freezing times, it may be severe and persist for many hours or even a few days. Oral aspirin and strong topical steroids may help. Swelling of the treated area and the surrounding skin begins within minutes, and where tissues are lax as in the periorbital area it may be dramatic. A blister, sometimes haemorrhagic, may ensue within a day or two but is not a prerequisite for resolution of the wart, and usually follows overtreatment. After the usual short freezing times, the reaction will be likely to have resolved within 2–3 weeks. Scarring is unlikely with freezing times under 30 s. Occasionally, damage to underlying tissues may result, for example to a tendon [43] or the nail matrix, and excessive freezing times should be avoided over nerves, for example on the sides of the fingers. Depigmentation may occur, and can be a significant cosmetic disadvantage in patients with darkly pigmented skin.

Laser. The carbon dioxide laser has been used to treat a variety of different forms of wart, both cutaneous and mucosal [44,45]. It can be effective in eradicating some difficult warts, such as periungual and subungual warts, which have been unresponsive to other treatments. Clearance at 12 months of up to 70% of individual warts is reported [46]. However, as a destructive method, carbon dioxide laser therapy can cause significant post-operative pain, scarring and temporary loss of function [47].

The pulsed dye laser produces less scarring and has been used to treat warts with varying degrees of success [48–50], with one study suggesting clearance in 48% of patients [51].

Infrared coagulator. As another destructive method, the infrared coagulator can be used to treat warts. The reported cure rate in a series of 44 warts was 70% [52], which compares favourably with cryotherapy.

Contact sensitization. Dinitrochlorobenzene has been used to elicit a repeated contact sensitivity reaction at the site of warts and to induce clearance [53,54]. It may not be of great advantage in treating plane warts [55]. There have been several open studies of contact sensitization with diphenylcyclopropenone (diphencyprone, DPC) using different protocols [56]. Cure rates of 44–88% of patients were obtained at the end of treatment [57,58]. Itching at

treatment sites was generally tolerated, but some patients developed dermatitis in other areas. Regression in plantar warts as well as common warts may be induced [59]. The use of squaric acid dibutylester as a contact allergen in such regimens may be equally efficacious and better tolerated [60].

Interferon [61]. Different interferons (IFNs) have been administered by different routes to patients with refractory warts in various sites. These studies are seldom directly comparable and the use of IFNs in warts is still experimental.

For the most part, IFN use has been disappointing. The majority of studies have involved patients with refractory genital warts. Of 28 patients given intramuscular recombinant human IFN-γ, two were cleared and 13 improved, although the treatment appeared to potentiate the response to subsequent cryotherapy [62]. In a larger multicentre trial, 172 patients received systemic IFN-α or placebo, but there was no difference in response between the groups [63].

IFN has been used as adjuvant therapy, together with surgery, cryotherapy or topical measures. No augmentation of clearance of HPV infection was observed by the addition of IFN-α therapy to caustic application or surgery [64], podophyllin [65] or laser ablation [66]. Used with cryotherapy, IFN-β and IFN-γ reduced the rate of acquisition of new lesions [67] but none of the IFNs when combined with cryotherapy produced any improvement in clearance rate compared with cryotherapy alone [67,68].

The most encouraging report is of complete clearance of injected warts in 11 of 12 patients with recalcitrant common and plantar warts treated with human IFN-α [69]. Cutaneous warts on the palms and soles may also be treated with intralesional IFN, using a needleless injector [70].

No lasting effect was observed in the treatment of recurrent respiratory papillomatosis with intramuscular human IFN-α [71].

Imiquimod. Topical immunomodulation is a promising new treatment for warts. Imiquimod as a 5% cream is currently licensed for treatment of genital warts [72]. Used three times a week for 16 weeks, the clearance rate is 65% with a 20% recurrence rate. Cutaneous warts have also responded to imiquimod treatment [73,74], although poor penetration through the keratinized surface may necessitate combination with occlusion, salicylic acid or more frequent application to achieve useful results.

Cimetidine. In adults, the use of cimetidine in wart treatment has given conflicting results. In an open study of 18 patients treated with 30–40 mg/kg daily for 3 months, two-thirds demonstrated complete resolution of their warts without recurrence after 1 year [75]; however, in a placebo-controlled trial of 54 patients, no significant benefit of cimeditine therapy was observed, with approximately one-third responding in both treatment and placebo groups [76]. Cimetidine has also been used in a small number of children to treat common warts [77] and plane warts following failed treatment with contact sensitization [78] and showed a potentially useful response.

Retinoids. Etretinate orally has been helpful in cases of extensive and hyperkeratotic warts in immunosuppressed patients, one with sarcoidosis [79] and one with chronic lymphatic leukaemia [80]. The bulk of the lesions was greatly reduced, but the warts were not eradicated and relapsed when the drug was reduced or stopped.

Hyperkeratotic warts in otherwise healthy patients may occasionally show a similar response during etretinate therapy [81,82]. This effect may be temporarily useful, perhaps in relieving pain or disability due to exceptionally hyperkeratotic warts, or in facilitating the use of other treatments.

Intralesional bleomycin. Doses of this cytotoxic agent are measured in units or milligrams; 1 mg contains 1500–2000 units. Protocols vary, but typically bleomycin sulphate 0.25–1 mg/mL is injected up to three times to a maximum total dose of 4 mg [83]; or 1000 units/mL to two injections and a maximum total dose of 2000 units [84,85]. A lower concentration of 500 units/mL seemed as effective [86]. Injections are into the wart itself, confirmed by observing blanching in the lesion, the volume per injected lesion ranging between 0.2 and 1.0 mL. Injections are very painful and preceding or concurrent local anaesthesia should be considered, especially for sensitive sites such as fingers and soles [87]. A haemorrhagic eschar develops 2–3 weeks later; it is pared down if it has not detached spontaneously. These studies reported wart cure rates for previously refractory warts of between 30 and 100% [86,88]; in addition, warts which do not clear commonly improve or become painless.

Used in this way, there has been no evidence of systemic toxicity. Local complications include nail loss [89] or nail dystrophy [90] following periungual injections, Raynaud's phenomenon in treated fingers and local urticaria [89]. The risk of systemic absorption is a contraindication for intralesional bleomycin in pregnancy [86].

Hayes and O'Keefe [86] give useful guidance on method and contraindications. Implantation of the bleomycin from a surface application using a bifurcated needle [91] or a sterile lancet [92] may be better tolerated.

Local heat. Repeated raising of the temperature of wart-affected skin to a maximally tolerated level of about 50°C is reported to induce wart clearance [93]. The Nd:YAG laser can be used to produce a similar effect [94].

Psychological methods. Most studies claiming that warts can be effectively treated by suggestion or 'magic' were inadequately controlled for spontaneous regression [95]. Formal hypnosis, however, has been reported to clear warts on only the suggested (the more severely affected) side in nine of 10 patients who achieved a satisfactory depth of hypnosis, the other side of the body acting as an internal control [96]. Children appear to have a higher rate of success than adults [97]. Persistent refractory warts disappeared following hypnosis in an uncontrolled study of three immunodeficient children [98].

Radiotherapy. The use of radiotherapy for warts should never be employed routinely as the first line of attack; moreover, the efficacy of safe doses is questionable [99]. A follow-up of 100 patients showed serious post-irradiation damage in 7% and slight radiodermatitis in 31% [100]. If used at all it should be reserved for selected cases and administered only by an experienced dermatologist or radiotherapist who is fully aware of the potential hazards. The correctness of the diagnosis must, of course, be beyond doubt.

Antiviral therapy. The large number of treatments listed above indicate the lack of an ideal method for eliminating warts. The antiviral cidofovir, a purine nucleotide analogue of cytosine, applied topically as a 1% gel or by intralesional injection (2.5 mg/mL) is extremely effective. Plantar, anogenital and laryngeal warts [101] resolve completely. Grade III cervical, vulval and penile intraepithelial neoplasia also respond to this drug.

Therapeutic vaccination. Although not yet available as a treatment modality for HPV disease, animal models to test the most effective approach to vaccination are available. In addition, clinical trials of therapeutic vaccination for cervical carcinoma, cervical intraepithelial neoplasia, genital warts, laryngeal papillomatosis and cutaneous warts are in progress. Recent reports of the use of intralesional *Candida* antigen to produce a local hypersensitivity reaction suggest that this approach could be effective wart treatment in recalcitrant cases [102].

HPV-associated epidermal dysplasia and neoplasia

HPVs have been associated with several different dysplastic or malignant conditions. An aetiological association between infection with high-risk HPVs and the development of cervical carcinoma is now recognized, but the precise role of HPV infection in other genital malignancies, cutaneous squamous cell carcinoma and a variety of other tumours is yet to be clarified. Only the relationship between genital and cutaneous malignancy and HPV infection is discussed in detail, although there are reported associations of HPV or warts with some other premalignant and malignant conditions.

1 Oral leukoplakia and carcinoma: HPV-16 and others [1].

2 Conjunctival and corneal dysplasia and neoplasia: HPV-16 [2].

3 Carcinoma of nasal cavities, oesophagus and larynx: mostly HPV-11 and HPV-16 [3] and also HPV-57b [4].

4 Carcinoma of lung [5,6], including a patient with laryngeal papillomatosis [7].

5 Basal cell carcinoma in immunosuppression: HPV-2 [8] and epidermodysplasia verruciformis-associated types (see p. 25.59).

6 Keratoacanthoma: HPV-25 [9] and HPV-16 [10], although absence of HPVs is also reported [11].

7 Adenocarcinoma of the cervix: HPV-18 is more commonly associated than HPV-16 [12].

Cervical intraepithelial neoplasia and invasive carcinoma [13]

These conditions are epidemiologically associated with sexual activity, including multiplicity of partners and a history of sexually transmitted diseases, in both the female patient and her male partner(s). Cervical intraepithelial neoplasia (CIN) is often associated with a personal history of overt genital warts [14], and with previous penile warts [15,16] or penile intraepithelial neoplasia [17] in the partner.

HPV is commonly detected in dysplastic cervical lesions and is found in 90–100% of cervical cancers [12,18]. Types 16 and 18 are the most commonly associated HPVs, accounting for 70–80% of HPV-positive lesions, although approximately 30 different HPV types can infect the cervix. In carcinoma cells, HPV DNA is integrated into the host cell genome, in contrast to its extrachromosomal location in benign and premalignant lesions [19].

Antibody to HPV-16 capsid antigens is present in about 75 or 50% of women with HPV-16-positive CIN or invasive carcinoma, respectively [20,21]. HPV-16 antibody may also predate the development of cervical disease as shown in a Finnish study where 18 000 blood donors were followed for up to 23 years after giving a baseline blood sample. Antibody was detected in 24% of those who subsequently developed cervical carcinoma compared with only 2% of the matched controls, a risk ratio of 12.5 [22]. Although the most important risk factor, HPV infection by itself does not appear to cause cancer; additional environmental co-factors are required [23].

However, HPV-16 can also be detected by sensitive PCR in a proportion, variously reported to be 5–80%, of cytologically normal cervices [24,25]. This association is highest in young, sexually active women, and one European study showed that only 5% of women aged 35–55 years carried the virus latently in the cervix [26]. In a study of over 200 cervical smears, HPV-16 DNA was found using a hybridization technique in 47% of patients with high-grade intraepithelial lesions (CIN-III) or invasive carcinoma [27]. The finding of a high-risk HPV type in the cervix increases the likelihood of progression of the disease [28].

The management of subclinical HPV infection, cervical dysplasia and neoplasia is beyond the scope of this book; however, the possible risk of the eventual development of these conditions when anogenital warts are diagnosed in either sex will affect the management of the wart patient.

Vulval intraepithelial neoplasia, penile intraepithelial neoplasia and Bowenoid papulosis [29] (Fig. 25.22)

Full-thickness epidermal dysplasia of the vulva or penis is now classified as grade III vulval intraepithelial neoplasia (VIN) or penile intraepithelial neoplasia (PIN) [30], although the term 'Bowenoid papulosis' is still used by many dermatologists. VIN-III and PIN-III are strongly associated with HPV-16 [31,32]. Small papules, usually multiple and sometimes pigmented, present on cutaneous and mucosal surfaces of the anogenital region in both

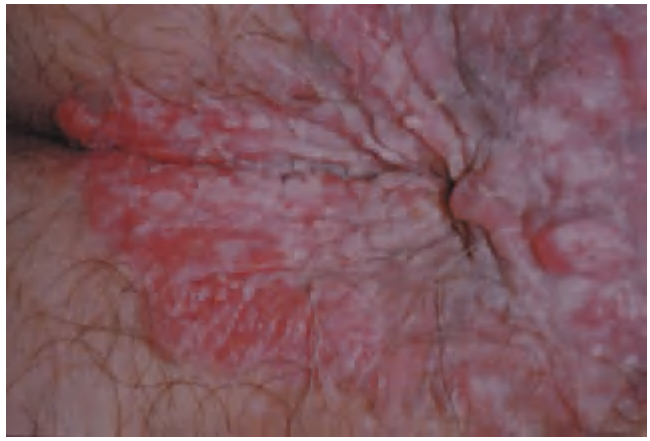

Fig. 25.22 Perianal intraepithelial neoplasia, grade III. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

Fig. 25.23 Buschke–Löwenstein tumour. (Courtesy of Dr A.S. Highet, York District Hospital, York, UK.)

sexes, often resembling simple warts, seborrhoeic keratoses or cellular melanocytic naevi. There may be areas of erythematous thickening or small erosions or ulcers. There is often a history of preceding genital warts and the disease is more common in smokers. It usually affects young to middle-aged adults, but no age is exempt. Low-grade and some high-grade lesions resolve spontaneously. For many years, progression to carcinoma has been considered rare, occurring in less than 5% [33], but a recent study of affected individuals in New Zealand has suggested that, untreated, VIN-III may carry a high risk of progression to invasion [34]. Analyses of carcinomas of the vulva, penis and anus have confirmed that many harbour high-risk HPVs, especially type 16 [17,35–38].

Conditions clinically similar to genital intraepithelial neoplasia include Bowen's disease and erythroplasia of Queyrat, which, in contrast, affect the middle-aged and elderly, present as one or a few larger flat plaques, show more advanced dysplasia and carry a significant risk of invasive malignancy.

Persistent and refractory cases of VIN-III and PIN-III may have underlying immune deficiency and may develop malignancy at other sites. Four such (HIV-negative) men had T-helper-cell depletion, anergy or both, and one developed squamous carcinoma of the tongue, which, like his Bowenoid papulosis, contained HPV-16 [39].

Treatment. Extensive surgery is generally not indicated and to remove all infected tissue could be mutilating. Simple excision of small areas, cryotherapy, carbon dioxide laser and diathermy can help to contain the disease. Good results without scarring have been reported for the Nd:YAG laser [40]. Oral retinoid therapy may be effective [41]. More recent studies with the antiviral cidofovir [42], the topical immunomodulator imiquimod [43] and therapeutic vaccination [44] offer hope of disease control.

Buschke–Löwenstein tumour (Fig. 25.23)
SYN. GIANT CONDYLOMA; VERRUCOUS CARCINOMA

This lesion enlarges from a pre-existing benign anogenital wart. It harbours HPV-6 or HPV-11 [45], which is often mutated. It is locally invasive on a broad front, but is well differentiated and rarely metastasizes. Clinically and histologically it resembles verrucous carcinoma, and some authorities classify it as such [46]. Treatment is usually surgical, although aggressive cryotherapy [47], bleomycin [48] and recombinant IFN-α-2a [49] and systemic retinoid [50] have also been used. Radiotherapy should be avoided as it may precipitate transformation to an anaplastic carcinoma.

Cutaneous squamous cell carcinoma without immunosuppression

The high- and low-risk HPV types that cause genital disease are also reported in certain extragenital warts and carcinomas. Although such cases are more common among the immunosuppressed, immunocompetent individuals may also be affected. A child with atopy and sickle-cell disease was found to have HPV-6 in pigmented warty lesions on the limbs [51]. Squamous cell carcinoma of the fingertip and nail bed has been associated with HPV-16 [52,53]. Cutaneous intraepithelial carcinoma of the skin (Bowen's disease) has been found occasionally to harbour HPV-2 [54], HPV-16 [55] and HPV-34 [56].

Malignant change may rarely develop in apparently normal warts, usually when very long-standing. A facial wart in an elderly man became invasive [57]. Plantar warts that have developed into carcinoma cuniculatum may develop from pre-existing plantar warts [58] and such lesions can be found to contain HPV sequences [59].

Ionizing radiation may act as a co-factor for malignant change in warts [60]. Widespread actinic keratoses and

cutaneous squamous cell carcinomas arising after arsenic treatment or PUVA photochemotherapy may also be associated with HPV infection [61,62]. With the advent of more sensitive PCR methods for detection of HPV DNA, the viral genome has been found in approximately 25–50% of keratoses and non-melanoma skin cancers of immunocompetent individuals [63]. It is DNA of the epidermodysplasia verruciformis-associated types that is present in these lesions. The viral DNA is not exclusive to dysplasia—it can also be found in normal skin and hair follicles in 45% of people tested [64]. The molecular role of the virus in the development of skin cancers is a subject of intense debate [65].

Epidermodysplasia verruciformis

Epidermodysplasia verruciformis (EV) is an inherited disorder in which there is widespread and persistent infection with HPV, giving rise to a characteristic combination of plane warts, pityriasis versicolor-like lesions and reddish plaques. Malignant change is very common but metastasis is rare.

Aetiology. Susceptibility to the virus is inherited, usually autosomal recessive, although autosomal dominant [1] and probable X-linked dominant [2] patterns have been reported. Two loci on chromosomes 17q25 and 2p21–p24 are associated with the disease within some studied families. Impairment of cell-mediated immunity, notably T-helper-cell number and function, is commonly but not invariably found, although EV patients are not unusually susceptible to other infections. These changes are similar to, but more pronounced than, those seen in ordinary wart patients, and may be secondary to the infection rather than a primary abnormality predisposing to it. The increased natural killer cell activity in EV patients infected with oncogenic HPV types is interpreted as an appropriate response [3].

There is no impairment of DNA repair [4] and no association with HLA-A or HLA-B antigens [5].

There are at least 20 HPVs characteristic of EV, including types 5, 8, 9, 12, 14, 15, 17, 19–25, 28, 29, 36–38, 47, 49 and 50. In addition, HPV-3 and HPV-10, which cause ordinary plane warts, are found in EV. There may be more than one HPV type in the same patient [6,7].

Pathology [1,8]. The histological picture is similar in the different clinical types of lesion. As in ordinary plane warts, hyperkeratosis and acanthosis are present. However, vacuolation in the keratinocytes is more extensive, and may affect the upper half to three-quarters of the Malpighian layer. Viral particles can be identified ultrastructurally not only in the Malpighian cells but also in basal cells and, perhaps due to apoptosis, below the basal lamina. There is a gradual progression towards dysplasia.

Clinical features [1,9–13]. Lesions on the face and neck are generally indistinguishable from plane warts, but on the trunk and limbs they tend to be larger and of two main types. Scaly macular lesions closely resemble pityriasis versicolor, showing depigmentation or varying degrees of brown pigmentation. Thicker plaques are dull pink to violet in colour and may resemble seborrhoeic keratoses.

There is a tendency for HPV-3 and HPV-10 to be found in plane warts in EV, as in other patients, but the correlation between HPV type and lesional appearance is not close [10], except that HPV-5 and HPV-8 are the main types associated with malignancy [6,7], with HPV-14, HPV-17, HPV-20 and HPV-47 occasionally involved [14].

Irregular confluence of neighbouring lesions to form lines or large plaques is often seen. Typical common warts are often present, especially on the sides of the fingers and on the palms and soles, and small warts on the vermilion border of the lips or in the urethra have occasionally been noted.

The warts usually develop rapidly in childhood but may first appear at any age. They are most numerous on the face and neck and dorsa of the hands and feet, and may be restricted to these sites, but there are often scattered lesions elsewhere and warts may be generalized over the entire body surface. Cases have been reported in which all the warts were larger and hypertrophic [15]. EV is remarkably persistent and may remain unchanged for decades. However, slow spontaneous regression following two pregnancies has been reported in a single case [16].

A family with probable X-linked dominant inheritance also had dystrophy of fingernails and toenails [2]. There

has been a report of a patient with EV who had palmar pits in addition to the more typical signs [17].

Dysplastic and malignant changes occur most often on exposed skin, commonly as actinic keratoses and Bowen's disease, suggesting that UV radiation is an important factor. Squamous cell carcinoma has ultimately developed in one or more lesions in about 20–30% of reported cases, even before the age of 20 and when the lesions have been present for under 10 years. However, metastasis is rare.

Diagnosis. Acrokeratosis verruciformis (see Chapter 34) is superficially very similar. Flat warty papules on the dorsa of hands and feet and on knees and elbows are present from infancy. The palms are diffusely thickened and show small keratoses and punctiform breaks in the papillary ridges. Histologically there is no vacuolation.

Similar cases that appear to be based on acquired immune deficiency, such as lepromatous leprosy [18] and treated Hodgkin's disease [19], might more appropriately be labelled generalized verrucosis.

In lichen planus (see Chapter 42) the papules, which are usually pruritic, are pink or lilac in colour and distinctive mucosal lesions are often present. The histology is diagnostic.

Treatment. Patients should be observed for the development of carcinomas and premalignant lesions, which should be excised or locally ablated. Avoidance of excessive sun exposure, with diligent use of effective sunscreen, should be advised.

The role of etretinate in EV is not clear. Substantial clinical improvement is often achieved at a typical starting dose of 1 mg/kg daily, but signs of viral infection persist histologically. The effect is dose dependent and relapse occurs if the drug is stopped. Some cases respond poorly [20]. Whether dysplastic or malignant change is prevented by etretinate is not yet known [1].

HPV in immunosuppression

Warts and HPV in immune deficiency

Chronic immune deficiency, especially of cell-mediated function, predisposes to clinically evident warts, perhaps by allowing the development of lesions from previously latent virus. The warts may be so widespread that they constitute generalized verrucosis or resemble EV.

This is seen especially in the long-term immunosuppression of organ transplantation. Of 120 renal transplant recipients, 15% had warts 1 year post transplant [1], but this can rise to 90% at the end of the fifth year [2]. Of 47 children with renal transplants, 18 (38%) had warts, some of unusual severity and, except for the mildest cases, refractory to standard methods of treatment [3]. In renal transplant recipients, HPV-2 and HPV-4 warts are the most frequent. Long-term immunosuppressed individuals may develop lesions very like those in EV, with small erythematous non-warty plaques and squamous cell carcinomas especially on sun-exposed areas. Viral analysis from flaking, keratotic or invasive lesions has shown heterogeneity of HPV types [1,4–6], including those associated with EV. Recent techniques using degenerate primers in PCR have shown that many more, some as yet incompletely characterized, HPV types may be present in dysplastic or malignant lesions of transplant recipients [7,8] and also in clinically normal skin and hair follicles [9,10]. The incidence of CIN is also increased [11].

The prevalence of warts is not increased by short-term immunosuppression given to bone marrow transplant recipients [12].

HIV infection and AIDS (see Chapter 26)

The incidence of warts is reported to be between 5 and 27% in HIV infection. Common and plantar warts are probably somewhat increased in frequency and severity but are not a major problem in most patients. There is an increased incidence of facial and intraoral warts, many of which contain HPV-7, the 'butcher's wart' virus [13]. Perianal warts, especially in homosexual men, may be florid and refractory to treatment. Malignant change including CIN is increased in incidence [14,15]. Patients with HIV infection may also develop an EV-like syndrome, with widespread plane warts, keratoses and development of cutaneous malignancy [13].

Other causes of immunodeficiency

The incidence of warts is increased in patients with Hodgkin's disease and, to a lesser extent, in those with other malignant lymphomas and chronic lymphatic leukaemia [16]. Of a series of patients with systemic lupus erythematosus (SLE), 45% had warts compared with 12% among controls [17]. Chronic extensive plane warts were reported in a woman with immune deficiency secondary to intestinal lymphangiectasia [18]. EV-like conditions have been associated with treated Hodgkin's disease [19] and with lepromatous leprosy [20].

Primary immune deficiencies, mostly involving cell-mediated immunity, may be accompanied by widespread warts, for example ataxia-telangiectasia [21], Fanconi's anaemia [22] and Wiskott–Aldrich syndrome [23].

The association of warts of palms and soles, seborrhoeic keratoses of the trunk and Bowen's disease of the face in two brothers, who also had congenital dislocation of the hips and kyphoscoliosis, has been labelled Bittner's syndrome [24]. The patients had low IgA levels and a poor cell-mediated response.

Hepatitis viruses

Hepatitis B

Aetiology and pathology [1,2]. Hepatitis B virus (HBV) is transmitted mainly percutaneously or sexually in Western developed countries like the USA and the UK, while in areas of high prevalence, for example the Far East and sub-Saharan Africa, perinatal transmission from the mother or horizontal spread from other children predominates.

In acute infection, three types of particle are seen in the serum by electron microscopy: 42-nm-diameter virions consisting of the viral DNA in the core (HBc) surrounded by surface antigen (HBsAg), and 20-nm round and tubular structures which are excess HBsAg. There are highly sensitive techniques for the detection of HBsAg and of antibodies to HBs and HBc. HBeAg is a soluble protein, part of the core (HBc) antigen, and its presence parallels that of complete virions and HBV DNA in the blood, providing an assessment of infectivity.

During the incubation period of 6 weeks to 6 months, antigenaemia can occur more than 4 weeks before symptoms; however, about two-thirds of those infected have an asymptomatic or unrecognized infection. In some people, early antibody is produced and becomes complexed with

this antigen, resulting in a serum sickness-like illness that precedes hepatitis.

After acute hepatitis in otherwise normal people, antigenaemia persists in about 5% of cases, who are called carriers; the carrier state is defined as the presence of HBsAg positivity for more than 6 months. In general, when HBeAg has disappeared and anti-HBe is present in a carrier, the infectivity is low. Most carriers have become infected in the neonatal period or are immunocompromised and do not give a history of hepatitis or suggestive symptoms.

Dermatological manifestations [1,3–5]. Apart from Gianotti–Crosti syndrome, the dermatological features of HBV infection are mostly believed to be associated with immune complex formation [6].

Serum sickness syndrome. This occurs in 20–30% of cases usually as a prodrome 1–6 weeks before the onset of clinical hepatitis, though occasionally coinciding with it, and sometimes without clinically evident liver disease. Urticaria and angio-oedema are common, and when histology has been performed it has confirmed the expected vasculitic basis [4]. More advanced vasculitis may manifest as petechiae, palpable purpura and erythema multiforme-like lesions. Macular, maculopapular and lichenoid eruptions and erythema nodosum [7] may occur. Arthralgia or arthritis, and headache [8] are commonly associated.

Polyarteritis nodosa. Urticaria, purpura and multiform exanthems occur in about one-quarter of cases of polyarteritis nodosa. HbsAg has been detected in 8 to over 50% of patients with polyarteritis nodosa [9,10]. In one study, when HBsAg disappeared and anti-HBs appeared in two patients, both had a dramatic clinical improvement. This suggests an immune-complex mechanism for the pathogenesis of hepatitis B-associated polyarteritis nodosa. Polyarteritis nodosa associated with hepatitis B infection has also cleared following treatment with lamivudine [11].

Prophylaxis. Active immunization is achieved by a course of three doses of recombinant surface-antigen vaccine. In many countries, universal immunization is given to infants with the added long-term goal of eradicating the disease. In other countries, a policy of selective immunization of high-risk groups has been followed [12]. The efficacy for young adults is about 90%, but decreases with age and in immunocompromised people. Response to the vaccine should be checked 2–3 months after the third dose of vaccine by testing for anti-HBs antibody. Responders retain long-lived immunological memory that effectively sustains immunity even when the level of antibody declines.

Passive immunization with high-titre anti-HBs human immunoglobulin is used (in conjunction with vaccine) for newborn babies of highly infectious (HBeAg positive) HBV-carrier mothers and for unimmunized people or in those who have failed to respond to the vaccine after accidental exposure (e.g. needlestick injuries).

Erythema nodosum, generalized granuloma annulare, thrombocytopenic purpura and Reiter's syndrome have followed hepatitis B vaccination [13–16].

Hepatitis C

Aetiology. Hepatitis C virus (HCV), previously called non-A, non-B hepatitis virus, is a member of the Flaviviridae. It is found throughout the world, although the prevalence of seropositivity varies between 1 and 10% depending on the region. It is spread parenterally by blood and blood products, by needle sharing and perinatally from infected mothers to their babies in 1–10% of cases. Sexual transmission is at a low rate.

The virus replicates in hepatocytes and blood mononuclear cells. Most acute infections are subclinical, but in 75% of individuals infection leads to a chronic hepatitis, which in some cases can progress to cirrhosis and occasionally development of hepatoma. Improved awareness

of HCV has led to a decrease in acute infection but, as yet, no change in chronic infection.

Cutaneous manifestations [1,2]. The immune response to the virus affects the degree and form of liver damage and may also contribute to extrahepatic effects.

Vasculitis. Cryoglobulins are commonly found in patients with HCV infection but only some develop clinical mixed cryoglobulinaemia, which presents as asystemic vasculitis, with symptoms of fatigue and arthralgia with hepatosplenomegaly and palpable purpura particularly of the lower legs. The effects are due to the precipitation of immune complexes of HCV virions or proteins with IgG and IgM. The skin lesions show the classic histological features of a leukocytoclastic vasculitis. Of patients with mixed cryoglobulinaemia, up to 80% are HCV positive.

Porphyria cutanea tarda. Liver disease is a well-recognized association of porphyria cutanea tarda, but the detection of antibodies to HCV in some non-familial cases has renewed the search for a possible aetiological link. Of sporadic cases of porphyria cutanea tarda in southern Europe, approximately 80% were seropositive for HCV [3–5], although the prevalence appears to be nearer 10% in northern Europe [5] and intermediate in North America.

HCV infection has also been reported in association with lichen planus [6], Sjögren's syndrome [7], urticaria [8], erythema multiforme [9], erythema nodosum [10], pruritus [11], prurigo nodularis [12], cutaneous polyarteritis nodosa [13], pyoderma gangrenosum [14], disseminated superficial actinic porokeratosis [15], generalized granuloma annulare [16] and necrolytic acral erythema [17], although the causality of these links is not yet certain.

Treatment. Supportive measures can help to minimize hepatitis-induced, immune-mediated effects on different organs. IFN-α (given as a dose of 3 million units regularly three times weekly for 6 months) produces a good initial response in mixed cryoglobulinaemia [18], but relapse is common and only 10–30% will achieve a satisfactory long-term response. The combination of interferon with ribavirin produces a better (30–50%) viral clearance rate for chronic HCV infection.

Parvoviruses

Human parvovirus B19 [1,2]

Aetiology. Parvovirus B19 is the only parvovirus of known pathogenicity to humans (Fig. 25.24). It is the cause of erythema infectiosum (fifth disease) [3].

The virus was detected first in serum in 1975 [4]. The name B19 comes from the serum panel (B), sample number (19) in which the virus was discovered. Subsequently B19 has been found to be a cause of aplastic anaemia [3,5].

Small outbreaks of fifth disease usually occur in the spring. The distribution is worldwide, with most cases being seen in children aged between 2 and 10 years. The incubation period from infection to viraemia is 6 days. The viraemia peaks at 8–9 days and at day 10 there is an almost complete loss of bone marrow erythroid precursors. The rash of erythema infectiosum appears about day 15, as the marrow recovers and IgM antibody becomes detectable. Spread occurs by droplets from the nasopharynx, with secondary attack rates of about 50% in susceptible household contacts. One infection gives lifelong immunity. In a group of 5–9 year olds in the USA, 21% had evidence of past infection. Between 20 and 50% of infections are asymptomatic, and in the UK 60% of adults are seropositive.

Pathogenesis. The major target for parvovirus B19 is the bone marrow erythroid progenitor cell. This viral tropism is mediated through the erythrocyte P antigen (globoside) and the rare person who lacks this antigen is not susceptible to B19 infection [6]. The virus is cytotoxic for these

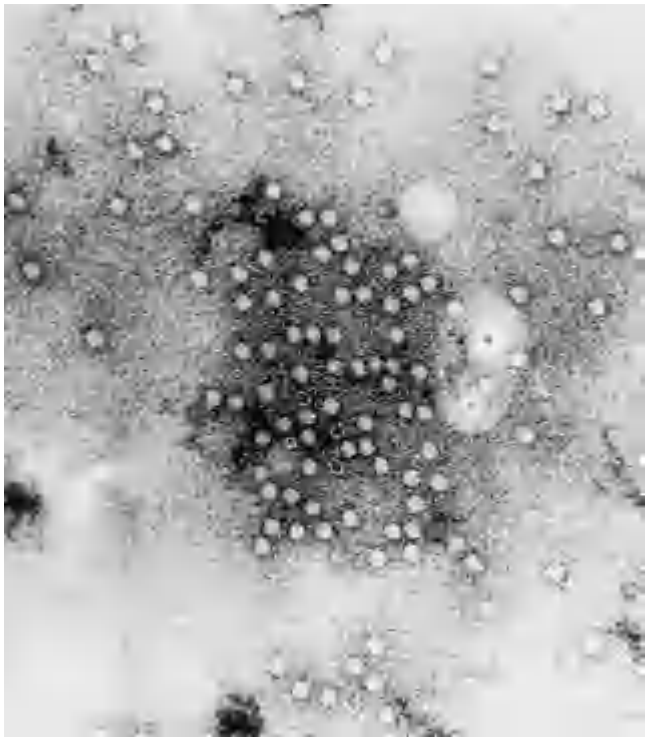

Fig. 25.24 Human parvovirus (B19) in serum of patient with aplastic crisis. Negatively stained electron micrograph, × 200 000. (Courtesy of Mr T.W. Lee, John Radcliffe Hospital, Oxford, UK.)

cells, which causes inhibition of red cell production. The bone marrow shows erythroid hypoplasia and occasional giant pronormoblasts. The exanthem and polyarthralgia are the result of antibody–antigen immune complexes and occur as bone marrow recovery is underway. Persistent infection causing severe chronic anaemia has been reported in people with congenital or acquired immune deficiency [7,8].

Infection in the pregnant woman has a transplacental transmission rate of about 33%. This may cause spontaneous abortion in the first trimester, and fetal hydrops in the second trimester [9]. Intrauterine death occurs in about 10% of B19 infections in pregnancy, although infants who survive have no evidence of congenital infection. The interval between maternal infection and fetal death is often 4–5 weeks, but may be up to 11 weeks.

Clinical features

Erythema infectiosum (fifth disease) [3,10–12]. The exanthem commonly develops suddenly without prodromal symptoms, although there may be mild malaise, myalgia or fever. Rose-red papules on the cheeks rapidly coalesce to form a hot turgid erythema, almost erysipeloid, giving a 'slapped cheek' appearance. There is often perioral pallor. During the next 2–4 days maculopapules appear on the proximal extremities and extend distally to the hands and feet and proximally to the trunk, often forming a lace-like pattern. The palms and soles may be involved and acral lesions may be petechial. Rarely lesions may be vesicular or pustular. There may be dark-red macules on the buccal and genital mucous membranes. The eruption usually fades in 6–10 days, but evanescent recurrences on previously affected sites may continue for up to 2 weeks [10,13].

In adults, polyarthralgia is often the predominant symptom of infection [14], and when the exanthem does occur the features of facial erythema are usually less marked than in children.

While the arthropathy usually resolves in a few weeks, joint symptoms persist for more than 2 months in 10% of infected women. In some cases, the combination of parvovirus infection with rash and arthritis is accompanied by other features diagnostic of connective tissue disease, such as SLE or rheumatoid arthritis [15,16].

During the early stages there is leukocytosis with relative lymphopenia: later an eosinophilia of up to 36% may be accompanied by a lymphocytosis.

Other manifestations. Systemic vasculitis in the form of polyarteritis nodosa, Wegener's granulomatosis and arterial occlusion have been reported in association with parvovirus B19 infection [17–19]. Urticaria and angio-oedema have also been reported. The papular pruritic gloves and socks syndrome is associated most commonly with parvovirus B19 infection.

Diagnosis. In the acute aplastic phase, virus can be detected in the serum by electron microscopy or PCR amplification of viral DNA. By the time the rash appears, the virus is rapidly disappearing from the blood and the diagnosis is made by finding specific IgM antibody to human parvovirus. This antibody is present for up to 2–3 months following the acute infection. Because clinically the picture can mimic rubella, it is of utmost importance to obtain laboratory diagnosis, especially of infections during pregnancy.

The exanthem shows a perivascular mononuclear cell infiltrate with a focal interface dermatitis [16].

Treatment. Erythema infectiosum is itself harmless and no treatment is required. Chronic B19 infection causing red cell aplasia should be treated with intravenous immunoglobulin infusions. Treatment may result in a cure, but if a relapse occurs a further course may be required some months later. Intravenous immunoglobulins may also be of benefit in B19-associated polyarteritis nodosum [19].

Retroviruses

Human T-lymphotropic virus

Human T-lymphotropic virus (HTLV)-1 and HTLV-2 belong to the deltaretroviruses or oncovirus group of the Retroviridae. HTLV-1 was first isolated in 1980 [1] and was associated with an aggressive form of adult T-cell leukaemia (ATL) that had been described in Japan [2]. This disease is also referred to as adult T-cell leukaemia–lymphoma (ATLL) because it usually begins as a lymphoma that progresses to a late leukaemia phase. It is widespread and endemic in south-west Japan, the Caribbean, sub-Saharan Africa and in south-east USA. Subsequently HTLV-1 has been associated with a chronic neurological disease, tropical spastic paraparesis (TSP) [3]. It is not known what determines the form of disease the infection can take. HTLV-1 nucleic acid has also been found in the skin and mononuclear cells of patients with cutaneous T-cell lymphoma and a pathogenetic role for the virus in this disease has been proposed. HTLV-2 has been isolated from patients with a T-cell variant of hairy cell leukaemia [4,5] but has not yet been conclusively linked to any human disease. HTLV-2 is endemic in intravenous drug abusers throughout the Western hemisphere and has also been found in some native American tribes.

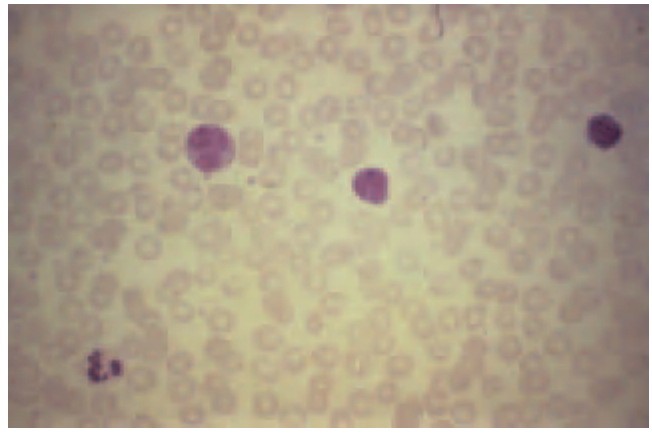

Fig. 25.25 HTLV-1 infection: 'flower cells' in peripheral blood. (Courtesy of Dr S. Whittaker, St John's Institute, London, UK.)

HTLV-1 infects $CD4^+$ T lymphocytes. After entering the cell the virus makes a DNA copy of its genome, using virally encoded reverse transcriptase. This integrates randomly into the cell genome. The pro-viral DNA produces proteins that regulate not only viral but also cellular promoters in adjacent genes and at a distance (a *trans*-activation mechanism). However, the role of these HTLV-1 gene products in transformation of the cell is still uncertain [6].

Only about one in 80 of those infected will develop ATLL. The leukaemic cells in ATLL represent a monoclonal expansion of cells, each of which carries one or occasionally more copies of the pro-viral DNA. These cells ('flower cells') (Fig. 25.25) are pleomorphic and display characteristically lobulated nuclei. Leukaemic cells can infiltrate the dermis or subcutaneous tissue to cause nodular cutaneous lesions that may appear many years before ATLL, as long as 21 years in one case report [7]. In endemic areas the prevalence of infection as manifested by antibody to HTLV-1 can be as high as 10–15%, and in the families of patients with ATLL this can rise to 30–40%. In non-endemic areas, HTLV-1 antibody prevalence rates are much lower. The major route of transmission of HTLV-1 is from infected mother to child via breast milk, with a 25% chance of the baby becoming infected. Horizontal spread is by sexual transmission (mainly from male to female) and by blood (leukocyte transfer is necessary). The incubation period for ATLL has been calculated to be 15–20 years or more but is considerably shorter for TSP—6 months to 3 years has been recorded following blood transfusion. The lifetime risk of developing ATLL, if infected with HTLV-1, is 2–5% and of developing TSP is about 0.25%.

Clinical features. Four clinical subtypes of ATLL have been defined: smouldering, chronic, acute and lymphomatous [8]. Typically, these subtypes appear in sequence in a

(a)

(b)

Fig. 25.26 Adult T-cell leukaemia/lymphoma: (a) widespread plaques; (b) papular lesions. (Courtesy of Dr S. Whittaker, St John's Institute, London, UK.)

patient. The principal features of infection are lymphadenopathy, hepatosplenomegaly, hypercalcaemia and skin lesions. ATLL has a rapid progressive course with a mean survival time of less than 1 year. The skin manifestations [9–11] (Fig. 25.26) include:

1 erythematous papules, plaques and nodules due to dermal aggregates of malignant lymphoid cells;
2 hyperpigmented rash on the face that may spread to trunk, arms and legs;
3 exfoliative dermatitis on the palms (in Afro-Caribbeans);
4 chronic infective eczema on the face without preceding atopic eczema.

T-cell leukaemia/lymphoma in a child with associated HTLV-1 infection has also been reported [12]. In this case, the disease appeared to be less aggressive than in most adult cases.

HTLV-1 infection has also been associated in rare cases with an inflammatory myopathy, which may show features suggestive of dermatomyositis [13]. However, it responds poorly, if at all, to systemic corticosteroids or other immunosuppressive drugs.

Diagnosis. HTLV-1 infection is confirmed by detecting antibodies to the virus in a serum sample. Cultivation and detection of the virus is only available in specialist laboratories. ATLL is diagnosed by the presence in circulating blood of pleomorphic leukaemic cells that express the surface markers of activated mature helper T cells ($CD2^+$, $CD4^+$, $CD7^-$, $CD8^-$) and have lobulated nuclei.

Biopsy of abnormal skin shows a heavy dermal infiltrate, often with a mixed population of cells in which lymphocytes predominate. There may be prominent atypical morphology of cells and epidermotropism. The lymphoma is most commonly classified as a pleomorphic lymphoma but cases of angiocentric lymphoma [14] and $CD30^+$ large cell lymphoma [15,16] have been reported.

Hypercalcaemia is a common and characteristic finding and erosions in the bones are frequently seen on X-ray [17]. The differential diagnosis includes Sézary syndrome and mycosis fungoides, although the latter may itself be associated with HTLV-1 [18,19].

Treatment. Combination therapy with zidovudine and IFN-α has successfully induced complete or partial remission [20]. Maintenance therapy may be needed to prolong remission and chemotherapy has been given for unresponsive relapses, although the latter therapy has been disappointing. Recurrent superficial fungal infection of the skin and other opportunistic infections are common in ATLL. They should be actively diagnosed and managed with appropriate therapy.

Viral insect-borne and haemorrhagic fevers

These conditions are conveniently grouped together and are classified as shown in Table 25.4. The epidemiology has been reviewed [1].

Thrombocytopenia is present in all viral haemorrhagic fevers and reduced levels of coagulation factors in many. Additional mechanisms that may apply in some cases are platelet dysfunction, disseminated intravascular coagulation, circulating anticoagulants and vascular injury [2].

Rubella belongs to the Rubivirus genus of the family Togaviridae but is neither insect-borne nor haemorrhagic, and is discussed separately on p. 25.70.

Togaviruses

The viruses of this genus are mostly mosquito-borne and include the equine encephalitis viruses and many others of limited geographical distribution causing febrile illness in humans and ungulates (Table 25.4). In the majority there is no exanthem (e.g. Venezuelan equine encephalomyelitis [1]), but Sindbis [2,3], Chikungunya [4] and O'Nyong-Nyong [5] in East, Central and South Africa are all acute febrile illnesses with severe joint pains and a maculopapular rash. In Australia and the Pacific islands, epidemic polyarthritis is associated commonly with Ross River and Barmah Forest viruses [6]. A disease with exanthem and arthralgia seen in Sweden in the 1960s (Ockelbo disease) and in Finland in 1974 (Pogosta disease) was found to be serologically related to Sindbis [7].

Ross River virus

Ross River virus infection is caused by a togavirus, spread to humans by a variety of mosquito species, and is common in Australia and Fiji, accounting for the majority of cases of epidemic polyarthritis [8]. Illness is characterized by polyarthritis and rash. After an incubation period of 3–21 days (mean 9 days) a mild fever with headache and tender and painful muscles occurs; 95% of patients develop polyarthritis commonly of ankles, knees, fingers and wrists. A non-itching maculopapular rash appears on limbs and trunk in 50–60% of those affected; it may begin several days before to 11 days after the arthritis and lasts 2–7 days. Many infections are symptomless but rarely a severe meningoencephalitis has been seen. The most common group affected are 30–40 year olds and illness is rare under 10 years of age.

Chronic arthritis and tiredness often persists for several months with acute exacerbation and relapses, and recovery can only be assessed after 1 month without symptoms. Full recovery is expected within 6 months and is followed by lasting immunity.

This infection must be distinguished from acute rubella and in its chronic form from rheumatoid arthritis. In the acute phase, virus can be isolated from the blood by intracerebral inoculation of suckling mice or more quickly by molecular identification of viral RNA [9]. The presence of IgM antibodies or a rising antibody titre to Ross River virus is also diagnostic.

Barmah Forest virus

This virus, another togavirus, has been reported in Australia to cause an illness similar to Ross River virus [10]. A rash occurs in 70–90% of those infected and is associated with polyarthralgia and lethargy. These togavirus infections are indistinguishable clinically but can be differentiated by the virus-specific IgM response and rise

Flaviviruses

This family contains the largest group of antigenically related types of both mosquito- and tick-borne viruses.

The majority of the diseases concerned, including the tick-borne encephalitides complex, have no cutaneous manifestations. HCV does not cause haemorrhagic fever.

Yellow fever

Yellow fever is a disease that primarily affects the liver and causes abnormal liver function. Jaundice, severe leukopenia and thrombocytopenia develop. As a result of the latter, bleeding may occur.

The live attenuated vaccine contains the 17D strain grown in chick embryos. It should be given to all visitors to areas where yellow fever is endemic. It is also used to halt an epidemic along with control measures to eradicate the mosquito vectors.

Dengue [1,2]

Dengue is perhaps the most important mosquito-borne (mainly *Aedes aegypti*) virus disease in humans, affecting 50 million people annually worldwide. Since the 1980s, this disease has been widespread in Africa, Central and South America and Oceania, as well as in South-East Asia, where annual epidemics are common. Travellers to these areas are not uncommonly affected. The virus causes a range of infections: asymptomatic; a febrile illness; and a haemorrhagic fever associated with a 1–10% mortality. Symptoms, especially if severe, are more common in secondary infections. There are four antigenically distinct dengue viruses (serotypes 1–4) and infection is followed by lifelong immunity to the infection serotype. The usual form after primary infection in childhood is asymptomatic. Dengue fever starts after an incubation period of 2–14 days as a fever (frequently biphasic) with nausea, vomiting, headache, joint and bone pain, severe backache and often a rash. The rash, maculopapular or scarlatiniform, appears on the third to fourth day of the fever. It may start on the legs and spread caudally or on the chest and trunk and spread to the face, arms and legs [3]. The rash fades as the fever subsides (day 7) but can be followed by petechiae on the arms and legs. In dark-skinned people the rash is frequently not visible.

Confirmation of dengue infection is obtained by culture or detection of the virus in blood by PCR in the acute phase or by serological studies on acute and convalescent sera.

Dengue haemorrhagic fever

This form of the infection occurs in areas where dengue is hyperepidemic and there is co-circulation of multiple serotypes of the virus. This is because people who have been infected with one serotype and are subsequently infected with a different serotype are at greater risk of developing dengue haemorrhagic fever. HLA type can also influence susceptibility and resistance to haemorrhagic fever. Typically, dengue haemorrhagic fever occurs in children. The acute fever is accompanied by a haemorrhagic diathesis, which is manifest as petechiae and can be demonstrated by a positive tourniquet test. There may be bleeding from the nose or gums.

After 2–7 days there is a fall in body temperature and shock ensues, at which stage the patient may die. Vascular permeability increases leading to plasma loss, some of which collects as effusions in the pleural and abdominal cavities.

Certain clinical diagnosis from other arbovirus infections, such as West Nile fever and Chikungunya, may not be possible. The diagnosis must be guided by knowledge of the infections locally endemic.

Measles and other exanthems may obviously require exclusion.

Treatment. Only symptomatic measures are available.

Other viral haemorrhagic fevers

These belong to the families Arenaviridae, Filoviridae and Bunyaviridae. Infections are accompanied by disordered haemostasis. This may be marked, with profuse bleeding, although non-haemorrhagic disease also occurs. Viral haemorrhagic fevers are endemic in many countries, particularly in the tropics. They may be caused by a variety of viruses (Table 25.4). Most are zoonotic infections, humans being an accidental host, although person-to-person transmission also occurs. Nosocomial infections have been reported as have outbreaks of Ebola in rural African hospitals.

Diagnosis. Diagnosis cannot be made by clinical features alone. As these infections may closely resemble typhoid fever and malaria, it is important to exclude these treatable conditions. Laboratory diagnosis by virus isolation or demonstration of virus-specific antibodies must only be carried out at the highest level of biological containment (class 4). Suspected cases of viral haemorrhagic fever must therefore be discussed with the microbiologist before any material is taken for laboratory testing.

Arenaviridae

There are two groups of arenaviruses that cause severe viral haemorrhagic fever in humans: Lassa and the Tacar-

ibe complex viruses [1]. Another arenavirus, lymphocytic choriomeningitis virus, causes meningoencephalitis not viral haemorrhagic fever. These arenaviruses are endemic in rodents.

Lassa fever [2]

The natural host is the multimammate rat, *Mastomys natalensis*, a common rodent in West African villages [3]. Transmission to humans produces short-lived outbreaks with secondary infections by person-to-person spread in households and hospital staff but few tertiary infections, presumably because of a rapid decline in infectivity with human passage. Transmission by sexual intercourse with an infected person has also been recorded. This disease was first recognized in humans in 1969 in West Africa. Serological surveys in Guinea and Senegal have shown that up to 50% of the population of some villages have had past infection.

Clinical features [4,5]. The incubation period of Lassa fever is 7–18 days. Fever, malaise, headache and non-productive cough herald the onset of disease. There is joint and lumbar pain in over 50% of patients. A painful sore throat, often with exudate, develops in most cases by the fifth day. High fever and severe prostration follow. Diarrhoea, renal damage with proteinuria, central nervous system involvement with confusion, coma and convulsions, and respiratory complications may all occur in the first week of illness.

Conjunctivitis is common. Apart from one 2-month-old child with a morbilliform rash [3], exanthems have not been a feature. A petechial rash occurred in two of 23 cases in an outbreak in Nigeria [6]. Bleeding is rare but indicates a poor prognosis. The overall mortality rate is 2–4% but rises in hospitalized patients to 10–20%. Lassa fever in the third trimester of pregnancy is associated with a mortality rate of more than 30%. In survivors, about one-quarter develop deafness in one or both ears, which may be permanent or slowly resolve.

Treatment [7]. Ribavirin (tribavirin), a guanosine analogue, is an effective antiviral drug in Lassa fever, especially if given within 6 days of the onset of illness [8]. In a therapeutic trial the mortality rate in severely ill patients, treated early, was reduced from 61 to 5%. Intravenous ribavirin is given as a 2-g loading dose followed by 1 g 6-hourly for 4 days and then 0.5 g 6-hourly for 6 days.

Prevention. Post-exposure prophylaxis with oral ribavirin is recommended for persons known to have been exposed to Lassa virus. Early diagnosis of the infection by RT-PCR amplification of the viral RNA in serum samples can identify those infected and help to prevent spread.

Argentinian, Bolivian and Venezuelan haemorrhagic fevers [9,10]

Argentinian, Bolivian and Venezuelan haemorrhagic fevers are caused, respectively, by Junin virus (natural host *Calomys musculinus*), Machupo virus (natural host *Calomys callosus*) and Guanarito virus (natural host *Sigmodon alstoni*). These viruses are grouped together as the Tacaribe complex viruses and the diseases they cause are clinically alike. The 7–10-day incubation is followed by a high fever, malaise and myalgia, erythema of the face, neck and thorax, a pharyngeal exanthem and petechiae. Epistaxis and haematemesis may also occur in the first week of the illness. Shock ensues in over half the patients. These infections are associated with about a 15% mortality rate.

Filoviridae

Marburg and Ebola disease

Aetiology. The disease was first observed in Marburg [1] and Frankfurt [2] in Germany and in Yugoslavia in 1967 when 30 infections, seven of which were fatal, followed the importation of a consignment of African green monkeys (*Cercopithecus aethiops*) from Uganda [3]. Three further cases of Marburg disease occurred in Johannesburg in 1975 in travellers from Zimbabwe [4], and a third outbreak occurred in Kenya in 1980 [5]. Serological surveys have shown evidence of infection of both monkeys and humans in Uganda and Kenya [2].

In 1976 a similar outbreak of several hundred cases occurred in northern Zaire and the Sudan, caused by the closely related but antigenically distinct Ebola virus [6]. More recently Ebola virus has been isolated from *Cynomolgus* monkeys imported from the Philippines to the USA [7] and was associated with four subclinical

but well-documented infections of humans. In 1995, an outbreak took place in Kikwit and the surrounding region of Zaire [8]. At least 296 people developed haemorrhagic fever due to Ebola virus. One-third of the cases were in health care workers, and the overall mortality rate was 79%. The natural reservoirs of these viruses remain unknown.

Person-to-person spread occurs, probably through direct contact with blood-stained body fluids, re-use of unsterile medical equipment and needlestick injuries. Aerosol spread has not been described. Body fluids may remain infectious for as long as 80 days.

Clinical features [9]. These are similar for both Marburg and Ebola diseases. The incubation period is usually 1–2 weeks followed by the sudden onset of headache and high fever and myalgia, especially lumbosacral. Diarrhoea and dehydration, hepatitis, haemorrhages and renal damage occur with many other changes due to the pantropic nature of the infection. Bleeding, commonly gastrointestinal and mucosal, begins about the fifth day of illness.

The acute febrile stage lasts about 2 weeks and death may occur as early as the eighth or as late as the 17th day. A measles-like rash develops, more obvious on white skins, between the third and fifth day. It is mainly on the buttocks, trunk and outer aspects of upper arms. Initially erythematous macules occur around the hair follicles; these progress to maculopapular lesions next day and become confluent. An enanthem may be present as a dark-red palatal discoloration and vesicles may occur on the soft palate at the time of or just before the exanthem. Severe cases have a diffuse livid erythema over the face, trunk and limbs. After about the 16th day, desquamation occurs in survivors.

Death is usually preceded by severe blood loss and shock. The mortality rate is 30–50%. Virus excretion continues for days to weeks in survivors.

Bunyaviridae

Crimean Congo haemorrhagic fever, Rift Valley fever and the febrile illness associated with Oropouche viruses are all caused by arthropod-borne members of the Bunyaviridae (Table 25.4). Infections with these viruses cause a serious influenza-like illness with hepatitis and haemorrhagic signs, which often progress to a fatal shock syndrome. In their more severe forms, these infections may be associated with petechial rashes (oral and on the upper body), mucosal bleeding, ecchymoses and uncontrollable haemorrhage.

The hantaviruses have a rodent reservoir and are transmitted directly from animal to human. Two types of infection are associated with the hantaviruses.

1 Haemorrhagic fever with renal syndrome [1], in its milder form, causes nephropathia endemica. Most infections are subclinical, but the classical illness presents abruptly as a flu-like illness followed by a hypotensive phase on day 5 and an oliguric phase on day 9. Petechial bleeding and substantial haemorrhage is recorded in less than 10% of cases. Mortality varies with the infecting strain from less than 1 to 10% and occurs typically in the oliguric phase. Recovery is accompanied by a diuresis in the third week of the illness.

2 Hantavirus pulmonary syndrome [2,3] was first recognized in 1993 in New Mexico and adjoining states, where the deer mouse, *Peromyscus maniculatus*, is the reservoir for the causative pulmonary syndrome hantavirus. This illness has a sudden onset, with fever, cough, myalgia and headache. Pulmonary oedema and respiratory failure (adult respiratory distress syndrome) rapidly ensue and are associated with a high mortality rate.

Rubella

Aetiology. Rubella virus is the only member of the Rubivirus genus of the Togaviridae. Unlike other togaviruses it does not require an insect vector to spread.

The disease occurs throughout the world and is endemic in large cities. Epidemics occur at irregular intervals, usually during the spring, and affect mainly older children and young adults. Transmission is by droplets from the nasopharynx and infectivity is greatest at the end of the incubation period and falls rapidly during the 4 days after the appearance of the rash. No distinctive pathological changes have been described.

Clinical features. After an incubation period of about 18 days (range 14–21 days) the rash appears without prodromes in the child but after a brief prodromal illness lasting 1–5 days in adolescents and adults, consisting of fever up to 39°C, headache and malaise, sore throat without coryza and suffusion of the conjunctivae with a gritty sensation. The symptoms subside as the rash develops [1].

An enanthem, Forschheimer's sign [2], is present in up to 20% of patients during the prodromal period or on the first day of the rash. Dull-red macules or petechiae are confined to the soft palate. Enlargement of lymph glands begins 5–7 days before the rash appears whether or not there are prodromal symptoms, and reaches its maximum on the first or second day of the rash. The enlargement is generalized but characteristically involves the suboccipital, post-auricular and cervical glands. However, these glands are not invariably affected and their involvement is not pathognomonic of rubella. The tenderness of the glands subsides after a day or two but palpable enlargement may continue for several weeks.

The rash appears first on the face and spreads rapidly downwards to the trunk and limbs. It consists of pink macules, at first discrete but soon becoming confluent on the face as a diffuse erythema. During the second day the face begins to clear and the macules on the trunk show some coalescence, those on the limbs remaining discrete. By the third day the trunk has cleared and by the fourth the eruption on the limbs has also faded. Recent epidemiological surveys show that the rash may be absent in some 40% of cases.

The blood count may be normal, or there may be a leukopenia with an inconstant increase in plasma cells.

Complications. These are few in childhood. In older children and adults arthritis is not uncommon and affects some 30% of females and 5% of males [3]. The clinical picture is variable. Either the small joints of the hands and feet or the knees, elbows and shoulders may develop pain and swelling associated with a return of fever as the rash is fading. The arthritis usually resolves within a month.

Rarely, purpura (thrombocytopenic or non-thrombocytopenic) occurs as a complication of rubella. An association between rubella infection and the development of the haemophagocytic syndrome has been noted in an adult [4]. Very rarely, encephalitis is reported.

Rubella in pregnancy. The prenatal damage produced by rubella in early pregnancy was first noted by Gregg in Australia in 1941 [5]. The overall risk of fetal damage now appears to be about 90% for primary maternal infection during the first 11 weeks [6]. Infection at this stage usually results in multiple defects. Between weeks 12 and 16 the risk of a rubella defect is about 25% and is principally that of deafness. Thereafter, although fetal infection occurs it does not result in damage. The number of women of child-bearing age at risk of primary rubella in the UK is now probably less than 10%. Although of considerably less risk, maternal reinfection, both symptomatic and asymptomatic, can be followed by intrauterine infection and malformation of the fetus.

Heart and eye damage is most frequent in embryos infected under 6 weeks; deafness and mental deficiency occur in embryos of all ages up to about 16 weeks. Mental retardation and microcephaly may not be apparent until a year or more after prenatal infection [7]. During the neonatal period congenital rubella may give rise to a number of manifestations that are self-limiting in those infants who survive [8,9]. The most frequent is thrombocytopenic purpura, which tends to clear after a few weeks. Other features are bone lesions, which may simulate congenital syphilis, and skin changes of jaundice. One child was reported to have a widespread eruption of pigmented macules and erythematous papules and plaques [10].

Prophylaxis. Active immunization by inoculation with live attenuated rubella virus is employed in many countries. It was introduced in the UK in 1970. It is now routinely offered to infants aged 1–2 years old, together with measles and mumps vaccine (MMR vaccine). A preschool booster of MMR is also recommended. If they are found to be susceptible, rubella vaccine is also given to selected groups of women who require protection, such as nursing staff and teachers [11].

Pregnancy is a contraindication to vaccine and should be avoided for 4 weeks after its administration. There have, however, been no reports of damage to the fetus following inadvertent vaccination of pregnant women [12]. Vaccinated females apparently do not infect their contacts [13]. Arthralgia is common in adult women 2–4 weeks after vaccination and in children a rubelliform rash may occur.

Diagnosis. In view of the fetal hazard it is unwise to rely on the clinical features for the diagnosis of rubelliform rashes. In the typical infection the morphology of the pink macules and their coalescence to a diffuse erythema on the face and trunk is suggestive, as are the presence of enlarged suboccipital glands and the sequence of onset and fading of the rash on the face, trunk and limbs, although these features can also be produced by enterovirus and human parvovirus infections.

Laboratory investigations must be carried out to confirm a diagnosis in pregnancy or immunosuppression. Serology remains the appropriate technique and the first clotted blood should be taken as soon as possible after the rash is noted. A second blood sample is required 7–10 days later and the haemagglutination inhibition test [14] provides a clear answer in most instances. When the patient does not present sufficiently early, the presence of specific IgM antibody is also diagnostic of a recent

infection. In pregnant contacts the presence of antibody within 14 days of contact is indicative of immunity from previous infection. In neonates the presence of IgM and continued antibody production are indicative of congenital infection.

Treatment. There is no specific treatment.

Picornaviruses

This group includes: (i) the enteroviruses (poliomyelitis, coxsackieviruses and echoviruses); (ii) the rhinoviruses, generally associated with the common cold but now also including foot and mouth virus; and (iii) hepatitis A.

The enteroviruses are widely distributed and comprise well over 70 antigenic types. They replicate in the alimentary tract so that spread is by droplets from the nasopharynx and by faecal contamination. Epidemics are common especially in the warmer months of the year and affect mainly children. Infection is transient without long-term persistence (but see echoviruses). The illnesses are generally mild and often subclinical, but can vary through exanthemic fevers to myocarditis and paralytic poliomyelitis. Poliomyelitis has no exanthem.

Coxsackieviruses

Coxsackieviruses are divided into two groups, A and B. There are 24 group A serotypes and six group B serotypes. Both are commonly found in the faeces of children in the absence of disease. Both may produce a febrile exanthematic illness, respiratory infections, aseptic meningitis and encephalitis.

Diagnosis. Infection can be confirmed by isolation of the virus from stool, vesicle fluid or nasopharynx in tissue culture or better in newborn mice, since only a few coxsackie A strains grow in tissue culture. Isolation from faeces alone may be misleading in the diagnosis of the disease, owing to the frequency of asymptomatic infection. Serology is of limited value. The enteroviral genome can be detected and typed in appropriate specimens by RT-PCR.

Coxsackie A strains cause herpangina and hand, foot and mouth disease. Group B coxsackieviruses are especially associated with epidemic pleurodynia (Bornholm disease), epidemic myalgia, myocarditis and pericarditis. A causal association between coxsackie B and juvenile dermatomyositis has been suggested [1]. As with other enteroviruses, the clinical syndrome produced by any one strain is very variable.

Herpangina

Aetiology. Herpangina is a specific infection caused by group A coxsackieviruses of types 2, 3, 4, 5, 6, 8 and 10 and group B type 3. It occurs throughout the world, affecting mainly children aged 1–7 years, but it is not uncommon in adults. Epidemics and sporadic cases are most frequent in the summer and autumn. Herpangina is often noted in cases with predominant features of hand, foot and mouth disease, as in the 1999/2000 epidemic in the Far East.

Clinical features. Fever of sudden onset, ranging from 38.5 to 40°C, is commonly the first manifestation of the disease and continues for 4 or 5 days. It is accompanied, or soon followed, by sore throat and dysphagia and occasionally by vomiting and abdominal pain. Up to 15 or 20 minute vesicles, 1–2 mm in diameter, with a vivid red areola, develop on the pharynx, tonsils, the pillars of the fauces, the uvula and soft palate. They erode to leave ulcers, which enlarge for 2 or 3 days and heal in 4 or 5 days. Complete recovery in 5–7 days is invariable.

Diagnosis. See above. The clinical differential diagnosis is discussed in Chapter 66.

Treatment. Symptomatic measures alone are usually adequate. Allopurinol mouthwashes have been reported to be of help [2].

Hand, foot and mouth disease

Aetiology and pathology. The characteristic but somewhat variable syndrome described as hand, foot and

Fig. 25.27 Hand, foot and mouth disease. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

mouth disease by Alsop [3] was first noted in Toronto in 1957 [4]. It has occurred in epidemic form in many parts of the world, and has usually been associated with human enterovirus A species, especially coxsackie A16, with outbreaks also caused by A5 [5,6], A10 [7] and other types such as human enterovirus 71. Most cases are in young children during the autumn months, although outbreaks have occurred in communities of adults [8].

Histology is not usually performed but shows spongiosis, intraepidermal splits progressing to vesicle formation, mononuclear cells entering the epidermis, and necrosis of individual keratinocytes. Electron microscopy shows viral particles in addition [9].

Clinical features [3,5,6,8–11]. The disease is usually mild, has an incubation period of 5–7 days and lasts about 7 days. The presenting feature in adults is usually a painful stomatitis, but in children this may be mild. The oral vesicles, which rapidly ulcerate, resemble those of herpangina but are rather larger and fewer in number and are irregularly distributed over the palate, buccal mucous membrane, gums and tongue. Fever is usually slight and of short duration. Skin lesions are inconstant, but when present may be characteristic, and in children may dominate the clinical picture. These lesions are small vesicles up to 5 mm in diameter, thin-walled, pearly grey, with a narrow red areola, oval or linear rather than rounded (Fig. 25.27). They are most common on the hands, usually occurring on the sides or dorsa of fingers and toes, especially around the nails, and around the margins of the heels, but may be seen in the finger flexures and on the palms and soles. They are often few in number, although there may be 50 or more, and they fade over 2 or 3 days. In some cases, especially in infants, there is a more extensive exanthem, papular or vesicular, favouring the buttocks, but sometimes generalized. Relapses are rare and a chronic intermittent course is exceptional. In an atopic infant the generalized vesicles resembled Kaposi's varicelliform eruption [12].

Other features. Complications of hand, foot and mouth disease include hyperglycaemia, encephalitis, meningitis, pulmonary oedema, myocarditis, paralysis and Guillain–Barré syndrome.

Diagnosis. See Chapter 66.

Other exanthematic coxsackievirus syndromes

Rashes have been reported in a proportion of cases in outbreaks of other coxsackievirus syndromes.

A vesicular stomatitis involving the anterior portions of the oral cavity and the lips, associated with erythema multiforme, was caused by coxsackie B5 [13], which can also give a morbilliform exanthem [14]. Coxsackie A4 has caused a widespread vesicular eruption lasting for up to 2 weeks [11]. The exanthem in these and other coxsackievirus infections presents few features that are sufficiently constant to suggest the diagnosis, although the association with oral lesions should arouse suspicion.

A Gianotti–Crosti-like eruption was associated with coxsackie A16 infection in a 2-year-old boy [15]. Congenital coxsackie B3 infection has been described in a child with florid papulovesicles with nodules and ulceration, plus associated pneumonia, carditis and hepatitis [16].

Echoviruses

The echo (*e*nteric-*c*ytopathic-*h*uman-*o*rphan) viruses were so called because they occur in the human intestinal tract, are cytopathic in tissue culture and were believed not to cause disease in humans. Many of the 34 distinct serological types are now known to cause a wide variety of syndromes, including encephalitis, aseptic meningitis, exanthematic fever and diarrhoea and vomiting. Typically, annual summer/autumn epidemics occur in which one or more serotypes predominate.

Rashes have been noted in association with at least half of the echovirus types, and are more likely to occur in children than adults. Macular, maculopapular, vesicular and petechial eruptions, and tonsillar and buccal exanthems may occur. The erythematous eruptions commonly affect the face and trunk. Close correlation between the morphology of the rash and the virus type is not seen, but the following associations have been reported.

1 Echovirus 9: rubelliform or morbilliform eruptions [1–3].
2 Echovirus 16: the 'Boston eruption', large pink macules on face and trunk, occasionally widespread including palms and soles, following a brief febrile illness in children or adults [4].
3 Echovirus 2: rubelliform rash [5].
4 Echoviruses 11 and 19: petechial rash [6].
5 Echoviruses 6, 11 and 25: maculopapular rashes [7,8].
6 Echoviruses 23 and 32: telangiectatic macular lesions [9].
7 Echovirus 19: punctate macular rash in infants [10].
8 Echovirus 11: vesicular eruptions [11,12].

Diagnosis. Echovirus and rubella infections are often present simultaneously in a community, and the eruptions they produce may be indistinguishable. It is therefore essential for any woman developing a rash in the early stages of pregnancy to be investigated for both enterovirus and rubella infection by isolation of virus in tissue culture from throat swab and secretions, faeces or cerebrospinal fluid for the former and by serological tests for the latter.

Chronic echovirus infection

In hypogammaglobulinaemia, a condition of chronic enteroviral infection has been reported [13]. This causes a progressive encephalitis that is fatal within about 4 years. A dermatomyositis-like syndrome may occur in the early stages in some of these patients. It is associated with mild non-pitting oedema of the lower legs and a transient erythematous rash.

Foot and mouth disease [1–3]

Aetiology and pathology. This common and serious epidemic viral disease of farm animals in Europe, Asia and Africa very rarely infects humans. Some cases reported under this diagnosis, but not confirmed by complement fixation or animal inoculation, may have been vesicular stomatitis or hand, foot and mouth disease. True foot and mouth disease has occurred in both adults and children in direct contact with infected stock. Type O virus has been isolated from some human cases. Loculated vesicles are formed in the deeper layers of the epithelium of mucous membranes and intranuclear inclusions are present in neighbouring cells.

Clinical features. The incubation period ranges from 2 to 18 days. Malaise, headache and fever, with burning of the oral mucous membranes, are followed after 2 or 3 days by vesicles of the buccal mucous membrane, tongue and lips, and on the palms, soles and interdigital skin. The vesicles are followed by ragged ulcers and may be accompanied by pain and oedema. Sometimes only the mouth or the hands are involved. The disease tends to be more severe in infants and children than in adults, but it is usually mild, the temperature falling after a few days and the lesions healing within a week.

Diagnosis. The other mucocutaneous syndromes must be excluded (see Chapter 66). The diagnosis is confirmed by isolation of the virus from the vesicles or by detection of

antigen from the vesicles or antibody in the serum by ELISA. The viral nucleic acid may be detected by RT-PCR in problematic cases.

Treatment. Only symptomatic measures are available.

Hepatitis A

The hepatitis A virus constitutes a unique genus in the Picornaviridae family. The virus is very stable in the environment and is spread by the faeco-oral route, by ingestion of contaminated food and water or through close person-to-person contact. In developing countries where hepatitis A is highly endemic, almost all the population has been infected and is immune by age 10 years. Developed countries with good water and sewage systems have very low rates of hepatitis A infection; consequently travellers from these countries to areas of high endemicity are at risk of infection.

Clinical features. The average incubation period is 30 days. Most people suffer a prodrome of a flu-like illness, anorexia and arthralgia in the week preceding the jaundice. Occasionally, in about 10% of cases, there is a transient eruption [1], usually maculopapular, petechial or urticarial. One patient has had a morbilliform eruption with predominance in sun-exposed sites [2]. During the prodrome and the early icteric phase, the patient excretes virus in the faeces and is infectious, although only a transient viraemia occurs. Jaundice develops in 65% of toddlers and about 90% of adults. Mortality in the over-50 age group is quoted as 2% [3].

Occasional reports of a vasulitic eruption with relapsing or persistent hepatitis A infection have been attributed to cryoglobulinaemia [4].

Diagnosis. Hepatitis A must be distinguished from other causes of jaundice. The diagnosis is confirmed by detecting hepatitis A IgM antibody. The presence of IgG antibody indicates past infection (or immunization) and gives protection.

Treatment. Symptomatic measures are usually sufficient. The infection is of a few weeks duration and no chronic carrier state exists. Alcohol should be avoided during the convalescent period. Patients with fulminant hepatitis should be referred to a specialized liver unit.

Prevention. Active immunization with inactivated vaccine or short-lived passive protection using human immunoglobulin are both available for susceptible contacts and travellers.

Vesicular stomatitis virus

Aetiology and pathology. Vesicular stomatitis is a specific virus infection of horses and cattle in the Americas, Asia and Africa. It is generally mild but can mimic foot and mouth disease. It is occasionally transmitted to humans by direct or indirect contact. As the name implies the virus can cause vesicles; these are intraepithelial. Intranuclear inclusions are present in infected cells.

Clinical features [1]. The incubation period is 2 days, after which there is fever with myalgia and malaise. This is occasionally followed by mild stomatitis with vesicles on the gums and buccal and pharyngeal mucosa, and lymphadenitis. Some patients develop vesicles of the fingers. Recovery takes about a week.

Myxoviruses and related RNA viruses

Two families are distinguishable, the Orthomyxoviridae, consisting of influenza viruses A, B and C, and the Paramyxoviridae, which comprises three genera:
1 Paramyxovirus, containing the parainfluenza virus and mumps;
2 Morbillivirus, in which the human representative is measles; and
3 Pneumovirus, which contains respiratory syncytial virus (RSV).

Cutaneous manifestations are not usually produced except in measles and occasionally in RSV infections.

Measles [1]

SYN. MORBILLI

Aetiology and pathology. Measles infection is transmitted

Fig. 25.28 Koplik's spots on buccal mucosa in measles. (Courtesy of Dr J. Kurtz, Oxford, UK.)

from human to human via the upper respiratory tract where initial replication occurs before wide dissemination throughout the body.

The cellular receptors for the virus are the CD46 and CD150 (signalling lymphocyte activation molecule, SLAM) molecules. During the prodromal period of establishment of infection in the reticuloendothelial system, there is lymphoid hyperplasia with formation of fused multinucleate giant cells. The prodromal rash [2] appears to be the result of viraemia with lodgement of antigen and virus in the capillaries. Cells in Koplik's spots also contain viral nucleocapsids. The conspicuous macular eruption on the fourth day is the result of the cell-mediated immune response against this material. If the response is defective as in leukaemia, especially when cytotoxic drugs are used, there may be no rash and progressive viral replication leads to giant cell pneumonia or a fatal encephalopathy [3].

Shortly after the rash appears, measles virus causes a transient depression of T-cell-mediated immune responses, which are an important feature of the infection [4]. This was observed by Von Pirquet [5] as a fading in sensitivity to tuberculin, and this anergy persists for 1–2 months. It is generally considered a mechanism that increases susceptibility to tuberculosis and may permit the invasion of the brain by measles virus, which later produces subacute sclerosing panencephalitis. Lifelong immunity follows natural measles infection.

Clinical features. After an incubation period of about 10 days, the prodromal symptoms of fever, malaise and upper respiratory catarrh begin acutely. The conjunctivae are injected and there may be photophobia. From the second day, Koplik's spots (bluish white spots with bright-red areolae) are usually present on the buccal mucous membrane opposite the premolar teeth (Fig. 25.28). Fever, catarrh and cough increase for 3–5 days. The exanthem characteristically develops on the fourth day on the forehead and behind the ears, and spreads within 24 h to the rest of the face, the trunk and the limbs. The rash is at first macular but soon forms dull red papules that tend to coalesce in irregularly concentric patterns but may be more diffusely confluent. From the 6th to the 10th day the rash fades, to leave some brownish staining and fine desquamation. In very severe forms it may be haemorrhagic.

An extensive bullous eruption may develop during the acute stage of measles. In some cases this eruption has the features of Stevens–Johnson syndrome [6], but in others it resembles epidermal necrolysis. It is possible that in some suspected cases drugs were responsible, but in others the eruption appears to have been directly related to the virus infection. It is sometimes inappropriately referred to as 'measles pemphigoid'.

Complications are more common in young children, the malnourished and the chronically ill. Bronchopneumonia, enteritis and otitis media are less frequent now as effective antibiotics are available. The most serious complication is encephalitis, which occurs in 1 in 2000 cases.

Diagnosis. The features of other infective exanthems are considered in this chapter. Drug eruptions should not cause confusion because the upper respiratory catarrh and conjunctival suffusion are absent. Specific measles antibodies are usually detectable 3 or 4 days after the appearance of the rash, and maximum titres are reached 2–4 weeks later. Virus isolation is not easy but viral antigen can be detected by immunofluorescence in cell smears prepared from nasopharyngeal aspirates taken early during the illness and in skin biopsy of the exanthem [7]. Molecular diagnosis of measles is possible [8] but not yet routine.

Treatment. The patient should be confined to bed and given symptomatic treatment. Children with measles, especially in areas of high mortality, should be given vitamin A (two doses of 200 000 units). Antibiotics may be required to control secondary bacterial complications. Passive protection is possible using normal human immunoglobulin given within 5 days of exposure, which prevents or attenuates the infection in contacts and is reserved for those children at special risk. Active immunization with the live attenuated vaccine has reduced the incidence of measles infections but a mild illness with a rash is common during the 3 weeks following the vaccine [8].

Respiratory syncytial virus

Aetiology and pathology. The virus is pleomorphic, a little smaller than measles, and derives its name from the multinucleate syncytia produced when grown in tissue-culture cells. There are two distinct subgroups, A and B, which differ most in their surface glycoprotein G. There appears to be no difference in severity between group A and B infections but group A viruses are more frequently detected [1]. RSV causes annual epidemics during the winter months or in the rainy season in the tropics. Most people have been infected by age 1 or 2 years and suffer repeated infections throughout life.

Clinical features. Infection occurs after an incubation period of 4–5 days. The virus is especially associated with bronchiolitis in babies. Bronchitis and pneumonia occur in a proportion of infections. In older children and adults, upper respiratory symptoms occur that are indistinguishable from a common cold. Again in old age, RSV pneumonia is not uncommon and in bone marrow transplant recipients is associated with a high rate of mortality [2]. A transient, fine, pink, macular rash on the face and trunk has been observed in a few instances in children, but is of no diagnostic significance. Occasionally it is more extensive and involves the arms, shoulders, chest, back and buttocks [3]. The diagnosis is achieved rapidly by examination of nasopharyngeal exudate cells for the presence of viral antigen [4]; growth in tissue culture takes longer and serology may be of occasional value.

Other cutaneous problems associated with viral infections

Several cutaneous syndromes are associated with viral infections or other triggering factors.

Papular–purpuric gloves and socks syndrome

An acute acral dermatosis, occurring predominantly in adults, was first described in 1990 [1]. The hands, wrists, feet and ankles are intensely pruritic and are affected with erythema and papular oedema. There may also be associated purpura and rarely petechiae. The cutaneous features are frequently accompanied by oral inflammation and ulceration. Malaise and fever can follow a few days after the onset of the eruption but the condition settles within 2 weeks. In many cases, no specific cause can be identified [2] but parvovirus B19 infection has been suggested to act as a trigger for the syndrome [3] and measles, hepatitis B and CMV infections have been reported in association [4–6].

TORCH syndrome

The term 'TORCH syndrome' was originally used to encompass congenital infection caused by ***To****xoplasma gondii*, **r**ubella, **c**ytomegalovirus or **h**erpes simplex types 1 and 2 in which the clinical presentation was somewhat similar. In practice, there are some distinctions between the manifestations of the various infections, although all may cause cutaneous and disseminated abnormalities. Skin abnormalities of jaundice, purpura and petechiae are most common. Vesicles and mucosal ulceration may occur with herpes infection. Since the acronym has been used, several other congenital infections are recognized to be of importance and the concept of TORCH is now of limited value [7].

Kikuchi–Fujimoto disease [8]

SYN. KIKUCHI'S DISEASE; HISTIOCYTIC NECROTIZING LYMPHADENITIS

The clinicopathological entity consists of painful lymphadenitis affecting mainly the cervical nodes associated with fever, malaise and upper respiratory tract symptoms. Occasionally symptoms may be severe enough to mimic a malignant lymphoma. Cutaneous involvement, especially overlying affected lymph nodes, may be present in 30% of cases. Erythematous indurated plaques but also macules and papules may be seen. Viral infections reported in association include EBV, parvovirus B19, HSV and HHV-6 [9], although not all investigators have confirmed these findings [10].

Erythema nodosum

Septal panniculitis presenting as erythema nodosum, most commonly on the shins, is associated with a variety of conditions (see Chapter 49). Viral infections implicated as possible precipitants include milker's nodule, infectious mononucleosis, HBV and HCV.

Erythema multiforme

Erythema multiforme may be precipitated by several different viral infections. HSV is the most commonly associated virus, but VZV, infectious mononucleosis, mumps, polio, orf, milker's nodule, HIV, HBV and HCV [11] may all need to be considered as trigger factors.

Polyarteritis nodosa

Inflammation of medium-sized vessels presenting with only cutaneous lesions or with systemic effects has been associated with infection with HBV and HCV (see pp. 25.60–25.62).

Gianotti–Crosti syndrome

SYN. PAPULAR ACRODERMATITIS OF CHILDHOOD

Aetiology. Gianotti–Crosti syndrome is a characteristic cutaneous response to viral infection [1,2]. The majority of the earlier reported cases had HBV infection, and indeed Gianotti concluded in 1979 [3] that the eruption was exclusively associated with that virus, and he distinguished the condition from other 'papulovesicular acro-located syndromes' that were clinically similar but not associated with HBV. Other authors have found the distinction between the eruptions less convincing [4] and have suggested that they should all be included within the Gianotti–Crosti syndrome, so that HBV infection is not a requirement for the diagnosis [2,5]. On this basis, several other viruses have been associated; the most common of these is EBV [2,6,7], including a case with primary infection with both HBV and EBV [8]. Infrequently reported, and of less certain significance, are coxsackie A16 [9], coxsackie B4 and B5 [7], echovirus 7 [10], echovirus 9 [11], poliovirus [12], CMV [7], RSV [12], parainfluenza virus [2], hepatitis A [13], parvovirus B19 [14] and HIV [15]. Occasional cases following immunization, for example diphtheria, pertussis and influenza [7,16], are of uncertain significance. A preceding upper respiratory tract infection was found to be common in patients or family members [2]. In a minority of cases, no evidence of viral infection can be found.

The syndrome mainly affects children between the ages of 6 months and 12 years, though occasional adult cases have occurred [3]. Small epidemics or clustering of cases is often observed.

Pathology [2,17]. The skin lesions show slight or moderate acanthosis and hyperkeratosis. In the oedematous upper dermis an infiltrate of lymphocytes and histiocytes surrounds dilated capillaries. The lymph nodes show a diffuse reticulum cell hyperplasia, often of severe degree. When histology of bone marrow or liver is indicated, they show what appears to be a generalized, low-grade, inflammatory reaction of the entire reticuloendothelial system.

Clinical features [2,3,18]. Over the course of 3 or 4 days a profuse eruption of dull, red, flat-topped papules develops first on the thighs and buttocks (Fig. 25.29), then on the extensor aspects of the arms, and finally on the face. The distribution is often asymmetrical. The fleeting appearance of a few lesions on the trunk is occasionally noted. The individual papules are 5–10 mm in diameter, and their characteristic deep-red colour may later be modified by purpuric staining, especially on the legs. Itch is said not to be a feature of the HBV cases, but may occur in those due to other viruses. The eruption fades in 2–8 weeks with mild desquamation. Recurrence is unlikely but has been reported [19].

Generalized lymphadenopathy, mostly axillary and inguinal, is common but not invariable, and persists for months after the rash. Constitutional symptoms are not usually marked, although there may be mild fever and lassitude. The changes in the peripheral blood are inconstant: there may be a leukopenia or a slight leukocytosis with 2–15% of monocytes; the erythrocyte sedimentation rate is not raised.

In the HBV cases, liver involvement appears to be invariable, usually mild and anicteric, but occasionally there is jaundice, and histological recovery may take between 6 months and 4 years. Rarely there is persistent hepatitis. Hepatomegaly and liver function abnormalities each occasionally occur in HBsAg-negative cases [2].

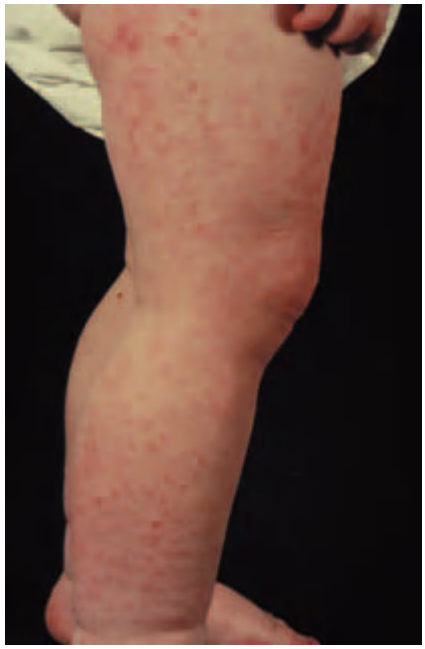

Fig. 25.29 Gianotti–Crosti syndrome: papular eruption on leg. (Courtesy of Dr N.P. Burrows, Addenbrooke's Hospital, Cambridge, UK.)

In some otherwise typical cases the exanthem is absent or minimal.

Diagnosis. The skin lesions are sufficiently distinctive in morphology, distribution and duration. It may in selected cases be worth examining clotted blood for hepatitis B antigen and assessing liver function.

Treatment. There is no specific treatment. Emollients and topical steroids may help to relieve pruritus.

Pityriasis rosea

Definition. Pityriasis rosea is an acute self-limiting disease, probably infective in origin, affecting mainly children and young adults, and characterized by a distinctive skin eruption and minimal constitutional symptoms.

Aetiology [1–4]. Pityriasis rosea is relatively common throughout the world. In temperate regions, it is more frequent during the winter months. In tropical areas, there may also be some seasonal variation. Changes in incidence from year to year, though not great, may be statistically significant [3].

A large series of 249 cases in Minnesota [2] showed a female/male ratio of 1.5 : 1, although previous large studies in Sweden [1] and England [5] showed equal susceptibility of the sexes.

Most cases of pityriasis rosea occur between the ages of 10 and 35 years and it is uncommon in early childhood or old age, although it has occurred in infants and in the ninth decade. Susceptibility to the disease appears not to be influenced by race or other genetic factors. Earlier suggestions of an association with atopy [1] were not confirmed in the Minnesota study [6].

The cause of pityriasis rosea is uncertain, but many epidemiological and clinical features suggest that an infective agent may be implicated.

True epidemics have not been reported, and the possibility that recent clinical experience of the disease might increase the tendency to diagnose subsequent cases could lead to erroneous impressions of contagiousness. However, reported epidemiological evidence for (admittedly low) infectivity includes occasional family or household outbreaks, seasonal and year-to-year fluctuations [1,3,5,7], statistical evidence for clustering in space and time [8], and a higher incidence among dermatologists than among ear, nose and throat surgeons and pre-specialization dermatologists [9]. The natural history of the disease, i.e. a

primary lesion that could correspond to the site of inoculation, a disseminated secondary eruption after an interval, a self-limiting course and the infrequency of second attacks, shows features paralleled by many diseases of proven infective origin. Occasional mild constitutional symptoms are reported and might support an infective cause, but were found to be no more frequent in 108 patients with pityriasis rosea than in the same number of controls [1]. Exacerbations accompanying oral steroid therapy were noted in a small series [10] and pityriasis rosea-like eruptions have been reported after bone marrow transplantation [11], although several aetiological effects could be implicated in such a situation.

The search for a microorganism continues. Earlier suspicions about fungi, streptococci, spirochaetes [7] and *Legionella* [12] have not been confirmed, and most speculation now centres on a viral aetiology. Attempts to culture virus from affected skin have been fruitless [13,14]. Virus-like particles were detected ultrastructurally many years ago [15,16] and more recently herpes virus-like particles have been found in 71% of pityriasis rosea lesions [17]. Involvement of two herpesviruses, HHV-6 and HHV-7, has been suggested as a cause for the eruption. The viral DNA is reported to be present in peripheral blood mononuclear cells and lesional and unaffected skin of the majority (80–100%) of individuals with acute pityriasis rosea. HHV-7 is detected slightly more frequently than HHV-6, but often both viruses are found [18,19]. However, evidence for the presence and activity of HHV-6 or HHV-7 is also found in a proportion (10–44%) of unaffected individuals, suggesting that if there is a causal relationship, infection with the viruses does not always lead to disease. Not all groups working in this field have confirmed the presence of these viruses in patients with pityriasis rosea [20,21] or found a weaker association [22].

There are several reports associating pityriasis rosea-like eruptions with drugs. The rashes caused by arsenic, bismuth, gold and methopromazine seem more likely to have been atypical lichenoid reactions [1]. Other drugs implicated include metronidazole [23], barbiturates, clonidine, captopril [24] and ketotifen [25]. In some reports the resemblance of the eruption to pityriasis rosea has not been close, and in others coincidence might explain the association. Thus, while some drug eruptions may somewhat resemble the condition, there is no convincing evidence that typical pityriasis rosea can be caused by drugs.

Pathology [14,26–28]. The herald patch and the secondary lesions are similar histologically. The changes are not diagnostic.

In the epidermis, spongiosis, vesicles and patchy parakeratosis are common. The upper dermis shows oedema and a mononuclear cell infiltrate from which there is exocytosis into the epidermis, where these cells may form pustules, mainly subcorneal. The infiltrate comprises mainly helper T lymphocytes but also Langerhans' cells, and HLA-DR antigens are expressed on the keratinocyte surface. Occasional dyskeratotic keratinocytes are seen, sometimes adjacent to a Langerhans' cell. These findings suggest a cell-mediated immune reaction in the epidermis [28].

Clinical features [1,4,7] (Fig. 25.30). The eruption of pityriasis rosea follows a distinctive and remarkably constant pattern and course in some 80% of cases. Prodromal symptoms are usually absent and the vague complaints of headache and slight malaise elicited by direct questioning may not be more frequent than in healthy control subjects. The first manifestation of the disease is usually the appearance of the herald patch, which is larger and more conspicuous than the lesions of the later eruption and is usually situated on the thigh or upper arm, the trunk or the neck; rarely it may be on the face, scalp or the penis. It is a sharply defined, bright-red, round or oval plaque, soon covered by fine scale. It rapidly reaches its maximum size, usually 2–5 cm in diameter but occasionally much larger. Rarely, there may be more than one herald patch. After an interval, which is usually between 5 and 15 days but may be as short as a few hours or as long as 2 months, the general eruption begins to appear in crops at 2–3 day intervals over a week or 10 days. Less often, new lesions continue to develop for several weeks. In its classical form the eruption consists of discrete medallions often oval in outline and dull pink in colour covered by fine, dry, silvery-grey scales. The centre tends to clear and assumes a wrinkled atrophic appearance and a tawny colour, with a marginal collarette of scale attached peripherally, with the free edge of the scale internally. The long axes of the lesions characteristically follow the lines of cleavage parallel to the ribs in a Christmas-tree pattern on the upper chest and back. The medallions are commonly associated with pink macules of varying size and the eruption may be exclusively macular.

The lesions are usually said to be confined to the trunk, the base of the neck and the upper third of the arms and legs. These sites are certainly most consistently and severely affected but involvement of the face and scalp is quite common, especially in children, and in one large series of cases lesions were found on the forearms and lower legs in about 12% and 6%, respectively. Lesions on the palms are exceptional but can occur. There may be discrete, scaly, red patches, diffuse redness and scaling or scattered small vesicles. Involvement of the oral mucous membrane is also unusual but is probably often overlooked. Either ill-defined red patches, with some desquamation or with punctate haemorrhages, or bullae may be observed. Oral lesions are not infrequently present [29] and, exceptionally, there may be lesions on the vulva.

Fig. 25.30 Pityriasis rosea: (a) with herald patch on right of abdomen, shown in close-up in (b); (c) with herald patch on right of chest. (a,b, Courtesy of York District Hospital, York, UK; c, courtesy of Dr A.S. Highet, York District Hospital, York, UK.)

Subjective symptoms are usually absent but there may be slight or moderate pruritus, particularly as a result of injudicious attempts at treatment. Occasionally, slight fever, malaise and enlargement of lymphatic glands, generalized or confined to the cervical glands, may be present; exceptionally, more severe constitutional symptoms have been recorded, although their extreme rarity suggests that they may have been fortuitously associated and may not be a manifestation of the disease.

The skin lesions commonly fade after 3–6 weeks, but some clear in 1 or 2 weeks and a few persist for as long as 2 months. A longer duration, except in the localized forms considered below, is very unusual. There may be temporary hyperpigmentation or hypopigmentation, but usually the lesions vanish without trace.

Second attacks of pityriasis rosea occur in about 2% of cases [1] after an interval of a few months or many years, but this may be an underestimate [3]. Rarely, partial or complete relapse of a fading eruption may be seen.

Pityriasis rosea may be atypical in the appearance or distribution of the lesions or in its course [30,31]. The herald patch is absent or undetected in about 20% of cases. The 'secondary' eruption varies greatly in extent. It may be almost generalized or may be limited to a few lesions, often around the herald patch. At times the eruption is confined to a single region, or may be maximal on the extremities almost sparing the trunk. Unilateral pityriasis has been reported [32]. Especially in children, the lesions may be predominantly papular or urticarial in the early stages, but they are soon surmounted by an inconspicuous ring of fine scales. Acute purpuric lesions have occasionally been reported [33]. Papulovesicular, vesicular and even pustular forms also occur, and erythema multiforme-like lesions formed part of the eruption in one child [34]. In a variant of the papular form more common in Africans than Europeans, small lichenoid papules are thickly set in the edges of the lesions [7].

In pityriasis circinata et marginata of Vidal [35], sometimes regarded as a special form and seen mainly in

adults, the lesions are few and large, and are often localized to one region of the body, especially the axillae or groins. They tend to become confluent and may persist for several months. Rarely, this form may follow a typical generalized pityriasis rosea, but it usually occurs alone.

Diagnosis. In the typical fully developed case the diagnosis usually presents little difficulty as the distribution, morphology and absence of constitutional symptoms are sufficiently distinctive. Some patterns of drug eruption may have to be excluded. An acute onset without a herald patch, pruritus and a tendency for the lesions to become lichenoid in appearance are suggestive features. A progressive, irritable, atypical pityriasiform eruption in a patient taking a drug known to provoke reactions of this nature can be tentatively accepted, in the absence of any method of laboratory confirmation.

Seborrhoeic dermatitis may be pityriasiform. There is no herald patch, the lesions often develop slowly and are most numerous on the upper trunk near the midline, on the neck and in the scalp, and they are duller in colour with thicker and more greasy scales. Small, scaly, follicular papules may also be present. The eruption is persistent if untreated.

Secondary syphilis is the classical trap but the resemblance is not very close. The genital and oral mucosae should be examined. There is no herald patch and the lesions are roseolar or maculopapular.

The acute urticarial forms in childhood can sometimes not be identified with complete certainty on first examination unless a herald patch can be discovered. Re-examination after 2 days enables a confident diagnosis to be confirmed.

Guttate psoriasis and pityriasis lichenoides may sometimes need exclusion. In both, the lesions are papular and persistent. In psoriasis they are surmounted by silvery scales. In pityriasis lichenoides they are polymorphic, some showing haemorrhagic crusting and some adherent scales.

The hypopigmented patches with dry branny scales of pityriasis alba are most frequent on the face, and are seen mainly in young children.

The herald patch and the localized forms such as pityriasis circinata are easily, and in practice frequently, confused with ringworm. The lesions of ringworm are red and oedematous and may show marginal vesiculation. In case of doubt scrapings from the edge of the lesions should be examined microscopically for mycelium.

Treatment. The common asymptomatic and self-limiting cases require no treatment [36]. Oral erythromycin given at a dose of 200 mg four times a day has been shown in one study to hasten the clearance of the lesions when compared with placebo [37]. If itch is troublesome or the appearance distressing, a topical steroid, usually of moderate strength, or UVB irradiation [38] can be helpful.

Chapter 26

AIDS and the Skin

C.B. Bunker & F. Gotch

Introduction

It is now 20 years since acquired immune deficiency syndrome (AIDS) was first recognized as a novel disease. Within 2 years of defining AIDS as a distinctive syndrome in 1981, the human immunodeficiency virus (HIV) was identified as the causative agent. HIV infection is acquired sexually, from blood or blood products, or vertically from an infected mother during pregnancy, birth or breastfeeding. The virus infects immunocompetent cells including CD4 T cells and macrophages. It creates variable patterns of disease in individuals, groups and races but all are characterized by evolving, sometimes fulminant immunodysfunction (AIDS) affecting many systems of the body.

Dermatological involvement in AIDS has been appreciated since the disease was first recognized as a cryptic acquired immune deficiency illness in homosexual men and before the causative virus was identified. Mucocutaneous involvement establishes criteria for diagnosis and staging; the prognostic significance of some complications, for example pruritic papular eruption/eosinophilic folliculitis, hairy leukoplakia and Kaposi's sarcoma (KS), was well recognized before specific treatments were introduced. The proportion of patients with skin complications and the number of these manifestations in any one patient increase as HIV progresses and AIDS develops. The incidence and severity of several common cutaneous diseases (such as mollusca, herpes simplex, seborrhoeic dermatitis) are increased in patients with HIV and this correlates in many instances with the absolute numbers of CD4 T-helper cells. The effect HIV infection may have on some dermatological conditions such as psoriasis and atopic dermatitis is less clear-cut. Since the recognition of AIDS there have been many case reports of rarer dermatoses in HIV-positive patients where an association is speculative. HIV has been demonstrated in the dermis of infected individuals and may be present in Langerhans' cells. Different cytokine expression patterns distinguish different cutaneous manifestations. The advent of highly active antiretroviral therapy (HAART) has been largely beneficial to patients with HIV-associated skin disease, but novel side effects of these drugs (such as lipodystrophy) have emerged and the skin can be affected by the immune reconstitution syndrome.

The dermatological complications of HIV and AIDS may be distressing to patients and difficult for dermatologists to diagnose and manage. However, they are of further interest in that the 'experiment of nature' sheds light on both the immunopathological natural history of HIV infection and the aetiology of common and rarer dermatoses that happen to be found with a higher incidence in HIV-infected than non-HIV-infected patients. Their occurrence emphasizes the importance of the skin as a dynamic immunological organ.

HIV infection

Epidemiological trends

AIDS was first described as a distinct clinical entity in 1981 [1]. HIV.1 infection now represents a global pandemic and in the past 20 years there have been an estimated 21.8 million AIDS deaths worldwide. Of AIDS cases, 95% occur in non-industrialized countries, 75% in sub-Saharan Africa; 36.1 million people are currently believed to be living with HIV infection [2].

Global trends in the HIV pandemic are shown in Table 26.1. These data are sourced from UNAIDS [2] who take estimates available from published studies and combine them with unpublished data, collected as part of AIDS control programmes in many countries, to provide national estimates of prevalence and deaths.

Table 26.1 Global trends in the HIV pandemic. (From UNAIDS [2].)

Region	Epidemic started	Adults and children living with HIV/AIDS	Adult prevalence rate* (%)	HIV-positive adults who are women (%)	Main mode of transmission for adults living with HIV/AIDS
Sub-Saharan Africa	Late 1970s, early 1980s	25.3 million	8.8	55	Heterosexual
North Africa and Middle East	Late 1980s	400 000	0.2	40	Heterosexual, IDU
South and South-East Asia	Late 1980s	5.8 million	0.56	35	Heterosexual, IDU
East Asia and Pacific	Late 1980s	640 000	0.07	13	IDU, heterosexual, MSM
Latin America	Late 1970s, early 1980s	1.4 million	0.5	25	MSM, IDU, heterosexual
Caribbean	Late 1970s, early 1980s	390 000	2.3	35	Heterosexual, MSM
Eastern Europe and Central Asia	Early 1990s	700 000	0.35	25	IDU
Western Europe	Late 1970s, early 1980s	540 000	0.24	25	MSM, IDU
North America	Late 1970s, early 1980s	920 000	0.6	20	MSM, IDU, heterosexual
Australia and New Zealand	Late 1970s, early 1980s	15 000	0.13	10	MSM
Total/mean		**36.1 million**	**1.1**	**47**	

IDU, transmission through injecting drug use; MSM, sexual transmission among men who have sex with men.
* The proportion of adults (15–49 years of age) living with HIV / AIDS in 2000.

In the UK, an average of more than 2500 HIV infections was reported each year between 1991 and 1997 [3]; 66% of these were from London. During this time 57% of infections were in homosexual men, 29% were as a result of heterosexual sex, and intravenous drug use accounted for 7%, except in Scotland, where it accounted for 20% of infections. During this time less than 1% of HIV infections diagnosed were attributed to blood, tissue or blood-factor treatment, and almost all of these infections were acquired before the widespread introduction of screening of donors.

Molecular epidemiology

One of the major characteristics of HIVs is their extremely high genetic variability. This extensive heterogeneity is a result of the high error rate of reverse transcriptase [4] and the extremely fast turnover of virions in HIV-infected individuals [5,6]. In addition, the reverse transcriptase enzyme is highly recombinogenic [7], so that radically different genomic combinations may be generated in individuals infected by genetically diverse viruses. Recombination requires the simultaneous infection of a cell with two different pro-viruses, allowing the encapsidation of one RNA transcript from each pro-virus into the heterozygous virion. After the subsequent infection of a new cell, the reverse transcriptase, moving back and forth between the two RNA templates, generates a newly synthesized retroviral DNA sequence that is a recombinant between the two parental genomes [7–9]. It is now well established that recombination events between different subtypes or clades of HIV are relatively common, and may result in circulating recombinant forms (CRFs) of HIV. Members of one distinct CRF should resemble each other over the entire genome, with similar break-points reflecting similar ancestry from the same recombination event(s).

Two main types of HIV infect humans: HIV.1 and HIV.2. Worldwide, HIV.1 is by far the commonest cause of AIDS. HIV.2, which differs in a number of its regulatory genes and is found predominantly in West Africa, apparently causes immune deficiency and AIDS more slowly than HIV.1, and is less infectious with lower rates of either sexual or mother-to-child transmission.

Phylogenetic analyses of many samples of HIV.1, isolated from diverse geographical origins, have revealed that they can be divided into *groups*, *subtypes* (or *clades*), *sub-subtypes* and *CRFs* [10–13]. Groups are the distinctive HIV.1 lineages: M (major), N (new) and O (outlier). The vast majority of HIV.1 strains found worldwide and responsible for the pandemic belong to the M lineage. Group O is endemic in Cameroon and neighbouring countries, and group N has only very recently been identified in West Central Africa.

Within group M there are further genetic subtypes or clades which are approximately equidistantly related to each other and represent a homogeneous group not resembling any other subtype across their entire genome. There are presently nine subtypes of HIV.1 identified: A–

Table 26.2 Clades of HIV.

Clade	Estimated incidence 2000 (%)	Primary geographical distribution
A	27	East, West and Central Africa, Eastern Europe
B	12.3	USA, UK, Australia
C	47.2	South Africa, India, China
D	5.3	East Africa
A/E	3.2	South-East Asia
F, G, H, J, K	5.0	Central Africa, Caribbean, Latin America

D, F–H, J and K. All known representatives of what was initially described as subtype E appear in fact to be recombinants of subtypes A and E and are now designated CRF01-AE. Within some subtypes further phylogenetic structure can be identified, for example subtype or clade F is divided into two sub-subtypes or subclades F1 and F2. It is also clear that clades B and D might be better considered as subclades of a single subtype, but for historical reasons it is difficult to change these descriptions [14].

Different subtypes of HIV.1 are predominantly found at different geographical locations, although in no country of the world is a single subtype circulating alone. The contribution of the different clades to the worldwide pandemic has been calculated [15–17] (Table 26.2).

Virology

HIV is a single-stranded RNA virus. The structure of the virus is complex, with three major structural genes: *gag* (coding for nuclear proteins), *pol* (coding for reverse transcriptase) and *env* (coding for the envelope). The rate of transcription of the genome is controlled by a number of regulatory genes including *rev*, *tat* and *nef*, and there are a number of other small accessory genes important for infection (*vif*, *vpu*, *vpr*).

The virus gains access to the cells by docking the envelope protein on the CD4 receptor and on co-receptors (primarily CCR5 on monocytes/macrophages, and CXCR4 on T cells). The process of fusion and inward passage of the genetic material of the virus is accomplished by the transmembrane envelope protein gp41 coming into contact with the cell surface. Components of the *gag* protein have an important chaperone function within the cell and allow reverse transcription to occur and the circular DNA product to be transported to the nucleus of the cell. There, a virally encoded enzyme, integrase, cleaves the circular DNA and inserts it into the host DNA, repairing the insertion sites. Pro-viral DNA may remain integrated for a substantial period of time before viral transcriptional events are triggered when the cell becomes activated. Initial transcriptional products are the regulatory proteins *rev*, *tat* and *nef*. The *tat* protein increases viral transcription, and *rev* acts in cis to enhance replication by interacting with *rev* regulatory elements within the viral genome; *nef* has a number of putative functions, one of which may be to reduce the amount of major histocompatibility complex (MHC) class I antigen on the cell surface and thus impede recognition of the infected cell by cytotoxic T cells (see below). The *vpr* gene is involved in nuclear transport and may down-regulate cellular apoptosis. The *vpu* gene may down-regulate the amount of CD4 receptor protein being produced in the endoplasmic reticulum. Viral products of transcription are then transported to the cytoplasm, where the nuclear capsid proteins may again have an important chaperone function. Viral proteins are produced as a long polyprotein that is split into active proteins by the virally encoded protease enzyme. Viral RNA and viral proteins are then assembled around the nuclear capsid antigen, and when the virus is fully assembled it buds from the cell surface.

It is now realized that enormous amounts of viral RNA are continually released into the plasma ($> 10^8$ viral particles per day) in untreated HIV-infected patients [5,6].

Immunology

The immune system is capable of mounting very strong attacks on invading pathogens and in many cases is able to eliminate them completely. Unfortunately this does not seem to be the case with HIV infection, except perhaps in a very few individuals in whom exposure to the virus has resulted in specific cellular immune responses to the virus, but who have neither seroconverted nor become productively infected [18]. Although often strong and apparently useful anti-HIV responses are induced in HIV-infected individuals, these do not seem to have the capability of clearing viral infection; however, in some individuals immune responses apparently play a role in allowing the host to coexist with the virus without progression to disease (long-term non-progressor patients; see 'Natural history' below and [19]).

Primary infection with HIV results in natural or innate immune responses that are mobilized within hours of infection and include inflammation, non-specific activation of macrophages, natural killer cells and complement, and release of cytokines.

After antigenic stimulation, acquired immune responses are primed. These responses emerge at the same time as

clearance of viraemia and rebound of CD4 T cells is seen. These HIV-specific responses are outlined below.

Specific humoral or antibody responses [20]: neutralizing antibodies to the envelope proteins of the virus and other non-neutralizing antibodies to internal viral proteins such as *gag*. Specific secretory IgA mucosal antibodies are also produced. Neutralizing antibodies are usually measurable by 12 weeks after infection.

Specific cellular (T-lymphocyte) responses [21]. $CD8^+$ T lymphocytes or cytotoxic T cells (CTL) form a primary component of the critical cellular immune response induced by HIV infection. CTL are differentiated from existing CTL precursors, and express T-cell receptor molecules capable of recognizing specific viral epitopes presented in the context of human leukocyte antigen (HLA) or MHC molecules at the surface of infected target cells. Mature CTLs are functional 5–10 days after antigenic stimulation, recognizing, binding and then lysing the infected target cell. Virus-specific CTLs evolve faster than antibody responses and are often induced before seroconversion and before viral RNA has reached peak titres. Thus $CD8^+$ CTLs are temporally associated with the fall in viraemia during acute infection, and there is good evidence that CTLs play a major role in the control of HIV infection at this time and later in HIV disease. Evidence for strong $CD8^+$ antiviral pressure can be appreciated by the number and variety of strategies which viruses have evolved to avoid apoptosis and CTL recognition, thus prolonging the life of the virally infected cell and enabling viral replication and dissemination [22]. In addition to the lysis of infected cells, CD8 T cells can reduce viral replication by the production of soluble factors. These factors are not antigen specific but their production requires specific T-cell activation. Anti-HIV effects have been found for interferon (IFN)-γ, interleukin (IL)-10, IL-13, IL-16 and the C-C chemokines MIP-1α, MIP-1β and RANTES. Such soluble factors may also have profound effects on other opportunistic infections including those affecting the skin.

$CD4^+$ T-cell responses induced by HIV infection provide help to both HIV-specific CTLs and B cells. CD4 T-helper cells recognize antigen in the context of HLA class II molecules on the surface of antigen-presenting cells such as dendritic cells. CD4 responses to a variety of HIV proteins (including *env*, *gag* and *nef*) have been demonstrated in early disease, but immunological abnormalities in T-helper function occur very early in HIV infection, even before CD4 T-cell numbers diminish. Reduced proliferative capacity and diminished IL-2 production in response to stimulation by exogenous antigens (including those from HIV and other pathogens) is one of the hallmarks of HIV disease.

On recognition of their specific antigen, naive CD4 T cells differentiate from a common (Th0) precursor into T-helper (Th)1 cells, which differentially secrete IL-2, IFN-γ, transforming growth factor-β and IL-12 and can activate macrophages and 'help' CTLs, or into Th2 cells, which secrete IL-4, IL-5, IL-6 and IL-10 that can activate B cells to proliferate and differentiate into antibody-producing plasma cells.

Central to the cellular immune response is the dendritic cell, which is the most potent antigen-presenting cell. However, such cells on mucosal surfaces (Langerhans' cells) may be some of the first targets in transmission: as well as transporting viral antigens across mucosal barriers and presenting them to CD4 cells, dendritic cells may themselves become infected with HIV, and their function compromised.

It should be noted that the immunosuppressive nature of HIV infection, where CD4 T cells are infected and destroyed, may have a profound effect on immune responses to other pathogens, many of which result in dermatological disease and are described later in this chapter. It is interesting to observe that HAART, which has a profound effect on HIV replication and enables some CD4 T-cell reconstitution, may also result in the re-emergence of useful opportunistic infection-specific cellular immune responses. Unfortunately, for reasons which are not well understood, HIV-specific responses are often not reconstituted. However, many AIDS-defining opportunistic infections, including diseases of the skin, may be resolved or avoided, and consequently HAART has had a profound effect on morbidity and mortality in HIV disease.

AIDS case surveillance definition

The case definition of AIDS in adults is shown in Table 26.3 [23]. The indicator conditions used in the case definition of AIDS in adults are shown in Table 26.4. The rank order of AIDS diagnoses reported to the Centers for Disease Control (USA) in 1996 is shown in Table 26.5.

Changes in the natural history of HIV which have followed the introduction of HAART in the mid-1990s include a sharp reduction in the frequency of KS and a decrease in *Pneumocystis carinii* pneumonia, reflecting the impact of prophylaxis and possible reconstitution of immune responses specific for opportunistic pathogens. The median CD4 T-cell count at the time of an AIDS-defining complication in those parts of the world where HAART is available is now 67×10^6/L. However, it should be remembered that, at present, such efficacious therapy is not available to more than 90% of persons infected with HIV.

It should also be noted that the AIDS case definition in children may be different from that in adults [24]. Furthermore, in contrast to the surveillance definitions described in Table 26.3, in clinical care HIV disease should be viewed as a continuum, rather than just the presence

Table 26.3 Case definition of AIDS in adults.

	Clinical category		
CD4 T-cell count	A: asymptomatic persistent generalized lymphadenopathy or acute HIV infection	B: symptomatic* (not A or C)	C: AIDS indicator condition (see Table 26.4)
1) > 500 × 10^6/L (> 29%)	A1	B1	C1†
2) 200–499 × 10^6/L (14–28%)	A2	B2	C2†
3) < 200 × 10^6/L (< 14%)	A3†	B3†	C3†

* Symptomatic conditions not included in category C that may be attributed to HIV infection or indicative of a defect in cell-mediated immunity, or may be considered to have a clinical course or management that is complicated by HIV infection. Examples include, but are not limited to, bacillary angiomatosis; thrush; vulvovaginal candidosis that is persistent, frequent or poorly responsive to therapy; cervical dysplasia (moderate or severe); cervical carcinoma *in situ*; constitutional symptoms, such as fever (> 38.5°C) or diarrhoea > 1 month; oral hairy leukoplakia; herpes zoster involving two episodes or more than one dermatome; idiopathic thrombocytopenic purpura; listeriosis; pelvic inflammatory disease; and peripheral neuropathy.
† All patients in categories A3, B3, C1, C2 and C3 are considered to have AIDS based on the AIDS indicator conditions and/or a CD4 T-cell count of < 200 × 10^6/L.

Table 26.4 Indicator conditions in the case definition of AIDS in adults.

Candidosis of oesophagus, trachea, bronchi or lungs
Cervical cancer, invasive*
Coccidioidomycosis, extrapulmonary*
Cryptococcosis, extrapulmonary
Cryptosporidiosis with diarrhoea for > 1 month
Cytomegalovirus of any organ other than liver, spleen or lymph nodes
Herpes simplex with mucocutaneous ulcer for > 1 month or bronchitis, pneumonitis oesophagitis
Histoplasmosis, extrapulmonary*
HIV-associated dementia: disabling cognitive and/or motor dysfunction interfering with occupation or activities of daily living
HIV-associated wasting:* involuntary weight loss of > 10% of baseline plus chronic diarrhoea (more than two loose stools per day for > 30 days) or chronic weakness and documented enigmatic fever for > 30 days
Isosporosis with diarrhoea for > 1 month*
Kaposi's sarcoma in patient younger than 60 years (or older than 60*)
Lymphoma of brain in patient younger than 60 years (or older than 60*)
Lymphoma, non-Hodgkin's of B-cell or unknown immunological phenotype and histology showing small non-cleaved lymphoma or immunoblastic sarcoma
Mycobacterium avium or *M. kansasii*, disseminated
Mycobacterium tuberculosis, disseminated*
Mycobacterium tuberculosis, pulmonary*
Nocardiosis*
Pneumocystis carinii pneumonia
Pneumonia, recurrent (bacterial)*
Progressive multifocal leukoencephalopathy
Salmonella septicaemia (non-typhoid), recurrent*
Strongyloidosis, extraintestinal
Toxoplasmosis of internal organ

* Requires positive HIV serology.

Table 26.5 Rank order of AIDS diagnoses reported to the Centers for Disease Control (USA) in 1996.

Pneumocystis carinii pneumonia	20%
Wasting	14%
Cytomegalovirus disease	6%
Kaposi's sarcoma	6%
Tuberculosis	5%
Disseminated *Mycobacterium avium–intracellulare* infection	4%
Chronic herpes simplex	4%
Recurrent bacterial pneumonia	4%
HIV-associated dementia	4%
Toxoplasmosis	3%

or absence of AIDS. This continuum includes primary infection, symptomatic infection, early symptomatic state (previously known as AIDS-related complex), late symptomatic disease and advanced disease.

Natural history

Prospective epidemiological studies in HIV-infected but untreated individuals with known dates of seroconversion have allowed us to quantify many aspects of the natural history of HIV disease, and have shown that the course of HIV infection may vary considerably in different individuals. Thus, although some individuals develop AIDS within 2–3 years and are termed 'rapid progressors', others remain free from AIDS for more than 10–15 years and are termed 'long-term non-progressors' or 'long-term survivors'. In the absence of treatment, the average time from seroconversion to the development of AIDS is 8–11.6 years, with a median time of approximately 10 years. Interestingly this median survival time is the same in the USA as it is in Uganda [25]. It should be noted that most existing data were obtained before the availability (in the West) of antiretroviral drugs and prophylaxis for *Pneumocystiis carinii* pneumonia. Clearly such drug treatment, when available, has a profound and beneficial effect on the natural history of HIV disease.

Certain clinical and laboratory factors are known to influence and help predict the rate of disease progression to AIDS in the HIV-infected individual. Rates of progression

appear similar by gender, race and risk category after adjustment for access to health care. The predictors for progression to AIDS may be summarized as follows.

- *Transmission risk group*. Time from HIV seroconversion to AIDS is approximately 7 years in transfusion recipients, 10 years for haemophiliacs, 10 years for intravenous drug users and 10–12 years for homosexual men.
- *Age at onset of infection*. It has been reported that for patients aged 16–24 years at time of HIV acquisition the median time from seroconversion to AIDS is 15 years, whereas for those aged over 35 at seroconversion it is 6 years.
- *Clinical indicators*. Patients with symptomatic primary HIV infection progress more rapidly than those with asymptomatic seroconversion. Other clinical markers of progression include the development of oral thrush, oral hairy leukoplakia, herpes zoster, constitutional symptoms and weight loss.
- *CD4 T-cell count*. CD4 T-cell counts and their decline over time are very important predictors of disease progression. On average the CD4 T-cell count decreases by $40–80 \times 10^6$/L annually; an acceleration in CD4 T-cell decline heralds progression of disease. A CD4 T-cell count of $< 200 \times 10^6$/L is diagnostic of AIDS, and the median survival time in an untreated patient with a CD4 T-cell count of $< 200 \times 10^6$/L is 38–40 months. The average CD4 T-cell count for the most common AIDS-defining conditions is in the range of $20–100 \times 10^6$/L.
- *Viral load*. Plasma HIV RNA viral load correlates well with the extent of viral replication in an infected individual. Progressively increasing HIV RNA concentrations can signal the development of advancing immunodeficiency. A single measurement of plasma RNA viral load early in infection is a powerful predictor of the subsequent risk of progression to AIDS and death. The combined measurement of CD4 T-cell count and viral load is an extremely accurate method for assessing the prognosis of infected patients.

Other factors that may be predictive of HIV disease progression have not been well defined. Thus co-infection with other pathogens such as cytomegalovirus (CMV), Epstein–Barr virus, hepatitis B or malaria has not been shown conclusively to accelerate disease progression. Although the genetic background of the patient may have relevance, very few genetic markers of progression have been defined. The size and route of the initial inoculum of virus may have an important role to play, as may the pathogenicity, virulence, attenuation state or genotype of the infecting virus.

HIV treatment

Antiretroviral treatment of HIV began in the mid-1980s with the nucleoside analogue zidovudine (azidothymidine) and the demonstration that this was better than placebo in the treatment of symptomatic disease. However, the treatment of HIV infection was revolutionized in developed countries as a result of the introduction of HAART. This has reduced short-term mortality and markedly increased quality of life by preventing opportunistic diseases [26]. HAART has developed as a result of controlled trials showing that dual nucleoside analogue therapy improves survival compared with zidovudine monotherapy [27], and that three-drug therapy consisting of two nucleoside analogues and a protease inhibitor is superior to two drugs [28].

One of the causes of drug failure is the development of viral mutations displaying reduced sensitivity to drugs. Such mutations may arise either because of selection of mutants already existing in the viral swarm or the *de novo* generation of new mutations as a result of selective pressure by the drugs. Avoidance of the development of drug resistance requires drugs to be used in combination, making selection or generation of new resistant mutations more difficult, and by the use of potent therapy, which suppresses viral replication as completely as possible.

The dramatic improvements in survival with the use of HAART coincided with the development of two potent classes of drugs. Following incorporation of viral DNA into the host genome, viral progeny are produced as a result of the transcription of this DNA, which accompanies cell activation. This produces polyproteins, which to be effective have to be digested by a virally coded protease. A variety of inhibitors of this protease are now available to clinicians and all are extremely potent.

The other potent class of compounds are the non-nucleoside reverse transcriptase inhibitors (NNRTIs). As described previously, the virus encodes for a unique enzyme, reverse transcriptase, that is responsible for converting viral RNA into a DNA copy, which is then incorporated in the host genome. The originally introduced therapies for HIV were all nucleoside analogues, which act as chain terminators of the growing DNA chain. Reverse transcriptase can also be inhibited very potently by a variety of chemicals that act in a pocket of the reverse transcriptase closely adjacent to the catalytic site. The potency of these drugs was only appreciated when they were given to individuals who had not previously received treatment, accompanied by nucleoside analogues [29]. This combination inhibits viral replication sufficiently completely to prevent selection of viral mutants with resistance to the NNRTI class [30].

The original hypothesis for optimum treatment of HIV infection was 'hit hard and hit early' [31], i.e. to use potent regimens and to use them early in the disease course with the hope of completely eradicating evidence of infection within a finite period. Unfortunately, as our understanding of the pathogenesis of HIV infection has improved, this hypothesis has turned out to be unrealistic, perhaps most importantly because HIV is also incorporated into

Table 26.6 Nucleoside analogue reverse transcriptase inhibitors. (After Moyle & Gazzard [38]; Ward *et al*. [39].)

Drug	Side effects
Zidovudine (AZT/ZDV)	Nausea, bone marrow suppression, myopathy
Zalcitabine (ddC)	Peripheral neuropathy
Didanosine (ddI)	Nausea, bloating, diarrhoea, pancreatitis, peripheral neuropathy, gynaecomastia, gout
Stavudine (d4T)	Peripheral neuropathy, gynaecomastia
Lamivudine (3TC)	Nausea, bone marrow suppression, peripheral neuropathy
Abacavir, tenofovir (nucleotide)	Nausea, diarrhoea

Table 26.7 Non-nucleoside reverse transcriptase inhibitors. (After Moyle & Gazzard [40].)

Drug	Side effects
Nevirapine	Clinical and biochemical hepatitis
Delavirdine	Biochemical hepatitis
Efavirenz	Insomnia, nightmares

Table 26.8 Protease inhibitors. (After Moyle & Gazzard [41].)

Drug	Side effects
Amprenavir	Nausea, diarrhoea,
Indinavir	Nausea, nephrolithiasis, haematuria, hyperbilirubinaemia, porphyria, hyperaesthesia
Nelfinavir	Diarrhoea
Ritonavir	Nausea, vomiting, dysgeusia, biochemical hepatitis, hyperaesthesia
Saquinavir, lopinavir	Nausea, diarrhoea

long-lived cells which generally divide very occasionally [32]. It is only during the process of cellular replication that anti-HIV drugs are active, and therefore the early hopes of eradication within a 3–4 year period have not been realized, and it is likely that present treatment will be required lifelong to continually suppress viral replication. Early treatment was also advocated because it was assumed that HIV caused irreversible deletions in the immune repertoire and so if treatment was started late patients would remain susceptible to opportunistic infections. Fortunately this has been shown not to be the case. Even individuals treated in late disease show considerable reconstitution of the immune repertoire [33,34].

Perhaps the most important practical reason for renewed caution about the timing of initiating antiretroviral therapy has been the emergence of a variety of drug toxicities that were unsuspected at the time the drugs were originally licensed. For the nucleoside analogue class this includes mitochondrial toxicity and hyperlactataemia [35], and for the protease inhibitors a variety of abnormalities of lipid metabolism.

However, the greatest problem to a more complete understanding of these syndromes is that, of necessity, most of the present studies are cross-sectional and represent the end result of processes which have been present in the patient for some years. New drugs are being developed in the presently available classes, i.e. nucleoside analogues, NNRTIs and protease inhibitors. The main objective of such new drugs is to improve adherence to treatment by enhancing the convenience of the regimen or to diminish side effects. Thus a new protease inhibitor, atazanavir, appears to be free of blood lipid abnormalities in controlled trials [36], but whether this will translate into freedom from the lipid redistribution syndrome remains to be determined. Classes of drugs that attack new targets within the replication cycle of HIV are also being developed; the most advanced of these are those which inhibit the process of fusion. This is an important example of where an understanding of the detailed mechanisms involved in viral fusion have led to the development of new drugs. The most advanced of these is Roche T20; this drug inhibits the contraction of the helical coils associated with gp41, which normally contract and bring the surface of the envelope protein of the virus (gp120) into close contact with the cell surface. The disadvantage of this drug is that it has to be given by subcutaneous injection once or twice a day, and it is therefore unlikely that this drug will be tolerated in the long term for naive patients. Its chief benefit is likely to be in patients who are failing other therapies. Also in the process of development is a variety of small molecules that are orally bioavailable and which may inhibit the interaction between HIV and the second receptor on the host cell surface, i.e. CCR5 or CXCR4. Such drugs have been shown to produce viral load reductions in phase I studies by inhibiting the CCR5 receptor, although the drug AM3100, which inhibits CXCR4, has not shown equivalent benefit [37]. At an even earlier stage of development are products that inhibit the interaction between the CD4 receptor and the conserved portion of gp120. These molecules are highly potent *in vitro*; some HIV strains are relatively resistant to its action. However, in the future it is hoped that a variety of fusion inhibitors may act synergistically, thereby allowing some of the older drugs with an important side effect profile to be used less often.

Those drugs in current usage are listed by class in Tables 26.6–26.8. The principal non-dermatological side

effects are included. Lipid abnormalities and lipodystrophy are discussed on p. 26.20. Mucocutaneous side effects are detailed on pp. 26.19 and 26.20, and in Table 26.18. Dermatologists should be aware of the risks of drug interactions in treating patients with HIV on HAART, particularly because of the metabolism of protease inhibitors by the cytochrome P-450 system in the liver.

Dermatological manifestations of HIV infection

Skin disease may provide the first suspicion of the diagnosis of HIV infection, cause significant morbidity as the disease progresses and point to a diagnosis with important systemic implications. The number of mucocutaneous diseases, like the CD4 T-cell count, is a prognostic indicator of the development of AIDS and overall survival [1]. Some skin problems are less consequential than other manifestations of HIV infection but many are very distressing to patients and some potentially very serious or fatal. Although some situations are clinically straightforward and readily amenable to satisfactory intervention, all of the dermatological complications of HIV infection can be a challenge to diagnose and manage. They may present with unusual symptoms and signs, coexist with other pathologies, be altered by treatment and drug reactions are common [2–5].

In general, HIV dermatology presents four broad challenges to the dermatologist. Firstly, there is the

opportunity to make the initial diagnosis of HIV in patients with a seroconversion illness or with subtle or florid manifestations of one or other dermatoses associated with underlying HIV infection. Next, there is differentiating whether a skin problem is caused by HIV infection or by HIV therapy. Thirdly, the dermatologist's therapeutic imagination and experience is occasionally tested. Lastly, there are the implications of HIV-associated skin disorders for the better understanding of the skin in health and disease: the virus has been demonstrated in the cutis of infected individuals; cutaneous dendritic cells and Langerhans' cells may be the main targets in acute HIV infection [6] and the cause of skin disease in chronic infection; different cytokine expression patterns distinguish different cutaneous manifestations [7,8]; and involvement of cutaneous nerves may contribute to the pathogenesis of HIV-related dermatoses [9].

Until recently, suspecting, or failing to suspect, that a patient presenting with a common dermatosis known to be associated with HIV infection might be HIV positive has not been so important. Indeed, in the past the patient's best psychological and fiscal interests might have been better served by relative ignorance. However, the benefits of earlier diagnosis that have ensued from HAART place a greater onus on the dermatologist than hitherto to discuss HIV risk with patients presenting with skin diseases known to be associated with HIV and to recommend assessment, counselling and testing if the overall clinical situation dictates it. A high index of suspicion is essential, especially in assessing high-risk patients. The commoner scenario is the evaluation of the patient already known to have HIV infection who presents with dermatological symptoms and whose physician is concerned that the skin condition is a complication of HIV or its treatment.

Classical clinical dermatological history-taking and examination is the beginning of the diagnostic endeavour. Some dermatoses can be diagnosed confidently on clinical grounds, but experience has shown that it is easy to be misled. Immunopathophysiological and neurovascular mechanisms in the skin determine the symptomatic and morphological presentation of all skin diseases, so it is not surprising that 'things look different' in HIV-infected patients. Several cutaneous conditions may coincide sometimes within a single lesion. The commonest dermatological conditions associated with HIV infection are listed in Table 26.9.

Investigations are frequently necessary. Skin scrapings may be examined microscopically in the clinic (after clearing with potassium hydroxide) for the presence of fungal hyphae or spores. Swabs for bacteria and viruses and scrapings for fungi may be taken for laboratory microscopic examination and culture. Skin biopsy is often undertaken. The operator and assistants should wear gloves, gowns and eyeglasses. Representative samples of lesional skin should be carefully selected for histopathology and culture for fungi and acid-fast bacilli. Many laboratories decline to perform direct immunofluorescence. It is the responsibility of clinicians to take due care in the collection and submission of all pathological material for investigations so that no hazard is created for themselves, staff or other patients.

Table 26.9 Common dermatological conditions in HIV infection. (After Bunker & Staughton [5].)

Pruritus/xerosis/ichthyosis
Eosinophilic folliculitis
Pruritic papular eruption
Seborrhoeic dermatitis
Psoriasis
Folliculitis
Drug eruptions
Herpes simplex
Herpes zoster
Viral warts
Mollusca
Tinea (including onychomycosis)
Scabies
Basal cell carcinoma
Squamous cell carcinoma

Acute primary HIV infection/seroconversion

Acute primary HIV infection may be clinically silent but up to 90% of patients develop a non-specific symptomatic illness 1–6 weeks after exposure that lasts a few days to several months but usually less than a fortnight [1]. Symptoms and signs are often those of a non-specific viral infection, like infectious mononucleosis with lassitude, fever, arthralgia, myalgia and lymphadenopathy. Weight loss, nausea, vomiting and diarrhoea are common. Headache and photophobia may signify aseptic meningitis and cognitive dysfunction encephalitis, although other recognized

Sore eyes	12	13
Genital ulcer	7	14
Tonsillitis	7	13
Depression	6	23
Dizziness	6	11

neurological presentations include Bell's palsy, brachial neuritis, radiculopathy, peripheral neuropathy and Guillain–Barré syndrome. Table 26.10 lists the frequency and duration of the principal clinical manifestations of primary HIV infection [2].

The principal dermatological manifestations of seroconversion are given in Table 26.11 [3]. A rash is found in up to 75% of people with symptomatic seroconversion. A symmetrical maculopapular erythematous exanthem, notably of face, palms and soles, occurs. Pale pink macules and perifollicular erythematous papules have been described. Occasionally there may be urticarial or vesicular lesions, and alopecia. The histology is characterized by a perivascular lymphocytic infiltrate with or without epidermal changes, ranging from vacuolar change and spongiosis to epidermal necrosis [4]. Painful oral ulceration, genital ulceration, erythema multiforme and Stevens–Johnson syndrome may occur [5–8]. Acute erosive genitocrural intertrigo has been described [9]. If the CD4 count falls precipitously, oral candidosis can develop. The exanthem may represent infection of cutaneous Langerhans' cells and the orogenital lesions sites of viral inoculation [10].

Thus primary infection, including non-specific dermatological reaction patterns, may go unnoticed, unreported or undiagnosed. And because the dermatological and

Syphilis
Rheumatic fever
Toxoplasmosis
Drug reactions

other manifestations of seroconversion are non-specific, there is a differential diagnosis (Table 26.12). Syphilis was the great imitator: perhaps now it is HIV [11]. It must also be appreciated that two (or more) illnesses may coexist.

The more severe and numerous the manifestations, and the more prolonged the duration, the more likely a more rapid progression of HIV disease in that individual (Table 26.13) [12–14].

Precise diagnosis and exclusion of other causes can be complicated in the acute stage by interpretation of bacteriological and virological results (e.g. serological diagnosis of syphilis). There may be lymphopenia (usually a modest fall in CD4 count, mild rise in CD8 and inverted CD4/CD8 ratio) and thrombocytopenia and a biochemical hepatitis or cholestatic biochemical profile. A skin biopsy may not be helpful showing non-specific histology; spongiosis, apoptosis, interface dermatitis and mild perivascular chronic inflammatory infiltrate. Seroconversion illness is

Table 26.13 Useful prognostic indicators around primary infection. (From Hawkins [14].)

Clinical (soon after initial infection)	Laboratory (3–4 months after infection)
Presence of symptoms	CD4 T-cell count
Duration of symptoms (> 14 days)	Quantitative viral load (HIV RNA measurement)
Number of symptoms (more than three symptoms)	Polymerase chain reaction
	b-DNA
Candidosis	β_2-Microglobulin
Acquisition of HIV from an individual with advanced HIV disease	
Neurological involvement	

b-DNA, branched chain DNA.

Table 26.14 Diagnosis of primary HIV infection. (From Hawkins [2].)

Essential assays
Enzyme-linked immunosorbent assay (ELISA)
Western blot (should also be able to detect HIV. 2 infection)
HIV. 1 p24 antigen testing
HIV DNA or RNA polymerase chain reaction (PCR)
Supplementary tests after inconclusive ELISA results
HIV DNA or RNA PCR if not previously performed
HIV RNA quantification (especially if antiretroviral therapy is being contemplated)
T-cell subset enumeration
Exclusion of other viral illnesses (e.g. cytomegalovirus, Epstein–Barr virus)

diagnosed by positive plasma HIV polymerase chain reaction (PCR) alongside negative or equivocal HIV antibody tests (Table 26.14) [2].

Established HIV infection

Pruritus, xerosis, ichthyosis

These are common in HIV and can be variably symptomatic [1]. HIV belongs in the differential diagnosis of generalized pruritus (see Chapter 16) [2]. Patients must be evaluated carefully for other pruritic dermatoses (e.g. scabies, atopic dermatitis, papular eruption of HIV and eosinophilic folliculitis) and the other medical causes of generalized pruritus (e.g. hepatic and renal disease). Excoriations, eczematization and impetiginization can complicate scratching. IgE estimation and skin swabs, scrapings and biopsy may be helpful. Treatment follows conventional lines and includes phototherapy [1,3–5]. The mechanism is uncertain but cutaneous peptidergic neuronal loss has been demonstrated [6]. Severe intractable pruritus with eosinophilia may indicate a subset of HIV-infected patients with hyperactivation of humoral immunity and augmented viral load [7]. Pruritus and xerosis are also side effects of protease inhibitors (see Chapter 16) [8].

Inflammatory dermatoses

The commonest of the inflammatory dermatoses associated with HIV infection (see Table 26.9) are discussed below. Table 26.15 lists rarer inflammatory dermatoses that have been observed in the context of HIV infection.

Erythroderma may have several causes and the same differential diagnostic approach employed in general dermatology is recommended: in a young black patient, erythroderma may be a marker for HIV infection [1].

Proctitis, piles, perianal ulceration, abscess, fissure and fistula are prevalent in homosexual men and HIV infection [2–4] and are discussed in Chapter 68.

Thrombocytopenic purpura may present to a dermatologist: it can be mistaken for KS (Fig. 26.1) [5,6].

Seborrhoeic dermatitis

Only 1–3% of the general population have seborrhoeic dermatitis compared with 20–85% of patients with HIV. Seborrhoeic dermatitis is more common in seropositive homosexual men than seronegative homosexuals, and among infected patients it is commoner and has an earlier onset in homosexuals and bisexuals compared with intravenous drug users [1]. Although found in seropositive individuals who are otherwise well, its severity is increased at CD4 T-cell counts below 100×10^6/L. This phenomenon is not adequately explained. The consensus is that classical seborrhoeic dermatitis represents an aberrant cutaneous reaction to commensal *Malassezia* yeast species. Probably the cutaneous immune dysfunction caused by HIV alters the host–organism relationship. The severity of seborrhoeic dermatitis may be related to yeast density or yeast strain [2,3]. There is a correlation between the numbers of yeast cells intimately associated with keratinocytes and the clinical severity of seborrhoeic dermatitis in patients with AIDS [4]. Patients taking ketoconazole have a lower prevalence of seborrhoeic dermatitis [5]. Also, imidazole treatment elicits clinical improvement, with a concomitant decrease in the numbers of *Malassezia* organisms per keratinocyte [6]. Abnormalities of skin surface lipids are not associated with the development of seborrhoeic dermatitis but are associated with HIV infection itself [7]. Seborrhoeic dermatitis has been related to low plasma zinc levels but this may not be significant [8]. Neuroendocrine and sebotropic factors are influenced by HIV infection and seborrhoeic dermatitis and neurological disease may coexist in some patients. Seborrhoeic dermatitis is essentially a hyperproliferative dermatosis and keratinocyte stimulation may result from HIV infection because of either monocyte-derived lymphokines or a direct effect of the virus itself [9].

Itchy scaly patches are found at the classical sites (Fig. 26.2) and elsewhere. There may be folliculitis. Erythroderma has been reported [10]. An association of erythroderma, xerosis and seborrhoeic dermatitis with the development of dementia and spinal cord disease has been noted [9]. Extensive refractory seborrhoeic dermatitis appears to occur in particular conjunction with pulmonary tuberculosis and AIDS in Zambia [11].

The differential diagnosis includes other causes of erythroderma, eczema, psoriasis and dermatophytosis. Scrapings can be examined for fungi to exclude tinea, and *Malassezia* sp. may be seen in large numbers. Biopsy may show hyperkeratosis, acanthosis, spongiosis, spotty ker-

Fig. 26.2 Seborrhoeic dermatitis on the face. (Courtesy of Dr C.B. Bunker and Medical Illustration UK Ltd, Chelsea and Westminster Hospital, London, UK.)

atinocyte necrosis, leukocytosis and subcorneal neutrophil infiltration. A deeper lymphocytic infiltration of sebaceous glands and a more perivascular neutrophilic (with occasional leukocytoclasis) and plasma cell infiltrate is seen in HIV compared with classical seborrhoeic dermatitis [9,12]. The histology may be very similar to psoriasis.

Management follows conventional lines: emollients, topical steroids and antifungals and oral imidazoles. Although clinical improvement of seborrhoeic dermatitis is often reported after immune reconstitution with HAART, Schaub *et al*. [1] have opined that antiretroviral treatment does not influence the prevalence, onset or disease-free survival times.

Atopic dermatitis

Atopic dermatitis or an atopic dermatitis-like condition appears to be common in children with HIV [1], although it should be borne in mind that atopy is common anyway. In adults there have been reports of patients whose atopic eczema recurred or worsened during the course of HIV infection [2,3] and hyper-IgE syndrome has also been described [4]. Others believe atopic dermatitis is not affected by HIV [5,6]. A decreased frequency of atopic diseases, fewer positive radioallergosorbent tests and lower average levels of IgE in HIV-positive compared with HIV-negative homosexual individuals has been found [7], as has dysregulation of IgE synthesis [8]. Fungal allergen-specific IgE responses may contribute to the pathogenesis of eczematous skin disease in HIV-infected individuals [9].

Psoriasis

Psoriasis is prevalent (2%) in the general population and can worsen or appear for the first time (often very severely) in HIV infection [1,2] but may regress preterminally [3]. It may (5%) [4] or may not (1%) [5] be more prevalent in the HIV-infected population. HIV-associated psoriasis provides some insights into the pathogenesis of psoriasis. Most patients with HIV-associated psoriasis are positive for HLA-Cw0602 as are all HIV-negative patients with streptococcal-associated guttate psoriasis [6,7]. There

Fig. 26.3 Severe plantar psoriasis in HIV infection. (Courtesy of Dr C.B. Bunker and Medical Illustration UK Ltd, Chelsea and Westminster Hospital, London, UK.)

are decreased numbers of epidermal Langerhans' cells in the skin of HIV-infected individuals, as there may be, contentiously, in psoriasis [8–11]. Langerhans' cells are infected by HIV and either the viral burden or HIV gene products may alter the antigen-presenting function of the cell. HIV gene products may have a role in the pathogenesis of proliferative epidermal disorders: transgenic mice that express some HIV genes in skin develop a diffuse psoriasiform epidermal hyperplasia [12]. There may be a selective defect in soluble antigen recognition by CD4 T lymphocytes, and numbers of CD8 T lymphocytes increase until just before death. Polyclonal B-cell activation, increased numbers of γδ T lymphocytes, decreased natural killer cell function and defective reticuloendothelial cell function have all been reported.

The classical clinical presentations of psoriasis are detailed in Chapter 35. Psoriasis in HIV-infected patients may be florid, severe and atypical (Fig. 26.3). Reiter's syndrome (arthritis, urethritis and conjunctivitis), within the same clinical continuum as psoriasis in genetically predisposed individuals, occurs in HIV, sometimes very severely [13,14].

The differential diagnosis of psoriasis includes seborrhoeic dermatitis, atopic dermatitis, dermatophytosis, drug eruption and mycosis fungoides. A psoriasiform eruption with the histological features of verruciform xanthoma has been described [15]. Investigations include mycology and skin biopsy.

Conventional treatment options for psoriasis serve most patients well. Moderate to severe psoriasis (with or without arthritis) should be regarded as an indication for HAART. There is no evidence that the theoretical risks and complications of phototherapy are *clinically* deleterious to individual patients [16–19]. T-cell numbers are unaffected and the *gag* p24 antigen and HIV RNA levels may or may not increase [17,20]. Overriding the theoretical concerns about immunosuppression and photocarcinogenesis is the clinical need to relieve the morbidity of the severe, atypical, refractory psoriasis often seen in HIV [5]. PUVA may be superior to UVB therapy [21].

Ciclosporin [22] and methotrexate have caused serious complications in HIV-infected patients, such as leukopenia and fulminant KS [23]. The synthetic retinoid etretinate and its successor acitretin have been most useful therapies for severe Reiter's syndrome and psoriasis in HIV infection, often alongside phototherapy [1,13,14,24]. Treatment with zidovudine improves psoriasis [1]; specific constituents of HAART regimens (e.g. zalcitabine and ritonavir) appear to do likewise, with comcomitant improvement of the clinical condition and virological status of the patient [25,26]. Etanercept has been used with good effect in HIV-related psoriasis and arthritis in one patient but had to be discontinued because of frequent infectious complications [27]. Claims have been made for the efficacy of cimetidine [28]. Serendipitous success due to carbamazepine has been witnessed [29].

Eosinophilic folliculitis

Eosinophilic folliculitis is an HIV-specific disorder [1,2] related to Ofuji's disease (see Chapter 17). Originally thought to be an *early* sign of HIV infection, it occurs at CD4 T-cell counts of $250–300 \times 10^6$/L and therefore identifies patients at immediate risk of developing opportunistic infections. It may be part of the same spectrum as papular pruritic eruption of HIV and this complicates interpretation of published studies. The cause is unknown but Th2 cytokines (IL-4, IL-5), RANTES and eotaxin are increased in lesional skin [3]; foscarnet has been implicated in the development of eosinophilic folliculitis [4].

Eosinophilic folliculitis presents as a centripetal (face and trunk) eruption of pruritic, erythematous, perifollicular papules and pustules (Fig. 26.4). Patients with eosinophilic folliculitis may be subclinically photosensitive [5]. It mimics staphylococcal or *Pityrosporum* folliculitis and acne vulgaris, with which it can coexist. Histology is characteristic, with degranulating eosinophils and mast cells in a perifollicular distribution. There may be a peripheral eosinophilia and elevated levels of IgE. Swabs are negative: the lesions are sterile. Treatment can be problematic but the disease has virtually disappeared in the developed world in recent years with the introduction of HAART, although exacerbations have been reported [6]. Phototherapy is the most successful treatment modality but other treatments that have been tried include topical sodium cromoglicate (disodium cromoglycate), potent topical steroids, oral antibiotics (erythromycin, tetracyclines, co-trimoxazole), oral antihistamines such as astemizole and cetirizine, oral dapsone and oral isotretinoin [7–10]. Eosinophilic folliculitis may be an indication for HAART.

Pruritic papular eruption

Pruritic papular eruption (PPE) is a common cutaneous manifestation of HIV, the prevalence varying between 10 and 45% depending on geographical area [1,2]. It has some interesting similarities with the papular eruption of pregnancy (see Chapter 70). Insect bite hypersensitivity, as in papular urticaria (see Chapter 33), is a speculative pathomechanism [3]. For example, Palungwachira *et al*. [4] suggest that the fact that PPE is the commonest HIV-associated dermatosis in Thailand might be due to the prevalence of mosquitoes. Of patients with PPE, 75% have circulating bullous pemphigoid autoantibodies and up to 30% meet the diagnostic criteria for bullous pemphigoid on histology, Western blotting, immunofluorescence and immunoelectron microscopy [5]. PPE is a sign of an advanced degree of immunosuppression, occurring at CD4 T-cell counts below $100–200 \times 10^6$/L [2,6], and may often be the first sign of HIV. Conversely, it has been suggested that it most frequently complicates established HIV infection. PPE presents as excoriated, erythematous, urticarial papules associated with eosinophilia and elevated IgE. The differential diagnosis includes papular urticaria and eosinophilic folliculitis: it is possible that eosinophilic folliculitis and PPE are part of the same spectrum of disease and this can cause confusion in interpreting the literature. Both are idiopathic. However, the cytokine pattern of PPE differs from that of eosinophilic folliculitis [7,8]. The treatment of PPE is similar to that of eosinophilic folliculitis, with phototherapy the linchpin; thalidomide and pentoxifylline (oxpentifylline) have been claimed to be efficacious [9,10].

Granuloma annulare

Localized, generalized and atypical forms of granuloma annulare (see Chapter 57) occur in HIV infection [1,2] (Fig. 26.5). Violaceous lesions may mimic KS and a perforating variant has been described [3]. Some cases have been associated with zalcitabine treatment [4]. Cultures are negative [2].

Porphyria cutanea tarda

Porphyria cutanea tarda (see Chapter 57) is polyfactorial in HIV [1]. Familial influences, viral hepatitis B and C (e.g. in haemophiliacs), alcohol and sunlight may be involved. *N*-acetylcysteine has been used for treatment [2].

Table 26.16 Side effects of drugs in patients with HIV/AIDS. (After Bunker & Staughton [10].)

Morbilliform toxic erythema
Erythema multiforme, Stevens–Johnson syndrome, toxic epidermal necrolysis, hypersensitivity syndrome (see Table 26.17)
Erythroderma
Anaphylaxis, urticaria, angio-oedema
Xerosis, cheilitis
Lichenoid reactions
Psoriasis
Photodermatitis
Purpura
Orogenital ulceration
Neutrophilic eccrine hidradenitis: zidovudine (AZT)
Vasculitis
Fixed drug eruptions
Pentamidine: also causes ulcers at the site of injection
Foscarnet: penile ulceration
Saquinavir
Palmar/plantar keratoderma: glucan
Flagellate erythema: bleomycin
DRESS syndrome: nevirapine
Eosinophilic folliculitis: foscarnet
Porphyria: indinavir
Granuloma annulare: zalcitabine (ddC)
Lipodystrophy
Gynaecomastia: stavudine (d4T), didanosine (ddI), indinavir
Panniculitis: ritonavir, nelfinavir
Acrocyanosis: butylnitrite

DRESS, drug rash with eosinophilia and systemic symptoms.

Table 26.17 Causes of hypersensitivity syndrome, erythema multiforme, Stevens–Johnson syndrome and toxic epidermal necrolysis in patients with HIV/AIDS. (After Coopman & Stern [1]; Bunker & Staughton [10]; Rustin *et al*. [11]; Penneys [12]; Vidal *et al*. [13]; Rzany *et al*. [14].)

Pyrimethamine
Sulfadoxine
Sulfadiazine
Thioacetazone (thiacetazone)
Streptomycin
Phenytoin
Probenecid
Griseofulvin
Fluconazole
Vancomycin
Nevirapine
Indinavir
Efavirenz
Abacavir

Drug reactions

Drug reactions (see Chapter 73) are commonly encountered in HIV infection [1–4]. Of patients with *Pneumocystis carinii* pneumonia treated with co-trimoxazole (sulfamethoxazole–trimethoprim), 60% experience fever, nausea, vomiting and a rash [5]. Amoxicillin (amoxycillin)–clavulanate causes a skin eruption in about half of HIV-infected patients who receive the drug compared with more than 90% of patients with acute lymphoblastic leukaemia or infectious mononucleosis and 3–10% of the general population [6]. Dapsone, pentamidine and antituberculous chemotherapy, especially with rifampicin, thioacetazone (thiacetazone) and ethambutol, pose particular risks [7,8]. Probenecid (given to reduce the nephrotoxicity of cidofovir) can cause a hypersensitivity reaction [9].

The types of drug eruptions that have been encountered in HIV infection and AIDS are summarized in Table 26.16. A morbilliform toxic erythema is the usual drug reaction seen (with fever, arthralgia, abnormal liver function tests and eosinophilia) but erythema multiforme, Stevens–Johnson syndrome or toxic epidermal necrolysis/Lyell's syndrome [1,10–14] (Table 26.17), erythroderma [8], vasculitis, fixed drug eruptions, cutaneous photosensitivity, photocutaneous drug eruptions, and skin sensitivity to radiotherapy have all been experienced [2,15,16]. Glucan has been implicated in causing palmar/plantar keratoderma [17]. The striking flagellate erythema due to bleomycin has been observed [18,19], but this is relatively common in general oncological practice. Pustular psoriasiform reactions to pegylated doxorubicin (used for KS) have been seen [20]. Fixed drug eruptions have been reported with pentamidine, which can also cause ulcers at the site of injection [12,21], and foscarnet, which causes penile ulceration [22]. Interferons may precipitate ulceration at injection sites [23]. Hydroxyurea can result in mucocutaneous hyperpigmentation (and melanonychia; see later) [24]. Butylnitrite may produce acrocyanosis [25].

The cutaneous side effects of the antiretroviral drugs are listed in Table 26.18 [10,26]. The side effects of anti-HIV drugs on the oropharynx, hair and nails are discussed below (see also Tables 26.22 & 26.23). Zidovudine (AZT) can cause skin, mucosal and nail discoloration, vasculitis, insect bite hypersensitivity and possibly neutrophilic eccrine hidradenitis [26–28]. Patients with black skin have a tendency to develop progressive but reversible proximal melanonychia and also mucocutaneous hyperpigmentation during zidovudine (AZT) therapy. Some patients on zidovudine (AZT) have developed polymyositis [29] and vasculitis [30].

Exanthems, erythema multiforme, Stevens–Johnson syndrome and toxic epidermal necrolysis can be complications of the components of HAART [31–34]. As in other causes of toxic epidermal necrolysis, intravenous gammaglobulin may be an effective treatment [35]. An exanthematous pustulosis has been described [36]. Nelfinavir can cause urticaria [37]. Xerosis and cheilitis are common with protease inhibitors [38]. A syndrome of drug rash with eosinophilia and systemic symptoms (DRESS) has been reported with nevirapine [39] and erythroderma, abdominal pain and renal failure with indinavir [40]. An anaphylactoid reaction and allergic contact dermatitis to

Ritonavir	Toxic erythema Haematoma IgA-mediated hypersensitivity Panniculitis Paraesthesia Bullae
Indinavir	Toxic epidermal necrolysis Erythroderma Paronychia/pyogenic granuloma Striae Paraesthesia
Saquinavir	Photosensitivity Fixed drug eruption
Nelfinavir	Urticaria Panniculitis
All protease inhibitors	Lipodystrophy Toxic pustoloderma Pruritus and xerosis Panniculitis Tendon xanthomas Hypersensitivity syndrome

lamivudine have been described [41,42]. Ritonavir can cause an IgA-mediated hypersensitivity syndrome and haematoma formation [26]. Didanosine (ddI) has been associated with papuloerythroderma of Ofuji [26]. Some cases of granuloma annulare have been blamed on zalcitabine (ddC). Fixed drug eruption has been reported with saquinavir [40]. Photosensitivity and photoallergic dermatitis have been documented with saquinavir and efavirenz [43–45]. Gynaecomastia has complicated stavudine (d4T) and didanosine (ddI) treatment [46]. Indinavir has precipitated acute porphyria [47]. Panniculitis has been blamed on ritonavir and nelfinavir [48]. Painful perioral and peripheral paraesthesiae and bullae have been associated with ritonavir and peripheral paraesthesia with indinavir [33].

The mechanisms of common drug reactions are not clearly known but correspond to classical immunopathological models. In HIV, acute or reactivated Epstein–Barr virus, CMV or other viruses, polyclonal B-cell activation, hypereosinophilia, hypergammaglobulinaemia, immune complex formation, and the generation of autoantibodies and autoreactive T-cell clones may interact with drug or tissue complexes. Also, the pattern of immune dysregulation (decreased Th1 cytokines; increased Th2 cytokines; increased IgE, IgA and eosinophils) predisposes to drug hypersensitivity. For example, co-trimoxazole exacerbates this hypersensitivity by decreasing Th1 responses; macrolides increase Th1 responses [49,50].

It is common experience that adverse reactions to co-trimoxazole may disappear with continued therapy and that some patients will tolerate rechallenge with amoxicillin–clavulanate. *N*-acetylcysteine pretreatment may prevent co-trimoxazole hypersensitivity [51]. Prednisolone does not prevent nevirapine-induced cutaneous hypersensitivity [52]. Tolerance has been induced for nevirapine and nelfinavir [53]. Drug hypersensitivity can also disappear at very low CD4 T-cell counts ($< 20 \times 10^6$/L) and before death occurs. Therefore, a prior drug reaction does not constitute an *absolute* contraindication to continued or further treatment with a particular drug.

The ability of all protease inhibitors and some nucleoside reverse transcriptase inhibitors, especially stavudine (d4T), to cause lipodystrophy is a matter of both intense clinical frustration (because the appearances are distressing and stigmatizing to patients) and mechanistic fascination. Fat loss from the periphery, with fat accumulation in the abdominal and dorsocervical (buffalo hump) and mammary regions, is accompanied by hyperlipidaemia, insulin resistance and lactic acidaemia. Mitochondrial toxicity is one proposed mechanism. There is concern about accelerated atherosclerosis and cardiovascular disease [54–57]. Benign symmetrical lipomatosis [58], striae [59] and tendon xanthomas [60] have been reported.

Of equal interest to dermatologists are the retinoid-like effects of the protease inhibitors, particularly indinavir—paronychia, periungual pyogenic granuloma-like lesions, xerosis and cheilitis, and curly hair. The mechanism is uncertain [61–64] but experience shows that isotretinoin can be used safely and effectively alongside protease inhibitors. Concomitant administration has paradoxically resulted in *lower* plasma retinoid levels [65].

Infections

Cutaneous bacterial infection in HIV-infected patients poses the risk of bacteraemia and septicaemia or may signify systemic infection. Central lines, concomitant chemotherapy, intravenous drug use and the presence of other skin diseases present additional risks [1]. The clinician must be alert to the dermatological signs of systemic bacterial infection, such as splinter haemorrhages and acral papulonecrotic lesions. A high index of suspicion and a low threshold for performing microbiological investigations and skin biopsies (including Gram stain and special stains and cultures) should be inculcated to allow precise diagnosis and specific treatment. Systemic antibiotics should be chosen on the basis of the clinical situation and sensitivities, when they become known. Abscesses should be treated by surgical drainage but also biopsied and cultured: cutaneous malacoplakia has been encountered [2].

Bacterial infections

The differential diagnosis of folliculitis is a common challenge in the patient with HIV. Clinical differentiation between staphylococcal folliculitis, malassezial folliculitis, dermatophyte folliculitis, eosinophilic folliculitis and, very rarely, micrococcus folliculitis and herpes simplex and zoster viral folliculitis may be impossible and they may coexist [1–4]. Cryptococcosis has presented as a corporeal pseudofolliculitis [5]. On the face, demodicidosis and acne vulgaris are other possibilities. A facial folliculitis due to *Clostridium perfringens* has been observed [6]. Intertriginous staphylococcal folliculitis may mimic candidosis.

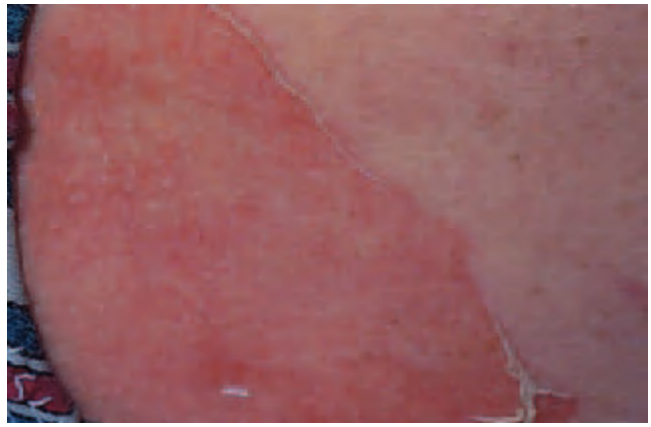

Fig. 26.6 Staphylococcal scalded skin syndrome: staphylococcal pneumonia in HIV-positive intravenous drug addict. (Courtesy of Dr C.B. Bunker and Medical Illustration UK Ltd, Chelsea and Westminster Hospital, London, UK.)

Secondary staphylococcal infection of the skin may be a commonplace complication of many of the inflammatory dermatoses discussed above. Methicillin-resistant *Staphylococcus aureus* (MRSA) may present particular problems, although MRSA carriage does not seem to be an appreciable problem in HIV-positive outpatients [7–10].

Other staphylococcal infections found in HIV include *bullous impetigo* [11], *ecthyma* and *staphylococcal scalded skin syndrome* (Fig. 26.6) [12–14]. Subcutaneous abscesses due to staphylococci may complicate injection or intravenous-line sites. Sometimes uncommon organisms are isolated. Severe streptococcal cellulitis (erysipelas) with lymphadenitis has been reported [15].

Pseudomonas aeruginosa is an important potential cutaneous pathogen in HIV infection and AIDS. *Ecthyma gangrenosum* and *panniculitis* [16–19] may be pointers to *Pseudomonas* septicaemia.

Fournier's gangrene is a hazard with a high mortality in AIDS and may complicate chemotherapy [20].

Bacillary angiomatosis, originally entitled 'epithelioid (haem)angiomatosisis', is caused by the Gram-negative cat-scratch disease organism *Bartonella* (previously *Rochalimaea*) *henselae* affecting the skin [1,21]. When it was first encountered, clinicians were intrigued by the similarity of bacillary angiomatosis to the cutaneous stigmata of chronic infection with *Bartonella bacilliformis*, the 'forma mular of verruga peruana'. These lesions may occur in the chronic phase of Oroya fever and are clinically and histologically very similar to those of bacillary angiomatosis. The abnormal vascular spaces, lined with proliferating endothelium, contain *B. bacilliformis*. Bacillary angiomatosis presents with purple, papular and nodular vascular lesions resembling KS (Fig. 26.7). Patients with bacillary angiomatosis do not appear to have an overt acute febrile haemolytic illness. Diagnosis is made by biopsy. Histologically, bacillary angiomatosis is distinguished from

Fig. 26.7 Bacillary angiomatosis: purple nodules on the face. (Courtesy of Dr C.B. Bunker and Medical Illustration UK Ltd, Chelsea and Westminster Hospital, London, UK.)

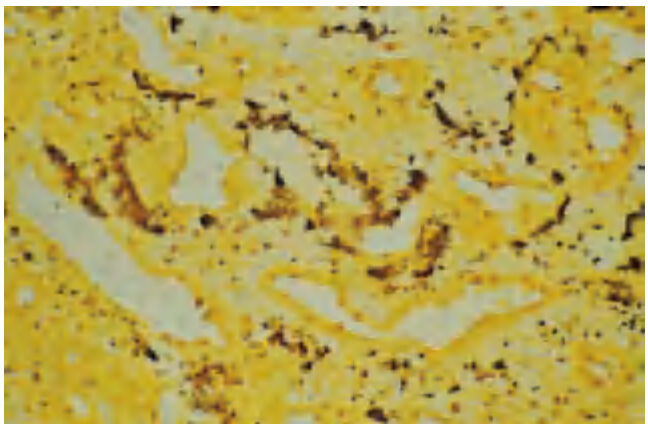

Fig. 26.8 Bacillary angiomatosis: Warthin–Starry silver staining of *Bartonella bacilliformis* and proliferative vascular channels. (Courtesy of Dr N. Francis, Imperial College School of Medicine, London, UK.)

KS by being a vascular proliferation where the abnormal endothelial cells are epithelioid rather than spindled and by having a prominent neutrophilic infiltrate. The organisms can be demonstrated by Warthin–Starry silver staining (Fig. 26.8), immunoperoxidase staining of lesional tissue (where the bacilli are found within the abnormally proliferative cutaneous vasculature) or electron microscopy. Bacillary angiomatosis responds to oral erythromycin in most patients; isoniazid, rifampicin, ethambutol or clofazimine, either in addition to or instead of erythromycin, have also been used.

Syphilis (see Chapter 30) may present differently in HIV infection [22]. This may confound the clinical recognition of the classical dermatological manifestations of primary chancre, the papulosquamous eruption of secondary syphilis and gumma [23]. The interpretation of serological tests can be complicated. Dermatologists should regard all genital, perianal and oral ulceration and any papulosquamous eruption with great suspicion and handle them with circumspection [24]. Rarer manifestations of syphilis not previously encountered by this generation of physicians, such as keratoderma and lues maligna (necrotic red nodules), have been reported [25].

Similar problems with *yaws* [26] and *leprosy* [27,28] have not been extensively encountered. *Lyme borreliosis* pseudolymphoma [29] and a persistent erythema chronicum migrans (with meningoradiculitis) have occurred [30].

Reinfection with, or reactivation of, *Mycobacterium tuberculosis* seems to occur early in HIV infection and extrapulmonary, including cutaneous, tuberculosis (see Chapter 28) is common [31] and becoming commoner [32]. The clinical presentation is diverse, including scrofula [33], scattered violaceous papules [34], acute miliary tuberculosis of the skin [35,36], keratotic papules, nodules and palmar/plantar keratoderma [37] and tuberculides [38]. Tuberculous lymphadenitis has been said to be a characteristic manifestation in HIV and in intravenous drug users co-infected with tuberculosis [39]. Management of co-infection (about one-third of the estimated 30–40 million people infected with HIV) poses particular challenges and is a specialist field [40].

Atypical mycobacterial skin disease in patients infected with HIV is usually due to *Mycobacterium avium–intracellulare*. This occcurs as part of a disseminated infection in up to one-third of patients [41] at CD4 T-cell counts below 50×10^6/L (rare below 200×10^6/L). Lesions described include violaceous papules, nodules and ulcers [42]. Skin disease has also been reported with *M. kansasii* [34], *M. haemophilum* [43,44], *M. fortuitum* [45] and *M. marinum* [46]. In these instances the eruption has probably occurred after primary infection of the skin by the organism but a fatal case of disseminated *M. marinum* has occurred [47]. Sporotrichoid spread (see Chapter 28) can involve an affected limb emanating from a distal primary site [48]. Concomitant *M. tuberculosis*, *M. avium–intracellulare* and CMV has been seen [49]. *M. avium* complex has been isolated from an HIV-positive woman with erythema multiforme [50].

The diagnosis of mycobacterial infection can be problematic because characteristic histopathological features such as caseating granuloma may be absent due to diminished cell-mediated immunity [51]. All biopsies where tuberculosis and/or atypical mycobacterial infection are suspected should be stained for acid-fast bacilli (which may be very numerous because of diminished cell-mediated immunity) and a separate portion sent for mycobacterial culture.

Prophylaxis and treatment of tuberculosis and atypical mycobacterial disease depends on the clinical scenario (including CD4 count) and the results of microbiological investigations (including sensitivity testing) and is an expert area. HAART and specific conventional antituberculous drugs are used. Atypical mycobacterial infection is treated with a macrolide and ethambutol.

Other bacterial infections. Extragenital donovanosis [52], an unusual presentation of chancroid [53], a paranasal ulcer due to *Chryseomonas luteola* [54] and a disseminated papular eruption caused by *Serratia marcescens* have been described.

Fig. 26.9 Chronic perianal ulceration in herpes simplex infection before highly active antiretroviral therapy.

Fig. 26.10 Chronic verrucous herpes zoster. (Courtesy of Dr C.B. Bunker and Medical Illustration UK Ltd, Chelsea and Westminster Hospital, London, UK.)

Viral infections

Herpes simplex. Severe chronic ulcerative perianal disease (Fig. 26.9) caused by herpes simplex virus (HSV)-2 (human herpesvirus 2, HHV-2) was one of the first features of AIDS to be reported [1]. HSV-1 and HSV-2 infections are extremely common during the course of HIV illness [2,3]. Although anogenital involvement is frequent, any site can be affected with acute lesions that are vesicobullous but which become chronic, eroded and crusted, vegetative, or ulcerating; HSV infection may not be self-limiting as it is in normal individuals. Persistent necrotic digits [4] and perioral ulceration may occur. A facial folliculitis (sycosis) has been reported [5]. Secondary bacterial infection is probably universal. Concomitant infection of the skin with CMV has been seen [6]. Resolution can occur with specific treatment for HSV and general HIV treatment. However, herpetic lesions recur: the impact of HAART has been to improve this situation, although Fox *et al*. [7] have reported persistent erosive and verrucous anogenital disease with erosion and ulceration in several heterosexual Ugandan men despite HAART and multiple systemic and topical treatments, possibly representing an immune recovery/reconstitution/restoration phenomenon (immune restoration disease) (see Fig. 26.28).

Diagnosis depends on clinical suspicion supported by electron microscopy of fresh lesional fluid, DNA hybridization, immunofluorescence and viral culture; additionally, acute and convalescent sera may be examined for HSV antibodies (IgM and IgG). A skin biopsy may show typical cytopathic signs and positive immunostaining for HSV. In the USA, the Tzanck test is popular for rapid identification of multinucleate giant cells, which are not pathognomonic because they are seen also in varicella, herpes zoster and pemphigus [8,9].

The treatment of HSV infection in HIV requires the systemic deployment of specific antiviral drugs (of which aciclovir is the prototype), including prophylactically [2]. The approach should be aggressive because HSV activates HIV replication [10]. Topical and systemic treatments for secondary bacterial infection are often necessary. HSV mutants (i.e. those with mutant or absent viral thymidine kinase) are responsible for HSV resistance, although progressive HSV-2 infection has been reported despite aciclovir therapy and demonstrable sensitivity of isolates to aciclovir. Intravenous vidarabine has been effective in aciclovir-resistant herpes simplex, but foscarnet (trisodium phosphoformate), which is a direct inhibitor of HSV DNA polymerase, is better for severe HSV-2. Famciclovir [11] and valaciclovir are alternatives to aciclovir. Cidofovir is a DNA polymerase inhibitor used in CMV infection, but is also effective against HSV.

Varicella-zoster virus. Reactivation of varicella-zoster virus (HHV-3; see Chapter 25) frequently accompanies HIV infection and can be severe [2,12]. Recurrences of HHV-3 do occur in HIV-negative people and in up to 20% of HIV-negative immunocompromised patients. The frequency of recurrence in HIV-positive individuals is unknown. It is controversial whether all patients presenting with dermatomal HHV-3 should be counselled about HIV testing but it is regarded as a predictor of HIV infection in African patients [13]. Reactivation of HHV-3 is the commonest cutaneous manifestation of immune restoration disease [14].

The distribution of the eruption is characteristically dermatomal but differentiation from herpes simplex may

not always be clinically certain. Ophthalmic zoster may be complicated by conjunctivitis or optic neuritis, so ophthalmological input is advised. The involvement of sacral nerves may cause acute retention of urine, haemorrhagic cystitis and constipation. Other manifestations include motor zoster, zoster encephalomyelitis and purpura fulminans.

A non-bullous folliculitis has been described [5]. A chronic verrucous dermatomal form can occur (Fig. 26.10). An atypical, sometimes protracted, disseminated HHV-3 eruption of sparse but ecthymatous necrotic lesions is occasionally seen, but there is usually a concomitant dermatomal recurrence. The differential diagnosis includes *Pseudomonas* ecthyma gangrenosum and disseminated infection with atypical mycobacteria, fungi, vaccinia or HSV. Central nervous system and pulmonary involvement should be suspected. The clinical diagnosis is supported by virological methods and occasionally by biopsy.

An important component of management is the treatment of pain. Potent analgesia may be supplemented by carbamazepine and doxepin. Intractable post-herpetic neuralgia may require specialized pain control. A topical or systemic antibiotic is often needed for secondary infection. Oral prednisolone is given by some. Systemic parenteral therapy with aciclovir is indicated in HIV-associated herpes zoster especially when sight, sphincteric function and facial expression are threatened and where pulmonary or neurological involvement is suspected. Disseminated HHV-3 infection can be severe with a poor prognosis. Intravenous high-dose aciclovir is the treatment of choice. Intercurrent intramuscular HHV-3 immunoglobulin has been used to prevent recurrences and may be used intravenously if aciclovir fails. Emerging aciclovir resistance may become a problem but vidarabine and recombinant IFN-α are possible alternatives [15]. Vaccination may boost immunity and varicella immune globulin can prevent or modify the clinical illness [12].

Cytomegalovirus. Reactivation of CMV in HIV infection occurs with a CD4 count below 50×10^6/L. Despite the frequency of ocular (blindness), gastrointestinal (dysphagia, diarrhoea), neurological (encephalopathy) and adrenal (postural hypotension) disease, skin involvement with CMV is relatively uncommon in HIV but when CMV affects the skin the mortality is about 85% in 6 months [16]. It is possible that cutaneous involvement goes unnoticed and hence is underdiagnosed. Purpura, papules, nodules, verrucous plaques and ulcers (Fig. 26.11), and nodular prurigo (Fig. 26.12) have been described [17]. The differential diagnosis of these clinical possibilities is broad. HSV and CMV skin involvement may be seen concurrently [9] and concomitant CMV, *M. tuberculosis* and *M. avium–intracellulare* has been documented [18].

CMV infection should be suspected histologically if dermal capillary neoangiogenesis, fibrinoid thrombi, necrotic endothelial cells, epidermal hyperplasia, acantholysis and keratinocyte degeneration are seen. Keratinocytes and endothelial cells contain characteristic CMV inclusions. Syringosquamous metaplasia has been observed [19,20]. Immunohistochemistry, *in situ* hybridization and electron microscopy may be employed. Skin biopsy material can be cultured with human fibroblasts to demonstrate the cytopathic effect; the demonstration of CMV viraemia can be similarly achieved by the co-culturing of a patient's leukocytes [21]. Serological testing may be difficult to interpret.

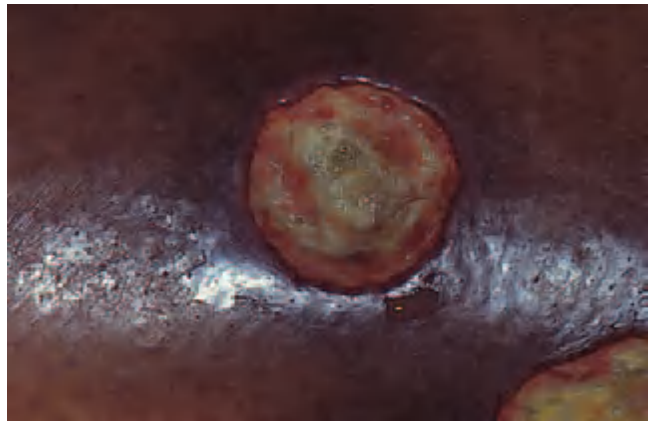

Fig. 26.12 Cytomegalovirus vasculitis: leg ulcers. (Courtesy of Dr C.B. Bunker and Medical Illustration UK Ltd, Chelsea and Westminster Hospital, London, UK.)

Treatment and prophylaxis centres on immunoreconstitution with HAART, although a severe cutaneous ulcerative eruption (see Fig. 26.29) has been reported after the initiation of HAART and possibly represents immune restoration disease [22]. Intravenous foscarnet, ganciclovir and cidofovir are specific treatments [23]. Mutations in the viral kinase allow the development of drug resistance. Other drugs are under evaluation.

Human papillomavirus. Human papillomavirus (HPV) infection of the skin is discussed in Chapter 25. Warts are found in about 5–30% of patients with HIV [2,24,25]. Anogenital warts (condylomata acuminata) may be a non-specific and insensitive marker for HIV infection. HPV-6 and HPV-11 (not associated with malignant potential) have been identified as the types most frequently found [26]. Anogenital HPV infection is a risk factor for anogenital cancer particularly of the anus (and cervix) yet it is rare for condylomas to contain HPV-16, which has a well-documented association with anal carcinoma. Homosexual men have a higher incidence of both perianal warts and *in situ* and invasive anal carcinoma. Yet Reynaud-Mendel *et al*. [27] have found that genital warts are more frequent in seropositive intravenous drug users. HIV infection may alter and worsen the expression and consequences of anogenital HPV infection [28,29]; HPV-16 and other oncogenic types have been found in carcinoma *in situ*, and high-grade dysplasia has been found in genital warts from HIV-positive individuals [30,31]. Overall, the risk of progression of anal intraepithelial neoplasia associated with anal HPV wart infection to invasive squamous carcinoma is low [32], although HPV infection is thought to be linked to the incidence and aggressiveness of anal carcinoma in AIDS. The same is probably true of penile cancer. Invasive cervical cancer is not more common but does behave more aggressively and is an AIDS-defining diagnosis.

The clinical diagnosis of warts is straightforward when classical sites are involved with lesions of typical morphology. In patients with HIV, warts may be extensive (Fig. 26.13), numerous, exuberant and admixed with other pathologies (e.g. mollusca). HPV may be found in, and presumably contributes to the causation of, Bowen's disease, erythroplasia of Queyrat and Bowenoid papulosis (clinically like viral warts, often pigmented, with the histology of Bowen's disease/squamous carcinoma *in situ*), and invasive penile, anal and cervical cancer. A pattern resembling the rare inherited condition epidermodysplasia verruciformis can occur (Fig. 26.14), presenting in some patients as a pityriasis versicolor-like eruption [33–36].

CD4 T-cell estimation and HIV testing should be considered in any patient with atypical clinical presentations of viral warts. Occasionally, a skin biopsy may be necessary particularly if *in situ* or invasive squamous malignancy is suspected. Conventional treatments may fail. Topical imiquimod and cidofovir have been used [37,38]. HAART can lead to regression of warts [39,40], but some patients have been seen whose warts persist or return after many years remission and this seems to be related to low nadir or mean CD4 counts [41].

Fig. 26.15 Atypical mollusca: flesh-coloured papules and nodules on the forehead. (Courtesy of Dr C.B. Bunker and Media Resources UCL, London, UK.)

Molluscum contagiosum. Molluscum contagiosum is caused by infection with molluscipoxvirus (see Chapter 25) and frequently affects the skin of patients with HIV [42], homosexual seropositive patients more than intravenous drug users [27]. There may be several or many papular or larger nodular lesions, particularly on the face and neck. Often, in the context of HIV infection, the lesions do not manifest pathognomonic classical morphology (Fig. 26.15) and are not typically domed in shape and lack the characteristic central umbilication or delling [43]. A cheek abscess has been described [44]. The differential diagnosis includes sebaceous hyperplasia, syringoma, warts, cryptococcosis and histoplasmosis, and even basal cell carcinoma. These entities can all concur and be found in the same clinical lesion. Molluscum is diagnosed with the greatest confidence by skin biopsy because the morphology in the HIV-positive patient may not be pathognomonic. The classical histological features (see Chapter 25) are usually present [9].

Molluscum varies widely in its response to conventional treatment [2] but the introduction of HAART can be very effective [39]. Topical imiquimod may also be effective. Systemic and topical cidofovir may be effective for severe recalcitrant molluscum [38,45]. Electron-beam treatment has been employed [46].

Other viral infections. Parvovirus B19 can cause cutaneous vasculitis [47] and a persistent papular–purpuric gloves and socks syndrome with anaemia [48].

Fungal infections

Candidosis. Oral candidosis has classically been associated with immunosuppressive states and was one of the first features to be recognized in the early days of the HIV epidemic before the syndrome was clearly defined and the causative agent identified [1]. Oesophageal candidosis is an AIDS-defining diagnosis. It is commoner in homosexual seropositive patients than intravenous drug users [2]. Treatment is with ketoconazole or fluconazole. Resistance can occur. Long-term prophylaxis with azoles is avoided. Oral candidosis predicts AIDS in a median of 2 years so is an indication for institution of prophylaxis for *Pneumocystis carinii* and HAART.

Candida is also responsible for paronychia, onychodystrophy, angular cheilitis and intertriginous candidosis [3,4]. Practically all people with HIV infection will have *Candida* as a pathogen at some stage in their disease [5].

Fig. 26.16 Tinea corporis and faciei. (Courtesy of Dr C.B. Bunker and Medical Illustration UK Ltd, Chelsea and Westminster Hospital, London, UK.)

Dermatophytosis. Generally, dermatophytes are only occasionally responsible for cutaneous infection in immunocompromised patients [6], but the situation is subtly different in HIV infection [7]. Homosexual men are very likely to have a superficial fungal infection regardless of their HIV status. For example, in Sweden, Torssander *et al*. [8] showed that 37% of seropositive homosexual men had mycologically proven toe cleft dermatophytosis, usually *Trichophyton rubrum*, compared with about 30% of seronegative homosexual men and about 9% of heterosexual men. Clinical findings, for example interdigital scaling, similar to those of tinea pedis are very common in men. Dermatophytes can be isolated from normal toe clefts in about 7% of homosexual men (regardless of HIV status) but not from clinically normal toe clefts in heterosexual men. Tinea incognito secondary to chronic potent topical steroid misuse for another dermatosis may develop, as sometimes seen in lupus erythematosus. Widespread dermatophytosis is not common in HIV/AIDS: Torssander *et al*. found dermatophytes only in the groins, toe clefts and toe nails. However, folliculitis and extensive and deep dermatophytosis (Fig. 26.16), including Majocci's granuloma and deep abscess, can occur [7,9].

Onychomycosis is very common in HIV and AIDS. *Trichophyton rubrum* is the commonest pathogen [10]. Psoriasis and the yellow nail syndrome should be

Fig. 26.17 Cryptococcosis: necrotizing papules and nodules on the right ear and neck. (Courtesy of Dr C.B. Bunker and Medical Illustration UK Ltd, Chelsea and Westminster Hospital, London, UK.)

considered in the differential diagnosis of nail discoloration and dystrophy. Mycological confirmation should be obtained. Improvement of onychomycosis with HAART in the absence of specific antifungal treatment has been observed [11].

Esoteric superficial fungal infections have been reported. A patient presented with 'dirty' brown spots on the scrotum from which were co-cultured the dematiaceous fungi *Bipolaris* and *Curvularia* [12].

Dermatophyte infection is treated with conventional topical and systemic therapy (see Chapter 31) depending on clinical assessment and the results of mycology. Oral terbinafine is safe and efficacious [13].

Cryptococcosis. *Cryptococcus neoformans* infection affects 5–10% of patients with AIDS in the UK and USA and 30–40% in Africa. Brain, lung and skin are sites of predilection. Up to 20% of patients with disseminated disease may have skin involvement. In HIV/AIDS cryptococcal skin involvement should be suspected when papulonodular necrotizing skin lesions with central umbilication, like molluscum contagiosum (Figs 26.17 & 26.18), are encountered in the context of neurological or pulmonary disease. Herpetiform lesions, violaceous lichenoid lesions, an acneiform papulopustular and nodular eruption on the chin, rhinophyma, a warty tumour on the foot, a pseudofolliculitis and *Cryptococcus* admixed with, and mimicking, KS have also been described [14–16].

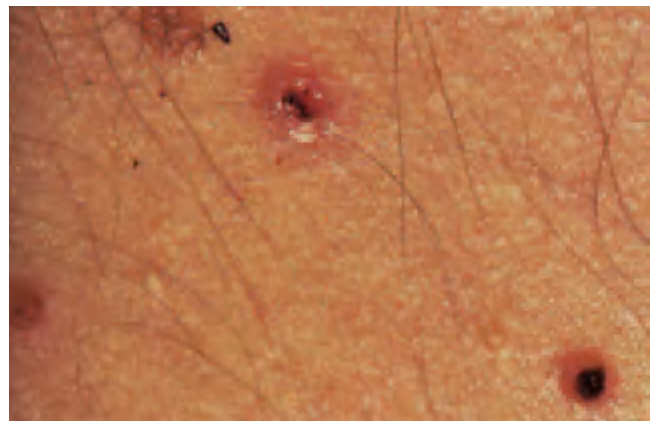

Fig. 26.18 Cryptococcosis: necrotizing papules. (Courtesy of Dr C.B. Bunker and Medical Illustration UK Ltd, Chelsea and Westminster Hospital, London, UK.)

Systemic diagnosis is by serology, blood culture, urine culture and lumbar puncture (including serology, culture and India-ink staining). Cutaneous diagnosis is by skin biopsy with special stains for the cryptococcal capsule (e.g. mucicarmine) and culture, or Tzanck preparation [17].

Treatment aims to eradicate the disease in the immunocompetent patient and to control symptoms in the patient with advanced HIV disease. Intravenous liposomal amphotericin and oral fluconazole are the mainstays of treatment. Primary and secondary prophylaxis is with oral fluconazole. Cryptococcal meningitis has a poor prognosis even with treatment.

Histoplasmosis. Infection with histoplasmosis is an AIDS-defining illness. It is very rare in the UK, although commoner where histoplasmosis is endemic so a travel history is important. In endemic areas 20–50% of patients with AIDS will develop histoplasmosis at CD4 counts below 200×10^6/L. The systemic presentation can mimic tuberculosis. There is fever, lymphadenopathy, hepatosplenomegaly, lung disease and pancytopenia. Disseminated histoplasmosis may produce skin involvement in 10% of patients. An exanthem, lesions resembling molluscum contagiosum, lesions admixed with KS, acneiform folliculitis, psoriasiform eruptions, depressed pits on the palms and soles, and oral involvement have been described [7,18–21].

Systemic diagnosis is by chest X-ray, Wright's staining of a blood film (demonstrating intracellular fungi), blood cultures, and lymph node, liver or skin biopsy or Tzank cytology [17,22] and culture. *Histoplasma capsulatum* can be demonstrated by Gomori methenamine silver stain of a skin biopsy section.

Treatment is with itraconazole or amphotericin with long-term itraconazole secondary prophylaxis because relapse is so common.

Other fungal infections. Coccidioidomycosis is endemic in south-west USA: extrapulmonary disease is an AIDS-defining diagnosis but skin lesions seem rare [7]. Numerous ulcers have been attributed to cutaneous sporotrichosis [5]. Paracoccidioidomycosis [23], blastomycosis [24], nocardiasis [25,26], primary cutaneous aspergillosis [27,28] and penicilliosis (especially in northern Thailand) [29,30] have all been reported to cause skin lesions in HIV/AIDS.

Protozoal infections

Pneumocystis carinii pneumonia is common in HIV infection but disseminated disease and cutaneous involvement is rare [1,2]. Two patients have been described with mass lesions in the external auditory canal. Spread from middle ear infection (itself due to retrograde spread from the pharynx via the eustachian tube) was the probable mechanism. Lesions masquerading as KS have been described [3].

Disseminated amoebiasis may rarely cause skin involvement and the dermatological manifestation may lead to diagnosis of the systemic illness. A solitary papule of the thigh, a soleus muscle abscess and cutaneous ulceration have been described [4–6]. Genital ulceration due to amoebiasis should lead to the suspicion of underlying HIV infection [7].

Cryptosporidiosis and microsporidiosis can cause skin lesions [8,9]. Endemic protozoal diseases such as leishmaniasis [10–12] may behave differently in the HIV-infected patient and also mimic or complicate KS and dermatofibroma: cutaneous nodules and ulcers, digital necrosis, linear brown macules of the digits and palms, ulceration of the tongue, a tattoo reaction and cutaneous hyperpigmentation and post kala-azar dermal leishmaniasis have been described [13–18]. Reactivation of American trypanosomiasis (Chagas' disease) in AIDs may manifest with skin lesions [19].

Scabies

Scabies (see Chapter 33) occurs frequently in HIV-infected patients [1,2] and may have unusual clinical features (Fig. 26.19) when it arises in the context of HIV infection, for example the skin of the head and neck is often involved, which is highly unusual in non-HIV-infected adults. It is important to have a high index of suspicion. Scabies has been endemic in the HIV population in London and there are occasional epidemic outbreaks on HIV wards, in hospices and in the community. Transmission is by sexual intercourse, nursing, comforting and massage. Norwegian/crusted scabies [3] is highly contagious and its diagnosis should arouse suspicion of underlying HIV infection (AIDS 2002). Crusted scabies in HIV infection may be localized to the soles [4]. Eccrine ductal and follicular mucinosis have been found on histology [5]. Treatment follows conventional lines but eradication may be difficult. Topical sulphur and oral ivermectin can be useful [6,7].

Miscellaneous

Demodex (see Chapter 33) can cause dermatological morbidity in HIV-infected patients. A pruritic papulonodular eruption on the face and neck that responded to acaricide treatment has been attributed to *Demodex* [1], as has a rosaceal eruption [2] and an ivory white, poorly defined, indurated plaque on the temple [3].

Cutaneous larva migrans has presented with fever in an HIV-infected individual after commencement of treatment with zidovudine (AZT) and didanosine (ddI) [4].

Kaposi's sarcoma (see Chapter 53)

Classical sporadic KS, African endemic KS, Greek (Peloponnesian) endemic KS, iatrogenic immunosuppression-associated KS and AIDS-related KS are recognized [1,2]. KS has been encountered in HIV-negative homosexual men [3]. The prevalence of KS in patients infected with HIV has declined throughout the epidemic. It has been shown that KS is caused by HHV-8, which may be transmitted sexually, probably more by the faeco-oral route or the ejaculate than by blood, in HIV-positive homosexual men [4,5]. However, KS is also seen in non-homosexuals and in children arising from other routes of transmission, for example saliva [6,7].

HIV/AIDS-related KS may be a disseminated disease with gastrointestinal and pulmonary involvement. Cutaneous KS is multicentric and often involves the face, oral mucosa, palate (see Fig. 26.26) and genitalia. Lesions may be multiple, follow skin creases and may be grouped or linear and koebnerize (Fig. 26.20). Lymphoedema may eventuate [8]. The classical lesion in HIV is a purple patch, plaque or nodule, which may ulcerate; phimosis may occur [9]. There may be diagnostic difficulty with morphologically banal lesions in at-risk or worried individuals and the importance of index of suspicion and skin biopsy must be stressed. The common differential diagnosis (Table 26.19) [10] includes naevi, histiocytoma and lymphangioma [11], although cryptococcosis [12,13], histoplasmosis [14], leishmaniasis [15,16], lesions due to *Pneumocystis* [17], and dermatophytosis [18] may also mimic and/or complicate KS. Pyogenic granuloma and bacillary angiomatosis masquerading as KS are important to consider and confirm or exclude.

The differential diagnosis of oral lesions is discussed below and includes the other causes of mouth ulcers and tumours, *Candida*, lichen planus, drug eruption and angina bullosa haemorrhagica. The differential diagnosis of genital lesions includes psoriasis, lichen planus, lichen sclerosus, fixed drug eruption, Zoon's balanitis and erythroplasia of Queyrat.

Diagnosis is either clinical or clinicopathological. The histological features of KS are well described [19] and consist of dilated, irregularly shaped, vascular structures that are typically slit-like in a fully developed nodular lesion. The differential diagnosis may be clarified by immunohistochemical techniques that identify endothelial cells (immunostaining for factor VIII-related antigen and *Ulex europaeus* lectin), which have been thought to be the cell of origin of KS. Staging of KS takes into account tumour bulk, systemic illness and immunosuppression (Table 26.20) [20].

Systemic and local treatment of KS is summarized in Table 26.21. HAART itself can be very effective [21,22]. Radiotherapy can cause significant sequelae, for example radiodermatitis, in survivors.

Table 26.20 Modified AIDS Clinical Trials Group staging of Kaposi's sarcoma (1997). (From Bower & Portsmouth [20].)

Condition	Good risk (all the following) T0 I0	Poor risk (any of the following) T1 I1
Tumour (T)	Confined to skin, lymph nodes or minimal oral disease	Tumour-associated oedema or ulceration Extensive oral Kaposi's sarcoma Gastrointestinal Kaposi's sarcoma Kaposi's sarcoma in other non-nodal viscera
Immune status (I)	CD4 count > 150 cells/μL	CD4 count < 150 cells/μL

Table 26.21 Treatment for Kaposi's sarcoma. (After Bunker & Staughton [10]; Bower & Portsmouth [20].)

Local treatment
Cryotherapy
Radiotherapy
Topical retinoids: alitretinoin [23]
Topical antivirals: cidofovir, docosanol [24]
Intralesional, e.g. TNF-α, IFN-α, vinca alkaloids
Surgery, e.g. curettage, cautery, infrared coagulation [25]
Laser
Photodynamic therapy
Cosmetic camouflage
Systemic treatment
Highly active antiretroviral therapy (HAART)
Isotretinoin (cidofovir)
Aggressive chemotherapy, e.g. daunorubicin, doxorubicin, bleomycin, paclitaxel [26], vincristine, etoposide
Human chorionic gonadotrophin [27]
Interleukin-4 [28]

IFN, interferon; TNF, tumour necrosis factor.

Melanoma and non-melanoma skin cancer

It is evident that there is an increased incidence of non-melanoma skin cancer (basal cell carcinoma [1], squamous cell carcinoma [2,3]) and melanoma (Fig. 26.21) [4–13] in people with HIV infection, particularly in association with actinic damage. Actinic keratoses are very common. Squamous cell carcinoma may be multifocal, aggressive and present atypically (Figs 26.22 & 26.23) [14]. Basal cell carcinoma may be multiple and of the infundibulocystic [15] or micronodular neurotropic [16] variants, and even metastatic [17]. Porokeratosis is associated with immunosuppression, sun damage and HIV [18]. Anogenital

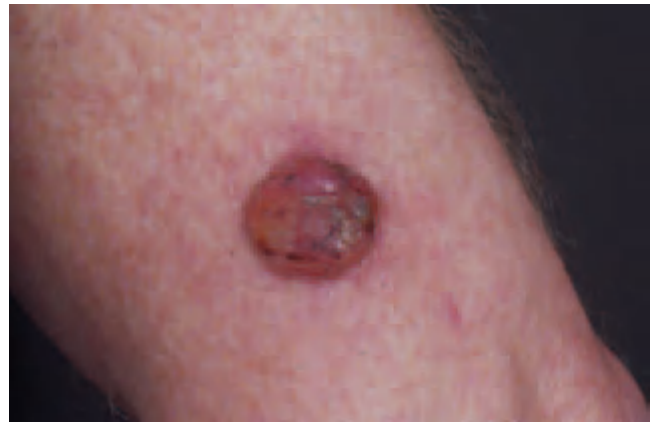

Fig. 26.21 Melanoma: rapidly growing (2/12) amelanotic nodule on the left arm. Breslow thickness > 10 mm. (Courtesy of Dr C.B. Bunker and Medical Illustration UK Ltd, Chelsea and Westminster Hospital, London, UK.)

Fig. 26.22 Squamous carcinoma: ulcerated nodule on the right upper eyelid. (Courtesy of Dr C.B. Bunker and Medical Illustration UK Ltd, Chelsea and Westminster Hospital, London, UK.)

Fig. 26.23 Metastatic squamous carcinoma: zosteriform ulceration on the left axilla and chest. (Courtesy of Dr C.B. Bunker and Imperial College School of Medicine, London, UK.)

squamous cancer and precancer and its relationship to HPV and HIV are discussed in Chapter 68 [19–22].

Patients receiving HAART and therefore surviving HIV longer, even indefinitely, need to have careful dermatological evaluation and follow-up, including of the anogenital skin and mucosa. They should be warned about the possible synergistic risk of the sun and HIV. All new or changing skin lesions should be evaluated assiduously, with a low threshold for biopsy.

Other tumours

The appearance of eruptive naevi, which presented in crops as the patients became more symptomatic from HIV infection, has been reported. These patients did not have the full-blown atypical naevus syndrome, although biopsy showed dysplastic features [1].

Other benign and malignant skin neoplasms have been reported in association with HIV, including: dermatofibrosarcoma protuberans [2]; sebaceous carcinoma [3];

Merkel cell carcinoma [4]; metastatic tufted angioma [5]; histiocytoma (solitary and multiple and eruptive forms) [6,7], including one case where the histiocytoma was parasitized by leishmaniasis [8]; pilomatrixoma (in association with myotonic dystrophy) [9]; leiomyoma [10]; xanthoma [11], including normolipaemic xanthomas [12,13].

Lymphoma

A spectrum of involvement of the skin with lymphoma is seen in HIV/AIDS [1]. Non-Hodgkin's B-cell lymphoma, common in HIV [2], can cause skin lesions [3,4]. The relationship of Hodgkin's disease to HIV is still controversial [3,5]: several hundred cases have been reported. HIV-associated Hodgkin's disease differs from non-HIV-associated disease by manifesting 'B' symptoms more commonly, a more advanced stage at presentation, extranodal disease, a higher incidence of Epstein–Barr virus in affected tissue, predominant mixed cellularity and lymphocyte-depleted histologies, a less complete response rate, a higher relapse relate and a significantly shortened median survival [5]. It can present as a panniculitis [6].

Cutaneous T-cell lymphoma (mycosis fungoides and Sézary syndrome) may be associated with HIV/AIDS [7]. Atypical cutaneous lymphoproliferative disorder, which has been called 'pseudo-Sézary' or 'cutaneous T-cell lymphoma simulant' is a rare reactive inflammatory condition that rarely progresses to frank lymphoma [8]. Castleman's disease has been seen [5,9]. Multiple myeloma has presented in the skin with primary cutaneous plasmacytomas [10].

Hair and nails

The abnormalities of hair and nails found in HIV infection are listed in Table 26.22 [1–4]. A striking case of kwashiorkor has been documented [5].

Acquired trichomegaly of the eyelashes may be an early marker of HIV infection [6]. Alopecia areata (Fig. 26.24) and alopecia universalis are reported associations [7]. Hair loss has been reported with indinavir, lamivudine and stavudine [8–11]. Colebunders and Vandenbruaene [9] have described curly hair (with lipodystrophy) during HAART.

Cribier *et al*. [2] reported that nearly 70% of HIV-infected individuals have nail changes. Onychomycosis is usually due to *T. rubrum* or unusual *Candida* species [2]. Some African patients with the yellow nail syndrome [12] have AIDS *and* tuberculous pleural effusion or pneumonia: the yellow nail syndrome is a recognized association of chronic pulmonary disease (see Chapter 62). Paronychia and ingrown toenail are particular complications of indinavir and probably not lamivudine, as has been suggested [13]. Blue nails are a sign of HIV infection [14].

Table 26.22 Abnormalities of the hair and nails in HIV infection. (After Prose *et al*. [1]; Cribier *et al*. [2]; Bunker & Staughton [3]; Ward *et al*. [4].)

Hair
Patchy and generalized alopecia
Hypertrichosis of the eyelashes
Eyelash trichomegaly
Hypertrichosis including of the eyelashes: zidovudine (AZT)
Alopecia: indinavir, lamivudine (3TC), stavudine (d4T), didanosine (ddI)
Alopecia universalis: HAART
Curly hair: HAART
Nails
Clubbing
Half and half nails
Transverse (Beau's lines) and longitudinal ridging
Loss of the lunula
Leukonychia
Onycholysis and onychoschizia
Periungual erythema [15]
Longitudinal melanonychia
Blue nails [14]
Onychomycosis
Longitudinal melanonychia: zidovudine [16]
Melanonychia: hydroxyurea [17,18]
Paronychia/pyogenic granuloma: zidovudine (AZT), lamivudine (disputed)
Ingrown toenail and paronychia/pyogenic granuloma: indinavir

HAART, highly active antiretroviral therapy.

Oropharynx

Many oral manifestations have been reported in acute HIV infection and seroconversion [1]. Transient intraoral redness, erosions and ulcers and candidosis are all described. Xerostomia is common. Salivary gland swelling is frequently seen in children but less so in adults infected with HIV [2].

Distressing mouth ulceration occurs frequently in established HIV. The differential diagnosis includes malignancy (KS and lymphoma), HSV, CMV, fungal infections, Behçet's disease, zalcitabine- and didanosine-induced ulceration, and idiopathic aphthous ulceration. Thalidomide has proved useful for the last of these [3] at a dose of 100 mg nightly for 2 weeks followed by maintenance therapy of 100 mg every 5 days, with monitoring to avoid peripheral neuropathy [4].

Oral candidosis is common in HIV-positive individuals and almost universal in AIDS. The extent and persistence of the disease are responsible for much morbidity in patients with HIV and AIDS. Sometimes the entire oropharynx, larynx and oesophagus may be involved but mild forms with just angular cheilitis and/or focal red or white patches on the oral mucosa, palate or tongue are seen [1,5].

Severe periodontal disease is also not unusual [1]. Gangrenous stomatitis, due to opportunistic anaerobic organisms and *Candida*, *Pseudomonas* and staphylococci, causes severely symptomatic perioral ulceration complicated by pain, bleeding and inability to feed [6].

Hairy leukoplakia is a new clinical entity that has emerged during the HIV epidemic and is probably associated with Epstein–Barr virus infection. It is particularly important because it is an early specific sign of HIV

Fig. 26.25 Hairy leukoplakia. (Courtesy of Dr C.B. Bunker and Media Resources UCL, Trust, London, UK.)

infection, with the sinister implication that 75% of patients develop AIDS within 2–3 years. It is usually asymptomatic, although patients have often noticed the appearance of a roughened patch along the lateral margin of the tongue (Fig. 26.25). To the patient it may feel rough and to the physician it may look craggy but it is not truly 'hairy'. Other intraoral sites have been reported. The differential diagnosis includes trauma, *Candida*, leukoplakia, lichen planus and white-sponge naevus. Hairy leukoplakia has not yet been shown to involve other mucosal or extramucosal sites. White-sponge naevus may be familial and may occur on the tongue. Biopsy may be necessary. Hairy leukoplakia is now known to occur in other immuncompromised people and has even been reported in healthy individuals [1]. Treatment is with oral aciclovir [7].

HSV infection is common in and around the mouth. Painful red eroded lesions are characteristic and the extent and chronicity or frequent recurrences cause much debility. Just over 1% of HIV-infected individuals have oral HPV infection [2]. CMV may present similarly.

KS occurs frequently in the mouth, often the palate. It appears as red patches, plaques or nodules (Fig. 26.26). The early red lesions may be mistaken for HSV or *Candida*. The differential diagnosis also includes the other causes of mouth ulcers and tumours, lichen planus, drug eruptions and angina bullosa haemorrhagica (see Chapter 66).

Other problems that can affect the oral cavity include petechiae from thrombocytopenia [2], disseminated histoplasmosis [8,9], sporotrichosis [10], paracoccidioidomycosis [11], hyperpigmentation and oral labial melanotic macules [2,12] (Fig. 26.27), warts and warty carcinoma due to HPV [13], lymphoma, and the side effects of radiotherapy and drugs (Fig. 26.27, Table 26.23) [2,14,15]: foscarnet, IFN and zalcitabine are particular causes of mouth ulceration.

Women and children

Women and children represent the fastest growing subpopulation of HIV-infected patients in the developed world. There are few significant differences in dermatological morbidity between HIV-infected men and women save that women have less KS and hairy leukoplakia and possibly onychomycosis and that mollusca may appear earlier in women [1].

There are some important differences in children compared with adults. Vertical transmission from an infected mother is the usual mode of infection. There exists a challenging and broad differential diagnosis of immunosuppression in children (Table 26.24) [2]; all of these conditions may have cutaneous manifestations.

Dermatological disease is common in children with AIDS [3–5]. An eruption resembling seborrhoeic dermatitis has been described. Atopic eczema is found in increased frequency but unclassified eczematous eruptions are also seen. Widespread nappy dermatitis can occur. The pruritic papular eruption is common and, as in adults, so are drug eruptions.

Malignancy
Congenital infections
Iatrogenic immunosuppression
Graft-versus-host disease

About half of children with advanced HIV disease can be expected to suffer a serious bacterial infection and 20% of these involve the skin. The commonest organism is *Staphylococcus aureus* and the usual clinical patterns are of cellulitis, impetigo, folliculitis and abscess formation; a persistent staphylococcal folliculitis may also be seen. The most common fungal infection is candidosis, 75% of 36 children in one study. Dermatophyte infection is frequently encountered (tinea capitis, tinea corporis and onychomycosis). HSV infection of the skin and mucosae is common and may be very serious and chronic; likewise disseminated zoster infection. Persistent verrucous varicella in a 3-year-old girl has been described as the first manifestation of HIV infection [6]. In HIV infection, molluscum lesions have a predilection for the face rather than the trunk. Perianal warts have been reported and it is likely that persistent HPV infection at other sites will become more widely seen, although digital warts and verrucae are a common if not universal experience in childhood.

KS is rare (about 5%) and often affects other organs, with sparing of the skin. Non-Hodgkin's and other lymphomas with cutaneous involvement are even rarer.

There have been reports of skin changes compatible with pellagra, scurvy and acquired zinc deficiency (acrodermatitis enteropathica), the latter attributed to malabsorption associated with chronic infectious diarrhoea caused by opportunistic organisms [7].

Non-specific findings in paediatric HIV practice include exanthematous rashes and cutis marmorata or livedo appearance [8], cold urticaria and idiopathic urticaria, long eyelashes requiring frequent trimming, patchy alopecia (common), erythema dyschromicum perstans (ashy dermatosis) and pyoderma gangrenosum [9]. Children infected with HIV are at risk of child abuse [5].

Haemophiliacs

Atopic eczema, seborrhoeic dermatitis, candidosis, dermatophyte infection and folliculitis occur with increased prevalence in HIV-positive compared with HIV-negative haemophiliacs. These conditions may develop earlier in infected haemophiliacs than in homosexuals [1,2].

Intravenous drug users

Drug abusers often have severe ecthyma and abscesses complicating injection sites but there is often concomitant malnutrition and liver disease [3]. Oral candidosis and seborrhoeic dermatitis are the most common skin problems; KS and oral hairy leukoplakia are rare [4]. Reynaud-Mendel *et al*. [5] found that genital warts were commoner in HIV-infected intravenous drug users than in male homosexuals.

Immune restoration disease

Patients with AIDS starting treatment with HAART and undergoing immune reconstitution can suffer exacerbations of immune or inflammatory disease such as progressive multifocal leukoencephalopathy, uveitis or vitreitis in CMV retinitis, sarcoidosis, hepatitis C reactivation and lymphadenitis in tuberculosis and *M. avium–intracellulare* infection [1–5]. Of dermatological import are chronic oroanogenital herpes simplex (Fig. 26.28) [6], reactivation of herpes zoster [2,5], cutaneous warts [7], acute multifocal cutaneous ulceration due to CMV (Fig. 26.29) [8], mycobacterial disease [9], post-kala-azar dermal leishmaniasis [10], eosinophilic folliculitis [2], 'immune recovery folliculitis' (possibly re-emergent hypersensitivity to *Demodex* and *Malassezia* [11]) and alopecia universalis associated with Graves' disease [12], all of which have been reported in the context of relatively successful treatment of HIV/AIDS by HAART.

Chapter 27

Bacterial Infections

R.J. Hay & B.M. Adriaans

Introduction

The normal human skin is colonized by huge numbers of bacteria that live harmlessly as commensals on its surface and within its follicles. At times, overgrowth of some of these resident organisms may cause minor disease of the skin or its appendages. On other occasions, bacteria not normally found there may colonize the epidermis and lead rapidly to disease. Apart from the arrival of these frankly pathogenic organisms, a wide range of bacteria land more or less fortuitously on the skin, and linger briefly in small numbers before disappearing, unable to multiply and thrive in this relatively inhospitable environment. Bacteriological sampling will reveal the presence of these otherwise unsuspected 'transients' [1]. Organisms not normally considered as resident members of the skin flora may sometimes colonize and become established in modest numbers for relatively long periods. Bacteria of this intermediate category have been labelled temporary residents [1]. Furthermore, certain sites such as the skin of the face may be repeatedly contaminated from the nostrils or mouth by *Staphylococcus aureus* or β-haemolytic streptococci, giving the false impression that these organisms are members of the normal facial flora. As they do not reside and replicate there, they are, as far as the face is concerned, transients.

When the skin is inflamed or otherwise abnormal, it is often difficult to determine whether an organism isolated from its surface is causing or contributing to the observed pathology [2,3]. Bacteriology reports must be interpreted with caution in the light of the known capabilities of the organism isolated. If the skin is damaged or the immune status of the subject impaired, bacteria usually regarded as non-pathogenic on the body surface may assume the role of opportunist pathogens. The number of organisms in the inoculum is of considerable importance. Within a given species there are also strain differences in virulence. Some strains have a particular tendency to cause disease, perhaps due to greater adherence to epithelial cells, perhaps because of differences in enzyme production. The underlying mechanisms are not fully understood, but the principle is well recognized.

From the point of view of host defence, there are three aspects to be considered: first, the nature and health of the epithelial surface including its ability to replicate and produce secretions; second, the interactions between commensal organisms of the normal flora and the potential parasite; third, the cellular and humoral factors acting

within the body—both classical immune mechanisms and non-specific mechanisms.

Even on the skin, the most accessible of sites, the complexities of host–parasite relationships remain incompletely understood. Detailed quantitative studies of pathogens and commensals, and investigations of epidermal replication and of the immune capabilities of the host, are becoming feasible in a research setting. The lessons they teach must be used to interpret the problems found in daily clinical practice, where such sophisticated methods are generally unavailable.

There is now a considerable literature on the microbiology of human skin of which these references are some of the most important texts [4–6]. For general microbiology and infectious disease Mandell *et al*. [7] and Collier and Balors [8] are recommended.

Normal flora of the skin

Methods of sampling

Numerous methods have been used to sample the normal or commensal flora of the skin, as no one method is satisfactory for all sites or for all aspects of the work [9]. Simple qualitative studies, especially when large numbers of subjects must be sampled, are usually performed by swabbing. This should be done in a standardized manner. The number of organisms is increased by the duration of rubbing, pressure exerted and moistening the swab. Semi-quantitative data and some information as to the spatial distribution of bacteria are provided by sticky tape sampling, roll tubes or replica plating. The best quantitative estimates of the total bacterial flora are determined by applying an open-ended cylinder of known cross-sectional area to the skin, introducing a small, known volume of suitable liquid vehicle (phosphate buffer plus Triton X-100) and scrubbing the surface of the skin to free the organisms. This method is useful for studying changes in the number of organisms under different environmental conditions in small numbers of subjects, but it is very time consuming and gives a poor yield of the intrafollicular anaerobes. Full-thickness skin-biopsy material should in theory provide the best sample, but in practice it is not easy to handle and this method is of course traumatic to the subject [4].

The disposal of organisms can be studied quantitatively by air sampling techniques using either settle plates or an impaction sampler while the subject performs a specified activity, for example undressing in a small room [10].

The media used for isolation clearly influence the results of sampling. Noble, although recognizing the special value of selective media, recommends in general the use of ordinary blood or serum agar for aerobic organisms and solid Brewer's thioglycolate medium without indicator but with 1% Tween 80 for *Propionibacterium acnes* [1].

The normal flora

The concept of a stable normal resident flora composed of large numbers of organisms belonging to relatively few species is well established [5]. There are some variations from subject to subject and perhaps in a given subject with time. A few geographical differences have also been noted [9].

Temporary resident bacteria may confuse the picture, being less easy to distinguish from stable commensal organisms than obvious transients. These problems are discussed at length by Noble [1]. It is possible, however, to describe a basic pattern of colonization of healthy human skin from which some variations may be observed. In simple terms, dry skin supports a low level of colonization, while moist areas and those well supplied with sebaceous glands are heavily populated. Most organisms reside on the surface of the stratum corneum in the crevices between squames in the rather loose outermost layers. These surface dwellers are not evenly distributed but are aggregated into microcolonies of varying sizes comprising perhaps 50 or several hundred cells. Some may be larger still. The hair follicles are inhabited by anaerobes (*Propionibacterium* spp.) in their deeper parts and nearer the surface aerobic cocci in addition to *Pityrosporum* spp. of yeasts. There are, however, no bacterial inhabitants of sweat ducts or glands, eccrine or apocrine.

The resident aerobic flora consists of Gram-positive cocci of *Staphylococcus* spp., *Micrococcus* spp. and a variety of Gram-positive rods, the coryneforms or diphtheroids. These coryneform organisms are mainly *Corynebacterium* spp. but some have recently been recognized as *Brevibacterium* spp. The only significant Gram-negative residents are *Acinetobacter* spp., previously known as *Mima* and *Herellea*.

Propionibacteria are regularly found in the follicles in adult skin and are the main anaerobic residents. The species *Peptococcus saccharolyticus* (Micrococcaceae) is now thought to be an anaerobic *Staphylococcus* and is a member of the normal flora in about 20% of subjects. Streptococci are notable by their absence, although they may frequently be found as transients (from the mouth) on perioral skin, or other sites prior to the onset of impetigo [11].

Most cutaneous microbiologists have now accepted that the Kloos and Schleifer [12] scheme for classifying staphylococci and micrococci (Micrococcaceae) is more meaningful, at least from an ecological standpoint, than the much used Baird–Parker system [1]. Kloos and Schleifer separate *Staphylococcus* spp. and *Micrococcus* spp. on the basis of several tests. For example, *Staphylococcus* spp. are able to produce acid aerobically from glycerol in the presence of erythromycin (0.4 μg/mL), and they are sensitive to lysostaphin and nitrofuran at defined concentrations, whereas *Micrococcus* spp. are not. Separation of

the two genera by these criteria is supported by molecular genetic techniques.

Within the genus *Staphylococcus*, 10 different species have regularly been isolated from normal skin. The coagulase-positive species *S. aureus*, however, should not be considered as a resident on healthy skin in most subjects, although it is frequently found in the anterior nares. It occurs there as a resident in about one-third of most populations and is carried on perineal skin in perhaps 20%. Healthy axillary skin, and toe clefts in shoe-wearing populations, may also harbour it in a smaller percentage of subjects. On damaged skin, for example in eczema or psoriasis, *S. aureus* may be found, sometimes widely over the skin surface.

Of the coagulase-negative resident *Staphylococcus* spp., *S. hominis* and *S. epidermidis* (moist sites) are the most important numerically, but *S. capitis*, *S. cohnii*, *S. haemolyticus*, *S. saprophyticus* and *S. warneri* have also been isolated from many subjects. Interestingly, *S. xylosus* has also been found to be fairly common on North American skins but does not seem to be a cutaneous resident in the UK. *S. simulans* is another recognized but uncommon cutaneous *Staphylococcus* on both sides of the Atlantic.

Organisms of the genus *Micrococcus* are less numerous than *Staphylococcus* spp. on healthy skin but are relatively more important on sparsely populated dry sites and in childhood. *Micrococcus luteus* and *M. varians* appear to be the dominant species but *M. kristinae* and *M. sedentarius* are accepted as residents and *M. lylae* may have significance in infancy [1].

Coryneforms

The coryneform (or diphtheroid) organisms are aerobic, Gram-positive pleomorphic rods. The coryneform bacteria are difficult to separate by conventional taxonomic methods, and chemotaxonomic methods, such as identification of specific protein patterns on gel electrophoresis and restriction fragment length polymorphism (RFLP) analysis, are time consuming and unsuitable for routine use. A recently proposed scheme in which the aerobic coryneforms are divided into four *Corynebacterium* spp. complexes, *C. bovis*, *C. minutissimum*, *C. xerosus* and *C. hofmani*, with *Brevibacterium epidermis* and an apparently aerobic *Propionibacterium* spp. making up a total of six groups, has the obvious value of simplicity, which all its predecessors lacked [1]. It is notable, however, that a trichomycosis axillaris associated group is not defined, and it is not clear whether the strains included in the *C. minutissimum* complex are closely associated with clinical erythrasma. *Brevibacterium* spp. are clearly separable from the genus *Corynebacterium* by cell-wall composition studies, nutritional requirements and by the production of methane thiol. These relatively recently recognized organisms have now been established as normal inhabitants of the skin (at least in a sizeable minority of subjects) and are particularly associated with (but not confined to) moist sites. They are related to *Brevibacterium* spp. isolated from dairy products, and by the production of methane thiol are the probable cause of the cheesy odour of sweaty feet [13].

A further group of coryneforms, implicated as copathogens in the superficial fungal infection of hair shafts, white piedra, has been identified as *Brevibacterium mcbrellneri* [14].

Three species of Propionibacteria, which are anaerobic, Gram-positive, rod-shaped organisms, are now generally acknowledged as members of the resident flora in adults. *Propionibacterium acnes* and *P. granulosum* are widespread but particularly associated with follicles that have large sebaceous glands over the face and upper trunk. They have both been associated with acne lesions in which their role is a matter of considerable interest. The third species, *P. avidum*, is found in moist sites, particularly the axillae and groins. Its pathogenic potential on the skin is unclear.

Quantitative studies

The population of Micrococcaceae on the skin has been estimated as 600/cm^2 for the hand, 60/cm^2 for the forearm, 300/cm^2 for the scapular region and 500 000–1000 000/cm^2 in the axilla [1]. Total anaerobic organisms, i.e. including diphtheroids as well, were reported by Williamson as averaging 1.46×10^6/cm^2 for the scalp and 2.41×10^6/cm^2 for the axilla [15]. Figures for the forehead were 200 000/cm^2, whilst for the forearms there were two populations of normal subjects, one tending to have high counts, with an average of 4500 organisms/cm^2 and one with low counts with just over 100/cm^2. For the back, the average for the whole group was a little over 300/cm^2. Anaerobic organisms are most numerous in those regions with large follicles—face, chest and back—and reports suggest numbers from 50 000 up to several million/cm^2 [16]. The follicular location of many of these organisms makes their estimation technically difficult, but Puhvel *et al*. [17], using microdissection techniques, have found the mean anaerobic count to be 3.8×10^4 per follicle. The number of organisms on a particular subject's skin varies little with time. There is, however, considerable variation within the population. Some individuals habitually carry high, and others very low, numbers of bacteria, but this distribution does follow a 'log normal' curve.

Modifying factors

The influence of various factors on the microbial population has been investigated by using a quantitative sampling technique. Abstinence from washing does not increase the count. Taking a shower probably produces a brief temporary reduction in the bacterial flora, but because it leads to the break-up of the microcolonies on

the skin and a more even distribution of bacteria, it may actually cause increased dissemination of bacteria for an hour or two afterwards [1]. Season has little effect apparently, but in one investigation an increase in the number of organisms was reported with increase in external temperature and humidity, but not when either of these factors operated alone [3].

The effects of increased hydration have been studied by covering the skin with plastic film [2]. The total flora increases greatly; in the early stages, coagulase-negative staphylococci and micrococci predominate, but later lipophilic coryneforms become numerous and micrococci diminish in importance. Gram-negative rods increase steadily with time. In jungle conditions, *Pseudomonas aeruginosa* is commonly isolated from moist areas, and in neonates nursed in high-humidity atmospheres, colonization and infection with *P. aeruginosa* occur with increased frequency [18].

Age, sex and race differences

The human skin becomes colonized from birth. In infants the bacterial flora is somewhat unstable and varied, being more likely to include, probably as temporary residents, streptococci and spore-forming bacilli [19]. *Micrococcus* spp. appear to be more prominent than on the adult skin, but *Propionibacterium* spp. require the increased skin lipid levels of puberty before becoming established, and are present at very low levels, if at all, before the onset of puberty. In elderly subjects, streptococci make an appearance as residents, and in this age group enteric organisms are found more often, particularly in moist sites. There is evidence that males carry higher numbers of bacteria, at least of aerobic organisms, than females [1], a fact which probably accounts for the observation that men are more likely to be disseminators of *Staphylococcus aureus*, if they are perineal carriers, than are women [20]. The subject of dispersal, of considerable importance in surgery, has been extensively reviewed by Noble [21].

Racial differences have been demonstrated in the nasal carriage of *S. aureus* in children—white individuals (at 41% positive) being more likely than black individuals (at 30%) to carry this organism [22], but comparative data on the densities of the bacterial populations of the main groups of resident organisms are lacking.

Other influences

Changes in normal flora, including an increase in the number of subjects carrying Gram-negative organisms, may occur in seriously ill patients, apparently to an extent that cannot be accounted for by the treatment they are receiving [23].

Antiseptics applied to the skin, as in the preparation of operation sites, generally remove the transient flora and reduce the resident organisms [4]. The application of agents that specifically inhibit Gram-positive cocci is generally followed by an increase in the population of Gram-negative rods [9]. Carriage of *Staphylococcus aureus* may also be affected by cold weather, duration of hospital stay or needle injection [24].

The role of the normal flora

The normal flora of the skin appears to have several functions, of which the most important is probably defence against bacterial infection through bacterial interference. It is almost certainly responsible for the production of free fatty acids from skin lipids. There is now considerable evidence that *Propionibacterium acnes* and the Gram-positive cocci are capable of hydrolysing lipids of sebum to produce free fatty acids [25]. It seems likely from their localization, and from evidence comparing the effects of systemic tetracycline administration with topical neomycin application, that *P. acnes* deep in the follicles actually undertakes most of this hydrolysis [26].

Apocrine sweat is sterile and odourless when secreted. The odour develops due to bacterial action, mainly attributable to aerobic corynebacteria. Deodorants are effective largely through their antibacterial activity [27].

The flora of specialized areas

Certain areas of skin have specific floras, which differ quantitatively or qualitatively from the general picture outlined above, and are therefore worthy of special consideration.

The nasal vestibule

The common organisms found on swabbing are coagulase-negative staphylococci, micrococci and coryneforms. *Staphylococcus aureus* is present as a resident in about 35% of healthy subjects [1]. *Streptococcus pyogenes* is not rare. The percentage incidence varies greatly with different populations but, as nasal carriers sometimes disseminate large numbers of organisms, their detection and treatment are most important in the control of streptococcal infections.

External auditory meatus

In addition to coagulase-negative staphylococci and coryneforms, *Proteus* spp., *Escherichia coli, Neisseria catarrhalis* and *N. flora* have been isolated in small but significant numbers from normal ears.

Axilla

This site supports a very high level of bacterial colonization, mostly staphylococci, micrococci and coryneforms.

Some individuals have a mainly coccal flora; in others aerobic coryneforms predominate. *Propionibacterium acnes* is usually present and *P. avidum* is often found, as are *Acinetobacter* spp.

Toe clefts

In shoe wearers, the fourth toe cleft is often hyperhydrated and the skin macerated. Such conditions sustain an extraordinarily large number of bacteria, mainly the common organisms of the general resident flora, but Gram-negative organisms are also found in this site. The toe web is an important site for *Brevibacterium* spp., and not surprisingly *Acinetobacter* spp. are often isolated, as are *Alkaligenes* spp. In the elderly and in tropical climates, coliforms and other organisms of the intestinal flora may be present [28].

The vulva

Organisms regularly isolated from this area include the expected coagulase-negative staphylococci, micrococci and coryneforms, with coliforms and enterococci occurring frequently as residents and as transients from faecal sources. Group B streptococci may be cultured from this site, usually in small numbers.

The perineum and groin

Coagulase-negative staphylococci, micrococci and a variety of aerobic coryneforms are usually present. Gram-negative organisms of the intestinal flora rapidly disappear after faecal contamination, but *Acinetobacter* spp. are resident in about 15% of subjects.

Umbilicus

The umbilicus of the newborn is frequently colonized by *Staphylococcus aureus* shortly after birth. The incidence varies greatly, but for infants born in hospital it is probably not very different from the nasal colonization rate.

The umbilicus of the newborn may also be colonized by *Streptococcus pyogenes*, and look normal. The organisms can readily spread from infant to infant in a hospital nursery. Searches for the source of staphylococcal and streptococcal infection in a maternity unit should always include umbilical swabs from the babies.

Adherence

The ability of bacteria to stick to the skin surface, the process of adherence, is still not well understood. On wet surfaces, the hydrophobic nature of many bacterial walls promotes close apposition between the bacterium and human cells. In addition, there are smaller elements of the outer surface, adhesins, which also promote adhesion [29].

These are usually specific and interact with the host cell via a receptor site. Examples of bacterial adhesins include lipoteichoic acid [30] found in both staphylococci and streptococci; in the latter this is located in fine cell-wall projections or fibrillae. Similar filamentous structures, fimbriae or pili, occur in many Gram-negative bacteria. Adhesins not only allow the organisms to remain on the epithelial surface, they may also regulate the relationship between different bacteria, such as the composition of microcolonies, via the interaction of complex excreted material covering the bacterial surface. The secretion of extracellular material, such as slime, allows bacteria to adhere to foreign surfaces as well as stratum corneum [31]. Where this involves suture materials or plastics such as percutaneous cannulae, heavy colonization may then be followed by invasion resulting in abscess formation or septicaemia.

The skin and defence

The skin provides a dry, mechanical barrier from which contaminating organisms are constantly being removed by desquamation. Investigators have spread organisms on the skin surface, studied their disappearance and attempted to elucidate the factors concerned.

The early theories that the acid pH of most of the skin surface was an important defence mechanism against bacteria have now been completely rejected [1]. Desiccation appears to account for the difference in the rate at which implanted bacteria disappeared from acid and alkaline areas, the alkaline areas being more moist.

Ricketts *et al*. [32] investigated the survival of several bacteria species on the forearm skin under plastic films of two kinds, one permeable to water vapour and one not. The plastic films were held by a frame of adhesive tape, so that the inoculated area could be sampled at intervals up to 7 days. By studying the survival of bacteria on the dry and on the moist areas thus produced, these workers concluded that a chemical mechanism was largely responsible for the destruction of *Streptococcus pyogenes*, whereas drying was responsible for the destruction of *Escherichia coli* and *Pseudomonas aeruginosa*. Both factors appeared to contribute to the elimination of *Staphylococcus aureus*. They then investigated the nature of the chemical mechanism and concluded that unsaturated fatty acids, particularly oleic acid, were the active agents. These may be produced on the skin surface as a result of the splitting of esters in the sebum by the commensal flora (Chapter 43).

Lacey has confirmed that extraction of the fatty acids from the skin diminishes resistance to colonization by staphylococci, and that fatty acids may be neutralized to some extent by binding with neomycin [33].

The phenomenon of bacterial interference is sufficiently closely related to skin defence to be mentioned here. Colonization of some sites by one strain of staphylococci interferes with the subsequent colonization by a different strain. Shinefield *et al*. [34] deliberately colonized the noses and umbilical stumps of newborn infants against infection and disease caused by epidemic strains of *S. aureus*, and obtained most encouraging results. A similar method has been used in an attempt to prevent recurrent attacks of boils, but the technique has not found general acceptance, largely because the avirulence of the inoculated strain cannot be guaranteed. Competition for available nutrients is thought to explain this phenomenon.

Selwyn has drawn attention to the importance of antibiotic production by normal skin bacteria [35]. It seems that more than 20% of normal subjects carry some skin bacteria that produce antibiotics capable of inhibiting other microorganisms. On nearly one in 10 of normal human skins, these antibiotic producers actually predominate, in which case they appear to be helpful in protecting against staphylococcal wound infection after surgery.

Gram-positive bacteria

Staphylococcus aureus

Staphylococcus aureus, distinguished from other staphylococci by a positive test for coagulase, is among the most important causes of skin infections and of serious, and sometimes fatal, systemic disease. Many of the conditions of modern life have tipped the precarious balance between commensalism and parasitism in its favour. Crowded cities and hospitalization of the sick provide increased opportunities for dissemination of the organism, and the wide use of antibiotics results in selective survival of resistant strains [1].

Carriage

The frequency with which *S. aureus* can be isolated from the skin has been extensively studied by many different techniques. If a sufficient number of sites are sampled frequently enough, the carrier rate may approach 100%, especially if enrichment culture techniques are used. With conventional techniques and random sampling, approximate rates for the resident carriage sites of *S. aureus* are: anterior nares 35%, perineum 20%, axillae 5–10% and toe webs 5–10% [2]. Resident carriage on other, dry, healthy skin surfaces is believed not to occur, but contamination from carriage sites is common, notably of the hands from the nose. In the same person, different phage types may colonize different areas.

Nasal carriage has been studied in most detail. Serial examinations suggest that some 20% of individuals are persistent nasal carriers, 60% are intermittent carriers and 20% are resistant to nasal colonization [3].

Genetic factors, perhaps involving bacterial adherence [4] and immune responses, are suggested by higher nasal carriage rates in white people than in black people [5], by studies of families and twins [6], by higher-than-normal rates in patients with phenylketonuria [7], by increased adherence in atopic eczema [8] and by an association of nasal carriage with human leukocyte antigen (HLA)-DR3 [9].

In those susceptible to nasal colonization, the overall rate depends on the extent to which the many transient carriers acquire the organism by contact with persistent carriers. This at least partly underlies the increase in carriage rates following hospital admission [2], higher rates in urban than in rural areas [10] and variation in carriage rates with age.

The neonatal nose and umbilical stump [11] tend to be rapidly colonized by *S. aureus*, perhaps partly because colonization by saprophytic cocci has not yet taken place. The nasal carriage rates are rather higher (e.g. 72%) [12] in infants born in hospital and lower in those receiving antiseptics on the umbilicus. The hospital-born baby may transmit infection to other family members [13]. The nasal carriage rate falls to a minimum of 10–15% at the age of 1 year and rises again to reach adult levels by the age of 5 years [12].

Within the nasal passage, the anterior nares are the most readily colonized parts and are the site usually sampled. However, carriage of *S. aureus* on the mucosal surfaces of the turbinates is common, and recolonization by these organisms may partly explain the difficulty of eradicating nasal *S. aureus* by topical application [2].

High rates of nasal carriage in atopic eczema (79%) [14] may partly derive from the heavy load of *S. aureus* on the skin, but increased adhesion of the organism to nasal mucosal cells may be relevant [8].

In patients on ambulatory peritoneal dialysis, those carrying *S. aureus* in the nose are much more likely to get infection of the exit site, which is usually with the same bacterial strain [15].

Suppression of carriage of S. aureus. Carriage of *S. aureus* is physiological and is not in itself an indication for treatment. Reasonable indications include prophylaxis in those whose occupations would render staphylococcal dispersal a significant hazard to others, such as operating theatre and neonatal nursery staff, and confirmed carriers among patients suffering frequent recurrences of staphylococcal infection and their household contacts [16].

Permanent eradication of carriage of *S. aureus* is not possible, but temporary elimination or a substantial reduction in numbers may be of significant clinical benefit. If the organism is cleared, eventual recolonization is to be expected, as was confirmed in a study of an isolated and well-motivated group of 28 men in an Antarctic base [17].

Minimum efforts to reduce carriage are regular, long-term application of chlorhexidine cream to the appropriate sites (anterior nares, perineum or axillae) and use of an antiseptic, typically chlorhexidine or povidone iodine, in a detergent base for daily bathing or showering including hair washing [18]. Oral or topical antibiotics may contribute to elimination of the organism, but in general recolonization occurs soon after the treatment is stopped [19], with two main exceptions. Intranasal mupirocin eliminated nasal *S. aureus* after a 5-day course in all patients treated, and 50% remained free of the organism after 5 months [20]. Oral rifampicin, 600 mg daily for 7–10 days cleared the organism for 3 months in 80% of cases [21]. Good results also were obtained with long-term, low-dose clindamycin, 150 mg daily for 3 months [22].

Bacterial interference. Nasal inoculation of *S. aureus* strain 502A, of relatively low virulence, has been advocated as an artificial method of achieving bacterial interference against more virulent strains. In a study of families with recurrent furunculosis, colonization with strain 502A persisted for 6 months in 83% of treated patients and the infections became much less frequent [23]. However, strain 502A may cause occasionally severe infections, including a case of fatal septicaemia [24], and its use cannot be generally recommended [25,26].

Colonization of diseased skin by *S. aureus*

Moist lesions and those in which the integrity of the epidermal barrier is disrupted are readily colonized by *S. aureus*. Loss of a physical barrier against invasion is one factor, but the reported inactivation by serum of the inhibitory effect on *S. aureus* of linolenic acid [27] is of interest.

In atopic eczema high numbers of *S. aureus* are present. The organism can be isolated from 91% of chronic plaques and 100% of acute exudative lesions [28] and from uninvolved skin in 76% of patients [13]. Numbers of *S. aureus* correlate with the severity of the eczema [29]. Adherence of *S. aureus* to nasal mucosal and skin epithelial cells [8], including specifically corneocytes [30], is increased in atopic eczema. Patients taking retinoids may develop mucocutaneous side effects, such as cheilitis and blepharo-conjunctivitis. These are often associated with *S. aureus* infection.

Biologically active substances produced by *S. aureus* [26,31]

Staphylococcus aureus can produce several toxins, some of which contribute to invasion and survival of the organism in the tissues.

More specific in the dermatological context are the exfoliative toxins (epidermolytic toxins ET-A and ET-B) responsible for the generalized staphylococcal scalded skin syndrome (SSSS) (Chapter 14) and bullous impetigo. The superantigen toxic shock syndrome toxin 1 (TSST-1), and probably other toxins, are involved in toxic shock syndrome. Staphylococcal scarlatina is thought to be mediated by staphylococcal erythrogenic toxin or other byproducts of the organism [32]. Superantigens from *S. aureus* may also affect the evolution of atopic dermatitis.

Staphylococcal cell-wall products (teichoic acid, peptidoglycan and protein A), exert many effects on the host immune system [33,34]. Protein A may be involved in adherence of the bacterium to the host cell [30], and it can bind to the Fc portion of IgG in addition to the specific Fab fragment of IgE [35,36].

Table 27.1 Involvement of *Staphylococcus aureus* in cutaneous disease.

Direct infection of skin and adjacent tissues
Impetigo

Toxic shock syndrome
Staphylococcal scarlatina

Resistance to staphylococcal infection [26]

The main host defence against invading staphylococci is ingestion and killing by phagocytes. Antibodies to various *S. aureus* antigens are universally found, but appear to make a relatively small contribution to host defences and are of limited diagnostic and prognostic value [37]. Cell-mediated responses to *S. aureus* occur but their role in immunity is uncertain.

Resistance to staphylococcal infection is reduced in patients with poorly controlled diabetes [38], renal insufficiency, haematological malignancies, nutritional deficiency or alcoholism, and in those receiving corticosteroid or cytotoxic therapy.

In acquired immune deficiency syndrome (AIDS), staphylococcal bacteraemia may occur [39], and angular stomatitis and facial impetigo and folliculitis are common (Chapter 26).

The increased incidence of *S. aureus* infections in patients on retinoids may be partly due to increased adherence to epithelial cells [40].

Pure deficiency of cell-mediated immunity appears not to predispose to staphylococcal cutaneous infection. Immunoglobulin deficiency, including selective IgM deficiency [41], may contribute to staphylococcal skin infection, as may certain deficiencies of the complement system (Chapter 59).

In the Chediak–Higashi syndrome (Chapter 39) and chronic granulomatous disease (Chapter 59), deficiencies of granulocyte function underlie a strong predisposition to staphylococcal and other infections. An isolated deficiency of neutrophil killing function in two siblings responded to ascorbic acid [42]. Cyclical neutropaenia has also been associated with recurrent infected eczema [43].

In Job's syndrome (Chapters 14 and 17), hyper-IgE syndrome and Buckley's syndrome [44] an increased incidence of severe staphylococcal infection is associated with eczema, markedly raised serum levels of IgE and defective neutrophil chemotaxis [45]. Staphylococcal and other infections are associated with eczema in the Wiskott–Aldrich syndrome (Chapter 14), in which a number of immunological abnormalities occur inconstantly, including hyper-IgE. Recurrent pyoderma and folliculitis with atopic eczema were associated with deficiencies in both lymphocyte and granulocyte function in a boy and his father. The clinical and immunological abnormalities responded to conventional (H_1) antihistamine treatment [46].

Cutaneous staphylococcal infection

The main skin diseases due to *S. aureus* are listed in Table 27.1.

Staphylococci cause infections by direct invasion of the skin, or by the release of toxins which may affect the skin or other organs.

Staphylococcus aureus and eczema. Staphylococcus aureus is very frequently isolated, often in heavy growth, from lesions of eczema, especially of atopic type. The extent to which the bacteria may play a pathogenic role in the eczema has been controversial, and may be difficult to assess in the individual case.

In true infective eczema, bacteria, including *S. aureus*, are regarded as the primary stimulus for an eczematous response, although the mechanisms are uncertain (Chapter 17).

Cytotoxic antibody and IgE reactions against bacterial (including *S. aureus*) antigens may be important in atopic and discoid eczema (Chapters 17 and 18) [47].

Staphylococcus aureus was isolated from 14 of 20 children with infantile seborrhoeic dermatitis, but its pathogenicity was uncertain [48].

Secondary colonization and infection have been studied most in atopic eczema; there is a high rate of staphylococcal carriage in this condition. When overt signs of infection

[49] are present, a pathogenic role is generally accepted. There is also evidence that high bacterial density (over $10^6/cm^2$) on lesions, short of overt signs of clinical infection, significantly aggravates the eczema [28]. The staphylococci may produce exotoxins with superantigenic properties, which may cause T-cell activation, cytokine release and mast cell degranulation [50].

The significance is still uncertain of reports in atopic eczema of impaired neutrophil chemotaxis [49], specific antistaphylococcal IgE [36], altered reactivity to protein A [51] and increased [52] or decreased [53] cell-mediated responses to staphylococcal extracts or antigens [34].

When bacteria are regarded as significant in a case of eczema, combined steroid and antibacterial therapy is appropriate [54,55].

Antibiotic resistance. The application of antibiotics to the skin with its large potential culture area and its resident flora may increase the likelihood of the development or the transfer of antibiotic resistance [56]. Of special importance is gentamicin resistance, which can be transferred between strains of *S. aureus*, and also between coagulase-negative staphylococci and *S. aureus* [56].

Gentamicin should not be used as a first-line topical antibiotic. Topical fusidic acid and mupirocin are associated with a low incidence of resistance when used to treat acute infections in the community setting. With prolonged use, the incidence of resistance increases. Fusidic acid resistance has been reported from a dermatology unit following cross-infection by a single strain [57].

During the past few decades, epidemics of methicillin-resistant *S. aureus* (MRSA) infection have increased in frequency throughout the world. Many hospitals have had to institute control measures to contain the spread of the infection [58]. Unfortunately, MRSA carriage may persist for years, and increases the risk of spread if patients who are carriers are readmitted to hospital [59]. Although the glycopeptides (vancomycin and teicoplanin) have been the agents of choice, some strains of MRSA are also now becoming resistant to these agents. Alternative therapies now include quinupritin/dalfopristin, a semi-synthetic streptogramin, and linezolid, an oxazolidinone antibacterial agent [60]. However, resistant enterococci have emerged already, and linezolid should only be used when other antibiotics have failed or are inappropriate because of bacterial resistance.

Coagulase-negative staphylococci

These organisms are members of the normal skin flora and contribute to resistance against colonization by pathogenic bacteria [1].

Staphylococcus epidermidis [2–4] is the main pathogen of the group. In the otherwise healthy patient it is probably an occasional cause of minor skin infections including superficial folliculitis, although its significance in an individual case may be difficult to judge. Secondary infection of pre-existing dermatoses, such as eczema, seems not to occur. *Staphylococcus epidermidis* may cause infections in wounds and especially around implanted surgical devices. The ability to adhere to foreign bodies and produce extracellular slime during the course of colonization is thought to be important for pathogenicity [5]. As implantations become more frequent, these infections have increased and are recognized as a cause of major internal infections including endocarditis and septicaemia, especially in patients with immune deficiencies. A case of cellulitis in a woman with acute myelocytic leukaemia was reported [6], and the organism has been associated with vasculitis in a patient on cytotoxic therapy for ovarian carcinoma [7]. A single isolate of *S. epidermidis* from blood culture could be due to contamination, but if found repeatedly it may be regarded as probably significant. *S. saprophyticus* is a recognized cause of urinary tract infection, especially in young women [8].

Multiple antibiotic resistance is common and may be transferred to *S. aureus*.

Streptococci

The streptococci are Gram-positive catalase-negative cocci characteristically arranged in chains. They are nearly all facultative anaerobes, i.e. they can grow aerobically or anaerobically [1,2].

Lancefield group antigens are the usual basis for routine classification of streptococci. There are at least 18 (A–R). The system covers not only the β-haemolytic streptococci, to which it was originally applied, but also some α-haemolytic and non-haemolytic (γ-haemolytic) organisms.

The involvement of streptococci in skin disease is summarized in Table 27.2.

Table 27.2 Involvement of streptococci (mostly group A) in cutaneous disease.

Direct infections of skin or subcutaneous tissue
Impetigo
Ecthyma
Erysipelas
Cellulitis
Vulvovaginitis
Perianal infection
Streptococcal ulcers
Blistering distal dactylitis
Necrotizing fasciitis
Others
Secondary infection
Eczema, infestations, ulcers, etc.
Tissue damage from circulating toxin
Scarlet fever
Toxic shock-like syndrome
Skin lesions attributed to allergic hypersensitivity to streptococcal antigens
Erythema nodosum (Chapter 49)
Vasculitis (Chapter 49)
Skin disease provoked or influenced by streptococcal infection (mechanism uncertain)
Psoriasis, especially guttate forms (Chapter 35)

Streptococcus pyogenes

The major streptococcal pathogens in humans belong to group A, collectively referred to as *Streptococcus pyogenes*. These may be subdivided according to M and T surface-protein antigens. The M proteins protect the organism against phagocytosis, affect adherence to different epithelial tissues and contribute to virulence. Lipoteichoic acid, expressed on the surface of group A streptococci, is involved in adhesion of the organism and extracellular products, including streptolysin O, hyaluronidase and pyrogenic exotoxins, and contribute to the virulence of the organism.

Carriage. Streptococcus pyogenes is carried in the throat by about 10% of the normal population and in the anterior nares less frequently. Natural antibiotic production by some other members of the throat flora may contribute to resistance to colonization by *S. pyogenes* [3], but carriage is often not eradicated by therapeutic antibiotics. Carriage rates are higher after clinical infection. However, in persistent throat carriers, the streptococci tend to lose their M proteins and consequently their virulence [4].

The normal skin does not provide a favourable habitat for *S. pyogenes*, perhaps due partly to a bactericidal effect of skin lipids [5], and transient skin carriage is found in only 0.5–1.0% of individuals [6]. However, the duration of survival of streptococci on the normal skin of patients with infections, and on the hands and arms of those handling such patients, may be sufficient to allow their dispersal by this route.

Asymptomatic anal carriage is an occasional source of significant infection in contacts [7].

Streptococci colonize damaged skin, although less readily than staphylococci. They can frequently be isolated from eczematous and other moist lesions, although the borderline between colonization and infection is often difficult to define.

Strains in skin and throat [8]. *Streptococcus pyogenes* can be divided broadly into 'throat' and 'skin' serotypes. Stronger adherence of the former to mucosal cells and of the latter to skin cells, and better survival of the latter in oleic acid and in nutritionally poorer media, may be relevant [9]. Throat strains survive poorly on skin and are infrequently found on the healthy skin even of patients with streptococcal throat infection. The strains isolated from normal skin are usually those common in streptococcal pyoderma: in a study of endemic disease [10], colonization of normal skin preceded the development of lesions in a majority of patients. Small numbers of skin strains may colonize the throat or the nose, but no streptococcal respiratory disease occurred among 1300 cases of streptococcal pyoderma in a military establishment [11].

Initiation and complications of infection. On experimental application under occlusion to intact normal skin, several strains of *S. pyogenes* failed to cause disease and indeed rapidly died; localized superficial infection occurred only if the skin had been scarified [12].

It is widely assumed that skin damage, albeit minor, is necessary for the development of naturally occurring streptococcal pyoderma.

Rheumatic fever is a complication of *S. pyogenes* pharyngitis, but occurs after pyoderma rarely if at all. The serotype of the organism does not appear to be relevant [5].

Acute glomerulonephritis follows both throat and skin infections with certain 'nephritogenic' serotypes of *S. pyogenes*. There are reports of glomerulonephritis infrequently following throat infections but apparently not skin infection with group C and group G streptococci [13–15].

Erythema nodosum and psoriasis are known to follow a streptococcal throat infection.

Scleredema of Bushke has also been linked with streptococcal infection of the throat.

Management of carriage and control of epidemics. The mere presence of *S. pyogenes* in an asymptomatic subject is not in itself an indication for attempts to eradicate it. Furthermore, such attempts are often unsuccessful [16].

Different approaches may be considered: surveillance of contacts of infected patients for clinical signs of infection;

instruction in hygiene and use of antiseptics; bacteriological investigation for carriage of the organism in patients and asymptomatic contacts with a view to antibiotic treatment of positive cases; and routine penicillin administration to those at risk without prior bacteriological investigation. Factors affecting the policy in individual cases include the extent of the outbreak, the closeness of contact, a special risk of infectivity by virtue of occupation [11], and the actual or expected risk of nephritis (and, for throat infections, rheumatic fever) [17,18]. Residents in nursing homes may be at risk of infections with *S. pyogenes* because of the propensity of the organism to cause disease in the elderly, and the ability of the organism to spread from person to person [19].

Other streptococci

Group C [20] streptococci are relatively frequently found colonizing diseased skin, but they are occasional causes of impetigo, erysipelas and cellulitis. Group G streptococci [21] colonize the pharynx, intestine, vagina or skin and may be implicated in the aetiology of cellulitis or erysipelas in patients with vascular disease or those who have undergone cardiac surgery and venous ligation [22].

Group B streptococci frequently colonize the anorectum (probably its natural habitat) [7,23,24] and, secondarily, the vagina. It is a major cause of severe infections, especially in neonates [24]. Group B streptococci may be associated with invasive disease in adults, particularly in patients with chronic disease.

In the skin, it appears to have a causal role in bacterial intertrigo, and may rarely cause erysipelas, cellulitis, necrotizing fasciitis and blistering distal dactylitis. Group F streptococci may be important secondary pathogens in suppurative hidradenitis.

Group D streptococci (enterococci) are usually harmless, but have uncommonly been implicated in cellulitis and necrotizing fasciitis. These organisms only cause infection in previously damaged tissues. More recently, the enterococci have been given genus status distinct from streptococci since they differ from streptococci in many respects [25].

Lancefield group L streptococci have been reported to cause skin sepsis in two meat handlers [26], and a facial abscess [27].

Of the α-haemolytic streptococci, *Streptococcus viridans* is commonly transferred to the skin of the face and hands from its normal habitat in the mouth; it seems to have little cutaneous significance.

Non-haemolytic streptococci are occasionally found as transients on the skin, but are feebly pathogenic under normal conditions.

Of the microaerophilic and the true anaerobic streptococci, some species can colonize wounds and are important in progressive bacterial synergistic gangrene and in some cases of necrotizing fasciitis [28].

Streptococcal serology [16,29]

Type-specific antibodies to the M proteins of group A streptococci persist for a few months or a year or two and protect against reinfection by the specific strain only.

The antistreptolysin-O (ASO) titre is an indicator of previous infection by streptococci of groups A, C or G. The upper limit of normal is 200 U/mL and highest titres range from 2000 to 3000 U/mL. In streptococcal skin infection; however, the ASO response is weak and an unreliable guide to diagnosis.

Similarly, antibody to nicotinamide adenine dinucleotidase (NADase) may indicate group A, C or G infection but is unreliable in skin infection.

Antibodies to deoxyribonuclease (DNase) B [30] and to hyaluronidase are more regularly raised in streptococcal skin disease. DNase B antibodies are probably specific for group A streptococci. One hyaluronidase antibody is specific for group A, and another for groups C and G jointly [29]. Susceptibility of neonates to group B streptococcal infection is related to the level of capsular-type-specific antibodies in the maternal serum [24].

In some countries where streptococcal infection is common, the ASO titre may be persistently elevated, so that raised titres may not be indicative of recent infection. More specific investigations may thus be required.

Impetigo

Definition. Impetigo is a contagious superficial pyogenic infection of the skin. Two main clinical forms are recognized: non-bullous impetigo (or impetigo contagiosa of Tilbury Fox) and bullous impetigo. Bullous impetigo is accepted as a staphylococcal disease, although streptococcal bullous impetigo has been reported [1]. The non-bullous form may be caused by *Staphylococcus aureus*, by streptococci, or by both organisms together.

Bacteriology [2,3]. Non-bullous impetigo may be caused by both *S. aureus* and streptococci, but there has been controversy as to the relative importance of the two genera. This may partly depend on geographical variations, the streptococcal form being more prevalent in warmer climates. Some confusion may have been semantic, as some authors use the term pyoderma to apply to the streptococcal disease reflecting the clinical differences between the two forms, and others regard pyoderma and impetigo as synonymous. *Staphylococcus aureus* may be a secondary invader in streptococcal impetigo and in some such cases, depending on bacteriological techniques, it may be the predominant or the only isolate, and the evidence for streptococcal involvement may rest on serology [4].

Detailed studies of endemic pyoderma among children in the Red Lake Indian Reservation in northern Minnesota [5] detected both *S. aureus* and streptococci, each alone in a sizeable minority, but both together in 58% of cultures. Early lesions were more often purely streptococcal; in cases with both types the streptococci lasted longer, and the strain of *Staphylococcus* changed more often than that of the *Streptococcus*. The authors concluded that, in many of the mixed-culture cases, the disease was primarily streptococcal with *S. aureus* a secondary colonizer.

Recent publications suggest that the staphylococci may be the predominant infectious agent in most areas [6].

The preponderance of group II phage types seen in bullous impetigo seems also to apply to the non-bullous staphylococcal disease [3]. In streptococcal impetigo (streptococcal pyoderma) Lancefield group A is by far the commonest, but there are occasional infections with group G and group C organisms [5,7].

Bullous impetigo is a superficial cutaneous infection with *S. aureus*. The organism can generally be cultured from blister fluid. Injections of bacterial isolates from affected patients into newborn mice result in a generalized SSSS [8]. Epidermolytic toxin has been recovered from the blister fluid of some cases [9] and is accepted as the basis for the bulla formation. The toxin is produced commonly but not exclusively by staphylococci of phage group II. The localization of the epidermal splitting in bullous impetigo compared with the widespread involvement in the generalized form is probably related to local production of the toxin, whereas in SSSS the toxin is disseminated haematogenously [10].

Epidemiology. Pure staphylococcal non-bullous impetigo [3,6,11] is relatively frequent throughout the world, and large outbreaks often occur. It is commoner than the streptococcal disease in temperate climates. In warmer and more humid areas, for example the southern USA, the streptococcal form predominates and is endemic. The peak seasonal incidence is in late summer. Preschool and young school age children are most often affected. In adults, males predominate and large outbreaks may be troublesome in barracks and similar communities [12]. Although over-crowding, poor hygiene and existing skin disease, especially scabies, predispose to infection, many cases occur in previously healthy subjects with good living standards.

Streptococci isolated from fomites outside epidemics are frequently non-infective [13], but in epidemics, frequently handled materials like gymnasium equipment and room dust may be important in transmitting disease [12]. Biting insects may transfer the disease, but in addition small non-biting flies of the genus *Hippelates* can contribute to the rapid spread of the streptococcal infection in tropical and subtropical regions [14].

Bullous impetigo is usually sporadic, but clusters of cases may occur in families and other groups, and larger outbreaks are occasionally seen in institutions [15]. It is most

Fig. 27.1 Staphylococcal impetigo. (Courtesy of Dr A.S. Highet, York District Hospital, York, UK.)

Fig. 27.2 Streptococcal (group A) pyoderma. (Courtesy of York District Hospital, York, UK.)

frequent in the summer months. Bullous impetigo occurs at all ages. It is said to be commoner in childhood but adult cases are probably under-reported [16]. In the newborn, bullous impetigo may be especially widespread and was formerly called pemphigus neonatorum (Chapter 14).

Minor abrasions and other skin lesions may predispose to infection if the patient or a contact carries an appropriate strain of staphylococcus [17]. An increased incidence in hospital workers has been noted [18].

Pathology. In *bullous impetigo*, the epidermis splits just below the stratum granulosum forming large blisters. Neutrophils migrate through the spongiotic epidermis into the blister cavity, which may also contain cocci. Occasional acantholytic cells may be seen, perhaps due to the action of neutrophils. The upper dermis contains an inflammatory infiltrate of neutrophils and lymphocytes. Cases with positive pemphigus-like antibodies on direct or indirect immunofluorescence have been reported [19–21].

The histology is similar for *non-bullous impetigo* except that blister formation is slight and transient.

Clinical features [6]. In *non-bullous impetigo*, the initial lesion is a very thin-walled vesicle on an erythematous base. The vesicle ruptures so rapidly that it is seldom seen as such. The exuding serum dries to form yellowish brown crusts. (Fig. 27.1) which are usually thicker and 'dirtier' in the streptococcal form (Fig. 27.2). Gradual irregular peripheral extension occurs without central healing, and multiple lesions, which are usually present, may coalesce. The crusts eventually dry and separate to leave erythema, which fades without scarring. In severe cases, there may be regional adenitis with fever and other constitutional symptoms. The face, especially around the nose and mouth, and the limbs are the sites most commonly affected, but involvement of the scalp is frequent in tinea capitis, and lesions may occur anywhere on the body, especially in children with atopic dermatitis or scabies. Involvement of the mucous membranes is rare. There is a tendency to spontaneous cure in 2–3 weeks but a prolonged course is common, particularly in the presence of underlying parasitic infestations or eczema, or in hot and humid climates. In heavily pigmented skin, the lesions may be followed by temporary hypopigmentation or hyperpigmentation.

In *bullous impetigo*, the bullae are less rapidly ruptured and become much larger; a diameter of 1–2 cm is common but they may be of very considerable size, and persist for 2 or 3 days. The contents are at first clear, later cloudy. After rupture thin, flat, brownish crusts are formed. Central healing and peripheral extension may give rise to circinate lesions (Fig. 27.3). Although the face is often affected, the lesions may occur anywhere, and may be widely and irregularly distributed, often favouring the sites of existing skin disease, especially miliaria or trivial injuries such as insect bites. The buccal mucous membrane may be involved. Commonly, rather few lesions are present, but the picture is very variable. Regional adenitis is rare.

Complications [22]. Infective complications are uncommon in the absence of systemic disease or malnutrition,

Fig. 27.3 Bullous impetigo after disruption of bullae.

although deeper infections like cellulitis occasionally occur with the streptococcal disease.

Streptococcal impetigo accounts for the majority of cases of post-streptococcal acute glomerulonephritis (AGN) [11,23]. The incidence of AGN in different series of patients with streptococcal impetigo depends on the nephritogenic potential of the infecting strain. Some never cause nephritis [12], but 25% of patients with pyoderma due to *S. pyogenes*, type M-49 are affected. The overall incidence of post-streptococcal AGN has declined in recent decades. The latent period for development of nephritis after streptococcal pyoderma is 18–21 days, compared with about 10 days for throat infection, raising the unproven possibility that early treatment of skin infection might offer a better chance of preventing the renal disease.

Scarlet fever, urticaria and erythema multiforme may follow streptococcal impetigo [22].

Rheumatic fever is not a complication of streptococcal impetigo [11,24].

Treatment. In mild and localized infection, a topical antibiotic alone may suffice. Topical mupirocin is an effective antibiotic with a low incidence of adverse effects and, in localized disease, may equal oral erythromycin [25]. Fusidic acid is also effective against both organisms, but in order to reduce the likelihood of the development of resistance because of its value in systemic infection, it may be prudent to restrict its use as first-line topical therapy to the community if suitable alternatives are available. Topical neomycin is effective in staphylococcal infections, but less active against streptococci; bacitracin has activity against both, and the two drugs are often used in combination.

If the infection is widespread or severe, or is accompanied by lymphadenopathy, or if there is reason to suspect a nephritogenic *Streptococcus*, an oral antibiotic such as flucloxacillin or erythromycin is indicated [6]. Local patterns of resistance need to be considered, as resistance of *S. aureus* to penicillin, erythromycin and to tetracycline is now common even in developing countries. The addition of a topical antibiotic or antiseptic is likely to hasten the response and help to limit the spread of infection.

Antiseptics are less effective than appropriate antibiotics but are a useful adjunct to systemic treatment, and are a rational sole therapy for impetigo where antibiotics are unavailable. Either chlorhexidine or povidone–iodine would be suitable.

Removal of infected crusts is bacteriologically and cosmetically helpful. Frequent application of an ointment, preferably containing an antibacterial agent, and washing with soap and water are as effective as messier regimens.

In developing countries where impetigo is endemic among children, measures to reduce the transmission frequency of infections should be adopted. These include installing indoor water supplies, distributing medical resources more efficiently, educating the population on health matters and instituting treatment early in the course of the disease. Emphasis should be placed on the identification of predisposing factors such as insect bites, pediculosis, scabies and minor trauma.

Ecthyma

Definition. Ecthyma is a pyogenic infection of the skin characterized by the formation of adherent crusts, beneath which ulceration occurs.

Aetiology. The bacteriological status of ecthyma is essentially similar to that of impetigo. It was formerly regarded as a streptococcal infection, since many cases yield a pure culture of *Streptococcus pyogenes*. From others both streptococci and staphylococci are isolated, and from some staphylococci only. Group A streptococci were grown from all of 66 cases, and coagulase-positive staphylococci from 85% of these [1]. It may prove to be a synergistic infection. In Europe, most cases occur in children, but in the tropics, where the disease is very much more common, it may occur at any age. Poor hygiene and malnutrition are predisposing factors, and minor injuries or other skin conditions, particularly scabies, may determine the site of the lesions. Several of these predisposing factors, may coexist in drug addicts.

Clinical features. Small bullae or pustules on an erythematous base are soon surmounted by a hard crust of dried exudate (Fig. 27.4), which increases in size by peripheral accretion. The base may become indurated and a red oedematous areola is often present. The crust is removed with difficulty, to reveal a purulent irregular ulcer. Healing occurs after a few weeks, with scarring. The lesions are usually few but new lesions may develop by autoinoculation over a long period. The buttocks, thighs and legs are most commonly affected.

Treatment. Improved hygiene and nutrition, and the treatment of scabies and any other underlying disease, are important. The antibiotic chosen should be active against both *Streptococcus pyogenes* and *Staphylococcus aureus*.

Cellulitis and erysipelas

Definition. Cellulitis is strictly an acute, subacute or chronic inflammation of loose connective tissue, but the term has been applied mainly to inflammation of subcutaneous tissue in which an infective, generally bacterial, cause is proven or assumed. Erysipelas is a bacterial infection of the dermis and upper subcutaneous tissue; its hallmark is a well-defined, raised edge reflecting the more superficial (dermal) involvement. However, cellulitis may extend superficially and erysipelas deeply so that in many cases the two processes coexist and it is impossible to make a meaningful distinction. Current usage tends to regard erysipelas as a form of cellulitis rather than a distinct entity, so that the definition of cellulitis would include inflammation of dermal as well as subcutaneous tissue. The closely similar bacteriology of the two conditions [1,2], and the demonstration of streptococcal antigens in both dermis and subcutis in both conditions [1], support this view. However, the two terms are still sometimes used in the traditional sense, especially when their typical distinctive features are being contrasted. Erysipelas is classically a facial infection, but, as defined above, it is not confined to the face, and the authors do not support the definition [3] of erysipelas as simply cellulitis of the face.

Bacteriology. Bacteria are present in affected tissue in small numbers, and attempts to culture them, from biopsy material, from swabs of biopsy sites, from needle aspiration of saline-injected tissue, and even from fluid from blisters or erosions when present, are often unsuccessful. Blood cultures and swabs from possible entry sites, for example wounds or inflammatory lesions, generally situated distally to the infection, occasionally yield presumably relevant organisms. Cultures of biopsy specimens, needle aspirates and probable sites of entry in 50 patients

with cellulitis gave a positive result in only 26% [4]. Streptococcal serology may be helpful retrospectively [2], and immunofluorescence may identify streptococcal group antigens in biopsy specimens [1].

These studies confirm the traditional view that cellulitis and erysipelas in the immunologically normal patient are predominantly streptococcal diseases, usually involving group A organisms, but they have also demonstrated streptococci of other Lancefield groups, especially G but also C and B, in both conditions. Group B infections are seen especially under the age of 3 months [5,6]. In adults, group B streptococci may cause pelvic erysipelas especially after surgery [7]. In cellulitis (as opposed to erysipelas), *Staphylococcus aureus* is occasionally implicated alone or together with a *Streptococcus*. There is a suspicion [2] that a primary pathogenic role should not be accepted for it in all cases, as in that study all cases treated with benzyl-penicillin improved rapidly even when *Staph. aureus* was detected; however, detailed accounts of bacterial sensitivities and individual responses to treatment were not given. *Staphylococcus aureus* is occasionally isolated from lesions of erysipelas. However, in three cases out of 27 in which it was the sole isolate, there was serological evidence of streptococcal infection [1]; and another two cases responded slowly to penicillinase-sensitive penicillins in keeping with a streptococcal cause [8]. *Staphylococcus aureus* should be regarded as an occasional cause of cellulitis, but rarely if at all of classical erysipelas. *Haemophilus influenzae* type b is an important cause of facial cellulitis in young children, especially up to the age of 2 years [9–11], but rarely causes cellulitis in adults [12].

In cellulitis in a setting of venous or lymphatic compromise, including limbs on which saphenous venectomy has been performed, non-group-A streptococci, especially group G, predominate [13].

Other bacteria. A variety of other bacteria are occasionally implicated in cellulitis and erysipelas, usually in specific situations of exposure or in immunocompromised patients.

Thus, while the bacteriology of periorbital cellulitis is similar to that in other sites, orbital cellulitis that usually results from sinusitis involves the major sinus pathogens, i.e. *Strep. pneumoniae*, other streptococci, *Staph. aureus*, *H. influenzae* and penicillin-sensitive anaerobes [2]. Cellulitis due to *Aeromonas hydrophila* can complicate injuries contaminated by water (usually fresh) or soil [14]. A case of cellulitis due to the marine organism *Vibrio alginolyticus* has been recorded [15]. Cellulitis is part of the spectrum of infection due to *Pasteurella multocida* inoculated by animal bites [16].

Erysipelas-like infections and cellulitis due to *Strep. pneumoniae* [17,18], *Pseudomonas aeruginosa* [19] and *Campylobacter jejuni* [20] have been reported, mostly in the immunocompromised. In such patients, *P. aeruginosa* may cause gangrenous cellulitis and ecthyma gangrenosum [21,22]; and cellulitis may be caused by *Acinetobacter calcoaceticus* [23] and *Staph. epidermidis* [24]. A case of *Bacteroides fragilis* cellulitis responding to metronidazole has been reported [25]. *Yersinia enterocolitica*, an intestinal pathogen, may also cause cellulitis [26].

Clinical features (Fig. 27.5). Erythema, heat, swelling and pain or tenderness are constant features. In erysipelas, the edge of the lesion is well-demarcated and raised, but in cellulitis it is diffuse, although cases showing both types of edge or an intermediate picture are not uncommon. In erysipelas, blistering is common, and there may be superficial haemorrhage into the blisters or in intact skin, especially in elderly people. Severe cellulitis may show bullae and can progress to dermal necrosis (Fig. 27.6), and uncommonly to fasciitis or myositis. Lymphangitis and lymphadenopathy are frequent. Except in mild cases, there is constitutional upset with fever and malaise. Classical erysipelas starts abruptly and systemic symptoms may be acute and severe, but the response to treatment is more rapid.

The leg is the commonest site, and here there is usually a wound, even if superficial, an ulcer or an inflammatory lesion, including interdigital fungal or bacterial infection, which can be identified as a possible portal of entry. The next most frequent site for classical streptococcal erysipelas is the face, where a traumatic entry site is less commonly seen and where bilateral infection occasionally occurs.

Without effective treatment, complications are common —fasciitis, myositis, subcutaneous abscesses, septicaemia and, in some streptococcal cases, nephritis—and the more severe infections may be fatal, especially in infants and in the debilitated or immunosuppressed.

Childhood facial cellulitis due to *H. influenzae* type b is typically unilateral and often associated with ipsilateral otitis media, the presumed source in those cases. The patient presents with systemic illness and the affected cheek or periorbital tissue shows induration and discoloration, occasionally pink, but characteristically purplish blue. A similar violaceous colour may occur in childhood periorbital and buccal pneumococcal cellulitis [27].

Otherwise, periorbital cellulitis follows trauma to the eyelids or local skin sepsis and is usually streptococcal, occasionally staphylococcal. If the infection is behind the orbital septum, in the deeper orbital tissues, the term orbital cellulitis applies, and it is commonly a sequel to sinusitis, although it is to be distinguished from the periorbital oedema which may also accompany sinus infection. In addition to cutaneous signs, proptosis, ophthalmoplegia and loss of visual acuity may occur. Periorbital and orbital cellulitis may be complicated by cavernous sinus thrombosis, orbital, subperiosteal or cerebral abscess formation, or meningitis [11,28].

Fig. 27.5 Cellulitis/erysipelas. (a) Lower leg. (b) Extensor aspect of elbow. (c) Pinna. (d) Face. (Courtesy of Dr A.S. Highet, York District Hospital, York, UK.)

Severe myocardial depression has been reported in a previously healthy young woman with streptococcal cellulitis [29].

Cellulitis of the tongue in neutropenic patients may cause upper airway obstruction [30].

In the immunodeficient, the presentation may be atypical, as in two cases of erysipelas without erythema [31], and previous antibiotic treatment may modify the clinical appearances in the otherwise healthy patient.

Recurrent streptococcal cellulitis (or erysipelas) is attributed to lymphatic damage, which, although sometimes initially clinically inapparent, predisposes to further

(a) (b)

Fig. 27.6 (a) Cellulitis with early dermal necrosis. (b) The same foot after 11 days; the dermis is forming a black eschar, which eventually sloughed off; the resulting ulcer healed rapidly. (Courtesy of York District Hospital, York, UK.)

infection and further lymphatic impairment manifesting as lymphoedema (Fig. 27.7). Venous insufficiency often predisposes to recurrent erysipelas of the leg [32].

Perianal streptococcal infection is discussed in Chapter 68.

Diagnosis. Specimens for bacteriological examination should be taken from vesicle fluid or eroded or ulcerated surfaces, in addition to blood cultures. Exudative, fissured or traumatized sites distal or adjacent to limb infections may yield relevant organisms. Surface swabs from intact skin are unlikely to be helpful, but in the case of facial infections the pathogen should be sought in nose, throat, conjunctiva and sinuses. Aspiration of tissue fluid, alone or following subcutaneous infiltration of saline, occasionally results in a positive culture, but is not routinely recommended. Skin biopsy is often similarly disappointing. Identification of soluble streptococcal antigens is more effective [1]. If either of these invasive techniques is considered, care should be taken not to penetrate the fascia. However, as discussed earlier, even a combination of such techniques commonly fails to yield the pathogen, and the possibility of contamination must be remembered [1,2,4].

Serological studies may provide evidence of streptococcal, and less commonly staphylococcal, infection. An initial high titre may be regarded as suggestive, especially in a patient presenting several days or more after the onset, but paired sera from days 1 and 14 would be more reliable in retrospective diagnosis. Early use of antibiotics may, however, limit the antibody response. The antibodies and their significance are discussed below.

Fig. 27.7 Post-streptococcal lymphoedema of pinna; this patient had frequent recurrences of cellulitis requiring long-term penicillin. (Courtesy of Dr A.S. Highet, York District Hospital, York, UK.)

In differentiating cellulitis of the leg from deep-vein thrombosis, phlebography, plethysmography and Doppler ultrasound examination may be helpful. The protein concentration in 0.3–0.5 mL of oedema fluid aspirated from

swollen subcutaneous tissue provides a rapid and inexpensive alternative; in deep-vein thrombosis the average concentration was 5.5 g/L while in cellulitis it was 19.8 g/L; a level over 10 g/L was found only in cellulitis [33].

Fungi may cause cellulitis in the immunocompromised [34].

A cluster of cases closely resembling cellulitis, but bacteriologically negative and unresponsive to antibiotics, was attributed to insect bites, plant toxins or an unidentified virus [35].

Treatment. A clinical assessment as to the likely pathogen(s), as discussed earlier, should guide the initial choice of treatment. Appropriate antibiotic(s) should be given in full dosage, by the intramuscular or intravenous route in the more severe cases that are associated with septicaemia, arthritis or suspected fasciitis, although oral treatment may suffice for the milder infections. In all cases, initial treatment should cover streptococci and, for facial infections in young children, *H. influenzae*. For presumed streptococcal infections, penicillin is the treatment of choice, given as benzylpenicillin 600–1200 mg i.v. 6-hourly in the more severe cases. Treatment should be continued for at least 10 days. A macrolide antibiotic or clindamycin are alternatives [36]. Anticoagulant therapy should be considered if there is associated thrombophlebitis. A wider range of organisms should be considered in patients with deficient immunity, in the special situations discussed earlier and in those not responding to initial treatment.

In recurrent cases, long-term penicillin, 500–2000 mg daily can prevent attacks. Vigorous treatment of any local skin damage is important to prevent recurrent disease. In patients allergic to penicillin, an alternative drug, such as clindamycin or erythromycin, should be taken. Some patients may require lifelong prophylaxis [37].

Inflammatory diseases of hair follicles

Staphylococcus aureus, coagulase-negative staphylococci and physical or chemical irritation are common causes of superficial folliculitis. The deeper forms of staphylococcal folliculitis, furuncles and carbuncles are discussed separately.

Other microbial causes of folliculitis are considered elsewhere: *Pseudomonas aeruginosa* later in this chapter; Gram-negative folliculitis developing in antibiotic-treated acne in Chapter 43; *Pityrosporum* yeasts in Chapter 31; and dermatophytes in Chapter 31. Patients with human

immunodeficiency virus (HIV) disease may have 'itchy folliculitis' of uncertain cause (Chapter 26).

Pseudofolliculitis due to ingrowing hairs is discussed below and in Chapter 22.

There are, however, a number of inflammatory diseases involving the hair follicle whose aetiology is complex or uncertain; although the role of bacterial infection may be partial, secondary, unknown or absent, these disorders are included in this chapter for convenience: sycosis barbae, folliculitis cheloidalis, acne necrotica, perforating folliculitis, trunk folliculitis, actinic folliculitis, disseminate and recurrent infundibulofolliculitis, eosinophilic pustular folliculitis, suppurative hidradenitis and perifolliculitis capitis. Folliculitis decalvans is considered in Chapter 63.

Superficial folliculitis

Subacute or chronic folliculitis, in which the inflammatory changes are confined to the ostium or extend only slightly below it, and which heals without scar formation, is an extremely common condition, but is usually of such little clinical importance that it has not been thoroughly investigated.

Superficial folliculitis is not always primarily or exclusively infective in origin. Physical or chemical injury to the skin may be associated with a folliculitis, the pustules of which may be sterile or may contain coagulase-negative staphylococci. Occupational contact with mineral oils or therapeutic or occupational exposure to tar products very typically produce such lesions, which in the case of oil folliculitis are associated with conspicuous oil plugging of many follicles. Other chemical irritants can cause folliculitis, which may be the only visible change, or may accompany an eczematous reaction. Beneath adhesive plasters or adhesive dressings, a sterile folliculitis is common. Following epilation, a traumatic folliculitis may develop [1].

Occasional isolated lesions are also frequent on the neck and beard, and heal so rapidly, that they are commonly ignored. Also frequent, but more persistent, are papules or pustules on the thighs and buttocks of adolescent and young adult males, and occasionally females, especially those with acne. They are usually too few and small to have attracted the patient's attention. On culture, the pustules may be sterile, but coagulase-negative staphylococci are sometimes isolated. Clinically, the lesions present as small, follicular papules or pinhead pustules. They are rarely painful. Sometimes, small crusts cover a red, pouting, follicular orifice.

Staphylococcus aureus superficial folliculitis (follicular impetigo of Bockhart) is an infection of the follicular ostium with *S. aureus*. Use of topical steroids, especially of the stronger grades, is a predisposing factor. Otherwise, it is commonest in childhood, and occurs mainly in the scalp or scalp margins or on the limbs. The individual lesion is a domed, yellow pustule, sometimes with a narrow, red areola. The pustules develop in crops and may heal within 7–10 days, but sometimes become chronic. In older children and adults, the infection may extend more deeply in some follicles as furuncles or as sycosis. In some cases, recurrent or chronic staphylococcal folliculitis may merge imperceptibly with folliculitis decalvans and related processes (Chapter 63). However, acute staphylococcal folliculitis is common and the many clinical variants of cicatrizing folliculitis are rare.

Chronic folliculitis of the legs [2,3] has been described mainly in young adult males in India. The profuse eruption of superficial and deep follicular pustules on the thighs and lower legs persisted for many years and was resistant to treatment. *Staphylococcus aureus* was regularly isolated. No systemic abnormality could be detected other than hypergammaglobulinaemia. The pustular dermatitis atrophicans of the legs [4], described as accounting for 0.5% of skin disease in Lagos in West Africa, appears to be a similar condition. It occurs predominantly in males and affects symmetrically the anterior tibial surfaces of the legs, sometimes involving thighs and forearms. Miliary pustules are followed by atrophic scars.

Diagnosis. Follicular pustules are readily confused by the inexperienced with the non-follicular lesions of pustular miliaria, which should be considered when a widespread papulopustular eruption develops in hot and humid conditions, on previously normal skin, or studding an existing inflammatory dermatitis. Follicular pustules are also a feature of subcorneal pustular dermatosis, in which they are grouped around the margins of plaques of erythema and scaling (Chapter 41).

Follicular pustules may occur in ringworm. The more-or-less simultaneous development of pustules on a circumscribed, red and oedematous or scaling plaque should arouse suspicion.

Treatment. Superficial folliculitis of external chemical or physical origin will settle if the irritant is removed.

Mild staphylococcal folliculitis is often self-limiting, or may respond to cleansing or topical antiseptics. In more severe cases, antibiotics, topical or systemic, may be required. If the infection is persistent or recurrent, the usual sites of staphylococcal carriage should be sought in the patient and his or her contacts.

Daily application of 6.25% aluminium chloride hexahydrate in completely anhydrous ethyl alcohol was reported to be very effective treatment for chronic folliculitis of unspecified type, except for scalp lesions [5].

Pseudofolliculitis

SYN. PILI INCARNATI

Aetiology [1]. Inflammation results from penetration into the skin of sharp tips of shaved hairs. If shaven too long, or if it escapes shaving for a few days, the hair may curve backwards after emerging from the follicle to penetrate the adjacent skin [2]; conversely, if cut very short so that it retracts into the follicle, it may directly penetrate the follicle wall [3].

Curly hair is more liable to both of these aberrations so that the condition is very common and more severe in black people [2]. Skin folds or irregularities due to scarring may allow ingrowth of straight hairs. Any shaved surface in either sex [4], may be affected, but the male beard area is naturally the most common. Plucking may cause pseudofolliculitis [5,6]. There is evidence of genetic predisposition [7].

Coagulase-negative staphylococci may sometimes be grown from the lesions but the condition is not primarily infective.

Clinical features (Fig. 27.8). The patient complains of minor discomfort and cosmetic embarrassment from papules and pustules on shaven skin. In the beard area, the skin of the neck and over the jaw is most commonly affected, although in black people lesions on the cheeks are also frequent. The papules may be large in black individuals: scarring, keloid formation and hyperpigmentation may ensue. It is generally possible to identify some penetrating hairs but they may not be visible in all cases.

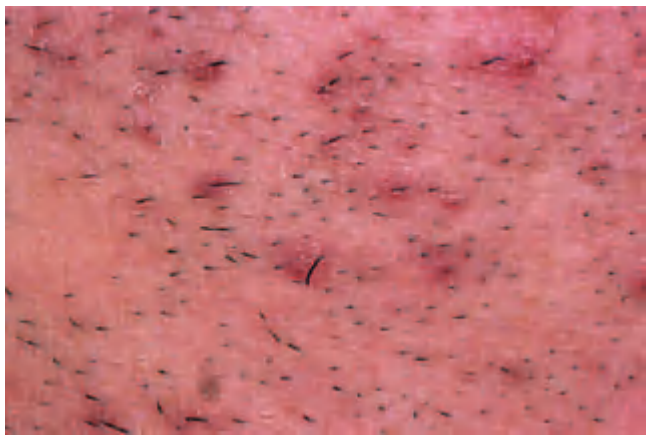

Fig. 27.8 Pseudofolliculitis.

Pseudofolliculitis of the scalp was reported in four brothers who were black and whose father had shaved their scalps [8]. Cut nasal hairs may ingrow similarly [9].

Treatment [1,10]. The only certain cure is to stop shaving for a minimum of 4–6 weeks, but resumption of shaving will lead to relapse. Lifting out of re-entrant hairs with a needle is helpful but tedious: brushing with an abrasive sponge or toothbrush is less effective but quicker. Hair should be left about 1 mm long. This may be achieved by adjustment of individual shaving technique, or by specially designed razors [11] or electric clippers. Plucking should be avoided. Some relief is possible with topical steroid–antimicrobial combinations combined with intensive use of emollients.

Furuncle

SYN. BOIL

Definition. A furuncle is an acute, usually necrotic, infection of a hair follicle with *Staphylococcus aureus*.

Aetiology. Furuncles are relatively uncommon in early childhood in temperate climates except in atopic subjects, but increase rapidly in frequency with the approach of puberty, and in adolescence and early adult life are a common disability [1]. In adolescence, boys are affected more than girls and the peak incidence parallels that of acne vulgaris. In the UK, furunculosis occurs mostly during the early winter months [2]. As with other superficial staphylococcal infections, the factors responsible for the outbreak and its persistence are unknown. There is seldom any evidence of impairment of the immune response. Reports on the possibility of impairment of neutrophil function are conflicting [3,4]. The infecting strain

of *Staphylococcus* is usually also present in the nares or the perineum [5], which may imply that the repeated and heavy inoculation that occurs in the chronic carrier may be a necessary condition for the development of furunculosis. The surface defence mechanism, and hence the normal balance of microflora, may be disturbed in favour of the staphylococci, which may be carried for some months in the neighbourhood of recently healed lesions. From the sites of carriage, the infection is disseminated by the fingers and by clothing. Mechanical damage to the skin, even the friction of collars and belts, may determine the distribution of the lesions. Malnutrition is an important predisposing factor in some countries. Diabetes is widely believed to predispose to furunculosis, although the published evidence does not uniformly confirm this [6]. Furunculosis is common in patients infected with HIV (Chapter 26). Hyper-IgE syndrome is also a predisposing factor [7]. However, in a high proportion of cases in healthy young adults, no convincing predisposing factor can be incriminated.

Epidemics of furunculosis attributable to specific strains of staphylococci have occurred, and in such cases the attacks are often severe but short, and obvious predisposing factors are usually absent. From the very common, milder, persistent and recurrent cases a wide variety of strains common to many types of staphylococcal infection may be grown, and predisposing factors must be assumed to be of relatively greater significance, although their nature is often difficult to establish. The observation of families over a period of years showed that the same phage type may be responsible for irregular episodes of infection between long intervals of clinical quiescence [1].

Pathology. A furuncle is an abscess of a hair follicle, usually of vellus type. The perifollicular abscess is followed by necrosis with destruction of the follicle.

Clinical features. A furuncle first presents as a small, follicular, inflammatory nodule, soon becoming pustular and then necrotic, and healing after discharge of a necrotic core to leave a violaceous macule and, ultimately, a permanent scar. The rate of development varies greatly, and necrosis may occur within 2 days or only after 2 or 3 weeks. Tenderness is invariable, and in the more acute and larger lesions there may be throbbing pain. Lesions in the nose or external ear canal can cause very severe pain. The lesions may be single or multiple, and tend to appear in crops. Occasionally, there may be fever and mild constitutional symptoms. Pyaemia and septicaemia are favoured by malnutrition. On the upper lip and cheek, cavernous sinus thrombosis is a rare and dangerous complication.

The sites commonly involved are the face and neck, the arms, wrists and fingers, the buttocks and the anogenital region.

Attacks may consist of a single crop, or of multiple crops, at irregular intervals with or without periods of freedom. The prognosis cannot be reliably determined during a first attack. In some individuals, crops continue to develop for many months, or even years.

In HIV disease, furuncles may coalesce into violaceous plaques [8] (Chapter 26).

Diagnosis. Other pustular lesions must be differentiated. Furuncles are deep-seated nodules, in contrast to the lesions of superficial staphylococcal folliculitis. The vesicopustules of disseminated herpes simplex are umbilicated and appear simultaneously in large numbers on sites of active or healed eczema (Chapter 18).

The pustules of acne are but one type of lesion in a polymorphic syndrome. They are associated with papules and comedones, and are usually confined to the face and trunk. Pustules can also occur in halogen eruptions (Chapter 73), usually symmetrical and of rapid onset. Nodules and abscesses occur mainly in the axillae and perineum in hidradenitis. Single or few, large, suppurating nodules on exposed skin raise the possibility of myiasis.

Prognosis. The course of the untreated disease is infinitely variable [1] and the prognosis cannot be reliably determined during a first episode. Some patients suffer only one attack while others continue to develop recurrences over months or years, with or without periods of freedom.

Treatment. Each episode may need to be treated systemically with flucloxacillin or another penicillinase-resistant antibiotic. A topical antibacterial agent reduces contamination of the surrounding skin. Occlusive dressings should be avoided.

In recurrent disease [9], further lesions develop after the end of each course of antibiotic. It may be prudent in these cases to exclude diabetes and other possible underlying conditions. Nasal and perineal carriage of *S. aureus* in the patient and other household members should be sought; the management of carriers is discussed earlier in this chapter. Low-dose clindamycin may be helpful [10].

Carbuncle

Nomenclature. In French, Spanish and some other Latin languages, 'anthrax' is the term commonly applied to a carbuncle, whilst 'charbon' (French), or a similar related word, describes infection with *Bacillus anthracis*.

Aetiology. A carbuncle is a deep infection of a group of contiguous follicles with *Staphylococcus aureus*, accompanied by intense inflammatory changes in the surrounding and underlying connective tissues, including the subcutaneous fat. Carbuncles occur predominantly in men, and usually in middle or old age. They may be seen in the apparently healthy but are more common in the presence of diabetes, malnutrition, cardiac failure, drug addiction or severe generalized dermatoses, such as exfoliative dermatitis or pemphigus, and during prolonged steroid therapy.

Clinical features. The term carbuncle is derived from the Latin word for a small, fiery coal, and describes the painful, hard, red lump that is the initial stage of the infection. It is at first smooth, dome-shaped and acutely tender. It increases in size for a few days, to reach a diameter of 3–10 cm or occasionally more. Suppuration begins after some 5–7 days, and pus is discharged from the multiple follicular orifices. Necrosis of the intervening skin leaves a yellow slough surmounting a crateriform nodule. In some cases, the necrosis develops more acutely without a preliminary follicular discharge, and the entire central core of the lesion is shed, to leave a deep ulcer with a purulent floor.

Most lesions are on the back of the neck, the shoulders or the hips and thighs and, although usually solitary, they may be multiple or associated with one or more furuncles.

Constitutional symptoms may accompany, or even precede by some hours, the development of the carbuncle. Fever may be high, and malaise and prostration may be extreme if the carbuncle is large or the patient's general condition poor.

In favourable cases, healing slowly takes place to leave a scar. In the frail and ill, death may occur from toxaemia or from metastatic infection.

Diagnosis. Anthrax presents the only important problem. In the typical case, the haemorrhagic crust and the vesicular margin are quite unlike a carbuncle, but sometimes certain clinical differentiation is difficult. A swab must be taken, but treatment should not be postponed until bacteriological confirmation is available.

Treatment. Flucloxacillin or another penicillinase-resistant antibiotic should be given. Diabetes and other possible underlying conditions should be sought.

Sycosis

Definition and nomenclature. Sycosis is a subacute or chronic pyogenic infection involving the whole depth of the follicle. If the follicles are destroyed with clinically evident scarring, the term lupoid sycosis, or its cumbersome synonym ulerythema sycosiforme, is applied. Folliculitis decalvans (Chapter 63) is essentially the same process involving the scalp. Many sites may be involved in the same individual.

Aetiology. Sycosis occurs only in males after puberty, and commonly involves the follicles of the beard. Most cases begin in the third or fourth decade, but we have seen a severe infection in a boy aged 14 years. The infecting organism is *Staphylococcus aureus*, the same phage type of which can often be isolated from the nose [1], but unknown constitutional factors must be accorded the major role in determining susceptibility, for the staphylococci do not normally penetrate more deeply than the follicular ostia. Many patients are seborrhoeic, with a greasy complexion and chronic blepharitis. Clerical and other indoor workers are affected more often than those who work in the open air.

Pathology. The affected follicle is packed with polymorphonuclear leukocytes, which infiltrate its wall. Around the follicle there is a chronic granulomatous infiltrate in which lymphocytes, plasma cells, histiocytes and foreign-body giant cells are conspicuous. The sebaceous gland, or the whole follicle, may be destroyed and replaced by scar tissue.

Clinical features [2]. The essential lesion is an oedematous, red, follicular papule or pustule centred on a hair. The individual papules remain discrete, but if neighbouring follicles are involved the perifollicular oedema may coalesce, to produce the raised plaques studded with pustules, which suggested the appearance of a ripe fig to the ancient author who coined the term sycosis. In the common subacute forms, the lesions may be scattered irregularly over the beard, or grouped especially on the upper lip and below the angles of the jaw. Attacks of varying duration occur at irregular intervals over months or years. In more chronic forms, the lesions are typically clustered into plaques, especially on the upper lip and

chin, and may persist for very long periods—nearly 20 years in one case [3]. There is often some crusting and scaling, but the hairs are retained and there is no evident scarring.

In lupoid sycosis, the follicles are destroyed by scarring, and active papules and pustules fringe the advancing margin around a pink atrophic scar. Granulomatous inflammatory changes may give the papules a lupoid appearance. The process usually begins in front of one ear or under the chin and extends irregularly in any direction. The scalp may be extensively involved. Rarely, a similar process affects axillary and pubic hair, or the lower legs, thighs and arms. Lupoid sycosis tends to persist indefinitely, although the rate of extension may vary from time to time.

Diagnosis. The most frequent misdiagnosis is certainly the pseudofolliculitis caused by ingrowing hairs. The papules and pustules are irregularly scattered over the sides of the neck and the angles of the jaw and are not grouped but may lie in skinfolds.

Mycotic sycosis, a kerion of the beard (Chapter 31), usually occurs on the chin or cheeks. The oedematous plaque of grouped pustules of acute onset is easily recognized. The diagnosis is suggested by the patient's contact with cattle, and confirmed by mycological examination.

Lupoid sycosis rarely simulates lupus vulgaris. The presence of pustules establishes the diagnosis. Biopsy can be undertaken if doubt remains. The scarring of lupoid sycosis may have medicolegal implications if the patient falsely attributes it to the use of radiotherapy during its early stages.

Treatment. The subacute forms are relatively easily controlled by antibiotic ointments, but tend to relapse when the application is stopped. If a nasal swab indicates a chronic carrier state, the antibiotic should also be applied to the nasal vestibules.

The chronic forms respond less readily to antibiotics, although the response may sometimes be enhanced by using a steroid–antibiotic combination. The application must often be continued indefinitely and potential sensitizers, such as neomycin, should therefore be avoided. In resistant cases a 10- to 14-day course of a systemic antibiotic deserves a trial. Any chronic nasopharyngeal sepsis should be treated.

Folliculitis keloidalis

SYN. ACNE KELOID

Aetiology. Folliculitis keloidalis is a chronic inflammatory process involving the hair follicles of the nape of the neck and leading to hypertrophic scarring in papules and plaques. It occurs only in males after puberty and is most frequent between the ages of 14 and 25 years, especially in black males. Many patients have, or have had, significant acne, and a patient with previous hidradenitis has been reported [1]. No specific organism can be isolated, although *Staphylococcus aureus* is often isolated [2]. Although friction from the collar is often incriminated, the evidence is unconvincing [2]. The location on skin which is often closely shaven, and the observation of foreign-body granulomas surrounding fragments of hair, has led to the suggestion that the process begins with penetration of cut hair into the skin, as in pseudofolliculitis [3]. However, Brauner of the US Army [4] had no experience of the condition despite the persistence of close-shaven hairstyles among soldiers, and he pointed out that the ingrowing of hair could well be secondary to the scarring. Whether the initial event is pseudofolliculitis, bacterial folliculitis or some other process, there is significant individual predisposition especially as regards the severity of the scarring process.

Associated keloids in other sites seem not to have been reported, and the process is regarded as hypertrophic scarring rather than true keloid [1].

Pathology. The most frequent histological finding is dense hypertrophic scar tissue and a patchy perivascular infiltrate of plasma cells, which can simulate syphilis. Serial sections may reveal evidence of folliculitis or a foreign-body reaction to hair and follicular remnants.

Clinical features. Follicular papules or pustules, often in irregularly linear groups, develop on the nape of the neck just below the hair line. Less often, they extend upwards into the scalp. The early inflammatory stage may be inconspicuous, and the patient may first be aware of the hard, keloidal papules that follow the folliculitis. The papules may remain discrete, or may fuse into horizontal bands or irregular plaques. In other cases, the inflammatory changes are persistent and troublesome, with undermined abscesses and discharging sinuses.

The condition is extremely chronic and new lesions may continue to form at intervals for years.

Treatment. Bacterial infection should be treated if present, and antiseptics may help to reduce further or secondary infection. Avoidance of closely shaven hair on the back of the scalp may be advised. Intralesional steroids may reduce scarring and inflammation. Oral steroids prescribed for another condition helped, but long-term treatment is

unlikely to be justified [1]. In general, medical treatment is disappointing, and in troublesome cases the affected area may be excised and grafted, excised and allowed to heal by secondary intention, or treated with a carbon dioxide laser [5] and again allowed to heal by secondary intention. Surgery followed by radiotherapy has also been advocated previously.

Acne necrotica (varioliformis)

Nomenclature. There are few clinical syndromes with a more confused nomenclature. The term acne necrotica has included a chronic follicular necrotizing process, which evolves into small, round scars, affecting mainly areas close to scalp margins (acne necrotica varioliformis); this is the entity discussed here. Also included has been a milder disease occurring throughout the scalp without significant scarring (acne necrotica miliaris). The relationship between the two is still uncertain, but we regard the latter as possibly synonymous with *Propionibacterium acnes* folliculitis of the scalp [1,2], which is considered below.

Aetiology. Acne necrotica varioliformis is much less common than acne necrotica miliaris. It occurs slightly more frequently in men than in women, and is usually seen between the ages of 30 and 50 years, but never before puberty.

The lesion is essentially a folliculitis, but the cause is uncertain. The most widely suggested pathogens have been *Staphylococcus aureus* and *P. acnes*, but neither is universally accepted, and whichever (if any) microorganism(s) may be involved, it is the follicular and perifollicular necrosis, presumably mediated by host response mechanisms, which characterizes the condition.

Staphylococcus aureus is often isolated from surface swabs, but the lesions are very frequently crusted or excoriated, so that the *Staphylococcus* may be a surface contaminant or secondary pathogen, and this finding may not reflect a primary pathogenetic role [3]; in addition, treatment appropriate for staphylococcal infection is usually disappointing.

Emotional disturbance has been a frequent finding in some studies [3,4]; it has been suggested that repeated excoriation of lesions of a primary folliculitis leads to more destructive changes [3]. Histologically, however, acne necrotica varioliformis can be distinguished from excoriations as well as from pyogenic infections [5].

A response to tetracyclines is in keeping with a primary role for *P. acnes* [5,6], as in acne necrotica miliaris, but the greater severity of the varioliformis type suggests a qualitative difference in host response.

Pathology [5]. Early lesions show a lymphocytic folliculitis with extensive individual cell necrosis of keratinocytes in the external root sheath and the surrounding epidermis, and marked subepidermal oedema. Later, the follicle and adjacent epidermis and dermis show confluent necrosis.

Clinical features. The typical lesion of acne necrotica is a red papule 2–5 mm in diameter, often umbilicated and rapidly transformed by necrosis into an adherent haemorrhagic crust, which separates after 3 or 4 weeks to leave a permanent scar, which may be varioliform. Some burning or pruritus may precede or accompany the development of new lesions, but subjective symptoms are seldom severe. The lesions are usually few in number at any one time, but exceptionally may develop in large crops. The most frequent sites are the temples and the anterior margin of the scalp. In some patients, the greater part of the hair line may be involved, but lesions more than a centimetre or two within the scalp are unusual. Much less commonly affected are the midline chest and back, and the cheeks and nose. On the nose, the lesions may be exceptionally large and destructive. In many patients they remain confined to the same region in successive attacks, for example, the temples. In some patients in whom two or three lesions develop at long intervals, acne necrotica is of little significance, but in others in whom recurrences are frequent and the lesions more numerous they may ultimately produce disfiguring scarring.

Diagnosis. Both the distribution and the relatively short course, rarely exceeding 6 weeks, of the individual lesions should differentiate the papulonecrotic tuberculides (Chapter 28). In tertiary syphilis, the lesions are larger, grouped and asymmetrical, and not pruritic. In acne necrotica miliaris (described as *P. acnes* folliculitis below) the lesions are typically distributed throughout the scalp, and are smaller, usually more numerous, non-scarring and more itchy.

Treatment. If *S. aureus* is isolated, a course of an appropriate antibiotic should be given, and an antiseptic shampoo may be advised. Otherwise, and if there is no response or only transient improvement, prolonged courses of an oral antibiotic as for acne, for example a tetracycline, should be given. Topical clindamycin in addition has been

recommended [3]. Excoriation should be discouraged, and any significant emotional disorder managed appropriately. Doxepin has been suggested for both its psychotropic and antipruritic effects [3]. Isotretinoin has been successful in some difficult cases [7].

Perforating folliculitis

This largely asymptomatic eruption of chronic follicular papules occurs mainly on the limbs of young adults. Histologically, the follicles are dilated and plugged with keratin. The follicular epithelium shows one or more perforations into the dermis. Hair is frequently seen close to the epithelial perforations and sometimes within the dermis, as if the inflammatory changes were a reaction to mechanical damage by the hair. Of 25 patients in the original report [1], one was diabetic, but none of the others had systemic disease.

A similar process, less regularly involving hair follicles, and with frequently superimposed nodular prurigo, is associated with renal disease and diabetes (separately or together) [2–4]. Recent studies have included such cases under the more general title of acquired perforating dermatosis [5,6].

Trunk folliculitis

The authors have seen several cases of a papular and pustular folliculitic eruption on the trunk of young and middle-aged adults. Lesions number a few dozen, widely scattered over the upper trunk unlike *Malassezia* folliculitis, and miconazole–hydrocortisone cream is ineffective. Routine bacteriology is negative, and comedones and facial acne are absent. There is no improvement on tetracyclines, erythromycin or trimethoprim–sulfamethoxazole in short or long courses. The response to UVB therapy is good, but the condition tends to relapse within a month of stopping and repeated courses or maintenance treatment are required.

Actinic folliculitis

Actinic folliculitis has been described in young to middle-aged adults of both sexes, and occurs repeatedly within 24 h of sun exposure. One description is of numerous superficial follicular pustules on the upper trunk and upper outer arms, with a burning sensation at the onset, resolving within 10 days [1,2]. Another report describes itchy pustules and papules on the lower face resolving within 4 days [3]. The mechanism is unknown. Sunscreens give partial protection at best. Standard acne therapy is ineffective, but the two facial cases responded to isotretinoin [3].

Disseminate and recurrent infundibulofolliculitis

This uncommon condition affects mainly black people [1], but has been reported in white people [2,3]. Beginning in childhood or in adult life, there is a widespread eruption of follicular papules on the trunk and limbs sparing the flexures (Fig. 27.9). Itch is often but not always present. Occasionally pustules develop. The course is chronic or recurrent. No infective agent has been isolated. Histologically, inflammatory changes are confined to the infundibular portion of the follicles. Apart from oral vitamin A, which seemed beneficial in some cases [3], no effective treatment has been reported.

Eosinophilic pustular folliculitis

SYN. OFUJI'S DISEASE

Aetiology [1,2]. Eosinophilic pustular folliculitis has been reported mostly from Japan. Small numbers of cases in Europe and the USA have included patients of oriental extraction, but also some white people. The male/female ratio is about 5 : 1. The peak age incidence is the third decade, but cases have occurred in all age groups.

The pustules are sterile and the cause is unknown. An association with past or present acne has been noted, and the affected areas are usually those with high sebaceous activity. Eosinophil chemotactic factors have been detected in skin of normal subjects and it has been suggested that they may serve to localize excessive circulating eosinophils [3]. An abnormal response to saprophytic organisms has been suggested, but there is little supporting evidence.

Pathology. The follicle, heavily infiltrated with eosinophils, is necrotic with degeneration of the outer root sheath. The blood eosinophil count is raised.

Clinical features. The face is the commonest site, and is the site of onset in most cases. The trunk and the upper outer arms are frequently involved, legs and scalp occasionally. Widespread involvement has occurred [4]. In about 20%, there are pustules of palms or soles, simulating palmoplantar pustulosis.

Groups of papulopustules extend peripherally with central clearing, sometimes forming by confluence annular lesions or plaques, typically 3–5 cm in diameter, before subsiding to leave slight pigmentation. Lakes of pus and erosions are sometimes seen. Itch is frequent but not invariable. Patients are systemically well. The overall course is chronic, with new crops of lesions repeatedly reappearing in affected areas, although a few cases have entered spontaneous remission.

One otherwise well patient developed pyoderma gangrenosum with a fatal outcome [5].

Cases of eosinophilic pustular folliculitis have been reported in patients with AIDS [6] (Chapter 26).

Treatment. No treatment has been consistently effective. Systemic corticosteroids are usually but not always helpful, and topical steroids are sometimes partially effective. Dapsone works well in some cases and may be the drug of first choice [2,7,8]. Other reported therapies include non-steroidal anti-inflammatory drugs, for example indometacin [9], minocycline and colchicine [1]. UVB therapy was helpful in six AIDS-associated cases [10]; maintenance treatment was required.

Eosinophilic pustulosis

Eosinophilic pustular folliculitis of the scalp was first reported by Lucky *et al*. [1]. The lesions that develop in infancy or childhood are characterized by recurrent crops of itchy, sterile pustules, which recur over several months or years. The sterile pustules develop on the scalp predominantly, but lesions may occur at other sites. Children may develop axillary, inguinal or cervical lymphadenopathy [2].

Histologically, the lesions demonstrate a heavy eosinophilic infiltrate in the dermis. Bacteriology is usually negative. The condition is self-limiting, but as recurrent lesions are common, dapsone may be helpful.

Fig. 27.10 Perifolliculitis capitis. (Courtesy of St John's Institute of Dermatology, London, UK.)

Perifolliculitis capitis (abscedens et suffodiens)

SYN. DISSECTING CELLULITIS OF THE SCALP

Definition. Perifolliculitis capitis is a rare, chronic, suppurative disease of the scalp.

Aetiology. It occurs predominantly between the ages of 18 and 40 and almost exclusively in men, and is more common in black than white men. It usually occurs alone, although often in acne subjects, but is occasionally associated with acne conglobata and suppurative hidradenitis, leading to suggestions that these three conditions may have a similar basic pathogenesis in follicular occlusion. It has been regarded as infective in origin, but the evidence is inconclusive, and the response to antibiotics is usually disappointing. The suggestion that it is a granulomatous response to keratin requires confirmation: keratin may be found in the dermis as a result of destruction of the follicle by other mechanisms.

Pathology [1,2]. An intense folliculitis and perifolliculitis destroys the follicles, and a chronic inflammatory infiltrate with clumps of foreign-body giant cells extends widely in the dermis. In some areas, the inflammatory changes are more acute and polymorphonuclear leukocytes predominate. The epidermis is atrophic.

Clinical features [1,3] (Fig. 27.10). The earliest lesions are firm, tender nodules, usually developing in close groups at short intervals. The hairs overlying the nodules are soon shed or are easily extracted and the follicular openings discharge pus. Nodules may coalesce to form roughly cerebriform ridges, devoid of hair on their summits, but still hairy in the clefts that separate them. Eventually, the nodules may cover the greater part of the scalp and may persist for years, before eventually healing to leave irregular scarring, which may be keloidal. Fatal squamous carcinoma has been reported [4].

Diagnosis. The diagnosis is not usually difficult. Very extensive infection with ringworm of animal origin may produce a massive kerion of the scalp, but the short history and the morphology of the lesions should suggest the diagnosis, which must be confirmed mycologically.

Treatment. Bacterial pathogens should be sought and treated, but cultures are often negative and antibiotics often disappointing, including long-term regimens as in acne. Anecdotal reports of substantial but temporary improvement has been reported with isotretinoin. One patient improved on 1.0 mg reducing to 0.5 mg/kg/day for 16 weeks, with partial regrowth of hair, but relapsed if the dose was reduced further [5]. Another healed completely with full regrowth after a course of 0.5 mg/kg/day but relapsed 3 months after stopping treatment; a further successful 12-week course of 1 mg/kg/day did not delay the second relapse [6].

Zinc sulphate 400 mg three times a day for 12 weeks, followed by half that dose for 10 weeks, resulted in complete healing with satisfactory hair regrowth in one patient with no relapse within 5 years [7]. Combined therapy with fusidic acid (both topical and systemic), and oral zinc also proved helpful especially when zinc was continued over 6 months [8].

Oral prednisolone 60 mg daily, initially in combination with antibiotics, produced rapid improvement in one woman. The dose was gradually reduced to a maintenance level of 5 mg on alternate days and healing was complete with full regrowth of hair [9].

The carbon dioxide laser has been reported to be successful [10]. In recalcitrant cases, widespread excision and grafting may be considered [11,12]. There are no comparative trials of any of these treatments.

Toxin-mediated staphylococcal disease

Staphylococcal scalded skin syndrome

Definition. SSSS is an exfoliative dermatosis in which most of the body surface becomes erythematous and the necrotic superficial epidermis strips off. The syndrome was first described in children, but adults may be affected. Factors such as renal failure, malignancy, immunosuppression or alcohol abuse predispose adults to the disease [1]. Outbreaks of SSSS in nurseries have been reported [2].

Aetiology. The epidermal changes are produced by the exfoliative (or epidermolytic) toxins of the staphylococci. The majority of strains responsible are phage group II, but other phage groups have been described [3]. A mouse model of the disease confirms that the disease is caused by the exfoliative toxins [4]. In adults, blood cultures are often positive for the staphylococci, whereas this is rarely the case in children.

Clinical features [1]. The initial event is usually a localized staphylococcal infection. This may be in the skin or at a distant or 'occult' site. A few days later, patients develop fever, irritability and skin tenderness. A widespread erythematous eruption follows, which progresses rapidly to blister formation. The tender skin becomes gathered into folds and, as it shrinks, leaves raw areas which are extremely painful. The condition usually heals within 7–14 days. Swabs and cultures of blister fluids do not usually grow the staphylococci, as the blisters are toxin mediated. The toxins are disseminated haematogenously. The staphylococci may be isolated from the original septic site.

Pathology. Histologically, there is splitting of the epidermis between the granular and spinous layers. A few lymphocytes surround the superficial blood vessels. The disease is caused by one or more epidermolytic toxins elaborated by some strains of *Staphylococcus aureus*. Two of the toxins (A and B) have been shown, by immunofluorescence, to bind to keratohyalin granules [5]. Immunological methods to detect and identify the causative toxins have been described [6].

The same toxins are involved in bullous impetigo, which may be regarded as a localized form of SSSS. Toxin A is chromosomally encoded whereas toxin B is plasmid derived [7]. There is some evidence that the toxins are proteases [8].

Management. The prognosis is good in children and, if antibiotics are administered early, the mortality rate is low. Children usually recover within 7 days. In adults, the overall mortality rate seems to be higher. Those patients without underlying disease recover more rapidly. Parenteral antibiotics such as methicillin, flucloxacillin, a cephosporin or erythromycin are required.

'Scalded skin syndrome' has been used as a synonym for toxic epidermal necrolysis (TEN). However, it is now clear that cell necrosis does not occur in the staphylococcal disease, and it is widely accepted that the term 'staphylococcal TEN' is inappropriate. Where there is doubt about the diagnosis, a frozen section of peeled skin will confirm the split in the granular layer in SSSS. Alternatively, a Tzanck preparation from a freshly denuded area may be helpful. In SSSS, there are a number of epithelial cells with large nuclei but no inflammatory cells, whereas in TEN there are only a few rounded epithelial cells but many inflammatory cells.

Toxic shock syndrome

Definition. Fever, a rash followed in 1–3 weeks by desquamation, circulatory shock and multisystem disease characterize this syndrome, which is mediated by one or more toxins elaborated by *Staphylococcus aureus*.

Aetiology. Nearly all cases have been infected or colonized by *S. aureus*. Staphylococcal infection of any severity, at any site, at any age and in either sex may cause toxic shock syndrome [1]. However, in most of the early cases the organism was isolated from the vagina of menstruating women using tampons in the USA; in these cases, symptomatic vaginitis was common but not invariable. It seemed likely that staphylococci, perhaps introduced by hand or from perineal skin, found appropriate conditions for growth in the medium of the menstrual blood, facilitated in some way by superabsorbent tampons. Avoidance of these tampons was followed by a dramatic fall in the incidence, so that after 1985 the majority of US cases were non-menstrual [2].

TSST-1, previously identified as staphylococcal enterotoxin F or as pyrogenic exotoxin C [3], is produced by 80–90% of *S. aureus* isolates from affected cases, and is believed to be the main bacterial mediator of the disease. Other toxins, including staphylococcal enterotoxins A–D and H have also been implicated in the pathogenesis of some cases [4].

A similar disease has been associated with severe infections with *Streptococcus pyogenes* [5], and may be mediated by re-emergent scarlet fever toxin A [6].

Clinical features [7–9]. The onset is acute with fever and rash. Vomiting and diarrhoea are common early features, and involvement of muscle, liver, kidneys and central nervous system may follow. Circulatory shock may be severe and the mortality rate is about 7%.

The rash may be the presenting feature or may develop within the first day. A widespread macular erythema, sometimes faint, and clearing within 3 days, is commonest, but scarlatiniform and papulopustular eruptions are also described. Oedema of hands and feet may be marked. There is generalized mucous membrane erythema, especially intense in the conjunctiva, under which there may be haemorrhage. Oral, oesophageal, vaginal and bladder mucosae may ulcerate. Occasionally, vesicles and bullae may form. Towards the end of the second week, the majority of patients develop a widespread, itchy, maculopapular, sometimes urticarial, rash, which is thought not to be drug induced in most cases. Thrombocytopenia may cause purpura. Desquamation is highly characteristic. It occurs 10–21 days after the onset, and may be confined to the fingertips, may affect all the palmar and plantar skin or may be generalized. Reversible patchy alopecia or telogen effluvium, and transverse ridging and partial loss of nails are later non-specific findings.

Pathology. There are no specific histological features. A perivascular mononuclear cell infiltrate and papillary oedema may occur in the dermis. In cases with blister formation the split is subepidermal [8].

Diagnosis. The diagnosis is primarily clinical, supported by the confirmation, in the great majority of cases, of staphylococcal infection. Fever, rash and later desquamation, are required for the diagnosis; shock is a marked feature in the fully developed disease, but postural dizziness may suffice for the diagnosis in mild cases.

Septic shock and other infections should be excluded by appropriate investigations. Some reported adult cases of Kawasaki disease may have had toxic shock syndrome. The diseases have features in common, but Kawasaki disease can usually be differentiated by prolonged fever, cardiac involvement, generalized lymphadenopathy and absence of peripheral shock. Reports of staphylococcal scarlatina may represent milder cases of toxic shock syndrome. Ehrlichosis may present with a life-threatening illness similar to toxic shock syndrome [10]. *Clostridium sordellii* infection may be associated with toxic shock syndrome and a high mortality rate. The disease resembles the staphylococcal syndrome except that there is no associated rash; it may follow postpartum infections [11].

Treatment [2]. Appropriate systemic antibiotic therapy should be given. Intensive general supportive measures are essential.

Recalcitrant, erythematous, desquamating (RED) disorder

Definition [1]. Primarily associated with AIDS, this disorder shows some similarity with toxic shock syndrome. Fever, hypotension and a macular eruption characterize the disorder.

Aetiology. *Staphylococcus aureus* has been isolated from most patients with RED disorder. The staphylococci often produce TSST-1. Group A streptococci have also been cultured.

Clinical features [1,2]. RED disorder has a rather prolonged course with a mean duration of 50 days. This is unlike toxic shock syndrome, which has an abrupt onset and evolves more rapidly. RED is a multisystem disease associated with fever, hypotension, diffuse macular erythema, ocular and mucosal injection and delayed acral desquamation. Patients often have underlying medical conditions, which may result in higher mortality rates from the condition.

Treatment. Antibiotics, hydration and supportive care are required, particularly as the underlying medical condition may require treatment as well.

Toxin-mediated erythema

Definition [1]. First described in 1996, this condition is characterized by a diffuse macular erythema in the perineal area. This develops abruptly and lasts for a few days. There may be associated pharyngitis, a strawberry tongue and acral erythema. Recurrent episodes are common.

Aetiology. The disease is thought to be caused by the toxins produced by either *Staphylococcus aureus* or *Streptococcus pyogenes*. The organism has been cultured from the pharynx.

Clinical features. Patients develop macular erythema in the perineal area. This usually follows an episode of pharyngitis. Episodes are recurrent and may be associated with hypotension, fever and mucosal oedema.

Treatment. Treatment with oral antibiotics is helpful.

Other staphylococcal and streptococcal infections (see also Table 27.1)

Periporitis staphylogenes [1] is secondary infection with *Staphylococcus aureus* of miliaria of the newborn. It is an infection of sweat glands and should not be confused with folliculitis or furunculosis, which are rare in neonates. Pustular miliaria itself is sterile.

Staphylococcal blepharitis [2] commonly presents with hard scales on the lid margins ('squamous' type). If thicker crusts form around the lashes, their removal may leave ulceration of the follicle ('ulcerative' type). Conjunctivitis is nearly always associated.

A sporotrichoid distribution of infected nodules was reported in two cases [3], one involving *S. aureus* alone and the other a combined infection with *Streptococcus pyogenes*.

Staphylococcal fissure of the lower lip [4], may be caused by *S. aureus*, where there is persistent fissuring at or close to the midline of the lower lip. The fissures may start in cold weather but persist for many months despite the use of emollients. Traditional signs of infection are absent, presumably because any exudate is promptly licked away. There is a rapid response to a topical antibiotic.

Acute paronychia (Chapter 62) is commonly due to *S. aureus*.

Staphylococcal scarlatina is a scarlatiniform rash, clinically indistinguishable from streptococcal scarlet fever, but without the accompanying exudative tonsillitis, which may complicate staphylococcal infection, beginning 1–9 days after the initial symptoms [5–11]. Negative Schultz–Charlton tests with streptococcal scarlet fever antitoxin suggest that the staphylococcal and streptococcal toxins are antigenically distinct [6,10].

Some of the reported cases were hypotensive and the similarity to milder forms of toxic shock syndrome has been noted [12–14], although it would be premature to regard the two conditions as pathogenetically identical. There is insufficient evidence for the proposed inclusion [15] of staphylococcal scarlatina within SSSS.

Streptococcal vulvovaginitis

Streptococcus pyogenes accounts for 10% of cases of vulvovaginitis in prepubertal girls [1]. Perianal infection

occasionally coexists. The child complains of genital soreness or irritation and the skin is acutely erythematous. There may be purulent discharge or dysuria. Other bacterial causes, including *Neisseria gonorrhoeae*, cannot be distinguished clinically. The infection responds to oral penicillin or erythromycin.

Perianal streptococcal infection

The term 'cellulitis' [1,2] seems inappropriate for this superficial infection that lacks fever and other systemic symptoms, although surface swabs yield group A streptococci in all cases.

Most patients are children aged 1–10 years, but occasional adult cases are seen. Some, but not all, patients were found to harbour *Streptococcus pyogenes* in the throat, usually of the same strain, and sometimes there is a recent history of pharyngitis in a family member. In some reported cases, there had been symptoms for many weeks or months suggesting that chronic infection may occur. Perianal soreness or irritation, pain on defaecation and sometimes secondary faecal retention are typical presenting symptoms. The affected skin is bright red, swollen and may be fissured. A purulent discharge with balanoposthitis may occur. Guttate psoriasis and, in girls, vulvovaginitis are occasionally associated.

The condition responds to an oral antibiotic. Penicillin is often successful, but recurrences in some patients respond to erythromycin and topical mupirocin [3]. A 2-week course is recommended [2].

Streptococcal ulcers

Acute ulcers, often on the legs and feet, are one of the more frequent forms of streptococcal pyoderma under humid tropical conditions [1]. Chronic ulcers of streptococcal origin may follow insect bites or abrasions, and are not uncommon [2]. Serpiginous in outline with an undermined edge and an uneven, roughly granular floor, they may persist for many months but heal rapidly with antibiotic treatment.

Blistering distal dactylitis

This is nearly always a group A streptococcal infection in children or teenagers [1,2], but group B organisms are occasionally involved [3], and a group B infection in a diabetic adult has been described [4]. A large blister containing thin, seropurulent fluid forms on the distal phalanx, usually of a finger, and typically on the palmar pad (Fig. 27.11), although it may extend to the nail folds, and more proximal involvement of the palmar skin is sometimes seen [3]. An upper respiratory tract infection is sometimes present. One recurrent case occurred beside an ingrowing toe nail [5]. The organism is cultured from blister fluid and responds to oral antibiotic treatment.

Streptococcal intertrigo [1]

Intertrigo of simple mechanical origin or associated with other dermatoses is readily colonized by many organisms. Haemolytic streptococci may become established and

Fig. 27.11 Blistering distal dactylitis. (Courtesy of York District Hospital, York, UK.)

may give rise to crusting and fissuring in the depth of the affected flexure. Such fissuring is a characteristic feature of infective eczematoid dermatitis behind the ears, and may complicate intertrigo in any site.

The fissure may be healed with appropriate antibiotics, but recurrence is frequent unless the predisposing factors can be effectively eliminated.

Sporotrichoid nodular lesions yielded both *Staphylococcus aureus* and *Streptococcus pyogenes* in one case, and *S. aureus* only in another [2].

A woman with streptococcal septicaemia developed TEN for which no other cause was found [3].

Streptococcal throat infection was suggested as a cause of acute urticaria in children [4].

Toxin-mediated streptococcal disease

Scarlet fever

SYN. SCARLATINA

Aetiology [1–4]. Scarlet fever is an acute infection caused by strains of *Streptococcus pyogenes* producing pyrogenic exotoxin (erythrogenic toxin, erythrotoxin), of which there are three antigenically unrelated types, A, B and C. All three are capable of producing scarlet fever. Toxin production appears to depend on the presence of a temperate bacteriophage and is exclusive to group A streptococci, a single strain of which may produce none, one, two or all three toxins [5]. In the 1970s and 1980s, type B was the most frequent toxin in the USA, Germany and England, and type C was also seen; type A is believed to have been responsible for the severe disease seen several decades ago. Whether an infected individual develops scarlet fever or a septic streptococcal illness, such as tonsillitis or cellulitis, depends on the level of antitoxic immunity, normally acquired by previous exposure.

The disease occurs throughout the world but the full syndrome is uncommon in the tropics, where surveys suggest that subclinical infections must be frequent [6]. Scarlet fever is endemic in large towns but the incidence varies greatly from year to year. The incidence in the Oxford (UK) region at a time of greater frequency of the disease was 0.30 confirmed, and 1.25 suspected, cases per 1000 per year [7]. In the last few decades, scarlet fever has been less severe than in the late 19th and early 20th centuries, perhaps because of the virtual disappearance of type A toxin [8].

The upper respiratory tract is the usual portal of entry and, although infection of surgical and other wounds may sometimes be responsible, most reports of this association have not included bacteriological examination of the throat. Droplet infection is commonest but the disease may be spread by fomites or by milk. Most cases occur between the ages of 1 and 10 years, and infections are rare in infancy and old age.

Pathology. The erythrogenic toxin is responsible for cutaneous vasodilatation, which may be associated with oedema and a perivascular cellular infiltrate. The toxin may also produce a degenerative myocarditis. The bacterial component of the syndrome consists of septic lesions in many organs, with abscess formation. Glomerulonephritis depends on an immunological mechanism.

An attack with a rash confers permanent specific antitoxic immunity. The toxin produced by other strains is not neutralized, hence second attacks, although rare, can occur. Bacterial immunity is temporary and there is therefore no permanent protection against the septic manifestation of infection by the same or related strains of *Streptococcus*.

Clinical features [9]. After an incubation period, which is usually 2–5 days, fever, anorexia and vomiting usher in the infection. If the throat is the portal of entry, there is an acute follicular or membranous tonsillitis, with painful lymphadenopathy. If the infection has entered a wound, there may be increased tenderness and some serous discharge.

The rash, which appears on the second day, first on the upper trunk, is a finely punctate erythema which has been likened to 'sunburn with goosepimples'. It generalizes within a few hours or over 3 or 4 days. Transverse red streaks in the skin folds due to capillary fragility are known as Pastia's lines. The face is flushed but rarely shows punctate erythema, and relative pallor around the mouth is characteristic. The lower legs are involved last and least. After 7–10 days the rash is succeeded by desquamation, branny in most areas but in large, lamellar scales on palms and soles.

The oral mucous membranes are bright red and there may be deeper red puncta on the palate. The tongue is at first heavily coated, but by the second or third day scattered, swollen, red papillae give the 'white strawberry tongue' appearance. As the epithelium is shed, the tongue becomes smooth and dark red ('red strawberry tongue') before returning to normal.

Fever usually settles in 7–10 days. The typical course of the mild or moderate case may be modified if either the toxic or septic manifestations are severe.

In the severe toxic form the eruption is very intense and may be purpuric. Fever is high and the patient is delirious or comatose. Myocarditis is often present.

In the septic forms, the local pharyngeal lesions are severe and there may be extensive oedema. Otitis media and peritonsillar abscesses are frequent. The rash may be slight.

Complications are caused either by the toxin, or by bacterial invasion of tissues by local extension or by haematogenous dissemination, or by a probably allergic reaction. Of the toxic manifestations, myocarditis is the most important. The suppurative complications include arthritis, meningitis and osteomyelitis. Rheumatic fever and glomerulonephritis are presumed to be allergic in origin.

The prognosis is now good and the mortality of treated cases is under 1%.

Second attacks are more frequent in patients in whom early antibiotic control of the initial attack has impaired the immune response [10].

Diagnosis. The classical form of the disease associated with tonsillitis is unlikely to be misdiagnosed if it is considered. The diagnosis may be supported by culture of a haemolytic *Streptococcus*, a rising ASO titre and blanching of the rash around the point of injection of antitoxin: the Schultz–Charlton test. The peripheral blood usually shows polymorphonuclear leukocytosis.

Rubella, the early stage of smallpox and some drug reactions can simulate scarlet fever. The lack of pharyngeal lesions and the distribution of the exanthem will usually enable the diagnosis to be established. Rarely, staphylococcal infections are accompanied by a scarlatiniform erythema.

In the so-called recurrent scarlatiniform erythema, repeated attacks of a somewhat similar rash, followed by exfoliation, occur without discoverable cause.

Treatment. Penicillin should be given in full dosage for 10 days as soon as the diagnosis is suspected. The management of the complications lies beyond the scope of this book, but the possibility of myocardial or renal damage should always be borne in mind and careful and prolonged supervision is obligatory.

Streptococcal toxic shock syndrome

Definition. Fever, myalgia and flu-like symptoms are followed by pain in an extremity or in the abdomen. A rash followed by desquamation, circulatory shock and multisystem disease characterize the streptococcal toxic shock syndrome (STSS).

Aetiology. This disorder has been associated with the recent re-emergence of invasive group A streptococcal infections. Group A streptococci, producing streptococcal pyrogenic exotoxin-A, are usually cultured from the blood, although other streptococci have been isolated too. Several streptococcal toxins are likely to be responsible for this condition, although the exact pathogenic mechanisms are currently still unknown.

Clinical features [1,2]. The disease may occur in immunocompetent children or adults.

The disease is similar to staphylococcal toxic shock syndrome, although there may be some differences. Cases of STSS are associated with severe invasive group A streptococcal disease, whereas staphylococcal toxic shock syndrome may be associated with either severe or trivial infection. Surgical wounds, throat infections, vaginal infections postpartum or soft-tissue infections due to group A streptococci, may be followed by the STSS. The disease is associated with a higher mortality rate than staphylococcal toxic shock syndrome. Complications include myositis, endophthalmitis, peritonitis and renal failure [3].

Diagnosis. Blood cultures are frequently positive, and swabs from the site of clinical infection almost always yield group A streptococcal M types 1, 3, 12 and 28. The streptococcal pyrogenic exotoxins A and B are produced in the majority of these cases.

Treatment. Penicillin, erythromycin or clindamycin would be the treatment of choice for most soft-tissue infections caused by group A streptococci. Where necrotizing fasciitis or myositis have developed, debridement, fasciotomy or amputation may be required. Intravenous gammaglobulin may be helpful to neutralize the toxin [4].

Coryneform bacteria

The term coryneform bacteria is currently used to describe Gram-positive, non-sporing, rod-shaped organisms commonly referred to as diphtheroids [1,2]. This heterogeneous group has a wide distribution in nature and is of considerable importance to the dermatologist. It embraces *Corynebacterium diphtheriae*, the cutaneous aerobic coryneforms, *Corynebacterium* and *Brevibacterium* spp., as well as the anaerobic *Propionibacterium* spp. Two animal species that may cause human diseases, *Listeria monocytogenes* and *Erysipelothrix insidiosa*, may be included in this group (Table 27.3).

Aerobic coryneforms of the resident normal flora

Many different strains of aerobic coryneform bacteria may be isolated from the normal human skin. Their classification remains unsatisfactory, but recent attempts to divide them into a mere six species complex on the basis of obligate lipophilicity, glucose fermentation, tyrosine clearance and nitrate reduction are encouraging to the non-specialist [1]. Apart from *Corynebacterium* spp., it is now clear that *Brevibacterium* spp., non-lipophilic coryneform organisms, can be isolated regularly from most human skin, especially the toe clefts [2]. It is generally accepted that trichomycosis axillaris and erythrasma are caused by an overgrowth of resident coryneforms, and there are grounds for suggesting that the organism involved in pitted keratolysis is also a resident coryneform. In trichomycosis, a variety of different strains of aerobic coryneforms have been implicated, not a single species (*C. tenuis*) as originally thought. In erythrasma, the term *C. minutissimum* is still used, but it is probably wise to recognize that this label implies a species complex of fluorescent aerobic coryneforms capable of initiating, alone or with others, the characteristic scaling and pigmentary changes of that condition.

Table 27.3 Coryneform bacteria.

Human commensals or pathogens	
Aerobic	
Corynebacterium diphtheriae	Primarily throat
C. haemolyticum	
C. pyogenes	
C. xerosis	
C. hofmannii	Primarily skin
C. minutissimum	
Brevibacterium epidermis	
Anaerobic	
Propionibacterium acnes	
P. granulosum	Primarily follicular
P. avidum	
Pathogens of other vertebrates sometimes infecting humans	
Listeria monocytogenes	
Erysipelothrix rusiopathiae

Diphtheria

Aetiology. In temperate regions, and probably also in urban areas in the tropics, *Corynebacterium diphtheriae* is isolated predominantly from the nose and throat of healthy carriers who have recovered from an attack of faucial diphtheria. In some tropical rural areas, the organism is found only rarely in the nose and throat, but is present in 30–60% of skin lesions of various types—impetigo, yaws, infected abrasions—in the indigenous population [1].

However, generally the rates of infection are considerably less in individuals receiving adequate courses of immunization, and where infections occur they are usually less severe in these groups than in the non-immunized [2]. It is likely that widespread immunization programmes have been in part responsible for the decreased incidence of diphtheria, even though the numbers of new cases of infection were falling before the introduction of toxoid. One interesting observation is that isolates of *C. diphtheriae* from immunized subjects are less likely to be toxogenic than those from the non-immunized.

The diphtheria toxin consists of two fragments: the A polypeptide, which is the active segment, and the B fragment, which binds to cell-surface receptors. The A segment inactivates transfer RNA translocase, preventing protein synthesis.

Strains of *C. diphtheriae* differ in toxigenicity, and those isolated from chronic skin lesions often produce little toxin. All strains are lysogenic for temperate phages: strains which lose their phage lose their ability to produce toxin.

The association of *C. diphtheriae* with yaws in the Pacific area is statistically significant, and suggests that the lesions produced by the spirochaete may provide particularly suitable conditions for colonization by diphtheria.

Cutaneous diphtheria is rarely reported in temperate climates, but the diagnosis is easily overlooked [3]. An outbreak occurred in Vancouver, Canada, in all numbering

44 cases. Another report from northern Canada has stressed the persistence of diphtheria in spite of high immunization rates, and the more frequent isolation of *C. diphtheriae* from Native Americans, than from Eskimos or white people [4]. In the tropics, especially where hygienic standards are low, the infection is more readily established in pre-existing skin lesions, and in the southern USA cutaneous infections have been shown to be significant in the epidemiology of diphtheria, particularly in poor communities [5,6].

Pathology. Colonization of skin lesions by a strain of low virulence may not modify their morphology or produce any remote toxic effects. Such strains may provide a sufficiently strong antigenic stimulus for immunity to develop.

A toxigenic strain induces local necrotic changes and systemic effects.

Clinical features [3,4]. The typical early lesion is a superficial ulcer, rounded, oval or irregularly linear, with a clearly defined, overhanging edge. Exudate from the ulcer floor tends to form a tough grey or brownish grey adherent membrane. Later, the ulcer may deepen and its edge become rolled, raised and avascular. There may be moderate enlargement of the regional lymph nodes. In temperate climates, the lesions occur most commonly at the umbilicus, behind the ears, in the genitocrural flexures, in a toe cleft or in a finger or toe, where a whitlow may be simulated. They may, however, develop in any pre-existing skin lesion, and in the tropics commonly complicate such conditions as impetigo, scabies or desert sores. Cutaneous diphtheria may persist for 6–12 weeks, healing with scar formation.

In many cases, the lesions are less distinctive and may simulate impetigo or ecthyma. A rare clinical form has been described in children with eczema: varicelliform vesicles or pustules are succeeded by diphtheritic ulcers. For this reason the role of *C. diphtheriae* in the pathogenesis of skin lesions has been questioned, particularly as other potentially pathogenic bacteria, such as staphylococci and streptococci, may be present [3].

Systemic manifestations are characteristically absent or mild in cutaneous diphtheria but are occasionally severe, especially in infants. In all forms, neurological complications, on which the retrospective diagnosis of diphtheria is sometimes based, occur in some 30% of cases and myocarditis in 5–10%.

Faucial diphtheria may be associated with adherent haemorrhagic crusts around the nose and mouth.

Diagnosis. The diagnosis may be suspected in persistent ulcers with an adherent membrane, but must be confirmed bacteriologically. The organisms are easily seen on a Gram stain. Swabs should be taken for culture and toxin assessment.

Treatment. Specific antitoxin should be administered as soon as the diagnosis is suspected: 20 000–50 000 U i.m. should be given. Penicillin or erythromycin should also be prescribed. The subsequent management will depend on whether there is neurological or cardiac involvement, and will be facilitated if the toxigenicity of the infecting strain can be established.

Erythromycin is probably the most effective compound for eradicating skin carriage.

Corynebacterium haemolyticum infection

This organism has been reported as a cause of throat infections associated with a maculopapular rash. Patients usually presented with sore throats, mild to moderate in severity with little malaise or fever, and approximately half developed a maculopapular rash [1,2].

Corynebacterium pyogenes infection

Corynebacterium pyogenes has been connected with outbreaks of skin ulceration in Thailand [1]. The clinical appearances of the lesions closely resemble those seen with other forms of pyoderma including tropical ulcers. Spread by flies in the area has been suggested. The pathogenetic mechanism by which these organisms produce skin necrosis has yet to be established.

Erythrasma

Definition. Erythrasma is a mild, chronic, localized superficial infection of the skin caused by a group of closely related aerobic coryneform bacteria, usually known as *Corynebacterium minutissimum*.

Aetiology. For over a century, erythrasma was thought to be due to an actinomycete, for which the name *Nocardia minutissima* was proposed. It is now recognized that the Gram-positive rods and filaments always found in the scales of erythrasma are coryneforms. The name *C. minutissimum* has been given to the organisms isolated, but possibly more than one species may be involved [1,2]. The epidemiology of erythrasma has not been fully elucidated. There seems to be little doubt that the organisms responsible are frequently members of the normal flora, at least in the toe clefts, and that some shift in the host–parasite relationship results in the development of classical erythrasma. A warm, humid climate is a predisposing factor.

Clinical infection may occur at any age but is more common among adults than children. In institutions, the incidence may increase steadily with age [3]. Among normal populations, mild toe-cleft scaling with pink fluorescence is common. Clinically important infections of the groins are much less frequent and those of the axilla are uncommoner still. Within closed communities, the condition is likely to be more prevalent: in one hospital for the mentally subnormal, the incidence in the toe clefts was 30%, in the groins 18% and in the axillae 4% [4]. The incidence of erythrasma has been reviewed by Noble [3].

A variety of erythrasma that affects the axillae, inframammary folds and large areas of the trunk, as well as the groins, is particularly common in obese, middle-aged black women. Diabetes was found to coexist in eight of 13 patients with lesion of this type [5].

Clinical features [6] (Fig. 27.12). Erythrasma, as detected by Wood's light examination, involves the toe clefts more frequently than any other site. As clinically manifest lesions it occurs most commonly in the groins, axillae and the intergluteal and submammary flexures. In the groins it affects the area of one or both thighs in contact with the scrotum. Lesions on the glans penis and beneath the prepuce have rarely been reported [7] but have probably seldom been sought. The patches are of irregular shape and sharply marginated, at first red, but later becoming brown. New lesions are smooth, but older lesions tend to be finely creased or obviously scaly. In the generalized form, the sharply marginated, reddish brown plaques may cover extensive areas of the trunk and limbs.

In temperate climates most lesions are symptomless, but in the tropics particularly, irritation of lesions in the groins may lead to scratching and lichenification. Involvement of the perianal skin may present as pruritus ani, of which erythrasma is an uncommon cause.

Toe-cleft infections are often asymptomatic; the scaling, fissuring and maceration that may be present are not necessarily caused by the corynebacteria. Rarely *C. minutissimum* has been associated with systemic disease, such as recurrent abscesses or endocarditis.

Fig. 27.12 Erythrasma. (Courtesy of St John's Institute of Dermatology, London, UK.)

Fluorescence under Wood's light. Coral-red fluorescence with Wood's light is attributable to coproporphyrin III and strongly suggests erythrasma, although it does not necessarily indicate active infection. The persistence of fluorescence after eradication of the coryneforms may depend on the thickness of the horny layer for it is common at the margins of the toe webs [3].

Pink fluorescence is also demonstrable in some necrotic tumours and on the normal tongue where it is not apparently caused by coryneforms. It is seen in the follicular openings of the normal skin of the face and the upper trunk, where corynebacteria or propionibacteria are the likely cause. In the groins and axillae, acanthosis nigricans may fluoresce a brilliant pink colour, presumably due to heavy colonization with fluorescent coryneforms, although other bacteria may show pink fluorescence.

Differential diagnosis. Pityriasis versicolor (Chapter 31) is most commonly confused with erythrasma, but it occurs predominantly on the upper trunk, and the individual lesions are small and are not erythematous. On the thighs, groins and pubic area, tinea cruris may be simulated, but the relative lack of inflammation, complete absence of vesiculation and absence of satellite lesions point against tinea. It is difficult to differentiate erythrasma of the toe clefts from tinea pedis or *Candida* infection, but, as in all varieties of erythrasma, the presence of coral-red fluorescence under Wood's light is diagnostic. Since many

patients have both tinea pedis and erythrasma, mycological examination of scales is important.

Prognosis. Without treatment the condition tends to persist indefinitely, although there may be spontaneous fluctuations in severity.

Laboratory identification. Scrapings from the affected skin may show bacteria and fine filaments if stained with Gram or Giemsa or even with simple potassium hydroxide clearance. Culture on Tissue Culture Medium 199 (without antibiotics) with 20% calf serum and 2% agar yields colonies that fluoresce coral red under Wood's light after 18–36 h. *Corynebacterium minutissimum* may resemble *C. jeikeium* but the latter does not grow on triple sugar iron agar, whereas the former does. Cultural confirmation is not normally necessary if the clinical appearance is typical and Wood's lamp examination of the patient is positive [2].

Treatment. Erythrasma responds well to most topically applied azole antifungal agents, such as clotrimazole and miconazole [5]. The duration of therapy varies, but 2 weeks is usually sufficient. For more extensive lesions, erythromycin is probably the most effective approach. Alternatives include topical fucidin and oral tetracycline. Relapse is a problem in some patients. In these cases the usual approach adopted is to give long-term antiseptic soaps, such as povidone–iodine, and to use drying agents, such as powders, in the affected areas.

Trichomycosis axillaris

SYN. TRICHOMYCOSIS NODOSA

Definition and aetiology. This is a superficial infection of axillary and pubic hairs with the formation of adherent granular nodules—yellow, black or red—on the hair shaft. The misleading term 'trichomycosis' is retained in the absence of a generally agreed alternative, although it has been clear for many years that the causative agent is not a fungus [1]. Studies using transmission and scanning electron microscopy [2] have shown that the concretions consist almost exclusively of tightly packed bacteria. They grow within and between the cuticular cells and may invade the cortex [2]. Cultural studies have shown a variety of different biochemical types of aerobic *Corynebacteria* to be involved and not a single species, *C. tenuis*, as was at one time believed. These biotypes probably reflect the range of resident coryneform types in the normal axilla. It has been shown that the changes in chemical environment of these organisms may induce pigment production, perhaps explaining the different colours of the nodules, which are not attributable to different bacterial strains [3].

Clinical features. Trichomycosis occurs in both temperate and tropical climates and is not limited by race or sex. It is usually asymptomatic and the patient is often unaware of its presence. Yellow, black or red concretions are present on the hair shaft and these may be hard, or soft and nodular, or more diffuse. In the nodular varieties, the hair may be brittle and easily broken [2]. The underlying skin is normal. The axillary sweat may be yellow, black or red according to the colour of the concretions, and the clothing may be stained. The yellow type is the most common and the black the rarest. The few figures available on the prevalence of trichomycosis show it to be common.

Axillary infection was present in 27% of adult male students in one UK survey, and in 42% of male patients but only 7% of women patients in a hospital for the mentally subnormal [4]. This sex difference is largely explained by absence of axillary hair in the women. Pubic infection is less common but should not be forgotten [5].

Differential diagnosis. Pediculosis pubis, which may affect axillary as well as pubic hair, and piedra should be considered. Examination under Wood's light is helpful. Microscopical confirmation of the diagnosis is desirable.

Laboratory identification. Potassium hydroxide mounts show the bacteria as narrow bacillary organisms in the yellow or red concretions. They are Gram-positive. For culture, the hairs must be surface sterilized, and this may be satisfactorily done by immersion in 70% alcohol. Incubation at 37°C in blood agar is recommended.

Treatment. Clipping the affected hairs and the application of an antimicrobial ointment such as benzoic acid compound ointment or 1% aqueous formalin are effective. However, the use of an effective antiperspirant such as anhydrous aluminium chloride is a rapid means of therapy.

Pitted keratolysis

SYN. KERATOLYSIS PLANTARE SULCATUM

Definition and aetiology. A superficial infection of the skin apparently caused by a species of *Corynebacterium* and producing circular erosions on the soles [1]. Filamentous and coccoid microorganisms were originally observed in skin scrapings and the organism was named *Actinomyces keratolytica*. Other reports tended to incriminate a species of *Streptomyces*, but a species of *Corynebacterium* has also been isolated, and recent work suggests that either a *Streptomyces* or a *Corynebacterium* or both, and possibly other organisms too, invade keratin softened by sweat [1,2]. The problem is, however, not fully resolved: an actinomycete identified by histological appearances as *Dermatophilus congolensis* was present in some cases [3].

Histology. Filamentous microorganisms may be seen in abundance in the most superficial parts of the stratum corneum [4].

Laboratory identification. The organisms are not always easy to find in potassium hydroxide mounts but are more easily detected in Gram-stained scrapings. Culture on brain–heart infusion agar, incubated at 37°C in a mixture of pure nitrogen containing 5–10% carbon dioxide, gives minute, irregular, colourless colonies within 3–5 days [5].

Clinical features (Fig. 27.13). There are numerous superficial erosions of the horny layer of the soles and the undersurfaces of the toes. All parts of both soles may be affected. Conspicuous, discrete, shallow, circular lesions with a punched-out appearance coalesce in places to produce irregular erosions. There is occasionally green or brown discoloration of the horny layer. Hyperhidrosis is often associated, sometimes with maceration and a foul odour. Soaking the feet in water for 15 min causes swelling of the horny layer and accentuates the lesions. Irritation is minimal and in most cases patients are unaware of the condition. Under battle conditions, soreness and pain have been reported in severe cases [1,6].

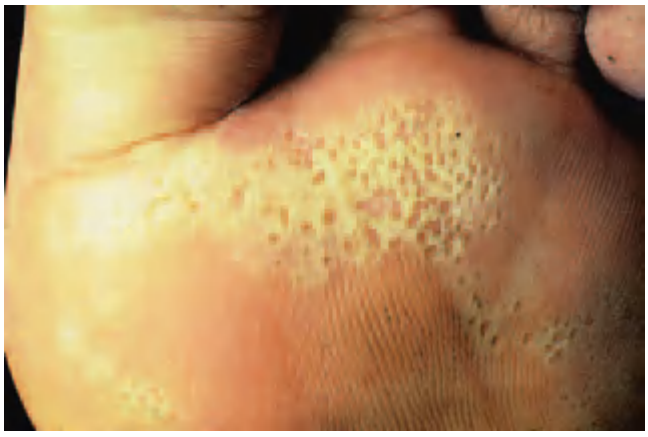

Fig. 27.13 Pitted keratolysis. (Courtesy of St John's Institute of Dermatology, London, UK.)

Similar changes affecting the palms have been described on rare occasions in the Far East, UK and southern USA.

Differential diagnosis. The lesions are easily recognizable, but simple hyperhidrosis, erythrasma and tinea pedis have to be considered.

Treatment. Treatment of hyperhidrosis (Chapter 45) slowly brings the condition under control, but a more rapid response may be obtained with fucidin ointment. Other topical antibiotics and imidazoles such as clotrimazole are reputed to be effective [1].

Propionibacteria

Definition. Propionibacteria are anaerobic coryneforms of the resident normal flora. These Gram-positive, pleomorphic bacilli are found in large numbers and are widely distributed over the whole skin. Though formerly all termed *Corynebacterium acnes*, it is now recognized that they are more properly classified as propionibacteria and may be divided into three species. *Propionibacterium acnes* and *P. granulosum* are found predominantly in the pilosebaceous follicles of those sites where sebum is plentiful, and *P. avidum* is mainly isolated from moist intertriginous zones [1].

From its location, it is unlikely that *P. avidum* has any part in the causation of acne. *Propionibacterium acnes* and *P. granulosum* may well have a key role, but on present evidence it is difficult to be dogmatic on this point or to blame one species more than the other. The importance of *P. acnes* and *P. granulosum* in acne is considered in Chapter 43.

In addition to its association with acne, *P. acnes* has been isolated from cases of endocarditis and meningitis associated with the presence of ventriculoatrial or ventriculoperitoneal shunts. It has also been proposed as a cause of indolent folliculitis [2].

Anthrax

Aetiology [1]. Anthrax is a specific infection with *Bacillus anthracis*, a Gram-positive, aerobic, encapsulated organism, which can survive as spores for over 20 years in soil. It is primarily an infection of herbivorous animals, but occasional outbreaks occur in other species. Animals are infected by ingesting the spores. Animal infections, and hence human infections, are still a serious problem in Africa (e.g. Zimbabwe and Chad), Pakistan, India, Iran, the Middle East and parts of Russia. Only occasional cases are seen in other areas. However, sporadic cases are easily overlooked as the diagnosis is not considered. In the endemic areas, humans are infected directly from animals or animal products, and male adults are most at risk, but in some rural communities children minding cattle may be infected.

Anthrax most often follows occupational exposure during care of livestock or the handling of products. In western Europe, most cases of anthrax formerly occurred among workers in the wool, hair or bristle industries, or those handling animal materials imported from India, Pakistan or Africa. In many countries, stricter codes of practice for hygiene in the work place has been followed by a decline even in sporadic infections. Unsterilized imported bone meal, or sacks contaminated with it, remains a potential hazard, although warning labels on this product appear to be effective in reducing the danger still further.

Human resistance to infection is normally high. Cutaneous inoculation is favoured by minor trauma or pre-existing skin lesions, and pulmonary and intestinal forms result from the inhalation or ingestion of spores.

Pathology. The anthrax bacillus induces an inflammatory tissue response in which haemorrhage and necrosis are associated with a gelatinous oedema, which contains much bacterial capsular material. The bacillus is present in large numbers in the skin lesions, and in the blood in systemic infections. The virulence factors are encoded on two plasmids—one inhibits phagocytosis of vegetative forms and the other carries the genes for synthesizing the exotoxins. These exotoxins (oedema toxin, lethal toxin and protective antigen) account for the pathology [2].

Clinical features [1]. The lesion of cutaneous anthrax, the malignant pustule, commonly occurs on exposed skin, especially the face, neck, hands or arms, and is usually single but may be multiple. Between 1 and 5 days after infection an irritable papule develops at the site of inoculation. A bulla on a red oedematous base soon follows. The bulla ruptures and forms a haemorrhagic crust around which is a zone of oedema and erythema in which there may be several small vesicles. The surrounding tissues are oedematous, and although the regional lymphatic glands may be tender, their involvement is slight in relation to the severity of the lesion and lymphangitis is unusual. In some cases, particularly when the face is involved, the oedema may be extreme and the localized pustule inconspicuous or absent. The clinical picture is very variable and purely or predominantly bullous lesions have been reported.

Constitutional symptoms may begin 3 or 4 days after the onset of the pustule. In severe untreated cases, malaise, high fever, toxaemia and prostration may be followed by delirium, collapse and death. In most cases, general symptoms are mild and healing occurs in 2–3 weeks.

The mortality of untreated cutaneous anthrax is between 5 and 20%. Severe oedema or toxaemia are of poor prognostic significance. With early and adequate antibiotic treatment, all cases are curable.

Other forms of anthrax include respiratory and gastrointestinal varieties. In the respiratory type, a mild primary illness is followed in 2–4 days by respiratory distress. The gastrointestinal type may cause haematemesis and diarrhoea with abdominal pain. Oesophageal involvement may also give rise to massive swelling of the neck. During 2001, several cases of confirmed anthrax infection occurred in the USA after about 20 years absence. None of these followed conventional exposure and were thought to result from bioterrorism [3]. There were several fatal cases.

Diagnosis. Staphylococcal infection, vaccinia, cat scratch disease (formerly named para-anthrax), North American blastomycosis and sporotrichosis may need exclusion. In the authors' experience, both staphylococcal infections and cowpox can simulate anthrax very closely. Both may show the central black haemorrhagic crust and the zone of oedema and erythema. The history, rapid course, clinical appearance and lack of lymphangitis should suggest the diagnosis, which must be confirmed by bacteriological examination. A Gram stain of the fluid from a cutaneous lesion may show the bacilli. Blood cultures confirm systemic infections. Smears should be chemically fixed as the spores may survive the standard fixation with a flame. A serological test is also available, although antibody levels in this disease are often very low [1].

Treatment [1,4]. For cutaneous anthrax, oral ciprofloxacin, doxycycline or amoxicillin may suffice for 7–10 days.

Where biological warfare is suspected treatment should continue for 60 days. For systemic disease, treatment should not be withheld until bacteriological confirmation has been obtained. Penicillin G should be given i.v. for 7–10 days, in a dose of 4 million units 6-hourly for the first 3–4 days. Tetracycline or erythromycin can be given in the presence of allergy to penicillin or in the very rare cases in which the bacillus is resistant to penicillin. If the patient is already severely toxic when treatment is started, intravenous fluids and corticosteroids are advisable. Where biological warfare is suspected, ciprofloxacin is the drug of choice at a dose of 400 mg every 12 h for up to 60 days. Penicillin may be added if meningitis is suspected.

Vaccination gives some protection [5] and should be offered to those who are exposed in the course of their occupations, but prevention should be directed primarily at control of the disease in animals and disinfection of animal products.

Other *Bacillus* spp.

Rarely, other species of the genus *Bacillus* may cause deep subcutaneous infections resembling necrotizing fasciitis [1]. *Bacillus cereus* and *B. subtilis* may cause a variety of different infections of the eye ranging from conjunctivitis to panophthalmitis.

Listeriosis

Aetiology [1–3]. Listeriosis is an infection caused by *Listeria monocytogenes*, a Gram-positive microaerophilic, motile bacillus easily confused with coryneform organisms. It can survive low temperatures and will grow at 4°C.

The organism is found in water and soil, and has been isolated from sewage sludge and inferior silage. It infects animals, farm, wild and laboratory, worldwide. Direct infection from cattle and sheep is a hazard to veterinary surgeons [4] and farmers, but food, especially milk, cheese and poultry, is the main source of human disease [5]. Transplacental and birth canal infections are a well-recognized hazard to the fetus and neonate [6]. Infection of a baby from the mother's milk has been reported [7]. Otherwise, direct transfer from human to human does not seem to occur. However, *L. monocytogenes* may be carried asymptomatically in the human gut as well as in the cervix and vagina, at least for short periods, so the potential for transfer of infection does exist.

Clinical features [8–11]. Most adult infections are now thought to be subclinical, but a mild febrile illness with gastrointestinal symptoms and loin pain may occur. More serious infections with a meningitic or glandular fever-like illness are well known, and in immunocompromised patients meningitis or pneumonia may dominate the picture. Cutaneous lesions are uncommon in these cases, but when present are purpuric. During pregnancy, an indeterminate febrile illness, not necessarily severe, may arouse no suspicions but the infant may be stillborn or premature, and may develop a combination of respiratory and gastrointestinal symptoms with granulomas of the posterior pharynx, generalized erythema and dark-red or bluish papules, especially on the trunk and legs [12]. Meningitis and septicaemia may be seen later in the neonatal period [6].

In veterinary surgeons, a mild, predominantly cutaneous form of the disease may occur 1–3 days after contact with an infected animal [4]. Fever and malaise are followed after a day or so by an eruption of discrete, dull-red papules, some of which later show central pustulation. In serious adult infections, in the immunocompromised patient and in the neonate, the prognosis is poor without treatment, at least 60% of cases being fatal [6].

Diagnosis. As there are no specific clinical features, the diagnosis will be missed unless it is borne in mind in unexplained fevers, glandular fever-like illness and meningitis. In those at risk through occupation, or predisposing states, the diagnosis is established by blood culture and, if a high index of suspicion towards diphtheroids is maintained, through isolation from other sites. Cold enrichment may help. Unfortunately, serology is unreliable [3].

Treatment. The drug of choice is ampicillin, but the organism is also susceptible to penicillin, erythromycin and tetracycline. Gentamicin may advantageously be used with ampicillin or penicillin, as synergism occurs.

Erysipeloid

Aetiology [1,2]. Erysipeloid is an acute, rarely chronic, infection with *Erysipelothrix rusiopathiae* (formerly known as *E. insidiosa*). This organism is widespread in nature as a commensal or pathogen in a wide variety of animal species; it can survive in soil, although its survival time in this environment is unknown. It colonizes a wide variety of animals worldwide, including mammals, birds, fish and shellfish, and causes disease in many of these, especially in pigs. Human infection is contracted by direct contact, occasionally from living animals, but more commonly from carcasses, so that erysipeloid usually affects slaughtermen, butchers, cooks, fishermen, farmers and veterinary surgeons. Scratches or pricks with fish, rabbit or chicken bones are sources of infection in housewives [3]. The existence of L forms might explain the occasional chronic or recurrent infections [1]. The organism, *E. rusiopathiae*, produces a neuraminidase and a hyaluronidase, both of which are believed to be virulence determinants.

Pathology [1]. Cultures of biopsy material from the advancing edge of recent lesions occasionally yield the organism, but are commonly negative. Histology shows epidermal spongiosis or vesiculation, dermal oedema, lymphangitis, capillary engorgement and infiltration with neutrophils and eosinophils. Organisms have only rarely been detected by light microscopy. However, electron microscopy has demonstrated cell-wall-deficient bacteria (L forms), which may explain the difficulty of demonstrating the bacteria by conventional methods.

Clinical features [1,2]. Three clinical syndromes have been distinguished in humans: localized cutaneous, which is much the most common (erysipeloid of Rosenbach), generalized cutaneous and systemic, in which skin lesions may occur.

Most human infections are localized and self-limiting. About 3 days after inoculation, a hot violaceous and tender erythema develops around the inoculation site and extends centrifugally, but irregularly, with a sharp and sometimes gyrate border, which may be vesicular. Most lesions are on the hand, fingers or forearms, but any exposed area may be involved. Fever and mild constitutional symptoms such as arthralgia are present in only some 10% of cases. Extension continues for 3 or 4 days, rarely for as long as a week, but the area eventually involved is seldom more than 10 cm in diameter. Without treatment, healing normally occurs spontaneously in 2 weeks without desquamation or suppuration.

Widespread skin lesions are rare, described as violaceous, with a variable, pink advancing border and with central resolution. There may be systemic symptoms, but blood cultures are negative. This form is also usually self-limiting, but runs a more protracted course with the possibility of recurrences.

The commonest manifestation of the rare systemic *E. rusiopathiae* infection is endocarditis, but joint, bone, brain and pleural involvement have been described. Patients are ill, lose weight and may show localized cutaneous swellings with central necrosis, or scattered perifollicular papules. Blood cultures are usually positive with appropriate techniques.

Diagnosis [2]. The diagnosis of the cutaneous disease is mainly clinical. Compared with erysipelas/cellulitis, erysipeloid usually lacks constitutional symptoms and lymphangitis, the lesions are more purplish, and local joint involvement is more common. Diagnosis is by culture of aspirated material or biopsy specimen. The organism is a non-motile, non-sporulating Gram-positive bacillus.

Treatment [1]. The usual choice is penicillin, given parenterally in severe infections. Ciprofloxacin or erythromycin are alternatives. Tetracyclines are often satisfactory, but the sensitivity of the organism is variable.

Gas gangrene

Aetiology. Gas gangrene designates a clinical syndrome caused by the infection of wounds with various species of *Clostridium*, alone or in combination with anaerobic streptococci, and often with aerobic organisms such as *Proteus*. The most important *Clostridia* spp. are *C. perfringens*

(formerly *C. welchii*), *C. oedematicus*, *C. septicum* and *C. histolyticum*, but other species may play a minor role [1].

The clostridia are anaerobic, Gram-positive, spore-forming bacilli, widely distributed in the soil and in the gastrointestinal tracts of humans and other mammals. *C. perfringens* can be isolated from the skin of the thighs, groins and buttocks of many healthy persons [1]. A high proportion of war wounds are contaminated by clostridial spores, but clinical infection usually develops only in the presence of severely damaged anoxic muscle. The incubation period varies from 12 h to 5 or 6 days, according to the species predominantly involved.

Gas gangrene used to be an infection of the greatest importance in war time; better management of casualties has reduced its incidence enormously. It is an uncommon but well-documented complication of civilian trauma and of orthopaedic surgery, particularly above-knee amputations in ischaemic limbs. In these latter patients, the organism usually originates in the patient's own bowel [1,2].

Clinical features. Deep and dirty wounds in the muscular regions of the body are most susceptible. However, abdominal and intrauterine infections also occur. The affected area becomes painful and swollen and there is increasing serous discharge from the wound. Toxaemia is severe; tachycardia and prostration develop rapidly and the patient is pale and apprehensive but often not febrile [1,3]. The oedema around the wound continues to spread and is associated first with brownish staining and mottling, then with bullae and later with the formation of black sloughs. Crepitation from gas in the tissues is classical but inconstant. There are usually severe systemic symptoms including tachycardia, irritability and hypotension.

Diagnosis. The diagnosis must be made promptly on clinical grounds supported in due course by bacterial examination of the ooze from lesions, which contains large numbers of typical Gram-positive bacterial rods. Necrotizing fasciitis, Meleney's synergistic gangrene and anaerobic streptococcal infection should be considered.

Treatment. The immediate surgical debridement of all damaged tissue is essential. Penicillin in high dosage (10–20 million units) is the usual treatment [4], although there are reports of penicillin resistance among *Clostridium* spp. Alternatives include chloramphenicol, metronidazole and imipenem [5].

The role of hyperbaric oxygen remains controversial because of the lack of controlled studies, and unless readily available may lead to delays in essential surgery [6]. There are, however, experimental data indicating that it reduces the mortality rates.

Suppurative myositis may also be caused by *Clostridium* spp. This complication is seen most often in intravenous drug abusers. However, there is less toxaemia than with gas gangrene [7].

Gram-negative bacteria

Meningococcal infection

Aetiology [1,2]. *Neisseria meningitidis* is a Gram-negative coccus. It can be divided into different serotypes on the basis of capsular polysaccharides, types A, B and C being the most important. All types are pathogenic. This bacterium colonizes the human upper respiratory tract, and is transmitted by droplet from patients or healthy carriers. It may cause localized infections, such as conjunctivitis and otitis media, or severe and potentially fatal disease with septicaemia and often meningitis. The factors determining whether the organism is a mere colonizer or causes mild or severe disease in the individual case are not understood. Severe disease affects mainly children under the age of 10 years, but epidemics in adults may occur, for instance in institutions such as military barracks.

Bacteraemia is believed to be the primary event in all forms of the infection, and to be the route by which the organism reaches the meninges.

Pathology. The early petechial skin lesions result from the presence of the organisms in capilliary endothelium accompanied by disseminated intravascular coagulation, with necrosis of the vessel wall or thrombosis [1]. The skin lesions occurring late in the course of acute infections or in chronic infections show a vasculitis thought to be produced by soluble antigen–antibody complexes [3].

Clinical features. Acute meningococcal septicaemia and meningitis may present as a fulminating illness, and the rash may be a very useful clue to early diagnosis. The incidence of rash is estimated at between 40 and 90%, perhaps depending on the thoroughness with which lesions in the more sparsely affected cases are sought [1]. Early skin lesions are not always haemorrhagic, and may take

the form of discrete pink macules or papules a few millimetres in diameter on any part of the body, including palms and soles [4]. Purpura follows in many cases. Transient erythematous, morbilliform or urticarial eruptions are occasionally seen.

A purpuric eruption is characteristic, and occurs mainly on trunk and limbs. The petechiae are usually small and scanty, but vary in size and number. In severe cases, larger purpuric lesions may occur including extensive ecchymoses and necrotic ulceration, particularly in dependent areas and under pressure sites, and are associated with a high mortality [5].

Vasculitis may occur during the acute illness, beginning 5–9 days after the onset, even if adequate antibiotic treatment has been given. Nodules or bullae may be sparse and confined to the limbs, or may be more numerous and widespread; the lesions may ulcerate [6]. Arteritis and episcleritis may be associated. Similar vasculitic lesions occur in chronic septicaemic infection [7], in which milder maculopapular eruptions are also seen.

Diagnosis. The diagnosis is confirmed by isolation of *N. meningitidis* from blood or cerebrospinal fluid.

Treatment and prophylaxis [1,8]. Intravenous benzylpenicillin in high doses is the treatment of choice [9]. Chloramphenicol and cefotaxime are suitable alternatives.

Rifampicin for 2 days is recommended as prophylaxis for close family contacts, but does not eliminate the need for close clinical surveillance [8].

Gonococcal infection

Aetiology and pathology [1,2]. *Neisseria gonorrhoeae* is a Gram-negative, aerobic diplococcus. It causes gonorrhoea, one of the commonest and most important sexually transmitted diseases. The incidence in industrialized countries fell after the high levels of World War II, and rose during the 'sexual revolution' of the 1960s and 1970s. There were an estimated 2 million cases in the USA in 1983. The incidence is high among homosexual men. Prostitutes are an important source of the infection, especially in developing countries [2].

The incubation period is 2–5 days (1–14 days). Genital infection affects primarily the urethra in both sexes, but may spread especially in the female to para-urethral glands and cervix, and more deeply (pelvic inflammatory disease) to endometrium, fallopian tubes and peritoneum. Local spread may involve the skin. Anorectal and oropharyngeal infections may follow relevant sexual contact. Most cases of childhood gonorrhoea are sexually transmitted [3], although accidental inoculation may account for some cases. If a mother has genital infection at the time of delivery, gonococcal ophthalmia may occur in the neonate. In the adult, the conjunctivae may be infected by autoinoculation from the genitalia [4]. Primary cutaneous infection is discussed below. Asymptomatic infection of genitalia, pharynx and rectum is common.

Disseminated gonococcal infection, which may include cutaneous lesions, occurs in about 1–3% of cases, and usually involves strains that are resistant to the killing effect of host serum, but very sensitive to penicillin [5]. Histologically, the metastatic lesions show haemorrhage, thrombosis and vasculitis [6]. Diplococci may be detectable in the vessel wall and in the surrounding inflammatory infiltrate. Immunofluorescence may identify gonococcal antigen where Gram stain and culture are negative [7–9].

Clinical features. Gonococcal infection may be cutaneous, oral or disseminated and there may be local complications.

Primary cutaneous infection. Areas contaminated by the urethral, vaginal or rectal discharge may show multiple erosions, 0.5–2.0 cm in diameter, sharply marginated, rounded or oval but often ragged, with a light-red surface and a vivid, non-indurated areola. The erosions heal when the discharge ceases. Very rarely, there may be discrete pustules of the coronal sulcus. A gonococcal ulcer of the penis in a patient without urethritis is unusual [10] as is a chancriform primary infection of the female thigh [11].

Pustular primary lesions have been described on fingers, but in each case the skin had been injured prior to exposure [12,13]. Similarly, minor trauma from fetal monitoring electrodes is likely to have facilitated scalp infection with *N. gonorrhoeae* in offspring of infected mothers [4,14].

Primary oral infection [15]. Direct oral infection may occur alone or in association with genital infection. The clinical picture may be that of acute or chronic tonsillitis, or of gingivitis. Asymptomatic pharyngeal colonization is a well-recognized occasional finding, which responds poorly to antibiotic treatment but seems to clear spontaneously

within weeks. It does not apparently lead to mouth-to-mouth infection [16].

Local complications. Infection of Tyson's glands causes the development of firm, tender nodules on one or both sides of the fraenum. Ecthymatous lesions of the supra-pubic region have been reported in association with urethritis [17]. Infection of the median raphe of the penis presents as an indurated, red and sometimes tender ridge on the surface of the penis. Dorsal lymphangitis may lead to oedema of the penis. Infections of Littré's glands may be followed by abscess formation. An indurated nodule along the course of the urethra may discharge externally.

Infection of Bartholin's glands is the only local complication in the female which involves the skin. An acutely tender abscess up to 10 cm in diameter distends the labium (Chapter 68).

Disseminated gonococcal infection [2,5,9,18]. The usual features are pain and swelling in or around one or several joints, fever and chills, and skin lesions, although none of these is invariable. Mucosal infection is often asymptomatic, but a positive culture is usually obtained from the site of primary infection. The joint disease may be tenosynovitis, when blood cultures are commonly positive, but synovial fluid cultures negative; or suppurative arthritis, usually without skin lesions, in which synovial fluid cultures are often positive but blood cultures are negative. Fever is intermittent and may be high. The skin lesions, to which some authors apply the term septic gonococcal dermatitis [9], occur early in one or more crops, usually three or four, each of which consists of relatively few lesions, usually less than 20, scattered over the limbs. Initially there may be macules, papules or small vesicles with a red halo, but they soon develop into pustules or bullae, which may become haemorrhagic or necrotic. They heal after a few days and may leave small, superficial scars. Gonococci are only rarely cultured from the skin lesions. Erythema nodosum, erythema multiforme and urticaria have been described.

In the rare acute septicaemic forms, the patient is gravely ill, with high fever, and meningitis or endocarditis may occur. Skin lesions may be of the type described, but often take the form of non-specific transient erythema or purpura.

Diagnosis. In bacteraemic and septicaemic forms, certain clinical diagnosis is usually impossible. There is not always a history of genital infection. Genital foci should be sought and should be cultured repeatedly. The haemorrhagic vesicles are distinctive but not pathognomonic: they may also occur in septicaemia caused by the related *N. meningitidis* and *Acinetobacter* spp. and less often by other organisms. They may simulate *Varicella*, but they spare the scalp.

Gram stain and culture of exudate or secretion remain the essential methods. In the disseminated form, repeated blood cultures and culture of aspirated fluid from affected joints are required.

Other methods including immunological and molecular biological techniques are not universally applicable or available.

Treatment [19]. Effective drugs recorded in the past include certain penicillins, i.e. intramuscular aqueous procaine benzylpenicillin (procaine penicillin), or oral ampicillin or amoxicillin, all with oral probenecid; intravenous benzylpenicillin; ceftriaxone; cefoxitin; tetracycline; doxycycline; spectinomycin; and erythromycin. The choice of drug and regimen depended on the clinical condition, bacterial sensitivities, anticipated patient compliance, drug allergies and the coexistence of other suspected or confirmed diseases such as syphilis and chlamydial infection. However the more recent recommended single-dose regimens for gonorrhoea include ceftriaxone, cefixime, ciprofloxacin, ofloxacin, azithromycin or doxycycline [20].

Acinetobacter infection

The Gram-negative organisms *Mima* and *Herellea* are now renamed *Acinetobacter*. *Mima polymorpha* has become *Acinetobacter calcoaceticus* var. *Lwoffi* and *Herellea vaginicola* is *Acinetobacter calcoaceticus* var. *anitratus*. These closely related *Acinetobacter* organisms are found as members of the resident skin flora in the axilla and groin in about 20% of normal subjects and may occur in the toe webs and on drier sites [1–3]. They have been isolated from skin pustules and from cellulitis [4,5], but their main importance lies in their role as uncommon but undoubted opportunistic pathogens. *Acinetobacter* spp. have been found to cause septicaemia, meningitis, osteomyelitis, synovitis, burn sepsis and wound infections. In the very young and the very old particularly, the source of infection may be exogenous, but endogenous infection clearly occurs, and indwelling intravenous catheters are likely routes in septicaemia. Reports of summer peaks of infection due particularly to *A. calcoaceticus* var. *anitratus* suggest that increased sweating leading to higher carriage levels may be important [6].

The role of these organisms in primary skin infections is unclear, but as cutaneous bacteria capable of causing nosocomial infections and exhibiting multiresistance, *Acinetobacter* demand attention.

Moraxella infection

These organisms were previously grouped with *Mima* and *Herellea* spp. (now *Acinetobacter* spp.). They are now regarded as distinct. *Moraxella osloensis* has been reported as a cause of gonococcaemia-like systemic infection with skin lesions [1], and arthritis with skin lesions has been attributed to another *Moraxella* spp. [2]. These cases apart, *Moraxella* are more closely associated with conjunctival inflammation than cutaneous colonization or disease [3].

Chancroid

SYN. SOFT SORE; CHANCRE MOU

Definition. Chancroid is a venereal disease caused by *Haemophilus ducreyi*, a Gram-negative bacillus, forming short chains.

Aetiology. The disease is prevalent in Africa, the Far East and Central and South America in communities with low hygienic standards [1]. Although previously rare in western Europe and the North American continent, it has in recent years become much more common, for example in France, Holland, Greenland and North America [2,3]. It is, however, difficult to be certain of the true incidence of this disease, as isolation of *H. ducreyi* from classical cases often failed in the past. In many studies therefore there is no bacteriological confirmation of the diagnosis. There is general agreement that clinical infection is reported very much more commonly in men than women, but the existence of an asymptomatic carrier state is not proven [4]. Chancroid may affect prostitutes.

Pathology. There is a non-specific inflammatory infiltrate. Involvement of the walls of small blood vessels in the region leads to ulceration.

Clinical features [5–7]. After an incubation period of 5–8 days, ranging from 1 to several weeks, a small, red papule develops and rapidly becomes pustular and then ulcerated. The ulcer, usually rounded or oval, has a ragged, undermined edge, surrounded by a red, very vascular, areola. It is tender and sometimes painful, but not indurated, enlarges slowly and often gives rise to satellite ulcers; two to five in a cluster are quite often present. Multiple ulcers are commoner in women than men.

In the male, the prepuce, the balanopreputial fold or the shaft of the penis and in the female, the labia majora, the posterior commissure and the perianal region are the commonest sites of infection. Extragenital lesions, although rare, do occur.

The course is variable. Without treatment, the lesion may rarely disappear spontaneously in a few days. Usually it persists for some weeks and may be complicated by severe phimosis and even by gangrene, or by destructive ulceration from secondary fusospirochaetal infection. In about 50% of cases, even if the initial lesion has been transient, inguinal adenitis develops about a week after the appearance of the ulcer. The glands on one or both

sides are enlarged and tender and may suppurate leading to chronic draining lesions.

Diagnosis. The chancre of syphilis is indurated and painless, and develops after a longer incubation period, but clinical differentiation is not always easy, and mixed infections can occur. Herpes simplex may also coexist in genital lesions with *H. ducreyi* [8].

Haemophilus ducreyi may be identified in the form of chains of coccobacilli in smears from the ulcer, or preferably of pus from a bubo. Ideally it should be cultured on one of the modern selective media at 33°C in an atmosphere of high humidity [9]. Even if the organism is present, dark-ground examination for *Treponema pallidum* and serological tests for syphilis should be undertaken.

Treatment [10–12]. The main treatment for chancroid is erythromycin given over at least 7 days. Resistance to sulphonamides, tetracyclines and trimethoprim has been reported in several countries. Ceftriaxone or azithromycin are alternatives given as a single dose.

Salmonella infection

Aetiology. The *Salmonella* spp. are Gram-negative, motile bacilli, which are widely distributed parasites of mammals and birds. Some species, notably *S. typhi* and *S. paratyphi*, are primarily human pathogens; others are primarily pathogenic for other animals, but may infect humans. A third group is pathogenic only in animals other than humans. All are transmitted by contaminated food or water, with a portal of entry in the gastrointestinal tract.

The exanthematic cutaneous manifestations accompany active infection but metastatic abscesses may occur in carriers during periods of lowered resistance.

Veterinary surgeons handling infected cattle may develop skin lesions due to *S. dublin*. *S. typhimurium*, *S. abortus equi* and *S. saint-paul* have produced a similar clinical problem.

Clinical features [1–3]. Exanthematic eruptions are seen most frequently in untreated infections with *S. typhi*, and occur in about 50% of cases. The classical rose spots are crops of pink papules about 5 mm in diameter, each lasting for 3–5 days, and continuing to appear at irregular intervals from the end of the first week for 10–14 days. They are most numerous on the abdomen, chest and back. Exceptionally, vesicular or haemorrhagic rashes may be seen.

In infections with *S. paratyphi* B the eruption occurs less frequently but may be more extensive, involving the face and limbs as well as the trunk.

In *S. typhi*, *S. paratyphi* C and other *Salmonella* infections, for example *S. rostock*, single or multiple metastatic cutaneous and subcutaneous abscesses may develop [4,5].

Infections contracted by direct inoculation present as inflammatory nodules with central pustulation. In veterinary surgeons, forearm lesions may be small, inconspicuous papules or pustules, but larger painful nodules also occur. Malaise and fever are typically absent and spontaneous resolution within a few days is usual.

An ulcerative vulvitis or vulvovaginitis may rarely be the presenting symptom of *Salmonella* infection [1].

Diagnosis. The diagnosis of systemic infections must be established by culture from faeces or blood, or occasionally from the skin lesions, and confirmed by a rising antibody titre. The organism may be isolated directly from lesions contracted by inoculation. In such cases, the antibody titre does not rise.

Treatment [6]. Chloramphenicol remains an effective treatment for many systemic infections, but ampicillin, cotrimoxazole, cefotaxime and ciprofloxacin are also useful drugs for treating carrier states and cases of chloramphenicol resistance. Unfortunately, these are becoming increasingly common and in many cases it is advisable to use a quinolone such as ciprofloxacin or ofloxacin.

Pseudomonas infection

Aetiology and pathology [1–3]. *Pseudomonas aeruginosa* (*P. pyocyanea*; *Bacillus pyocyaneus*) is an aerobic, Gram-negative rod, which occurs only as a transient member of the skin flora, mainly in the anogenital region, axillae and external ear, and is normally kept in check by the dominant Gram-positive cocci. It occurs in soil and water and is present in the intestine of a small percentage of adults and a high proportion of infants. It readily colonizes burns, ulcers or other moist skin lesions, and frequently contaminates bedpans, urine bottles, polythene sheeting and the hands of nurses in wards in which such patients are treated. It is mainly a nosocomial pathogen. Jars of ointment may also be contaminated [4]. Systemic infections are seen frequently, largely as a result of medical practices, such as the increased use of antibiotics in a variety of patients and high-humidity environments in nursing the newborn [3]. There is some evidence that the numbers of cases may be declining slightly, but this infection is still common. In older children and adults, clinical infections occur mainly in patients with debilitating diseases. *Pseudomonas* infections are frequent in intensive therapy units, in neutropenic patients and as causes of nosocomial pneumonia.

However, the repeated application of bactericidal agents effective against the Gram-positive flora, or prolonged maceration as in the syndrome of tropical immersion foot, favours the establishment of *Pseudomonas* even in previously healthy adults [1], and clinical infections eventually develop in a large proportion.

Experimental superhydration of the skin for 7 days with water-soaked cotton pads produced a vesiculopustular rash from which *Pseudomonas* was isolated [5]. Epidemic outbreaks of a follicular rash in areas of skin covered by swimsuits have affected users of overcrowded, heated swimming pools.

Under experimental conditions, *Pseudomonas* is pathogenic only in massive dosage or in damaged tissue, a pattern of behaviour that parallels that observed in humans. *Pseudomonas* appears to play a part in modifying and perpetuating some paronychial infections [6]. It is commonly isolated from chronic leg ulcers and from many other persistently moist lesions, including chronic external otitis, and, although its presence may be clinically apparent, it is uncertain to what extent it is pathogenic under these conditions. It is believed to be capable of maintaining the inflammatory changes after other organisms have been eliminated.

Fig. 27.14 *Pseudomonas* infection of the foot. (Courtesy of St John's Institute of Dermatology, London, UK.)

Typical strains produce two pigments, the blue-green pyocyanin, a phenazine derivative, and a greenish yellow pyoverdin.

Other species of *Pseudomonas* are sometimes of clinical significance. *P. cepacia* has caused lesions of the toe webs in troops training in swamp conditions [7]. The same species caused endocarditis and gangrenous ecthyma in a heroin addict [8]. This organism has now been transferred to another genus, *Burkholderia cepacia*.

Clinical features [9,10]. The commonest local infection in infancy is periumbilical, with a foul-smelling, bluish green discharge and spreading erythema. In some cases, usually under conditions of high humidity, widely scattered pustules may break down to form necrotic ulcers. Perionychial pustules may be accompanied by green discoloration of the nails. Involvement of the lips and cheeks may be followed by progressive gangrene. Sometimes, in the severely ill or in compromised neutropenic patients, primary cutaneous invasion with extensive necrosis may develop around a local erosion [11].

Inhibition of the Gram-positive flora or dermatophytes by maceration or antibiotics allows the development of a distinctive *Pseudomonas* infection of the toe webs [1] (Fig. 27.14), also called tropical immersion foot, characterized by sharply demarcated maceration, sometimes tinged with green, and showing green fluorescence under Wood's light. The sodden plaque tends to break down and secondary invasion by *Candida* may follow [7].

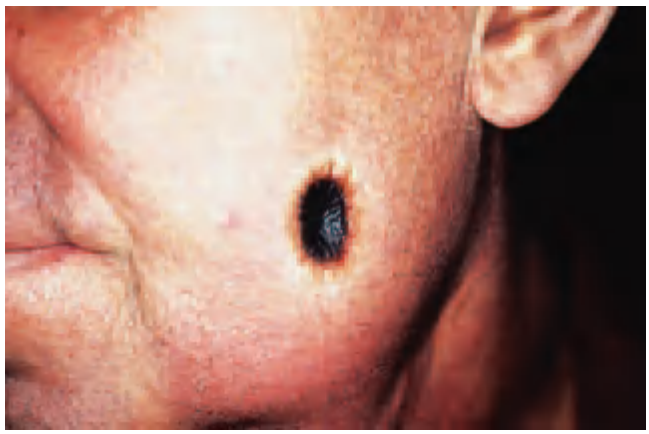

Fig. 27.15 Ecthyma gangrenosum. (Courtesy of Dr G. Scott, University College Hospital, London, UK.)

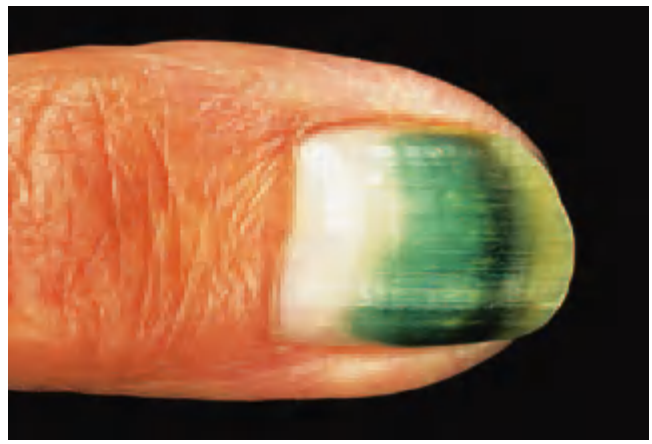

Fig. 27.16 *Pseudomonas* infection of the nail. (Courtesy of St John's Institute of Dermatology, London, UK.)

Pseudomonas can also invade superficial wounds, particularly burns [12]. This complication still carries a high mortality as large quantities of these organisms may thrive in burn eschar, and secondary septicaemia may result. Secondarily infected burns show discoloration of the slough with extensive surrounding oedema. Fever and shock may supervene.

Gram-negative folliculitis seen in swimming pool users is now a well-documented entity [13,14]. It may include macular, papular or pustular lesions. Some are urticarial, suggesting insect bites. Any part of the body that has been immersed may be affected but often the worst areas are those in contact with bathing costumes. In most cases, the rash settles spontaneously within 7–10 days in the absence of re-exposure. Hot tubs and whirlpools have also been associated, although changes to their outflow drainage has reduced this hazard. *Pseudomonas*, usually of serotype II, may be cultured from the skin and the infected water.

Pseudomonas septicaemia most commonly occurs in the severely compromised host [15]. Usually there are no skin lesions, but in a minority of patients the skin is affected and in a variety of ways. There may be non-specific erythema, which can be tender or spontaneously painful [16], purpura, or a cellulitis-like picture. Bullae may form, particularly in moist areas, such as the axillae, perineum and the buttocks. These may rapidly rupture to give necrotic ulcers—ecthyma gangrenosum (Fig. 27.15).

In elderly diabetics and neutropenic patients, the *Pseudomonas* is sometimes associated with a serious necrotic infection of the external ear known as malignant external otitis [17]. *Pseudomonas* spp. have also been implicated in severe exacerbations of acne vulgaris [18]. The presence of *Pseudomonas* spp. beneath nails with onycholysis gives rise to characteristic green discoloration (Fig. 27.16).

The prognosis of systemic infections is always grave, even with early treatment. Local infections in infants or patients with debilitating illnesses should be regarded as potentially dangerous, for systemic extension occurs readily. The invasion of damaged skin in the otherwise normal subject may be difficult to control permanently until the lesions are healed, but has no serious significance.

Diagnosis. Bacteriological confirmation of the diagnosis is readily obtained by cultures from the skin lesions or blood. The significance of the isolation of *Pseudomonas* from non-specific lesions must be carefully evaluated on the clinical findings.

Treatment. Superficial lesions respond best if drying out is possible. One per cent acetic acid compresses, potassium permanganate soaks and silver sulfadiazine cream may be of value, but topical antibiotics (e.g. polymyxin) are generally disappointing.

In the case of burns, extensive debridement followed by topical applications of silver sulfadiazine therapy is useful, although in some cases carbenicillin can also be used. In every case where antibiotics are contemplated it is important to base therapy on the results of *in vitro* sensitivity tests.

In septicaemia or where a severely compromised patient has superficial infection, systemic therapy using intravenous antibiotics should be started promptly under a bacteriologist's guidance. Ciprofloxacin, gentamicin, piperacillin, azlocillin, tobramycin and amikacin as well as ceftazidime may be used in appropriate combinations [19].

Melioidosis

Definition and aetiology [1,2]. *Pseudomonas pseudomallei*, the causative organism, is a saprophytic bacterium, which may be isolated from soil and water in low-lying rice-growing regions of the Far East, particularly northern Thailand. It also occurs in Central and South America, Australia, the West Indies and Madagascar [3]. Although wild and domestic animals may become infected, it is no longer thought that animals form an important natural reservoir of infection. Transmission in humans is thought to follow environmental contamination of a minor injury. In humans, *P. pseudomallei* typically causes a severe glanders-like illness, which may be fatal, but serological evidence and retrospective enquiries suggest that mild febrile illnesses and subclinical infections occur in human subjects and probably in animals [1]. Other rare modes of transmission include inhalation or ingestion; the incubation period is very variable.

Clinical features [2,4]. The disease may run an acute, subacute or chronic course. The acute form with fever, prostration, gastroenteritis and pneumonia may be fatal within 2–4 days, but acute pulmonary infection due to *P. pseudomallei* is the commonest clinical manifestation of the illness. Septicaemia may complicate pneumonitis or appear without localizing signs elsewhere.

Many cases are subacute and last from one to many weeks. If the initial lesion is cutaneous, local abscess formation is rapidly followed by lymphangitis, lymphadenitis and septicaemia; characteristically multiple abscesses develop, subcutaneously, or in muscles, lung, liver and spleen. After infection by inhalation, pneumonic symptoms precede the septicaemic stage. In many cases, however, the clinical picture is variable, with unexplained fever and disseminated pyogenic lesions.

Chronic forms also occur: pulmonary symptoms and metastatic abscesses are most commonly seen, and in one such patient an associated severe urticaria cleared after treatment with tetracycline. Rarely, the infection remains limited to skin and regional lymph nodes, without systemic symptoms.

Diagnosis. The acute pneumonic and septicaemic forms can simulate tuberculosis, typhoid or staphylococcal infections. The diagnosis is established by isolating the organism or by detecting a rising antibody titre.

Treatment. A combination of high doses of tetracyclines and sulphonamides, supplemented by chloramphenicol in serious cases, should be continued until lesions have resolved. Alternatives include imipenem, piperacillin and cefotaxime. Abscesses require surgical drainage once antibiotic treatment is established. Resistance to some antibiotics including co-trimoxazole has been reported in some endemic areas [5], and where possible antibiotic sensitivities should be determined [6].

Glanders

SYN. FARCY; EQUINA

Definition [1,2]. Glanders is a specific infection of horses and donkeys by *Pseudomonas mallei*.

Aetiology. It is now extremely rare worldwide. No accurate figures for the present world incidence are available but the disease is still endemic in horses in parts of Asia

and South America. Humans are infected by direct contact with horses, the bacillus usually gaining entry through an abrasion or through the conjuctiva or nasal mucous membrane. Very rarely there may be no discernable portal of entry.

Pathology. *Pseudomonas mallei* gives rise to a local adenitis, followed by necrosis and abscess formation. The infection spreads by the regional lymphatics and by metastasis.

Clinical features [2]. Glanders may be an intensely acute, rapidly fatal disease or may run a chronic relapsing course over months or years. After an incubation period varying from a few days to 2 or 3 weeks, malaise, headache and fever accompany the development at the site of inoculation of an area of cellulitis, which soon breaks down to form an irregular ulcer with an offensive, haemorrhagic, purulent discharge. If the primary site is cutaneous, the regional lymphatics become swollen and tender, and dull-red nodules along their course break down to form abscesses and sinuses. If the nasal or oral mucous membrane is the site of inoculation, there is extensive necrosis and destruction of the septum and palate. After a variable interval—a few days or many weeks—metastatic lesions begin to appear: grouped, dull-red papules, pustules or bullae, especially over the joints and face, are followed by ulcers that enlarge and coalesce. Deep subcutaneous abscesses with multiple sinuses may also occur. The symptoms that accompany septicaemia are, as expected, rigors, headache and confusion. Chest X-ray appearances range from acute abscess formation to lobar infiltration.

At this stage of dissemination meningitis, pneumonia and polyarthritis may also develop.

Although some cases survive for long periods with intermittent bacteraemia with severe constitutional symptoms and metastatic manifestations, others are rapidly fatal and in general the mortality without treatment is very high.

Diagnosis. The different clinical variants may simulate sporotrichosis, acute pyogenic infections or gangrenous pyoderma. The diagnosis may be suspected on the history of contact with horses, in which, however, the infection may sometimes be clinically inapparent, but must be confirmed by isolation of the organisms and by serological tests.

Treatment [2,3]. There are few reports on the response of glanders to the newer antibiotics, but it responds to sulphonamides. It would seem advisable to combine sulphonamides with other antibiotics, perhaps tetracycline or chloramphenicol as is recommended in melioidosis. Alternatives which show potential promise in melioidosis are co-trimoxazole, ceftazidime and imipenem, although the latter has not been fully assessed in either condition.

Stenotrophomonas maltophilia infections [1]

Stenotrophomonas maltophilia, previously classified as a *Pseudomonas* spp., is the rare cause of opportunistic infection seen in intensive care settings or in neutropenic patients. It can cause pneumonia or septicaemia. However, in addition it can cause cellulitis, particularly around catheter insertion sites. It can also be isolated from wound infections. Sometimes the cutaneous lesions are nodular and accompany septicaemia.

Rhinoscleroma

SYN. SCLEROMA

Definition. Rhinoscleroma is a chronic, slowly progressive, potentially fatal, infectious and mildly contagious disease caused by the bacterium *Klebsiella rhinoscleromatis* (or *Klebsiella pneumoniae rhinoscleromatis*) that affects the upper and lower airways. It is originally localized in the nasal fossae, and invades the upper respiratory tract and lacrimal apparatus, where it produces an infiltrating granuloma with a marked tendency to sclerosis and subsequent obstruction. It is a condition difficult to cure.

Incidence [1]. The disease occurs sporadically almost all over the world and is endemic but rare in certain countries including Central, East and West Africa, and Central and South America and the USA. The disease is acquired by direct or indirect contact with the nasal exudate of an infected person. The infection occurs in both sexes at any age, but it is more frequent between the ages of 20 and 40 years. It is more common in rural areas where social and hygienic standards are low.

Aetiology [1]. Rhinoscleroma is caused by *K. rhinoscleromatis*. This bacillus measures about 3 μm in length. It appears isolated, in pairs, or even in short chains, and is encapsulated, non-motile and Gram-negative.

Koch's postulates were not fulfilled until 1961, when Steffen and Smith [2] injected the bacillus into the nasal cavity and intracranially in mice and produced a

pneumonia that in some cases became chronic and granulomatous.

Pathophysiology [3]. The disease probably begins at the junction between the stratified squamous epithelium of the vestibule and the respiratory epithelium of the nose. Most investigators agree that the mucopolysaccharide in the capsule of the bacterium may be responsible for most of the damage.

Histopathology [1]. The histopathological picture is pathognomonic. A dense infiltrate is observed consisting mainly of plasma cells and two types of highly characteristic cells, the association of which allows this process to be distinguished from other granulomas. These cells are the Mikulicz cell and the Russell body. The Mikulicz cell is a large, round, vacuolated histiocyte measuring 100–200 μm in diameter. With Giemsa or Gram staining, numerous bacilli (A granules) or amorphous clusters of mucopolysaccharide (B granules) can be observed within the cytoplasm.

The Russell body or colloid body, measuring 20–40 μm, is a structure in the cytoplasm of the plasma cells, elliptical in shape, homogeneous, and extremely eosinophilic, and as such stains bright red.

Polymorphonuclear leukocytes actively phagocytose the bacilli as they enter the nasal mucosa. These cells then degenerate, either disintegrating or being engulfed by histiocytes and Mikulicz cells present in the stroma. These findings suggest that, while inside the Mikulicz cells, the bacilli are protected from therapeutic products in the blood, and hence there is a need for long-term therapy to be active against the bacteria when they are released [4]. Scar formation may be prominent.

Clinical features [1,5]. The first manifestations are usually nasopharyngeal. Since the disease runs a very slow progressive course and the lesions are indolent, the patient tends to seek medical advice only when it has been present for several years, as general health is not impaired.

The disease progresses through three overlapping stages:

Exudative (catarrhal), rhinitic or atrophic stage. This begins with symptoms of a common cold. There is headache and difficulty in breathing, a foetid, purulent rhinorrhea of long duration (weeks or months), with scabs, dryness of the throat and occasional epistaxis (Table 27.4). Hypertrophy of the mucous membrane can be observed, especially on the septum.

Proliferative or granulomatous stage. First, there is the infiltrative period. As the symptoms of coryza begin to subside, infiltration and obstruction of the lower portion of the nasal fossae occur, with an exuberant, friable granulation tissue, crusting and induration, which later extends to the pharynx and larynx. At this time a change in the modulation and tone of the voice (hoarseness) is produced. Anaesthesia of the soft palate is frequent.

Table 27.4 Frequency of initial symptoms of rhinoscleroma, determined by review of literature.

Symptom	Frequency (%)
Nasal obstruction	94
Nasal deformity	32
Hoarseness	12
Epistaxis	11
Upper lip swelling	10
Sore throat	6
Epiphora	4

Table 27.5 Approximate frequency of sites involved in rhinoscleroma, determined by review of literature. (From Miller *et al*. [6].)

Site	Frequency (%)
Nose	95
Palate	31
Pharynx	18
Larynx	14
Upper lip	12
Paranasal sinuses	4
Lacrimal sac	4
Trachea	2
Orbit	1

Later on, the nodular period supervenes. From the initial localization in the septum, the disease may spread forward to invade the nasal lobule and the upper lip. Backward extension may produce laryngeal and tracheal involvement, obstruction of the respiratory tract (Table 27.5), loss of the senses of smell and taste, epistaxis and epiphora (affecting the lacrimal apparatus). Bony destruction and cervical node involvement can occur. Breathing becomes difficult and painful, and tracheotomy is sometimes necessary.

Fibrotic (sclerotic) stage. Clinical improvement occurs. The previously inflamed tissue is replaced by dense collagen. The healing process (spontaneous or after therapy) leads to anatomical distortion and stenosis of the structures affected during the proliferative stage [7].

Radiographic findings. These include non-specific paranasal sinus opacification, nasal turbinate atrophy, nasal mass with bone destruction, transglottic narrowing, vocal cord thickening, and discrete subglottic narrowing, which can be shown using plain radiography and computed tomography [8].

Laboratory findings [1]. The identification of the bacterium is not easy, and is based on its biochemical activity, which distinguishes it from other *Klebsiella* spp. However, *K. rhinoscleromatis* has a unique antigenic marker, 02K3, with 0 representing the smooth somatic antigen and K the capsular antigen. This antigenic marker allows immunological identification using the peroxidase–antiperoxidase immune complex method. Serological reactions, such as the complement-fixation test, agglutination test and intracutaneous test, are of doubtful value.

Diagnosis. The diagnosis is based on:
1 the clinical features—especially when the lesions are advanced or pronounced;
2 the characteristic histopathological picture;
3 the finding of Frisch bacilli, adequately identified bacteriologically;
4 complement-fixation tests, which give inconsistent results.

Differential diagnosis. Rhinoscleroma must be differentiated from other diseases involving the nasal fossae and upper respiratory tract. At the early stages, chronic bacterial rhinosinusitis and atrophic rhinitis should be considered. At the late stages, the following enter the differential diagnosis: mucocutaneous or American leishmaniasis, which is highly destructive but not as proliferative or obstructive as scleroma, and paracoccidioidomycosis, which affects especially the mucous membranes of the mouth and is accompanied by marked adenopathy and granulomatous lesions that bleed easily ('blackberry' stomatitis). Rhinosporidiosis presents with polyps in the form of soft masses with minute white spots that represent sporangia. Lethal midline (facial) granuloma, Wegener's granulomatosis and malignant epithelial tumours and sarcomas can be differentiated by their rapid evolution. Other diseases that must be considered are: tertiary syphilis with bone involvement, sarcoidosis, nasal tuberculosis, which produces atresia rather than destruction by proliferation, yaws, with its destructive form called gangosa and its proliferative osseous form called goundou, leprosy, lymphomas and nasal polyps.

Prognosis. This is essentially a chronic disease with a slowly progressive course. Relapses are frequent after apparent bacteriological cure. Involvement of trachea or bronchi inevitably worsens the prognosis. The disease is rarely associated with AIDS [9].

Treatment [10,11]. *Klebsiella rhinoscleromatis* may be sensitive to several antibiotics, including trimethoprim–sulfamethoxazole, streptomycin, tetracycline, chlortetracycline, triacetyl-oleandomycin, kanamycin, gentamicin, cephaloridine and rifampicin. It is advisable to determine the antibiotic sensitivity of each strain and to continue the treatment until bacteriological cure is obtained.

Tetracycline is one of the drugs of choice for long-term treatment, at a dose of 2 g/day, given in divided doses for 6 months, followed by 1 g/day for a similar period of time. In case of recurrence, cephalexin, at similar doses and duration, should be tried [6]. Ciprofloxacin, 250–500 mg twice a day with meticulous nasal lavage with saline twice a day for 4 weeks, has recently been advocated [12]. The local treatment of rhinoscleroma with nasal packs of a 2% aqueous solution of acriflavine (a mixture of 2,8-diamino-acridine and 2,8 diamino-10-methylacridinium chloride), continued for 8 weeks, has been reported as effective [11]. Trimethoprim–sulfamethoxazole, 160–800 mg twice a day (based always on *in vitro* sensitivity studies), and betamethasone sodium phosphate, 4 mg i.m. every 3 weeks for 6 months, have been used.

During the healing process, scarring affects the upper respiratory tract, the nose, pharynx and larynx [9]. In this inactive fibrotic stage, surgical treatment may be required to correct severe structural and functional abnormalities, such as the narrowing of the nasal vestibule, nasopharyngeal stenosis and laryngeal web formation [6]. Nasal endoscopic techniques and the carbon dioxide laser have been used for the treatment of the obstructive scars [9].

Tularaemia

Aetiology and pathology [1,2]. Tularaemia results from systemic infection with the Gram-negative bacteria, *Francisella tularensis*. Wild rodent or other small animal populations are probably the main reservoir of infection, which is transmitted to humans by the bites of ticks, usually species of *Dermacentor*, or of other arthropods, or by direct contact with infected rodents [2]. The epidemiological

pattern is extremely variable and infected food and water have sometimes been responsible for outbreaks in schools or camps. Most cases are sporadic. The disease is endemic in the northern hemisphere, including the USA and many parts of Europe apart from the UK. Sportsmen and women and campers are most exposed to infection, but cases have occurred in laboratory workers and in housewives.

Francisella tularensis is a pleomorphic, non-motile, Gram-negative coccobacillus, which produces a powerful endotoxin. It is a facultative intracellular parasite. Histologically, the rather variable tissue reaction consists largely of reticuloendothelial cells and monocytes with focal necrosis.

Clinical features [3,4]. The incubation period varies from 1 to 10 days. The clinical manifestations depend on the portal of entry: skin, eye, or respiratory or gastrointestinal tracts. Most sporadic cases are of the ulceroglandular, glandular or oculoglandular type. An ulcerated nodule at the point of inoculation is associated with enlargement and tenderness, and later with breakdown of the regional lymph nodes [3]. Systemic symptoms and toxaemia may be severe, but are often moderate, although pneumonia may occur. The typhoidal and pulmonary forms, which present with severe generalized or respiratory symptoms, respectively, run a more fulminating course.

During the toxaemic stage of all forms, cutaneous lesions may develop: a generalized eruption, maculopapular, or resembling erythema multiforme or profuse crops of nodules, usually on the limbs, may occur [3,5]. Nodular lesions resembling erythema nodosum have also been described.

Untreated, the course may be prolonged; the mortality of the typhoidal and pulmonary forms exceeds 30%, and that of the oculoglandular form is about 5%.

Diagnosis. The organism may be cultured from the primary lesion, the lymph nodes or gastric or pharyngeal washings. Specific agglutinins appear in the serum after about 10 days and increase in titre for some 4 weeks. Cross-agglutination with the *Brucella* antigen is a possible source of error. An enzyme-linked immunosorbent assay (ELISA) is available in some laboratories.

In differential diagnosis, cat scratch disease and sporotrichosis must be excluded, as must melioidosis and glanders.

Treatment [6]. Streptomycin 12-hourly i.m. in high doses (30–40 mg/kg body weight/day) for 3 days followed by half dosage for 3 days more, is recommended. Kanamycin and gentamicin are potentially useful alternatives [7]. Tetracycline controls symptoms but does not eradicate the organisms, and so relapses are frequent.

A live attenuated vaccine against tularaemia is available in some centres but it is usually restricted to laboratory workers at risk [8].

Pasteurella infection

Pasteurella multocida infection

Aetiology [1]. *Pasteurella multocida* is a small, Gram-negative bacillus widely distributed as a member of the normal flora of the respiratory tract or intestines of many domestic and wild animals, in which it may cause haemorrhagic septicaemia if the resistance of the host is low. The organism does not normally occur in humans, but may be demonstrable in the sputum of patients with bronchiectasis. Most human infections follow bites by cats, dogs or other animals, and scratch injuries (usually from cats) may also become infected.

Clinical features and diagnosis [1–3] (Fig. 27.17). Most lesions are on the hands, arms or lower legs. The clinical picture is influenced by the extent and depth of the bite. Redness and swelling around the wound may spread rapidly over a wide area and may break down to discharge greyish yellow haemorrhagic pus through one or more sinuses. In other cases, the inflammatory changes, often associated with great tenderness, remain localized to the edges of the wound. If the bite is deep, there may be osteomyelitis or synovitis. About 15% of patients, particularly those patients with internal disease affecting the abdominal cavity or lung, have no history of exposure to animals.

The diagnosis will be suggested by the history and is confirmed by the isolation of the slow-growing Gram-negative bacillus.

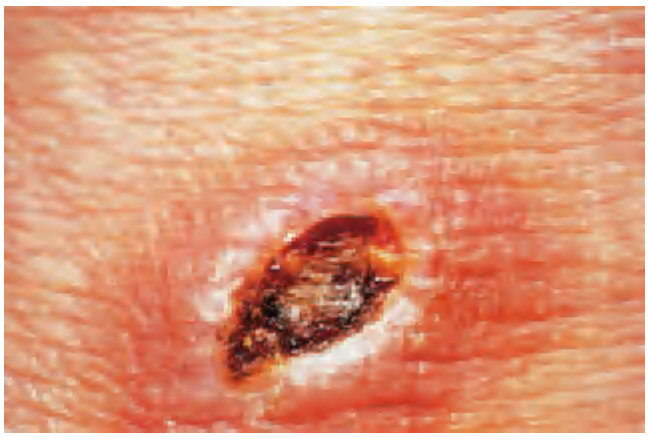

Fig. 27.17 *Pasteurella multocida* infection. (Courtesy of St John's Institute of Dermatology, London, UK.)

Treatment. The infection responds to penicillin, ampicillin and tetracyclines.

Other *Pasteurella* spp.

Other rare causes of animal-bite infections are other *Pasteurella* spp., such as *P. haemolytica*, *pneumotropica* and *ureae*. Their clinical manifestations are similar to those produced by *P. multocida* [4].

Plague and *Yersinia* infections

Aetiology and distribution. *Yersinia pestis* [1], the cause of plague, is a small, Gram-negative, non-sporing and non-motile bacillus. With Giemsa it shows characteristic bipolar staining. It is a zoonotic infection that affects a wide variety of rodents, but particularly the urban and domestic rats, *Rattus rattus* and *R. norvegicus*, and is conveyed from them to humans by the bites of fleas (patient-to-patient transfer rarely occurs in pneumonic plague), or humans may be infected after contact with contaminated material. Plague is endemic in parts of India and the Far East, and in Madagascar and Southern and Central Africa [2,3]. Sporadic outbreaks occur in North Africa and the Middle East and there are foci of infection in the USA [4]. Occasional cases are recognized elsewhere in travellers from the endemic areas. The incubation period is 3 or 4 days, but it may occasionally be over 7 days. Following inoculation of the organism by a flea bite, the regional lymph node becomes swollen (the classic bubo of bubonic plague), and systemic spread, typically with a severe febrile illness, develops, frequently leading to death within days. Lung involvement occurs in some cases, with sputum that is highly infectious. If *Y. pestis* is inhaled, it is likely to lead to primary pulmonary infection (pneumonic plague), which is almost invariably fatal within 3 or 4 days.

In plague epidemics, mild bubonic infections with no systemic spread and truly subclinical infections both occur. Conversely, a patient may rapidly die of flea-transmitted plague without ever developing a bubo. In some instances, cerebral symptoms may be severe.

Clinical (cutaneous) features [2,5]. Although typically there is no distinct lesion at the site of the initial flea bite, an erythematous plaque may appear, become bullous and then crusted like an anthrax lesion. Such primary cutaneous lesions may occur in 10% of patients. The bubo arises in the regional lymph nodes several days later. The bubo is a swollen lymph node that becomes acutely painful. During the bacteraemic phase, a macular, erythematous or petechial rash may develop, sometimes frankly purpuric (the black death). Necrotic lesions that closely resemble ecthyma gangrenosum may develop [5]. These are the result of vasculitis and occlusion of vessels with fibrin thrombi.

In a few cases, umbilicated vesicles or pustules are seen particularly over the trunk [3]. This atypical eruption has been a notable feature of certain epidemics and is generally associated with a high mortality. If bubos are excluded, cutaneous lesions probably occur in about 10% of cases in most epidemics.

Diagnosis. Despite the short incubation period, air travel may carry infected individuals to any part of the world. Even in endemic areas, sporadic cases are often misdiagnosed. The adenitis is the most characteristic feature. Aspiration of a bubo and direct examination of smears and culture confirm the diagnosis. The culture of blood and sputum should also be undertaken.

Treatment [6]. Streptomycin, tetracycline and chloramphenicol are all effective and are preferable to the traditional sulphonamides for pneumonic cases.

Yersinia enterocolitica infection

Yersinia enterocolitica is an important cause of a syndrome in which diarrhoea and pain similar to appendicitis occurs. In some reported cases there is polyarthritis, and a high proportion of patients, 30% in some series, also have erythema nodosum. Lesions appear from 2 to 20 days after the onset of abdominal symptoms [1].

Brucellosis

Aetiology and pathology. Brucellosis is a widespread infection of cattle and sheep, goats and pigs with *Brucella abortus*, *B. melitensis* and *B. suis*, respectively. Humans are infected by the ingestion of contaminated milk or milk products, or by direct contact with infected animals. The incidence is therefore highest in veterinary surgeons and farmers.

The organism—a Gram-negative, aerobic coccobacillus—colonizes the cells of the reticuloendothelial system and induces a granulomatous tissue response.

The histological changes in the skin lesions [1] are usually not distinctive, but there may be intense inflammatory changes around vessels showing gross intimal proliferation, and granuloma formation may occur.

Clinical features [2,3]. After an incubation period, which is usually between 5 and 30 days but may be longer, headache, backache and general malaise accompany the onset of an intermittent fever. Other symptoms, gastrointestinal or nervous, are variable. The lymph nodes and spleen are enlarged in about 50% of cases and the liver in about 25%. Skin lesions develop in about 10% but are not pathognomonic. Morbilliform, scarlatiniform and roseolar exanthems are described. Less often there may be papular, bullous or haemorrhagic lesions. Erythema multiforme-like nodules of the legs have also been reported [4,5].

The course of brucellosis is variable. The illness usually lasts for 3 or 4 months, but both acute fulminating and extremely chronic forms occur. In the latter there may be persistent infection of bone, gall bladder or other organs.

Contact brucellosis [3]. Veterinary surgeons, and others who are in frequent contact with infected animals, may develop a high degree of allergic sensitivity to *Brucella* antigens. Contact with the secretion of an infected animal, usually during delivery, gives rise to pruritus, erythema and wealing within a short time of contact, often followed within 48 h by a profuse eruption of fine follicular papules, many of which become vesicular or pustular, and heal in 10–14 days to leave small scars. Secondary eruptions of erythema multiforme type may develop remotely from the sites of contact.

The contamination of abrasions by *B. suis* may cause indolent ulcers [6].

Diagnosis. Systemic brucellosis can be reliably diagnosed by laboratory investigation only. There is usually no leukocytosis but there may be a relative lymphocytosis. Specific agglutinins in a titre over 1 : 100 must be regarded as suspicious and over 1 : 300 as diagnostic. Positive blood cultures can sometimes be obtained.

Treatment. The recommended course of treatment for brucellosis now includes doxycycline and rifampicin, both of which should be given for at least 6 weeks. Shorter periods of therapy are frequently followed by relapse. Co-trimoxazole is an alternative drug. However, both this and single drug regimens, such as tetracycline or streptomycin, are reported to have a 10–40% relapse rate [7]. An alternative combination regimen is streptomycin and tetracycline, and the use of oxytetracycline plus gentamicin for an initial period of 5 days has been successful in children over the age of 8 years. Other drugs such as ciprofloxacin are active *in vitro* against *Brucella* spp., but their clinical role has not been fully evaluated [8].

Infections due to *Bartonella* spp.

There has been a certain amount of taxonomic change about the position of species of the genus *Bartonella*, which were formerly classified as members of a distinct genus,

Rochalimea. Originally classified as Rickettsiae, they are now regarded as bacteria more closely related to *Brucella* than to other genera [1]. The human diseases associated with these organisms are trench fever due to *B. quintana*, bacillary angiomatosis (*B. henselae*, *B. quintana*) cat scratch disease (*B. henselae*) and Oroya fever (*B. bacilliformis*). Other newly decribed *Bartonella* spp. such as *B. elizabethae* have rarely been associated with human disease, for example bacteraemia.

Trench fever

Trench fever is caused by *Bartonella quintana*, which is transmitted to humans by the body louse [2]. It has been diagnosed in many different countries, usually under conditions where there have been very poor levels of hygiene. There is no known animal reservoir and it appears to be spread from person to person. After an incubation period of 5–38 days, there is a recurrent febrile illness. Most cases have a widespread maculopapular eruption, most prominent on the trunk, which fluctuates with the fever. The illness is usually mild with spontaneous recovery.

Cat scratch disease

This is a syndrome characterized by the development of peripheral lymphadenopathy after a cat scratch or bite. The causative agent is *Bartonella (Rochalimea) henselae* [3,4]. Patients with the syndrome usually have antibodies to this organism, which has also been isolated from lymph nodes. The same organism also causes a chronic form of bacteraemia in cats without any apparent ill effects.

Epidemiology [5,6]. The disease is worldwide and is most common in autumn and winter. It affects all ages, but mostly children and teenagers; 87% of 1200 cases were aged 18 years or under [6]. There is a history of cat contact, not necessarily prolonged or close, and of a local wound. In many cases it is believed that the cat is the source of the organism and the wound is the portal of entry. A scratch by a cat fulfils both requirements and is the commonest mode of infection. In a study of 1200 cases, it was found that while a bite or scratch from another animal may provide a route for infection, a feline source could nearly always be identified [6]. The cat is usually young but not ill. In only 3.5% of families was more than one member affected, and epidemics did not occur.

The diagnosis may easily be missed in mild cases, and subclinical infection may be frequent if skin-test surveys are valid, which give a 4% positive result in the general population, 18% in the families of patients and 23% in veterinary surgeons.

Pathology [6,7]. Both the primary lesions and the regional lymph nodes show characteristic, although non-specific, changes. In the early stages, there is focal reticulum-cell hyperplasia, which forms granulomas of sarcoid type. Later, there are microabscesses surrounded by a palisade of epithelioid cells and occasionally Langhans' giant cells.

The earlier a lymph node is biopsied, the greater the numbers of bacilli visible with the Warthin–Starry silver stain; they are usually undetectable by the time suppuration has occurred.

Clinical features [5,6]. Three to 5 days after the inoculating event, a papule (occasionally a group of papules) may form which progresses through vesicular and crusting stages in 2 or 3 days, and may ulcerate. This lesion may be inconspicuous, or may take several weeks to regress and then often leaves a superficial scar. Its identification is of diagnostic importance, and by diligent searching including examination of the scalp, ears and fingers, the inflammatory lesion or a residual scar can be found in over 90% of cases. About half are on the hands and arms and one-quarter on the head and neck.

Constitutional symptoms are usually mild, but fever is present in 60% of cases, persisting for a few days or 1 or 2 weeks. Illness lasting more than 2 weeks is uncommon [8].

Lymphadenopathy is present in all cases, and usually develops within 1 or 2 weeks of the initial papule, although it may not be noticed until later. The affected node is in the drainage path of the primary lesion but there is no lymphangitis. It is solitary in 85% of patients; two or three are seen occasionally. Uncommonly, bilateral lymphadenopathy is seen, but this can be explained by separate inoculations or a single one close to the midline. The glands are painful and tender and occasionally progress to suppuration and discharge before regressing in a period of weeks or months; persistent enlargement is uncommon. Recurrent lymphadenopathy is exceptional [8].

Primary inoculation of the eye, which does not require injury, causes a granulation, usually painless, and usually on the palpebral conjunctiva, followed by enlargement of the preauricular gland, constituting one of the forms of Parinaud's oculoglandular syndrome [9].

Unusual cutaneous manifestations include a maculopapular rash, urticaria, thrombocytopenic purpura, erythema nodosum, erythema multiforme and erythema marginatum; they appear to be more common among patients with severe or systemic disease [8].

Rarely, there may be systemic involvement [6,8,10] with arthritis, osteolytic lesions, intra-abdominal or intrathoracic lymphadenopathy, encephalopathy [11], myelitis [12], radiculitis, cerebral arteritis [13], pneumonia, pleurisy or granulomatous infection of liver [14] or spleen.

In the uncomplicated case, there may be a polymorphonuclear leukocytosis and a slight elevation of the sedimentation rate.

Cat scratch disease, even when accompanied by the more severe complications, is benign and self-limiting.

Diagnosis. Unilateral lymphadenitis is the usual presenting feature. A history of a cat scratch days or weeks previously resulting in a granulomatous nodule distal to the gland would immediately confirm the diagnosis, and the importance of actively seeking these two features has been emphasized [6]. If they are lacking, the clinical diagnosis is made by exclusion.

Primary tuberculosis, other mycobacterial infections, lymphogranuloma, pyogenic adenitis and sporotrichosis must be considered, and in the absence of a visible inoculation lesion, lymphoma or sarcoidosis must also be excluded.

Histochemical demonstration of the bacilli in the inoculation lesion or, more commonly by the time of presentation, in the lymph node, would confirm the diagnosis. However, the organisms are increasingly difficult to detect as the disease progresses. Otherwise, histology is not specific, and biopsy is not routinely recommended. Skin testing with cat scratch disease antigen made from pus from affected lymph nodes has its advocates [6] but is not generally advised.

Treatment [6]. Antibiotics are not effective, despite the fact that they are used with success in bacillary angiomatosis. Fluctuant glands may be aspirated, but should not be incised as chronic drainage may occur. Excision of lymph nodes is not justified therapeutically, although it may occasionally be indicated for histology.

Bacillary angiomatosis

Aetiology. Bacillary angiomatosis is an uncommon disease found in AIDS patients and occasionally other patients with severe immunosuppression [15]. It is characterized by the development of friable angiomatous papules and nodules. Two *Bartonella* spp. have been associated with this infection: *B. henselae* and *B. quintana* [16]. The appearance of these lesions follows a septicemia, which is usually mild and often passes unnoticed.

The disease has been described mostly from the USA although it is also seen in Europe. The infection is sporadic and there is not necessarily a history of exposure to cats or of skin injury. There are no known differences between infections caused by the two species of *Bartonella*.

Clinical manifestations. The lesions of bacillary angiomatosis are very variable [17]. They may be solitary or appear in crops. They may be small papules of dermal nodules. The more superficial lesions closely resemble pyogenic granulomas. They can involve any site including mucosal surfaces. Local lymphadenopathy is common. Very extensive lesions may cover parts of the face or trunk.

There is lobular proliferation of small blood vessels that contain swollen endothelial cells. These contain granular material, which consists of clumps of bacteria seen with the Warthin–Starry stain.

Complications include bacillary peliosis, where cyst-like inflammatory structures may develop in internal organs such as the liver. Again the endothelial cells lining these spaces contain large numbers of organisms.

Diagnosis. The diagnosis is made by the appearances of the typical lesions and the presence of large clusters of bacteria on Warthin–Starry staining. Cultures are not usually taken as they are technically difficult to process. However, polymerase chain reaction (PCR) is now increasingly used [18]. Lesions have to be distinguished from those of pyogenic granulomas, molluscum contagiosum, Kaposi's sarcoma and deep fungal infections disseminated to skin. They are also very similar to those of verruca peruana.

Treatment. There are no controlled studies of treatment of this condition, but doxycycline or erythromycin are usually given. It may be necessary to use long periods of treatment for 8 weeks or longer. Relapses are common.

Oroya fever and verruga peruana

SYN. CARRION'S DISEASE

Definition [19]. Oroya fever is an infectious disease transmitted by *Phlebotomus* spp. and caused by the small, rod-shaped organism *Bartonella bacilliformis*.

Aetiology. It is endemic in parts of Peru, and epidemics have occurred in neighbouring Latin American countries. In the endemic areas, most individuals are infected in childhood and acquire a permanent immunity.

Clinical features [20]. The incubation period is usually about 3 weeks but ranges from 2 to 6 weeks. Two forms of infection are recognized: Oroya fever and verruga peruana; these are now known to represent two stages of infection. In the first stage (Oroya fever) there is a sudden onset of pyrexia accompanied by a rapidly progressive haemolytic anaemia. Hepatosplenomegaly and generalized lymphadenopathy occur and a petechial or ecchymotic rash may develop. The mortality is high and many cases are accompanied by *Salmonella* septicaemia.

Verruga peruana may develop without previous Oroya fever, or may follow it weeks or months later. The eruption is composed of erythematous papules, which appear in crops and often become nodular or pedunculated. Some lesions become very large, others may be haemangiomatous or haemorrhagic. They are most numerous on the face, neck and limbs but may also involve mucous membranes. Mild constitutional symptoms and fever coexist in this form of infection, which may settle spontaneously. Lesions may persist for months or years. One

characteristic is that they may be present in different stages of evolution in the same patient [21].

Diagnosis. The diagnosis should be considered only if the patient has visited the endemic areas. Verruga peruana must be distinguished from yaws, acquired haemangiomas and Kaposi's sarcoma.

The biopsy appearances of verruca peruana show lesions containing numerous small blood vessels with endothelial proliferation. There is a variable infiltrate of chronic inflammatory cells and lesions heal with fibrosis [22].

In Oroya fever, the organism can be seen in blood films or isolated in blood cultures. Blood cultures are also positive during the active phase of the benign form, and in skin biopsies *B. bacilliformis* can be seen in the cytoplasm of endothelial cells.

Treatment. In Oroya fever, chloramphenicol 2 g/day for a week is the treatment of choice because of the frequent coexisting *Salmonella* infection, but *B. bacilliformis* itself responds to penicillin, tetracyclines and streptomycin. In verruca peruana, response to antibiotics is unsatisfactory; most lesions evolve and eventually settle uninfluenced by treatment.

Ehrlichiosis

Ehrlichia spp. are small, Gram-negative bacteria. They form clusters of intracellular inclusion bodies known as morulae. Formerly associated predominantly with veterinary infection, a human form of the disease has been recognized more recently as a tick-borne zoonosis. A number of different species have been recognized in humans, although *E. chaffeensis* and *E. sennetsu* are most commonly involved. Most cases have been described from the USA [1], although patients with this infection have been recognized in Europe. In the USA, the distribution of the dog tick, *Dermacentor variabilis* and the Lone Star tick, *Amblyomma americanum*, coincide with the distribution of human cases. The main target cell for these bacteria are macrophages.

The median incubation period is 7 days and patients generally present with fever, malaise, headache and myalgia. Over 30% of patients have a diffuse maculopapular rash and in some this becomes petechial [2].

Leukopenia and thrombocytopenia may develop. *Ehrlichia sennetsu* infections that occur rarely in the Far East are similar in presentation, although rashes are uncommon [3].

The diagnosis is difficult as cultural techniques are complicated and a serological assay using immunofluorescence is employed instead. The clinical history is also important. It is important to distinguish erhlichosis from Rocky mountain spotted fever in which more patients develop a rash.

Treatment depends on the use of tetracycline or doxycycline.

Other Gram-negative bacilli

On occasions, other Gram-negative bacteria have been associated with skin disease. *Actinobacillus actinomycetemcomitans* is frequently isolated from lesions of actinomycosis along with the usual *Actinomycete* cause, giving rise to the view that it is involved in the pathogenesis of this condition [1].

The aeromonads may occasionally cause cellulitis. These bacteria are inhabitants of water and cause infections in fish and reptiles. Cellulitis or necrotizing fasciitis caused by *Aeromonas* spp. is rare, but may follow contamination of a wound in contact with fresh water [2]. It may also occur in immunocompromised patients. *Aeromonas hydrophila* is sensitive to co-trimoxazole and chloramphenicol, but usually resistant to ampicillin and other penicillins. Cellulitis can spread rapidly and may involve muscle tissue or periosteum unless treated promptly [3].

Members of the bacterial group known as dysgonic fermenters (DF), such as DF-2, may also cause severe skin lesions. These organisms are Gram-negative rods that grow poorly on most cultural media. They are thought to be zoonotic in origin, and have been isolated from the oral cavity of dogs. DF-2 causes infections in patients who have undergone splenectomy or have other predisposing conditions, where it causes an acute septicaemic illness. More indolent infections including cellulitis are seen in otherwise healthy patients [4]. However, septicaemia may also develop in this group. Eugonic fermenters (EF agents) have also been isolated from dog bites.

Eikenella corrodens, an anaerobic, Gram-negative bacillus, may cause abscesses of the skin in intravenous drug abusers. It has also been isolated from wounds caused by human bites [5].

Vibrio vulnificus infections

Certain non-cholera vibrios have been found to cause severe cellulitis. *Vibrio vulnificus* is the best known of these organisms. It is found in warm sea-water areas such as around the gulf of Mexico, South America, Asia and Australia and may invade via the gastrointestinal tract, for instance, after eating raw oysters, or contaminate superficial wounds [1,2]. In predisposed patients, such as those with diabetes or chronic liver disease, and occasionally in the otherwise healthy, it may cause a septicaemic illness of rapid onset. A characteristic is the appearance, in almost two-thirds of patients, of erythema and haemorrhagic bullae or vesicles which progress to ulceration. Systemic signs include hypotension and rigors leading to multiorgan failure. The infection is often rapidly progressive and fatal. Alternatively, it may cause cellulitis, necrotizing fasciitis and ulceration after infection of a skin wound, which may then progress to septicaemia [3]. Direct Gram stains of smears will show curved Gram-negative bacilli. The main treatment is large doses of ceftazidime, ciprofloxacin or tetracycline and surgical debridement where necessary.

Anaerobic bacteria

Anaerobic bacteria are organisms that cannot grow on a solid surface in the presence of oxygen. They can be divided into those that are strict anaerobes, such as *Treponema* spp., and the moderate anaerobes such as *Bacteroides fragilis*. They include both Gram-positive (e.g. *Propionibacterium* spp.) and -negative (e.g. *Bacteroides* spp.) organisms and certain spiral bacteria. Most of the bacteria considered in this section are Gram-negative.

The family Bacteroidaceae consists of Gram-negative, rod-shaped bacilli with rounded or pointed ends. Some are fusiform. They are non-motile, do not form spores and are strict anaerobes [1]. Within the family are four genera: *Bacteroides*, *Prevotella*, *Porphyromonas* and *Fusobacterium*. These include the *Bacteroides fragilis* group, many of which are gastrointestinal tract commensals. The *Prevotella* spp. includes the organisms formerly known as *B. melanogenicus* and *B. oralis*, now *P. melanogenica* and *P. oralis*, respectively. The different genera can be classified according to nutritional requirements, pigmentation and morphology. Classification within the genus, *Fusobacterium* spindle-shaped bacilli, is unsatisfactory and, although a few species have been clearly defined, many isolates of commensal fusiform bacteria from animals and humans cannot be reliably identified as named species. *Fusobacterium necrophorum*, the cause of calf diphtheria and a variety of human infections, and *F. nucleatum*, a member of the

normal flora of the human mouth with a pathogenic capacity, are well-characterized exceptions. A newly described species, *F. ulcerans*, has been isolated exclusively from tropical ulcers and contaminated mud from endemic areas.

Leptotrichia buccalis is the single species recognized in the *Leptotrichia* genus. It is a long, rod-shaped organism with pointed ends, not truly spindle-shaped, and sometimes forming lengths of separate filaments. *Leptotrichia buccalis* is possibly synonymous with Vincent's fusiform organism, and therefore should not be labelled a *Fusobacterium* spp. It is an oral commensal in humans.

Bacteroides spp. are now recognized as common causes of Gram-negative bacteraemia and of abscesses. They are occasionally important in suppurative hidradenitis and in infected pilar cysts. Their role in decubitus ulcers is unclear but their frequent presence is not in doubt. Mixed infections are characteristic of this group of bacteria. In diabetic ulcers, in particular, *Bacteroides* spp. may be isolated and appear to be contributing to the clinical condition [2].

Prevotella infections dominate in intraoral infections including piorrhoea and Ludwig's angina. In many cases they may act in concert with other bacteria.

Fusobacterium organisms, although a well-known cause of infections in animals, are less often isolated today from human pathological material. In the past, *F. necrophorum* was regarded as an uncommon but important human pathogen among those in contact with animals. The term necrobacillosis was applied to such infections, characterized as they were by necrosis and abscess formation. *Fusobacterium nucleatum* can be found in severe intraoral infections.

In common with many anaerobic bacteria, fusibacteria appear to synergize with other organisms, including spiral bacteria, to produce disease. They have been implicated in the pathogenesis of cancrum oris (noma) as well as tropical ulcer (*F. ulcerans*), where the production of butyric acid by these organisms contributes to tissue necrosis.

Clinical manifestations. This group of organisms are important causes of a variety of infections from sinusitis and oral abscesses to endocarditis. *Bacteroides*, *Prevotella* and *Porphyromonas* spp. may also cause abscesses below the waist area. They have also been associated with other severe cutaneous infections such as necrotizing subcutaneous infection (see below).

Treatment. Treatment of anaerobic Gram-negative infections is largely empirical, and testing the organisms for sensitivity is difficult. The choice of drugs includes metronidazole, clindamycin, imipenem and amoxicillin–clavanulate. However, advice should be sought before selecting therapy.

Tropical ulcer

SYN. TROPICAL PHAGEDENIC ULCER; TROPICAL PHAGEDENA

Aetiology. Tropical ulcer is a synergistic bacterial infection that follows invasion of the skin by at least two organisms, one of which is a *Fusobacterium* spp., usually *F. ulcerans*; the others include spirochaetes or other anaerobic bacteria [1,2]. It occurs very commonly throughout the hot and humid tropical regions, in some of which, for example northern Papua New Guinea [3], it is the commonest skin disease. It has acquired in different parts of the world numerous local names, but there are few minor differences in its clinical features and course.

There is no clear evidence that host-predisposing factors play a part in the pathogenesis of this condition. Previously, malnutrition was thought to be critical to the development of tropical ulcers, but it is likely that social factors such as overcrowding are equally important. Recent studies have not shown a correlation between nutritional indices and the development of tropical ulcer [4], although the possible role of deficiencies in micronutrients is unknown. Zinc therapy, however, does not appear to hasten healing of lesions [5].

There is now considerable evidence to suggest that this disease is an infection [6]. The condition has been shown to be transmissible by inoculation of material from affected patients [7]. Recently, the appearance of early ulcers and preulcerative papules has been correlated with the isolation of *F. ulcerans*, a fusobacterial species unique to tropical ulcers [1]. Other anaerobes are also sometimes isolated, and a consistent feature is the presence of spiral bacteria, which have not been isolated in culture but which have the ultrastructural features of *Treponema* spp. In late-stage ulcers, other bacteria including many aerobes such as *Staphylococcus aureus* can be found in tropical ulcers. *Fusobacterium ulcerans* causes destruction of tissue-culture cells and can synergize with other bacteria to cause destructive skin lesions in experimentally infected animals [1]. It is likely therefore that the infection is a synergistic anaerobic infection confined to parts of the humid tropics. While the reservoir of *F. ulcerans* is not known, it has been isolated from mud and stagnant water in endemic areas [8].

Clinical features (Fig. 27.18). Most tropical ulcers develop at a site of potential trauma, a scratch, cut or insect bite,

Fig. 27.18 Tropical ulcer. (Courtesy of St John's Institute of Dermatology, London, UK.)

and are therefore commonest on the lower legs and on the unshod foot. They are not unusual on the arms, and may occur anywhere. Ulcers developing in skin that was apparently previously healthy begin as a small papule or bulla, which may be haemorrhagic, and which soon breaks down rapidly to form a sharply defined ulcer, with a slightly indurated edge that may be undermined. An important feature is the rapid breakdown of the preulcerative papule to form a tropical ulcer [8].

The floor is covered by a foul-smelling, greyish, purulent slough. Pain is usual, and there may be fever and constitutional symptoms. There is usually no regional adenitis. If the lesion is treated promptly, even with careful dressing, the spread is limited to a lesion 2–4 cm in diameter, which heals slowly. In about 4–15% of cases, depending to some extent on the availability of primary health care, chronic ulcers may form and may involve deep structures such as tendons and periosteum [8]. Squamous epithelioma develops after 10 years or more in some such cases.

Diagnosis. While pleomorphic fusiform and spiral bacteria are important pathogenic organisms, their presence or absence is not diagnostic and their isolation in culture impracticable. The mainstays of diagnosis are the rapid onset of lesions, their clinical appearance and the clustering of cases in the locality. In endemic areas, the main differential diagnosis is between yaws, leishmaniasis, ecthyma and mycobacterial ulcers. Sores due to infected skin lesions are more indolent and smaller in size.

Treatment. Rest, elevation of the limb and adequate diet are of great importance. Any underlying chronic disease should be treated. During the early stages of the disease, penicillin or metronidazole are recommended, combined with bland local applications, and a plaster boot may be helpful in allowing early ambulation when infection has been controlled.

Early grafting has been very successful in the rapid treatment of tropical ulcers, but it is dependent on the availability of the necessary expertise and patient compliance [3].

Granuloma inguinale

SYN. GRANULOMA VENEREUM; DONOVANOSIS; ULCERATING GRANULOMA OF THE PUDENDA

Definition. Terminological confusion with the chlamydial disease lymphogranuloma inguinale must be avoided. Granuloma inguinale is a chronic granulomatous infection of the genitalia and surrounding skin caused by *Calymmatobacterium granulomatis*, formerly known as *Donovania granulomatis*. This organism has not been isolated in pure culture and therefore its taxonomic status is uncertain.

Aetiology [1]. Granuloma inguinale is widespread in the tropics and subtropics, but in most areas is relatively uncommon. It is mainly seen in Africa, South America, the Caribbean and New Guinea. Cases are rare outside these areas. In some countries, males are more frequently affected than females, but in others, such as Brazil, the disease is commoner in women. Venereal transmission, although almost certain, is not entirely proven, and infectivity is undoubtedly low. Most patients are young adults, and homosexual men are said to be more frequently infected, suggesting perhaps that the gastrointestinal tract is the natural habitat of this organism.

Calymmatobacterium granulomatis is a small, pleomorphic, non-motile, Gram-negative bacillus showing bipolar staining. It is fastidious and must be isolated on the yolk sac of the chick embryo, although it may subsequently be grown on media containing egg yolk. In tissue scrapings stained by Wright's method, *C. granulomatis* may be seen within characteristic large mononuclear cells as Donovan

bodies. *Calymmatobacterium granulomatis* cross-reacts serologically with *Klebsiella rhinoscleromatis*.

Pathology. The histological changes are not specific. In the inflammatory reaction that infiltrates the cutis and subcutis, plasma cells and polymorphonuclear leukocytes predominate. There are also some lymphocytes and large mononuclear cells containing Donovan bodies [2]. In chronic lesions, fibrosis and epithelial hyperplasia are also present to a variable degree.

Clinical features [3,4]. The incubation period, which is not always easy to determine, is probably 9–50 days. The earliest lesion is a firm papule or nodule, which breaks down to form an ulcer with a sharply defined, overhanging edge. The ulcer is not painful and there is no adenitis.

The lesion subsequently evolves in a variety of ways, dependent on the balance between healing and destruction and the degree of epithelial hyperplasia.

Deep and rapidly extending ulceration is seen mainly in women. Serpiginous extension with or without vegetative epithelial changes occurs in the groins and other flexures.

The initial lesion is usually on the pubis, the genitalia, the perineum, the groins or the perianal region. While clinically it may appear that the lymph nodes in the groins are enlarged; this is usually caused by a subcutaneous granuloma, which may subsequently undergo necrosis. Rectal lesions have also been described.

In 3–6% of cases [5], the lesion is extragenital, occurring especially on the face, where it favours the nose and lips, but it sometimes occurs on the limbs.

Healing may occur at any stage, or slow or rapid extension may continue intermittently and irregularly for years. Secondary infection may be severe and may lead to adenitis. Temporary remissions may be followed by recrudescences, which may occur in healed scars. When the lesions are extensive, cachexia may, after a long course of many years, predispose to death from intercurrent infection.

In some patients, usually women, metastatic involvement of liver, spleen and bones may occur.

Diagnosis. In the early lesions, syphilis must be excluded by dark-ground examination and serology, and at all stages the possibility of associated syphilitic infection must be remembered.

Smears should be taken and searched for Donovan bodies. It is convenient to take the smear from part of a biopsy from the edge of the lesion, the remainder of the specimen being examined histologically. This organism cannot be cultured.

Treatment [6]. The tetracyclines, erythromycin, streptomycin, azithromycin, gentamicin and chloramphenicol are all effective. Tetracycline must be given in a dose of 500 mg four times a day for 10–20 days. Minocycline or doxycycline may also be used. Resistance of the organism to tetracycline, although previously unknown, was reported in a single case in 1973. The most effective of the current drugs is probably azithromycin, which has the added advantage of being active against other sexually transmitted bacteria such as *Treponema pallidum* and *Haemophilus ducreyi* [7].

Spirochaetes and spiral bacteria

Spirochaetes are long, flexible, spiral organisms, motile but without external flagella. Many exist in nature in aquatic habitats [1,2]. Three genera include important human pathogens and commensals: *Treponema*, *Borrelia* and *Leptospira*. *Treponema pallidum* causes syphilis; *T. pertenue* causes yaws; *T. carateum* causes pinta (Chapter 30). *Borrelia recurrentis* causes louse-borne relapsing fever; *B. duttoni* and other species cause tick-borne relapsing fever; *B. burgdorferi* is the name for the *Ixodes dammini*-associated spirochaete, the cause of Lyme arthritis with associated erythema chronicum migrans. *Leptospira interrogans* complex causes leptospirosis including Weil's disease. Commensal spirochaetes occur in the mouth (*T. microdentium* and *T. macrodentium*) and around the genitalia (*T. refringens*), as well as in the intestine. They appear to have no pathogenic potential but they are important as they may be confused with *T. pallidum*, from which they differ morphologically.

Spirillium minor, the cause of one form of rat-bite fever, is a spiral bacterium which is short, rigid and has bipolar flagella.

Relapsing fever

Aetiology. There are two forms of this disease: louse-borne or epidemic relapsing fever due to *Borrelia recurrentis*, for which the human body louse is the vector, and tick-borne endemic relapsing fever caused by various species of *Borrelia*, for example, *B. duttoni* and *B. hermsi*. The louse-borne epidemic form is found in Ethiopia, the Sudan, other parts of Africa and the Far East, while the milder sporadic tick-borne cases occur worldwide [1,2].

Clinical features [1,3]. The very variable symptom complex develops after an incubation period of about a week. High fever, headache, myalgia, vomiting and respiratory symptoms usher in the acute attack. Jaundice and hepatosplenomegaly with liver tenderness are common, and a petechial or purpuric rash, predominantly on the trunk, is found in up to 60% of patients. A remission occurs after a few days, to be followed by a relapse, and this pattern may continue for weeks. The cutaneous eruption does not, however, recur after the initial episode.

Diagnosis. Diagnosis is best confirmed by demonstration of the spirochaete in blood films using stained preparation or dark-ground illumination.

Treatment. The usual treatment is either tetracycline or erythromycin. Penicillin is an alternative. In the case of louse-borne infections, this is given as a single dose, for example, 0.5 g tetracycline [4]. Because treatment failures are more frequent in the tick-borne group, the course of therapy is usually prolonged, for instance, by giving 6-hourly treatment for up to 10 days. A severe reaction similar to the Jarisch–Herxheimer reaction is very common at the outset of treatment, particularly in louse-borne relapsing fever treated with penicillin [5].

Borrelia burgdorferi and Lyme disease

Definition. *Borrelia burgdorferi* is a spirochaete transmitted to humans by tick bites. The resulting clinical conditions are encompassed in the term Lyme disease (or Lyme borreliosis), named after the town of Lyme in Connecticut, USA, where the disease was first recognized in 1977. The characteristic eruption, erythema chronicum migrans (ECM), at the site of inoculation, is a common early manifestation, and dissemination of the infection may cause disease of the nervous system, heart and joints, in addition to other dermatoses. Differences in the disease spectrum in different geographical areas have been noted, and may be due to variation within the bacterial species [1] or to differences in diagnostic criteria and treatment practices [2].

Aetiology [1]. The principal vector of *B. burgdorferi* infection is the *Ixodes* tick, different species of which predominate in different parts of the world, their distribution corresponding to that of Lyme disease. Patients usually live close to, or have visited, woodland areas, where small mammals are necessary hosts for immature stages in the life cycle of the tick. Adult ticks may infest larger mammals, especially deer.

Lyme disease has been reported in most parts of the world but especially in the USA, where it is the commonest vector-borne infection, and in Europe, particularly in Scandinavia and central Europe. All ages and both sexes are affected. High rates of infection have occurred in areas in which the tick had recently become established in high numbers [3]. In contrast, 10 of 40 agricultural workers, with long-standing high exposure to tick bites, had positive *B. burgdorferi* serology, but Lyme disease was infrequent and mild in this group, a possible interpretation being that frequent tick bites may confer a degree of immunity [4].

Infection may occur at any time of year. Young nymphal ticks feed in early summer, when there is a marked peak in incidence of acquisition of human Lyme disease. The smaller autumn peak noted in some studies is associated with bites from adult ticks [3,5]. Deer, in particular, appear to harbour the infection in endemic areas.

After *B. burgdorferi* infection, specific antibodies are produced, but if the patient is treated early in the course of the disease, antibodies may disappear within a period of months and reinfection may occur.

Clinical features [1,6–9]. Of patients ultimately diagnosed as having Lyme disease, about 50% recall a tick bite; a bite by the autumn and winter feeding adult tick is more likely to be noticed than a bite by the summer feeding nymphs. About 90% develop ECM at the site of inoculation (Fig. 27.19). The eruption appears 1–36 (average 9) days after the bite, and is due to local spread of the spirochaete, usually in a ring formation enlarging at a rate of several centimetres per week. In some cases the erythema is intense, in others barely detectable; it

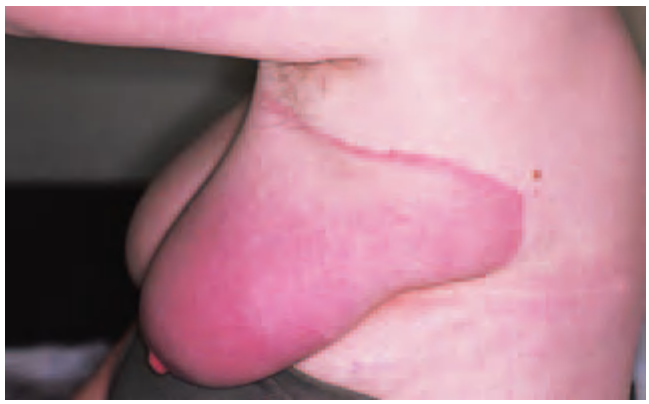

Fig. 27.19 Erythema chronicum migrans (ECM). (Courtesy of Dr A.S. Highet, York District Hospital, York, UK.)

may be entirely flat or show elevation at the centre, the periphery or both. Slight scaling is occasionally seen. Older areas of residual erythema may become dusky blue. There may be a zone of clearing behind the advancing ring producing a target-like morphology. Moderate burning or itching occurs in one-third of cases. If untreated, the lesion fades, usually within a few weeks, but the duration may vary between 1 day and 14 months. Regional lymphadenopathy and mild constitutional symptoms may occur.

Dissemination of the infection may occur within days or weeks of inoculation. Spirochaetes have been detected in affected organs, although immunological processes may also contribute. Of the over 5000 cases reported to the US Centers for Disease Control between 1983 and 1986 [5], 57% had arthritis; 18% had neural involvement, characteristically meningitis, cranial nerve palsies and peripheral radiculoneuritis; and 10% had heart disease including myocarditis, pericarditis and conduction defects. In a European series, neurological disease was prominent, but arthritis and carditis are not commonly diagnosed [6,10]. Migratory joint pains, myositis, conjunctivitis, hepatitis, generalized lymphadenopathy and splenomegaly may occur.

Two cases of fatal intrauterine infection have followed first-trimester maternal infection. In a prospective study of 19 women infected in various stages of pregnancy, there was an adverse fetal outcome in five, including one intrauterine death, but without proof of cause [11].

Other cutaneous manifestations. With dissemination of the infection, secondary lesions of ECM are seen in about 10% of patients, and are typically smaller and less migratory than the original lesion. Malar erythema in febrile cases, and a diffuse maculopapular rash, may occur. Localized urticaria, generalized urticaria, urticarial vasculitis [12] and septal panniculitis have been reported.

Lymphadenosis benigna cutis, or solitary lymphocytoma, developing near the site of the original ECM and occasionally coexisting with it, has been reported from Sweden [13]. The lesion is seen mainly on the ears or on the breast areola. *Borrelia burgdorferi* serology is usually positive, spirochaetes can be demonstrated in affected tissue, and the lesion subsides within 5 weeks of antibiotic therapy.

Acrodermatitis chronica atrophicans (ACA) (Chapter 46) is a late cutaneous manifestation of *B. burgdorferi* infection seen mainly in northern, central and eastern Europe, although a case has been reported from England [14]. The eruption develops 1 or more years after the original infection. Typical sites are hands, feet, knees and elbows. The lesion begins as an erythematous plaque, which slowly enlarges and gradually becomes violaceous and atrophic. Spirochaetes have occasionally been cultured, but *B. burgdorferi* serology is strongly positive in all cases. Lesions respond to appropriate antibiotic therapy.

Evidence for an aetiological role for *B. burgdorferi* in morphoea and lichen sclerosus has come mainly from Austria and Germany, and comprises clinical associations of these conditions with ACA and with neural disease consistent with neuroborreliosis [15]; positive *B. burgdorferi* serology in some patients with morphoea [15,16]; and histological identification of spirochaetes in biopsy material [15] and their culture from it [16,17]. However, other studies using more specific serological methods in the UK [18] and Denmark [19] have not confirmed the association.

Histology. A superficial and deep perivascular and interstitial lymphohistiocytic infiltrate containing plasma cells is characteristic of ECM [8,20]. The Warthin–Starry stain identified spirochaetes in 40% of cases [7].

In ACA, plasma cells are prominent within the lymphohistiocytic infiltrate; the epidermis is atrophic and there may be liquefaction degeneration of the basal layer and telangiectasia of the papillary dermis. Spirochaetes may be identified by the Warthin–Starry stain [14,21].

Diagnosis. In the differential diagnosis of ECM, other forms of insect- or spider-bite reactions, cellulitis and drug eruptions may be considered. Erythema multiforme may resemble multiple ECM, but in the latter, palms, soles and mucous membranes are spared [7].

Confirmation of *B. burgdorferi* infection is mainly by serology, although this is often negative in the first few weeks after inoculation. The main tests available are an ELISA, an indirect immunofluorescence test and a Western blot. The latter is particularly useful for screening negative sera or those showing indeterminate results. The incidence of false-positive results may decline with the advent of increasingly specific methods [1,22,23]. False-negative tests may be due to sequestration of antibody in immune complexes [24]. The detection of intrathecal

antibody is useful in the diagnosis of Lyme neuroborreliosis [23]. PCR is increasingly being used and provides a rapid diagnostic test [25].

Treatment [1,26–28]. Patients with solitary lesions of ECM, and no more than regional lymphadenopathy and minor constitutional symptoms, i.e. those in whom there is no evidence of bacterial dissemination, respond well to oral antibiotic treatment, and the incidence of serious sequelae is reduced [26]. Amoxicillin 500–1000 mg three times a day (perhaps with probenecid), or doxycycline 100 mg two or three times a day, is recommended. A 3-week course is suggested and, because of the possible severe sequelae, early treatment is advised. Cefuroxime and erythromycin are alternatives, although the latter is less active against *B. burgdorferi in vivo*.

After dissemination has occurred, the results of even intensive therapy are less impressive; whether this is due to incomplete eradication of the organism or to an immunological pathogenesis is not known. Mild systemic disease may be treated as above, but the more severe cases require intravenous treatment. Ceftriaxone 2 g daily i.v. for 2 weeks seems best, but there is still a 15% failure rate. Benzylpenicillin 24 mU daily for 2–3 weeks is also useful and chloramphenicol is a possible alternative.

Prophylactic treatment following tick bites in endemic areas may be considered, but careful inspection of the skin after walking in endemic areas and removal of ticks may be more useful.

Leptospirosis (including Weil's disease and canicola fever)

Leptospirosis is an infection caused by organisms of the *Leptospira interrogans* complex [1,2]. These leptospires are commonly carried by rodents, particularly rats, but also pigs, dogs, cattle and wild animals, such as hedgehogs and moles. Rodents especially may excrete the organism in urine persistently after recovering from infection. Human infections occur mainly in sewer workers and in those handling animals but are occasionally seen in those swimming or fishing in contaminated water. The portal of entry is usually the gastrointestinal tract but may be a cut or abrasion.

After an incubation period of 1–2 weeks, an acute febrile illness begins abruptly. The most distinctive features are muscular pains and tenderness, and intense conjunctival infection. Headache and respiratory symptoms are frequent. In some forms—Weil's disease, for example—jaundice and purpura are associated [3]. In others, such as the leptospiral form of pretibial fever and canicola fever, there is a blotchy erythema most constant on the legs. In many forms, there is a polymorphonuclear leukocytosis of the peripheral blood.

In Weil's disease, the mortality may reach 10%, but in the other forms spontaneous recovery occurs after about a week.

The diagnosis must be established by specific agglutinin reactions.

Treatment with large doses of penicillin [4] (or tetracycline if renal function is satisfactory) is recommended but must be given early. Haemodialysis or peritoneal dialysis may be required. In less severe cases oral ampicillin, doxycycline or amoxicillin can be given.

Rat-bite fevers

Spirillum minor rat-bite fever

SYN. SODOKU

This form of rat-bite fever is caused by a spiral flagellate organism *Spirillum minor*, and is usually transmitted by the actual bite of a rat. It is rare, with most cases being reported in Japan. It may cause disease in animal technicians bitten during the course of their work [1].

Ten or more days after the bite, the wound shows persistent inflammation and an eschar may form. A fever develops accompanied by malaise and regional lymphadenopathy [2]. A macular or maculopapular rash may become widespread, extending from the original lesion. A recurrent course with remissions and relapses accompanied by increasingly severe local inflammation and a generalized cutaneous eruption is characteristic. Arthritis, however, is rare in this type of rat-bite fever.

Sodoku may be differentiated from streptobacillary fever by finding the spiral organism in exudate or blood. Animal inoculation—intraperitoneally into mice or guinea pigs—is necessary as culture on artificial media cannot be achieved.

Untreated, most patients with *S. minor* infections recover without complication, but penicillin in low dose is rapidly effective and streptomycin or tetracycline are useful alternatives.

Streptobacillary rat-bite fever and Haverhill fever

Streptobacillus moniliformis is a natural inhabitant of the nasopharynx of rats and is the cause of the commoner and more severe form of rat-bite fever. When infection with this organism occurs in the absence of a rat bite, the term Haverhill fever is often used in recognition of an epidemic in Haverhill, Massachusetts, USA, when raw milk was thought to be the source of infection. The organism is a pleomorphic facultative anaerobic bacillus, sometimes showing beaded swellings.

When a rat bite is the origin of infection with this bacillus, the incubation period is short: 2–9 days. There is no sign of inflammation at the site of injury but (in most patients) a macular or petechial rash develops and involves the extremities, particularly the palms and soles [1]. There is characteristically a high fever and arthralgia of large joints [2]. Other manifestations of this infection include endocarditis and, particularly in children, diarrhoea [1]. The clinical picture is similar if not identical in Haverhill fever in which papules, vesicles, pustules and crusted lesions have been described along with late-onset pharyngitis.

The diagnosis is confirmed by blood culture. Without treatment, most cases eventually settle, but chronic arthritis and complications such as abscesses, pneumonia and endocarditis have been recorded. Penicillin is the drug of choice continued for at least a week with high-dose therapy in patients with complications; streptomycin and the tetracyclines are alternatives.

Legionellosis

Legionellosis is an acute respiratory infection caused by a variety of different species of the genus *Legionella*, of which *L. pneumophila* accounts for over 90% of cases [1]. One of the major features of the infection is the clustering of cases, often associated with exposure to organisms in the environment such as water-cooling systems, showers and humidifiers. The disease may present with a flu-like illness without pneumonia (Pontiac fever) or with pneumonia. In the latter a variety of different rashes from maculopapular eruptions to pretibial erythema have been described. These exanthems are not diagnostic [2].

Botryomycosis

SYN. ACTINOPHYTOSIS; BACTERIAL PSEUDOMYCOSIS

Definition and aetiology [1,2]. Botryomycosis is a chronic granulomatous reaction to bacterial infection, containing granules resembling the sulphur granules of actinomycosis. Most cases are caused by *Staphylococcus aureus*, but from some a pure culture of *Pseudomonas* [3] has been obtained. Botryomycosis may develop in the skin or elsewhere and a variety of underlying predisposing factors have been described.

Very extensive skin forms have been described, for instance in association with diabetes [4]. In AIDS, different forms have been reported, ranging from disseminated cutaneous papules [5] to extensive perianal sinus formation [6]. In addition, botryomycosis has been recorded in a patient with follicular mucinosis [7].

A history of injury is common in skin cases, and the literature relating to experimental models as well as some early case reports stresses the importance of a foreign body as well as infection [1]. The size of bacterial inoculation may be crucial—a delicate balance between host and pathogen has been regarded as significant [8].

Pathology [2,9]. The granules contain masses of bacteria. The surrounding tissue reaction is not distinctive: histiocytes, plasma cells, lymphocytes and foreign-body giant cells predominate.

Clinical features [1,10–12]. The resemblance to actinomycosis is also evident clinically. Most lesions are on the limbs, but other sites including the perianal region and the face have been affected. In the primary cutaneous form, single or multiple abscesses of skin and subcutaneous tissues break down to discharge serous fluid through multiple sinuses, and heal after a course of many months to leave atrophic scars. The general condition may remain good. Patients may present with a smaller painful papule without sinus formation.

The pulmonary form may reach the skin and present as irregular masses with multiple sinuses.

Diagnosis. The key to the diagnosis is the presence of a small cluster of microorganisms on biopsy. This cluster resembles the grain of a mycetoma or sulphur granule of actinomycosis. Gram stains are often ineffective in distinguishing the morphology of the organisms, but the methenamine silver stain often works well with bacteria and their shape can be distinguished. The organisms should be identified by culture.

Treatment. Treatment depends on the nature of the organism and, where appropriate, antibacterial sensitivities should be determined. For *S. aureus* infections, flucloxacillin or erythromycin are usual. Sometimes an alternative approach such as flucloxacillin and fusidic acid can be used for very extensive lesions. The response is often determined by the presence or absence of underlying predisposing disease.

Necrotizing subcutaneous infections

There is a group of infections in which the principal focus of disease lies within soft tissues of the deep dermis, adipose tissue and subcutaneous fascia, where the hallmark of infection is extensive necrosis accompanying cellulitis [1,2]. The affected patient is usually severely ill and toxic, and there is a mortality of over 45% reported in some series [3]. The extent of infection is clearly variable with, in some cases, pathology restricted to a zone bound by fascia while in others infection extends to involve muscle and deep vessels. The bacteria isolated from patients with these conditions have varied between different studies, and in some cases adequate bacteriological data are notably absent. This has complicated the clinical classification of these infections, as it has not been possible to validate the causative organisms. However, it has been suggested [4] that there are at least two distinct groups of infections—those caused by β-haemolytic, usually group A, streptococci and others that depend on an infection with multiple organisms, one of which is usually an anaerobe. The presence of a streptococcal aetiology is often difficult to establish with certainty and infections without a proven cause may show striking increases in antistreptococcal antibody titres, suggesting that this may

have been the original or a contributory cause [5]. The pathogenesis of the mixed bacterial infections is not well understood. Other variations include the presence or absence of muscle involvement.

While it is difficult to provide accurate data on the incidence of this infection, figures from Canada suggest that the annual incidence of necrotizing fasciitis is 1/200 000 with a 25% mortality [6].

While a complete and taxonomically valid list is difficult to compile, these infections include the following proposed types.

1 Clostridial cellulitis (gangrene).
2 Necrotizing cellulitis or fasciitis due to
  (a) streptococci, or
  (b) other bacteria.
3 Progressive bacterial synergistic gangrene.
4 Gangrenous cellulitis due to other pathogens such as *Pseudomonas* spp. or zygomycete fungi (mucormycosis). These are mainly seen in the immunocompromised patient.

To complicate the issue, eponymous titles have been used, and Meleney's name has been associated both with streptococcal necrotizing cellulitis [7] and with progressive bacterial synergistic gangrene [8]. Likewise, Fournier's gangrene, which describes a specific cellulitic necrotizing process affecting the lower anterior abdominal wall and the scrotal fascia, probably includes at least two aetiologically different conditions, but in this specific site [9].

The clinical hallmark of all these infections is the appearance of necrosis in addition to cellulitis, which is often accompanied by a rapid course and considerable toxaemia. In practice, the main features of these infections are difficult to separate on clinical grounds, although there are some variations due to site of infection, and it is possible that they are part of a continuum of disease from cellulitis to myonecrosis. Death is a frequent outcome in such cases. Predisposing factors include trauma, infection, diabetes mellitus and previous surgery.

Necrotizing fasciitis, including streptococcal necrotizing cellulitis, may follow entry of group A streptococci, *Staphylococcus aureus*, *Aeromonas hydrophila*, *Vibrio vulnificus* (see above) or a mixture of other bacteria, including at least one anaerobic organism, into the skin, most commonly on the head and neck or the limbs [3]. While the portal of entry is thought to be a cut or even a surgical wound, it may be difficult to pinpoint the site of entry. Patients usually present with a hot, tender area of swelling, which is erythematous, occasionally dusky [10]. Bullae and necrosis of underlying tissue may intervene and the overlying skin may become anaesthetic. Unfortunately, the onset may be indolent, giving rise to a false sense of lack of urgency [11]. Swabs from the skin surface are usually negative.

The most important step in diagnosis and management is surgical exploration in which subcutaneous tissues down to the fascia are found to be necrotic and may contain chains of Gram-positive bacilli. The skin appears to be undermined. Occasionally, group A streptococci, rarely groups B, C or D can be isolated, or serological evidence of streptococcal infection found. In other patients, a wide range of different aerobic and anaerobic bacteria are cultured. This should not, however, delay therapy, which consists of surgical debridement of the infected tissue and the immediate surrounding area. The overlying skin is usually surgically removed, although in some cases this has been laid back as a flap once the necrotic tissue has been removed. Treatment with intravenous penicillin G in high doses is recommended; metronidazole may also be used in addition. However, if antibiotics are given without surgical intervention, therapy is rarely successful. Heparinization should be used to control disseminated intravascular coagulation.

Progressive synergistic gangrene is usually seen in association with abdominal or other surgery, where there is contamination of the wound by leakage of bowel contents [12]. It may occur without apparent injury to the skin surface [13]. The organisms vary but microaerophilic streptococci, *Bacteroides* spp. or other anaerobes as well as Gram-negative bacteria are found. The wound becomes extended with surrounding necrosis and oedema, and the patient becomes toxic and unwell. The extending infection may affect muscle. Rapid deterioration of the patient's clinical state occurs with dehiscence of the surgical wound and toxaemia. Once again it is difficult to diagnose bacteriologically, and although careful culture with appropriate swabs being taken for anaerobes should be carried out, waiting for the results should not hinder start of therapy. The presence of gas in the tissue may suggest the diagnosis, but its absence does not exclude this infection. Computed tomography is a more precise method of demonstrating gas in tissues than X-ray [14].

The wound has to be explored surgically and necrotic tissue removed. The patient should receive penicillin in high dosage and a second drug should be added depending on the sensitivity of organisms isolated, but once again surgery is the most important aspect of therapy. The response rates are not high. There is no clear clinical difference between this disease and necrotizing fasciitis as long as a streptococcal aetiology is considered.

Pyoderma gangrenosum (Chapter 49) can easily resemble this disorder and indeed may sometimes be localized around a surgical wound.

Fournier's gangrene occurs where there is infection around the lower abdominal fascial plane in men, with tracking of the infection into the scrotum [8]. It may be caused by group A streptococci or multiple organisms, although it is commoner with the latter. The management is identical to that used for these infections in other sites.

It is important to consider other potential causes of acute necrosis and toxaemia, particularly in the neutropenic patient, where cellulitis associated with single, such

as *Pseudomonas*, or multiple organisms can occur. The zygomycete fungal infection, mucormycosis, should also be considered and impression smears taken from the wound edges or biopsy material may be helpful in excluding this possibility.

Mycoplasma infections

Mycoplasmas, formerly known as pleuropneumonia-like organisms, are the smallest free-living organisms. They lack a rigid cell wall but can grow, although slowly, on artificial media. There are about a dozen species known to be associated with humans [1,2]. Some, for example *Mycoplasma orale* and *M. salivarium*, are commensals in the mouth; others such as *M. hominis* and *Ureaplasma urealyticum*, are found in the healthy genital tract and may, at least in the case of *U. urealyticum*, be a cause of urethritis, as may *M. genitalium*. *Mycoplasma incognitus*, a variety of *M. fermentans*, is associated with lesions in patients with AIDS as well as other immunocompromised patients.

Mycoplasma pneumoniae is a well-recognized cause of pneumonia and minor upper respiratory tract infections, particularly in young people [3]. This organism has also been associated with meningoencephalitis, polyarthritis and other syndromes [4], such as severe erythema multiforme (Stevens–Johnson syndrome) [5,6]. The commoner minor form of erythema multiforme in patients without clinical evidence of lower respiratory tract infection is in a relatively small proportion of cases also causally related to *M. pneumoniae* infection, as established by a rising titre of complement-fixing antibody and the isolation of the organism from the skin lesions. Raynaud's phenomenon has also been reported in patients with *M. pneumoniae* infection.

In outbreaks of upper respiratory infection by *M. pneumoniae*, about one-third of patients developed rashes of various types [7,8].

Diagnosis. Cold agglutinins are produced in the majority of patients. In addition, complement-fixing antibodies can also be demonstrated. The agglutinins are raised early in the infection, whereas it may be several days before raised complement-fixing antibody titres can be demonstrated. Culture is time consuming. There is a new DNA probe assay, which is currently under investigation [9].

Treatment. Tetracycline and derivatives are effective in *M. pneumoniae* infections; an alternative is erythromycin. There is no evidence that the use of antibiotics triggers the appearance of skin rashes.

Chlamydiae [1,2]

Chlamydiae are obligate intracellular parasites, but in their infectious form they have a cell wall, contain both DNA and RNA, replicate by fission, and are susceptible to broad-spectrum antibiotics, notably tetracyclines; they are therefore classed with the bacteria. There is a single genus with two subgroups or species.

Chlamydia trachomatis or subgroup A is classified into 15 serotypes with different pathogenic properties: Types A, Ba, B and C cause trachoma, an endemic ocular infection in many developing countries, frequently leading to blindness; types D to K, which are sexually transmitted, most commonly cause urethritis, but also deeper

infections such as cervicitis, endometritis and salpingitis [3]. Eye infection may result from contact with infected genital secretions. There is evidence for a role in post-urethritic reactive arthritis including Reiter's syndrome (Chapter 35) [4].

Types L1, L2 and L3 infect predominantly lymphatic tissue and cause the sexually transmitted disease lymphogranuloma venereum.

Chlamydia psittaci or subgroup B is endemic in many species of birds and occasionally causes an interstitial pneumonitis in humans known as psittacosis or ornithosis.

Lymphogranuloma venereum

SYN. LYMPHOGRANULOMA INGUINALE; NICHOLAS FAVRE DISEASE; CLIMATIC BUBO

Note: This disease should not be confused with granuloma inguinale (granuloma venereum, donovanosis) caused by *Calymmatobacterium granulomatis* (see above).

Aetiology [1–3]. Lymphogranuloma venereum is caused by *Chlamydia trachomatis* types L1, L2 and L3. The organism is difficult to isolate and the diagnosis mainly depends on the serological response. Since the complement-fixation test is based on a group antigen, it is necessary to interpret with caution early records or prevalence based on this test because the respiratory and genital chlamydia cause cross-reactivity.

The human is the only natural host. Infection declined in the UK and Scandinavia without specific attempts at eradication. Most infections are sexually transmitted and the disease is common in tropical countries.

Pathology [1,4–6]. The lymphogranulomatous chancre usually shows no specific changes, but the necrotic area may be surrounded by epithelioid cells and a zone of granulation tissue rich in plasma cells.

The lymph nodes first show scattered foci of epithelioid cells, with occasional giant cells. These foci enlarge irregularly and undergo necrosis to form the stellate abscesses characteristic of the disease. The abscesses, which contain polymorphonuclear leukocytes and macrophages, are surrounded by epithelioid cells and chronic granulomatous tissue with numerous plasma cells.

In the later stages, very extensive fibrosis and large areas of coagulation necrosis are usual.

Clinical features [1,3,4,7]. After an incubation period of about 10 days (5–21 days) a small papulovesicle develops on the external genitalia, or occasionally elsewhere. The chancre is inconspicuous, heals rapidly and is often unnoticed. After an interval that is usually between 1 and 4 weeks, but may be longer, the regional lymph nodes enlarge—'climatic bubo'. The subsequent course of the disease depends on which glands are involved and on the extent and severity of the constitutional disturbance. Some cases resolve spontaneously within a few months, but in the majority chronic symptoms persist, often with irregular acute episodes.

The inguinal syndrome is the most frequent manifestation in men. Inguinal adenitis is unilateral in 60% of cases. Lymphatic glands are at first hard and tender, but soon become matted together and within a week or two develop small areas of fluctuation, some of which break through the reddish purple overlying skin to form chronic sinuses. The groin fold frequently divides the glands characteristically into upper and lower groups—the sign of the groove. Palpable enlargement of the iliac glands often develops and may be considerable. Suppuration does not occur and spontaneous resolution ultimately takes place.

The rectal syndrome occurs mainly in women, in whom the primary lesion is often in the vagina. The pelvic glands are involved and periproctitis and proctitis are followed by a rectal stricture usually between 5 and 10 cm from the anal margin, around which fistulae frequently develop. Carcinoma is not uncommon later.

The genital syndromes occur in both sexes. Most characteristic is genital lymphoedema, which may develop a few weeks or many years after infection and gives rise to elephantiasis. The association of elephantiasis of the vulva with scarring and fistulae of the buttocks and thighs is known as esthiomene. Occasionally, small abscesses develop along the course of the superficial lymphatics draining the primary lesion and break down to form ulcers.

Urethral lesions may cause strictures and fistulae, and lymphoedema may produce a 'saxophone penis'. Extragenital primary lesions have produced a wide variety of syndromes.

Constitutional symptoms often accompany the glandular enlargement but vary greatly in severity. Fever is usually slight, but general malaise is frequent and many patients complain of joint pain and stiffness. The spleen and liver may be enlarged. Rarely, there may be encephalitis.

Erythema nodosum occurs in about 10% of females and 2% of males, usually in the bubo stage but sometimes later.

Light sensitivity is common in white patients and develops in 30% of women and 12% of men in the subacute stage and in about 50% of chronic cases. It is first apparent about 10 weeks after infection and may persist as

long as the disease remains active. Papular, urticarial or plaque-like lesions are confined to light-exposed skin and may be associated with restlessness and headache.

Occasionally, erythema multiforme and exanthemata of various types may occur during periods of activity.

Prognosis. The untreated disease usually runs an average course of 6–8 weeks and may then resolve completely. Many cases are left with the sequelae of lymphatic obstruction and some show periodic recrudescences of activity for many years. The disease is not transmitted transplacentally in humans [8].

Diagnosis. Fluctuant or discharging, painful and often unilateral adenitis, with or without a history of a primary lesion, is most likely to be confused with cat scratch disease, pyogenic infection and tuberculosis. The adenitis of infectious mononucleosis, syphilis, granuloma inguinale, Hodgkin's disease or leukaemia is less acute and usually not painful.

A suspected diagnosis should be confirmed serologically by demonstration of a rise in chlamydia group-specific, complement-fixing antibody, although this is not always conclusive because the production of antibody may be reduced by antibiotic therapy. A fluorescence antibody test is more specific [9].

Culture is not practical. Biopsy of a lymph node or a smear of the bubo pus may be helpful.

In general, the results of laboratory investigations must be assessed with caution.

Treatment. Lymphogranuloma is best treated with chlortetracycline 500 mg four times a day for 14 days. Where there may be infection by *Haemophilus ducreyi*, it is preferable to give erythromycin or doxycycline instead. This infection also responds to a single dose of azithromycin.

Early cases will usually show a response in 7–10 days, but some early, and most late, cases will require prolonged or repeated courses.

Fluctuant buboes may require aspiration to prevent spontaneous rupture, the needle being passed inferiorly from above through normal skin to reduce the risk of sinus formation [1]. Surgical incision and excision of buboes should be avoided. Other complications will often require surgical treatment.

Psittacosis

SYN. ORNITHOSIS

Nomenclature. The name 'psittacosis' was introduced because human infections were acquired from parrots (psittacines). Subsequently, many non-psittacine birds, for example domestic and sea birds, were found to carry the infection and 'ornithosis' was introduced as a more general term. The terms are now used synonymously.

Aetiology. The disease is endemic not only in the parrot family, but also in over 120 species of birds, including pigeons, domestic fowl, ducks and finches, all of which have caused human infection; transmission occurs from inhalation of infected dust from excreta of sick or latently infected birds.

However, in many cases no bird source can be identified. Human-to-human spread by infected respiratory tract droplets is known to occur and may be commoner than previously recognized [1–3].

Clinical features [2,4,5]. The incubation period is about 2 weeks. The manifestations are very variable. There may be severe pneumonia, with cyanosis and collapse, myocardial involvement, jaundice, encephalitic symptoms and death, but many cases present only the symptoms of a mild respiratory infection without special characteristics. There may be headache and sore throat at the onset, and cough after a few days, with complete recovery during the second week. Even milder attacks are probably frequent.

Exanthemas occur occasionally, including a morbilliform eruption, and in severe cases lesions resembling the rose spots of typhoid, although sometimes of a darker hue. Erythema nodosum was noted in five of 150 cases [3] and may occur irrespective of the severity of the primary illness. Of six cases of psittacosis with erythema nodosum, two also had erythema multiforme [4]. Disseminated intravascular coagulation has been reported [5].

Diagnosis [3]. The diagnosis is based on the demonstration of complement-fixing antibody, appearing about 10 days from the onset and often present as soon as the

diagnosis is suspected, so that examination of a single serum may be helpful. Confirmation by a rise in titre may require a further 10 days, as antibody production is slow and reduced by antibiotic therapy.

The antibody is group-specific but this is not a practical limitation since the diseases caused by *Chlamydia trachomatis* are quite different.

Treatment. Tetracyclines are the drugs of choice and early administration can be life-saving. A dose of 500 mg four to six times a day should produce a response in about 48 h and should be continued for 10 days. Erythromycin is recommended for children [2].

Rickettsial infections

Rickettsiae are regarded as small bacteria, and most are obligate intracellular parasites. They are spread by the bites of blood-sucking arthropods and cause widespread infection in endothelial cells, which may result in vascular infarcts, extravascular fluid loss and disseminated intravascular coagulation. Rickettsiae can be classed into five main groups on clinical and serological grounds (Table 27.6) [1]. Q fever has no exanthem and is not considered further.

Epidemic typhus [1]

Aetiology and pathology. Epidemic typhus is caused by *Rickettsia prowazeki* and is transmitted by the human body louse. It occurs throughout the world but epidemics are mainly associated with the displacement of populations by war or natural disasters. Humans are the only reservoir of infection.

The essential pathological lesion is produced by the multiplication of rickettsiae in the endothelial cells of small blood vessels, leading to obstruction, thrombosis, haemorrhage and perivascular inflammatory infiltration. The lesions are widely distributed but are often numerous in the skin, brain and heart.

Clinical features. After an incubation period of 7–14 days the abrupt onset of fever, headache and malaise ushers in the illness, which at first has no distinctive features. The symptoms increase in severity for several days. Between the fourth and seventh day a rash develops in over 80% of cases. It consists of crops of pink macules about 5 mm in diameter, which appear first on the sides of the trunk and spread centrifugally, but spare the palms and soles, and spare the face, which is usually flushed with intensely injected conjunctivae. During the second week, the rash becomes deeper red and often frankly purpuric, and in severe cases may be confluent.

The other clinical manifestations and the outcome depend on the degree of involvement of the myocardium and the central nervous system. Gangrene of fingers, toes, genitalia or nose may result from vascular obstruction. Untreated, up to 40% of cases are fatal, but serious sequelae are unusual in those who recover. Death, or recovery, occurs between the second and third weeks.

Brill–Zinsser disease [1]

SYN. SPORADIC TYPHUS

This is the recrudescence of epidemic typhus, sometimes after many years, in individuals who have previously recovered from an attack. The clinical features are those of the primary attack, but often milder and less often with a rash.

Table 27.6 Rickettsial infections.

Group	Disease	Rickettsia	Vector	Distribution
A. Typhus	Epidemic typhus and Brill–Zinsser's disease	*Rickettsia prowazecki*	Louse	Worldwide
	Endemic murine typhus	*R. mooseri*	Rat flea	Central and South America, Malaya
B. Spotted fever	Rocky Mountain spotted fever	*R. rickettsi*	Tick	North and South America
	Tick typhus			
	(a) African	*R. conori*	Tick	Mediterranean, Africa
	(b) Siberian	*R. siberica*	Tick	Russia, Central Asia
	(c) Queensland	*R. australis*	Tick	Australia
	Rickettsialpox	*R. akari*	Mouse mite	North America, Russia, Africa
C. Scrub typhus	Tropical typhus or Japanese river typhus	*R. tsutsugamushi*	Mite	South-East Asia
D. Q fever	—	*Coxiella burneti*	—	Worldwide (except Scandinavia)
E. Trench fever		*Rochalimaea quintana*	Body louse	Europe, Africa, North America

Murine typhus [1]

SYN. ENDEMIC TYPHUS

Aetiology and pathology. Murine typhus is caused by *Rickettsia mooseri* and is spread to humans from the rodent reservoir by the rat flea, *Xenopsylla cheopsis*. The infection occurs throughout the world, but the incidence is highest in Central and South America. The pathological changes are similar to those of epidemic typhus.

Clinical features. The clinical features parallel those of epidemic typhus, but are very much milder. The rash is sparse and seldom haemorrhagic, and gangrene and other complications are rare. Recovery occurs during the second week in all but 1 or 2% of cases.

The spotted fever group

The infections in this group (Table 27.6) are spread by ticks or mites. Similar infections caused by distinct species occur in the tropical and subtropical regions of all continents. The incidence of this group of infections increased during the 1970s and 1980s [2,3].

Rocky Mountain spotted fever [1,4–6]

Aetiology and pathology. This is the most virulent of the rickettsial infections. The organism *Rickettsia rickettsii* is transmitted by the bite of various species of the tick, *Dermacentor*. It occurs in the Rocky Mountain areas of North America, in Maryland, Virginia and North Carolina, and in Mexico, Colombia and Brazil. Widespread inflammatory and destructive changes are produced in the small blood vessels, especially in the skin and central nervous system.

Clinical features. Five to 7 (range 3–12) days after the tick bite, a short period of malaise and headache is followed by fever, which sometimes rises to 39–40°C. After 3 or 4 days a maculopapular eruption appears on the wrists and ankles and soon spreads centrally to limbs, trunk and face. The palms and soles are usually involved. Except in the mildest cases, the rash becomes haemorrhagic, and in the most severe may be confluent. Acral gangrene may occur. In favourable cases, the high, irregular fever subsides during the third week, but without treatment the mortality exceeds 20%.

Tick typhus [1]

SYN. MEDITERRANEAN FEVER; FIEVRE BOUTONNEUSE; KENYA TICK TYPHUS; AFRICAN AND INDIAN TICK TYPHUS

Aetiology. Tick typhus is caused by *Rickettsia conori*, which is transmitted by the bites of a variety of ixodid ticks. It is endemic in the countries of the Mediterranean littoral and in many parts of Africa and India. This diagnosis is often not considered in returning travellers who fail to associate the characteristic black eschar at the site of the bite with the febrile exanthem for which they seek treatment [7]. The pathological changes follow the usual rickettsial pattern (see Epidemic typhus above).

Clinical features. After an incubation period, which is usually between 5 and 7 days, the onset of fever is accompanied by headache, malaise, joint and stomach pains and, sometimes, mental confusion. Fever of 39–40°C lasts for 7–14 days. In some 80% of cases the onset of fever coincides with the development of a small ulcer—the tache noire—at the site of the tick bite. The ulcer, which is 2–5 mm in diameter has a black necrotic centre and a red areola. The regional lymph nodes are enlarged and tender. Three or four days later, a pink, maculopapular eruption develops first on the forearms and then rapidly generalizes, involving the face, palms and soles. It increases in density for a few days and in severe cases may be haemorrhagic. The rash fades slowly after the fever subsides. Apart from weakness and lassitude, convalescence is uneventful and recovery is usual, except in the severe forms in frail or elderly people.

Leukocytoclastic vasculitis has been reported in occasional cases of *R. conori* infection [8].

Other forms of tick typhus

Other tick-borne rickettsial infections have been reported from many parts of the world, and the number of distinct infections recognized increases each year as more refined serological techniques are developed and are more widely applied.

The clinical syndromes, while showing variations in the extent of the eruption and the severity of the constitutional symptoms, all follow the same general pattern: a primary lesion, the eschar, develops at the site of the bite together with fever and influenza-like symptoms. A few days later a generalized maculopapular eruption develops and may become haemorrhagic.

Rickettsialpox [1,9]

Aetiology. *Rickettsia akari* is a parasite of the house mouse, which is transmitted to humans by the mite, *Allodermanyssus sanguineus*. It was first identified in 1946, in New York but cases have since been reported from other areas of the USA, from Central Africa and from Russia. Because the reservoir and the vector are widely distributed, the disease may be worldwide.

Pathology. Vacuolar degeneration in the basal layer results in blurring of the dermal–epidermal junction and

vesiculation best regarded as subepidermal, although regenerating epidermis may give an impression of intraepidermal separation. The superficial and middle dermal layers contain a neutrophilic and mononuclear cell infiltrate, but light and electron microscopy fail to demonstrate the organisms.

Clinical features. After an incubation period of 7–14 days, a papule appears at the site of the mite's bite, enlarges, becomes vesicular and dries to form a crust. The regional lymph nodes are enlarged. The patient often fails to notice the lesion. A few days later, influenza-like constitutional symptoms develop and persist for 4 or 5 days. Their onset is accompanied, or soon followed, by a generalized eruption of papules surmounted by small vesicles, which crust and heal in a few days. The distribution and extent of the eruption are very variable. The illness is usually mild and recovery is complete.

Many cases are probably diagnosed as atypical varicella, but the lesions of rickettsialpox are papules surmounted by vesicles, their distribution is irregular and there is usually, but not invariably, a discoverable primary lesion.

Scrub typhus [1]

Aetiology. The infective agent of scrub typhus, *Rickettsia tsutsugamushi*, is conveyed to humans from its natural rodent reservoir by the bites of the mites, *Trombicula akamushi* and *T. deliensis*, and probably by related species. The disease is widely distributed throughout the Far East and the South-West Pacific, and was a serious source of morbidity in troops in World War II.

The pathological changes are a focal vasculitis, involving the skin, lungs, heart, brain and kidneys.

Clinical features. After an incubation period of about 10 days (6–21 days) an acute fever with headache and conjunctivitis accompanies the development of the primary lesion, which is more frequently seen in white people than in Asian people. The primary lesion, or eschar, is a firm papule up to 1 mm in diameter surmounted by a vesicle, which dries to form a black crust. The regional lymph nodes are enlarged and tender. After about a week, a generalized macular or maculopapular eruption develops and may fade rapidly or persist for 7–10 days.

The clinical picture varies with the virulence of the strain. Pneumonitis and myocarditis are frequent and without treatment the mortality in some outbreaks reaches 60%. In favourable cases, the fever subsides and recovery occurs during the second or third week.

Diagnosis of rickettsial infections [1,5]

Various serological techniques and other methods are available, but are generally of retrospective value, and treatment should be started on the basis of a clinical diagnosis.

Treatment of rickettsial infections

Tetracyclines are the drugs of choice and treatment should be started as soon as the clinical diagnosis is made. The drug is given in full dose as a standard course, except that epidemic typhus and scrub typhus respond to a single 200-mg dose of doxycycline (100 mg for children) [1]. Chloramphenicol is also effective and has been recommended for Rocky Mountain spotted fever in pregnant women and children aged 8 years and under [10]. General supportive measures are necessary in severe cases.

With louse-borne disease (epidemic typhus, trench fever), isolation and effective delousing are necessary to control the spread of infection.

Actinomycete infections

The actinomycetes are higher bacteria whose members cause two uncommon but important human infections: actinomycosis and nocardiosis. They show a number of unusual characteristics. *Actinomyces* spp. usually form large granules *in vivo* and *Nocardia* spp. are partially acid fast. Both form branching filaments *in vitro* and *in vivo*.

Actinomycosis

Definition. A chronic, spreading suppurative and granulomatous disease caused primarily by *Actinomyces israelii*: draining sinuses are formed through which the characteristic sulphur granules are discharged [1].

Aetiology. Actinomycetes are bacteria producing filamentous branching hyphae. Most of the pathogenic actinomycetes occur in nature and belong to the soil saprophytic flora. Pathogenic anaerobic actinomycetes are normal inhabitants of the human mouth, and actinomycosis is therefore acquired endogenously. In some respects, actinomycosis and mycetoma are similar. Actinomycosis differs from mycetoma in being caused by endogenous and anaerobic agents, and in having no tendency to be confined to the extremities.

Actinomycosis is caused by the invasion of the tissues by *A. israelii*, the most ubiquitous of the pathogenic actinomycetes [2]. *Actinomyces bovis*, which is isolated usually from cattle but rarely from humans, closely resembles *A. israelii*, and is considered to be identical by some authorities. Recent studies using serological and biochemical procedures have not resolved this controversy. *Actinomyces naeslundii*, *Arachnia propionica* and *Bifidobacterium eriksonii*, all inhabitants of the mouth, are rare causes of human disease [3,4]. *Actinomyces israelii* occurs in the normal mouth, and the higher incidence of the disease in rural tropical areas and in agricultural workers is difficult to explain. It has been suggested that it is more likely to affect people who live in remote areas, partly because of poor dental hygiene, and secondly because of poorer access to antibiotics to which the organisms are extremely sensitive. Trauma is thought to provide the portal of entry, and it is commonly found that actinomycosis of the jaw develops after dental extractions, pyogenic abscesses, etc. The disease is worldwide in its distribution but is seldom common. It can occur at any age, including infancy, but is rare under the age of 10 years. Although adult males are more commonly affected than females, the sex incidence is equal in childhood. Full-blown actinomycosis is also rare now in most countries where dental care is readily available. It is possible that it may cause minor dental infections, which are treated with antibiotics before major pathology can develop or a definitive diagnosis be established.

Histology [3]. The usual appearance is that of a suppurating fibrotic inflammatory process. Small abscesses and pus-filled sinus tracts are formed. Blood spread to distant organs is unusual. In the tissues, the organism forms granular colonies from which radiate delicate mycelial filaments, some of which bear club-shaped processes (ray fungus). Surrounding the colonies a chronic neutrophil and lymphocytic infiltrate extends towards the skin, irrespective of where the primary lesion is, and this readily breaks down to form multiple fistulae from which pus containing the granules may be discharged. These so-called sulphur granules are lobulated masses of intertwining filaments. Lesions of actinomycosis almost always contain other bacteria besides *Actinomyces*, and it is thought that some of these associated organisms have a synergistic role in the development of the infection.

Clinical features. Actinomycosis can affect all organs and tissues of the body [3]. Apart from the very common minor infections of the lacrimal apparatus, five main clinical types can be recognized, depending on the primary site of infection; namely, cervicofacial (lumpy jaw), thoracic, abdominal, primary cutaneous and pelvic. In a large series, published long before pelvic infections were recognized, 56.7% of cases were in the cervicofacial area, 22.3% in the lungs and 15% in the abdomen.

Cervicofacial actinomycosis [5]. This presents as a dull-red, indurated nodule on the cheek or submaxillary region. Multiple sinuses, puckered scarring and the formation of new nodules produce an uneven, lumpy surface. The sinuses may close temporarily and later reopen or they may be replaced by other sinuses. The characteristic sulphur granules may be found in the discharging pus. The primary lesion is usually in the mandible or maxilla, and probably arises as a direct extension from a periodontal abscess formed in turn as the result of carious teeth, dental extraction or trauma to the jaw. Maxillary lesions may extend to the orbit, bones of the skull and brain. Lesions may also extend from the tonsillar crypts to the mandible. Involvement of bone occurs early, usually before sinuses are formed. Periostitis is followed by osteomyelitis with cystic spaces within the bone. The induration felt in the skin is very hard (board-like). This is the least uncommon type and is the type most often seen by dentists.

Thoracic actinomycosis. The thoracic type of actinomycosis may simulate active tubercolosis with cough, haemoptysis, night sweats and weight loss. There are no cutaneous changes unless the thoracic wall is secondarily involved. The lung may be affected as the result of aspiration of *Actinomyces* from the mouth. It is doubtful whether the normal lung can be infected, and most cases are thought to result from secondary infection of a lung abscess, tuberculosis, lung cancer, bronchiectasis, etc. Once again the organism tends to extend outwards from the lung to the skin through the thoracic wall, perhaps with osteomyelitis of the ribs and eventually with multiple draining sinuses [4].

Abdominal actinomycosis [3]. It usually begins in the appendix or caecum and is manifest either as appendicitis or a slow-growing mass with constitutional disturbance. It is thought that the organisms reach the gastrointestinal tract from the mouth and tonsils. Extension to the liver with resulting jaundice is frequent. Likewise, extension to the ovaries, kidneys, bladder or spine may occur. The organism may extend into the abdominal wall with the resultant sinus tracts appearing on the skin surface. Blood spread to distant organs occurs but is very rare.

Primary cutaneous actinomycosis. This is very uncommon

and usually occurs on the exposed skin. Subcutaneous nodules extend slowly and break down to form sinuses [6] and the regional lymph nodes may be affected. This is thought to follow a similar pathogenetic mechanism to mycetoma, through implantation.

Pelvic actinomycosis. Recognized as a distinct form of the disease is pelvic actinomycosis, associated with the use of intrauterine contraceptive devices [7]. The skin is not affected in pelvic actinomycosis, but many patients with other forms of actinomycosis do have involvement of the skin causing tumour-like lesions.

Prognosis. The prognosis of any variety of actinomycosis without treatment is generally poor but the cervicofacial and cutaneous varieties may remain localized for long periods.

Differential diagnosis. Actinomycosis has a fairly typical appearance, but as the disease is rare the diagnosis may not be suspected. The condition resembles other chronic inflammatory diseases, such as tuberculosis, syphilitic gummata, appendicitis, osteomyelitis and liver abscess, and also lung and intestinal cancer. The diagnosis is established by identifying the granules in the pus and on histological examination. Diagnosis should be confirmed by culture.

Laboratory identification. Attempts should be made to detect the characteristic sulphur granules, which provide a strong presumptive diagnosis of actinomycosis. They can generally be seen macroscopically as yellow granules up to 1–2 mm in diameter, often adherent to gauze dressings. When crushed and examined microscopically, narrow bacillary forms and elongate hyphae with occasional branching may be found. Cultures of *A. israelii* appear after anaerobic incubation at 37°C for 2–4 days on enriched media (brain–heart infusion glucose agar) as white, glistening, nodular colonies with somewhat irregular margins. Colonies of *A. bovis* are smooth, convex and shiny with clear margins.

Treatment. Actinomycosis is a chronic disease producing a marked fibrotic reaction, and it is difficult to obtain effective drug levels where required, so that a quick response to treatment should not be expected [8]. *Actinomyces israelli* is sensitive to those antibiotics that are effective in the treatment of Gram-positive bacterial infections. It is sensitive to sulphonamides, streptomycin, penicillin, chloramphenicol, chlortetracycline, oxytetracycline, tetracycline, rifampicin and erythromycin, but high doses of long-term penicillin is the therapy of choice. In severe cases, 10–12 million units of penicillin a day are administered i.v. for 12 h daily for 30–45 days. This is followed by wide surgical excision of the infected tissue and then 2–5 million units of penicillin given i.m. daily for 12–18 months, or 5 million units of penicillin V given by mouth. In an average case, daily i.m. penicillin in doses of 1–6 million units for periods of 6–8 months have been employed.

Large-scale trials are not possible with this disease, but alternatives to penicillin include tetracycline derivatives, erythromycin, chloramphenicol [8] and, more recently, imipenem [9]. Erythromycin is the most active antimicrobial *in vitro* [10].

Nocardiosis

Definition. An acute-to-chronic suppurative disease caused by the aerobic actinomycete *Nocardia*. The primary infection is usually pulmonary, but there may be haematogenous spread to other organs. The central nervous system is frequently attacked. Primary cutaneous nocardiosis as well as mycetoma due to *Nocardia* spp. are both well described.

Aetiology. Nocardiosis is caused by the bacteria *N. asteroides*, *N. brasiliensis* and *N. otitidis caviarum* [1]. Like many of the fungi causing systemic mycoses, pathogenic strains of *N. asteroides* have been isolated from soil. There is general agreement that infection is therefore exogenous, for example by inhalation of contaminated dust. The frequency of mild subclinical nocardiosis is unknown, but since the organism is known to cause fatal infections in humans, the demonstration of *N. asteroides* in sputum or other materials should therefore not be disregarded. Although uncommon, the disease is no longer a rarity, as improved technique has led to the recognition of more examples of this infection. In one review, 179 cases were recorded [2].

In addition, *Nocardia* spp. can cause localized skin infections presumably after implantation. *Nocardia asteroides*,

in particular, may cause a localized abscess without dissemination—primary cutaneous nocardiosis. *Nocardia brasiliensis*, and less commonly other species, is also a common cause of actinomycetoma following entry via a wound. *Nocardia* is an opportunistic pathogen and is often found in people with progressive chronic disease or with some defect in immune response, including AIDS, and in solid organ transplant recipients. It has also been reported with Cushing's syndrome, diabetes and following the use of corticosteroids in the treatment of various diseases. Nosocomial outbreaks of nocardiosis associated with contamination of ventilation systems have been described [3].

Clinical features. In systemic nocardiosis, the clinical picture may closely simulate pulmonary or meningeal tuberculosis. Pulmonary involvement, with cough, dyspnoea, haemoptysis and fever, occurs in 75% of cases [4,5]. Involvement of the brain or meninges is present in 30% of cases, and of the skin in 30%. Infection of the skin and subcutaneous tissue produces multiple abscesses, which may involve muscles and bones [6]. The prognosis without treatment is poor.

A lymphangitic form with multiple suppurative nodules and a primary chancriform syndrome [7], which usually presents with a localized cold abscess, have been described.

Actinomycetoma due to *Nocardia* spp. is described elsewhere (Chapter 31).

Differential diagnosis. Nocardiosis should be considered in obscure pulmonary and meningeal syndromes and in chronic suppurative disease of skin and bones.

Laboratory diagnosis. Pus or sputum smears are examined after staining by Gram, methenamine silver and acid-fast techniques for the narrow (less than 1 μm) branching hyphae, which are only partially acid fast. Cultures can be obtained on Sabouraud's glucose agar and on other isolation media from which antibacterial antibiotics are withheld. Colonies are compact, folded and glabrous, ranging from cream to red.

Treatment. The treatment most widely used is co-trimoxazole, although sulphonamides are also active [8–10]. Alternatives that have been reported to be effective include ampicillin, minocycline, amikacin and, more recently, imipenem. There is also difficulty in correlating the results of *in vitro* assessments of sensitivity with clinical responses [9]. In most cases it is still preferable to initiate therapy with co-trimoxazole and modify this later in the light of the clinical response.

Dermatoses possibly attributable to bacteria

There are many distinctive clinical syndromes in the causation of which bacteria appear to play a principal or secondary role, but in which the lesions cannot be correlated with the known pathogenetic activities of the species isolated. An abnormal response of the tissues of the host has therefore to be postulated.

In some such syndromes, allergic hypersensitivity to the infecting organisms or their products has been demonstrated, and in others it is believed to be an important factor in determining the altered response to the bacteria.

The clinical features of many infections are modified by defects, inherited or acquired, in the host's capacity to produce a normal antibody and leukocytic response. Chronic granulomatous disease of childhood, for example, results from the failure of leukocytes to destroy certain species of ingested bacteria.

Chancriform pyoderma

This uncommon condition occurs more often in children than in adults. Cases have been reported from Europe and from North and Latin America [1]. The aetiology is uncertain, but a necrotizing reaction to a strain of *Staphylococcus aureus*, inoculated by minor trauma, has been suspected. The lesion, which is usually solitary, is often situated around the eyelids or near the mouth, or occasionally on the genitalia [1,2]. A sharply marginated ulcer, sometimes exceeding 1 cm in diameter, with an indurated base and a bright-red areola, enlarges slowly for a few days. The regional lymph nodes are enlarged and tender. Without treatment the ulcer may persist for several weeks before healing to leave a superficial scar. Treatment with antibiotics shortens the duration but the response in our experience is not dramatic.

The importance of the lesions lies in the possibilities for diagnostic confusion. Epithelioma, syphilis, primary

tuberculosis, accidental vaccination, swimming-pool granuloma, leishmaniasis and dequalinium necrosis must be excluded.

Dermatitis vegetans

SYN. PYODERMA VEGETANS

Definition and nomenclature. Dermatitis or pyoderma vegetans is a condition of uncertain aetiology characterized by the development of epithelial hyperplasia and chronic granulomatous changes [1]. Crusting, sinus tract formation and ulceration may all occur in this disease. Dermatitis vegetans is thus difficult to define and almost certainly the name has been used to describe a number of differing skin rashes, such as blastomycosis-like pyoderma [2] and possibly superficial granulomatous pyoderma [3]. As the aetiology of the disease is unknown, it is not known whether these share a common pathogenesis.

Aetiology. Dermatitis vegetans may develop in any site, but the flexures are often involved. Commonly, either *Staphylococcus aureus* or group A streptococci are isolated from lesions but, as the rash does not usually respond to antibiotics alone, the role of these bacteria in the pathogenesis of the condition is unclear. The disease has been described in patients with a variety of underlying conditions, such as ulcerative colitis [1], alcoholism, lymphoma [4] and in association with a primary immunodeficiency state that responded to treatment with transfer factor [5]. For this reason it has been suggested that it is a response to heavy bacterial colonization or epidermal invasion in a patient with defective immunity [6]. The pustule-fringed variety called pyodermite vegetante of Hallopeau has been described in association with ulcerative colitis.

Pathology. The main hallmarks of the histological response are the appearance of chronic granulation responses and epithelial hyperplasia. Eosinophils are often present in the infiltrate, particularly in pyodermite vegetante. In some ways, it is the absence of other diagnostic features that supports the diagnosis of pyoderma vegetans.

Clinical features [4,5,7]. In some cases, encrusted and hyperplastic plaques appear on the skin surface. These may break down and weep and there is often central clearing. Where a prominent edge with crust formation is seen, the lesions may mimic blastomycosis. Alternatively, there may be ulceration, the condition resembling a form of pyoderma gangrenosum. In pyodermite vegetante, crusted, red plaques containing pustules have been described in multiple sites from the flexures to the scalp. Oral involvement may also occur with white plaques and pustules. Lesions may heal spontaneously but generally this is a chronic disease.

Diagnosis. This is difficult and largely depends on the exclusion of other conditions, such as specific infections, iododerma, pyoderma gangrenosum and pemphigus vegetans.

Management. It is important to exclude underlying disease such as ulcerative colitis, lymphoma or leukaemia. In doubt, repeat biopsies from the skin lesion may be necessary. There is usually a poor response to antibiotics alone, and the widespread application of antiseptics, although the latter may help to dry lesions. In some cases, topical corticosteroids appear to produce some response.

Dermatitis gangrenosa infantum

The aetiology of this rare condition is unknown. It is mainly reported to occur within the first 2 years of life. The infant presents with multiple necrotic ulcers on the skin surface. While these may arise *de novo*, they often appear on a pre-existing skin rash such as varicella or severe seborrhoeic dermatitis. The affected child is usually acutely ill with a high pyrexia and rapid deterioration follows [1], often ending in death. The histology of the few reported cases shows an acute necrotic reaction involving dermis and epidermis similar to that seen in pyoderma gangrenosum. While it is possible that, in some cases, this may be a form of infantile pyoderma gangrenosum, secondary complications, such as septicaemia, dominate the clinical picture. *Staphylococcus aureus* may be isolated from cutaneous ulcers, but it is not clear whether this is a secondary event.

Kawasaki disease

SYN. MUCOCUTANEOUS LYMPH-NODE SYNDROME

This condition is a disease usually seen in children, often affecting those under 2 years of age [1]. It presents with fever and a generalized exanthem with lymphadenitis. Complications include myocarditis and arthritis. The aetiology is unknown, although recent evidence would support a role for bacterial superantigens as possible trigger factors.

Aetiology. The disease was first described by Kawasaki in 1967 from Japan, and since then other cases have been recorded from a wide variety of different countries [1]. The condition does not appear to show a significant geographical variation in distribution. It is also more common than originally thought, with over 3000 cases occurring annually in the USA [2]. Males are more commonly affected, and the condition is also seen more often in siblings than in the general population, suggesting the possibility of transmission; however, epidemics of the disease have not been recorded [3].

Various hypotheses have been advanced to account for its symptoms. Initially, these included a rickettsial illness, as small inclusion bodies had been found in vascular endothelium. Some epidemiological evidence suggested that exposure to house-dust mite was a potential risk factor—with the possibility of transmission of an infection through contact with mites. There were also antibodies to a canine rickettsia in some patients' sera.

There has been recent evidence, however, that certain subsets of T lymphocytes ($V\beta2^+$ and $V\beta8^+$) are stimulated, suggesting activation by superantigens [4]. Superantigen (e.g. toxic shock antigens) producing strains of both *Staphylococcus aureus* and *Streptococcus pyogenes* have been isolated from the majority of patients with Kawasaki disease [5]. It has been suggested that these cause disease through widescale activation of immune mechanisms, with cytokine release bringing other cell types, including vascular endothelium, into an uncontrolled immunological reaction. This hypothesis has to be confirmed.

The major complication, the development of small aneurysms of the coronary arteries, is secondary to a vasculitis centreing on these vessels with subsequent damage to the elastic layer [6].

Clinical features. The disease occurs in childhood, often before the age of 2 years, although cases are rarely seen in adults [1,2,7,8]. The onset is acute, with a high fever, which lasts for at least 5–7 days. The mucosae and conjunctivae are injected. In the mouth, the lips are dry and fissured, the tongue appears red with prominent papillae (strawberry tongue), and the throat is injected. After 3–4 days, there is a widespread exanthem on the limbs and trunk, although it becomes localized over the distal extremities, hands and feet [9]. The area affected on the limbs becomes oedematous, and this is followed by scaling over the area previously affected, usually starting with the digits and in the periungual area. In other cases, the rash is morbilliform or erythema multiforme-like.

There is accompanying cervical lymphadenitis in many patients, although it is not always present, and may only involve a single node. Fever resolves after 1–2 weeks, but conjunctival infection and lassitude may persist. In about one-quarter of cases there is accompanying myocarditis, which may be followed by symptomatic coronary artery disease and in 1–2% by myocardial infarction. Myocarditis presents with arrhthymia or tachycardia; pericarditis and valve incompetence may also occur. Coronary disease occurs secondary to aneurysms of the coronary arteries, which may thrombose. However, these also regress over a couple of years in most patients.

Other complications include arthralgia, arthritis, severe erythema multiforme, iritis, proteinuria, hepatitis and aseptic meningitis.

Diagnosis. Abnormalities on investigation include leukocytosis and thrombocytosis with a raised erythrocyte sedimentation rate. The raised platelet count is most often seen in the post-acute phase. There is no specific diagnostic test for this syndrome.

While this condition may resemble a number of virus-associated exanthems, the presence of the typical rash and accompanying myocarditis are characteristic.

Treatment. Intravenous gammaglobulin in high dosage (2 g/kg in a single infusion over 10 h) is very helpful, and reduces the overall mortality and complications of the disease, including the risk of coronary aneurysms [10]. The treatment appears to work rapidly with resolution of fever. Aspirin is also helpful in reducing the risk of platelet aggregation, and is used short term in most patients and long term if there is evidence of coronary aneurysms.

Suppurative hidradenitis

SYN. APOCRINITIS; HIDRADENITIS SUPPURATIVA

Definition. Suppurative hidradenitis is a chronic relapsing inflammatory disease originating in apocrine gland follicles, which may become chronic and often indolent due to subcutaneous extension with induration, scarring, destruction of skin appendages and sinus formation.

Aetiology. Hidradenitis begins after puberty, when the apocrine glands are fully developed. Most sizeable studies show a preponderance of females, for example 62 of 95 [1]; 40 of 62 [2]; 19 of 32 [3]; and 22 of 24 [4]; but the reason for this is not known. Onset after the age of 40 years is uncommon, although chronic recurrent disease may occasionally persist into the seventh decade. The size and density of apocrine glands are the same in patients as in normal adults [5].

Many apocrine glands do not open directly to the skin surface, but into the upper portion of the pilosebaceous duct above the sebaceous gland. Comedones are not normally present in apocrine gland-bearing skin, but are generally seen in or around affected skin in hidradenitis patients. Comedonal occlusion of the 'apocrine gland follicle' unit therefore obstructs the outflow of the apocrine gland in addition to that of the sebaceous gland, and is believed to be the initiating event in hidradenitis. The association of suppurative hidradenitis with severe or conglobate acne and with perifolliculitis capitis (the 'follicular occlusion triad', or tetrad if pilonidal sinus is included) is impressive in a few cases [6], but is not seen in the majority of hidradenitis patients. In a series of 70 women with hidradenitis, acne was not more frequent than in controls [7]. In a genetic study involving 62 patients, eight had acne conglobata, and five of these were from one family [2]. In most cases therefore the aberrant and characteristic occlusive process is limited to apocrine sites. Whether the earliest inflammatory changes in the occluded gland and its associated follicle are based on pyogenic bacterial infection, or more closely resemble the acne process, is not known. After that, bacterial infection seems to be important in the extension of the disease and probably in the destructive scarring, and once the sinuses have formed, secondary bacterial infection is readily understandable. Considering the volume and purulence of the discharge in some cases, the frequent negative results on routine bacteriological examination are striking, but with attention to laboratory technique, a higher yield of potential pathogens can be obtained. In one study of 32 patients with inguinal perineal hidradenitis, the majority had pathogenic bacteria at some stage in their course; from correlation with disease activity, and the generally partial but occasionally impressive responses to antibiotic treatment, there was evidence that certain bacteria contributed to the disease process [3]. These included *Staphylococcus aureus*, anaerobic streptococci and, notably, the microaerophilic organisms *Streptococcus milleri* (Lancefield group F), a recognized cause of purulent disease and abscesses [8,9]. Micro-aerophilic streptococci had been identified in six of the 13 cases studied in detail by Brunsting in 1939 [10]. Cases with *Bacteroides* spp. responding to appropriate treatment have been reported [11]. In other studies including stated or probable cases of hidradenitis, *S. aureus*, anaerobic streptococci and *Bacteroides* spp. were cultured [12,13], although not all cases yielded pathogenic bacteria.

As the apocrine gland extends well below the dermis into the less supportive subcutaneous tissue, the suppuration readily breaks through the gland and extends under the skin. The subsequent scarring process is poorly understood, but the resultant induration, tissue distortion, obliteration of appendages and the formation of partly epithelialized sinuses are hallmarks of the fully developed disease process.

There is evidence for hormonal effects in hidradenitis, apart from the necessity for pubertal development of the apocrine glands [14]. Improvement during and relapse after pregnancy, and premenstrual and menstrual exacerbation, are commonly noted by women patients, suggesting that low levels of oestrogen predispose to disease activity. Seven women developed hidradenitis while they were taking oral contraceptives, generally those with androgenic progestogens and a low oestrogen/progestogen ratio [15]. Androgen levels were on average increased compared with controls, but were normal in many individual patients [16]. In that study, hirsutism was commoner than expected, but there is no evidence of systemic virilization [7]. End-organ sensitivity may be the main mechanism for the effects of androgens in hidradenitis [14], but it is not known whether this applies to the sebaceous gland or the apocrine gland or both. Hidradenitis and acne were presenting features of acromegaly in two men [17].

Various immune defects presumably predispose to the infective element of the disease in individual cases [18–20]. Seven of 27 patients with hidradenitis had a marked reduction in T lymphocytes and a higher frequency of HLA-A1 and -B8 [21]. However, immunity in most patients appears to be intact [22].

Two of 27 cases were diabetic and a further four had impaired glucose tolerance [22]. There is no evidence to incriminate shaving, chemical depilation, deodorants or talcum powder [23]. A genetic study of 26 probands

eliciting a total of 62 cases found that 48 belonged to 11 families with patterns in keeping with autosomal dominant inheritance [2]; a reluctance to admit to the disease was noted and the authors suspected under-reporting. Of 70 women with hidradenitis, 18 had a family history of the disease [7].

Pathology. In the predestructive stages, keratin plugs are seen in the apocrine gland follicles, along with inflammatory changes within and around the apocrine glands, the ducts of which may be distended with leukocytes. There is some evidence that occlusion of abnormal hair follicles may play an important part in the initiation of these lesions [24]. Groups of cocci may be seen within the glands and in the dermis. Later, the suppuration extends into the adjacent and subcutaneous tissues, where there may be a chronic inflammatory cell infiltrate involving histiocytes and giant cells related to remnants of glandular epithelium and keratinous debris. Amid dense fibrosis, there are sinus tracks lined partly by granulation tissue and partly by squamous epithelium. Skin appendages are obliterated by scarring [10,25].

Clinical features [10,26]. Suppurative hidradenitis occurs in skin containing apocrine glands. The axillae (Fig. 27.20) and the perineal region (including genital, pubic, inguinal (Fig. 27.21), and perianal areas, buttocks and upper thighs) are therefore the main sites, the more severe disease usually occurring in the latter. The disease may also affect the female breast, the neck, the posterior aspect of the ears and the adjacent scalp, and the back. Onset and resolution of active inflammation often occur independently in the different areas.

Comedones, often polyporous, are usually present in or beside affected skin. Pruritus and vague discomfort may precede the development of one or more small, firm, subcutaneous nodules with pain and tenderness, and for weeks or months there may be no clinically obvious suppuration except that small pustules may surmount the nodules. If subcutaneous extension occurs it leads to indurated plaques, or, in lax, flexural skin as in the axillae and groins, to thick linear bands. Inflammatory nodules often rupture externally, giving rise to chronic sinuses with intermittent or persistent discharge of fluid consisting of serous exudate, blood and pus in varying proportions. Ulceration sometimes occurs and burrowing abscesses may perforate neighbouring structures.

The severity and the course are variable but persistence for many years with partial remissions and acute relapses is common. Episodes of acute cellulitis are sometimes a feature accompanied by fever and toxicity.

Complications. The formation of fistulae to urethra, bladder, rectum or peritoneum has occurred rarely [6,27]. Sequelae of chronic inflammation include secondary anaemia [28], hypoproteinaemia, amyloidosis, renal disease [29], interstitial keratitis [30], and peripheral and axial arthropathy [31]. Squamous carcinoma, sometimes metastatic, is an occasional complication in long-standing cases, which has occurred mainly in perineal disease [32,33]. Chronic malaise and depression are understandably present in many severe cases.

Diagnosis. Possible misdiagnoses are numerous, and vary with the stage and site. Axillary and inguinal lesions that have ulcerated may be confused with scrofuloderma. Inguinal lesions may simulate actinomycosis, granuloma inguinale or lymphogranuloma venereum. When only

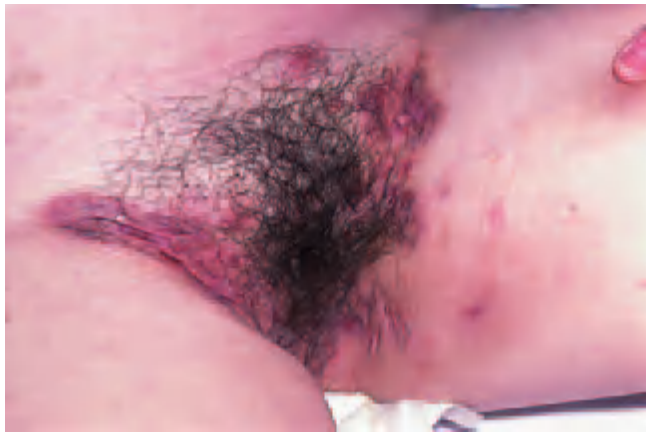

Fig. 27.21 Inguinal suppurative hidradenitis. (Courtesy of York District Hospital, York, UK.)

one of a few nodules and sinuses are present in the anogenital region, pilonidal sinus, sigmoidal diverticulitis and Crohn's disease must be excluded.

In atypical cases, the diagnosis may be difficult. The characteristic comedones should be sought and the non-specific histological changes may be negatively useful.

Treatment. Improvement in local hygiene, including weight reduction in the obese and the use of antiseptic–detergent agents for washing, is advisable.

Acute episodes and relapses should be treated as bacterial infections. Repeated specimens, and active collaboration with the microbiologist, are essential. Plausible pathogens should be treated with full doses of appropriate antibiotics, probably for 2 weeks in most cases [3]. Penicillins seem often to be disappointing, perhaps due to inadequate penetration into scarred and sequestered lesions. Erythromycin, combined with metronidazole if tolerated, may be a suitable initial choice pending the results of bacteriological examination. Clindamycin [11] and minocycline are each useful in some cases. The response to this bacteriological approach is variable; a few patients achieve lasting remission, but in most the improvement is partial and reinfection is common.

Long-term antibiotics, usually tetracyclines or erythromycin, in an acne-type regimen are useful in some patients. As in acne, efficacy may eventually be lost, but may be restored after a short break, for example 1 month [34]. Topical clindamycin appeared useful in a double-blind trial [35].

The anti-inflammatory effects of systemic corticosteroids may be useful in acute exacerbations, for example prednisolone 60 mg daily [36], and lower maintenance doses may give some degree of long-term control.

The choice of oral contraceptive for women with hidradenitis should probably be made from preparations with a high oestrogen/progestogen ratio, and possibly also with low androgenicity in the progestogen [16]. An oral contraceptive containing 50 mg ethinyloestradiol was shown to be useful in some cases as the sole therapy apart from topical antiseptic [37]; a regimen with the same oestrogen combined with cyproterone acetate 50 mg was no more effective, but in another study, cyproterone acetate 100 mg was superior to 50 mg [38].

Retinoids appear useful in some cases. Isotretinoin in a dose of about 1 mg/kg/day for 4 months was accompanied by improvement in four out of eight patients [39], but others have not seen a response [40,41]. Isotretinoin does not affect the size of apocrine glands [42]. Etretinate (or acitretin) may be more useful at least in some cases: a woman who had failed to respond to isotretinoin 2 mg/kg daily, improved on acitretin 0.5 mg/kg daily for 6 months; a relapse after 11 months responded to a further course [43]. The drug's effects on inflammation and on epithelial differentiation may be relevant. Lithium may trigger hidradenitis suppurativa [44].

Surgery should be considered in refractory cases. Relatively minor techniques include exteriorization, curettage and electrocoagulation of sinus tracts [45], and simple excision of troublesome areas with direct closure or grafting. However, severe disease unresponsive to medical treatment is best treated by deep and wide excision of the whole of the disease-bearing skin along with a margin of at least 1.5 cm, following which silastic foam dressings to permit eventual spontaneous healing are an alternative to grafting [46]. Following this method, recurrence rates were lower for axillary and perianal lesions than for anterior perineal disease, although results in all these groups were generally satisfactory; however, the outcome for inframammary hidradenitis was disappointing [1].

Chapter 28

Mycobacterial Infections

V.M. Yates & G.A.W. Rook

Introduction

The genus *Mycobacterium* contains more than 80 species, most of which are harmless environmental saprophytes. A few species are important pathogens of humans and other vertebrates. The most important obligate human pathogens are *Mycobacterium tuberculosis* and *M. leprae*, but others such as *M. avium* and *M. ulcerans* are also significant. Disease-causing mycobacteria other than *M. tuberculosis* have been variously known as atypical, environmental or opportunistic mycobacteria, but are perhaps now best referred to as non-tuberculous mycobacteria [1].

Tuberculosis (TB) is likely to be as old as the human race. The DNA of *M. tuberculosis* has been detected in a Peruvian mummy, indicating that the disease crossed the Atlantic well in advance of Columbus [2], and it has recently been demonstrated in a skeleton from 300 BC. Tuberculosis has become a global emergency, and there are now more cases than ever before. The situation is aggravated by synergy with human immunodeficiency virus (HIV) [3], the breakdown of health care systems and the inexorable rise in multidrug-resistant (MDR) tuberculosis [4].

This chapter will deal first with the general properties and characteristics of the mycobacteria, before moving on to discuss tuberculosis and then infections with other mycobacteria. Leprosy is considered separately in Chapter 29.

Characteristics of the mycobacteria

The term 'mycobacterium' was given in 1896 to a large group of bacteria producing mould-like pellicles when grown on liquid media. All are slender, non-motile, aerobic, non-sporing rods with a waxy coating that makes them resistant to most stains. Once stained, however, they are not easily decolorized (acid-fast).

The genus can be subdivided into two subgenera, known as the fast (or rapid) growers [5] and the slow growers (which include most of the pathogens). The techniques of biochemistry and molecular biology have made the early classification of Runyon [6] obsolete for the modern mycobacteriology laboratory, since it has no true taxonomic validity [7]. Nevertheless, it is still useful for the classification of those species that may cause human disease. Runyon grouped mycobacteria by their ability to produce a yellow pigment in the dark or only in the light, and by their rate of growth (Table 28.1). This approach is being superseded because the entire sequence of the genome of *M. tuberculosis* is now known [9], and several other species of mycobacterium are also being sequenced [10].

The cell wall of the mycobacteria, which is responsible for their acid-fast staining properties, has a complex structure. The typical peptidoglycan backbone of a Gram-positive bacterial cell abuts onto a typical phospholipid plasma membrane. Outside the peptidoglycan layer, and covalently bonded to it, there is a branched polymer arabinogalactan. Onto this are attached the long chain (C60–C86) fatty acids termed mycolic acids. Numerous other lipids and glycolipids are non-covalently inserted into this lipophilic outer layer. Lipoarabinomannan (LAM, a phosphatidylinositol mannoside) is inserted into the plasma membrane and reaches out through the layers of the wall to the exterior [11].

Epidemiology

The re-emergence of *M. tuberculosis*

Tuberculosis is an ancient disease, but in Europe it was industrialization and urbanization which provoked a sharp rise in its incidence. From the mid-1700s for about a century, a pandemic of tuberculosis swept Europe. By 1800, a quarter of all deaths were caused by it [12]. Migration spread the disease to the Americas, where rates in the former Europeans peaked 50–80 years later, and to South Asia, and Central Africa, where the incidence peaked 100 years later [13]. Nevertheless, right up until the mid-20th century, the disease was being newly introduced into previously uninfected populations—for example, the Inuit of north Canada and the highland natives of Papua New Guinea [14]. In the indigenous population of western Europe, tuberculosis rates declined from 1800 [13].

The organism responsible for tuberculosis was identified over 100 years ago; diagnostic skin tests were developed about 100 years ago; a tuberculosis vaccine has been in use for over 60 years, and chemotherapy for over 30 years. It is one of the anomalies of modern health care that, despite the availability of effective treatments and a trend of decline over the last few decades, tuberculosis is now becoming more common and represents a huge international health problem [15]. The World Health Organization (WHO) has calculated that the global incidence of tuberculosis will rise from about 7.5 million cases in 1990 to about 12 million in 2005 [16]. Increases are due to the arrival of immigrants from countries with a high prevalence of tuberculosis [17], to epidemics in certain communities [18], to co-infection with HIV [3], and to wars and the breakdown of health care systems and economies. It is estimated that one-third of the world's population (i.e. 1.86 billion) is infected (though mostly without any apparent disease) [19]. There are 7.96 million (95% CI, 6.3–11.1 million) new cases per year and 1.8 million deaths (95% CI, 1.4–2.8 million) [19]. The case fatality is 23% overall, but more than 50% in some African countries.

Notification rates for tuberculosis were declining in most developed countries until the mid-1980s, but between 1988 and 1992, tuberculosis notification rates increased by 12% in England and Wales in the poorest 30% of the population [20]. In England and Wales, the incidence of tuberculosis in the white population is about 4.6 per 100 000 per year [16]. This represents 37% of cases. Among immigrants from the Indian subcontinent, the annual incidence is 120 per 100 000 overall (38% of cases). The incidence in the black/African population was the highest (210 per 100 000; 13% of cases). More than 50% of all cases were born overseas, and the incidence during the first 3 years after entry to the UK is as high as 400/100 000 [17]. An estimated 3.3% of all adults with tuberculosis in the UK were co-infected with HIV, so HIV co-infection has had a relatively small impact [17].

In the USA, HIV infection is undoubtedly the most important cause of the increase in tuberculosis, a breakdown in control programmes being a contributing factor [21]. In the USA, the incidence of tuberculosis in inner cities has risen to 150 per 100 000, and MDR has become a problem [4,22]; although the overall frequency of MDR in new, previously untreated, cases is about 1%, it is much higher in some countries (see also p. 28.26). Poverty, unemployment and homelessness all increase the risk of tuberculosis and of drug resistance, because of the difficulties of management in these circumstances [21,23].

The global impact of HIV on the incidence of tuberculosis

It is estimated that 4 million people are co-infected with HIV and with *M. tuberculosis*, and that three-quarters of these live in sub-Saharan Africa [24]. It is estimated that 50% of HIV-infected individuals in the developing world are co-infected with tuberculosis [25]. The risk of active tuberculosis in people infected with HIV and *M. tuberculosis* is 3–8% per year, with a lifetime risk of 50% or more [26]. The WHO estimates that there will be a fivefold increase in HIV-associated tuberculosis deaths over the next 10 years [27].

The epidemiology of non-tuberculous mycobacterial infections

In addition to the recent rise in incidence of *M. tuberculosis* infection, there has been a relative increase in infections caused by other mycobacteria which are widespread in nature. They are found in soil, animal and human faeces, vegetation, and water in lakes, rivers, swimming pools and aquaria [1]. They are essentially environmental saprophytes and can elicit an immune response in humans without causing overt infection. Skin tests using tuberculins prepared from different non-tuberculous mycobacteria have been used to estimate the frequency of such covert

infections in various populations [28,29]. The results have been hard to interpret, as different species share many antigens and may cross-react, but it is clear that reaction rates are high in many populations, especially in country areas in comparison with cities.

Because these organisms are of relatively low pathogenicity, some host impairment is generally needed for the development of disease. The lungs, bones, joints and—less frequently—the skin are the chief target organs, but the clinical manifestations are as variable as those of tuberculosis itself. A mycobacterial cause should always be suspected for lesions developing at the site of trauma if these follow a chronic course despite antibiotic therapy.

The passage of infection from person to person is exceedingly rare with the opportunistic mycobacteria; it follows from this that established control methods, known to be effective in tuberculosis, have no effect upon the incidence of opportunistic mycobacterial infections [30].

In addition, the isolation of such organisms does not necessarily imply that they are causing disease [30]. Of the 105 strains of mycobacteria isolated from house dust in Queensland, Australia, for example, only 56% were potentially pathogenic; *M. fortuitum* was isolated 11 times [31]. On the other hand, in a series extending over 10 years, non-tuberculous mycobacteria were the cause of skin disease in seven patients in whom the diagnosis had not been made clinically [32].

Immunology of tuberculosis

The three major paradoxes

Three factors in the immunology of tuberculosis remain poorly explained, as discussed below. These are the latent state, the balance between protection and immunopathology after previous exposure, and failure to eliminate persistent mycobacteria.

Following infection, only 5–10% of individuals develop progressive disease, but some bacteria remain viable in the tissues of the subclinically infected individuals. When tissues from healthy individuals living in TB-endemic

countries are examined by *in situ* polymerase chain reaction (PCR), DNA from *M. tuberculosis* can be detected not only in macrophages, but also in cells such as fibroblasts and type II pneumocytes, located in lung tissue devoid of lymphocyte infiltration [1]. Neutralization of tumour necrosis factor-α (TNF-α) for the treatment of rheumatoid arthritis can lead to reactivation and progressive disease [2], and so can extreme stress, living in war zones and immunosuppression. Clearly, we need to understand more about the nature and significance of the latent state.

About 5–10% of exposed individuals manifest disease. Such overtly diseased individuals usually develop a powerful necrotizing skin-test responsiveness to the antigens of *M. tuberculosis*, and this immunopathological reaction is also likely to account for much of the lung damage. Robert Koch in the 1890s observed that killed bacteria or culture supernatant injected into the skin of tuberculous guinea pigs would evoke necrosis both at the injection site and in existing tuberculous lesions —the 'Koch phenomenon' [3]. At first, he mistakenly believed this phenomenon to represent a protective mechanism. However, attempts to treat the human disease by provoking the Koch phenomenon were often fatal, because necrosis was induced in pre-existing lesions, whether in the lung or spine [4]. Subsequent studies in the 1940s proved that guinea pigs that had been immunized so that they developed the Koch phenomenon before challenge with living bacteria were in fact more susceptible than animals that had not been immunized at all [5]. The same is true in humans. Protection correlates with small tuberculin reactions such as those seen in recipients of bacille Calmette–Guérin (BCG) vaccine, rather than with large necrotizing reactions [6]. A crucial question is therefore the difference between protection and immunopathology.

The inefficiency of this immunopathological response as a microbicidal mechanism has a second important consequence. When patients with tuberculosis are treated with the conventional antibiotics and chemotherapeutic agents, most of the organisms are killed rapidly by the drugs. However, there are 'persisters' (which may be biologically distinct from the latent bacteria discussed above) that are not eliminated by the drugs or by the immune response. The failure of the immune response to eliminate persisters, even when virtually all bacteria have been killed by drugs, is attributable to the fact that the immunopathological response does not quickly revert to the non-necrotic protective mechanism characteristic of the responses in successfully BCG-vaccinated individuals. Therefore treatment must continue for at least 6 months, or relapse will occur [7]. A research priority is the development of immunotherapy that will 'turn off' the Koch phenomenon, and boost protective mechanisms, and so allow shorter treatment regimens.

Protective immunity to *M. tuberculosis*

The cell wall of the mycobacterium is resistant to damage mediated by antibody and complement, and immunity depends on the presence of an intact T-lymphocyte response. Experiments in mice using gene knockout and neutralizing antibodies have shown that immunity is mediated by Th1 lymphocytes that recognize antigens from *M. tuberculosis* and as a result secrete cytokines including interleukin-2 (IL-2) and interferon-γ (IFN-γ). These cells activate macrophages and enhance formation of cytotoxic T cells, which are effector systems involved in killing of the mycobacteria [8–11].

Definitive evidence that the type 1 response is also crucial for immunity to tuberculosis in man has come from the study of children with genetic defects of the type 1 cytokine system. Vaccination with BCG, an avirulent derivative of the organism responsible for bovine tuberculosis, occasionally causes disseminated infection. The IFN-γR1 gene in such a child had a single nucleotide deletion that resulted in the creation of a premature stop codon near the N terminus [12]. A different defect in the IFN-γ receptor was identified in another study of four children with disseminated *M. fortuitum*, *M. avium* (two strains) and *M. chelonei* [13]. IL-12 receptor deficiency has also been found in otherwise healthy individuals with mycobacterial infections [14].

Despite this understanding, the precise effector mechanisms that kill *M. tuberculosis* remain controversial. There may be several pathways, some involving activation of macrophages by IFN-γ and TNF-α [15], others involving killing of the infected macrophage by cytotoxic $CD8^+$ T cells (or γ/δ T cells), with simultaneous killing of the contained bacteria [16–18], and some involving death of the bacteria during certain types of apoptosis of the infected cells [19,20]. It has proved extremely difficult to demonstrate convincing killing of *M. tuberculosis* by human peripheral blood or lung lavage cells *in vitro.*

The issue is further complicated by the multitude of T lymphocyte types, in addition to conventional $CD4^+$ and $CD8^+$ cells, that recognize components of *M. tuberculosis*. In humans and other large long-lived animals, there are several types of T cell—including αβ T lymphocytes negative for both CD4 and CD8 molecules (so-called double-negative T cells), γδ T cells and certain $CD4^+$, $CD8^+$, $CD8\alpha/\alpha^+$ cells and natural killer (NK) lymphocytes—that recognize mycobacterial LAM, mycolic acids or isoprenoid glycolipids, presented by the major histocompatibility complex (MHC) class 1-like molecules of the CD1 family [21,22]. It is fascinating that the different forms of CD-1 'survey' different intracellular compartments, and so will encounter products of *M. tuberculosis* in different ways [23]. Nevertheless, the role of these cells is unclear, partly because the appropriate forms of CD1 are not present in the mouse, in which most experiments are performed.

A dominant theme in other domains of immunology is the regulatory T cell ('T_{reg}'), though these cells have received little attention in the context of tuberculosis. T_{reg} cells characteristically release IL-10 and transforming growth factor-β (TGF-β), and suppress inflammation in models of allergy, inflammatory bowel disease and autoimmunity [24]. It has been claimed that T cells cloned from the bronchoalveolar lavage of human patients with tuberculosis make both IFN-γ and IL-10, and so may be a form of T_{reg} [25]. At least one mycobacterial species has been formally proven to evoke regulatory T cells, so inappropriate or premature activation of T_{reg} is clearly a possible mechanism of failure of the immune response, and failure to eliminate persisting bacteria [26].

The role TNF-α in tuberculosis

TNF-α is crucial for protection in the early stages of tuberculosis in the mouse [27], but becomes toxic in the later stages [28]. Proof of the protective role of TNF-α in man is available only in relation to latent tuberculosis. An antibody that neutralizes TNF-α has been achieving some success as a treatment for rheumatoid arthritis, but a clear consequence in some individuals is the reactivation of latent tuberculosis [2]. As in mice, the role of TNF-α in late progressive disease changes, and it becomes toxic [29]. This may be related to the mechanism of the immunopathology as discussed in the next section.

Immunopathology

At present, the only viable hypothesis is that the immunopathology is related to a switch towards expression of Th2 cytokines such as IL-4. Since IgE is IL-4-dependent, the discovery some years ago that tuberculosis patients have specific IgE antibody that binds to *M. tuberculosis* should have made this clear [30]. Recent work has proved that IL-4 and IL-13 production are increased in human pulmonary tuberculosis, and correlate with cavitation and with the immunopathological features [31–35]. It was particularly $CD8^+$ cells secreting IL-4 (or more probably IL-4δ2; see below) that correlated with cavitation in van Crevel's work [33]. It was also shown by quantitative reverse transcriptase polymerase chain reaction (RT-PCR) that the IL-4 mRNA copy number correlated significantly with serum IgE, serum soluble CD30 and extent of cavitation [31,32]. Similarly, IL-4 expression can be detected in many lesions from severe tissue-damaging tuberculosis by *in situ* hybridization [36].

Not only are expression levels markedly increased in fresh unstimulated blood cells from tuberculosis patients [31], but T cells from tuberculosis patients cloned in response to *M. tuberculosis in vitro* release IL-4 when driven by TB antigen [34]; however, the cytokine profile secreted returns to Th1 after successful treatment [34]. This, together with the presence of *M. tuberculosis*-specific IgE [30], indicates that the increased IL-4 secretion is a true result of a response to TB antigens. Similarly, there is accelerated disease in mice with pre-existing Th2 responses to the 'common' antigens shared with environmental saprophytic mycobacteria [37], to protein antigens of *M. tuberculosis* [38], or even to a single 16 amino acid epitope from ovalbumin expressed within the strain of recombinant *M. tuberculosis* used for challenge [39].

Interestingly, the IL-4 response in human tuberculosis differs from the Th2 response that accompanies allergic disorders, in that it involves both IL-4 and the splice variant of IL-4, IL-4δ2 [32]. In contrast, in allergic disorders there is a disproportionate rise in expression of IL-4 itself [40]. Moreover, in tuberculosis the IL-4 response occurs in the presence of a much larger Th1 response than is the case in allergic diseases.

As IL-4 expression increases, so TNF-α becomes more toxic [28,37], as is also seen in models of schistosomiasis [41] and *Trichinella spiralis* [42]. As mentioned earlier, this increasing toxicity of TNF-α is also seen in the human disease [29].

The tuberculin test

The tuberculin test depends upon delayed-type hypersensitivity to mycobacterial antigens, mediated by lymphocytes, following an intradermal injection of purified protein derivative (PPD). PPD is stable but not particularly specific, so a positive test can result from clinical or subclinical infection, from BCG vaccination or from contact with environmental mycobacteria. More species-specific 'new tuberculins' are available [1], prepared by the ultrasonic disruption of other mycobacteria—these include, for example, burulin, prepared from *M. ulcerans* [2]. These may be of particular value in difficult cases in which mycobacteria other than *M. tuberculosis* may be involved. Reactions to environmental non-tuberculous mycobacteria explain the high proportion of non-specific reactions to tuberculin in certain areas such as south-eastern USA.

Tuberculin sensitivity appears within a few weeks of the onset of an infection with *M. tuberculosis*, and is usually lifelong. In any community, the number who react strongly to tuberculin relates to the prevalence of active tuberculosis. It does not necessarily imply immunity to tuberculosis. Indeed, the risk of developing clinical tuberculosis in tuberculin-positive children is roughly proportional to the strength of their tuberculin reaction [3], and protection consistently correlates with small non-necrotizing responses, while large necrotic responses indicate either susceptibility or actual disease [4]. Presumably this represents the switch from a protective Th1 response to the immunopathological Koch phenomenon discussed earlier.

Weaker reactions do not correlate with the amount of active tuberculosis in a community. Some, as mentioned earlier, are due to infection with other mycobacteria, and others are due to the waning of reactivity under various influences, including ageing. Reversion after a primary infection occasionally occurs in children, and the maintenance of reactivity may depend on continuing exposure to environmental mycobacteria. Eskimos, for example, who live in an almost mycobacterium-free environment, do not always remain tuberculin-positive after the use of BCG, but may still be protected by it. The significance of a positive tuberculin test, therefore, depends partly upon the origin of the patient.

In addition, misleading negative reactions occur in anergic patients, who are usually those who are very ill (for instance, with miliary tuberculosis), or whose delayed

hypersensitivity reactions are non-specifically reduced by other diseases, e.g. an acute viral infection, sarcoidosis, malnutrition or malignant disease (particularly lymphoma). Similarly, tuberculin reactions can be altered by immunosuppressive drugs, including corticosteroids, and by calciferol therapy.

The Mantoux test

PPD is injected intradermally into the volar aspect of the forearm using a 27-gauge needle. This test has the advantage of allowing different or serial strengths of tuberculin to be delivered to the dermis. The test is read at 48–72 h, and the diameter of the area of induration (in millimetres), not the area of erythema, is recorded (although some authors feel that persistent erythema may be important [5]). Five or 10 tuberculin units (TU) may be used initially unless active tuberculosis is suspected, in which case a dose as low as 1 TU may be selected. Serial testing might start with 1 TU, which can be followed by 10 TU and 100 TU if negative. Using 5 TU, induration of more than 10 mm is strongly suggestive of a past or present tuberculous infection.

The Heaf test

This is performed with a spring-loaded instrument, which causes six short needles to penetrate through a solution of PPD or old tuberculin to a depth of 1.2 mm. Heaf testing is reliable and the equivalent of 100 TU by standard testing [6]. Four to six papules constitute a grade I reaction; a continuous circle of induration grade II; a plaque of 12 mm grade III; and a grade III reaction with added vesication or ulceration is termed grade IV. Grade III or IV reactions suggest past or present tuberculous infection. Grades I and II may be due to other mycobacteria or past BCG vaccination.

Diagnosis of mycobacterial infections

Some mycobacterial infections may be suspected from their clinical features, geographical location, or the interests or occupation of the patient. For example, *M. marinum* infections are seen in tropical aquarium owners or dolphin trainers. Others such as *M. ulcerans* may not be recognized so easily. Any obscure granulomatous or ulcerative lesion of the skin should pave the way for a laboratory diagnosis. This may well take several weeks in the case of 'slow growers', and treatment may have to be initiated on the basis of clinical probabilities. The histology, if granulomatous, as with *M. marinum* infections, will be helpful. Sections should always be stained for acid-fast bacteria. Impression smears or curettage samples may provide a more rapid answer, as in *M. ulcerans* infections. The techniques of molecular biology are now making it possible to identify different species rapidly by using nucleic acid probes to recognize specific DNA or RNA base sequences. These newer diagnostic methods have been reviewed [7,8], and their utility in the real world of clinical diagnostic medicine has been critically considered [9].

Co-infection with *M. tuberculosis* and HIV

The risk of active tuberculosis in people infected with HIV and *M. tuberculosis* is 3–8% per year, with a lifetime risk of 50% or more [10]. It is estimated that 50% of HIV-infected individuals in the developing world are co-infected with mycobacteria [11]. Two-thirds of the isolates are organisms of the *M. avium* complex, and 10% are *M. tuberculosis*. The two other organisms most commonly isolated are *M. kansasii* and *M. scrofulaceum*, but more unusual species such as *M. terrae* or *M. xenopi* are also reported [12–14].

Roughly 5% of patients with acquired immune deficiency syndrome (AIDS) develop disseminated mycobacterial infections which cause their death. Their tuberculosis seems usually to be the reactivation of a latent infection, and is often extrapulmonary. In HIV-infected patients, the clinical and radiographic appearance of pulmonary tuberculosis is often atypical, and extrapulmonary involvement, including involvement of the skin, is frequent [15]. For example, acute miliary tuberculosis of the skin and scrofuloderma may be seen [15,16]. With non-tuberculous mycobacteria, the portal of entry is often intestinal, perhaps via contaminated drinking water, and the symptoms may include chronic diarrhoea.

The question has been raised of chemoprophylaxis with antituberculous drugs in patients with HIV and coexisting *M. tuberculosis* infection, to prevent reactivation of latent tuberculosis [17]. Prophylaxis with isoniazid, in a 12-month study in Haiti, reduced the incidence of tuberculosis from 10.0 to 1.7 per 100 person-years, and delayed the progression of HIV disease [18,19]. Single-drug prophylaxis does not increase drug resistance in the community unless used in patients with active disease, and so screening for this has to be carried out if prophylaxis is being considered [18]. The cost of prophylaxis in developing countries has been assessed as favourable when compared with a course of standard antituberculous therapy.

The increased risk of problems with BCG vaccination [20], and recommendations covering this, are discussed in the section on BCG vaccination below.

Tuberculosis

Introduction

In western Europe, tuberculosis of the skin had become relatively uncommon as the incidence of all forms of tuberculosis fell up to the late 1980s [1]. Since then, numbers of notified cases of tuberculosis have risen, especially in urban areas and in minority ethnic groups, notably those of the Indian subcontinent and black African origin and where there is HIV co-infection [2]. In one UK district, cutaneous tuberculosis made up 4.4% of all cases of tuberculosis notified between 1981 and 1995 [3]. In India in the 1950s and 1960s, cutaneous tuberculosis affected 2% of all skin outpatients. By the 1980s, this had fallen to 0.15% [4] and in two recent series this had fallen to 0.1% [5,6]. A current problem is that atypical and even standard presentations may be overlooked through lack of familiarity with them.

Natural history

M. tuberculosis and *M. bovis* are pathogenic to humans. *M. bovis* is also found in a wide range of animal species. The majority of human disease is due to *M. tuberculosis*, *M. bovis* being found in only 1–1.5% of isolates [7]. Transmission of infection within and between species is mainly by inhalation of airborne droplet nuclei particles containing *M. tuberculosis* complex, resulting in pulmonary infection. *M. bovis* may also penetrate the gastrointestinal mucosa and lymphatic tissue of the oropharynx when ingested in milk. Direct inoculation of the skin by *M. tuberculosis* complex also occurs. Survival of *Mycobacterium* species in aerosols generated from human saliva is usually less than an hour, indicating that close and prolonged contact is required for transmission of infection [8]. Studies of contact tracing have shown that 1% of close contacts are affected [9].

Spread takes place rapidly via the lymphatics to the lymph nodes draining the area of infection, and then further spread occurs via the bloodstream. In persons with intact cell-mediated immunity, activated T cells and macrophages form granulomas that limit spread of the organism. The granuloma that forms at the site of pulmonary infection constitutes the Ghon focus, and this, together with the enlarged hilar nodes, is termed the primary complex. The tuberculin test becomes positive after 3–8 weeks; this may be accompanied by fever or erythema nodosum, which is therefore a sign of a recent primary infection.

The subsequent course varies, depending on factors of virulence, resistance and the immunological responses described earlier. Often the organisms fail to thrive and the disease is arrested; less often, it progresses. Sometimes organisms may lie dormant after a primary infection, only to reactivate later, causing a recrudescence of the primary infection.

In the lung, the Ghon focus may be absorbed, become fibrotic and calcified, or may break down, liquefy and discharge bacilli into the lung. On the skin, the primary focus is a tuberculous chancre (p. 28.11). If the contiguous regional lymph nodes break down, scrofuloderma occurs (p. 28.13).

To the epidemiologist, 'primary' tuberculosis means any lesions developing within 5 years of the original infection [10], while later lesions are considered as 'secondary'. There must always be difficulty in determining whether post-primary lesions are due to the reactivation of existing disease, for example as in patients with AIDS, or due to reinfection, particularly since BCG protection diminishes with time.

Exogenous reinfection is probably rare, but does occur [11], and the reactions seen in a host already sensitized by a previous infection differ from those of the unsensitized. A primary infection in the skin, for example, will be manifest as a cutaneous chancre whereas inoculation into a previously sensitized host may lead to tuberculosis verrucosa cutis (p. 28.12).

Histopathology [1]

Early non-specific inflammatory changes give rise after 3–6 weeks to a characteristic tubercle. At this stage, tubercle bacilli are rarely found, although inoculation cultures may be positive. The fully formed tubercle consists of a focus of epithelioid cells containing a variable, but usually sparse, number of Langhans' giant cells and a surrounding infiltrate of mononuclear cells. The centre of the tubercle undergoes caseation necrosis and sometimes calcifies. Endovascular or perivascular changes in the vicinity of the tubercle become more marked as necrosis proceeds, and are accompanied by a cellular reaction leading to fibrosis.

Such granulomas vary greatly in appearance, depending on the predominance of one or other of the elements mentioned. These variations and their correlation with the clinical types of cutaneous tuberculosis are described later. In general terms, the presence of bacilli is a sign of immunological poverty in the host. Typical or less well-developed tuberculoid granulomas occur in many conditions other than tuberculosis (see below).

Development of the granuloma

Histochemical studies have shown that the mononuclear cells of a tubercle are blood-derived monocytes with a high content of lysosomal enzymes. They develop into macrophages which then give rise to epithelioid cells, some fusing into multinucleated giant cells [2]. Caseation necrosis is due to the death and degeneration of these epithelioid cells.

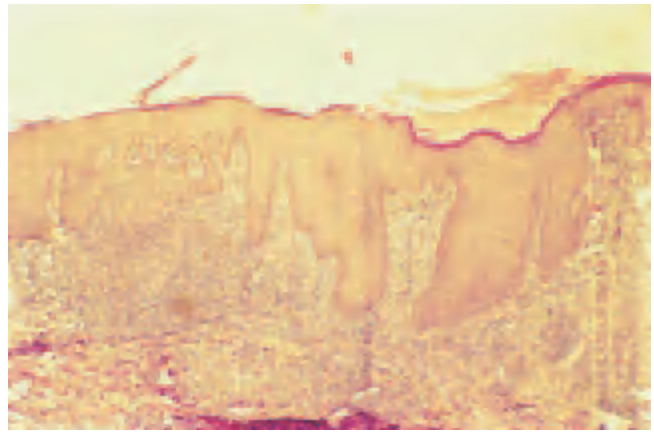

Fig. 28.1 Warty tuberculosis. The epidermis shows marked acanthosis, while the superficial dermis contains a mixed infiltrate of neutrophils and lymphocytes, deep to which there are granulomas. (Courtesy of Dr T.J. Stephenson, Royal Hallamshire Hospital, Sheffield, UK.)

Specific changes

Differences in the histopathological appearances depend on the balance between infection and immunological response. In the tuberculous chancre (p. 28.11), an acute necrotic neutrophilic reaction changes to a mononuclear infiltrate and, after 3–6 weeks, into typical tubercles in which the bacilli may no longer easily be seen. In *miliary* and *orificial* forms, the typical tubercle does not form or is imperfect or necrotic [3]. Bacilli are normally numerous, except in the milder neonatal form of miliary tuberculosis [4].

In *scrofuloderma*, the skin is destroyed by non-specific abscess formation and ulceration. Tubercle formation and caseation necrosis occur at the periphery, and bacilli can, with diligence, be found. In warty tuberculosis, the classical hallmarks are often missing, but there is marked hyperkeratosis, acanthosis and papillomatosis (which may be pseudoepitheliomatous) and an intense dermal infiltrate of neutrophils, lymphocytes and some giant cells (Figs 28.1 & 28.2). Bacilli are rarely demonstrable; typical tubercles are uncommon, and caseation is rare.

The appearances in *lupus vulgaris* (Fig. 28.3) are variable and may give rise to diagnostic difficulty. The typical changes are those of well-marked tubercle formation with epithelioid nodules embedded in sheets of lymphocytes. Occasionally, the epidermal changes resemble those of warty tuberculosis. Caseation is usually sparse or even absent, and the amount of lymphocytic infiltrate is variable. Bacilli are seldom demonstrated, although guinea-pig inoculation may be positive. As the lesions heal, increasing fibrosis strangles the remaining small foci of tubercle bacilli or epithelioid cells, which slowly become absorbed by the reparative process. Squamous and basal cell epithelioma may arise in long-standing lesions.

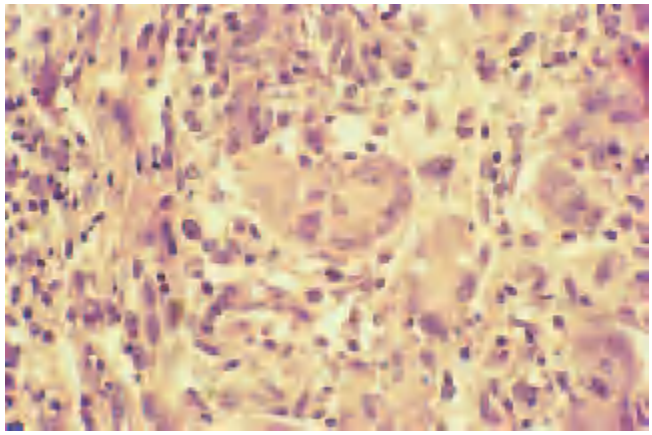

Fig. 28.2 The deep dermis in warty tuberculosis. The infiltrate consists of numerous histiocytes and epithelioid granulomas with prominent Langhans' giant cells (centre), characterized by a horseshoe-shaped configuration of nuclei. (Courtesy of Dr T.J. Stephenson, Royal Hallamshire Hospital, Sheffield, UK.)

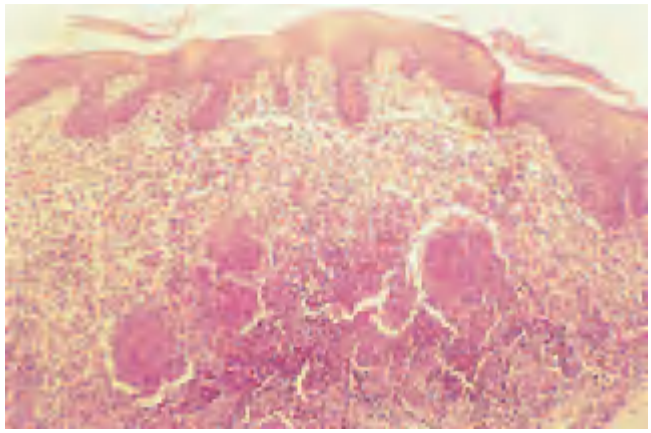

Fig. 28.3 Lupus vulgaris. The epidermis is mildly hyperplastic, while the mid-dermis contains a focus of caseous necrosis surrounded by well-formed epithelioid granulomas containing Langhans' giant cells. (Courtesy of Dr T.J. Stephenson, Royal Hallamshire Hospital, Sheffield, UK.)

Differential diagnosis

The histological signature of the tubercle bacillus is susceptible to forgery. The typical features are characteristic, but the variations invite confusion with many other diseases, especially if caseation necrosis is absent or the subject's immunity is poor.

It is impossible to differentiate the lesions of other mycobacterial infections except by successful culture at 25–30°C. In sarcoidosis, all the features except caseation necrosis may be present, and differentiation from lupus vulgaris may be impossible, although the epithelioid cell foci tend to be more scattered and well defined, and are surrounded by relatively fewer lymphocytes and by reticulin. In tuberculoid leprosy, a neural and perineural involvement is the only distinguishing feature. In leishmaniasis, one must rely on finding the causative organism; similarly with blastomycosis and chromoblastomycosis. Tertiary syphilis shows more pronounced vascular changes and a plasma cell infiltrate.

A non-specific tuberculoid infiltrate, with irregular groups of epithelioid cells in an inflammatory infiltrate but without the formation of typical tubercles—as seen, for example, in rosacea or panniculitis—may also cause confusion.

Tuberculosis of the skin

M. tuberculosis can induce a spectrum of cutaneous changes dependent on the route of infection and the immunological state of the host. Primary infection of the skin produces a tuberculous chancre in the non-immune host, whereas the so-called 'prosector's wart', or tuberculosis verrucosa cutis, occurs in primary infection in the immune host. Post-primary skin lesions such as lupus vulgaris, where single or multiple chronic skin lesions occur, are much more common manifestations of skin tuberculosis. Scrofuloderma results from contiguous involvement of the skin overlying tuberculosis in a deeper structure. This is most commonly lymphadenitis, bone or joint disease, or epididymitis. Metastatic tuberculous abscess can occur due to haematogenous spread from a primary focus. This usually occurs when host resistance is suppressed, can be part of miliary tuberculosis and results in single or multiple lesions. Orificial, perioral or perianal tuberculosis can occur following ingested mycobacteria from either swallowed respiratory secretions or milk contaminated with *M. bovis*.

Most of the tuberculides—once attributed to cutaneous immunological reactions to tuberculosis elsewhere in the body in an immune host—are now known to be true forms of cutaneous tuberculosis, following identification of *M. tuberculosis*-complex DNA in the skin lesions [1]. There are three main forms: micropapular, e.g. lichen scrofulosorum; papular, e.g. papulonecrotic tuberculide; and nodular, e.g. erythema induratum of Bazin.

The incidence of the different forms of cutaneous tuberculosis varies globally. Scrofuloderma was the commonest form in the most recent UK series [2], whereas lupus vulgaris occurred most commonly in a study from South Africa [3]. Reviews from Hong Kong have shown a

Table 28.2 Classification of cutaneous tuberculosis. (Modified from Beyt *et al*. [7].)

I *Inoculation* tuberculosis (exogenous source)	Tuberculosis chancre Warty tuberculosis (verruca cutis) Lupus vulgaris (some)
II *Secondary* tuberculosis (endogenous source)	
A Contiguous spread	Scrofuloderma
B Auto-inoculation	Orificial tuberculosis
III *Haematogenous* tuberculosis	Acute miliary tuberculosis Lupus vulgaris (some) Tuberculous gumma
IV *Eruptive* tuberculosis (the tuberculides)	
(i) Micropapular	Lichen scrofulosorum
(ii) Papular	Papular or papulonecrotic tuberculide
(iii) Nodular	Erythema induratum (Bazin), nodular tuberculide

change in the commonest form of skin tuberculosis in recent years from tuberculosis verrucosa cutis in 1968 [4] to erythema induratum in 1995 [5]. In India, scrofuloderma was the most frequently found form in childhood, whereas lupus vulgaris was the commonest form in adults [6].

Classification

No entirely satisfactory classification exists, reflecting the difficulty in classifying a disease whose diverse manifestations are dependent on so many factors, such as the host's cell-mediated immunity and route of infection. Darier separated proven tuberculosis lesions from the remainder. This led, inevitably, to a number of conditions being accepted as 'tuberculides' on circumstantial evidence. Confusion between true tuberculosis and a less specific 'tuberculoid' histology compounded the difficulty until the advent of effective antituberculosis drugs. Then the lack of response of many of the so-called tuberculides, and their tendency to resolve spontaneously, led to a more critical evaluation of their aetiology. With the advent of new methods to detect *M. tuberculosis*-complex DNA, the picture has become much clearer. The classification adopted here [7] (Table 28.2) has the merit of extreme simplicity, since it does not attempt to introduce immunological considerations.

Primary inoculation tuberculosis

SYN. TUBERCULOUS CHANCRE

Definition. A tuberculous chancre is the result of the inoculation of *M. tuberculosis* into the skin of an individual without natural or artificially acquired immunity to this organism.

Pathogenesis. The bacillus enters the skin through abrasions and minor injuries, usually on the face or limbs and commonly in children. Tuberculous chancres have followed ritual circumcision [1], infections with inadequately sterilized syringes [2], wounds [3], operations [4], ear-piercing, mouth-to-mouth artificial respiration [5] and tattooing [6]. In regions where tuberculosis is prevalent in the community, lesions may occur anywhere on the body from contact with sputum or following insect bites [7] or pyococcal infections of the skin. Sexual transmission has been reported [8,9].

Incidence. This is now a very uncommon primary presentation of tuberculosis, and a rare form of skin tuberculosis [10], except in Asia.

Histopathology. The early changes are those of acute neutrophilic inflammation with necrosis. Numerous bacilli are present. After 3–6 weeks, the infiltrate becomes more granulomatous and caseation appears, coinciding with the disappearance of the bacilli.

Clinical features. The earliest lesion may be a nondescript, brownish papule or nodule, or a ragged ulcer with an undermined edge and a granular haemorrhagic base. In time, the edge becomes firmer, and a thin adherent crust develops. When obvious trauma is absent, the initial lesion is often small, with a central silvery scale, and may show 'apple-jelly' nodules on diascopy. The lesions may be seen on the face [11]. Apparent healing may conceal active infection below the surface or be accompanied by regional lymphadenopathy. Occasionally, lupoid nodules occur around the healed ulcer or deeper infection simulates scrofuloderma. Lesions closely simulating paronychia have been described [12].

Mucosal lesions. Conjunctival lesions cause oedema and irritation [13]. Ulceration and oedema of the lids, with preauricular lymphadenitis, has been described [14]. Oral lesions are uncommon [5], but painless lesions, often

misdiagnosed, may form in a tooth socket or on the gums.

Diagnosis. Any painless unilateral, localized glandular swelling, especially in a child, should arouse suspicion; careful examination may reveal a small scar or a lupoid patch. Before adenitis occurs, the diagnosis can be confirmed by microscopy and culture. If acid-fast bacilli are seen, antituberculosis therapy should be started without waiting for further proof. At this stage, the lesion may be confused with tularaemia, sporotrichosis or actinomycosis [15]. Cat scratch fever (see Chapter 27) and especially *M. marinum* infections (p. 28.28) closely resemble primary tuberculosis, but are distinguished by their distribution or course, and cultural characteristics. The correct diagnosis is most likely to be overlooked in the anal and genital areas [1], particularly in children.

Course. The chancre will heal slowly, taking many months, but rarely may proceed to lupus vulgaris. Occasionally, fever is marked at the onset; more often, it is slight. Erythema nodosum developed in four out of 40 patients in one series [13].

The enlarged draining lymph nodes usually subside slowly, often calcifying; less often, cold abscesses and sinuses develop. Rarely, miliary tuberculosis supervenes.

Warty tuberculosis [1]

SYN. TUBERCULOSIS VERRUCOSA CUTIS

Definition. An indolent, warty, plaque-like form of tuberculosis occurring as a result of the inoculation of organisms into the skin of a previously infected patient who usually has a moderate or high degree of immunity. It was the predominant form of tuberculosis in the Chinese in Hong Kong in the 1960s [2].

Pathogenesis. Lesions arise in three ways. The first is by accidental superinfection from extraneous sources: physicians, pathologists and post-mortem attendants are traditionally at risk (thus, 'anatomist's warts', 'prosector's warts', 'verruca necrogenica') [3].

The second is by autoinoculation with sputum in a patient with active tuberculosis. Finally, children and young adults, already infected and having some degree of immunity, may become infected from sputum by sitting or playing where the organism is present [4,5].

Histopathology. There is a striking pseudoepitheliomatous hyperplasia with superficial abscess formation. The intense, mixed infiltrate may show only sparse tuberculosis foci. Bacilli are seen only occasionally.

Clinical features. Lesions occur on those areas exposed to trauma and to infected sputum or other tuberculous material. In Europe, the lesions are most likely to occur on the hands, but in Asia the knees, ankles and buttocks are mainly involved [5,6].

The lesion starts as a small, symptomless, indurated, warty papule with a slight inflammatory areola. By gradual extension, a verrucose plaque is formed. Irregular extension at the edges leads to a serpiginous outline with finger-like projections. The centre may involute, leaving a white atrophic scar, or the whole lesion may form a massive, infiltrated papillomatous excrescence (Fig. 28.4). The colour is purplish, red, or brown. The consistency is generally firm, but there may be areas of relative softening. Pus may sometimes be expressed from these soft areas or from fissures. The lesions may resemble lupus vulgaris [7], but the sites are different. At times, the appearance is psoriasiform (Fig. 28.5) or keloidal. Occasionally, exudative and crusted features are predominant. Perianal lesions from intestinal tuberculosis may be mimicked. Tuberculous lymphadenitis can occur, but is rare [8]. More commonly, lymphadenitis is due to secondary pyococcal infection.

Anomalous forms. Deeply destructive papillomatous and sclerotic forms may cause deformity of the limbs. A generalized form, associated with papulonecrotic and lupoid lesions [9], occurs in patients with active disease, but is best regarded as a haematogenous form with a variable

Fig. 28.4 Warty tuberculosis of the perianal skin.

Fig. 28.5 Warty tuberculosis of the hand.

tissue response. An exuberant granulomatous form was described in the Chinese in Hong Kong [5] and is also seen in other Eastern races [6]. Tumour-like forms can occur [10].

Differential diagnosis. Subungual and digital lesions must be distinguished from warts, and those on the hands from keratoses. Blastomycosis, chromoblastomycosis and actinomycosis may simulate exuberant forms, and crusted lesions may resemble leishmaniasis. Tertiary syphilis may be confused when the central scarring is surrounded by a serpiginous edge. Hypertrophic lichen planus and lichenification occasionally cause difficulty, but lesions of these disorders are multiple or itchy. Lupus vulgaris is not usually hyperkeratotic and shows apple-jelly nodules on diascopy (Chapter 5).

The lesions caused by non-tuberculous mycobacteria can usually only be distinguished by microbiological culture. *M. marinum* poses particular difficulties (p. 28.28). Pyoderma due to other organisms may simulate this condition; the histology differs only by the absence of tuberculoid foci.

Course. The condition responds to antituberculosis treatment; without it, extension is usually extremely slow and lesions may remain virtually inactive for months or years [11]. Spontaneous remission may occur and usually results in atrophic scars. Active disease of other organs should be looked for, as bone, glandular or pulmonary tuberculosis may coexist [5].

Secondary tuberculosis

Scrofuloderma

SYN. TUBERCULOSIS COLLIQUATIVA CUTIS

Definition and pathogenesis. Scrofuloderma results from the involvement and breakdown of the skin overlying a contiguous tuberculosis focus. This is usually a lymph gland, an infected bone or joint, or a lacrimal gland or duct (Figs 28.6 & 28.7) [1]. In a report which included details of 23 patients with scrofuloderma [2], the condition

Fig. 28.6 Scrofuloderma associated with tuberculosis of the axillary glands occurring in a 74-year-old Caucasian man prior to antituberculous therapy. (Courtesy of the Editor of the *British Journal of Dermatology*.)

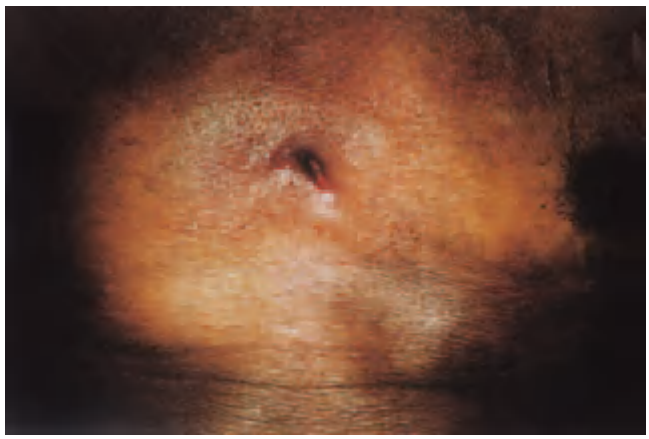

Fig. 28.7 Scrofuloderma associated with sternal tuberculosis occurring in a 62-year-old Pakistani man. (Courtesy of the Editor of the *British Journal of Dermatology*.)

occurred most commonly after cervical gland infection, less often with axillary, inguinal, epitrochlear and retroauricular gland infection, and in only two patients after infection of the tibia and fibula. The face and neck were again the most frequently affected sites for lesions in another series of 27 patients [3]. It was the commonest form of cutaneous tuberculosis in childhood in a recent large series from India [4] and in another series of adults from the UK [5].

Histopathology. There is usually an ulcerated dermal abscess with an ill-defined histiocytic component. Marked caseation necrosis, in which there are usually numerous bacteria, is seen in the deeper structures. Tubercle bacilli can usually be easily isolated from the pus.

Clinical features. A bluish-red nodule overlying the infected gland or joint breaks down to form undermined ulceration with granulating tissue at the base. Numerous fistulae may intercommunicate beneath ridges of a bluish skin. Progression and scarring produce irregular adherent masses, densely fibrous in places and fluctuant or discharging in others. Excessive granulation tissue may give rise to fungating tumours. After healing, characteristic puckered scarring marks the site of the infection. Sweet's disease has been described in association with scrofuloderma [6].

Diagnosis. The nature of the underlying lesion is usually evident. The diagnosis is confirmed bacteriologically. *M. intracellulare* lymphadenitis and the more benign *M. scrofulaceum* need to be excluded by culture.

Course. Spontaneous healing can occur, but the course is very protracted and leaves typical cord-like scars.

Orificial tuberculosis

SYN. TUBERCULOSIS CUTIS ORIFICIALIS; ACUTE TUBERCULOUS ULCER

Definition. Tuberculous infection of the mucosa or the skin adjoining orifices in a patient with advanced internal tuberculosis. It is now very rare. It occurs particularly in those with pulmonary, intestinal or anogenital disease [1]. Most of those affected are males.

Pathogenesis. This is normally a form of autoinoculation tuberculosis, although extraneous sources are occasionally responsible [1]. The lesions occur where there is

Fig. 28.8 Periorificial tuberculosis. Crusty erosions are evident on the gingival surface and mucosal surface of the lip. (Courtesy of Dr F. Nachbar, Ludwig Maximilian University, Munich, Germany, and the Editor of the *British Journal of Dermatology*.)

advanced pulmonary, intestinal or genitourinary disease from which large numbers of mycobacteria are shed and inoculated into the mucous membranes of orifices. In general, local trauma determines the site of the lesions.

Histopathology. The histopathological changes are variable and are often of non-specific inflammatory type, but tubercle bacilli are usually present.

Clinical features. The affected patient is usually a severely ill adult with advanced visceral tuberculosis who may have impaired cell-mediated immunity. Lesions occur most commonly in the mouth (Fig. 28.8). In a series of 42 patients with orofacial disease, 69% had oral ulceration, 21% had bone involvement and 14% salivary gland and/or lymph-node involvement [2]. A tooth socket may be involved after dental extraction. Other sites include the genitalia [3], around the anus in those with intestinal tuberculosis, and other locations adjacent to an orifice draining an active tuberculous infection.

Small oedematous red nodules rapidly break down to form painful shallow ulcers with undermined bluish edges. The ulcers seldom exceed 2 cm in diameter and show no tendency to heal spontaneously.

Diagnosis. Pain is the cardinal feature. There is usually evidence of disease elsewhere; 79% of one series had associated pulmonary disease [2]. The diagnosis is confirmed bacteriologically. Polymerase chain amplification of mycobacterium-specific gene segment has been demonstrated and may speed up diagnosis [4]. The tuberculin test is variable; in the later stages at least, the patient is often anergic.

Treatment. The source of the local infection must be traced and antituberculosis therapy instituted.

Haematogenous tuberculosis

Miliary tuberculosis

Definition and pathogenesis. Miliary tuberculosis of the skin occurs in association with generalized miliary tuberculosis and is due to haematogenous dissemination of mycobacteria into the skin. It is rare and usually affects young children or immunosuppressed patients such as those with concurrent HIV infection [1] or following viral infections such as measles [2].

Clinical features. The skin manifestations are often deceptive—profuse crops of minute bluish papules, vesicles, pustules or haemorrhagic lesions in a patient who is obviously ill. The vesicles may become necrotic to form small ulcers [3]. Erythematous nodules have been described [4]. The underlying disease may not be manifest, and the diagnosis is sometimes only made by the biopsy of a skin lesion showing acid-fast bacilli [5].

A search should be made for evidence of internal tuberculous infection [6].

Diagnosis. The development of an unusual exanthematic rash in an ill person with known tuberculosis or tuberculous contacts suggests the diagnosis, which should be confirmed by biopsy. Antituberculosis therapy should be started immediately if there is a strong suspicion. The tuberculin test is negative.

Course. The prognosis is poor, but response to treatment is possible.

Lupus vulgaris

Definition. A chronic progressive post-primary form of cutaneous tuberculosis occurring in a person with a moderate or high degree of immunity. The characteristic lesion is a plaque, composed of soft, reddish-brown papules, said by some on diascopy to resemble apple jelly. The edges of the lesion gradually extend in some areas and heal with scarring in others, sometimes causing considerable tissue destruction over many years.

Incidence. In recently published series from India and South Africa, lupus vulgaris was the most commonly found form of cutaneous tuberculosis in adults [1,2] and the second most prevalent after scrofuloderma in a series from the UK [3]. The condition appears to be more common in women than men.

Pathogenesis. Lupus vulgaris originates from an underlying focus of tuberculosis, typically in a bone, joint or lymph node, and arises by either contiguous extension of the disease from underlying affected tissue or by haematogenous or lymphatic spread. Sometimes the underlying focus is not clinically apparent, and in such cases reactivation of a latent cutaneous focus secondary to previous silent bacteraemia is postulated [4]. It can also arise after exogenous inoculation or as a complication of BCG vaccination [5].

Lupus vulgaris is typically a paucibacillary form of cutaneous tuberculosis, which often makes successful culture difficult. In one series, bacilli were cultured from only 6% of nearly 4000 patients [6]. Concomitant diagnosis by both culture and detection of mycobacterial DNA using PCR has been reported and may be useful where small numbers of mycobacteria are present [7].

Histopathology. The histological features are variable. Normally, tubercles with scanty or absent central caseation, surrounded by epithelioid histiocytes and multinucleate giant cells, are present in the superficial dermis. Peripheral lymphocytes are often prominent. Occasionally, tubercle bacilli may be numerous [8]; more often, they are hard to demonstrate. The epidermis may be ulcerated with an associated mixed inflammatory infiltrate, atrophic or acanthotic. If the acanthosis is severe, giving rise to pseudo-epitheliomatous hyperplasia, differentiation from squamous cell carcinoma may be a problem [9].

Clinical features. Lupus vulgaris commonly appears in normal skin as a solitary lesion, although it can arise at the site of a primary inoculation, in the scar of scrofuloderma or at the site of a BCG vaccination [5]. In Europe, over 80% of lesions are on the head and neck, particularly around the nose [6,10]. Next in frequency are the arms and legs, but involvement of the trunk is uncommon. In India, the face is affected less often and the buttocks and trunk more frequently [11].

The initial lesion is a small, reddish-brown, flat plaque of soft, almost gelatinous, consistency. On diascopy, the diagnostic apple-jelly nodules may be demonstrated. The lesion gradually becomes elevated, infiltrated and brown and grows by slow peripheral extension to become gyrate or discoid in shape with areas of atrophy. There is usually only a single focus, except in disseminated forms which usually occur in association with active pulmonary tuberculosis [12]. Sporotrichoid-like spread has also been reported [13].

The many clinical forms fall into five general patterns, depending on the local tissue response to the infection, but atypical forms are becoming more common.

1 *Plaque form* (Fig. 28.9). Flat plaques with irregular or serpiginous edge. The surface of the lesion may be smooth or covered with psoriasiform scale. Large plaques may show irregular areas of scarring with islands of active lupus tissue. The edge often becomes thickened and hyperkeratotic.

2 *Ulcerative and mutilating forms* (Fig. 28.10). Scarring and ulceration predominate. Crusts form over areas of necrosis. The deep tissues and cartilage are invaded and contractures and deformities occur. In milder forms, keratotic plugs overlying pinpoint ulcers are associated with slow scar formation.

3 *Vegetating form* (Fig. 28.11). This is characterized by marked infiltration, ulceration and necrosis with minimal scarring. Mucous membranes are invaded and cartilage is slowly destroyed. When the nasal or auricular cartilage is involved, extensive destruction and disfigurement ensue.

4 *Tumour-like forms* (Fig. 28.12). The hypertrophic form presents either as soft tumour-like nodules or as epithelial hyperplasia with the production of hyperkeratotic masses. In the 'myxomatous' form, huge soft tumours occur predominantly on the ear lobes, which become grossly enlarged. Lymphoedema and vascular dilatation are sometimes marked.

5 *Papular and nodular forms*. Multiple lesions occur in disseminated lupus—true 'miliary lupus'.

Mucosal involvement. The nasal, buccal or conjunctival mucosa may become involved, either primarily by a papule, nodule or ulcer, or by spread from a contiguous skin lesion. Nasal lesions start as nodules, which bleed easily and then ulcerate, leading sometimes to cartilage destruction. A dry rhinitis may be an early symptom. Granulating, vegetating or ulcerating lesions of the buccal mucosa, palate, gingiva or oropharynx may occur by direct extension or by lymphatic spread from nasal lesions. These can produce stenosis of the larynx and scarring deformities of the soft palate.

Prognosis and complications. Despite long periods of indolence, the natural course of an untreated lesion is

(a)

(b)

Fig. 28.9 (a) A huge plaque of lupus vulgaris on the right arm. (b) Lupus vulgaris of the right cheek. (Courtesy of Professor J.A.A. Hunter, Royal Infirmary, Edinburgh, UK.)

inexorably progressive. Scarring, contractures and tissue destruction are prominent features. The scars are usually thin, white and smooth, but are unstable and may break down or become keloidal. Active lupus vulgaris frequently reappears in scar tissue. Contraction may lead to ectropion or microstomia, which may require plastic surgery.

Squamous cell and, less commonly, basal cell carcinomas, or sarcomas, may occur insidiously in up to 8% of patients [14,15] and may be confused with renewed activity of the lupus itself (Figs 28.13 & 28.14). A plasmacytoid lymphoma developed in a patient with evidence of impaired immunity [16]. A previously well-controlled

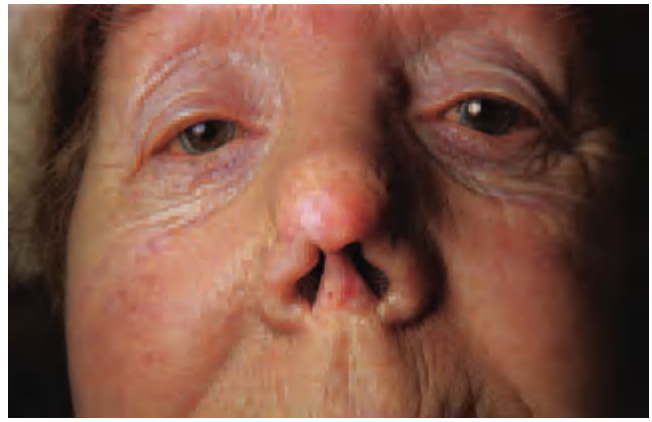

Fig. 28.10 Nasal deformity as a late sequela of lupus vulgaris.

Fig. 28.11 Vegetating lupus vulgaris on the nose. (Courtesy of Dr J.E. Bothwell, Barnsley District General Hospital, Barnsley, UK.)

case became fulminant when the patient developed Hodgkin's disease [17].

Diagnosis. Because of its rarity in the UK, the index of suspicion may be low [18]. The well-established plaque with central scarring presents few difficulties, but in the early stage lupus may easily be confused with lymphocytoma, Spitz naevus or lupus erythematosus. In older patients, syphilis must be excluded. The histological features and culture results will differentiate lupus vulgaris from the deep mycoses, which may closely resemble the vegetating and crusted type. The lupoid form of leishmaniasis may be impossible to distinguish clinically. On the face, lupus may be mistaken for rosacea [18] or for a port-wine stain [19], and on an extremity for other mycobacterial infections.

Leprosy and sarcoidosis, however, are the chief causes of diagnostic difficulty. The nodules of leprosy are firmer, and other signs are present. The nodules of sarcoidosis resemble grains of sand rather than 'apple jelly': this

Fig. 28.12 Hypertrophic form of lupus vulgaris on the ear lobe. (Courtesy of the Editor of the *British Journal of Dermatology*.)

Fig. 28.14 A basal cell carcinoma arising in an old area of lupus vulgaris.

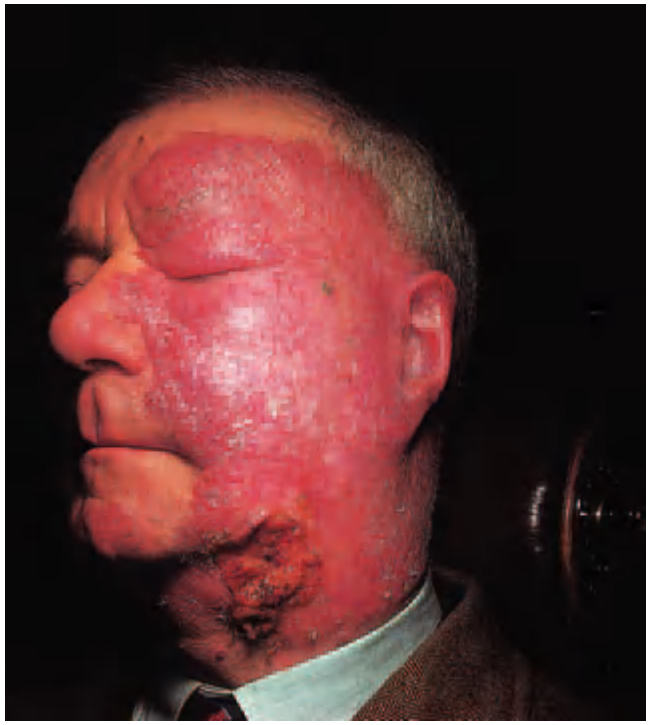

Fig. 28.13 Squamous cell carcinoma of the neck in a patient with lupus vulgaris of many years' duration.

applies to the feel on probing rather than to the colour, which is often greyish.

Lupus vulgaris may resemble psoriasis, but is more infiltrated and usually solitary; Bowen's disease can resemble both. Lupus vulgaris of the perianal area mimicking lichen simplex chronicus has also been reported [20]. Warty tuberculosis usually affects the hand and is more scaly and verrucous than lupus; the histological features are different. Wegener's granulomatosis may be mimicked by rapidly extending granulomatous lesions. It is important that biopsies are deep enough to be representative [18].

Treatment. Standard antituberculosis therapy should be given. Isoniazid has in the past been used as monotherapy, but this practice is strongly discouraged, as up to 26% of patients have clinical evidence of tuberculosis at other sites [1].

Metastatic tuberculous abscess

SYN. TUBERCULOUS GUMMA

Definition. This form of tuberculosis is the result of haematogenous dissemination from a primary focus during periods of lowered resistance, resulting in single or multiple lesions. It is seen particularly in malnourished children or in patients who are immunosuppressed, and has been noted after local trauma [1] and in association with underlying lymphoma [2].

Histopathology. The features are those of tuberculous granulation tissue, with necrosis and abscess formation. Tubercle bacilli can usually be isolated from the pus.

Clinical features. A tuberculous gumma presents either as a firm subcutaneous nodule or as a fluctuant abscess. The extremities are more often affected than the trunk. The overlying skin may break down to form an undermined ulcer, often with sinuses [2]. Lesions may be multiple. Unusual and transitional forms may occur [3]. Rarely, multiple abscesses have been noted during treatment of miliary tuberculosis [4]. Lesions causing carpal tunnel syndrome have been well documented [5].

Diagnosis. The diagnosis is confirmed by culture.

Unusual forms of cutaneous tuberculosis

Unusual forms of cutaneous tuberculosis are well recognized. Some of these have already been mentioned as anomalous forms of the various clinical entities. There remain a number of reported cases that are difficult to fit into any one category. They often resemble lupus vulgaris in histology and morphology, though not in site or behaviour [1,2]. Some of the bizarre manifestations seen in the past were assumed to be due to double infections, poor natural immunity or other coexistent disease as modifying factors.

Gangrenous or vegetating forms with underlying lung or glandular disease have been reported [3]. Patients with coexisting HIV infection may have atypical and widespread skin lesions [4]. Correct diagnosis requires a high index of suspicion and biopsy and culture of any unusual skin lesions. Tuberculous cellulitis-like lesions have been reported in a patient who was diabetic and taking oral corticosteroids [5]. Sehgal *et al*. reported patients with multifocal guttate tuberculosis verrucosa cutis and necklace lupus vulgaris [6].

Suspicion of a tuberculous aetiology should be aroused by painless abscess formation, indolent ulcers with bluish undermined edges, or by nodular, plaque-like or necrotic lesions that defy easy classification. It is not enough to demonstrate acid-fast bacilli—culture or PCR is necessary to confirm the species of mycobacterium. A therapeutic trial may be necessary and desirable, while awaiting laboratory results.

Congenital tuberculosis [1–3]

This is now exceedingly rare. The skin manifestations may be discrete, erythematous lesions, with a central necrotic dell, occurring in infants with a febrile systematic illness.

Malignant disease and cutaneous tuberculosis

Malignant disease may complicate or be associated with tuberculosis of the skin. Squamous cell and basal cell carcinomas may arise in areas of long-standing lupus vulgaris. They may only be detected when one area of the lesion fails to respond to treatment [1,2]. A plasmacytolymphoma has also been reported [3]. A pre-existing, well-controlled case of lupus vulgaris became fulminant with the onset of the lymphoma [4]. Erythema gyratum repens, usually seen in association with an internal malignancy, has been reported with pulmonary tuberculosis [5].

The tuberculides

Definitions. The concept of tuberculides was introduced by Darier in 1896. In contrast to true skin tuberculosis, tuberculides were explained as a hypersensitivity reaction to *M. tuberculosis* or its products in a patient with significant immunity. The main features of tuberculides are a positive tuberculin test, evidence of manifest or past tuberculosis and a positive response to antituberculous therapy. There is virtually always absence of bacilli in skin biopsy specimens and culture, although PCR has detected mycobacterial DNA in some forms. Several conditions once thought to represent tuberculides are now classified as variants of rosacea.

True tuberculides can be grouped as follows:

- Micropapular: lichen scrofulosorum
- Papular: papulonecrotic tuberculide
- Nodular: erythema induratum of Bazin: nodular tuberculide.

Aetiology. The pathogenesis of the tuberculides is poorly understood. All tuberculides are thought to be due to haematogenous spread of bacilli in a person with a moderate or high degree of immunity against *M. tuberculosis*. However, it is not usually possible to detect the tubercle bacilli in tuberculides, either because they are present in a fragmented form or because they have been destroyed at the site of the tuberculides by immunological mechanisms [1]. Mycobacterial DNA has been detected in significant numbers of the papular and nodular forms of tuberculide [2–4], but not as yet in the micropapular form, lichen scrofulosorum [1]. It has therefore been suggested [3] that the papular and nodular forms of tuberculide should be regarded as forms of true post-primary tuberculosis.

Fluctuations in the immunological state of the patient may determine the development and features of the eruption. The onset of lichen scrofulosorum has been noted to occur after the initiation of antituberculous treatment and probable shift in the cell-mediated immune status of the patients [1]. Papulonecrotic tuberculide developed in a patient with HIV infection after an increase in the CD4 T-lymphocyte count occurred following the addition of a second antiretroviral drug [5].

In a large study from Hong Kong, in which 150 patients with cutaneous tuberculide were identified, erythema induratum was by far the commonest tuberculide identified (93.3%), followed by papulonecrotic tuberculide (4.7%), then lichen scrofulosorum (2.0%).

Lichen scrofulosorum

Definition. Lichen scrofulosorum was first described by Hebra in 1868 and is a lichenoid eruption of minute papules occurring in children and adolescents with tuberculosis. It is usually associated with a strongly positive tuberculin reaction.

Fig. 28.15 Lichen scrofulosorum of the trunk. (Courtesy of Dr Antonio Torrelo, Hospital del Niño Jesus, Madrid, Spain.)

Pathogenesis. Previously a common tuberculide, it is now rarely seen in Europe, except among immigrants. It occurs mainly in association with tuberculous lymph nodes [1] and foci in bone [2,3]. More recently, it has been reported with pulmonary tuberculosis and generalized lymphadenopathy [4–6] and in association with *M. avium* infection [7]. It is thought to result from haematological spread. Its onset in some patients may be linked to an up-regulation of their immune system [4]. It has also been reported after BCG vaccination [8]. It has not been reported in association with miliary or meningeal tuberculosis, where the host's immune response is usually poor. Other forms of cutaneous tuberculosis such as lupus vulgaris, tuberculous gumma and tuberculosis verrucosa cutis may coexist [5].

Histopathology. Superficial dermal granulomas surround hair follicles and sweat ducts, and may occupy several dermal papillae. Epithelioid cells, lymphocytes and occasional giant cells are seen. Usually there is no caseation. Mycobacteria are not seen in the sections and cannot be cultured from biopsy material. Mycobacterial DNA has so far not been detected by the PCR, as it has in the other forms of cutaneous tuberculides [1].

Clinical features (Fig. 28.15). The eruption consists of symptomless, 0.5–3.0 mm, closely grouped lichenoid papules. The lesions are usually skin-coloured, but may be yellowish or reddish-brown. They are often perifollicular and appear in groups or in an annular arrangement. The papules may have an adherent crust or small pustule. They are mainly found on the abdomen, chest and back, and proximal limbs.

Diagnosis. Differential diagnosis includes all asymptomatic follicular lesions, where the lesions demonstrate a tendency to group together. These include lichen nitidus, in which the lesions are more shiny and tend to be peripheral; keratosis spinulosa, in which the lesions have spiny projections over lichenoid papules; keratosis pilaris, where the lesions are non-inflammatory and usually on the upper thighs and arms; and papular or lichenoid sarcoidosis, secondary syphilis and drug eruptions. The tuberculin reaction is normally positive, but was negative in one patient with AIDS [9].

Treatment. With specific antituberculous therapy, the lesions usually clear within 4–8 weeks without scarring [5].

Papulonecrotic tuberculide

Definition. An eruption of necrotizing papules mainly affecting the extensor aspects of the extremities and occurring in symmetrical crops. Individual lesions heal with varioliform scarring [1].

Pathogenesis. An associated focus of tuberculosis can be demonstrated in many patients. This ranged from 38% to 75% of patients in three different studies [2–4]. The rapid response to antituberculous therapy usually leaves no doubt of the aetiology when a tuberculous focus cannot be found. In a series of 91 patients, papulonecrotic tuberculide evolved into lupus vulgaris in four patients [2]. Papular tuberculide has also been described after BCG vaccination [5,6], indicating possible haematogenous

Fig. 28.16 Papulonecrotic tuberculide of the legs. (Courtesy of Professor Jamila Aboobaker, University of Natal, Durban, South Africa.)

bacterial spread as a cause of this tuberculide. Mycobacteria are rarely demonstrated in skin lesions, although they were found in two of the patients who had associated lupus vulgaris in the series discussed above [2], and *M. tuberculosis* DNA has been demonstrated in skin lesions using PCR [7]. Papulonecrotic tuberculide has occurred with *M. avium* complex in a patient with AIDS [8]. The tuberculin test is normally positive, often with a severe, and even necrotic, reaction appearing within 8–12 h.

Histopathology [4]. In fully developed lesions, a large central zone of coagulation necrosis is surrounded by inflammation extending from the superficial to the deep dermis, and sometimes into the subcutaneous tissues. A histiocytic palisade, similar to that of granuloma annulare, is seen around larger lesions. The involvement of adjacent small vessels is striking, ranging from a mild lymphocytic vasculitis to fibrinoid necrosis and thrombotic occlusion.

Clinical features (Fig. 28.16). The eruption consists of recurring crops of symmetrical, hard, dusky-red papules. These crust or ulcerate, leaving pigmented, sometimes atrophic, varioliform scars over the course of a few weeks. Lesions are usually asymptomatic. New crops may continue over months or years. In some cases showers of rapidly healing lesions occur, in others a chronic open ulcer may last for some months [3]. Phlyctenular conjunctivitis may be present.

Young adults are predominantly affected, but papulonecrotic tuberculide has also been seen in infants and young children. Two-thirds of a large South African series were under 30 years of age [2]. The legs, knees, elbows, hands and feet are the sites of predilection, but the ears, face, buttocks and penis—sometimes alone [9,10]—may be involved. Perniotic areas may be favoured. A transition to [2] and coexistence with lupus vulgaris [11] has been described and also an association with erythema induratum [12,13].

Diagnosis. Differential diagnosis includes pityriasis lichenoides, where the lesions may be more widespread and affect the palms and soles; leukocytoclastic vasculitis, whose lesions are more pleomorphic; and nodular prurigo. Biopsy and tuberculin testing should be carried out in all cases; a therapeutic trial of specific antituberculous therapy is usually decisive in doubtful cases.

Treatment. Full specific antituberculous therapy should be given.

The nodular tuberculides

Erythema induratum of Bazin [1], in which the main pathology is in the subcutaneous fat, is accepted as a true

nodular tuberculide. There have been recent proposals to separate out a nodular form where there is no ulceration and in which the pathology is at the junction of the dermis and subcutaneous fat; the term 'nodular tuberculide' has been proposed for this pattern [2]. Erythema nodosum, panniculitis and, rarely, nodular vasculitis may also be evoked by tuberculosis, though other causes are more common.

Erythema induratum [1]. This was first described by Bazin in 1861 as a condition occurring 'on the legs of female laundresses and in young and plump well nourished women with the typical phenotype of those with the scrofula'. The lesions are characterized by recurrent nodular and ulcerative lesions and occur secondary to tuberculosis elsewhere in the body. Lesions are usually localized to the lower legs, but can affect other areas. In most published series, the disease has occurred at least four times more commonly in women than men [3].

Pathogenesis. Past or active foci of tuberculosis are usually present and the tuberculin test is positive. *M. tuberculosis* is seldom recovered from the lesions, but mycobacterial DNA can be found in up to 77% of skin biopsy specimens [4]. It has been suggested that purified protein derivative-specific T cells capable of producing IFN-γ may be involved in the formation of erythema induratum as a type of delayed hypersensitivity response to mycobacterial antigens at the site of skin lesions [5].

Histopathology. The features are those of either focal or diffuse, lobular or septolobular, granulomatous panniculitis in association with neutrophilic vasculitis of either large or small blood vessels. There are areas of coagulative and caseation necrosis and, usually poorly developed, granulomas although mixed, pallisading and lipophilic granulomas can occur [6,7].

Clinical features (Fig. 28.17). An indolent eruption of ill-defined nodules, usually affecting the backs of the lower legs of young or middle-aged women. However, lesions may affect other body areas, such as the upper limbs, thighs, buttocks and trunk [6]. Follicular perniosis may be present. Lesions may ulcerate, and this may be precipitated by cold weather. The ulcers are ragged, irregular and shallow, with a bluish edge. Resolution may be slow, even with adequate therapy [8], if there are associated erythrocyanotic features.

Erythema induratum is rare in the UK, accounting for five out of 47 cases of cutaneous tuberculosis in a recent series, all of whom were from the Indian subcontinent [9]. It is now the commonest form of cutaneous tuberculosis found in Hong Kong [3]. It is associated with nasopharyngeal, renal and endometrial tuberculosis [10,11], and a search should be made for active tuberculosis elsewhere.

Fig. 28.17 Erythema induratum of the legs.

Treatment. Full specific antituberculous therapy should be given. There is no place for monotherapy as has been recommended in the past [12], as drug resistance is likely to develop, which means effectively that no treatment is being given.

Nodular tuberculide. Jordaan *et al*. [2] have documented four female patients with dull red or bluish-red non-tender, non-ulcerating, nodules 1 cm or slightly larger in size, located on the lower legs. Pathological changes of granulomatous vasculitis were situated at the junction of the deep dermis and adjacent subcutaneous fat. The Mantoux test was strongly positive in all patients, and associated pulmonary tuberculosis was present in two. All lesions cleared promptly with full antituberculous therapy. They argue that there is a case for a tuberculide where the pathological process occurs neither in the superficial dermis, as in papulonecrotic tuberculide, nor in the subcutaneous fat as in erythema induratum, but rather at the junction of the dermis and subcutaneous fat.

Erythema nodosum. This is fully discussed in Chapter 49. Tuberculosis is now a rare cause in western Europe and the USA, but a more frequent one in countries where the disease is still common. A tuberculous cause should always be considered in children. It occurred in nine out of 113 children with non-respiratory tuberculosis reported in the UK in 1978–79 [13].

Nodular vasculitis. This is fully discussed in Chapter 49. There is an obvious overlap with erythema induratum, though the lesions do not usually ulcerate. Women are most frequently affected, and the lesions are usually dusky, tender and persistent. Tuberculosis has caused some cases seen in the past in the UK [14]. Most authors would now accept those of tuberculous origin to be categorized as erythema induratum and to be separate from those of non-tuberculous origin. An exhaustive search for underlying tuberculosis should be made before

commencing oral steroids or other immunosuppressive agents [15].

Prognosis

Now revolutionized by modern therapy, the prognosis depends largely on early and accurate diagnosis. When tuberculosis has become generalized or has affected the meninges, the prognosis must be doubtful. The mortality in patients with dual tuberculosis/HIV infection is higher than in HIV-negative patients [1,2]. In infants and young children, tuberculosis is always a serious disease.

Tuberculosis confined to the skin usually responds well to multiple therapy, although the acute disseminated and orificial forms may respond less readily.

Diagnosis

Several circumstances may suggest the diagnosis of cutaneous tuberculosis, but the only absolute criteria are a positive culture of *M. tuberculosis* from the lesion or successful guinea-pig inoculation, or mycobacterial DNA identification by PCR (see below). Inoculations are rarely performed now, as equally reliable results can be obtained with multiple cultures. Rapid culture diagnosis, within 2–6 days, can be achieved with the Bactec system [3].

Other indications toward the diagnosis, which are by themselves unreliable, include the following:

1 The presence of active proven tuberculosis elsewhere in the body.
2 The presence of acid-fast bacilli in the lesion itself—this will also be seen in infections with other mycobacteria.
3 The histopathology.
4 A positive reaction to tuberculin.
5 The clinical history and physical signs.
6 The effect of specific therapy.

The difficulties in separating tuberculosis from a 'tuberculoid reaction' (p. 28.10), leprosy (Chapter 29), leishmaniasis (Chapter 32), deep mycoses (Chapter 31), infections with non-tuberculous mycobacteria (p. 28.28), syphilis (Chapter 30) and sarcoidosis (Chapter 58), are dealt with elsewhere.

Polymerase chain reaction

The *in vitro* amplification of specific DNA sequences using the PCR has become a valuable tool in the rapid detection of slow-growing organisms such as *M. tuberculosis*. Several systems have been reported for the molecular detection of mycobacterial DNA using different parts of the mycobacterial genome to generate highly sensitive and specific probes [4–6]. Some assay systems have amplified the insertion sequence IS6110 because of the repetitive nature of this element in the *M. tuberculosis* genome [7]. As few as two colony-forming units of *M. tuberculosis* cells, or as little as 15 fg of DNA, can be detected [8]. Using the PCR technique, mycobacterial DNA has been demonstrated in all the different histopathological variants of cutaneous tuberculosis and in two of the tuberculides (papulonecrotic tuberculide and erythema induratum) [8–12]. The technique reduces the time required for diagnosis in those cutaneous lesions where bacteria can be cultured easily, and may be particularly useful in paucibacillary lesions such as lupus vulgaris. The technique can be used in a variety of pathological specimens, including archival formalin-fixed tissue sections. A generic criticism of this technique lies in its sensitivity; tissue samples containing bacterial DNA may be positive because of bacteraemia and not necessarily because the organism is involved in the pathogenesis of the tissue lesion [11].

Treatment

General measures

In the UK, all patients with tuberculosis must be notified, as this is a statutory requirement [1] and initiates contact tracing if appropriate [2]. Attention to the patient as a whole is an essential part of the proper management of any cutaneous tuberculous lesion and involves a careful search for an underlying focus of disease and coexistent infections. Because of the rising incidence of drug-resistant tuberculosis, it is vital to confirm the diagnosis bacteriologically whenever possible and to obtain drug susceptibilities [3]. Tuberculosis, pulmonary or extrapulmonary, is an AIDS-defining illness. HIV testing, with informed consent and counselling, should be considered if a risk assessment shows the patient to be from an area or background with increased risk of HIV co-infection. If pulmonary, osseous, lymph-node or renal tuberculosis is found, a combined approach with other specialists is essential, as therapy will depend upon the organs involved, the extent of the lesions and the patient's immunity.

Drug therapy

The Joint Tuberculosis Committee (JTC) 1998 guidelines [4] recommend that the treatment of all patients should be supervised by physicians with full training in the management of tuberculosis and with direct working access to tuberculosis nurse specialists or health visitors. In most cases, this will be the respiratory physician of the hospital or district.

Patient non-compliance is currently the most important factor limiting successful treatment. Directly observed therapy (DOT), where the ingestion of every drug dose is witnessed, has shown improved cure rates in a number of countries [5,6] and is recommended for patients who are unlikely to comply. These include patients who are homeless, alcoholics or drug abusers, drifters, seriously mentally ill, patients with multiple drug resistances and those with a previous history of non-compliance with antituberculous medication [7]. DOT should be considered for new immigrants/refugees. DOT can be daily, but an intermittent regimen is often more convenient.

Standard drug regimens

Controlled trials have defined a number of highly effective short-course regimens, and the basic mechanisms of action of the key antituberculous drugs are now better understood [8]. Isoniazid is the most effective bactericidal drug, followed by rifampicin. Rifampicin and pyrazinamide are the most important sterilizing drugs and act by killing different populations of semi-dormant organisms or persisters. Isoniazid and rifampicin are the most effective drugs at preventing the emergence of resistance to other drugs. Streptomycin and ethambutol are weaker, but nevertheless effective, drugs.

Six-month regimens, including four drugs in the initial 2-month phase (rifampicin, isoniazid, pyrazinamide plus streptomycin or ethambutol), followed by rifampicin and isoniazid in the 4-month continuation phase, are highly effective in patients with fully sensitive organisms [9]. Combination tablets should be used whenever possible to aid compliance and to prevent monotherapy.

Drugs in present use [4]. A standard 6-month regimen for adults is now recommended by the British and American Thoracic Societies. It includes four drugs (doses for adults only are given here):

1 Isoniazid (300 mg daily) for the full 6 months
2 Rifampicin (450 mg daily for those weighing less than 50 kg and 600 mg daily above this weight) for the full 6 months
3 Pyrazinamide for the first 2 months (1.5 g daily for those weighing less than 50 kg; 2.0 g daily for those weighing over 50 kg)
4 Ethambutol for the first 2 months (dosage 15 mg/kg body weight daily).

All drugs are taken on an empty stomach once daily.

Isoniazid remains the standard drug, given in all regimens because of its efficacy, cheapness and low toxicity. Its commonest side effects are peripheral neuropathy (most common in elderly people), which can be countered by giving pyridoxine (10 mg daily) prophylactically from the start of treatment, and hepatitis in adults over 35 years of age.

During the first 2 months of *rifampicin* treatment, elevated serum transaminases are common, but therapy can usually be continued, though occasionally more severe liver damage necessitates a change of treatment. Urine,

sweat and tears may be coloured orange. The induction of liver enzymes by rifampicin may reduce the effectiveness of oral contraceptives.

Pyrazinamide causes hepatitis in 1%, arthritis and the precipitation of gout and cutaneous hypersensitivity in 3.5%. The side effects of *ethambutol* include visual disturbances and rarely a retrobulbar neuritis, which is reversible if detected early so that the ethambutol can be stopped. Patients should be warned of this risk and advised to stop the drug if visual symptoms develop. Visual acuity using a Snellen chart should be carried out before treatment starts. The drug is best avoided in young children and in those with renal impairment. Vertigo and tinnitus may limit the use of *streptomycin* in patients over the age of 40 years, and in those with impaired renal function.

In summary, all antituberculous drugs may cause adverse reactions; in one study, reactions occurred in 10% of patients treated. Reactions were significantly more common in those not receiving standard antituberculosis chemotherapy [10].

HIV disease. In HIV-infected patients, there have been no controlled trials of sufficient power to detect differences in efficacy between regimens. A small clinical study suggests that standard regimens, particularly if supervised properly, are as effective in HIV-positive as in HIV-negative patients [11], hence the JTC recommends the same 6-month regimen [4]. The response rate is the same as for non-HIV-infected patients, but there are higher drug reaction rates and higher reinfection rates.

Multidrug resistance. This is defined as resistance to rifampicin and isoniazid with or without resistance to other antituberculous drugs, and is now a worldwide problem. A recent global assessment of resistance [12] showed a median prevalence of 1%, but higher rates were observed in Estonia (14%), Henan province in China (10.8%), Latvia (9%), the Russian *oblasts* of Ivano (9%) and Tomsk (6.5%), Iran (5%) and Zhejiang province in China (4.5%). The situation is getting worse, and the prevalence of MDR is even higher amongst patients with previously treated tuberculosis; in such individuals, the prevalence of MDR can be as high as 34% (Henan province), 25% (Tamil Nadu, India) or 48.2% (Iran). The numbers affected are much higher in developing countries that do not have resources for effective treatment. Increasing rates of MDR tuberculosis in HIV-infected individuals have been reported mainly in the USA [13]. Treatment of such patients is complex and should only be carried out by experienced physicians in hospitals with appropriate isolation facilities and in consultation with appropriate mycobacterial reference laboratories [4]. Currently, only rifampicin resistance can be routinely detected by molecular probes on microscopy-positive or culture-positive tissue. No other drug resistance can be routinely checked without susceptibility tests.

Modification for dermatological practice. Yates and Ormerod have shown that the standard 6-month regimen is effective in treating cutaneous tuberculosis [14]. In their series of patients, over 50% had coexisting disease elsewhere, all had a good clinical response, and there were no relapses following treatment. Historically, some forms of skin tuberculosis have been treated by isoniazid alone [15]. This is no longer appropriate, as drug resistance is likely to develop with monotherapy—and if drug resistance to isoniazid is already present, it means, in effect, that no therapy is being given.

The excision of small lesions of lupus vulgaris or warty tuberculosis, if diagnosed early, may be effective. Surgery may be helpful in scrofuloderma, sometimes shortening the time needed for chemotherapy. Plastic surgery may help the disfigurement left by treated lupus vulgaris.

BCG vaccination [1]

BCG vaccines owe their origin to the *in vitro* attenuation by Calmette and Guérin, between 1906 and 1919,

of a strain of *M. bovis* [2]. Evidence of the efficacy of BCG vaccination derives from studies in infants [3] and schoolchildren. There are few data in adults to suggest that BCG vaccination offers protection if given over the age of 16 years [4,5], although absence of evidence does not necessarily mean absence of effect. In the UK, BCG vaccinations appear to reduce the incidence of childhood tuberculosis by 75% or more [6]. BCG vaccination protects the host by blocking the secondary haematogenous spread of the pathogen, limiting the primary infection to subclinical proportions [7]. In a recent report from northern India of childhood cutaneous tuberculosis, BCG vaccination appeared to protect against disseminated disease [8].

The protective effect of BCG in children is likely to last at least 15 years [9]. In the UK, it is still the policy–particularly in light of the rise in tuberculous notifications since 1987—that BCG is routinely offered in schools to all children aged 10–14 years [10,11] and to certain groups at higher risk of exposure to tuberculosis. These include infants and children of immigrants from countries with a high prevalence of tuberculosis [3], and children born to adults born in the UK but from ethnic groups originating in high-prevalence countries, children with a family history of tuberculosis, and tuberculin-negative travellers to areas of high prevalence. It should also be offered to tuberculin-negative health workers and to staff working in hostels for AIDS patients and the homeless.

Because of the risk of generalized BCG infection, BCG vaccination should not be given to individuals known to be HIV-infected in the UK [12].

Complications

After BCG vaccination, a local reaction usually occurs 2–6 weeks later as a small papule that may slowly enlarge and discharge purulent material to leave a shallow ulcer. Tuberculin conversion normally takes place within 12 weeks.

Complications are rare in relation to the number of vaccinations carried out. Excluding abnormal BCG primary complexes, all reported localized or generalized reactions among nearly 1500 million persons vaccinated between 1948 and 1974 made up less than two per million [13]. Of these, keloids, rashes and ocular manifestations accounted for 1.35 per million and 'tuberculosis-like' lesions for 0.16 per million.

Non-specific reactions to BCG include urticaria and erythema multiforme [14]. Unusual reactions have also occurred, such as generalized maculopapular or purpuric eruptions associated with arthralgia and abdominal pain or myalgia, usually after repeated vaccination [15,16]. Extensive or protracted ulceration sometimes occurs.

Fig. 28.18 *Mycobacterium bovis*–bacillus Calmette–Guérin infection of the glans penis, showing an infiltrated red plaque containing small, deep-seated, yellow papules. (Courtesy of Dr M. Ribera, Hospital Universitari Germans, Universitat Autònoma de Barcelona, Badalona, Spain, and the Editor of the *British Journal of Dermatology*.)

Specific complications include tuberculous processes caused by the BCG organism. Lupus vulgaris may develop at the vaccination site, usually a few months after vaccination, but cases have been reported as long as 3 years after vaccination [17,18]. This can be a recurrent problem [19] and is more likely to occur after multiple vaccinations [20]. Lichen scrofulosorum and papulonecrotic tuberculides have both followed vaccination [15]. Other reports have included the development of basal cell carcinomas in a BCG scar [21], and disseminated cutaneous granulomas in infants with immunodeficiency syndromes [22].

Therapeutic use

BCG is used as immunotherapy in the management of superficial and *in situ* transitional cell carcinoma of the bladder. The BCG vaccine is usually instilled into the bladder on a monthly basis. Primary infection of the glans penis by *M. bovis*–BCG has been described (Fig. 28.18) after intravesical BCG treatment [23]. Distant cutaneous granulomas have been described after BCG immunotherapy for malignant melanoma [24].

Non-tuberculous (atypical) mycobacteria

The non-tuberculous mycobacteria are *Mycobacterium* species different from *M. tuberculosis*. In the late 1950s and 1960s, these organisms were referred to as 'atypical', as they were thought to be unusual *M. tuberculosis* strains [1]. Non-tuberculous bacteria occur much more frequently in immunocompromised hosts, and with the advent of the AIDS epidemic their clinical importance has increased. This has led to recent major advances in our understanding of their biology, epidemiology and clinical presentations. Pulmonary disease remains the commonest clinical presentation following infection with this group of organisms. The commonest non-tuberculous mycobacteria that cause cutaneous infection are members of the *Mycobacterium fortuitum* complex (*M. fortuitum*, *M. peregrinum*, *M. chelonae*, *M. abscessus* and *M. mucogenicum*), *M. marinum* and *M. ulcerans*. In immunocompetent patients, cutaneous infection is usually related to trauma, and skin lesions tend to be localized. Immunocompromised hosts show a tendency to develop widespread or disseminated lesions [2].

M. marinum [3–4]

SYN. SWIMMING POOL GRANULOMA; FISH-TANK GRANULOMA

M. marinum (formally *M. balnei* and *M. platypoecilus*) was first isolated in 1926 by Aronson from saltwater fish carcasses in the Philadelphia aquarium [5]. In 1942, Baker and Hagan showed that the bacteria caused tuberculosis in freshwater platy fish and named the organism *M. platypoecilus*. The first report of human disease appeared in 1951 [6], when the organism was found to be the cause of granulomatous skin lesions in those using a contaminated swimming pool in Sweden and was named *M. balnei*. Subsequently, *M. balnei* and *M. platypoecilus* were shown to be the same organism, and they are now called *M. marinum*. In the late 1950s, *M. marinum* was found to be the cause of infections acquired from aquaria in humans [8].

Aetiology. The natural habitat of *M. marinum* is water, particularly enclosures of water that are not often replenished, such as swimming pools and aquaria [8]. Its distribution is worldwide, but the organism is especially prevalent in heated water in temperate climates and in the sea, natural pools, rivers and on beaches. Its vectors include fresh- or salt-water fish, snails, shellfish, dolphins and water fleas [4]. It can also be isolated from cracks in masonry, mud and from water even where chlorination appears to be sufficient [9].

On immunodiffusion analysis, the organism can be shown to possess antigens characteristic of the slow-growing mycobacteria [10], though its growth is more rapid than that of most members in that group. It will grow on ordinary laboratory media in 7–10 days if cultured at 30–33°C; significant inhibition of growth occurs at 37°C.

M. marinum is probably only pathogenic on abraded skin, although a history of trauma cannot always be elicited [11].

Fig. 28.20 *Mycobacterium marinum* infection showing sporotrichoid spread from the hand to the forearm in an aquarist. (Courtesy of Dr I.H. Coulson, Burnley General Hospital, Burnley, UK.)

Epidemiology. Occupational or recreational exposure to salt or fresh water occurs in the majority of cases. Most of the early proven cases of *M. marinum* infections were described in individuals frequenting swimming pools [12]. The first two cases of 'swimming-pool granuloma' in the UK were reported from Yorkshire in 1964 [13]. In one outbreak, over 300 cases were traced [14]. Similar outbreaks have occurred in Wales [15], France [16] and Germany [17]. The infection has also been contracted in natural bathing pools by the Dead Sea [18] and in the sea in the USA [19].

In many recent cases, the source of infection has been tropical fish tanks [20]. In a national survey of 63 culture-confirmed cases occurring in France between 1996 and 1998, inoculation related to fish tank exposure was documented in 84% of cases [21]. Fish tuberculosis is a chronic infection that causes wasting of the fish, but may take up to 12 months to cause death (Fig. 28.19). Most infections are acquired while cleaning out the tanks. *M. marinum* survives readily in water and can be cultured from dead fish, the sides of tanks, and sand and water samples [22]. One child developed the infection indirectly after bathing in the bath in which his father had recently cleaned a tropical fish tank [23].

Pathology. Lesions may show non-specific inflammation in the first few months, while older lesions show well-formed tuberculoid granulomas [24], with fibrinoid masses rather than caseation. Langhans' giant cells are not always present. Intracellular acid-fast bacilli—longer and broader than tubercle bacilli—are detectable in only approximately 10% of cases [11].

Clinical features. Skin lesions develop after an average incubation period of 2–3 weeks following inoculation of the organisms onto abraded skin. Occasionally, the incubation period can be as long as 9 months [25], leading to delays in diagnosis, as important clinical clues in the patient's history may be overlooked. The initial lesion is either a solitary nodule or pustule that may break down to form an ulcer or abscess, or remain as a verrucous plaque. Lesions are often multiple, and in the sporotrichoid form, which occurs in approximately 20% of cases [26], nodules may extend along the line of lymphatic vessels (Fig. 28.20). The regional lymph glands may be enlarged, but never break down. Deeper infections occurred in 29% of patients in one series [21] and resulted from direct extension of the cutaneous infection. Tenosynovitis, osteomyelitis and septic arthritis can occur [27]. Immunocompromised patients may develop disseminated lesions [28,29].

Lesions are most common on the elbows, knees and feet of swimmers, and on the dominant hand and fingers of fish fanciers. The inhibition of *M. marinum* growth at 37°C accounts for its ability to infect the cooler body extremities whilst rarely spreading systemically.

The infection probably resolves spontaneously in some cases, although complete resolution may take up to 2 years [20].

Diagnosis. As with all mycobacterial disease, the diagnosis requires a high index of suspicion. A history of contact with water, fish tanks, aquaria etc., combined with granulomatous histology, is suggestive of the diagnosis. A positive culture can be obtained in some 70–80% of cases if the organism is grown between 30 and 33°C. It is important to alert the microbiologist to the suspicion of *M. marinum* infection so that specimens are cultured in the appropriate manner. Cultures should be observed for 6 weeks, but generally colonies will be seen in 10–28 days [25]. Species-specific monoclonal antibody against 56-kDa *M. marinum* antigens may have potential use in rapid culture identification [30]. *M. marinum* infection has also been identified using PCR-reverse cross blot hybridization assay with species-specific gene probes [31]. This may

lead to more rapid diagnosis, but cultures will still be necessary to assess antibiotic sensitivities of different strains.

Cultures are of particular value in exclusion of leishmaniasis and sporotrichosis in endemic areas, as well as to identify other atypical mycobacterial infections such as *M. kansasii*, *M. chelonei* and *M. gordonae*, all of which may spread in a sporotrichoid manner. Skin tests using antigens specific to *M. marinum* are of little value [3].

Treatment. Optimal treatment of *M. marinum* infection has not yet been established, and most studies reflect the personal experiences and preferences of individual authors. Antibiotics that have been used include a combination of sulfamethoxazole and trimethoprim [31], the cyclins, particularly minocycline and doxycycline [33], rifampicin plus ethambutol [20,34] and clarithromycin, levofloxacin or amikacin [25]. Cures and failures have been described with all of these drugs. The optimal length of treatment is not certain, but the mean in the most recent study was 14 weeks, with the duration being significantly longer in those patients with infection involving deeper structures [25]. Surgical debridement of lesions is somewhat controversial, but may be useful when deeper structures are involved [35].

One recent study has attempted to draw recommendations for standardized treatments by looking at treatment outcomes [25], and there are also some potentially helpful *in vitro* studies of antibiotic susceptibility patterns for *M. marinum* [36,37]. Rifampicin and rifabutin were found to be the most active drugs in these studies. The mean inhibitory concentrations of minocycline, doxycycline, clarithromycin, amikacin, sparfloxacin, moxifloxacin and sulfamethoxazole were also acceptable. Minocycline consistently had a twofold higher activity than doxycycline, and the cyclines have been shown to give a high percentage cure rate *in vivo*, especially for superficial lesions [25]. Mean inhibitory concentrations were above concentration break points for ethambutol, ciprofloxacin, ofloxacin and levofloxacin and trimethoprim [36], making *in vivo* efficacy less probable. This correlates with results from one study [25] in which treatment failures were reported in half of the patients treated with these antibiotics. The place of the newer fluoroquinolone sparfloxacin still needs to be evaluated clinically. *In vivo* tests of the new glycycline, GAR936, showed similar activity to that of the parent minocycline compound [37].

The public health authorities should be notified when a public source of infection is identified, and other cases should be looked for. Maximum chlorination of swimming pools is effective [16].

Fish fanciers are seldom aware of the risk of mycobacterial infection from their hobby. Simple preventative measures, such as the use of gloves or covering of cuts and grazes should be recommended to fish handlers [22].

M. kansasii

M. kansasii is a slow-growing photochromogenic bacterium of Runyon Group I that grows optimally at 37°C. Water supplies, swimming pools and sewerage are usual habitats. It is found worldwide, but is particularly prevalent in temperate zones such as the USA, the UK, northern France and Belgium. Classically, *M. kansasii* infection produces a granulomatous pulmonary infection in middle-aged men with underlying lung disease [1]. It may also cause superficial cervical lymphadenopathy in young children [2], meningitis, tendonitis, synovitis, arthritis, osteomyelitis or carpal tunnel syndrome. It most commonly affects persons exposed to contaminated water, particularly after local trauma. There is no evidence of person-to-person spread. First reports of the organism as a cutaneous pathogen were not until 1965 [3], and it remains rare, with only 45 cases reported in the literature in a review in 2001 [4]. In 72% of those cases, an immunological disorder resulting from chemotherapy, autoimmune disease [5], AIDS [6], renal or cardiac transplantation [7] or other predisposing factors was noted [8]. Most patients who present with very localized primary cutaneous infection are immunocompetent, whereas the majority of persons with disseminated skin lesions or pulmonary infection are immunocompromised [1].

As a primary cutaneous disease, *M. kansasii* produces a variety of lesions, usually confined to a distal extremity. Sporotrichoid nodules [9], verrucous papules, papulopustules with necrotic centres, erythematous plaques, cellulitis [10], rhinophyma [11], single and multiple abscesses have all been reported. Papulonecrotic tuberculide skin lesions have been reported in one patient [12].

Skin lesions associated with disseminated *M. kansasii* have increased since the onset of the AIDS epidemic, and *M. kansasii* is the second most frequent cause of disseminated mycobacteriosis in AIDS patients after *M. avium* complex [13]. Disseminated visceral infection can be life-threatening.

The choice of treatment should be determined by *in vitro* sensitivity. Current recommended guidelines for treatment of *M. kansasii* extrapulmonary disease are rifampicin and ethambutol for 9 months, with continuation of therapy for a total of 15–24 months in those patients who are immunocompromised. The addition of prothionamide and streptomycin and/or a macrolide should be considered if the condition is not responding [14].

M. ulcerans

SYN. NUMEROUS LOCAL NAMES, INCLUDING BURULI ULCER (UGANDA)

Aetiology. *Mycobacterium ulcerans* is a slow-growing mycobacterium that classically infects the skin and subcutaneous tissue, giving rise to large, indolent, necrotizing ulcers. It grows optimally on routine mycobacteriological media at 32°C. Large ulcers, almost certainly caused by *M. ulcerans*, were first described by Cook in Uganda in 1897 [1]; however, the aetiological agent was not isolated and characterized until 1948 in Australia by MacCallum [2]. In the 1960s, the disease was noted to be endemic in refugee camps in Buruli, an area near the river Nile in Uganda. The disease has since become known as Buruli ulcer and has now been reported in at least 32 countries worldwide. It is the third most common mycobacterial disease in immunocompetent people, after tuberculosis and leprosy. It is prevalent in riverine and swamp areas of

the tropical zone in Africa, Asia, South America and a few scattered foci in Australia. Its emergence in West African countries over the past decade has been dramatic [3], and the socio-economic burden of Buruli ulcer for afflicted populations is formidable [4].

Epidemiology and transmission. The mode of transmission is unknown, but infection is probably acquired from mycobacteria present in soil, shallow water, certain vegetation or from insects living in or near water [5]. Infection probably results from small, penetrating injuries, which allow transmission of the bacterium to the subcutaneous fat [6]. Children outnumber adults in most reported series, and this fact may explain why many affected individuals have no record of previous injury. PCR-based assays to detect *M. ulcerans* have been developed [7] and have identified *M. ulcerans* in an irrigation system on a golf course on Phillip Island, Australia, and in samples from a swamp which drained onto the golf course [8]. Reduction in new cases of Buruli ulcer followed drainage of the swamp and restriction of irrigation. *M. ulcerans* has recently been isolated from the salivary glands of aquatic insects in the Daola region of the Ivory Coast, where Buruli ulcer is endemic [9]. Infections have also been recorded in koalas and opossum in Australia where the disease is enzootic [10]. Person-to-person transmission has only rarely been documented [11]. HIV infection does not seem to predispose to *M. ulcerans* infection or to render infection more aggressive [12].

Pathogenesis and pathology [13]. There is a latent period of 2 months or more before an infection becomes overt. After inoculation into the skin, *M. ulcerans* proliferates and elaborates toxins that lead to tissue necrosis. One of the toxins has been identified as mycolactone, a polyketone toxin [14], and phospholipase C has also been implicated [15]. The earliest change is an acute necrosis of dermal and subcutaneous tissue; characteristically, there is an extensive involvement of the subcutaneous fat as a septate panniculitis. The fat becomes necrotic and may calcify. Mycobacteria can be found, in spherical clumps, outside cells, in the layer of exudate on the ulcer floor, and in the fatty septa; some organisms show signs of degeneration and lose their usual rod-like shape. Necrosis of the dermis extends laterally, leading to the characteristic undermining of the ulcer edge. The organism selectively destroys those tissues within its own viable temperature range [16]; muscle is usually spared, perhaps because of its higher temperature. In the deeper dermis, a leukocytoclastic vasculitis is seen, affecting small and medium-sized vessels. After some months, healing starts and is accompanied by a lymphocytic or granulomatous reaction. The skin test to burulin—a 'new tuberculin' prepared from cultures of ultrasonically disrupted *M. ulcerans*—is positive. Fibrosis and scarring complete the sequence.

Fig. 28.21 *Mycobacterium ulcerans* in an 8-year-old child. (Courtesy of Professor Françoise Portaels, Institute of Tropical Medicine, Antwerp, Belgium.)

Clinical features [17]. About 70% of patients are children below 15 years of age. The initial lesion is a small, firm, mobile, subcutaneous nodule, usually on an arm or leg, which may be pruritic. Intradermal papules have been observed in some Australian cases. Well-demarcated painless plaques can also occur. Some cases do not progress further, but usually a nodule will break down to form a shallow necrotic ulcer, which extends rapidly and irregularly, with deeply undermined edges (Fig. 28.21) An ulcer may reach a diameter of several centimetres over the course of a few weeks. The floor of the ulcer is formed of necrotic fat, and there may be a clear mucoid discharge. Ulcers are usually single, though satellites may develop. Large lesions may be surrounded by extensive induration. There is little or no constitutional disturbance even with severe local disease. Rarely, the onset is a diffuse cellulitis-like infiltration, with massive oedema.

The course is variable, but usually prolonged. Healing may occur after 6–9 months, but small intractable lesions may persist longer. An ulcer may grow to more than 25 cm in diameter. Necrosis may extend to muscle or bone. The fibrosis and calcification, which accompany healing, may lead to contractures and severe deformity.

Unfortunately, because the ulcers are painless and victims often live in remote areas, most patients do not receive medical attention until the damage is extensive. A review of 102 patients in Ghana indicated that the average length of hospital stay was more than 100 days; the infection led to 10 amputations, 12 joint contractures and two deaths from tetanus and sepsis in these patients [4].

Diagnosis. In endemic areas, suspicion should allow an early diagnosis to be made. However, sporadic or anomalous cases, presenting when the patient has left the area [18], may be confused with tuberculosis, a deep fungal infection or cellulitis. Bacteriological examination of

smears, or of curettage or biopsy specimens, will reveal clumps of acid-fast organisms, which can be cultured at 32°C, although this may take 6–8 weeks. Identification using PCR methods is now feasible [7].

Treatment. As primary antibiotic therapy has been found to be ineffective, possibly because of low drug levels in necrotic tissue, lesions should be treated by surgical excision, followed by grafting if required [3]. Local recurrence is as high as 16% [19]. This is thought to be due to the fact that the margins of lesions are often difficult to define and residual organisms continue to proliferate. Antimicrobials may have a role in prevention of recurrences and metastatic infection, but this has yet to be established [20]. Several drugs, including clarithromycin [21], rifampicin, ciprofloxacin and sparfloxacin [20], have shown good *in vitro* activity against *M. ulcerans*. BCG vaccination for tuberculosis appears to have a partial cross-protective effect against *M. ulcerans* [3]. The protective effect of a DNA vaccine encoding antigen 85A from *M. bovis* BCG has also recently been demonstrated in *M. ulcerans*-infected mice [22].

Other slow growers

M. scrofulaceum, *M. szulgai* and *M. avium* are of dermatological interest.

M. scrofulaceum

Historically, *M. scrofulaceum* has been associated with cervical adenitis in young children, but in recent years, the frequency of cervical lymphadenitis caused by *M. scrofulaceum* has declined and there are now more cases caused by *M. avium* complex [1]. Submandibular and submaxillary nodes are usually involved, and the disease is often unilateral with few constitutional symptoms and can resolve spontaneously. Skin abscesses due to M. *scrofulaceum* infection have been reported [2] and also chronic ulcerative and nodular skin lesions and pulmonary infection in a patient with AIDS [3]. Surgical treatment of infected lymph nodes is the treatment of choice. For more widespread disease, regimens similar to those used for treatment of *M. avium* complex have been recommended, as isolates of *M. scrofulaceum* have been shown to have similar antibiotic susceptibility patterns [4].

M. szulgai

M. szulgai was first described in 1972 [5] and has a worldwide distribution. Infection is principally pulmonary, but infections have also involved bursae, tendon sheaths, bones, lymph nodes and skin. Skin lesions include diffuse cellulitis, nodules and sinuses [6], and multiple inflammatory skin lesions [7]. Intralesional or systemic steroids were found to be a risk factor for development of skin lesions in two-thirds of patients in one reported series [8]. Isoniazid, rifampicin, ethambutol and streptomycin have been used for treatment of *M. szulgai* infection [8].

M. avium complex

Incidence. Disseminated infections with *M. avium–intracellulare* were rare before the emergence of the AIDS epidemic, but their incidence is now rising sharply [9,10], and organisms of the *M. avium–intracellulare* complex are now one of the commonest causes of opportunistic infection in patients with AIDS [11].

Fig. 28.22 *Mycobacterium avium* complex infection of the left cheek and submandibular area, showing sinuses and resembling lupus vulgaris. (Courtesy of Dr P. Kullavanijaya, Institute of Dermatology, Bangkok, Thailand, and the Editor of the *British Journal of Dermatology*.)

Fig. 28.23 *Mycobacterium avium* complex infection presenting as an erythematous nodule with central ulceration on the extensor aspect of the forearm in an immunosuppressed patient with systemic lupus erythematosus. (Courtesy of Dr H. Kakinuma, Surugadai Nihon University Hospital, Chiyoda, Tokyo, Japan, and the Editor of the *British Journal of Dermatology*.)

Pathogenesis. The *M. avium* complex comprises *M. avium* and *M. intracellulare*; these are closely related organisms that cannot be differentiated by standard laboratory methods [12], although the separate genomes can be distinguished by PCR-aided DNA–DNA hybridization [13]. They are slow-growing organisms with optimal growth at 37°C and are ubiquitous saprophytes, found in tap water, soil, dairy products, animals and house dust [14]. Both the respiratory and gastrointestinal tracts serve as portals of entry for systemic infection, and as many as 30% of normal human faecal samples yield isolates of *M. avium* complex [15]. Skin involvement secondary to disseminated disease is uncommon and primary skin infection is rare [16].

Clinical features. Chronic pulmonary infection is the most common form of human disease, with lesions similar to tuberculosis. In immunocompetent hosts, infection usually occurs in patients with predisposing lung conditions, which include pneumoconiosis, silicosis and cystic fibrosis, and the prognosis is strongly influenced by the associated disease [14]. Osteomyelitis [17] and granulomatous tenosynovitis [18] have both been reported, and *M. avium* complex is now the commonest cause of cervical lymphadenitis in children [1,19]. Involvement of the skin is uncommon (Fig. 28.22), but can occur following traumatic skin inoculation in cervical lymphadenitis—with sinus formation giving lesions indistinguishable from tuberculous scrofuloderma—and in immunocompromised hosts, in whom *M. avium* may disseminate from primary visceral lesions. Skin lesions are of variable appearance and include multiple ulcers [20], nodules [21], ulcerated nodules (Fig. 28.23), abscesses [22], painless nodules and plaques resembling lepromatous leprosy [23] or lupus vulgaris [24], and also lesions resembling prurigo nodularis [25]. Lichen scrofulosorum has also been reported with *M. avium* infection [26].

In HIV-infected patients, the most common manifestation of *M. avium* complex infection is mycobacteraemia, but skin lesions may provide a clue to the presence of disseminated *M. avium* complex infection. Infection tends to occur late in HIV disease and most frequently in patients whose $CD4^+$ cell counts have fallen below 50 cells/mm^3 [14]. The incidence of disseminated and cutaneous lesions is decreasing in most centres because of the use of highly active antiretroviral therapy (HAART), which restores some immune competence, and the use of prophylactic antimycobacterial drugs [27]. On starting HAART, some patients may experience *M. avium* immune restoration disease due to restoration of delayed hypersensitivity responses to mycobacterial antigens. Symptoms include fever, lymphadenitis and cutaneous lesions [28].

A review of the published cases of disseminated infection in patients without AIDS emphasizes the frequent association with haematological malignancies (particularly hairy cell leukaemia), connective tissue disease and corticosteroid or cytotoxic therapy [29,30].

Diagnosis. The diagnosis may be made by blood culture, or by the culture of *M. avium–intracellulare* complex from bone marrow or liver biopsy. In patients with cutaneous lesions, culture of skin biopsy specimens or aspirated seropurulent fluid may give positive results [21]. Tissue staining for acid-fast bacilli is often negative. Histology shows non-caseating granulomas, and sometimes acid-fast bacilli within giant cells or extracellularly.

Treatment. Treatment of *M. avium* complex was unsatisfactory due to frequent MDR, but the introduction of the newer macrolides clarithromycin and azithromycin, and of rifabutin, has greatly improved treatment outcomes. These agents are, however, associated with many adverse effects and potential drug–drug interactions, particularly in those patients who are on antiretroviral therapy. Clarithromycin and azithromycin must be administered in combination with other agents such as ethambutol to prevent emergence of macrolide resistance [31]. Ciprofloxacin has also been used in some treatment regimens [32]. It is recommended that patients with lymphadenitis are treated surgically with complete excision of the nodes [33]. Surgical excision has also been used in some patients with localized skin lesions [21]. In immunocompetent patients with extrapulmonary disease, chemotherapy should probably be continued for 18–24 months. In patients with HIV disease, treatment should be lifelong unless there is confidence that the immune system has been restored by HAART [33]. Azithromycin appears to be protective against disseminated *M. avium* complex in those patients unresponsive or non-adherent to HAART, but does not appear to prevent the development of immune restoration disease [34].

Rapidly growing mycobacteria [1]

The species of rapidly growing mycobacteria capable of producing disease in humans are the *Mycobacterium fortuitum* group, the *M. chelonae/abscessus* group, and the *M. smegmatis* group. The *M. fortuitum* group includes *M. fortuitum* and *M. peregrinum* and the taxon known as the 'unnamed third biovariant complex'. *M. chelonae* and *M. abscessus* along with the newly recognized *M. immunogenum* are members of the group known collectively as the *M. chelonae/abscessus* group. The *M. smegmatis* group contains *M. smegmatis* and two newly described species, *M. goodii* and *M. wolinskyi* [2]. They cause skin, soft tissue, bone and pulmonary infection, as well as disseminated disease.

M. fortuitum complex, *M. chelonae*/*M. abscessus* and *M. smegmatis* group

These organisms are widely distributed in the environment in soil and water and may also be commensal organisms of human skin. They are extremely hardy; members of the *M. fortuitum* group and *M. smegmatis* group can grow at 45°C, and the *M. chelonae/abscessus* group and *M. mucogenicum* resist the activity of organomercurials, chlorine, 2% concentrations of formaldehyde and other commonly used disinfectants [3]. These organisms are commonly isolated from municipal tap water [4]. *M. chelonae* was found as a contaminant in a gentian violet solution [5] and *M. abscessus* has been isolated from contaminated lidocaine (Xylocaine) [6] and histamine solutions [7]. Pseudo-outbreaks have most commonly related to contaminated bronchoscopes and endoscopic cleaning machines, and to contaminated hospital water supplies [3].

Clinical cutaneous disease with these pathogens seems to follow two patterns. In the immunocompetent host, a traumatic injury is followed by the development of localized abscess formation [8]. In the immunocompromised individual, there may be no history of trauma and patients present with disseminated disease, with multiple subcutaneous nodular lesions, positive blood cultures, cervical lymphadenitis, keratitis and occasionally endocarditis [9]. Conditions associated with disseminated infection include organ transplantation, rheumatoid arthritis, renal failure and autoimmune disorders. Disease due to *M. chelonae* is strongly associated with concomitant corticosteroid therapy [10].

The *M. fortuitum* group accounts for 60% of community-acquired localized cutaneous infection caused by the rapidly growing mycobacteria, but is a rare cause of pulmonary disease. This group is also responsible for the majority of health care-associated (nosocomial) cases of post-surgical wound infections and catheter infections [1]. *M. fortuitum* infection of the sternum has been reported after open-heart surgery [11], as a cause of peritonitis in patients receiving continuous ambulatory peritoneal dialysis [12] and after localized microinjections (mesotherapy) for pain control [13]. A patient with lupus vulgaris-like lesions has also recently been described [14].

The *M. chelonae/abscessus* group (Fig. 28.24) is responsible for approximately 95% of disseminated cutaneous infections caused by the rapidly growing mycobacteria [1] and also causes chronic lung disease. Post-injection abscesses are probably the commonest skin lesions caused by *M. abscessus*. An outbreak in 12 patients at an ear, nose and throat (ENT) clinic in 1969 was due to contaminated histamine injections [7]. An alternative medicine practitioner infected a total of 232 patients with contaminated lidocaine injections [6]. Haemodialysis is also a risk factor [15]. A survey across the USA found that non-tuberculous mycobacteria were recovered from 83% of water supplies to dialysis units [4]. Two employees at a hot spring bath in Korea developed sporotrichoid lesions due to *M. abscessus* and were assumed to have been contaminated from the bath water [16].

Fig. 28.24 *Mycobacterium abscessus* infection causing abscesses. (Courtesy of Dr A.G. Smith, North Staffordshire Hospital, Stoke-on-Trent, UK, and the Editor of the *British Journal of Dermatology*.)

M. chelonae causes community-acquired disease—for example, post-traumatic skin or soft-tissue infection, bone infection and disseminated cutaneous infection; and sporadic nosocomial infections—for example, after surgery, after injections and related to catheter use [17]. Implanted porcine heart valves themselves may be contaminated with *M. chelonae* [18]. Disseminated erythematous subcutaneous nodules are the commonest manifestation, most commonly seen on the distal parts of the limbs (Fig. 28.25), or in a sporotrichoid pattern [19]. Localized cellulitis, subcutaneous abscesses and osteomyelitis (usually following skin injury), are also seen. Sixty-two per cent of patients infected with *M. chelonae* in one series were receiving corticosteroids and 72% were immunosuppressed [10]. Infection has also been reported after acupuncture [20]. Disseminated disease is rare and HIV infection does not seem to carry a risk for *M. chelonae* infection.

Infections involving the *M. smegmatis* group have included cellulitis, localized abscesses and osteomyelitis after trauma [21]. No cases of disseminated cutaneous infection have been reported to date. Sporadic cases of catheter sepsis and infection after plastic surgery have also been noted [1].

Pathology. Abscess formation in the dermis and subcutis is the rule, but tuberculoid granulomas with or without necrosis may occur.

Diagnosis. These infections are easily missed or attributed to foreign bodies, deep mycoses or osteitis. They should be considered in the differential diagnosis of chronic relapsing nodules and abscesses in immunocompromised

Fig. 28.25 *Mycobacterium chelonae* infection of the lower limb. (Courtesy of Dr R.D. Ead, Hope Hospital, Manchester, UK.)

individuals. Diagnosis is usually made by the culture of biopsy material, and in the case of abscesses a biopsy from the wall is more likely to yield the organism than is aspirated pus. They all have the distinctive ability to produce visible colonies between 5 and 7 days at temperatures ranging between 22°C and 45°C, but some strains may fail to grow at 37°C. Their identification is possible by differences in culture requirements, biochemical tests and DNA homology. Clinically, the lesions are not specific to the species involved in the infection [22].

Treatment [1]. In contrast to treatment for most slowly growing mycobacteria, antimicrobial therapy for rapidly growing mycobacteria is determined by the extent of the disease. Single-drug therapy is usually sufficient for localized or minor disease, with minimal risk of developing mutational drug resistance. In contrast, disseminated cutaneous disease and pulmonary disease require multiple antimicrobials. Newer drugs such as linezolid, an oxazolidinone, and the 8-methoxyfluoroquinolones gatifloxacin and moxifloxacin offer great promise compared to injectable medicines, but clinical experience is limited.

The *M. fortuitum* group is much less drug-resistant than the *M. chelonae/abscessus* group and strains are usually susceptible to amikacin, ciprofloxacin, sulfonamides, cefoxitin and imipenem. The presence of tetracycline-resistant genetic determinants in approximately 50% of members of the *M. fortuitum* group precludes the use of tetracyclines including doxycycline. Approximately 80% of isolates are sensitive to clarithromycin.

The treatment of localized infections due to the *M. chelonae/abscessus* group is with clarithromycin. Azithromycin appears also to work well, but there is less clinical experience with this drug. Acquired resistance to the macrolides has not been seen with localized infections, but it is suggested that more severe infections are treated for the first 2 weeks with an additional injectable agent. For extensive extrapulmonary disease or for disseminated infections involving *M. chelonae*, the injectable agents tobramycin plus imipenem have been used for 2–6 weeks in combination with clarithromycin. For serious disease with *M. abscessus*, amikacin plus cefoxitin or imipenem is used for 2–6 weeks in combination with clarithromycin. *M. abscessus* lung disease is still generally incurable with available therapeutic agents.

The *M. smegmatis* group is uniformly sensitive to sulfonamides, doxycycline, imipenem and amikacin.

Surgical debridement may be a useful adjunct to treatment in some patients. It is not certain how long chemotherapy should be continued for these infections, as there is no evidence from controlled clinical trails. If the response to initial treatment is anything less than optimal, then prolonged chemotherapy for up to 2 years would seem sensible.

M. haemophilum

This mycobacterium is an increasingly recognized pathogen in immunocompromised patients, including those with HIV infection, following organ transplantation, and in patients with haematological malignancies or with chronic conditions requiring prolonged immunosuppressive therapy. It causes cutaneous, synovial and, less frequently, pulmonary infections [1]. It has also been isolated from otherwise healthy children with lymphadenitis.

M. haemophilum causes multiple tender cutaneous nodules, often violaceous, which may develop into abscesses or ulcers (Fig. 28.26), and occasionally may present as annular plaques [2] or panniculitis. Lesions typically occur on the extremities and are often situated over joints. This may reflect low optimal temperature growth requirements and a predilection to grow on the cooler areas of the body. Systemic features such as weight loss, tenosynovitis, joint effusions, osteomyelitis or respiratory tract symptoms may coexist.

M. haemophilum may be cultured from the skin or other tissues or secretions, but has unique growth requirements and therefore may be relatively under-recognized and under-reported. It grows optimally at 30°C to 32°C and the growth media must contain iron.

Histologically, suppurative granulomas containing acid-fast bacilli are usually seen, but occasionally granulomas may be poorly formed and have varying amounts of necrosis [3].

Treatment is difficult. Lesions may persist despite therapy or relapse after treatment is stopped. Improvement of immunological status is the basis for successful treatment. There are no current recommended guidelines for treatment. A three-drug regimen containing clarithromycin, rifabutin and ciprofloxacin has been recommended [1,4]. In ill patients, the addition of amikacin and doxycycline is suggested [1]. In common with the response to treatment for some of the rapidly growing bacteria, an immune reconstitution syndrome may occur on starting treatment.

Other mycobacteria

The use of molecular testing has brought about the recognition of multiple newly characterized mycobacterial species that were previously unrecognized by standard techniques [5]. Some are non-pathogenic, but it is likely that the majority will cause clinical disease. There is also evidence that previously seldom-encountered mycobacteria are being increasingly recognized as causing human disease. These include *M. malmoense*, which was recently shown to be the cause of disseminated cutaneous infection in an immunocompetent patient [6]; *M. xenopi*, which was reported to cause lupus vulgaris-like skin lesions [7] and disseminated cutaneous lesions in immunosuppressed patients [8]; and *M. genavense*.

Chapter 29

Leprosy

D.N.J. Lockwood

Synonyms

Hansen's disease, hanseniasis and elephantiasis graecorum, and names in local languages in endemic areas.

Definition

A chronic granulomatous disease caused by *Mycobacterium leprae*, principally affecting peripheral nerves and skin.

History

Endemic in India and the Far East since ancient times, leprosy was imported into Europe in the 4th century BC, perhaps by the troops of Alexander the Great. The European epidemic peaked in the 13th century, then slowly died out [1]. French settlers took leprosy to Canada and black slaves took it to America. It is not known how the disease reached the Australian aborigines. Even after the discovery of the agent, *M. leprae*, by Armauer Hansen in Norway in 1873 (the first bacillus to be associated with a human disease), the infectious nature of leprosy was not readily accepted [2]. The slow spread of the disease and its familial association suggested that it was inherited. This belief, and the fear of the deformities that leprosy may cause, have contributed to the stigma and ostracization that still characterize attitudes towards leprosy. Stigma remains a major obstacle to leprosy control, despite advances in bacteriology, chemotherapy and epidemiology.

Aetiology

Mycobacterium leprae has never been grown *in vitro*. Limited growth has been achieved in the mouse footpad [3], and more widespread growth and disease in immunosuppressed and nude mice [4] and the nine-banded armadillo [5]. The latter has provided mycobacteria for genetic and biochemical analysis and the production of trial vaccines. A primate model of leprosy has been established in three species of monkey [6]. *Mycobacterium leprae* grows at 30–33°C, with a doubling time of 12 days. It is a remarkably hardy organism, remaining viable in the environment for up to 10 days [6]. The sequence of the *M. leprae* genome was published in 2001. *Mycobacterium leprae* has a 3.27-Mb genome that displays extreme reductive evolution [7]. Less than half the genome contains functional genes: many pseudogenes are present. One hundred and sixty-five genes are unique to *M. leprae*, and functions can be attributed to 29 of them. Comparison of biosynthetic pathways with *M. tuberculosis* shows that for lipolysis *M. leprae* has only two genes (*M. tuberculosis* has 22). *Mycobacterium leprae* has lost many genes for carbon catabolism, and many carbon sources (e.g. acetate and galactose) are unavailable to it. *Mycobacterium leprae* growth may be restricted to a few carbon sources on which it can maintain a balanced carbon metabolism. It has also lost anaerobic and micro aerophilic electron transfer systems. *Mycobacterium leprae* has many genes for haem and iron based proteins, but it is severely limited in its iron uptake capacity, since it has lost the ability to produce iron scavenging sideropores [8]. Restriction

fragment length polymorphism (RFLP) analysis [9] suggested that *Mycobacterium leprae* was a single species, but recent work based on amino acid sequencing of *M. leprae* proteins suggests that there are subtle strain differences, and this may enable new studies on transmission [10].

Mycobacterium leprae has a complex antigenic cell wall composed of lipids, carbohydrates and proteins. The organism also synthesizes a species-specific lipid, phenolic glycolipid (PGL) [11]. Several polymerase chain reaction (PCR) probes (18 kDa, 36 kDa, 65 kDa and ribosomal RNA sequences) have been developed for the detection of *M. leprae* DNA in tissues from leprosy patients [12]. Although these are specific, they are not yet sensitive enough to be useful in diagnosing patients whose skin is bacteriologically negative on conventional staining. The molecular basis for rifampicin resistance has been elucidated and it is now possible, using a polymerase chain reaction-single strand polymorphism (PCR-SSC) technique, to identify rifampicin resistant isolates within hours [13].

Geographical distribution

About 4 million people have, or are disabled by, leprosy. The apparent fall in registered patients from 12 million in 1988 to 0.82 million on treatment in 1999 hides an intriguing picture. Prevalence has fallen due to a combination of effective antibiotic therapy and a change in case definition. Incidence, however, remains stable at around 800 000 new cases annually, with high rates of childhood cases [1]. Intensive leprosy elimination campaigns held in 1998 and 1999 detected large numbers of new cases. A week-long campaign in Nepal found 11 696 new cases; this doubled the national case load.

India dominates the global picture with 70% of the world's leprosy cases; 86% of leprosy patients reside in six countries (India, Brazil, Indonesia, Myanmar, Madagascar and Nepal). Leprosy has not always been a tropical disease; it was endemic in Norway until the early twentieth century. Nearly all the new cases now seen in Europe and North America acquired their infection abroad [2].

Leprosy is a chronic disease with a long incubation period. An average incubation time of 2–5 years has been calculated for tuberculoid cases, and 8–12 years for lepromatous cases. American servicemen who developed leprosy after serving in the tropics presented up to 20 years after their presumed exposure [3].

Although leprosy is rarely a primary cause of death, patients have a standardized death rate at least twice that of the general population due to the indirect secondary effects of the disease [4]. It is estimated that 1 million disability adjusted life years (DALY) are lost globally each year due to leprosy, with 6.3 years of healthy life being lost per patient.

Age, sex, household contact and bacille Calmette-Guérin (BCG) vaccination are important determinants of leprosy risk: leprosy incidence reaches a peak at the ages of 10–14 years [5]. An excess of male cases has regularly been found, although this may be due to women being reluctant to present to health workers with skin lesions [6]. Clustering of cases is well recognized, particularly in low endemic areas [7]. Although poor nutritional status was thought to predispose to leprosy, no good evidence substantiates this. Improved socio-economic conditions, extended schooling and good housing reduce the risk of leprosy [8]. There are weak human leukocyte antigen (HLA) associations with leprosy; HLA-DR2 and HLA-DR3 occur at a higher frequency in tuberculoid (TT) patients than in lepromatous (LL) or borderline lepromatous (BL) patients in at least two populations [9], whereas HLA-DQ1 is associated with susceptibility to BL/LL leprosy in three different countries [10]. In South India an association has been found between paucibacillary leprosy and a locus on chromosome 10p13 [11].

Studies from Malawi [12], Uganda [13], Mali and south India [14] have not shown human immunodeficiency virus (HIV) infection to be a risk factor for leprosy. HIV/leprosy co-infected patients have typical skin lesions and leprosy histology, and granuloma formation even with low circulating CD4 counts [15].

Subclinical infection with *M. leprae* is probably common, but the development of established disease is rare. There is no reliable test for determining whether a person has encountered *M. leprae* and mounted a protective immune response. In contacts of leprosy patients, there is

frequently evidence of specific sensitization to *M. leprae* using markers of infection such as serum antibody levels, *in vitro* lymphocyte transformation tests (LTTs) and skin-test responses to soluble *M. leprae* antigen [16]. Contacts of an untreated elderly man with borderline lepromatous leprosy in a British residential home showed that 23/30 and 25/30 had positive Mitsuda skin test and positive LTT responses, respectively, to *M. leprae* sonicate, but only two contacts had positive antibody (IgM PGL) responses [17]. Self-healing often occurs in early monomacular tuberculoid cases [18]. Leprosy is probably analogous to tuberculosis, in which only 10% of infections manifest as clinical disease [19].

Nasal discharges from untreated lepromatous leprosy patients, who are often undiagnosed for several years, are the main source of infection in the community [20]. In Indonesia and Ethiopia, *M. leprae* DNA has been detected in nasal swabs in up to 5% of the population [21]. Infection probably also occurs through the nose. *Mycobacterium leprae* is inhaled, multiplies on the inferior turbinates and has a brief bacteraemic phase before binding to Schwann cells and macrophages.

The skin is unimportant in leprosy transmission. Bacilli are not excreted by the skin and are rarely found in the epidermis. The only evidence of bacilli entering via the skin comes from case reports of direct inoculation. Leprosy has been transmitted to nude mice through pricks from infected cactus thorns [22]. There is no evidence that biting arthropods transmit leprosy. It is surprising that, in contrast to tuberculosis, there are few documented cases of leprosy occurring in both the medical and non-medical attendants of leprosy patients.

Pathogenesis of leprosy [1]

The pathogenesis and thus the clinical features reflect four principle causes of tissue damage (Fig. 29.1):

1 The degree to which cell-mediated immunity (CMI) is expressed [2]. Lepromatous leprosy represents a failure of CMI specifically towards *M. leprae* with resultant bacillary multiplication, spread and accumulation of antigen in infected tissues. The absence of activated lymphocytes and macrophages means that nerve damage is slow and gradual in onset. In tuberculoid leprosy, CMI is strongly expressed, so that the infection is restricted to one or a few skin sites and peripheral nerves. Lymphocytic infiltration rapidly causes nerve damage. Between those two polar forms lies the borderline forms of disease, with the extent of disease reflecting the balance between CMI and bacillary load.

2 The extent of bacillary spread and multiplication. In lepromatous leprosy, haematogenous spread of bacilli occurs [3] to cool, superficial sites, including eyes, upper respiratory mucosa, testes, small muscles and bones of hands, feet and face, as well as peripheral nerves and skin. In tuberculoid leprosy, bacillary multiplication is restricted to a few sites and bacilli are not readily found.

3 The appearance of tissue-damaging immunological complications: lepra reactions [4]. Borderline patients (borderline tuberculoid, BT; borderline, BB; borderline lepromatous, BL) are immunologically unstable and at risk of developing immune-mediated reactions. Type 1 (reversal) reactions are delayed hypersensitivity reactions caused by increased recognition of *M. leprae* antigens in skin and nerve sites. Type 2 reactions, erythema nodosum leprosum (ENL), are due in part to immune complex deposition and occur in BL and LL patients who produce antibodies and have a large antigen load.

4 The development of nerve damage and its complications. Nerve damage occurs in two settings, in skin lesions

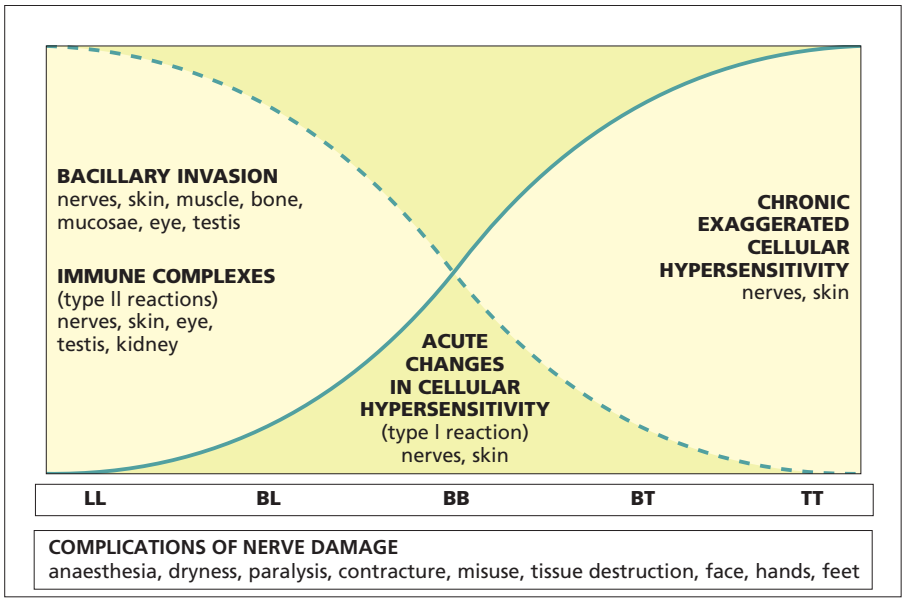

Fig. 29.1 Mechanisms of damage in leprosy, and tissues affected. Mechanisms under the broken line are characteristic of disease near the lepromatous end of the spectrum, those under the solid line of the tuberculoid end. They overlap in the centre where, in addition, instability predisposes to type 1 reactions.

and in peripheral nerve trunks. In skin lesions, the small dermal sensory and autonomic nerve fibres supplying dermal and subcutaneous structures are damaged, causing local sensory loss and loss of sweating within the area of the skin lesion [5]. Peripheral nerve trunks are vulnerable at sites where they are superficial or are in fibro-osseous tunnels. At these points, a small increase in nerve diameter leads to raised intraneural pressure, with consequent neural compression and ischaemia. Damage to peripheral nerve trunks produces characteristic signs, with dermatomal sensory loss and dysfunction of muscles supplied by that peripheral nerve. Physiological evidence of central and peripheral autonomic nerve involvement has also been reported [6,7].

Nerve damage leads to anaesthesia, muscular weakness and contracture, and autonomic dysfunction. These permit trauma, bruising, burns, cuts and, especially, tissue necrosis from prolonged, inappropriate or repetitive trauma, which in turn lead to ulceration, secondary cellulitis and osteomyelitis and loss of tissue, so that deformity is added to disability.

Histology [1]

Mycobacterium leprae has a predilection for neural tissue, and the first evidence of infection is often found in the peripheral nervous system. Patients with early leprosy of both tuberculoid [2,3] and lepromatous types have abnormalities in nerve conduction studies and a histological picture of small fibre loss, with segmental demyelination and remyelination [4]. Bacilli probably enter nerves via endoneural blood vessels [5], the target cell being the Schwann cell. In the dermis, the type and degree of cellular infiltrate reflects the degree of CMI. The classification of Ridley and Jopling [6] describes five groups on the immunological spectrum, which are designated tuberculoid (TT), borderline tuberculoid (BT), borderline (BB), borderline lepromatous (BL) and lepromatous (LL). In this classification, epithelioid cells and lymphocytes at the tuberculoid end of the spectrum give place to macrophages, which appear increasingly foamy as the lepromatous pole is reached.

Tuberculoid leprosy

Tuberculoid granulomas collect in foci surrounding neurovascular elements (Fig. 29.2). The granuloma invades the papillary zone and may even erode the epidermis, but acid-fast bacilli (AFB) are not seen. Cutaneous nerves that are not completely destroyed appear greatly swollen by epithelioid cell granulomas and surrounded by a zone of lymphocytes; occasionally there may be caseation within the nerve.

Lepromatous leprosy

Histological examination of skin lesions (H & E) shows

Fig. 29.3 (a) Lepromatous leprosy. Medium-power view (H&E) showing thin epidermis, a clear subepidermal zone and dense, uniform macrophage infiltrate in the dermis. Towards the bottom of the photograph there is an 'onion skin' perineurial lamination. (b) High-power view, Wade–Fite stain showing single and clustered acid-fast bacilli (AFB), part solid, part fragmented; bacillary index (BI) = 5. (Courtesy of Professor S. Lucas, United Medical and Dental Schools of Guy's and St Thomas' Hospitals, London, UK.)

thinning of epidermis and flattening of rete ridges (Fig. 29.3). The papillary layer of the dermis appears as a clear band, whilst deeper in the dermis lies the typical diffuse leproma consisting of foamy macrophages, with the addition of a few lymphocytes and plasma cells. The dermis contains enormous numbers of AFB, singly or in clumps (globi). With treatment, the leproma shows increased foamy change, vacuolates and breaks up into discrete foci with fibrocytes at the periphery. These foci shrink as treatment is continued and bacilli become fragmented and granular. In lepromatous neuropathy, there is quiet asymptomatic bacillation of Schwann cells leading to foamy degeneration of these cells. Demyelination,

damage and destruction of the axis cylinder are prominent features and later Wallerian degeneration occurs [7]. Despite the large numbers of organisms in the nerve there is only a small inflammatory response; ultimately the nerve fibroses and is hyalinized [8].

Borderline leprosy

In BT leprosy, the epithelioid cell granuloma is more diffuse than in TT with a free, but narrow, papillary zone. Giant cells tend to be foreign body rather than Langhans in type, and dermal nerves are moderately swollen by cellular infiltrate, or may show only Schwann cell proliferation. AFB are usually absent or scanty. In mid-BB, there is diffuse epithelioid cell granuloma with very scanty lymphocytes and no giant cells; the papillary zone is clear, nerves are slightly swollen by cellular infiltrate, and AFB are present in moderate numbers. In BL leprosy, macrophages may show slight foamy change. Lymphocytes are present in dense clumps or are widely distributed in parts of the granuloma; a few epithelioid cells may be seen occasionally. The formation of small granulomas is characteristic of borderline leprosy and granulomatous regions may abut strands of normal looking but heavily bacillated Schwann cells [9]. Nerve damage in borderline leprosy results from a combination of lepromatous bacillation and a tuberculoid tissue damaging response producing widespread nerve damage. Acute neuritis damage occurs particularly during reversal reactions: oedema of the epithelioid cell granuloma compresses the remaining Schwann cells causing rapid functional loss in an already compromised nerve. In ENL nerve damage occurs more slowly and is probably due to inflammation associated with ENL nodule formation in nerve trunks.

Indeterminate leprosy

This early and transitory stage of leprosy occurs in those whose immunological state has not yet been determined, and histologically there is a scattered non-specific histiocytic and lymphocytic infiltration with some concentration around skin appendages (Fig. 29.4). Rarely, a single bacillus will be found within a dermal nerve. The indeterminate phase may last for months or years before resolving or giving way to one of the determinate types of leprosy described above.

Reactions

Type 1 reactions are characterized by an increase in lymphocytes within lesions, severe oedema with disruption of the granuloma, and giant cell formation [10]. In type 2 (ENL) reactions polymorphs infiltrate the granuloma and there is vasculitis and macrophage degeneration together with breakdown of foam cells (Fig. 29.5).

Immunology [1]

The immune response to *M. leprae* determines not only whether disease will develop, but also which type of leprosy. Both T cells and macrophages play important roles in the processing, recognition and response to *M. leprae* antigens. The T-cell response to mycobacteria results in activation and proliferation of α/β CD4 T cells with release of interleukin-2 (IL-2). This cytokine amplifies the local response through recruitment and activation of T cells. In addition, IL-2 stimulates the expansion of α/β CD8 T cells and antigen non-specific natural killer cells in the lesion. All three types of cell can produce interferon-γ (IFN-γ), the major cytokine responsible for activating bactericidal mechanisms within the parasitized macrophage [2].

In tuberculoid leprosy, there is good evidence of a strong CMI response. Tests of T-cell function such as LTTs show that tuberculoid leprosy patients respond to *M. leprae* antigens as in whole *M. leprae*, separated *M. leprae* antigens [3] and cloned antigens (18 kDa and 65 kDa) [4,5]. Skin tests with lepromin, a heat-killed *M. leprae* sonicate preparation, are strongly positive in these patients. Staining of skin biopsies from tuberculoid lesions with T-cell markers show highly organized granulomas composed predominantly of CD4 cells and macrophages, with a peripheral mantle of suppressor/cytotoxic CD8 cells [6]. This strong CMI response has been misdirected at some stage, and the end result is a late strong cell-mediated response that clears antigen at the expense of local tissue destruction.

Lepromatous leprosy patients are unable to mount a CMI response to *M. leprae*, with a failure of the T-cell response, and lymphocytes from LL patients respond poorly in LTT to whole *M. leprae* and cloned antigens. Similarly, LL patients fail to mount a skin test response to intradermal challenge with lepromin. The anergy of the lepromatous patient is striking because it is specific for the leprosy mycobacterium. Lepromatous patients can respond to antigens of other mycobacteria such as *M. tuberculosis*, both in *in vitro* and in skin tests [7,8]. Identification of cell types in LL granulomas shows them to be a disorganized mixture of macrophages and T cells, mainly CD8 cells [9].

Both T-cell and macrophage dysfunction occur in lepromatous patients. The T-cell failure may be due to clonal anergy or active suppression [3]. Defects in cytokine production have been demonstrated in lepromatous patients; addition of IL-2 to T-cell culture media restored the proliferative response to *M. leprae* [10] in lepromatous patients, and intralesional injections of recombinant IL-2 reconstituted the local immune response with elimination of *M. leprae* from macrophages [11]. Macrophage defects described in LL disease include defective antigen presentation and recognition, defective IL-1 production, a failure of macrophages to kill *M. leprae* and a macrophage suppression of the T-cell response [2].

Studies of circulating cytokines in leprosy patients, and cytokine production in skin lesions, show that tuberculoid patients have a Th1 type response to *M. leprae* with predominant IL-2 and IFN-γ production, whilst lepromatous patients have a response characterized by Th2 type cytokines.

The inflammation seen in type 1 reactions is due to T-cell activity, with enhanced T-cell proliferation towards *M. leprae* antigens, increased numbers of $CD4^+$ and IL-2 producing cells in granulomas, and local production of cytokines such as IFN-γ [12] and tumour necrosis factor-α (TNF-α) [13]. Type 1 reactions are associated with an over-production of Th1-type cytokines [14]. ENL has classically been regarded as an immune complex disorder. This is supported by the presence of immunoglobulin and complement in the lesions and circulating immune complexes [15]. There is also evidence of enhanced T-cell activity during ENL episodes, with increased numbers of CD8 cells [16], increased circulating IL-2 receptors [17] and high levels of circulating TNF-α [18] in acute episodes. Despite increased immune activity during ENL

episodes, lepromatous patients revert to a state of immunological unresponsiveness after an episode.

Serology

Specific anti-*M. leprae* antibodies are produced against lipoarabinomannan (LAM), PGL and the protein antigens of *M. leprae*. No single antigen has been identified for use in a serological test to confirm disease and detect early subclinical infection. For all three types of antigen, multibacillary patients produce antibodies prolifically, while paucibacillary patients show a variable, often undetectable, response. The evaluation of PGL serology in extensive field studies shows that more than 90% of untreated multibacillary patients have positive serology in comparison with 40–50% of paucibacillary patients and 5–10% of healthy controls [19].

Lepromatous patients produce a range of autoantibodies, both organ-specific (directed against thyroid, nerve, testis and gastric mucosa), and non-specific, such as rheumatoid factors, anti-DNA, cryoglobulins and cardiolipin.

Clinical features of leprosy [1]

Early lesions and presenting symptoms

The commonest early lesion is an area of numbness on the skin, or a visible skin lesion. The classic early skin lesion, especially in surveys, is that of indeterminate leprosy, which is most commonly found on the face, extensor surface of the limbs, buttocks or trunk (Fig. 29.6) [2]. Scalp, axillae, groins and lumbar skin tend to be spared. Indeterminate lesions consist of one or more slightly hypopigmented or erythematous macules, a few centimetres in diameter, with poorly defined margins. Hair growth and nerve function are unimpaired. A biopsy may show the perineurovascular infiltrate, and only a prolonged search will reveal scanty acid-fast organisms. Alternatively, the initial skin lesion has features of one of the established forms of the disease.

Patients frequently present with signs of nerve damage [3]: weakness or anaesthesia due to a peripheral nerve lesion, or a blister, burn or ulcer [4] in an anaesthetic hand or foot. Borderline patients may present in reaction with nerve pain, sudden palsy, multiple new skin lesions, pain in the eye, or a systemic febrile illness [5,6].

Features of established leprosy

Careful attention to the eight different clinical aspects of leprosy listed in Table 29.1 will enable accurate recognition

Fig. 29.6 Indeterminate leprosy. Face of a Nepali child showing vague hypopigmented patch with some central healing. Note the mark of a recent slit-skin smear.

Table 29.1 Characteristics of lesions of polar leprosy.

	Tuberculoid	Lepromatous
Number of lesions	1–10	Hundreds, confluent
Distribution	Asymmetrical, anywhere	Symmetrical, avoiding 'spared' areas
Definition and clarity	Defined, edge, markedly hypopigmented	Vague edge, slight hypopigmentation
Anaesthesia	Early, marked, defined, localized to skin lesions or major peripheral nerve	Late, initially slight, ill-defined, but extensive, over 'cool' areas of body
Autonomic loss	Early in skin and nerve lesions	Late, extensive as for anaesthesia
Nerve enlargement	Marked, in a few nerves	Slight but widespread
Mucosal and systemic	Absent	Common, severe during type 2 reactions
Number of *Mycobacterium leprae*	Not detectable	Numerous in all affected tissues

Fig. 29.7 Tuberculoid leprosy (TT). Face of Pakistani lady showing erythematous plaque with a well-defined active edge, and a small satellite lesion. On the face, such lesions may not be anaesthetic.

and classification, which are prerequisites to correct treatment and accurate prognosis.

Tuberculoid leprosy

Only nerves and skin show clinical evidence of disease; lesions are few, often solitary. The condition may be purely neural, with pain and swelling of the affected nerve followed by anaesthesia and/or muscle weakness and wasting. Alternatively, a skin lesion appears with or without evidence of nerve involvement. The typical lesion is a plaque that is conspicuous, erythematous, copper coloured or purple, with raised and clear-cut edges sloping towards a flattened and hypopigmented centre (Figs 29.7 & 29.8). Dark skins may not show the erythema. The surface is dry, hairless and insensitive, and sometimes scaly. Sensory impairment may be difficult to demonstrate on the face because of the generous supply of sensory nerve endings. If the examiner runs a finger around the lesion, just beyond the outer edge, a thickened sensory nerve may be palpated or a thickened nerve trunk may be felt in the vicinity, e.g. a thickened ulnar nerve if the lesion is on the arm. Less commonly the lesion is a macule, erythematous in light skins and hypopigmented (never depigmented) in dark skins (Fig. 29.9). Such macules have a dry, hairless and insensitive surface.

Fig. 29.8 Tuberculoid or borderline tuberculoid (TT/BT) leprosy. Upper arm of Indian man, showing typical dry, hairless, hypopigmented plaque with scaly, erythematous edge. Such lesions are usually anaesthetic.

Lepromatous leprosy

The first clinical manifestations are usually dermal (because early nerve involvement is usually asymptomatic), but they may go unnoticed by the patient, who often complains of other early symptoms; these include nasal symptoms of stuffiness, discharge and epistaxis [7], and oedema of legs and ankles due to increased capillary stasis and permeability. Dermal signs comprise

Fig. 29.11 Lepromatous leprosy (LL). Forearm of an English man showing erythematous macules and infiltration, which characterize a relapse of dapsone-resistant lepromatous leprosy.

Fig. 29.12 Lepromatous leprosy (LL). Face of an Anglo-Indian man showing diffuse infiltration of the skin and appearance of nodules on nose and lip.

macules, diffuse papules, infiltration or nodules, or all four. Macules are small, multiple, erythematous or faintly hypopigmented, with vague edges and shiny surface (Fig. 29.10). Papules and nodules usually have normal skin colour but sometimes are erythematous (Fig. 29.11), with a bilaterally symmetrical distribution on face, arms, legs and buttocks, but may be anywhere apart from hairy scalp, axillae, groins and perineum (regions of skin with the highest temperature). Hair growth and sensation are not initially impaired over the lesions. In polar LL, diffuse infiltration and gradual thickening of the dermis may precede nodulation by months or years (Fig. 29.12). Lesions of oral mucosa occur as papules on lips and nodules on palate (which may perforate), uvula, tongue and gums (Fig. 29.13). The nasal mucosa is hyperaemic or ulcerated and bleeds easily; epistaxis is common (Fig. 29.14).

The longest peripheral sensory nerve fibres are first affected, causing numbness and anaesthesia on the dorsal surfaces of hands and feet, and later on extensor surfaces of arms and legs, and finally over the trunk. Infiltration of corneal nerves causes anaesthesia, which predisposes to injury, infection and blindness if there is also lagophthalmos due to damage to the facial nerve. The hands and feet swell and may become oedematous. Radiographs may show osteoporosis in the phalanges, small osteolytic cysts and often hairline or compression fractures. The fingers

may become crooked or short (Fig. 29.15). Nails are thin and brittle.

If the patient remains untreated the lines of the forehead become deeper as the skin thickens (leonine facies), eyebrows and eyelashes become thinned or lost (madarosis), ear lobes are thickened, the nose becomes misshapen, and may collapse due to septal perforation and loss of the anterior nasal spine, the voice becomes hoarse and the

upper incisor teeth loosen or fall out [8]. The skin of the legs becomes ichthyotic and thickened, ulcers may form on the legs when nodules break down, and a slow fibrosis of peripheral nerves results in nerve thickening and bilateral 'glove and stocking' anaesthesia. Sensation of palms and soles is retained until late in the disease. Leprous deposits in the eyes cause keratitis, iridocyclitis and iris atrophy. Testicular atrophy causes sterility, impotence and gynaecomastia.

One particular variety of lepromatous leprosy requires special mention, namely, the pure diffuse type described by Lucio and Alvarado in Mexico in 1852. The patients first notice impairment of sensation in hands and feet, and this is followed by gradual loss of eyebrows, eyelashes and body hair. At the same time, the skin of the whole body becomes diffusely thickened, rendering it stiff and smooth as in scleroderma. There may be alopecia, nasal and laryngeal involvement, and widespread small telangiectases, but cutaneous nodules and plaques do not develop. The eyes have a shining appearance [9].

Histoid lesions are distinctive round, regular, cutaneous nodules that stand out on normal skin. They are characteristic of relapse after treatment [10].

Borderline leprosy

Skin lesions are intermediate in number between those of the two polar types already described, depending on the position of the patient on the borderline spectrum, and are distributed asymmetrically. They may take the form of macules, plaques, annular lesions or bizarre-shaped bands. Plaques with a 'punched-out' appearance are characteristic of the middle of the spectrum (Fig. 29.16). Towards the tuberculoid end of the spectrum, lesions are fewer and drier (Figs 29.17 & 29.18), have more hair loss

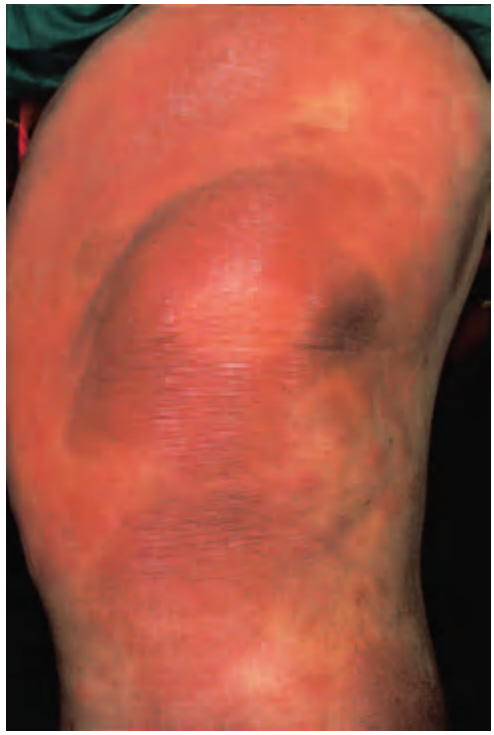

Fig. 29.16 Borderline (BB) leprosy. Knee of Saudi-Arabian woman, showing classical annular lesions with well-defined centres (?healing of old borderline tuberculoid, BT) contrasting with spreading erythematous infiltration. Slit-skin smears show acid-fast bacilli (AFB).

Fig. 29.17 Borderline tuberculoid leprosy. Back of Nigerian man showing large, well-defined, scaly macules with some marginal elevation. Extensive disease, such as this, may seriously impair sweating and heat control.

and anhidrosis, are more insensitive, and have fewer bacilli in smears and biopsies, and vice versa towards the lepromatous pole. One or more nerves are likely to be thickened and non-functioning (Fig. 29.19). Neural symptoms may precede the appearance of skin lesions by as much as 8 years [11]. When borderline leprosy

Fig. 29.18 Borderline tuberculoid leprosy. Arm of an Indian woman. A large, scaly macule is developing secondary ichthyotic change.

downgrades to lepromatous, the resulting subpolar lepromatous leprosy (LLs) can be differentiated from polar lepromatous (LLp) because, in addition to typical lepromatous skin lesions, there are several asymmetrical thickened nerves and one or more typical borderline skin lesions. Damage to structures other than skin and nerves will not be manifest clinically in borderline leprosy, even though bacilli may be present in other tissue. Borderline leprosy is the commonest type of disease encountered, with BT predominating in Africa and BL in Asia. Borderline disease is unstable and 'down-grades' towards lepromatous, especially if untreated, or 'upgrades' towards tuberculoid. The clinical change lags behind the immunological and histological changes (Fig. 29.20).

Pure neuritic leprosy

Pure neuritic leprosy presents with asymmetrical involvement of peripheral nerve trunks and no visible skin

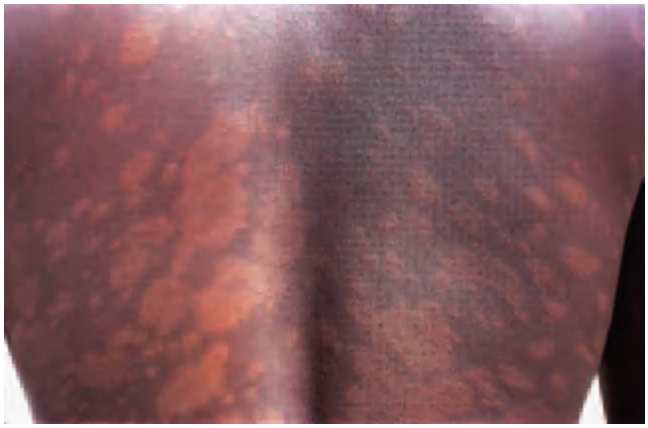

Fig. 29.20 Borderline leprosy (BL). Borderline tuberculoid (BT) down-grading to BL. Back of a Nigerian woman, showing typical well-defined hypopigmented macules of BT leprosy and many small lesions, some of which are papular. Slit-skin smears showed acid-fast bacilli (AFB).

lesions; on histology of a cutaneous nerve biopsy, all types of leprosy are seen [12]. It is seen most frequently, but not exclusively, in India and Nepal where it accounts for 5–10% patients [4,13].

Reactions

Type 1 reactions occur in borderline disease and are characterized by acute neuritis and/or acutely inflamed skin lesions [14]. Nerves often become tender with loss of sensory and motor functions. Existing skin lesions become erythematous or oedematous and may desquamate or rarely ulcerate. New lesions may appear (Fig. 29.21). Occasionally, oedema of face, hands or feet is the presenting symptom, but constitutional symptoms are unusual. Although type 1 reactions can occur spontaneously, the commonest time is after starting treatment and during the puerperium [15].

Type 2 (ENL) reactions occur in patients with multibacillary disease (LL and BL). They may occur spontaneously (roseolar leprosy) or whilst on treatment. During the dapsone monotherapy era, an estimated 50% of LL patients experienced ENL reactions; with the newer drug regimes containing clofazimine, this proportion has fallen to about 15%. Attacks are often acute at first, but may be prolonged or recurrent over several years and eventually quiet but insidious, especially in the eye. ENL manifests most commonly as painful red nodules on the face and extensor surfaces of limbs. The lesions may be superficial or deep, with suppuration (Fig. 29.22), ulceration (Fig. 29.23) or brawny induration when chronic [5]. Acute lesions crop and desquamate, fading over several days (Fig. 29.23). ENL is a systemic disorder producing fever and malaise and may be accompanied by uveitis, dactylitis, arthritis, neuritis, lymphadenitis, myositis and orchitis [16]. Peripheral nerve neuritis and uveitis with its complications of synechiae, cataract and glaucoma are the most serious complication of ENL.

The Lucio reaction only occurs in patients with Lucio leprosy [16]. It is due to infarction consequent upon deep cutaneous vasculitis, and causing the appearance of irregularly shaped erythematous patches which become dark and heal, or form bullae and necrose, leaving deep

painful ulcers that are slow to heal (Fig. 29.24). The systemic upset is severe and can be fatal.

Nerve damage [17]

Of the three physiological functions of nerves, the sensory component is commonly the first and most severely affected, but occasionally there is a pure motor lesion. Autonomic dysfunction is always present in severe nerve damage [18]. In skin lesions this is associated with loss of hair growth, and of sebaceous and sweat secretion, and poor pigment formation. In a limb it causes capillary stasis, cyanosis and dryness, which predispose to fissuring. Two large cohort studies with systematic nerve examination at entry showed that the posterior tibial nerve is the most frequently affected nerve, followed by ulnar, median, lateral popliteal and facial [19,20]. Ulnar and median nerve lesions are usually low, causing small muscle but not deep flexor weakness, and anaesthesia of the two halves of the hand. Isolated median nerve lesions are unusual. Common peroneal nerve lesions cause difficulty in dorsiflexion and eversion of the foot and anaesthesia of the outer border of the foot, a combination which predisposes to traumatic damage and plantar ulceration (Fig. 29.25). Posterior tibial nerve damage is serious

because it causes paralysis and contracture of the small muscles of the foot and anaesthesia of the sole.

Eye involvement in leprosy

Blindness due to leprosy is a devastating complication, especially for a patient with anaesthetic hands and feet. Eye damage results from both nerve damage and bacil-

lary invasion, and a recent cohort study found that 2.8% of multibacillary patients were blind at diagnosis, and a further 11% patients had potentially blinding ocular pathology [21]. Lagophthalmos results from paresis of the orbicularis oculi due to involvement of the zygomatic and temporal branches of the facial (VIIth) nerve. Facial lesions cause a 10-fold increase in the risk of facial nerve damage [22]. In lepromatous disease, lagophthalmos occurs later and is usually bilateral. Damage to the ophthalmic branch of the trigeminal (Vth) nerve causes anaesthesia of the cornea and conjunctiva, which results in drying of the cornea, a reduction in blinking, and leaves the cornea at risk of minor trauma and ulceration. Bacillary invasion of the iris and ciliary body makes them extremely susceptible to reactions.

Prognosis

Antibacterial treatment for leprosy is highly effective, with low relapse rates, but needs to be taken over many months. Left untreated, borderline patients will downgrade towards the lepromatous end of the spectrum, and lepromatous patients will suffer the numerous consequences of bacillary invasion. Borderline patients are at risk of developing type 1 reactions, which may result in devastating nerve damage. BL patients may suffer either type of reaction. Many patients present with established nerve damage which cannot be reversed. Treatment of the neuritis is currently unsatisfactory, and some patients with active neuritis will develop permanent nerve damage despite treatment with corticosteroids. It is not possible to predict which patients will develop reactions or nerve damage. Nerve damage and its complications may be severely disabling, especially when all four limbs and both eyes are affected. Women are at risk of reactions during the puerperium [23].

Diagnosis [1]

The diagnosis is usually made clinically on the basis of two out of three characteristic findings, or by the demonstration of AFB in slit-skin smears, or by histology typical of leprosy: The cardinal signs are:

1 anaesthesia of a skin lesion, or in the distribution of a peripheral nerve, or over dorsal surfaces of hands and feet;

2 thickened nerves, especially at the sites of predilection;

3 typical skin lesions.

The AFB load of a patient is determined by modified Ziehl–Neelson staining of slit-skin smears. Suspect lesions, and sites commonly affected in lepromatous leprosy, should be sampled (forehead, earlobes, chin, extensor surface of the forearm, buttocks and trunk). The density of bacilli is expressed using a logarithmic scale, extending from very few AFB to many per high power field. The number of AFB per field is scored according to a logarithmic scale. A mean score, the bacterial index (BI), is derived by adding the scores from each site and dividing by the number of sites sampled [2]. In untreated lepromatous leprosy, the BI is 5+ or 6+. The BI falls to zero in TT disease. Slit-skin smears only detect bacilli present at a concentration greater than 10^4/g tissue, and so cannot be

used as a test of microbiological cure. With treatment, bacilli disappear from BB lesions in a few months and from BL lesions in a year or two. It may take 6–10 years for the last bacillary remnants to disappear from the skin in LL.

Slit-skin smears [3]

The lesion is cleaned with ether or alcohol, and a fold is gripped firmly between thumb and forefinger to render it blood free. An incision 5 mm long and 3 mm deep is made with a small-bladed scalpel (size 15 Bard Parker blade); the blade is turned at right angles to the cut, and without relaxing finger pressure, the wound is scraped several times in one direction. Fluid and pulp from the dermis, collected on one side of the blade, are gently smeared on to a glass slide. A bloody smear is useless. The smear is then fixed over a flame and stained.

Skin biopsy [4]

The incision should be made down to subcutaneous fat, so that the whole depth of the dermis is included, otherwise leprous changes in the deeper layers of the dermis will be missed. The best fixative is 40% formaldehyde 10 mL; mercuric chloride 2 g; glacial acetic acid 3 mL; and distilled water to 100 mL. After 2.0–2.5 h, the specimen should be transferred to 10 mL of 70% alcohol, in which it can remain indefinitely.

Nerve biopsy

In pure neural leprosy a nerve biopsy is necessary to establish the diagnosis. A purely sensory thickened peripheral nerve should be sampled, e.g. radial cutaneous at the wrist, superficial peroneal in front of the ankle or sural nerve at the ankle.

Lepromin test

Lepromin is a crude, semi-standardized preparation of heat killed bacilli from a lepromatous nodule or infected armadillo liver. The lepromin test is a non-specific test of occasional value in classifying a case of leprosy. It is strongly positive in TT, weakly positive in BT, negative in BB, BL and LL, and unpredictable in indeterminate leprosy. Lepromin, 0.1 mL, is injected intradermally, and the reaction is read at 48 h (Fernandez reaction) or 3–4 weeks (Mitsuda reaction). The Fernandez response indicates delayed hypersensitivity to the soluble components of Lepromin. The Mitsuda reaction is a granulomatous response to particulate antigenic material. Neither test is diagnostic, since both may be positive in people with no evidence of leprosy.

Differential diagnosis

Leprosy tends to be over-diagnosed in endemic countries and under-diagnosed in non-endemic countries. Of new patients seen 1995–9 at the Hospital for Tropical Diseases, London, diagnosis had been delayed in over 80% of cases [5]. Patients had been misdiagnosed by dermatologists, neurologists, orthopaedic surgeons and rheumatologists. A common problem was failure to consider leprosy as a cause of peripheral neuropathy in patients from leprosy endemic countries. These delays had serious consequences for patients, with over half of them having nerve damage and disability. In any population it is also important for the doctor to know the normal range of skin colour and texture, the common endemic skin diseases, such as onchocerciasis, that may coexist with leprosy and the common medical and artefactual practices that may cause lesions resembling those of leprosy.

Macular lesions

Birthmarks are abnormally pigmented but otherwise physiologically normal. Vitiligo lesions are depigmented; leprosy lesions are never completely depigmented. Hypopigmented lesions of eczema, especially of pityriasis alba in children, are difficult to distinguish from lepromatous macules, but their surface is often scaly and smears do not contain AFB. Pityriasis versicolor is not always scaly, but central distribution on the trunk, and the presence of minute distinct macules, are contrary to the characteristics of lepromatous macules. Lesions of tinea corporis itch and may have a vesicular edge, characteristically absent in tuberculoid patches, and scrapings usually show the fungus.

Plaques and annular lesions

In addition to ringworm (above), granuloma multiforme, sarcoidosis and cutaneous tuberculosis may resemble tuberculoid leprosy, having a similar immunological basis and often indistinguishable histological pattern. However, the lesions are not anaesthetic. Peripheral nerves may occasionally be enlarged in sarcoidosis [6].

Nodules

Cutaneous leishmaniasis causes nodules, but they usually crust and ulcerate after some weeks or months, and are seldom as numerous as those of lepromatous leprosy. Slit-skin smears, appropriately stained, reveal leishmania, and the leishmanin test is positive. Lesions of the rare diffuse cutaneous leishmaniasis may be confusing, until slit-skin smears have been examined [7]. Post-kala-azar dermal leishmaniasis in India and East Africa has a similar distribution and appearance to the skin lesions of lepromatous leprosy [8].

Table 29.2 World Health Organization (WHO) multidrug therapy regimen.

	Drug treatment			
Type of leprosy	Monthly supervised	Daily self-administered	Duration of treatment	Duration of follow-up
Paucibacillary	Rifampicin 600 mg	Dapsone 100 mg	6 months	2 years
Multibacillary	Rifampicin 600 mg Clofazimine 300 mg	Clofazimine 50 mg Dapsone 100 mg	24 months	5 years

Nerves

Peripheral nerve thickening is rarely seen except in leprosy. Hereditary sensory motor neuropathy type III is associated with palpable peripheral nerve hypertrophy. Amyloidosis, which can also complicate leprosy, causes thickening of peripheral nerves. Peroneal muscular atrophy (Charcot–Marie–Tooth disease) is an inherited neuropathy that causes distal atrophy and weakness. Nerve biopsy is characteristic. The causes of other polyneuropathies such as acquired immune deficiency syndrome (AIDS), diabetes, alcoholism, vasclitides and heavy metal poisoning should all be considered where appropriate [9].

Likewise, there are many causes of eye disease in endemic countries which may cause signs that in isolation mimic leprosy, especially trachoma, in which trichiasis and entropion follow scarring of the lids, and onchocerciasis, which causes uveitis and its complications.

Treatment

There are five main principles of treatment:

1 Stop the infection with chemotherapy.
2 Treat reactions and reduce the risk of nerve damage.
3 Educate the patient to cope with existing nerve damage, in particular anaesthesia.
4 Treat the complications of nerve damage.
5 Rehabilitate the patient socially and psychologically.

These objectives can only be achieved with the patient's co-operation and confidence. In endemic countries, and in the patient's own town or village setting, this may be done through the leprosy outpatient clinic. In countries where leprosy is uncommon, or when the clinical or social situation is complicated, it is often best to admit the patient for a careful assessment and classification of the disease, to record accurately the degree of nerve and eye involvement and damage, assess disability and to start patient education and treatment.

Chemotherapy

All leprosy patients should be given an appropriate multidrug combination. The effectiveness of dapsone against *M. leprae* was discovered in the late 1940s, and it was used widely as a single agent. This lead to the widespread development of dapsone resistance, initially presenting as disease relapse 15 years after treatment with dapsone monotherapy, but then also as primary dapsone resistance in untreated patients [1]. In response to the failure of dapsone monotherapy, the World Health Organization (WHO) proposed a multidrug regime (MDT) for the treatment of leprosy [2]. In a multibacillary patient, there are three distinguishable types of bacilli: fully drug-sensitive bacteria, drug-resistant mutants and a small population of 'persisters', dormant non-multiplying bacilli. Treatment with a multidrug regime should eliminate nearly all organisms. The first-line antileprosy drugs are rifampicin, dapsone and clofazimine. Table 29.2 gives the details of drug dosages, duration of treatment and length of follow-up.

Rifampicin is a potent bactericidal for *M. leprae*. Four days after a single 600-mg dose, bacilli from a previously untreated multibacillary patient are no longer viable [3]. It acts by inhibiting DNA-dependent RNA polymerase, thereby interfering with bacterial RNA synthesis. Rifampicin is well absorbed orally. Hepatotoxicity may occur with a mild transient elevation of hepatic transaminases, but this is rare at the dosage and intervals recommended for leprosy, and is not an indication for stopping treatment. Because *M. leprae* resistance to rifampicin can develop as a one-step process, rifampicin should always be given in combination with other antileprotics [4].

Dapsone (DDS, 4,4-diaminodiphenylsulphone) acts by blocking folic acid synthesis. It is only weakly bactericidal. Oral absorption is good and it has a long half-life, averaging 28 h. Dapsone, in the doses recommended for leprosy, commonly causes mild haemolysis, and rarely anaemia or psychosis. Glucose-6-phosphate dehydrogenase deficiency seldom causes a problem and is not routinely looked for. The 'DDS syndrome', which is occasionally seen in leprosy, starts 6 weeks after commencing DDS and manifests as exfoliative dermatitis associated with lymphadenopathy, hepatosplenomegaly, fever and hepatitis, and may be fatal [5]. Agranulocytosis, hepatitis and cholestatic jaundice occur rarely with DDS therapy.

Clofazimine is a brick red, fat-soluble crystalline dye. The mechanism of its weakly bactericidal action against *M. leprae* is not known. It has an anti-inflammatory effect, which is useful in the management of ENL reactions. High drug concentrations are found in the intestinal mucosa, mesenteric lymph nodes and body fat. The most noticeable side effect is skin discoloration, ranging from red to purple-black, the degree of discoloration depending on the dose and amount of leprous infiltration. The pigmentation usually fades within 6–12 months of stopping clofazimine, although traces of discoloration may remain for up to 4 years. Urine, sputum and sweat may become pink. Clofazimine also produces a characteristic icthyosis on the shins and forearms. Gastrointestinal side effects, ranging from mild cramps to diarrhoea and weight loss, may occur as a result of clofazimine crystal deposition in the wall of the small bowel.

Fig. 29.26 Borderline leprosy (BL). Borderline leprosy up-grading to borderline tuberculoid (BT). Buttocks of an Indian man who 'relapsed' 3 years after completing multidrug therapy for BL leprosy. The lesions here are typical hypopigmented, erythematous, scaly, plaques of BT leprosy in reaction. No acid-fast bacilli (AFB) were seen on slit-skin smears. In this situation, the distinction between (bacterial) relapse and simple reversal reaction may be impossible.

Relapse

Relapsed multibacillary patients are also retreated with triple therapy regardless of any change in classification [6].

The distinction between relapse and reaction may be difficult (Fig. 29.26). Therefore, paucibacillary patients require 2 years, and multibacillary patients at least 5 years, monitoring after treatment. Patients can be discharged if there is no evidence of activity or reaction, but should be advised to return if new symptoms develop, especially in hands, feet or eyes. Patients with reactions or physical or psychological complications may need much longer care.

Published clinical outcomes for patients treated with the paucibacillary regimen show that 2–44% of patients had clinically active skin lesions at the end of treatment [7]. Nerve impairment occurred *de novo* in 2.5% of patients, and visible disabilities increased from 4% at enrolment to 7% at 8–10 years follow-up. Relapse rates are low, ranging from 0% in Ethiopia [8] to 2.5% over 4 years in Malawi [9]. For patients treated with the multibacillary regime for 24 months, one study in Thailand found that 29% of lesions were still active after 3 years and that visible disabilities increased from 5% at enrolment to 13% at 8–10 years follow-up [10]. Relapse rates have been reported from six observational studies varying from zero in China and Ethiopia to 2.04/100 person years in India. Data from West Africa [11] and India [12] shows that patients with a high initial bacterial load (BI > 4+) treated with 2 years of rifampicin, clofazimine and dapsone had a relapse rate of 8/100 person years, whereas patients treated to smear negativity had a relapse rate of 2/100 person years. These patients may form a subgroup who need treating to skin-smear negativity [13]. Susceptibility testing of *M. leprae* strains from relapsed multibacillary patients have shown them to remain drug sensitive.

Several new drugs bactericidal for *M. leprae* have been identified: fluoroquinolones, minocycline and clarithromycin. The fluoroquinolones pefloxacin and ofloxacin have a remarkable degree of bactericidal activity, with 22 daily doses killing 99.99% of viable *M. leprae* present in multibacillary cases at the start of treatment [14]. Multicentre trials of daily rifampin/ofloxacin are being conducted by the WHO and these may lead to a shortening in the duration of MDT. Daily minocycline (100 mg) treatment of multibacillary patients for 3 months resulted in killing of all viable *M. leprae* organisms [15]. Clarithromycin, given in 500-mg daily doses to multibacillary patients, has a similar bactericidal effect [16]. Antagonism between these new drugs has not been demonstrated [17]. Ofloxacin, minocycline and clarithromycin are established second-line drugs, and may replace dapsone and clofazimine. Minocycline may also cause hyperpigmentation of skin lesions, and so may not be an appropriate

substitute for clofazimine if pigmentation is to be avoided [18].

A single-dose triple-drug combination (rifampicin, ofloxacin and minocycline) has been tested in India for patients with single skin lesions; 47% of patients were completely cured 18 months after treatment. Although the study had major flaws, and single-dose treatment is less effective than the conventional 6-month treatment for paucibacillary leprosy, it is an operationally attractive field regimen and has been recommended for use by the WHO [19].

The recommended length of treatment for multibacillary patients has dropped from 24 months to 12 months. There was no controlled trial data to guide this decision, but the classification of multibacillary patients had been widened, so some patients who would previously have received paucibacillary treatment from 6 months are now receiving multibacillary treatment for 12 months. New proposals include testing a common 6-month regimen of dapsone, clofazimine and rifampicin for all patients [20]. This would simplify leprosy treatment but would give 60% of patients a third drug that they do not need, and under-treat patients with a high bacterial load [21].

Reactions and neuritis [22]

Nerve damage occurs before diagnosis, during and after multidrug treatment. It may occur during a reaction or without overt signs of nerve inflammation (silent neuropathy). In field cohort studies 16–56% of newly diagnosed patients have nerve damage [23]. In a Bangladeshi study 25% of multibacillary patients developed nerve damage during treatment [24]. Analysis from a large cohort study in Ethiopia showed that standardized nerve function testing was needed monthly to detect new nerve damage early [25].

Patients frequently seek medical advice for their leprosy only when a reversal reaction develops in a previously quiescent skin lesion, or when they develop pain, weakness or numbness. Awareness of the early symptoms of reversal reactions by both patient and physician is important, because if left untreated severe nerve damage may occur. The peak time for reversal reactions is in the first 6 months of treatment [26], so it is important to warn patients about reactions. The sudden development of reactional lesions soon after starting treatment is distressing and undermines confidence.

The treatment of reactions is aimed at controlling acute inflammation, easing pain, reversing nerve and eye damage and reassuring the patient. Multidrug therapy should be continued. Neuritis (nerve tenderness, new anaesthesia and/or motor loss) or moderately inflamed skin lesions should be treated with corticosteroids. Standardized courses of prednisolone have been used, starting at 40–60 mg daily, reducing by 5 mg every 2–4 weeks [27]. Patients with BT reactions commonly need 2–4 months of steroids, while BL reactions may need 6 months. A recent Indian study compared different starting doses (60 vs. 30 mg) and durations (12 vs. 20 weeks) and showed that the longer durations gave the best outcomes. A study looking at cytokine profiles in reactional patients showed that, even after 6 months of steroid treatment, some patients still had high levels of pro-inflammmatory cytokines in their skin lesions [28]. In another approach, the prevention of reactions has been explored. In one study, multibacillary patients were randomized to either prednisolone 20 mg daily or placebo for the first 3 months of their multidrug therapy. Reactional episodes were significantly lower in the prednisolone-treated group at 4 months, but the protective effect was lost by 12 months. These studies all demonstrate that reactions are difficult to prevent and to switch off once established. Other established immunosuppressants may have a role in treating reactions; in a pilot study in Nepal, patients had equivalent outcomes whether treated with an azathioprine/prednisolone combination or prednisolone alone [29]. Ciclosporin (cyclosporin) has also been used in reactions, and again is effective in skin and nerve inflammation, but patients relapse when treatment is stopped (Marlowe SN, Knuutilla FH, Bizuneh E *et al*., Verbal communication, 16th International Leprosy Congress, Brazil.).

This is a difficult condition to treat, and frequently requires therapy with high-dose steroids (80-mg daily, tapered down rapidly) or thalidomide. Since ENL frequently recurs, steroid dependency can easily develop. Thalidomide (400 mg daily) is superior to steroids in controlling ENL, and is the drug of choice for young men with severe ENL [30]. Women with severe ENL may benefit from thalidomide treatment. This is a difficult decision for the woman and her physician, and needs careful discussion of the benefits and risks (phocomelia when thalidomide is taken in the first trimester). Women should use double contraception and report immediately if menstruation is delayed. Unfortunately, the problems with thalidomide mean that it is unavailable in several leprosy endemic countries despite its undoubted value. Clofazimine has a useful anti-inflammatory effect in ENL and can be used at 300 mg/day for several months. Low-grade chronic ENL, with iritis or neuritis, will require long-term suppression, preferably with thalidomide or clofazimine. Acute iridocyclitis is treated with 4-hourly instillation of 1% hydrocortisone eye drops and 1% atropine drops twice daily.

Education of the patient

Educating a leprosy patient about their disease is the key to successful management. The patient needs to be reassured that within a few days of chemotherapy they will not be infectious and can lead a normal social life.

A clear explanation of the disease and refutation of myths about leprosy will help the patient come to terms with their diagnosis and may well improve compliance. It is important to emphasize that gross deformities are not the inevitable end point of disease, and that care and awareness of their limbs is as important as chemotherapy. Anxieties about transmission and reactions, as well as issues about compliance, should be addressed.

Complications of nerve damage [31,32]

The complications of nerve damage, which are the major causes of disability and deformity in leprosy, are preventable by early diagnosis, correct treatment and education of the patient. Monitoring sensation and muscle power in patient's hands, feet and eyes should be part of the routine follow-up, so that new nerve damage is detected early.

Dry skin should be treated by soaking in water, followed by rubbing with emulsifying ointment or petrolatum. Callus should be rubbed down with pumice or an abrasive nylon pad, and fissures need to be covered to allow them to heal.

The morbidity and disability associated with leprosy is secondary to nerve damage. A major goal in prevention of disability is to create patient self-awareness, so that damage is minimized. The patient with an anaesthetic hand or foot needs to understand the importance of daily self-care, especially protection when doing potentially dangerous tasks, and inspection for trauma. It is helpful to identify for each patient potentially dangerous situations, such as cooking, car repairs or smoking. Soaking dry hands and feet followed by rubbing with oil keeps the skin moist and supple.

An anaesthetic foot needs the protection of an appropriate shoe. For anaesthesia alone, a well-fitting 'trainer' with firm soles and shock-absorbing inners will provide adequate protection. Once there is deformity, such as clawing, shoes must be made specially to ensure protection of pressure points and even weight distribution.

The patient should be taught to question the cause of an injury so that the risk can in the future be avoided. Plantar ulceration occurs secondary to increased pressure over bony prominences. Ulceration is treated by rest. Unlike ulcers in diabetic or ischaemic feet, ulcers in leprosy heal if they are protected from weight-bearing. No weight-bearing is permitted until the ulcer has healed. Appropriate footwear should be provided to prevent recurrence.

Weakness or paralysis

These require physiotherapy, with the objective of permitting the return of function while preventing the formation of contracture. Patients with contractures are taught exercises to prevent fixation. Contractures of hands and feet, foot drop, lagophthalmos, entropion and ectropion are amenable to surgery.

Social, psychological and vocational rehabilitation

The social and cultural background of the patient determines the nature of many of the problems that may be encountered. The patient may have difficulty in coming to terms with leprosy. The community may reject the patient. Education, gainful employment, confidence from family, friends and doctor, and plastic surgery to correct stigmatizing deformity, all have a role to play.

Prevention and control

The current strategy of leprosy control in endemic countries through vertical programmes providing case detection, treatment with WHO MDT and contact examination, and supported by case finding campaigns, especially in schools, has been very successful. Effective treatment is not merely restricted to chemotherapy but also involves good case management with effective monitoring and supervision. An important secondary role of leprosy control programmes is the prevention of disabilities.

Vaccines against leprosy

The substantial cross-reactivity between BCG and *M. leprae* has been exploited in attempts to develop a vaccine against leprosy. Trials of BCG as a vaccine against leprosy in Uganda, New Guinea, Burma and South India showed it to confer statistically significant but variable protection, ranging from 80% in Uganda to 20% in Burma [33]. In Northern Malawi, BCG gives 50% protection against leprosy but no significant protection against tuberculosis [34]. A case–control study in Venezuela showed BCG vaccination to give 56% protection to the household contacts of leprosy patients [35]. The variability and unpredictability of BCG has lead to various attempts to improve its protective efficacy. Combining BCG and killed *M. leprae* is one approach, but in both a large population-based trial in Malawi [36] and in an immunoprophylactic trial in Venezuela [37] there was no advantage with BCG plus *M. leprae* over BCG alone. Possibly the variable protection induced by BCG is due to early contact with environmental mycobacteria priming the immune system and conferring protective immunity against *M. leprae*. Vaccination with BCG after contact with environmental mycobacteria will then contribute little towards inducing improved immunity against *M. leprae* [38].

The WHO declared that 'the elimination of leprosy as a public health problem' should be achieved by the year 2000 [39]. Whilst this has not been possible for all areas,

major progress has been made. Leprosy is unlikely to be eradicated until there is considerable improvement in general health, wealth, living conditions and education.

Chapter 30

The Treponematoses

The late R.S. Morton, G.R. Kinghorn & F. Kerdel-Vegas

Syphilis

General features

Definition. An infectious disease caused by *Treponema pallidum*. The systemic nature of the disease, in which there are florid clinical manifestations interspersed with periods of asymptomatic latency, is also characterized by transmission to offspring and chronic late disease in 25% of those who are untreated.

The name of the disease was drawn from a poem *Syphilis sive morbus gallicus*, written by Fracastoro of Verona in 1530, in which the mythical swineherd Syphilis refused to make sacrifices to Apollo and was smitten as a result.

Medicosocial background. Syphilis, 'the great imitator', is among the most fascinating of skin diseases. It may present to the dermatologist as a sexually acquired, contagious disease or as a congenitally acquired infection. When sexually acquired, it commonly coexists with at least one other sexually transmitted infection (STI).

The prevalence of syphilis in a community is determined by the socio-economic structure of the country concerned, and how that structure functions [1]. Humans and their social, economic and medical environment are in constant interaction. Changing attitudes determine changes in behaviour patterns and as these become integrated norms, so they become the custom. Thus, although syphilis is endemic worldwide, its steady decline over the last 400 years has been punctuated by epidemic peaks associated with unstable social conditions or upheavals. These changes include mass migrations and wars, as well as growing prosperity and economic reversals precipitating real or relative poverty.

The high incidence of syphilis in the Second World War peaked as thousands of demobilized men and women returned home to resettle. The period of relative socio-economic stability of the early 1950s saw a decline in all STIs, including syphilis. Its recrudescence, albeit modest compared with other sexual infections, began in the late 1950s [2–6]. It has been a variable manifestation. As in the 16th and 18th centuries in Europe and America, respectively, growing prosperity in the 1960s was not only associated with much scientific invention and technological innovation, but with the human's revolt against society's restraints and constraints—political, religious, social and sexual. A wide variety of changes thus determine the variations in incidence. At one extreme is the country recently freed from colonial domination, where health and social services have declined and disintegrated, and at the other is the country recently freed from written or unwritten laws controlling censorship, abortion and sexual activity.

In each case, socio-economic change disturbs some people's stability and sense of security, and exposes social and individual ineptitudes. West African countries lose control of yaws and it becomes common and disregarded.

In the UK and the USA, tens of thousands of young people manifest unprecedented high levels of medicosocial pathology in the form of self-poisoning episodes, premarital conception, sexual infection, and alcohol and drug abuse.

Unlike some STIs, the increase in the incidence of syphilis has been modest. The reasons are many and varied. For example, syphilis is not as infectious as some other STIs, and the infected are readily rendered non-infectious by even short courses of antibiotics given for a wide variety of infections—not least two common STIs, gonorrhoea and non-specific genital infection. In 1973, Felton [7] estimated that, in the UK, for every case of early syphilis diagnosed another remained undetected.

Population growth since the 1950s with a growing proportion of young people in many societies, like increasing population movement, has increased incidence rates more directly.

The extent to which available statistics reflect the incidence of syphilis depends on case-finding efforts, variation in notification practices and social factors that may limit increase or reduce the interaction between infected individuals and health services [8]. Comparison of one country with another is therefore essentially meaningless.

Incidence. The World Health Organization (WHO) estimates that the annual global incidence of syphilis is approximately 12.2 million cases, most of which occur in developing countries, where the disease has remained a prominent cause of genital ulcer disease in heterosexual men and women, of stillbirth, and of neonatal morbidity and mortality. The prevalence of pregnant seropositive women is 0.1–0.6% in developed countries, but it may exceed 10% in many developing countries. In some parts of Southern Africa, seroconversion during pregnancy has been reported to occur in more than 2% of women [9]. The growth of penicillin and other antimicrobial resistance amongst gonococci, for example in South-East Asia but increasingly also in Western Europe, and the use of drugs that are less treponemicidal may open the way for a greater prevalence of syphilis [10,11].

In North America and the developed countries of Northern Europe, syphilis had become predominantly a disease of homosexual men by the 1970s. There were renewed outbreaks of heterosexual and congenital syphilis in North America during the late 1980s in the wake of the human immunodeficiency virus (HIV) epidemic [12]. This resurgence was mainly observed in commercial sex workers, in whom it was often associated with selling sex for drugs (especially crack cocaine), and in other persons of lower socio-economic status. In 1994, there were 20 627 reported cases of primary and secondary syphilis in the USA (8.1 cases per 100 000 people, the rate being 60 times higher in non-Hispanic black people than in white people) compared with 304 cases in England (fewer than 0.6 cases per 100 000 people) [13]. Subsequently, incident syphilis cases have declined to less than four cases per 100 000 and syphilis has again been targeted for national elimination [14].

Eastern Europe experienced a 50-fold increase in reported syphilis cases between 1990 and 1997, with similar increases in the Ukraine, some central Asian countries and the Baltic States. Neighbouring Scandinavian countries have witnessed an increase in imported cases [15,16].

Although the overall incidence of syphilis in the UK was only 0.3 cases per 100 000 people in 1998, there have since been outbreaks in several cities where there was previously a low prevalence [17,18]. The outbreaks have been characterized by rapid increases in sexual networks with high rates of partner change; travel or migration links with high incidence areas; and an increasing predominance of homosexual transmission with a high proportion of HIV co-infection among incident cases. A similar trend in the increasing numbers of men who have sex with men engaging in unsafe sexual practises and who acquire syphilis and other bacterial STIs has also been observed in North America and elsewhere in Western Europe [19,20].

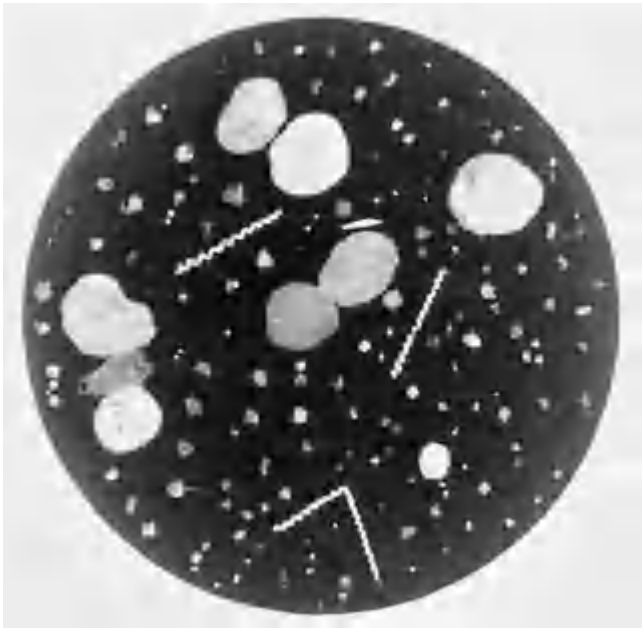

Fig. 30.1 *Treponema pallidum* showing regular spirals and marked angling.

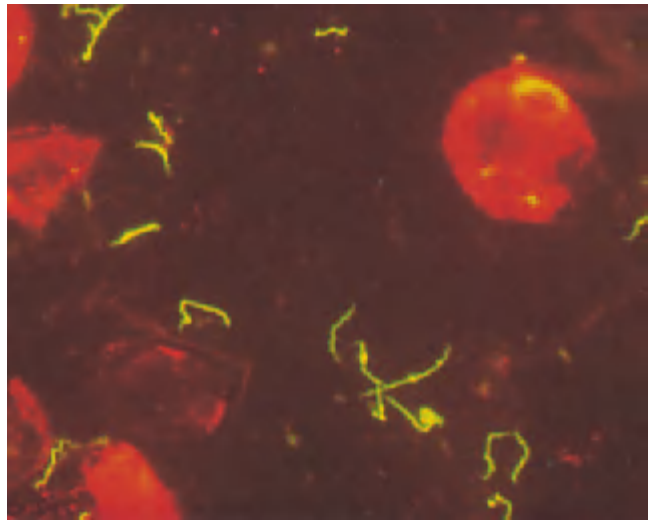

Fig. 30.2 Fluorescein-stained treponemes.

Causative organism

The causative spirochaete of syphilis, *Treponema pallidum* ssp. *pallidum*, was discovered by Schaudinn and Hoffmann in 1905 and originally was called *Spirochaeta pallidum*.

Treponema pallidum cannot be grown in the laboratory on any biochemical medium. Not all animals are susceptible to it. The rabbit, although liable to be a victim of a treponeme peculiarly its own, is commonly used in laboratory studies and as a source of *T. pallidum* used in diagnostic tests. *Treponema pallidum* cannot be differentiated from those treponemes involved in other forms of treponematosis, nor from Nichol's strain, which was isolated in 1912 from the brain of a patient and kept alive by passage through many generations of rabbits. Another experimental treponeme, the Reiter strain, is said to have been isolated in 1922. In contrast with the Nichol's strain, it is avirulent and can be cultivated on a relatively simple medium. Freeze-dried extracts were used for many years in the Reiter protein complement fixation test.

Morphology. In daily practice, *T. pallidum* is demonstrated by dark-field microscopy. It appears as a pale, white, fine, corkscrew organism with close and very regular coils (Fig. 30.1). Its length varies from 6 to 15 µm and its coils from 0.09 to 0.18 µm. There are between eight and 20 coils. As a practical guide, to help differentiate the organism from others like it, there are about seven to eight coils per diameter of a red blood corpuscle. It contains a periplasmic flagellum and is actively motile. The movements of the *T. pallidum* are pathognomonic. It rotates around its long axis and thus appears to quiver and screw slowly backwards and forwards; it shows a highly typical angling movement, forming both acute and obtuse angles. It shows both grace and elegance and these help to distinguish it from other genital or oral spirochaetal organisms. Treponemes can also be demonstrated by the direct fluorescent-antibody method [1,2], and by rapid immunofluorescent staining (RIS) of smears from lesions [3] (Fig. 30.2).

Of the several spirochaetes found in the genital area and requiring differentiation from *T. pallidum*, the most important are *Borrelia refringens* and *B. balanitidis*. Both are thicker than *T. pallidum* and have fewer and irregular coils. In addition, they move with more fidgety, snake and eel-like movements. *Borrelia gracilis* is finer than *T. pallidum*, with closer coils and a lack of typical movements. It can be found at the gum margins between teeth.

Microbiology. The organism is microaerophilic and has evolved to become a highly invasive and persistent pathogen with little toxigenic activity and an inability to survive outside the mammalian host. It has extreme nutritional requirements due to deficiencies in biosynthetic pathways, and has a narrow equilibrium between oxygen dependence and toxicity. It cannot be cultured on artificial media but it can be propagated in organ culture, such as rabbit testis. It has a slow growth rate, optimal at 33–35°C, with a doubling time of 30–36 h. The organism is similar to and shares extensive DNA homology with three other pathogenic treponemes, which cause yaws, bejel and pinta.

Analysis of the genome, which is contained on a single circular chromosome with 1 138 006 base pairs, shows that the organism lacks lipopolysaccharide and lipid biosynthesis mechanisms, as well as many metabolic pathways, including for the tricarboxylic acid cycle, components of oxidative phosphorylation, and for most

amino acids and vitamins. It requires D-glucose, maltose, and mannose but cannot utilize other sugars [4]. It is able to use exogenously supplied amino acids and is dependent upon serum components such as fatty acids.

Treponema pallidum initiates an inflammatory response at the site of inoculation and is disseminated during the primary infection. The organism has a surface-associated hyaluronidase enzyme, which may play a role in this process. Phagocytosis by cytokine-activated macrophages, as part of a predominant T-helper (Th1)-type early response, aids bacterial clearance and resolution of the primary lesion [5]. Virulent organisms promote adhesion of lymphocytes and monocytes to human vascular cells, and this is important in immunopathogenesis [6]. As with other organisms that cause chronic disease, *T. pallidum* has evolved mechanisms for evading immune responses. A Th1–Th2 switch occurs with macrophage suppression caused by prostaglandin E_2 down-regulation; however, the molecular mechanisms remain poorly understood [7]. Depressed cell-mediated responses occur during the later stages of syphilis, and a lowered $CD4^+$ lymphocyte count has been reported [8].

Pathogenesis. Relatively few genes are involved in pathogenesis. It has been postulated that the immunoevasiveness of *T. pallidum* is the result of the organism's unusual molecular architecture. The outer membrane lacks lipopolysaccharide and contains few poorly immunogenic transmembrane proteins; the highly immunogenic proteins are lipoproteins anchored predominantly to the periplasmic leaflet of the cytoplasmic membrane [9].

The dominant immunogen is a 47-kDa membrane lipoprotein, which can induce synthesis of tumour necrosis factor-α. Immunoblotting has also shown IgG responses to an antigen of 65 kDa that is shared with non-pathogenic treponemes and antigens of 44.5, 17.0 and 15.5 kDa that are specific for *T. pallidum*.

Natural history

Stages. The clinical presentation of syphilis is extremely diverse and may occur decades after initial infection. Syphilis, if untreated, may pass through four stages: primary, secondary, latent and late. The first two stages are contagious. They seldom last more than 2 years and do not exceed 4 years. Latency may last from 5 to 50 years. Only 25–30% of patients present with late, chronic, crippling or killing manifestations. The frequency of these late manifestations continues to decline, and in many countries they are now rare.

Incubation period. The incubation period of syphilis is generally given as 9–90 days, and varies inversely with the size of the spirochaete inoculum. Typically, most genital primary sores appear 3 weeks after exposure. Enlarged glands appear in one groin after a further week and can usually be detected in both groins 5 weeks after infection. Reactive reaginic serological tests are detectable at 5.5–6.0 weeks; the macular rash at 8 weeks; papular lesions at 3 months and condylomas at 6 months.

Course of untreated syphilis. Several investigations have helped to elucidate the natural history of untreated syphilis, for example the Oslo study of untreated syphilis [10] and the Tuskegee study [11]. Regarding the first of these, Caesar Boeck believed that *no* treatment was better than using mercury. He therefore kept some 2000 infectious syphilitics in hospital for 1–12 months (average 3–6 months), i.e. until all traces of their infection had gone. Gjestland [10] made a follow-up study of 1147 patients and summarized the findings as follows:

- 24% developed mucocutaneous relapses;
- 11% died of syphilis;
- 16% developed benign late manifestations, usually cutaneous nodules or gummata;
- 10% developed cardiovascular syphilitic lesions;
- 6% developed neurosyphilis.

It would appear therefore that long before the arsenicals and penicillin were introduced, at least 60% of people with syphilis lived and died without developing serious symptoms of their infections.

Histopathology

The fundamental pathological changes in syphilis are the same in early and late disease. They occur in and around blood vessels in the form of a perivascular infiltration of lymphocytes and plasma cells, accompanied by intimal proliferation in both arteries and veins (endarteritis obliterans).

In early lesions, perivascular infiltration by lymphocytes and plasma cells is accompanied by intimal proliferation in arteries and veins. This leads to ischaemia and ulceration. Organisms are most numerous in the walls of capillaries and lymphatic vessels. They can be demonstrated by Levaditi's silver stain or by the fluorescent antibody technique [12]. The papular skin lesions of secondary syphilis also show endothelial swelling in dermal vessels.

In late lesions, the characteristic lesion of mucocutanous surfaces is the syphilitic gumma. Granulation tissue forms with histiocytes, fibroblasts and epithelioid cells. Endarteritis obliterans and necrotic areas are pronounced. Gummata most often originate in subcutaneous tissues and spread in all directions. Spirochaetes are not readily demonstrable in these lesions.

Heubner's arteritis occurs in cardiovascular and meningovascular syphilis. It is characterized by lymphocytic and plasma cell infiltration of the vasa vasorum and adventitia of large and medium-sized vessels. Occlusion

of the vasa vasorum results in medial necrosis and fibroblast proliferation. There is associated subintimal proliferation, which leads to luminal occlusion and thrombosis.

Some manifestations of syphilis (e.g. neuropathy) are immune-complex mediated.

Transmission. Transmission occurs almost exclusively during sexual intercourse, including by oro-genital contact [13]. *Treponema pallidum* is very sensitive to drying and heat, and also to soap and weak disinfectants. It can probably penetrate intact skin and mucous membrane but more readily enters the body through microscopic or visible breaks in the epidermis. Treponemataemia is established even before the appearance of the primary lesion. Syphilis therefore can be transmitted by blood transfusion. In deep inoculation, as by accidental puncture with a needle or in transfusion, no primary lesion appears. This is called syphilis d'emblee.

Congenital syphilis is acquired by placental transmission of infection from the mother. The longer the mother has had syphilis, the less likely she is to transmit it.

Acquired syphilis

Primary syphilis (Figs 30.3–30.7)

The primary chancre appears at the site of initial treponemal invasion of the dermis. Initial lesions are papular but rapidly ulcerate. It may occur on any skin or mucous membrane surface and is usually situated on the external genitalia.

Fig. 30.3 Small but well-circumscribed primary syphilis. (All sores in the coronal sulcus are indurated.) Serology was negative.

Fig. 30.4 Primary syphilis: meatal chancre.

The typical primary sore appears as a regularly edged, regularly based, hard and button-like ulceration measuring up to a centimetre in diameter. Unless secondarily infected, primary sores are not painful. The ulcer is often surrounded by a narrow, red border, 1–2 mm wide. This marks the limits of the inflammatory reaction and is most productive of *T. pallidum*. The lesion may be crusted due to drying of serous exudate. The induration of the ulcer is probably the best-known characteristic but it should be

Fig. 30.5 Healing primary chancre of 3 weeks duration. It was accompanied by bilateral adenitis. Dark-field and serological tests were positive.

Fig. 30.6 Slightly indurated primary chancre of 2 days duration. It was neither painful nor tender. It points to the need for a high index of suspicion concerning all genital lesions. Dark-field microscopy prevents diagnostic error and embarrassment.

Fig. 30.7 Extragenital chancre of the lip. (Courtesy of Dr P. Taylor, Bristol Royal Infirmary, Bristol, UK.)

remembered that all lesions in the coronal sulcus of the penis are indurated. 'Kissing' ulcers, sometimes hourglass in shape, are not uncommon. Atypical lesions are common and around half lack one or more of the classical features. If the infection is inoculated into pre-existing lesions such as anal fissure, genital herpes or balanitis, the chancre may assume the shape of these conditions. In most cases, there is only a single chancre. Multiple chancres may appear simultaneously or within a few days of each other. Without treatment, the chancre persists for a period that can vary considerably, but seldom if ever exceeds 3 months. As a rule, it heals spontaneously in 3–8 weeks. In about one-third of cases, it leaves a regularly edged, slightly depressed, thin, depigmented, atrophic scar.

The appearance of the genital and perianal chancre is followed by swelling of the inguinal lymph nodes, usually one side and then the other. Maxillary and submental lymph nodes enlarge when infection is in or around the oral cavity. Wherever they appear, the enlarged glands are discrete, rubbery and free from fixation to skin or underlying tissues.

Sites. In men, the chancre most usually occurs on the glans penis, near the frenum or on the underside of the prepuce. Less commonly, the primary lesion appears on the shaft of the penis. If near the hilt, it may be called a 'condom chancre'. Less common sites are the pubic region or the external urinary meatus where it may masquerade as non-specific urethritis with scanty serous discharge. Lesions are often surrounded by oedema. Subprepucial lesions may be accompanied by some degree of acquired phimosis and it is in such cases particularly that lymphangitis dorsalis penis occurs; it is felt as an indolent 'string', some 2 mm in diameter.

In homosexually acquired syphilis, the anus and rectum may be sites of primary infection. Anal lesions may present as an indurated fissure difficult to distinguish from an ordinary fissure of the anal ring. Pain may be a feature as may itch and bleeding, especially after

defaecation. Like genital primary lesions, extragenital sores are accompanied by regional adenitis.

In women, most cases of early syphilis have reached the secondary stage when diagnosed [1]. A chancre is less frequently demonstrated, partly because the primary lesion may be on or in the cervix. The most common sites for a vulvar chancre are the labia minora or majora, around the urethral orifice, on the clitoris or quite commonly on the posterior commissure where it may masquerade as an indurated irregular fissure. Surrounding vulval oedema is common. Chancre very rarely occurs on the vaginal wall.

Extragenital chancres may be found on the lips as a result of kissing, cunnilingus or fellatio (Fig. 30.7). The indurated ulcer may be surrounded by oedema. Chancres of tongue and tonsil and primary lesions of the fingers, acquired occupationally or in sexual foreplay, also occur. Other extragenital chancres may follow from nibbling or biting the nipple, the ear, neck or arm.

Differential diagnosis. A wide variety of diseases can affect the genitals and must be considered. Genital herpes and balanoposthitis have typical clinical features, although they may occur with a chancre. Secondarily infected traumatic sores may look like chancres. Chancroid should be considered, and not only in subtropical areas of the world. Sporadic epidemic outbreaks of clinically modified chancroid have been reported in the UK, Canada and Kenya. Improved techniques for culture of *Haemophilus ducreyi* have been widely sought in several countries. The organism appears to be more common as a secondary invader than previously believed. Carrier states in both men and women are described. In general, the lesions described are rarely of the destructive and painful type previously believed to be classical [2].

As in chancroid, so in lymphogranuloma venereum, 'inflammatory bubo' may resemble the unilateral and bilateral adenitis of early syphilis. Unlike syphilis, the glands are usually matted, adherent to the inflamed skin and show a tendency to central fluctuation.

Excoriated secondary syphilitic papules in women can be confused with multiple small chancres. *Chancre redux* is a recurrence of the primary sore at its original site [3]. Tertiary syphilis, tuberculous ulceration, cancer or precancerous dermatoses such as erythroplasia of Queyrat and Bowen's disease, can occasionally cause difficulty. The papules of scabies on the glans or on the shaft of the penis may arouse strong suspicions. Any lesion at the site of a healed primary has been labelled pseudochancre redux [3,4].

On the cervix, a chancre may easily be taken for an 'erosion' or a cancer [5], especially when suspected syphilis is not the reason for examination.

With a chancre on the lip, the most important differential diagnosis is facial herpes simplex. Apart from the appearance, the recurrent nature of herpes is helpful.

Fig. 30.8 Secondary syphilis. Like the macular rashes of other infections, it is not associated with the presence locally of the causative organism. It also appears at a recognized time after exposure, in this infection, 8 weeks after exposure. It is most readily seen, following the lines of cleavage of the skin of the trunk, in daylight.

Secondarily infected traumatic lesions with oedema may closely resemble a chancre, as may cancer of the lip. Traumatic ulcers of the tongue can sometimes be infiltrated. Behçet's syndrome with both oral and vulvar lesions may present a problem. Tonsillar chancres may be mistaken for tonsillitis, glandular fever or Vincent's angina. When the accompanying angular or submental adenopathy is painless, syphilis should be seriously considered.

A long-standing whitlow or paronychia ought to lead to examination for both herpes virus and *T. pallidum*. Where epitrochlear or axillary adenitis is painless, serological tests for syphilis are indicated.

In 'modern' societies, all oral and rectal lesions should give rise to suspicion of possible syphilis. Anal fissures and anal warts, 'haemorrhoids', anal discharge and irritation or a finding of some form of sexually transmitted proctitis, for example due to gonorrhoea, herpesvirus or *Chlamydia trachomatis*, should alert the physician to the possibility of concomitant syphilis. In the rectum, a chancre may be mistaken for a cancer.

Secondary syphilis (Figs 30.8–30.19)

Secondary syphilis is the stage when generalized manifestations occur on the skin and mucous membranes. Serological tests are always positive in immunocompetent persons. Rashes in secondary syphilis have three common features:

Fig. 30.9 Papulosquamous secondary syphilis involving the palm. (Courtesy of Dr P. Taylor, Bristol Royal Infirmary, Bristol, UK.)

Fig. 30.10 Typical coppery red papules in secondary syphilis.

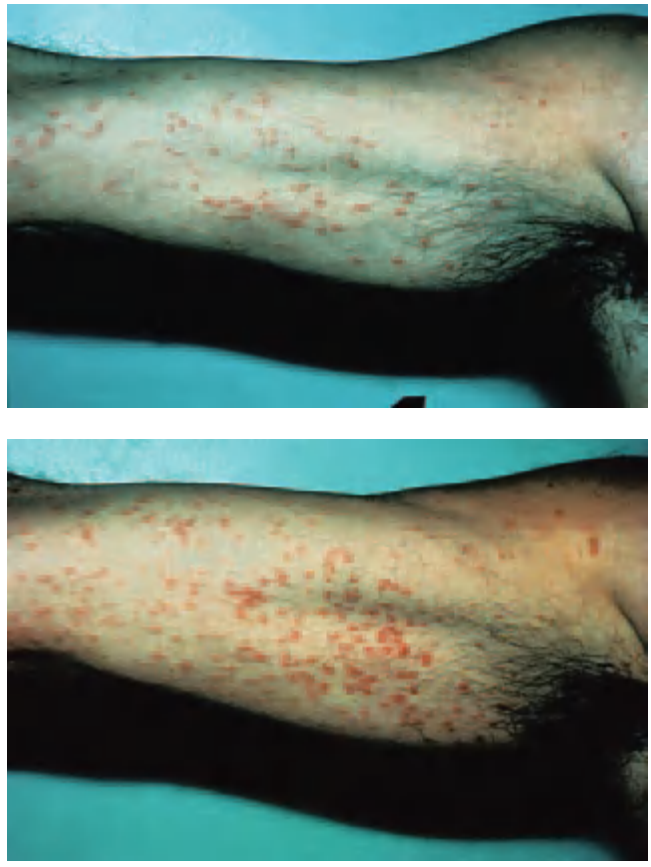

Fig. 30.11 Symmetrically distributed, coppery red and non-itchy rash typical of secondary syphilis. The only suggestion of syphilis in the partner was a history of laryngitis 5 months earlier. Her serological tests were strongly positive.

Fig. 30.12 Secondary syphilis imitating seborrhoeic dermatitis. Note the coppery red corona veneris.

1 they do not itch;
2 they are coppery red;
3 the lesions are symmetrically distributed.

The manifestations of generalized treponemal dissemination first appear at around 8 weeks. Constitutional symptoms consist of fever, headache, and bone and joint pains that are more pronounced at night. There is wide diversity in physical features.

Fig. 30.13 Secondary syphilis presenting as 'split' papules at the angles of the mouth.

Fig. 30.14 Secondary syphilis. This eroded papule was the only lesion. Similar solitary lesions, demonstrating *Treponema pallidum*, are occasionally found just inside the anus in asymptomatic contacts.

Fig. 30.15 Papules. These were the only evidence of reinfection in the regular consort of a pregnant women referred from an antenatal clinic with strongly positive serological tests for syphilis. She was an undeclared regular consort when the man was originally treated for primary syphilis, 18 months earlier.

Fig. 30.16 Psoriasiform papules in secondary syphilis. Such lesions, sometimes shiny when squames are shed, of palms and soles are most commonly found in people of African origin.

Fig. 30.17 Mucous patches around vaginal introitus.

Fig. 30.18 Here the lesions are more exuberant. The sodden surface epithelium has been shed to reveal lesions describable as 'moist papules'.

Fig. 30.19 When large opposing papules coalesce, as in the perianal region, the surface epithelium becomes sodden. Such lesions are called condylomata lata. *Treponema pallidum* organisms abound in them. They rarely appear in infections of less than 6 months duration.

Rashes are the commonest feature. They are initially macular and become papular by 3 months.

Macular syphilide (roseolar rash). This is the earliest generalized syphilide. It appears as symmetrical, coppery red, round and oval spots of no substance. On the back, the lesions clearly follow the lines of cleavage of the skin. The patients should be examined in daylight, as it is easy to overlook an early or fading rash. The roseolar spots do not scale or itch and, being in some patients sparse and evanescent, may pass unnoticed. Roseola is easily overlooked and seldom diagnosed in patients with deeply pigmented skin. When a roseola is fading, it sometimes leaves a pattern of depigmented spots on a hyperpigmented background. Such a *leukoderma syphiliticum* is most commonly located on the back or sides of the neck and was formerly known as 'the necklace of Venus'.

Papular syphilide. The papule is the basic lesion of secondary syphilis. Individual papules seldom exceed 0.5 cm in diameter. Its particular form of presentation can vary widely depending on the nature and colour of the patient's skin, the site affected and the climate, hygiene and clothing. Papular rashes may recur and be punctuated by spells of apparent latency. More usually, early papular rashes are in fact maculopapular and they have an even and generalized distribution all over the body. However, a purely coppery red papular rash, widely and symmetrically distributed, may also be seen.

The typical papule is firm and round, although the largest may be oval. Early papules tend to be shiny, but gradually a thin layer of scale forms and is quickly shed. This is the typical papulosquamous syphilide. Older lesions tend to be more pigmented. In the late phases of a papular syphilide, nummular lesions, 1–3 cm in diameter and covered by massive layers of scales, may closely resemble psoriasis. Because the underlying lesions are exuding serum, the scales are easily removed. Psoriasiform papules of the palms and soles are especially common in black people, as are annular and circinate papular rashes. Such rashes may resemble granuloma annulare, annular sarcoid or scaly varieties of tinea.

On macerated skin surfaces and mucous membranes, eroded weeping papules with a tendency to hypertrophy often appear. On the genitals, for example, at the penoscrotal junction, there may be small, eroded papules flush with the skin or hypertrophic, coalesced papules (condylomata lata). Such lesions more commonly occur around the anus and the vulva. In men, the papules frequently occupy the entire surface of the glans penis, the coronal sulcus and the inner aspect of the prepuce. Partial or complete acquired phimosis is not infrequent in such cases. The free margin of the prepuce may be a circle of tender fissured ('split') papules. In women, in the axillae and beneath the breasts, small, superficial, eroded, lentil-sized

(about 0.3 cm) papules are sometimes seen, but more typical are hypertrophic papules, which may affect the adjacent mucous membrane. In the last stages of pregnancy, hypertrophic, coalesced, sodden-surfaced papules may be very pronounced. Later, the papules are more irregularly distributed but show a predilection for certain sites, such as the corners of the mouth, angles of the nose, the palms and soles and body folds such as beneath the breasts or in the axillae. The face is often affected, particularly if the patient has greasy skin. The seborrhoeic areas involved are the same as those in acne vulgaris and seborrhoeic dermatitis. Sometimes, the papules form a line along the hair margin, the *corona veneris*.

Hyperkeratotic lesions of the palms and soles may flake, peel and fissure. Hypertrophic papules between the toes may resemble severe tinea pedis.

Micropapular and miliary eruptions. These are especially seen late in the second stage, i.e. about a year or more after infection. Characteristics of such a lichenoid syphilide include small conical or spinular elements, which tend to be arranged in groups of varying size over the body. A *corymbose syphilide* is one with a large central papule surrounded by small satellite papules.

Pustular ulcerative syphilide. These, which characterized the 16th-century epidemic, are now all but unknown. Lesions that most nearly resemble this nowadays are the crusted papules of the scalp, where brushing and combing tears papules, which ooze serum and which may become secondarily infected. Such lesions, unlike other syphilides, may leave scars. Atypical facial plaques or ulcerated nodules (lues maligna) are more common with coexisting HIV infection [6].

Syphilitic alopecia. Patchy hair loss is characteristic of syphilis. The hair falls leaving small, scattered, irregularly thinned, 'moth-eaten' patches of semi-baldness. The eyebrows and beard may be affected [7,8]. Syphilitic alopecia may be accompanied by a more generalized diffuse alopecia associated with generalized infection and anaemia.

Nails. Syphilitic paronychia with secondary onychia is sometimes seen in the secondary stage. It has no special characteristics.

Lesions of the mucous membranes. On the mucous membranes, the basic papular eruptions are less distinctive, but they tend to be symmetrically distributed (Fig. 30.17). As the surface epithelium dies, it turns grey and forms round or oval mucous patches on the palate or inner aspects of the lips and cheeks. These mucous patches may coalesce to form 'snail-track' ulcers. Ulceration is not common. Sharply defined, round or oval lesions devoid of dead epithelium may appear on the tongue and may be associated with flattened papillae. Bilateral syphilitic tonsillitis may coexist, as may syphilitic laryngitis associated with eroded papules and hoarseness.

Generalized lymphadenopathy. Occurs in 50% of secondary syphilis cases. As in the localized lymphadenopathy of primary infection, the nodes are painless, discrete, mobile, rubbery and vary in size from about 0.5–2.0 cm.

Neurological involvement. During the secondary stage, the central nervous system (CNS) may be invaded. Abnormalities in the cerebrospinal fluid (CSF), such as raised cell count and increased protein, can be found in at least 15% of cases. Less often, serological tests are positive in the CSF. The patient may complain of headache only. Occasionally, meningitis may present as paralysis of one or more cranial nerves. Meningomyelitis with paraplegia and double incontinence is rare.

Other systemic features of secondary syphilis include panuveitis [9], periostitis and joint effusions, glomerulonephritis, hepatitis, gastritis and myocarditis.

The lesions of secondary syphilis resolve spontaneously in a variable time period, and most patients enter the latency stage within the first year of infection. In some, especially the immunocompromised, primary or secondary lesions may recur.

Differential diagnosis. The skin manifestations of secondary syphilis are so variable that it must be considered in the diagnosis of all dermatoses that are in any way atypical. Some of these dermatoses have already been mentioned.

With the macular rash, drug eruptions must first be considered. The history, itching and lack of adenopathy aid differentiation. Measles and rubella may cause difficulty, but it is pityriasis rosea that is most often called into question. The presence of a herald patch and the collarette of scales distinguish this condition from macular syphilis.

With papular eruptions, many diseases can cause difficulty in diagnosis, and it has to be remembered that people with seborrhoeic dermatitis or psoriasis can also have syphilis. Lichen planus with its shiny, angled, violaceous lesions, should seldom cause difficulty. Acne vulgaris and seborrhoeic dermatitis may confuse the unwary, as may impetigo and, occasionally, leprosy or tuberculosis if the face is affected. In the anogenital region, condylomata lata have been diagnosed as haemorrhoids and as condylomata acuminata. Balanitis circinata, hyperkeratotic lesions of Reiter's disease and genital herpes may also lead to misdiagnosis.

The micropapular varieties of syphilis can be confused with keratosis pilaris, lichen scrofulosorum, trichophytide and lichen planopilaris. Eruptions of palms and soles may bear a striking resemblance to psoriasis and scaling mycoses.

With oral lesions, the question of aphthae has first to be considered. The painful nature of the lesions contrasts with syphilis and the aphthous lesions are markedly areolated [10]. Tonsillitis or tonsillar papules with lymphadenopathy may make differential diagnosis from infectious mononucleosis a difficult clinical problem. An accompanying morbilliform rash, perhaps precipitated by administration of ampicillin, may add to the confusion, especially as the condition is sometimes accompanied by false-positive serological tests for syphilis.

Latent syphilis

In latent syphilis there are no clinical stigmata of active disease, although disease remains detectable by positive serological tests. In early latency, within 2 years of infection, vertical transmission of infection may still occur, but sexual transmission is less likely in the absence of mucocutaneous lesions. The late manifestations of syphilis subsequently arise, often decades later, in about 25% of those who have latent syphilis.

To establish a diagnosis of latent syphilis, strict criteria are called for. Clinical evidence of active, early, late or congenital syphilis must be absent; the CSF must be normal and a chest X-ray (preferably posteroanterior and left oblique, to view the aorta at a right angle) must also be normal. Positive (reactive) serological tests for syphilis must be confirmed by examination of a second specimen.

The differential diagnosis may be from biological false-positive (BFP) reactions or from other treponematoses, particularly yaws in immigrants to Westernized countries. The presence of a scar of a primary chancre or leukoderma syphiliticum at the back of the neck may be helpful. Yaws is usually acquired by children living in poor rural conditions in the tropics. Presenting in adulthood with positive serological tests for syphilis, they may give a history of yaws or chronic sores or bone pains, or they may know of the disease in their family, school or parish. Some have clinical or radiological evidence of old periostitis in their long bones [11]. Much the same may apply to bejel [12].

Great care is called for in assessing immigrant patients. For example, in the UK, one would hesitate to diagnose old yaws in a West Indian immigrant under the age of 40 years. The WHO declared Jamaica free of yaws in 1950, and it has remained free of the disease. On the other hand, yaws has been recrudescing in West African countries for more than 20 years, and the differentiation of latent syphilis from old yaws in immigrants from that part of the world may now present problems.

Tertiary syphilis

After a period of latency of up to 20 years, manifestations of late syphilis can occur. However, screening for syphilis of 'captive' groups, for example blood donors and pregnant women, has contributed greatly to the prevention of late syphilis. In addition, since the commencement of the antibiotic era, many latent and asymptomatic late syphilitics have happened to receive penicillin or other treponemicidal antibiotics in circumstances unconnected with syphilis ('happenstance antibiotic therapy'). Such inadvertent therapy has also contributed to the decline of late syphilis, so that it is becoming rare in many parts of the Western world including the UK and the USA.

Fig. 30.20 Late syphilis. Coalescing circinate papular lesions. Note the typical coppery red colour. *Treponema pallidum* organisms are not found in such lesions. The clinical diagnosis is confirmed serologically.

Fig. 30.21 Late syphilis. Nodulocutaneous syphilide in a 62-year-old woman with positive serology. The lesions healed completely within 3 weeks of starting treatment with penicillin.

Late skin syphilis appears in two types: the superficial or nodular syphilide and a deeper gummatous syphilide. Transitional forms also occur.

Nodular or tubercular syphilide (Figs 30.20 & 30.21). The lesions are protruding, firm, coppery red nodules (larger than 0.5 cm diameter). On dependent limbs, they may be cyanotic. The nodules appear in groups with a tendency to a circinate arrangement, i.e. forming interwoven circles

Fig. 30.22 A gumma is a syphilitic swelling with a tendency to ulcerate. The ulcers tend to be 'punched out' in the case of skin gummata.

Fig. 30.23 Healing gumma. Delay in diagnosis is suggested by widespread pigmentation and scarring. Response to treatment was slow and the final scarring led to permanent oedema of the foot, sometimes called 'paradoxical healing'.

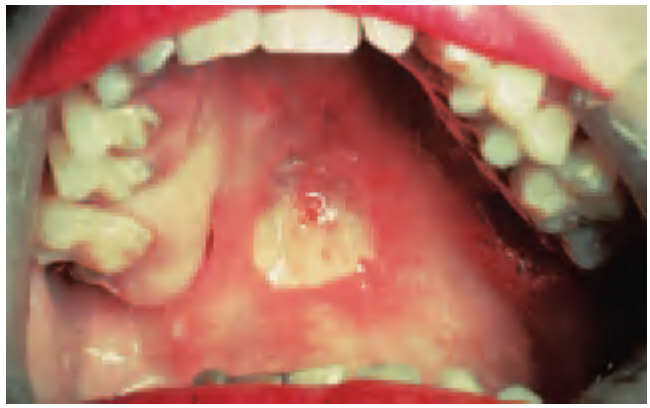

Fig. 30.24 Gumma of the palate. This is a favoured site for such lesions in both acquired and congenital syphilis.

and part of circles. As the disease heals centrally, it extends peripherally. The spread does not take place equally in all directions, so that the outline may be horseshoe shaped, tongued, kidney shaped or serpiginous. Some nodular eruptions resemble granuloma annulare or annular forms of sarcoid. Their histology resembles secondary syphilis. In other cases, the abundance of waxy scales gives the eruption a psoriasiform appearance. Most frequently, serpiginous nodulo-ulcerative eruptions are covered by massive crusts. Even the smallest ulcers have a punched-out appearance.

Lesions of nodular syphilis can appear anywhere on the body, but favour the extensor surfaces of the arms, the back and the face. They are symptomless. Where they have spread extensively, smooth, soft, finely wrinkled ('cigarette paper') central scarring is a feature. In their early stages, these scars may be pink, but after a year or two they are white. Nodular syphilis spreads slowly but more rapidly than lupus, producing a lesion of similar size in months rather than years.

Gummata (Figs 30.22–30.24). The characteristic lesions of tertiary syphilis appear 3–10 years after infection and consist of granulomas or gummata. The granulomas appear as cutaneous plaques or nodules of irregular shape and outline and are often single lesions on the arms, back and face. They have a tendency for central necrosis and ulceration and for peripheral healing with tissue-paper scarring. They most often originate in the subcutis, growing in all directions, i.e. into the dermis and epidermis as well as the deeper tissues. Gummata, which start in bone or muscle, also tend to ulcerate the skin, and their true origin may be difficult to determine. Gummatous changes sometimes take place more superficially with scattered small ulcerations along the margins. This form is difficult to differentiate from a nodular syphilide.

Gummata are usually painless even when they ulcerate. Their central necrotic tissue may turn into a slimy, stringy mass, and it is this that gives rise to the name 'gumma'. Multiple gummata tend to coalesce, the bridges of skin between them gradually undergoing necrosis. Such

ulcerations offer a wide variety of scalloped and geometrical patterns. A 'punched out' appearance is characteristic.

Gummata vary in size from 2 to 10 cm. They favour the scalp, face, sternoclavicular areas of the chest and lateral calf.

Late mucous membrane lesions. Gummata not infrequently attack the palate, both the hard and the soft, with tissue destruction that may lead to loss of the uvula and scarring or perforation of the hard palate. In cases of congenital syphilis, destruction of the nasal septum may also occur producing saddle-nose deformity. They may also cause painless testicular swelling, mimicking a tumour; portal hypertension and portosystemic anastomoses; and diffuse interstitial glossitis. Late syphilis of the tongue may present with localized or diffuse changes, i.e. the solitary gumma or diffuse gummatous infiltration. The latter often passes through a stage of chronic interstitial glossitis with fissuring and, later, obvious leukoplakia with patchy necrosis, sometimes associated with trauma from the teeth. In other cases, changes are more superficial, with red, smooth, glazed areas and loss of papillae. Although sometimes painless, these changes may be accompanied by discomfort on eating hot or acid foods. All the forms of tongue involvement described are recognized as precancerous, so that even after adequate antisyphilitic treatment, regular observation of the patient is an essential element of sound management.

Differential diagnosis. Skin reactions to bromides and iodides commonly deceived the physician in the past. On the face, lupus vulgaris, epithelioma and Bowen's disease can cause diagnostic difficulties. Midline granuloma, sycosis barbae, infiltrated forms of rosacea and lupus erythematosus have all been confused with late syphilis. On the trunk and limbs, it can resemble circinate psoriasis, leukaemic infiltrations and mycosis fungoides. On the legs, gummatous ulceration can look very like a venous ulcer. Bazin's disease may also be simulated.

The changes in the tongue should not be confused with the congenital deformity of scrotal tongue, when the tongue remains quite soft. Where leukoplakia is associated with interstitial glossitis or fibrotic nodules, biopsy is necessary to exclude carcinoma.

The serious forms of neurosyphilis such as tabes dorsalis and general paralysis, and cardiovascular syphilis, although detectable earlier, may take 20 or more years to become clinically evident.

Cardiovascular syphilis

The typical lesion of cardiovascular syphilis is aortitis affecting the ascending aorta and appearing 10–30 years after infection. The aortitis may be asymptomatic and detected as dilatation of the ascending aorta on chest X-ray, often accompanied by linear calcification of the aortic wall, or it may lead to stretching and incompetence of the aortic valve, left ventricular failure or aneurysm formation. Aneurysms may be associated with a variety of syndromes caused by pressure on adjacent structures in the mediastinum, and they may cause sudden death from rupture. Other symptoms include angina pectoris from associated coronary ostial stenosis. Cardiovascular syphilis is more commonly associated with neurosyphilis than with gummatous disease.

Neurosyphilis

Neurosyphilis is characterized by a number of heterogeneous syndromes [13,14]. The differential diagnosis of neurosyphilis covers the whole spectrum of neurological and psychiatric conditions. The onset can occur weeks or decades after treponemal dissemination.

Asymptomatic neurosyphilis. This precedes the development of clinically apparent disease and accounts for one-third of all neurosyphilis. It occurs in 10% of those with latent disease and has a peak incidence at 12–18 months after infection. It reverts spontaneously in 70% of patients.

Meningeal neurosyphilis. This usually has its onset during secondary disease and is characterized by symptoms of headache, confusion, nausea and vomiting, neck stiffness and photophobia. There may be focal seizures, aphasia, delirium and papilloedema. Cranial nerve palsies cause unilateral or bilateral facial weakness and sensorineural deafness [15].

Meningovascular syphilis. This occurs most frequently between 4 and 7 years after infection. The clinical features of hemiparesis, seizures and aphasia reflect multiple areas of infarction from diffuse arteritis.

Gummatous neurosyphilis. This results in features typical of a space-occupying lesion.

Parenchymatous syphilis. This appears later and has become rare in its classic forms in the antibiotic era. The peak incidence of general paralysis from parenchymatous disease of the brain used to be 10–20 years after infection. The onset is insidious with subtle deterioration in cognitive function and psychiatric symptoms that mimic those of other mental disorders. As the disease progresses neurological signs develop, including pupillary abnormalities, hypotonia of the face and limbs, intention tremors and hyper-reflexia.

Tabetic neurosyphilis. This was the most common form of neurosyphilis in the preantibiotic era, with an onset 15–25 years after primary infection. The most characteristic symptom is of lightning pains—sudden paroxysms of lancinating pain affecting the lower limbs. Other early

symptoms include paraesthesiae, progressive ataxia, and bowel and bladder dysfunction.

Syphilis and HIV infection

There is epidemiological synergy between HIV and other STIs [16]. Syphilis increases the risk of HIV acquisition and onward transmission. Infection with HIV may alter the natural history of syphilis.

In most patients with early HIV infection, the clinical features, serological test results and response to treatment are similar to those in non-HIV-infected persons. With advancing immunosuppression, all of these may be significantly altered. Lues maligna, neurological and ocular involvement [17–20] have been reported more commonly.

Congenital syphilis

Despite the fact that congenital syphilis can be prevented by detection and treatment of infected expectant mothers, it still occurs with distressing frequency in many parts of the world. This is in spite of the long-established cost-effectiveness of public health measures [1], and repeated reminders [2,3] showing that it is not enough to establish control and prevention of syphilis, but to ensure, year in year out, that both are maintained. Only a few countries, the UK included, have achieved and maintained single figures for incidence of early congenital syphilis over more than a decade [1–3]. The need for antenatal testing and treatment is greater in the multiparous than the primiparous. A woman in the early contagious stage will almost certainly infect her unborn child by haematogenous spread of treponemes to and through the placenta. The chances of the fetus being infected in the latent or late stages depends largely on the duration of the expectant mother's infection, and it may be overall as high as 60%. Whether syphilis in the fetus occurs as a first-trimester infection with *T. pallidum* is still debated [4].

The fetus may be overwhelmed by an infection, which is usually more massive than occurs in acquired syphilis. Abortion, stillbirth or early neonatal death are common outcomes. When infections occur late in pregnancy, or are milder, the child is born alive but prematurely. Some children are born apparently healthy and signs may be delayed for days, weeks or months. Children without early signs of congenital syphilis or with unrecognized signs may develop overt symptoms and signs in their teens. The division between early and late congenital syphilis is usually placed at the end of the second year of life.

Incidence. The incidence of congenital syphilis varies from one country to another, and probably depends more on the prevalence of early acquired infection in a country than the quality of the antenatal care [5,6]. In most of the Westernized world it is now rarely seen.

In the UK, the number of cases of congenital syphilis in children under 2 years of age declined from 17 in 1995 to 2 in 1999. The corresponding numbers of cases of congenital syphilis in those aged 2 years or more were, respectively, 27 and 21 [7,8].

The annual incidence of congenital syphilis in infants aged less than 1 year in the USA increased from 3.0 per 100 000 live births in 1980 to a peak of 107.3 per 100 000 live births in 1990. The very large increase in reported cases has been artificially elevated by the introduction of a new reporting system [9–11], which takes account of epidemiological factors, especially maternal treatment status, in addition to cases showing characteristic clinical stigmata. The annual incidence has since declined to 30.4 per 100 000 live births in 1996.

The clinical description of congenital syphilis includes:

1 early congenital syphilis;
2 late congenital syphilis;
3 the stigmata, including scars and deformities that are the consequences of early and later congenital syphilis.

Early congenital syphilis

Many infants with congenital syphilis are asymptomatic at birth. The placenta may show proliferative vascular changes and there may be acute inflammation of the umbilical cord (funisitis) [12]. Early congenital syphilis is manifest as rhinitis with serosanguinous nasal discharge, vesiculobullous eruptions of the skin and oral mucous patches. Skin lesions on the lips, nostrils and anus heal with radiating scars (rhagades). In addition, there are often bone abnormalities, characterized by diaphyseal periostitis, osteochondritis and a positive Wimberger's sign, which may present with limb pseudoparesis. Other features include chorioretinitis, visceral lesions causing pneumonia alba, hepatosplenomegaly associated with jaundice and the nephrotic syndrome.

Mucous membranes. Syphilitic rhinitis, generally described as 'snuffles', is the most important and frequent sign. It is manifest as a profuse, serous nasal discharge in which *T. pallidum* can readily be demonstrated. The inflammatory process can lead to severe nasal cartilage and bone destruction.

The skin. The rash resembles the acquired papular rash in being coppery red. Individual lesions may be relatively large. They are chiefly found on the extremities, especially the palms and soles, which may show a homogeneous, shiny, coppery red infiltration. Lesions on the face may present as deeply fissured ('split') papules at the angles of the mouth or lateral to the external nares. The eruptions often become papulosquamous and anal condylomas may be present. Paronychia is said to be typical. *Treponema pallidum* can be demonstrated in serum from any of these lesions.

'*Pemphigus syphiliticus*' occurs in some babies. The bullae most commonly occur on the red infiltrated palms and soles described in the previous section. Their serous contents contain abundant active treponemes. The bullae of staphylococcal impetigo (pemphigus neonatorum) erupt on normal skin. Other bullous diseases in neonates are described elsewhere (Chapter 40).

A napkin dermatitis is sometimes mistaken for syphilis. The syphilitic papules are generally less 'hypertrophic' and the appearance less eczematous than in napkin dermatitis.

Other features. Osteochondritis is an early and common sign. In a 1985 study in Zambia, X-ray changes were found in 95% of 202 cases less than 6 months of age [13]. Osteochondritis occurs at the end of long bones, particularly the lower end of the tibia and fibula. The zone between the bone and the cartilage becomes broad and irregular. It shows as a very tender, painful swelling and may lead to Parrot's pseudoparalysis. Even without treatment, it tends, like other signs, to disappear within the first year of life. It may be confused with rickets or trauma from physical abuse.

Later, there may be periosteal changes or, more rarely, a characteristic osteomyelitis syphilitica in one or more phalanges *(syphilitic dactylitis)*.

Hepatosplenomegaly and splenomegaly, sometimes with jaundice, are common, as is anaemia. Thrombocytopenia has been demonstrated [14]. Meningitis and meningoencephalitis with convulsions have been described, with bulging of the fontanelle, neck stiffness and, later, hydrocephalus and severe intellectual impairment. Choroiditis may occur, but anterior uveitis is rare.

Late congenital syphilis

In late congenital syphilis (presenting after 2 years of age) there may be a variety of skeletal developmental defects and a characteristic facies. Dental abnormalities occur. Other features include hydrocephalus and mental retardation, as well as other typical lesions of gummata and neurosyphilis.

The common problem is to differentiate latent or late acquired syphilis from late congenital syphilis. In some patients, the situation is further complicated by the possibility of non-venereal treponematoses. The results of serological tests for syphilis (STS), both reaginic and specific, are of marginal help at best. One must rely on a thorough history, including antibiotic history, and clinical examination to establish a diagnosis of late congenital syphilis. The examination of the mother and siblings, often essential, may have to be augmented by the examination of a spouse and children.

Late congenital syphilitic eruptions of skin and mucous membranes are essentially like those of late acquired syphilis, for example nodular syphilides, gummata and periostitis. Signs characteristic of congenital syphilis alone must therefore be sought. They are of great diagnostic importance as they generally appear in children from 5 to 16 years of age.

Interstitial keratitis. This is the commonest and most serious late lesion [15]. It is rare before 6 years of age and over 40 years of age [16]. Both eyes are usually affected and recurrences are recognized. Attacks may have a 3-month course. There is spotty or diffuse clouding of the cornea, with pronounced ciliary and pericorneal injection. 'Brush-like' vessels are seen penetrating from the sclera into the deeper layers of the cornea. This vascularization is best seen with a slit lamp [17]. Vision is soon affected, and photophobia and pain are marked features. Iridocyclitis and choroidoretinitis may coexist. The condition is not directly influenced by antisyphilitic treatment. Patients must be referred to an ophthalmologist. Corticosteroid eye drops or subconjunctival injections are indicated, and may well

have to continue for 3 months or longer to prevent relapse of this 'allergic' phenomenon [18]. Corticosteroid therapy, if well supervised, almost certainly eliminates the danger of blindness.

Clutton's joints. This is a painless synovitis affecting the knees. Apart from increased joint space there are no radiological findings. The condition resolves spontaneously over several months. It is uninfluenced by antisyphilitic treatment [19].

Bone involvement. Periostitis of the long bones is common, particularly of the tibiae, which may become thickened and bent anteroposteriorly ('sabre tibiae'). Exostosis and eburnation may occur. Rarely, there may be changes in the inner ends of the clavicles or localized destruction of the outer table of the skull. Gumma of the palate is common, with residual perforation of the hard palate. A similar condition of the vomer is well recognized.

Eighth-nerve deafness (neurolabyrinthitis). This is a characteristic and moderately common complication. It is eventually bilateral in most cases. It may follow interstitial keratitis after some years. Tinnitus and vertigo are common prodromal symptoms and may continue and accompany the increasing perceptive deafness. The condition is uninfluenced by antisyphilitic treatment. Corticosteroid treatment has a variable beneficial effect in a modest majority of cases [20].

Cardiovascular syphilis. If it occurs at all, it is extremely rare [21,22].

Neurosyphilis. Cerebrospinal changes are not rare. Juvenile general paralysis may start between 6 and 21 years of age. Tabes is less frequent.

Third-generation congenital syphilis. The possibility of third-generation congenital syphilis is very small.

Stigmata

Lasting changes in the shape of scars and defects caused by congenital infection have diagnostic importance in distinguishing it from acquired syphilis.

The teeth. One of the most common and characteristic stigmas is deformity of the upper, central incisor teeth [23]. These so-called '*Hutchinson's teeth*' are due to defective development of permanent teeth buds, and are often associated with abnormalities in the development of the upper jaw (Figs 30.25–30.27). The incisors are conical or barrel shaped, with a degree of notching at the free edge. They may be well separated and converge or diverge. Some are described as 'screwdriver teeth'. Rarely, other incisors may

Fig. 30.25 Late congenital syphilis. The upper central incisors may be peg- or barrel-shaped. They are called 'Hutchinson's teeth'.

Fig. 30.26 Hutchinson's teeth are commonly notched at the free margin.

Fig. 30.27 This 32-year-old woman, referred with positive serology from an antenatal clinic, had insisted on an impression of her teeth being taken before extraction. She had been wearing artificial Hutchinson's incisors for 2 years.

Table 30.1 Features of congenital syphilis. (Modified from Parish [24].)

	Early	Late
Birthweight	Low birthweight: may be < 2500 g	
Mucocutaneous	Snuffles	Rhagades
	Maculopapular rash	Gummata
	Pustules	Palatal perforation
	Mucous patches	
	Condylomata lata	
	Vesiculobullous lesions	
	Rhagades	
	Desquamation	
	Alopecia	
Dental		Hutchinson's teeth
		Mulberry molars
Laryngeal	Hoarse cry	
Ocular	Chorioretinitis	Interstitial keratitis
	Uveitis	Uveitis
	Glaucoma	Glaucoma
Gastrointestinal	Hepatosplenomegaly	
	Pancreatitis	
	Enteritis	
Renal	Nephritis	
	Oedema and ascitis	
Lymphatics	Lymphadenopathy	
Haematological	Thrombocytopenia	
	Anaemia	
	Disseminated intravascular coagulation	
Central nervous system	Aseptic meningitis	Mental delay
	Chronic meningovascular syphilis	8th-nerve deafness
	Cranial nerve palsies	Convulsive disorders
	Hydrocephalus	Paresis and paralysis
		Tabes dorsalis
Skeletal	Periostitis	Periostitis causing frontal and parietal bossing
	Osteochondritis causing pseudoparalysis	Sabre tibiae, scaphoid scapula
	Osteitis	Thickening of medial part of clavicle
		Short maxilla and protuberant mandible
		Saddle nose
		Clutton's joints

show damage, or the teeth are irregularly spaced. Another deformity, not so characteristic, is the 'mulberry molar'—usually the first molar—which has a flat, occlusive surface with only poorly enamelled rudiments of the usual cusps.

Interstitial keratitis, Hutchinson's teeth and eighth-nerve deafness form '*Hutchinson's triad*'. Other stigmata are rhagades at the corner of the mouth, broad-based, saddleback nose, 'dish face', Parrot's nodes on the skull, the 'pepper-and-salt' fundus, due to scarred choroiditis, and optic atrophy.

The features of congenital syphilis are summarized in Table 30.1 [24].

Fig. 30.28 Typical solitary, regularly edged, regularly based and indurated primary sore or chancre. Cleaned with saline and firmly rubbed with dry gauze it oozes serum. In view of endarteritis, bleeding is nearly absent. A specimen is being taken for dark-field microscopy.

Tests for syphilis

Dark-field microscopy

Treponema pallidum can be identified from lesions of primary, secondary or early congenital syphilis by dark-field microscopy. In primary syphilis, it makes the diagnosis possible before measurable antibodies appear. In secondary syphilis, it provides immediate confirmation of a clinical diagnosis. The organism has a characteristic morphology and motility, with a sinusoidal profile and a wavelength and amplitude of 1.1 and 0.4 μm, respectively [1].

The sore should be thoroughly cleaned with saline washes and/or saline compresses. A course of oral sulphonamides may be initiated. Where lesions are dry and crusted, it is necessary to scrape with a Volkmann's spoon or open scarifier. Suspected secondary lesions almost always require scarifying, and patience is needed if *T. pallidum* is to be demonstrated. Time must be allowed for red cells to settle so that clear serum can be obtained for microscopy (Fig. 30.28).

If the lesion is syphilitic, bleeding will not be marked. After scraping, some 5 min should be allowed for red cells to settle. The serum can then be collected and examined. Special care is indicated when assessing treponemes found in serum from oral lesions. If a suspected primary lesion has been treated with antiseptic or antibiotic remedies or if there is a marked secondary infection of the sore, the examination may not be successful. Repeat testing on two or more consecutive days is advised.

In all highly suspect genital and/or oral lesions where it proves impossible to demonstrate *T. pallidum*, lymph-node puncture material, mixed with injected sterile saline (0.5 mL), should be examined. Any treponeme found will always be *T. pallidum*.

In women, some 25% of the primary sores occur on or in the uterine cervix. A primary sore may be obvious on examination. In other cases, the cervix is oedematous, enlarged and pale. The suspicion that there is a primary lesion in the cervical canal can be confirmed by dark-field microscopy of material obtained 'blindly' from the cervical canal by a platinum loop. *Treponema pallidum* has also been demonstrated in material from the apparently healthy cervical canal of named contacts of early syphilis.

The organism can also be identified by direct immunofluorescent antibody testing where no facilities for dark field microscopy exist.

In biopsy specimens from late syphilis, or in atypical early lesions, it may be possible to identify the organism by silver stains such as Warthin–Starry preparations or by direct immunofluorescent antibody testing.

Molecular amplification tests

Polymerase chain reaction (PCR) diagnosis has been based upon primers and probes prepared from the 47-kDa gene. After a 40-cycle series of denaturing, annealing and extension, the PCR products can be visualized by electrophoresis or Southern blot hybridization with a ^{32}P-labelled probe and then autoradiography. This technique should be of greatest value in detecting the low numbers of treponemal products in neurosyphilis; it should also be useful in congenital syphilis, in which the interpretation of serological test results may be difficult. Molecular amplification tests have also been successfully used in multiplex systems to investigate the aetiology of genital ulcers.

RNA amplification is more sensitive than PCR, and positive results are indicative of living organisms. The reverse-transcriptase PCR uses the 16 S ribosomal RNA of *T. pallidum* as the template.

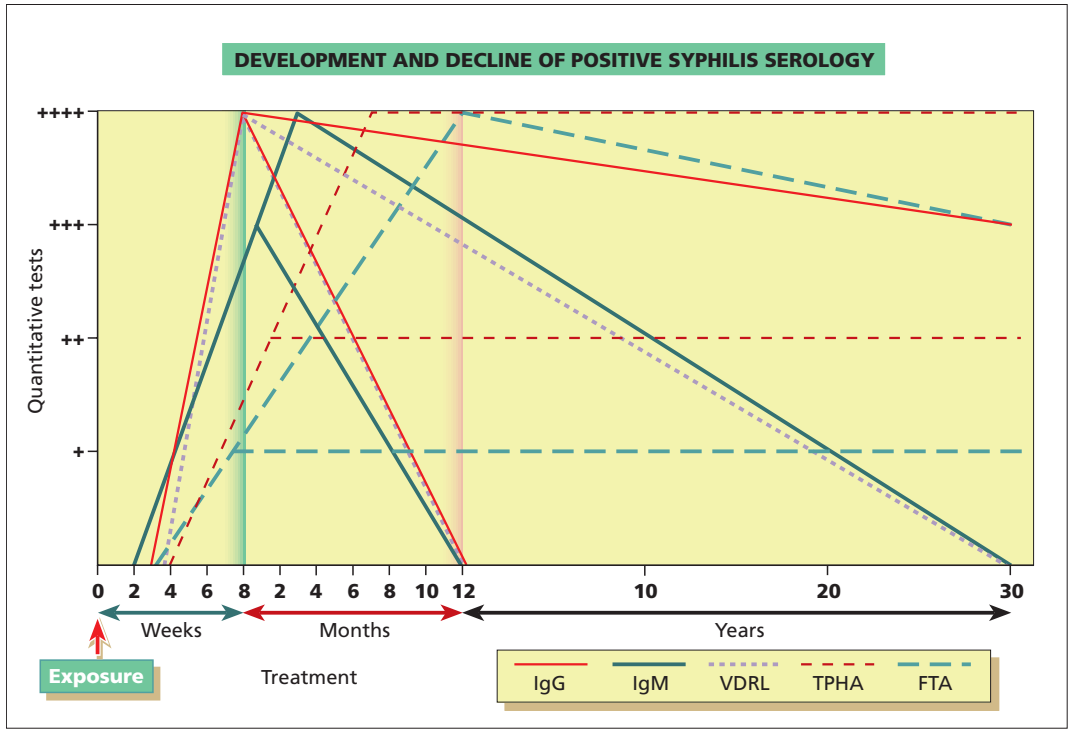

Fig. 30.29 Serological responses in syphilis as prompted by early infection, time and treatment.

Recently, molecular diagnosis on lymph node biopsy specimens has been described [2].

Serological tests (Fig. 30.29)

The STS and serological tests for other treponematoses can be divided into reaginic or non-treponemal tests, and specific or treponemal tests. The antibodies detected by the treponemal tests may be further divided into those generated by specific antigens, present only in pathogenic treponemes, and those shared with non-pathogenic treponemes (group antibodies). This distinction has significance in so far as different types of antibody may influence results of several serological tests. The immune responses in all the treponematoses appear to be the same, and there is no test that will differentiate one treponematosis from another.

Standard non-treponemal tests. The non-treponemal tests detect IgM and IgG antibodies to lipoidal material released from damaged host cells and to lipoidal-like antigens of *T. pallidum*. There are four tests available that use the venereal disease research laboratory (VDRL) antigen (consisting of cardiolipin, cholesterol and lecithin) as the principal component. These tests are quantitative and are useful in assessing response to treatment. Reactivity to these tests does not develop until 1–4 weeks after the chancre appears in primary syphilis. Titres are highest in secondary syphilis. The prozone phenomenon occurs in 2% of sera; undiluted sera give negative results because of antibody excess, the presence of blocking antibodies, or both. The titre slowly declines after the 1- to 4-week period following the appearance of the chancre, and it may spontaneously become negative in some cases of late latent syphilis and neurosyphilis.

The VDRL slide test is widely used and requires the microscopic demonstration of antigen–antibody flocculations in heat-inactivated serum.

The unheated serum reagin (USR) test is similar to the VDRL test but does not require preheated serum, because the antigen has been stabilized.

The rapid plasma reagin (RPR) test and toluidine red unheated serum test (TRUST) use either charcoal or red paint pigment added to the USR reagent to enhance visualization of the antigen–antibody flocculations. The flocculations are visible macroscopically. This test can be performed in consulting rooms, clinics and laboratories where facilities, experience and personnel are limited.

Treponemal antigen tests. Specific treponemal antibody tests are used for confirmatory testing. They detect antibodies to antigenic determinants of treponemes. They are qualitative procedures and are not helpful in assessing treatment responses; once positive, they tend to remain positive for life, irrespective of treatment. They are used to differentiate true-positives from false-positives in the standard non-treponemal antibody tests.

The hunt for a test giving 100% sensitivity and specificity has gone through several stages. In 1949, Nelson and Mayer [3] proved that serum from syphilitic patients contains an antibody, which in the presence of complement inhibits the normal movements of virulent *T. pallidum* (specific treponemal immobilizing antibody). For this test—the *T. pallidum* immobilization (TPI) test—virulent *T. pallidum* (the Nichol's strain) is obtained from rabbits. The reaction of the treponemes in the presence of the patient's serum is observed by dark-field microscopy. If 50% or more of the treponemes are immobilized, the test is reported as positive: if less than 20%, it is negative. In 99% of cases, the result is very clear-cut and certainly very specific, probably nearly 100% [4,5]. The test is time consuming and therefore expensive.

The TPI becomes positive a few days to a week later than the reagin tests, i.e. later in the primary stage. In the late stage it is almost always positive, although a negative result may occur. The great importance of the TPI has been its specificity, making it possible to distinguish BFP reaginic reactions from genuine positives.

With early treatment of syphilis, the TPI may become negative. However, if the disease has been untreated for more than 5–6 months, the reaction is likely to remain positive for the rest of the patient's life, despite any later treatment. The TPI became a 'gold standard'.

The fluorescent treponemal antibody absorption (FTA-ABS) test [6–8] and the FTA-ABS double-staining (FTA-ABS DS) test are both indirect immunofluorescent tests. The double stain test employs a fluorochrome-labelled counterstain for *T. pallidum* and an antihuman IgG conjugate labelled with tetra-methyl rhodamine isothiocyanate to detect antibody in patient serum. False-positive results may occur in about 1% of sera; possible causes include technical error, Lyme borreliosis, pregnancy, genital herpes, alcoholic cirrhosis and connective tissue diseases such as systemic lupus erythematosus and scleroderma.

The *Treponema pallidum* haemagglutination assay (TPHA) was first described by Rathlev in 1967 [9]. A microtechnique has since gained popularity. In all forms, the TPHA is simple to perform and results are readily reproducible [10]. The test is very sensitive and specific [11,12]. The microhaemagglutination assay for antibodies to *T. pallidum* (MHA-TP) detects passive haemagglutination of erythrocytes sensitized with ultrasonicated Nichol's strain *T. pallidum*. In many laboratories, the TPHA has been replaced by the similar *T. pallidum* particle agglutination (TPPA) test that uses gelatin particles rather than erythrocytes as the carrier. It is more sensitive than the FTA-ABS.

Treponemal enzyme immunoassay (EIA) commercial tests were initially designed as confirmatory tests for syphilis [13]. Serum is added to microwells coated with a treponemal antigen. After incubation, an enzyme-labelled antihuman immunoglobulin conjugate and enzyme substrate are added to detect antigen–antibody reaction. The test can be modified to detect specific IgM antibody.

Western blot. Treponema pallidum Western blot is available in some research laboratories and has similar sensitivity and specificity to the FTA-ABS test [14]. The presence of antibodies to the immunodeterminants with molecular weights of 15.5, 17.5, 44.5 and 47 kDa appears to be diagnostic for acquired syphilis. When an IgM-specific conjugate is used, the test has value in the diagnosis of congenital syphilis.

Guidelines for serological screening

There are many commercial tests in any given format whose performance characteristics vary. Recent studies suggest that a treponemal EIA used as a single test is an appropriate alternative to the combined VDRL/RPR and TPHA screen. It has a higher specificity than the FTA-ABS. The test also has advantages of automated or semi-automated processing and objective reading of results, and can be interfaced with laboratory computer systems to allow electronic laboratory report generation.

Screening can be performed by either EIA or the combined VDRL/TPHA. Positive results are confirmed with a treponemal test of a different type. It is essential to confirm the presumptive serological diagnosis of syphilis on a second patient specimen.

Biological false-positive reactions

All the tests in use can produce BFP results. Reagins can be found in the blood of most normal people, and it is possible to make tests for reagins so sensitive that a high percentage of positives can be demonstrated. Some apparently healthy persons produce reagins in excess. They are classified as BFP reactors. Biological false-positive reactions may be acute or chronic, i.e. they last less than or more than 6 months. The same occurs in association with acute and chronic diseases. Persistently low-titre positive reagin tests with repeatedly negative treponemal tests are the rule in acute BFP reactions. They rarely last more than 3 months. Strongly positive reactions are more common in chronic BFP reactors.

Among the commonest associations with acute BFP reactions are the following: malaria, leprosy (especially the lepromatous form) [15,16], typhus, respiratory tract infection (especially viral pneumonia), infectious mononucleosis, active pulmonary tuberculosis, hepatitis, subacute bacterial endocarditis, measles, chickenpox, filariasis, trypanosomiasis, leptospirosis and relapsing fever. Biological false-positive reactions are also reported in connection with pregnancy [17] and narcotic addiction.

Chronic BFP reactions are associated with 'collagen', autoimmune diseases and dysgammaglobulinaemia.

Chronic BFP reactions may exist for some time and herald the onset of 'collagen' disease by some years; for example, systemic lupus erythematosus (especially in rhesus-negative women), polyarteritis nodosa and rheumatoid arthritis [18,19].

Not all authors agree that the VDRL is the most likely test to be associated with BFP reactions. One study, which concentrated on the phenomenon associated with dermatological diseases, found that the FTA and FTA-ABS tests most often produced BFP reactions [20]. In some elderly persons, BFP reactions with FTA-ABS are associated with connective tissue diseases and, in addition, in healthy people with the prescence of 'rheumatoid factor'; but ageing itself may be responsible [21–23].

A completely new cause of false-positive FTA-ABS was described in 1986 by Hunter *et al*. [24] at the Centers for Disease Control and Prevention (CDC) in Atlanta, USA. They investigated patients with Lyme disease and compared their serological findings with specimens from patients with syphilis. Cross-reactivity with the causative spirochaete of Lyme disease could be absorbed out with *T. phagedenis* (Reiter's strain).

Examination of CSF

Indications for examination of CSF in syphilis include:

- neurological, ophthalmic, or auditory symptoms and signs;
- other clinical evidence of active infection—aortitis, gumma, iritis;
- treatment failure;
- HIV infection;
- serum non-treponemal titre of more than 32 if duration of syphilis is over 1 year; and
- non-penicillin-based treatment regimen planned.

Many syphilologists consider an examination of CSF unnecessary in the second stage, but prefer to examine it before discharging the patient as cured, after 1–2 years post-treatment follow-up. In untreated asymptomatic syphilis, a CSF examination should always be done. A normal CSF is by definition an essential prerequisite for a diagnosis of latent syphilis.

The typical CSF findings of neurosyphilis consist of:

- moderate mononuclear pleiocytosis (10–400 cells/mL),
- elevated total protein (0.46–2.0 g/L), and
- positive CSF VDRL.

The CSF VDRL is highly specific and false-positive results are rare in the absence of blood contamination. A negative CSF VDRL does not exclude neurosyphilis, although non-treponemal serological tests usually remain positive in both serum and CSF in such cases.

Reactivity to tests using treponemal antigens, particularly to the FTA-ABS test and/or TPHA test, may be caused by transudation of *T. pallidum*-specific IgG from the serum of patients with adequately treated disease, and therefore is not necessarily a sign of active CNS involvement. On the other hand, non-reactivity of the CSF to these assays in all probability excludes the diagnosis of neurosyphilis.

Evaluation of neonates for congenital syphilis

It is recommended that the following investigations be carried out in the children born to seropositive mothers if there has been no documented treatment completion at least 4 weeks before delivery, or if a non-penicillin regimen was administered, or if relapse or reinfection is suspected:

- examination for stigmata of congenital syphilis;
- X-ray long bones for evidence of periostitis; and
- CSF examination.

Infection of the neonate is also suggested if the serum non-treponemal antibody titre is four or more times more than the mother's, or if specific IgM treponemal antibody tests are positive. Passively transferred maternal IgG antibody can persist in the infant's serum for up to 12 months [25].

Management of syphilis

Overview (Table 30.2)

Current treatment regimens are based on over 50 years' clinical experience with penicillin, expert opinion and open clinical studies rather than on randomized clinical trials [1–4]. Many antibiotics, with the notable exceptions of the aminoglycosides and sulphonamides, have some treponemicidal activity, and their administration for other conditions may abort or modify the natural history of syphilis [5].

Parenteral penicillin G is the preferred drug at all stages of syphilis; the preparations used, the dosage and the duration of treatment depend on the clinical stage and disease manifestations. Penicillin remains not only the most effective treponemicide, but it is easy to administer, has few side effects and is relatively inexpensive. Results continue to be excellent in all forms and stages of treponemal disease, and there are no signs that *T. pallidum* has developed resistance to this antibiotic. Injectable penicillins are generally preferred to oral preparations, because of problems of patient compliance and uncertain absorption from the gastrointestinal tract.

Adequate treatment requires the maintenance of serum concentrations in excess of 0.03 U/mL for at least 10 days. A 600 000 U i.m. single dose of aqueous procaine benzylpenicillin (procaine penicillin) gives an effective serum concentration for at least 24 h; in comparison, 2 400 000 U i.m. single dose of benzathine penicillin G maintains effective levels for about 2 weeks. As this preparation may cause pain on injection, 1.2 mU are usually given in the upper and outer quadrant of each buttock.

Treatment of late syphilis theoretically may require a longer duration of therapy because organisms are dividing more slowly; however, the validity of this concept has not been addressed. The penetration of aqueous procaine benzylpenicillin into the CSF (as into the aqueous humour) is poor; that of erythromycin is poorer and that of benzathine penicillin, poorest of the three [6–8]. For treatment of neurosyphilis, high dosages of crystalline benzylpenicillin G plus probenicid should be considered. Desensitization of penicillin-allergic patients is recommended.

In patients who are hypersensitive to penicillin, regimens based on tetracycline, doxycycline, erythromycin, ceftriaxone and chloramphenicol have all been successfully used to treat syphilis; however, success is less assured than with penicillin. Azithromycin, given in dosages of 500 mg daily for 7 days, has recently been successful but experience is limited.

All patients with syphilis should be offered screening for other STIs and HIV. Serological testing for HIV should be repeated after 3 months in those persons presenting with primary syphilis who initially test negative.

Pregnant women. Only penicillin-based regimens have documented efficacy and desensitization should be considered in those who are allergic. Those women who have had documented treatment for syphilis in the past do not need retreatment in the current or subsequent pregnancies so long as there is no clinical evidence of syphilis, and the VDRL or RPR titre is negative.

First-line treatment is with procaine benzylpenicillin G. Benzathine penicillin regimens are generally not recommended. Alternative drug therapies include erythromycin or azithromycin.

Treatment of syphilis in HIV seropositive individuals. It is recommended that a CSF examination be performed in all patients with syphilis who are HIV seropositive, and that a penicillin-based regimen appropriate for neurosyphilis, regardless of the stage of infection, is administered. As *T. pallidum* can persist in the CNS in spite of adequate antibiotic treatment, some clinicians have recommended that chronic maintenance treatment be administered after initial formal treatment. Erythromycin has been reported to be ineffective. Close follow-up is essential, and CSF examination may be repeated after 6 months.

Treatment of congenital syphilis. The optimal treatment of congenital syphilis is unknown. Regimens that have been recommended for early congenital syphilis are aqueous crystalline penicillin G 100 000–150 000 U/kg/day i.v. given as 50 000 U/kg every 12 h for the first 7 days of life and every 8 h thereafter for a total of 10 days. An alternative is procaine benzylpenicillin G 50 000 U/kg/dose i.m. daily for 10 days for infants with normal CSF findings; intravenous benzathine penicillin 50 000 U/kg/dose i.m. in a single dosage has also been successful. In children who are identified as having reactive serological tests for syphilis after the neonatal period, maternal serology and records should be reviewed to assess whether the child has congenital or acquired syphilis. Any child at risk for congenital syphilis should be fully evaluated and tested for HIV infection. The recommended regimen is aqueous crystalline penicillin G 200 000–300 000 U/kg/

Table 30.2 Treatment of syphilis.

	First-line therapies	Dose	Penicillin allergies	Dose
Early syphilis	Aqueous procaine benzylpenicillin	600 000–900 000 U i.m. daily for 10 days	Doxycycline	100 mg p.o. twice daily for 14 days
	or	*or*	*or*	
	Benzathine penicillin	2.4 MU i.m. in single dosage	Erythromycin	500 mg p.o. four times daily for 14 days
			or	
			Azithromycin	500 mg p.o. daily for 14 days
			or	
			Oxytetracyline	500 mg p.o. four times daily for 14 days
			or	
			Ceftriaxone	500 mg i.m. or i.v. daily for 10 days
Late syphilis	Aqueous procaine benzylpenicillin	600 000–900 000 U i.m. daily for 15–21 days	Doxycycline	100 mg p.o. twice daily for 28 days
	or		*or*	
	Benzathine penicillin	2.4 MU i.m. weekly for 3 weeks	Oxytetracyline	500 mg p.o. four times daily for 14 days
	or			
	Amoxicillin	2 g p.o. three times daily for 28 days		
	plus			
	Probenecid	500 mg p.o. four times daily for 28 days		
Neurosyphilis	Benzylpenicillin G	1.8–2.4 g daily for 21 days (given as 0.3–0.4 g i.v. every 4 h)	Consider penicillin desensitization	
	or		*or*	
	Aqueous procaine benzylpenicillin	2.4 MU i.m. daily for 21 days	Ceftriaxone	2 g i.m. or i.v. daily for 10–14 days
	plus			
	Probenecid	500 mg p.o. four times daily for 28 days		
	or		*or*	
	Amoxicillin	2 g p.o. three times daily for 28 days	Doxycycline	200 mg p.o. twice daily for 28 days
	plus			
	Probenecid	500 mg p.o. four times daily for 28 days		

i.m., intramuscular; i.v., intravenous; p.o. *per os* (oral administration).

day i.v. administered as 50 000 U/kg every 4–6 h for 10 days.

In children with late congenital syphilis presenting after 2 years of age, regimens should be the same as those recommended for late acquired disease.

Penicillin reactions

Accidental deaths following treatment are very rare and mainly due to anaphylactic shock reactions to penicillin. In addition to early and late allergic reactions and the Jarisch–Herxheimer reaction, *Hoigne reactions* (acute psychotic symptoms due to procaine in procaine benzylpenicillin) are recognized.

If penicillin is used in patients with a history of allergy, it is advisable to keep the patient under observation for 15–20 min after the injection. An emergency kit should always be available. Many physicians use an alternative antibiotic rather than risk a reaction.

Jarisch–Herxheimer reaction. The Jarisch–Herxheimer reaction is an acute febrile reaction that occurs in many patients within 24 h of commencing treatment. It is mediated by cytokines. Headache, myalgia, bone pains and an exacerbation of skin lesions may accompany the fever. It must be differentiated from penicillin allergy. Patients should be advised that it might occur. Symptoms may be controlled by antipyretics. The fever (38–40°C) rarely persists more than 8 h.

In pregnant women the reaction may induce early labour or cause fetal distress. In late neurosyphilis and cardiovascular syphilis, the Jarisch–Herxheimer reaction can be more serious and may be associated with life-threatening sequelae. Many clinicians advocate a short course of corticosteroids to lessen its effects in these patients; one such regimen is to prescribe prednisolone 30–60 mg p.o. daily for 3 days, beginning syphilis treatment on the third day, and then tailing off the corticosteroid course by reducing the daily dosage by 10 mg each day during the succeeding week.

Follow-up

Follow-up for clinical and serological assessment should be done at 3, 6 and 12 months after the completion of treatment in early syphilis. Recurrence is due more often to reinfection than to relapse.

Reinfections are more likely during the first year after penicillin therapy. Non-treponemal antibody test titres correlate with disease activity and will usually become negative with time after successful treatment. In some patients, who are described as being 'reagin-fast', low titre positivity in these tests may persist for life. Apart from up to 25% of patients treated during the primary phase, the treponemal antibody tests will continue to remain positive after successful treatment.

In late latent or tertiary benign syphilis, a 2-year follow-up is adequate. Quantitative non-treponemal serological testing is repeated at 3 and 6 months, and each 6 months thereafter. Follow-up of cardiovascular and clinical neurosyphilis should be for life.

Treatment failure is suggested by a fourfold increase in titres, less than a fourfold decrease in pretreatment titres within 12–24 months and development of symptoms or signs attributable to syphilis. All treatment failures require CSF examination. In cases of serological or clinical relapse, retreatment with double doses is recommended.

In latent syphilis, a 2-year follow-up is adequate. The same applies to late benign syphilis. In neurosyphilis, it is usual to repeat the CSF examination every 6 months until the cell count has become normal. There is a slower response of the CSF VDRL and total protein. Retreatment should be considered if the cell count shows an inadequate response or if all of these parameters have not returned to normal by 2 years. In cases of serological or clinical relapse, retreatment with double penicillin doses is recommended. Patients treated for neurological or cardiovascular syphilis should be followed up for many years.

Management of sexual contacts

It is recommended that attempts be made to identify, trace and offer further investigation to at-risk sexual contacts. In early syphilis, these are those contacts occurring within 3 months plus the duration of symptoms for primary syphilis, within 6 months plus the duration of symptoms for secondary syphilis and within 1 year for early latent disease. All long-term partners of patients with late syphilis should be offered investigation.

Many clinicians recommend presumptive treatment of all sexual contacts within the 90-day period preceding patient presentation of early syphilis if serological test results are not immediately available and if follow-up cannot be assured.

Prognosis

Cure rates with initial treatment of early syphilis are better than 95%. The long-term outcome of adequately treated cases is excellent. In late syphilis, infection can usually be arrested although some treponemes may persist in less accessible sites (e.g. the eye and nervous system). As long as immune function is normal, this rarely has clinical sequelae. The outlook for HIV-positive and other immunocompromised patients appears to be less assured; however, long-term studies in these patients are needed.

Syphilis control

The risk factors for acquisition of syphilis mirror those of other STIs and primary prevention depends on similar methods, such as reducing the number of sexual partners and consistent use of condoms. Community outreach activities should target education at persons at high risk. Single-dose treatment with intramuscular benzathine penicillin G and oral azithromycin have been employed as treatment for incubating syphilis [1]. Administration of treponemicidal antibiotics to treat other STIs, such as gonorrhoea and chancroid, may also abort incubating concurrent syphilis. The development of a vaccine against syphilis has long been inhibited by the inability to grow the organism on artificial media, although the recent sequencing of the *T. pallidum* genome should advance new research efforts.

Secondary prevention by early diagnosis, treatment, partner notification [2], education and counselling remain the mainstay of prevention efforts [2,3]. Access to prompt and appropriate services for infected persons are essential. In many developed countries, clinic-based specialist services have long been established. In developing countries, the WHO has recommended that STI management be integrated into basic health care and reproductive health services [4–6].

Serological screening for syphilis remains a cost-effective measure for control. Congenital syphilis may be prevented by maternal screening and treatment during early pregnancy. In Europe, screening remains a routine part of antenatal care, usually at about 12 weeks' gestation. In developing countries, where congenital syphilis is more common, the disease occurs when there has been no maternal screening, when no treatment has been administered in response to positive tests, or when primary infection occurs later in pregnancy. Repeat screening during the final trimester or at delivery is advocated in high prevalence regions [7].

Compared with other STIs, the control of syphilis is relatively easy. It is favoured by a combination of factors:
1 low cost and ready availability of screening test;
2 effective, simple and inexpensive therapy;
3 a long incubation period with a relatively low transmission rate;
4 self-limiting symptomatic periods with long asymptomatic periods of presumably low infectivity.

Non-venereal treponematoses

Although the endemic treponematoses were eradicated from large parts of the world during the mass treatment campaigns organized by WHO and the United Nations Children's Fund (UNICEF) in the two decades that followed the Second World War, the progress made has not been sustained, and there is evidence of a resurgence in some countries. It is estimated that there are 2.5 million cases worldwide, most of which remain unreported. There is a very patchy geographical distribution, which is strongly influenced by both climatic and socio-economic conditions.

The endemic treponematoses consist of three diseases —endemic syphilis, yaws and pinta.

Characteristics

The causative organisms cannot be distinguished serologically or morphologically. Minor genetic differences have been reported in the causative organism of pinta, *Treponema carateum*, which can only be propagated in primates and is considered to be a separate species. The causative organisms of venereal syphilis, yaws and endemic syphilis are so similar that they are considered as

subspecies of *Treponema pallidum*. These organisms can also be propagated in rodent species. No specific antigenic differences have been demonstrated. Differences have been demonstrated in the *tp15* gene that permits rapid differentiation of pallidum strains from non-pallidum strains by restriction fragment length polymorphism. Further differences have been shown in the *gpd* and *tp92* genes. None of the genetic differences described to date can differentiate non-pallidum subspecies from each other [1].

These diseases have comparable natural histories and principally affect children under the age of 15 years, especially those in the most underprivileged and remote rural communities isolated from organized health and social services [2,3].

Transmission is by direct skin-to-skin contact and is assisted by breaks in the skin, especially in hot and humid conditions, where clothing is scanty. Mouth-to-mouth transmission may also be important in endemic syphilis. Sexual transmission does not play a role and congenital infection does not appear to occur.

The histopathological patterns of disease are similar and only vary in degree and range of tissues affected.

Protective immunity is induced by infection and is subspecies specific. The level of cross-protection is roughly proportional to severity of clinical disease induced by the initial infection.

Like syphilis, they have early (which includes primary and secondary lesions) and late stages of the disease. Lesions of the early stage are generally regarded as infectious or potentially infectious. This lasts for up to 5 years, with periods of latency between symptomatic episodes. All have a relapsing clinical course and prominent cutaneous manifestations. In yaws and endemic syphilis mucous membranes and bones are also infected. Late lesions affecting the cardiovascular and nervous systems are generally considered not to occur.

These infections are usually diagnosed by their typical clinical features, supported by the microscopic identification of their causative treponemes from the serous exudate of cutaneous and mucosal lesions, and serological testing.

Treatment is similar. Long-acting penicillin preparations such as benzathine penicillin G are administered to affected individuals, family members and other contacts. Tetracycline and erythromycin can be used as alternatives. Lesions usually heal within 2 weeks, but healing may be slower in pinta. Response to treatment can be assessed by changes in quantitative serological tests; however, the specific treponemal tests will usually remain positive for life.

So far, there have been no reports of the effect of HIV infection upon these conditions, probably because of the contrasting locations in which STIs and the non-venereal treponematoses are prevalent.

Endemic syphilis

SYN. BEJEL; FIRJAL; LOATH

Definition. Endemic syphilis is an infectious, contagious, chronic, relapsing, non-venereally transmitted disease caused by *T. pallidum* ssp. *endemicum*. It is a disease of hot and temperate climates characterized by latency interrupted by early infectious lesions and, after several years, by late destructive lesions of the skin and bones.

History. Endemic syphilis was previously seen in Northern European populations where it was known as the *sibbens* in Scotland, *radesgye* in Scandinavian countries and *skerlievo* in the Balkans. It also occurred in Russia and Mongolia. In the Near East and Eastern Mediterranean it is known as *bejel* and in Southern Africa as *njovera* or *dichuchwa*. Social and economic improvements in many of these areas made endemic syphilis a receding disease long before the availability of modern antibiotic treatment.

Aetiology. The causative organism is morphologically identical to other subspecies of *Treponema pallidum*.

Epidemiology. The disease is still encountered in dry desert regions and among children living in rural areas with primitive and unhygienic conditions. It occurs predominately among Sahel peoples of sub-Saharan Africa and nomads of Saudi Arabia. Transmission occurs by direct skin contact, kissing and perhaps by sharing of contaminated drinking cups or household utensils.

Histopathology. This does not show significant differences from that found in venereal syphilis.

Clinical features. The incubation period is usually around 3 weeks if a primary lesion is seen. These most often occur in the mouth and on the lips, and may also be found on the nipples of breastfeeding women.

More often, the disease presents after 3 months in the secondary stage with features that are similar to those of venereal syphilis. Characteristic lesions include mucous patches on the lips and oral mucosa. They may also affect the tongue, pharynx and vocal cords where they cause syphilitic laryngitis. Split papules and angular stomatitis are also seen. A generalized rash, condylomata lata affecting the intertriginous areas and generalized lymphadenopathy also occur. Painful periostitis of the long

bones, with symptoms worse at night, may affect the legs or hands. Untreated, crops of secondary lesions last for 6–9 months, and may recur after an apparent period of latency.

The late stages of endemic syphilis are characterized by gummata of the nasopharynx, which may cause gangosa, and destructive lesions of skin and bone. The development of sabre tibiae and of juxta-articular nodules resembles late yaws. Neurological and cardiac involvement does not occur, but ocular disease including optic atrophy, chorioretinitis and uveitis has been reported.

Attenuated endemic syphilis with reduced severity and numbers of lesions in the secondary and tertiary stages has been reported, in which the most frequent finding was of painful legs caused by osteoperiostitis.

Diagnosis. This is based on clinical features, microscopic identification of the causative treponemes and positive serological tests for syphilis.

Differential diagnosis. This is similar to that of venereal syphilis.

Treatment. The treatment is similar to that of other non-venereal treponematoses. Active infections in adults, as well as non-infectious cases, should be given 2.4 mU i.m. benzathine penicillin in a single injection. The WHO recommends treating all cases and contacts over 10 years of age with 1 200 000 U of benzathine penicillin, and half that amount for children and contacts aged less than 10 years. Tetracycline and erythromycin are the antibiotics of choice in cases of penicillin allergy.

Yaws

SYN. FRAMBOESIA (GERMAN AND DUTCH); PIAN (FRENCH); BUBA (SPANISH); BOUBA (PORTUGUESE); PARANGI (SINHALESE)

[F. Kerdel-Vegas, pp. 30.28–30.34]

Definition. Yaws is an infectious, contagious, chronic, relapsing, non-venereally transmitted disease caused by *T. pallidum* ssp. *pertenue*. It is a disease of tropical rural populations, in areas with high levels of humidity and rainfall, characterized by latency interrupted by early infectious lesions and, after several years, by late destructive lesions of the skin and bones, where the condition is limited. It is a crippling disease; in the late stages it can be very destructive.

History. Bone lesions with probable yaws have been traced to AD 854 on the Mariana Islands in the west Pacific. The disease made its entry to the New World with the black slaves introduced first in the Caribbean islands and then in the mainland of the Americas from the 16th century onwards; ever since it has remained mainly restricted to this population of African origin, especially on the coastline.

The causal organism was discovered by Aldo Castellani in 1906 in Sri Lanka, who described the condition as:

> A horrible disease in which the whole body is covered with red fungating excrescences the size of a cherry and with a granular, raspberry-like surface. The eruption disappears after a few months, but the infection remains dormant, and years later enormous ulcers develop and the bones are affected. The disease is not hereditary and a mother whose whole body is covered with horrible sores will give birth to a perfectly healthy and smooth-skinned baby [1].

Beginning in the 1920s, arsphenamine, neoarsphenamine and bismuth were used successfully in the treatment of yaws, until the efficacy of penicillin was demonstrated by Guimaraes in Brazil and by Findley and coworkers in the Gold Coast in 1943.

The eradication campaigns organized by the WHO and UNICEF in many endemic areas, from 1954 to 1963, surveyed 350 million persons, of whom 42 million received penicillin. The great success of these campaigns explains the lack of interest in a disease considered nearly extinct, but since 1967 there is evidence that yaws is returning in several countries from which it had disappeared.

Incidence. As shown in the map (Fig. 30.30), yaws is found in the Caribbean, Central and South America, throughout tropical Africa, the Far East, northern Australia and the tropical Pacific islands.

Clinically, it is very similar to the other forms of non-venereal syphilis known as bejel (Near East), njovera (Zimbabwe), skerlievo in the Balkans (Bosnia), dichuchwa (Botswana) and siti (Gambia); thus, in general, it can be said that yaws and/or other non-venereal treponematoses are endemic in the whole tropical belt between the tropics of Cancer and Capricorn.

Yaws used to be one of the commonest tropical diseases of the skin [2]. Over 40 years ago (1959), the WHO estimated that yaws affected more than 50 million people in the warm regions of the world, and its largest reservoir is found in Central Africa. Since that time, there have been intensive campaigns designed to eradicate the disease, but there are still 100 million people susceptible to yaws living in endemic areas where little has yet been done. In mass treatment campaigns against endemic treponematoses (mostly yaws) in 46 countries, about 160 million persons were examined during initial treatment surveys; another 400 million re-examinations were carried out during subsequent resurveys, and an estimated 50 million cases and contacts were treated [3]. The WHO and UNICEF-assisted mass campaigns against the endemic treponematoses (yaws, endemic syphilis and pinta) still remain important success stories in the history of medicine [4]. Resurgences of yaws have been reported from

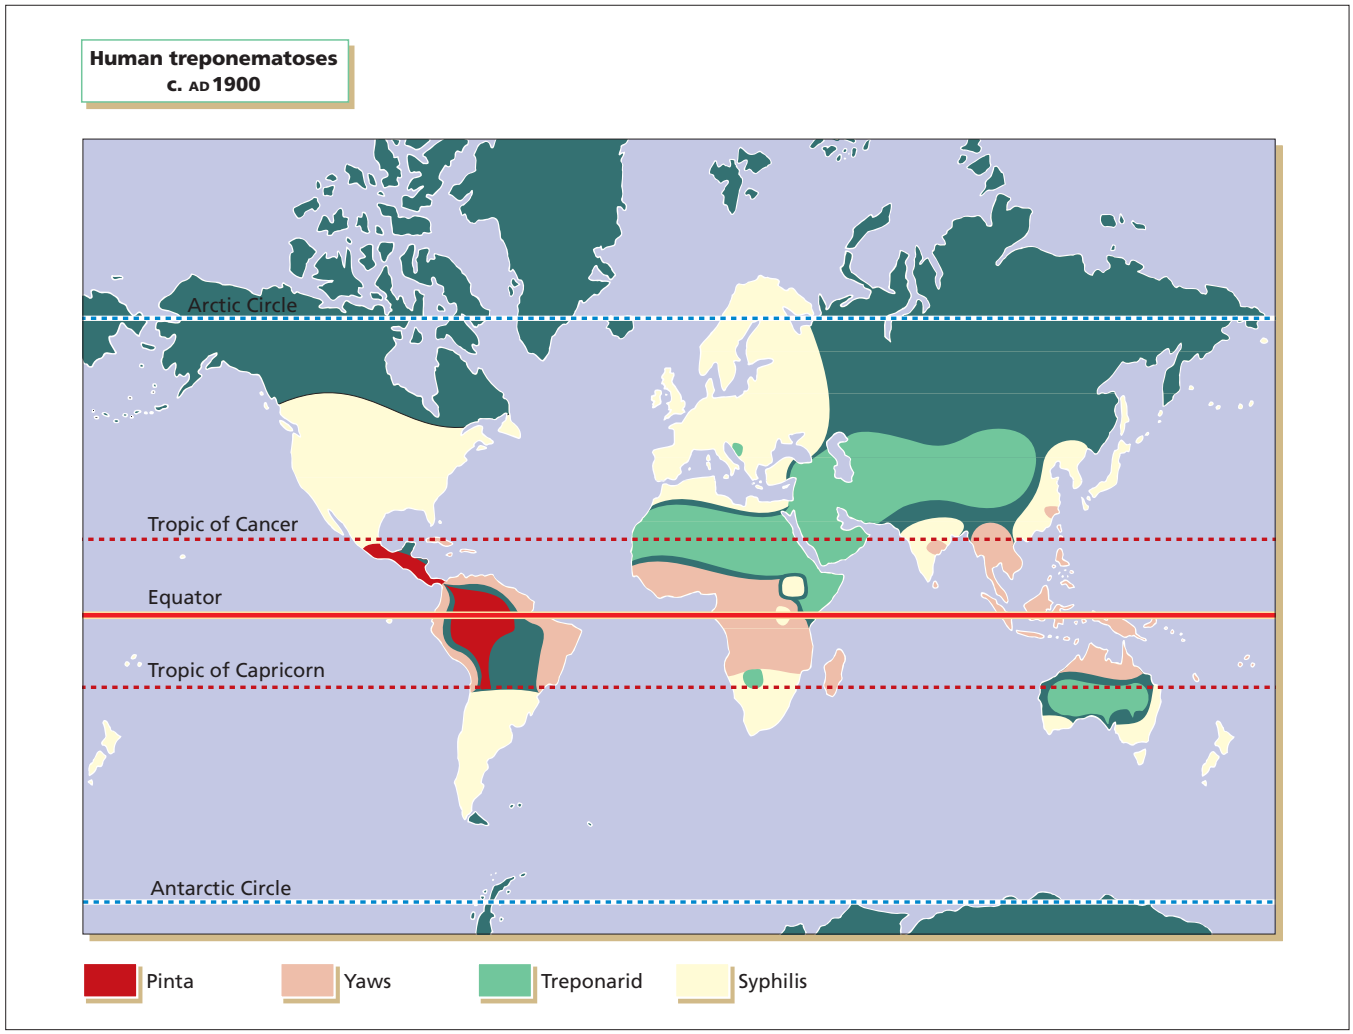

Fig. 30.30 World distribution of the treponematoses.

Karkar Island (on the northern coast of Papua New Guinea), Indonesia, the Solomon Islands, Burundi, Rwanda, Zaire and Ghana. In several African countries, including Ghana, Benin, Togo and the Central African Republic, the situation resembles the precampaign times; in others, such as Nigeria, the Ivory Coast and Mali, increasing seroreactivity has been reported [4].

It is a disease of rural areas, where living conditions are poor. It is said that yaws begins where highways end. Transmission is favoured by overcrowded conditions, where abrasions or other open lesions on the skin are common, and where little protective clothing is worn [4]. A hot or warm climate along with high humidity (over 100 cm of rainfall) lasting for more than 6 months, together with poor socio-economic conditions are requirements for the development of yaws [5]. Mutilating skin lesions due to yaws in the late stage result in severe disability but can be prevented if the disease is detected and properly treated at an early stage.

Aetiology. The aetiological agent is the *T. p. pertenue*, a rigid spirochaete that is 8 µm long and 0.2 µm wide, and has about eight to 16 regular spirals. It divides about every 30–33 h. All the treponemes causing chronic granulomatous diseases are morphologically and serologically indistinguishable; classification into species was based on clinical and epidemiological considerations. They have now all been reclassified as subspecies of *T. pallidum* [6], although clinically the diseases can be differentiated adequately. No serological differentiation between syphilis, yaws, endemic syphilis (bejel) and pinta can be made on the basis of routine laboratory tests. In 1989, Noordhoek *et al.* [7] reported that *T. p. pertenue* differs from *T. p. pallidum* by a single nucleotide. The only molecular difference so far detected between these two subspecies is in one amino-acid residue at position 40, in the subunits of the 190-kDa multimeric proteins TpF1 and TyF1. A difference in the flanking region of a lipoprotein gene has been reported, and this 'genetic signature' can differentiate the several subspecies [8].

Epidemiology. Although the identity of yaws and syphilis is still under discussion, there are important clinical and epidemiological differences between these conditions and it is therefore justifiable to consider them as two separate processes. Yaws is neither venereal nor congenital. It occurs predominantly in childhood—75% of new cases arise in persons under the age of 15 years [9]—and does not affect the CNS or cardiovascular system during its tertiary stage. The primary lesions in yaws are generally extragenital and indistinguishable in appearance from secondary lesions. Yaws is a disease particularly of warm climates and rural environments, whereas syphilis is predominantly an urban disease. It is rightly said that civilization and syphilis go together. Yaws is more frequent in men than in women, and predominantly affects the indigenous population.

The spirochaetes probably cannot enter intact skin, so that several factors are necessary for infection to occur. There must firstly be an individual with an open lesion and an exudate rich in treponemes (as in primary and secondary lesions) and, second, an uninfected person with skin excoriations, abrasions, wounds or bites to provide a portal of entry for the spirochaetes. In addition, there must be contact between these two individuals directly, or through contaminated fomites. The disease is usually acquired by direct personal contact. Mechanical transmission by the *Hippelates* fly has been established but perhaps does not account for a statistically appreciable proportion of cases. New cases appear more frequently during the rainy season.

It has been observed in some African nations from which yaws has been eradicated after a mass treatment campaign that venereal syphilis has risen sharply, suggesting a decline of herd immunity against yaws and, secondarily, to syphilis.

Histopathology. Cutaneous invasion is the most striking feature of the disease, and large numbers of treponemes are found in the epidermis at affected sites.

The epidermotropism of *T. p. pertenue*, compared with the mesodermotropism of *T. p. pallidum*, has been well established [10].

In the primary lesion, considerable acanthosis and papillomatosis are observed. The epidermis is oedematous, and shows a marked degree of neutrophil exocytosis, giving rise to intraepidermal microabscesses. The dermis displays a fairly dense infiltrate consisting chiefly of plasma cells, but neutrophils, eosinophils, lymphocytes, histiocytes and fibroblasts are also present. The blood vessels do not show endothelial proliferation, in contrast with syphilis.

The secondary lesions show similar histological changes to the primary lesions, and in fact closely resemble condylomata lata, from which they differ in that the dermal infiltrate is diffuse rather than essentially perivascular.

Fig. 30.31 Primary lesions of yaws.

The late lesions are ulcerated, and are very similar to those of tertiary cutaneous syphilis. Despite this clinical similarity, vascular changes are either discrete or non-existent. Keratotic lesions of the palms and soles show no distinctive characteristics. Hyperkeratosis with parakeratosis and acanthosis, and a moderate dermal infiltrate, are seen. It is said that *T. p. pertenue*, as well as *T. p. carateum*, is epidermotropic, contrasting markedly with *T. p. pallidum*, which is mesodermotropic.

Clinical features. As is the case with the other treponematoses, yaws has three distinguishable stages [11], although, as in pinta, they do not display the typical features seen in syphilis. The incubation period varies from 2 weeks to 6 months, although the former is more usual.

Primary stage. This stage is known by the names of protopianoma, buba madre, mamanpian (mother yaw), etc. It is characterized by the appearance, anywhere in the skin where the treponeme enters, of an erythematous infiltrated papule, which later ulcerates and is covered by a yellowish crust formed by the exudate. It grows by peripheral extension or by confluence with small satellite lesions. There is no itching or pain or other subjective symptom. Progressive growth gives rise to a large, raised rounded or oval ulcer, papillomatous or vegetative, bearing some resemblance to a raspberry (Figs 30.31 & 30.32) (the reason why Dutch and German authors originally called the disease framboesia), which bleeds easily but is almost painless. It is covered by serous fluid swarming with the easily identifiable treponemes. It may be accompanied by general symptoms such as fever, joint pains and constitutional disturbance, but these can be overlooked or may be absent. Other manifestations are regional adenopathy, adenitis without periadenitis and large, firm glands that are non-adherent and painless, and do not

Fig. 30.32 Predilection of primary lesions for warm and moist areas.

Fig. 30.33 Perianal yaws lesions.

tend to form abscesses. It is estimated that 'decapitated' yaws occurs in about 10% of cases; the mother yaw is not observed and the disease passes directly to its secondary stage.

The mother yaw persists for 2–6 months and heals spontaneously, leaving a large, atrophic and depressed scar, with an achromic or hypopigmented centre sometimes surrounded by a darker halo. Lesions may occasionally persist considerably longer, probably as a result of secondary pyogenic infection.

Secondary stage. After the primary lesion heals, or concurrently between the second and fourth month after the onset of the disease, or sometimes later, the secondary stage sets in, characterized by the appearance of small papules, which rapidly become raised, ulcerated and covered with yellow crusts. These exudative papillomas may resemble ripe raspberries and closely resemble the mother yaw except in size and number. They are termed daughter yaws, pianomas or framboesiomas, and are widely distributed, but are most often seen around the body orifices: mouth, nose, penis, anus and vulva (Fig. 30.33). Two clinical varieties are described: one very large, closely resembling the mother yaw, and the other very small, and known as the 'miniature yaw'. At times, peripheral extension of the framboesioma produces 'circinate yaws' (Fig. 30.34). When the lesions occur on palms and soles, they do not ulcerate but produce hyperkeratotic plaques called foot yaws ('crabs', or 'crab yaws'). When they arise in the periungual region, they produce deformities of the nail fold called pianic onychia.

Fig. 30.34 Secondary yaws. Note also the premature subcutaneous gummatous lesions.

The lesions of secondary yaws do not directly involve the mucosa, and the occasional invasion of body cavities is the result of the extension of contiguous framboesiomas. In general, these ulcerative lesions do not develop simultaneously but rather in successive crops of a few lesions. After a variable period of 6 months to 3 years, they

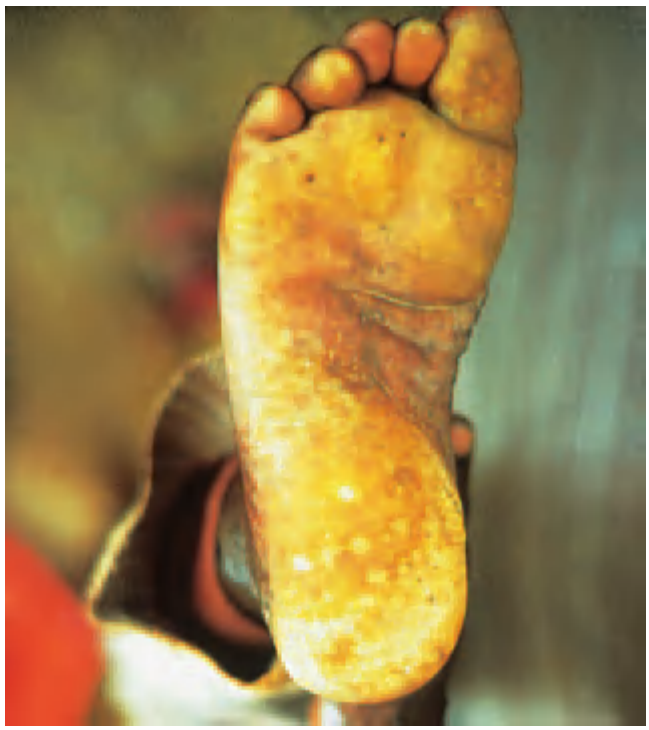

Fig. 30.35 Crab yaws, i.e. the painful fissures of yaws that typically incapacitate adult breadwinners.

Fig. 30.36 Periostitis in yaws may affect the outer table of the skull or the inner ends of the clavicles, but most commonly the long bones. This degree of bowing due to tibial periostitis is markedly severe.

involute, sometimes leaving scars but more frequently only hyperpigmented macules, which disappear completely after some months.

Sometimes, the secondary stage consists only of lenticular, hypochromic macules, which are believed to represent an 'ide' reaction, and are called 'bubides', 'framboesides', or 'pianides' ('yaws of the seven layers'). General symptoms that may precede this eruption include headache, fever, pain in the bones and joints, and generalized adenopathy of the syphilitic type, illustrating the importance of treponemal septicaemia.

After 3–4 years, the disease enters a chronic late phase, or tertiary stage.

Tertiary stage. The late manifestations of yaws affect the skin as well as the bones. The tertiary stage is characterized by ulcerated cutaneous lesions, nodular and tuberous lesions, keratoderma of palms and soles, juxtaarticular nodes, gangosa, lesions of the joints and bones, and goundou [12].

The most frequent sequelae of the disease are keratoderma and hyperkeratoses of palms and soles. These lesions can sometimes appear as raised, rounded nodules, which exfoliate from the trauma of walking, making the patient transfer his or her weight to unaffected areas, causing some degree of disability—'crab yaws' (Fig. 30.35). Also observed are hyperkeratotic plaques without nodules, which can present with fissures oozing serous fluid. Minute craters surrounded by hyperkeratotic papules, similar to keratoderma punctatum and also observed in syphilis, are sometimes seen; they are not painful and are known as 'hormiguillo'.

Periostitis and osteitis are important features of the disease. They are localized mainly in long bones (tibia, forearm), the metatarsals and metacarpals, where there is thickening of the periosteum and a reaction of the underlying bone, which gives rise to pianic osteoperiostitis. The condition is painful; in the tibia, the deformity can involve the entire anterior border of the bone, so that it closely resembles the sabre tibia of congenital syphilis (Fig. 30.36).

Gummatous lesions. In the limbs, particularly in the legs, the formation of subcutaneous nodules occurs. These are small at first, but slowly enlarge. They are hard, mobile and painless, but later tend to soften; the overlying skin ulcerates, allowing thick pus to escape. These are the 'gummatous framboesides'. Healing eventually takes place, to leave atrophic and pigmented scars. Juxtaarticular nodes, described by Jeanselme and Lutz, also appear.

Inflammation of the synovia and tendinous synovitis. Inflammation of the synovia can be observed in the knee, the

Fig. 30.37 Yaws may be intraoral and intranasal with septal and bone destruction.

ankle and the elbow. The entire joint appears encased in a gelatinous mass. These lesions are painful, and can cause severe disability. True synovial cysts also develop along the course of the tendons; they are painless, elastic and mobile, and must not be confused with ganglions.

Gangosa or deforming rhinopharyngitis. Gangosa is a hideous mutilation of the central part of the face (Fig. 30.37), which begins at the base of the nasal fossae or at the septum and, destroying the mucosa and cartilaginous and osseous structures of the septum, the palate and the posterior aspect of the pharynx, produces a cavity at the bottom of which the ethmoid mass can be seen.

The disease should be considered in any patient with an idiopathic septal perforation or nasal deformity (American leishmaniasis also produces these lesions) [13].

Goundou. This term is applied to the exostoses of the nasal bones and neighbouring osseous structures that appear in children who have suffered from secondary pyogenic infection.

Another manifestation of the late stage is so-called rheumatic yaws, producing pain in the joints but no gross objective changes.

Neurological and ophthalmological involvement have been debated, as some reports suggest that disc atrophy, optic atrophy and myeloneuropathies can be part of this disease [14].

Attenuation. Attenuated disease has been described in Surinam, South-East Asia and the Solomon Islands. This type of yaws has been seen during the last decade and is not the classical textbook yaws described above, with profuse collections of abundant, large elevated papillomatous lesions. Instead, a receding, attenuated yaws, characterized by scanty, less florid lesions is seen [15].

Laboratory findings. *Treponema pallidum* spp. *pertenue* is easily isolated from primary and secondary lesions, and can be identified by dark-ground examination or with silver stains. This treponeme can be inoculated into monkeys, rabbits and hamsters. The serological reactions for syphilis are positive in both non-treponemal and specific treponemal antibody tests.

Diagnosis. The country of origin (epidemiologically suspected diagnosis) and the clinical manifestations suggest a tentative clinical diagnosis, to be confirmed by the laboratory tests mentioned above.

Differential diagnosis. Framboesiomas must be differentiated from framboesiform syphilides, framboesoid leishmaniasis and paracoccidiodomycosis. Pianides or bubides may resemble pityriasis rosea, pityriasis versicolor or psoriasis. Syphilis produces keratoderma and infiltrative, ulcerative lesions indistinguishable from those seen in the later stages of yaws [16].

Treatment. Active infections, as well as non-infectious cases, should be given 2.4 mU i.m. benzathine penicillin in a single injection. The WHO recommends treating all cases and contacts over 10 years of age with 1 200 000 U of benzathine benzylpenicillin, and half that amount for children and contacts aged less than 10 years.

When the prevalence of cases with active lesions is above 10% of the population examined, penicillin should be administered to the whole community. When the prevalence is between 5% and 10%, penicillin should be administered to patients, contacts and children of less than 5 years of age. If the prevalence is less than 5%, the treatment should be limited to active cases and their contacts in the same household. Tetracycline or erythromycin, 500 mg p.o. four times daily, is the recommended treatment for patients allergic to penicillin.

Control and prophylaxis. It is very unlikely than non-venereal treponematoses can ever be eradicated (in contrast to the experience with smallpox) due to the fact that patients with these diseases do not develop lifelong immunity and remain contagious for prolonged periods of time. It is also unlikely that an effective vaccine can be developed, again due to the fact that the infection does not confer prolonged immunity [17]. The widespread use of soap has been mentioned as one of the reasons connected with the decline of the disease [1].

As spread of the disease is favoured by poor hygiene and overcrowding, the elimination of these factors will lower its incidence. Contact with patients with ulcerative lesions should be avoided. The use of insecticides reduces

the risk of transmission by a vector. Mass treatment with penicillin has given satisfactory results in extensive areas throughout the world.

Yaws control programmes have produced large yaws-free areas by carefully planned and executed campaigns, but the need for active surveillance, as the only way to prevent reintroduction or resurgence of the disease, has been painfully demonstrated in the recent past.

According to the WHO there were 460 000 new cases of endemic treponematoses in 1997 and, even when they remain very sensitive to penicillin, resistance to the antibiotic is always a possibility (plasmid DNA in *Treponema pallidum* is known) and penicillin treatment failures in Papua New Guinea and Ecuador have been reported [9].

Pinta

SYN. CARATE; CUTE; MAL DEL PINTO; MORADO; AZUL

[F. Kerdel-Vegas, pp. 30.34–30.36]

The term carate, of Carib origin, has priority over the others because it was used by native Americans before the discovery of America. In Mexico, the term used is pinta, meaning spotted (from the Spanish verb 'pintar', to paint); in Cuba, mal del pinto is employed; in Venezuela and Colombia, carate and cute; in Guatemala and Nicaragua, morado; and in Peru and Chile, azul (the two last terms meaning 'the bluish ones') [1].

Definition. Pinta is a chronic, non-venereal, infectious treponematosis caused by *T. p. carateum*, which affects only the skin, producing dyschromic eruptions and hyperkeratoses.

History. Pinta is an autochthonous disease of the American continent, originally reported by Gonzalo de Ovieto y Valdez and Hernán Cortés between 1505 and 1516 as a cutaneous manifestation common among the Carib and Aztec native Americans. Menk, González-Herrejón and Pallares found that the Wassermann reaction was positive in a high percentage of pinta patients. Alfonso-Armenteros, Grau-Triana and León y Blanco discovered the specific causative agent. León y Blanco autoinoculated himself with the disease and described its early lesions [2].

Incidence. Pinta is endemic only in the Americas; conditions that resemble pinta reported from the Pacific area are probably 'pintoid' yaws. Pinta is occasionally found in Central and South America, including Mexico, Venezuela, Colombia, Ecuador, Peru and Brazil. The incidence is lower in Guatemala, British Honduras, El Salvador, Honduras, Nicaragua, Haiti, Santo Domingo, Costa Rica, Panama and Bolivia. In other Caribbean islands (Cuba, Puerto Rico, Guadaloupe, Virgin Islands) and in the Guianas, it occurs only sporadically. The infection was supposed to be extinct in Brazil until 1975, when 20 new cases of pinta were found amongst the Tucuna native American tribe; later on several foci were detected in the area of the western Amazon, and 265 additional cases were diagnosed [3]. In Venezuela, pinta was found to be affecting the whole of a small community of Cuiva native Americans in the south-western part of the country.

There is no predilection for either sex. Exposed regions of the body are the most frequently affected during the early stages. Pinta appears more frequently at low altitudes in warm climates and is observed predominantly in persons who live in primitive, unhygienic conditions, as applies to certain native American communities. Generally, the condition is acquired during childhood by direct skin or mucous membrane contact; venereal transmission does not occur, as lesions of the genitalia are unusual. It is known that *T. p. carateum* penetrates cutaneous abrasions. Transmission by insects, as occurs with yaws, is possible but has never been proved. The large majority of patients acquire the condition during childhood.

Aetiology. The causative agent is *T. p. carateum*, morphologically indistinguishable from the treponemes causing syphilis, yaws and endemic syphilis (bejel). On the basis

of DNA homology studies, the treponemes causing venereal syphilis, endemic syphilis, yaws and pinta have been reclassified as subspecies of *T. pallidum*. However, despite limited reports of experimental infection in the chimpanzee, no animal model has been developed for *T. p. carateum* infection; consequently, *T. p. carateum* is the least studied of the pathogenic treponemes, and may yet be considered a separate species [4]. Experimental inoculation in humans reproduces the clinical manifestations of the disease, and apparently gives a degree of immunity to inoculation with *T. pallidum* and *T. p. pertenue*.

Experimental inoculation of human volunteers has been carried out by depositing lymph obtained from active pinta lesions on superficial scratches on the skin or by injection of the material intradermally [5]. The period of incubation varies from 6 days to 4 months, with a mean of 8–10 days. The initial lesion is a pink papule with moderate infiltration; it grows slowly, forming a plaque of about 7 cm after 9 months. After 2 months, the patches become erythematous and hypochromic, sometimes with grey or pale-blue pigmentation in the pigmented skin of native Americans. Some degree of scaliness is frequent in all lesions.

The experiments of Medina [6] demonstrated that the 'pintosos', with natural or experimental lesions, cannot be infected by artificial inoculation with *T. p. pertenue*, and that it is very difficult to infect them with *T. p. pallidum*. On the other hand, yaws and syphilis patients during any stage of their evolution are easily infected with *T. p. carateum*.

It has been reported that in the Purú–Purú native American tribe of the Amazon basin, a tribal religious ritual of whipping, in alternating sessions, by affected adults and unaffected youths is performed in order to transmit the disease [1].

Histopathology. The treponemes are located chiefly in the Malpighian cells, especially in limited areas of acanthosis in the epidermis. The treponemes can be visualized in the epidermis, sometimes in large numbers, by means of silver staining methods or immunofluorescence techniques [7]. The primary lesion shows migration of lymphocytes through an oedematous, slightly acanthotic epidermis. The basal layer shows loss of melanin and liquefaction degeneration. Numerous melanophages are found in the upper dermis, indicating that even in the initial phase the mechanism of normal pigmentation is grossly disturbed. In the dermis, in addition to melanophages, a moderately dense infiltrate of plasma cells, lymphocytes and some histiocytes and neutrophils can be seen.

In the secondary stage, the same changes are observed, but they may be pronounced, and large numbers of treponemes can be demonstrated.

In the tertiary stage, the clinically hyperpigmented area shows atrophy of the epidermis and absence of melanin in the basal layer. The dermis contains accumulations of melanophages with a moderate lymphocytic infiltrate. At this stage, there are still an appreciable number of treponemes among the epidermal cells. Hypochromic or achromic lesions show atrophy of the epidermis, and a complete absence of melanin, inflammatory infiltration and treponemes. This type of lesion represents the final or residual stage of the disease. However, recent achromic lesions can still reveal a discrete inflammatory infiltrate in the dermis and treponemes in the epidermis [8].

Clinical features. Infection occurs through skin or mucous membrane contact, generally before adolescence, and is manifested as early (active) disease followed by latent (inactive) infection; a course characteristic of all the treponematoses. Usually, the evolution of the disease is divided into three stages:

1 initial lesions;
2 generalized cutaneous phase;
3 late phase.

It is characteristic of pinta that these three stages are not clearly defined and frequently overlap [6].

Initial lesions. Multiple erythematous lesions, usually localized on exposed areas of the body, sometimes macular, sometimes slightly infiltrated, grow by peripheral extension, or by the development of satellite lesions at their edges, with a marked tendency to become confluent and form larger lesions.

Generalized cutaneous phase. After a lapse of months or even years, when the primary lesions can still be observed or when these have resolved spontaneously, the secondary lesions, called 'pintides', appear. Clinically there are three varieties: hypochromic, pigmentary and erythematosquamous. Usually, there are extensive lesions showing mottled pigmentation, and often the second and third stages occur simultaneously. The lesions always retain their tendency to merge together, producing progressive atrophy of the skin with a tendency to hypochromia and achromia, thus leading to the late phase.

The late phase [9]. This takes from 2 to 5 years to develop and has the following characteristics:

1 *Pigmentation* is irregular, with a range of different shades according to the site of deposition of melanin in the dermis; the colour may be greyish, steel, ashy or bluish. In general, the pigmentary changes present a spotted and highly characteristic appearance.
2 *Achromia* may occur in any part of the body, but more frequently in sites close to bony protuberances, such as elbows, knees, ankles, wrists and backs of hands.
3 *Hyperkeratoses* are found on the legs, forearms, elbows, knees and ankles; the skin becomes thick and often scaly; they may also appear on palms and soles.

4 *Atrophy* is the final stage, and a consequence of the previous ones. It is localized mainly in the neighbourhood of the larger joints, and is accompanied not only by thinning of the skin, wrinkling and dryness but also by loss of sweating and sebaceous secretions [3].
5 *Adenopathy*. Generalized adenopathy accompanies the last two stages of the disease, involving mainly the epitrochlear, cervical and inguinal nodes. It is difficult to demonstrate treponemes in these glands.
There are no systemic symptoms and the CNS and cardiovascular systems are not involved.

Laboratory findings. Confirmation of a diagnosis of pinta is made by isolating *T. p. carateum* in the lymph taken from primary, secondary or tertiary lesions (except in old achromic areas) and observing them under dark-ground illumination or phase-contrast microscopy. Antigenic cross-reactivity has been observed among the pathogenic treponemes; infection with any of them will induce reactivity in both non-treponemal and treponemal tests for syphilis. Non-specific and specific serological reactions for syphilis are positive, although it takes over 2 months from the beginning of the condition before they become positive. Eosinophilia has been described as a frequent feature of this disease.

Diagnosis. Dyschromia, hypopigmentation with hyperpigmented spots giving a characteristic mottled aspect, together with the country of origin of the patient, prompt one to suspect the presence of the disease and to initiate the necessary laboratory procedures to establish the diagnosis, which must be based on the finding of the treponeme.

Differential diagnosis. Erythema dyschromicum perstans, originally denominated 'pintoide' by Venezuelan authors because of its similarity to pinta and also known as 'dermatosis cenicienta' ('ash-coloured dermatosis') in Central America, is obviously the dermatosis that clinically resembles pinta most closely. Other hypochromic processes such as pityriasis alba, atrophic lichen planus, tuberculoid leprosy, various leukodermas and vitiligo must be considered in the differential diagnosis of the late phase. The initial lesions can be confused with plaques of tinea corporis, psoriasis, lichen planus pigmentosus, frictional dermatitis, lupus erythematosus, pellagra, melasma, tinea versicolor and eczema. The other two treponematoses, yaws and syphilis, must also be considered.

Course. The disease runs a progressive course, with increasingly widespread involvement of the skin. Medina [6] demonstrated, however, by means of experimental inoculations, that the disease could remain localized for many years. Visceral complications of any type are not recorded. This disease is confined exclusively to the skin and even lesions of the nail apparatus are infrequent.

Treatment. Benzathine penicillin should be given in total doses of 2 400 000 U i.m. for patients aged over 10 years, and 600 000 U i.m. for patients (and contacts) aged under 10 years, by a single injection [10]. Tetracycline and erythromycin are the antibiotics of choice in cases of penicillin allergy.

Prognosis. In the primary and secondary stages, and even in the early tertiary stage, there is total restoration of pigment, and the skin returns to normal. However, the lesions of the late stage, such as achromic and atrophic areas, will persist. As far as the general health of the patient is concerned, the prognosis is always good.

Prophylaxis. The disease can be eradicated by means of comprehensive penicillin treatment of infected patients, which so far has been restricted to the endemic zones previously mentioned.

Tribute

The late Dr Robbie Morton was a major figure in UK venereology for over 50 years. His career spanned the early days of antibiotic treatment during the Second World War, when syphilis was common, through to the present revolution in genomic medicine. He remained a very active author and research collaborator until his death on 4 May 2002.

Chapter 31

Mycology

R.J. Hay & M.K. Moore

Introduction

Every dermatologist should be familiar not only with the common superficial mycoses but also with the cutaneous manifestations of subcutaneous and systemic infections. With increasing numbers of people taking advantage of the ease of worldwide travel, mycoses that were previously regarded as geographically limited can now be seen in any part of the world. Furthermore, in recent years the number of fungi recognized as human pathogens has risen, caused partly by an increasing population of debilitated and immunocompromised patients. Fungi that were considered as non-pathogenic are now being recovered as opportunistic invaders. The identification of the majority of pathogenic fungi still relies largely on the direct observation of their morphology rather than comparison of DNA patterns, and this requires a knowledge of some of the fundamental features of fungal classification and structure. Over the last 20 years, a precise and complex terminology has been developed to describe the characteristic features that may be observed [1–4] and an outline knowledge of this is essential in order to appreciate the often subtle differences that distinguish fungal pathogens.

Fungi are ubiquitous, capable of colonizing almost any environment, and generally play an invaluable part in the decomposition and recycling of organic matter. Although they were once believed to be descended from plants, it was recognized over 20 years ago that they represented a distinct kingdom, and that certain features of their biochemistry, such as the pathway of lysine synthesis, were quite different from those found in bacteria and plants. With the use of molecular techniques, it is now recognized that the organisms originally included in this kingdom of Fungi contained at least three phylogenetically distinct groups, and some phyla have now been reclassified in the kingdoms Protozoa and Chromista. Almost all the fungi previously regarded as human pathogens, however, remain in the reclassified Fungi [5]. They have probably evolved from protozoan ancestors, and the kingdom Fungi is now believed to have originated before the separation of Animalia and Plantae. All fungi are heterotrophic and must exist as saprophytes or parasites. However, relatively few of the estimated quarter of a million species are pathogens of humans or other warm-blooded animals. The vast majority exist purely as saprophytes or plant parasites and, even among the few that do cause human disease, many have a well-established saprophytic or plant parasitic life cycle in which human infection has no role.

Members of the kingdom Fungi show all the typical eukaryotic features, such as the organization of genetic material into chromosomes enclosed within a membrane-bound

nucleus, mitochondria and ribosomes. Unlike animal cells, however, their cells are enclosed by a rigid cell wall containing varying amounts of chitin, a polymer of *N*-acetyl glucosamine, and β-glucans. The wall also contains mannans, glycoproteins and enzymes, some of which are secreted into the surrounding environment and break down complex organic compounds prior to their absorption. Fungi have an absorptive mode of nutrition. Within the cell wall, the cytoplasm is bounded by a plasma membrane in which the predominant sterol is not cholesterol, as in humans, but ergosterol.

The fungi may be broadly divided into two basic forms: moulds and yeasts. Moulds are made up of long multinucleate filaments called hyphae (singular hypha), which are either largely coenocytic (see Fig. 31.56) or divided into a series of cells by regular cross walls or septa (singular septum) (see Fig. 31.17a). Hyphae grow continuously at the apical tip, where the cell wall is constantly plasticized and new material added. This is the most metabolically active area of the cytoplasm. Further back, the cells may become vacuolated, and often the cytoplasm is reduced to a thin layer lining the cell membrane. Hyphae branch regularly, the branches diverging away from the parent hypha to utilize the environment to the maximum extent. Typically, the longest cell is at the apex of the hypha. The cytoplasm streams continuously, and the majority of septa contain pores that allow the movement of cytoplasm and even of organelles from one cell to another. An aggregation of hyphae is termed a mycelium, and the whole mass of the fungus is the thallus. Growth of a mould on solid media results in a circular colony, and in liquid media the mould forms a ball. Moulds produce cottony or velvety colonies in culture, and even large structures such as mushrooms are simply made up of a mass of hyphae.

In the yeasts, the main phase of the life cycle is unicellular, made up of ovoid to globose cells which usually reproduce by budding (see Fig. 31.43) or, more rarely, by fission. After budding, when the daughter cell separates from the parent, a distinct bud scar is left behind. In addition, however, some pathogens can also form filaments that may be true hyphae, similar to those of moulds or pseudohyphae which develop when two cells fail to separate after budding, and simply elongate and lie end to end forming a chain. Pseudohyphae may be distinguished from true hyphae by the characteristic constrictions that may be seen at the points where two cells meet (see Fig. 31.43), and the shortness of the apical cell. Yeasts produce soft, pasty or mucoid colonies.

Some fungi can completely switch their form of growth depending on the environmental conditions. These are termed thermally and nutritionally dimorphic fungi, and include several of the major respiratory pathogens such as *Histoplasma capsulatum* and *Coccidioides immitis*. When cultured at room temperature, these fungi are typical moulds, yet in human tissues or on special media at 37°C they convert into yeasts or other non-filamentous forms.

Fungi reproduce both sexually and asexually, sometimes simultaneously. The sexual phase is termed the teleomorph and the asexual phase the anamorph; when both are present the growth is termed the holomorph. Much confusion has arisen because at the moment it is quite legitimate to give the sexual and asexual stages of growth completely different names. Thus, the dermatophyte *Trichophyton mentagrophytes* was originally described and named in the asexual phase in 1896. When a sexual phase was discovered in 1967, it was called *Arthroderma benhamiae*. Currently, both names are correct and their usage is simply determined by the phase isolated. If both sexual and asexual forms are present simultaneously, the sexual name has precedence. In the laboratory, sexual phases of pathogens are rarely seen, as the majority of fungi are heterothallic, which means that sexual reproduction requires the presence of two or sometimes four different mating types. Relatively few fungi can reproduce sexually by the mating of hyphae from a single mycelium, a condition termed homothallic.

In an attempt to reflect true phylogenetic relationships, the formal classification of fungi is based upon the features of the sexual phase of growth. This involves the fusion of two nuclei followed by meiotic division. Unlike higher plants and animals, many of the fungi are haploid for the major part of the life cycle, the diploid phase being relatively short lived. Three groups of sexually reproducing fungi, *Zygomycota*, *Ascomycota* and *Basidiomycota*, contain human pathogens (Table 31.1). A fourth, completely artificial group, the *Deuteromycota* or Fungi Imperfecti, was originally created to include those fungi with no known sexual phase, and the asexual phases of the *Ascomycota* and *Basidiomycota*. With the more sophisticated techniques available today, such as ultrastructural data on septa and molecular sequencing, these asexual 'mitosporic' species can now be placed within the recognized sexual groups, and it is possible that at some time in the future the artificial form-phylum *Deuteromycota* will disappear from the literature.

The *Zygomycota* are all moulds, and reproduce sexually by the formation of thick-walled zygospores following the fusion of two outgrowths arising from the hyphae. The hyphae of the *Zygomycota* are very characteristic, being both extremely wide and often sparsely septate. The septa that are formed usually cut off sporing structures and old parts of the mycelium, and are complete, so that damage to any part of the hypha will result in the death of the whole aseptate length. Branching in this group is typically at right angles. Asexual reproduction is usually by means of sporangiospores formed by the cleavage of cytoplasm within a sporangium. This is a sac-like structure, which is supported by a specialized hypha, the sporangiophore (Fig. 31.1a).

Table 31.1 Classification of fungi.

Phylum	Growth form	Hyphae (if present)	Sexual propagules	Asexual propagules
Zygomycota	Moulds	Broad Few septa	Zygospores	Sporangiospores
Ascomycota	Moulds Yeasts	Narrow Regular septa	Ascospores	Conidia*
Basidiomycota	Moulds Yeasts	Narrow Regular septa Clamp connections	Basidiospores	Conidia*
Deuteromycota	Moulds Yeasts	Narrow Regular septa	None	Conidia

* The asexual conidia of the *Ascomycota* and *Basidiomycota* are classified in the *Deuteromycota*.

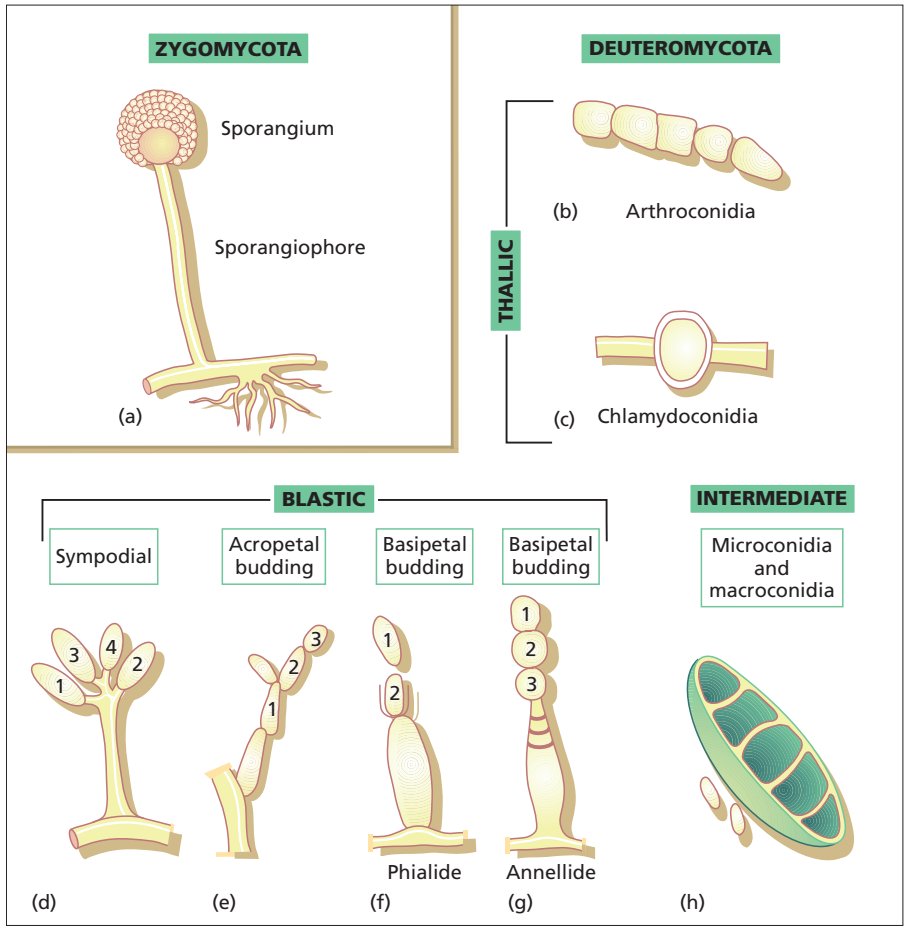

Fig. 31.1 Asexual reproduction in fungi. *Zygomycota*. The most characteristic form of asexual reproduction is the production of sporangia and sporangiospores (a). *Deuteromycota*. Asexual conidia may be formed by two main processes: thallic conidiation results in the production of arthroconidia (b) and chlamydoconidia (c). Blastic conidiation may take several forms, including sympodial conidiogenous cells (d), acropetal budding (e) and basipetal budding from phialides (f) or annellides (g). The conidia of the dermatophytes do not fit in with this thallic–blastic division, but show features of both. They are also examples of fungi that produce two kinds of conidia simultaneously, which differ in size. These are termed microconidia and macroconidia (h).

The *Ascomycota* contains both moulds and yeasts. Sexual reproduction is by the production of ascospores, formed within a sac-like ascus. These asci may themselves be contained within a specialized fruiting body or ascoma, which may be large enough to be visible to the naked eye. The hyphae of the *Ascomycota* have a lamellate cell wall, with a thin electron-dense outer layer and a thicker electron-transparent inner layer. The hyphae are narrow and regularly septate, but passage of cytoplasm and even nuclei from one cell to the next is made possible by the presence of a pore in the centre of each septum. When hyphae are damaged, however, this septal pore quickly becomes plugged by structures termed Woronin bodies, limiting the damage to those particular cells that were injured. A few of the *Ascomycota* have multiple pores in their septa.

In the *Basidiomycota*, sexual reproduction is by the production of basidiospores formed externally on sterigmata protruding from a club-shaped basidium. Many of this group produce the complex structures we know as mushrooms and toadstools, with gills, covered by basidia, raised above the ground to aid in airborne dispersal of the spores. Others, such as the rusts, smuts and basidiomycetous yeasts, are microscopic. The cell walls of the

Basidiomycota are lamellate and electron dense. When present, the hyphae are narrow and septate. The septal pore structure in this group is more complex and characteristic, and usually comprises a lip-like extension termed a dolipore, which may be surrounded by perforated membranes called parenthosomes. These allow passage of cytoplasm, but not nuclei, from one cell to the next. In the *Ascomycota* and the *Basidiomycota*, after fusion of hyphal initials of opposite mating type, subsequent fusion of the two nuclei may be delayed, so that for part of the life cycle these cells contain two nuclei of opposite mating type, a state termed dikaryotic. For this reason, some workers combine these two groups into the *Dikaryomycota*. It is characteristic of the *Basidiomycota* that when a dikaryotic hyphal cell divides, a hook-like structure known as a clamp connection is formed between the two resulting cells as a way of allowing one daughter nucleus of each type to migrate into each cell.

The form-phylum *Deuteromycota* was artificially constructed, as the phylogenetic relationships of many of the asexual fungi contained within it could not at that time be fully determined. The asexual propagules of all the fungi classified in this group were called conidia. Three main divisions were recognized in the *Deuteromycota* and are current in the literature: *Blastomycetes*, which are yeasts reproducing by budding; *Hyphomycetes*, which are moulds bearing the conidia exposed unprotected on the hyphae; and *Coelomycetes*, where the conidiogenous cells that produce the conidia are enclosed in a specialized protective fruiting structure, either a flask-shaped pycnidium or a saucer-shaped acervulus. The majority of fungi isolated in the laboratory are *Hyphomycetes*, and this group may be further subdivided according to colour into fungi that have dark hyphae—dematiaceous fungi—and those that are pale or brightly coloured—moniliaceous fungi. An amazing variety of conidia are formed by these fungi, and their laboratory identification still relies almost entirely on the study of the method of conidial formation or ontogeny and conidial morphology.

Two main methods of conidial production are seen in the *Hyphomycetes*: thallic and blastic (Fig. 31.1). In thallic conidiation, a whole cell or section of a hypha is transformed into the conidium. The most common examples of this are arthroconidia (Fig. 31.1b), when a hypha produces a series of septa, forming a chain of cells that separate at maturity, and chlamydoconidia, which are formed when a single cell becomes thick walled and acts as a storage and survival cell but does not disarticulate at maturity (Fig. 31.1c).

In blastic conidiation, the conidium is formed by 'blowing out' or budding from only a small weakened area of the cell wall of the conidiogenous cell. If both the outer and the inner cell wall are blown out to form the conidial wall the budding is termed holoblastic. If the first conidium ruptures the outer cell wall, and only the inner cell wall is blown out as the conidial wall, the budding is termed enteroblastic. An enormous range of blastic conidia are produced, but certain basic patterns of conidial development may be recognized. Holoblastic conidia include solitary conidia, which may simply be produced by the blowing out of a small part of the hyphal wall, to form a lateral or terminal conidium. In other fungi, more specialized conidiogenous cells are found, and these may produce a succession of holoblastic conidia. Examples of this include those fungi with sympodial conidiogenous cells (Fig. 31.1d), where after the first conidium has been formed, the conidiogenous cell continues to grow and produces a second conidium slightly ahead of and to one side of the base of the first conidium. It then repeats the process, forming a third conidium slightly ahead of and to the opposite side of the second conidium. This eventually results in a zig-zag appearance, with conidia coming off alternately on each side of the fertile cell. Such conidiogenous cells are very characteristic and are termed geniculate.

Many of the fungi with sympodial conidiation have multicellular conidia, either with transverse septa—phragmoconidia—or with both transverse and vertical septa—dictyoconidia.

Chains of holoblastic conidia may be formed by acropetal budding (Fig. 31.1e), where, after the cell has budded, the cells remain attached and a further conidium is produced by the budding of the daughter cell. This continues building up a chain of cells with the youngest at the tip of the chain. The chains may branch.

Enteroblastic chains of conidia with the youngest cell at the bottom of the chain are termed basipetal, and are formed by the repeated blowing out of the inner layer of the cell wall of specialized structures termed phialides and annellides. Phialides are often flask shaped, and may have a pronounced collarette—a flaring ring of wall material surrounding the apex of the cell. The phialoconidia are formed by repeated budding at exactly the same point at the tip of phialide, which does not increase in length during this process (Fig. 31.1f). In contrast, as a series of annelloconidia is formed, the cell apex proliferates slightly as each conidium is produced, leaving a series of ring-like scars at the tip of the cell, and the annellide becomes progressively narrower and longer (Fig. 31.1g). Conidia produced by phialides and annellides may aggregate to form balls rather than chains.

A number of pathogens produce conidia that are not strictly thallic or blastic, and which show a particular method of separation from the hypha. A specialized cell at the base of the conidium breaks, leaving a frill of wall material at the base of the conidium. These conidia are termed aleurioconidia.

Another feature that is seen in several fungal pathogens is polymorphism—the simultaneous production of more than one form of conidium. For instance, in the case of the

dermatophytes two types of conidia are formed, which differ greatly in size; in such instances, the larger conidium is termed a macroconidium and the smaller a microconidium (Fig. 31.1h).

Nomenclature. Nomenclature is the system whereby the correct names are applied to specific organisms, and is a necessary adjunct to any system of classification. In mycology, as in other sciences, the lack of a uniform approach towards the recognition and description of new species of fungi led to the accumulation of a bewildering number and variety of names in the literature. As an example, *Candida albicans* has been described and redescribed many times since its original description in 1850. A classic taxonomical work [1] lists no fewer than 110 species in 22 genera for this fungus. The need to provide a single name for a single species becomes obvious, particularly when so many synonyms have been proposed for one and the same organism. In order to provide some conformity and stability to the naming of fungi (separate consideration is given to bacterial and zoological nomenclature), a series of principles, rules and recommendations have been incorporated into an internationally recognized code, whose authoritative guidance has done much to bring order to a state of confusion.

As well as confusion in specific names, disease names have also given rise to controversy. As an increasing number of fungi have been shown to be capable of causing infection, particularly as opportunists in only a limited number of recorded cases, the habit of using the generic name of the fungus to produce a new disease name has become increasingly unwieldy, particularly when fungi are so frequently re-examined and often renamed. Well-established disease names have been retained, but where a new pathogen or pathology is involved the International Society of Human and Animal Mycology [2] recommends that individual mycoses should be named as often as possible in the form 'pathology A caused by pathogen B'. Thus, the use of such terms as fusariosis and trichosporonosis is best discouraged, and replaced by use of 'eumycetoma caused by *Fusarium* species' or 'disseminated mycosis caused by *Trichosporon* species'.

Disease names used throughout this text are based on lists published independently by the Council for the International Organization of the Medical Sciences (CIOMS) [3] and the International Society for Human and Animal Mycology [2].

Superficial and cutaneous mycoses

During the last decade, there has been an increasing tendency on the part of mycologists to separate the infections that affect hairs, skin and nails alone into two rather artificial groups: the superficial mycoses, which include diseases that generally do not provoke a significant histopathological inflammatory response in the host; and the cutaneous mycoses, where, although the fungus is confined to the non-living layers of the stratum corneum, pathological changes do occur in the host tissue. Among the superficial infections are pityriasis versicolor, tinea nigra, and black and white piedra.

The cutaneous infections include dermatophytosis, candidosis and a range of non-dermatophyte infections of the skin and nails, such as dermatomycoses caused by *Scytalidium* species and onychomycosis caused by other non-dermatophyte moulds. Some of the fungi causing these infections are present in the environment, but others, such as *Candida albicans* and *Malassezia* spp., have an intimate association with humans and are part of the normal flora of the gut and skin, respectively. Only a few, such as the anthropophilic dermatophytes, have evolved to the point where they have become almost completely reliant on the human host for survival.

Laboratory methods

The laboratory diagnosis of superficial and cutaneous mycoses relies first on the direct microscopical observation of the pathogen in samples from the affected area. This is usually followed by culture and the specific identification of the fungus. For the laboratory to provide the optimum performance, the quantity and the quality of the material examined is critical.

Collection of material

Skin

Disposable scalpel blades of the solid type held vertically to the skin are used to obtain scrapings. Alternatively, heat-sterilized blunt banana-shaped scalpels, which are

available from chiropody firms, may be used. Cleaning of the skin with alcohol may be useful if the patient has applied ointment or powder, but is not usually necessary. If the lesion has a definite edge, the material should be taken from the active margin, otherwise a general scraping is adequate. In cases of partially treated pityriasis versicolor, when very little scaling is present, it is possible to take a sample by pressing a strip of sticky tape (Sellotape®) on to the lesion and then on to a drop of mounting fluid on a slide and use this for the direct examination. The method is less suitable for direct examination of samples from the cutaneous mycoses [1]. If it is difficult to obtain sufficient material for culture in cases of dermatophytosis, transport swabs are a good back-up as is usual with candidosis. When blisters are present, a pair of fine scissors may be used to cut off a blister roof for microscopical examination and culture; such samples are often packed with hyphae.

The scrapings should be collected and transported in folded paper, which keeps the specimen dry, thus preventing contamination. Plastic containers are unsuitable, as the skin adheres to the sides and is difficult to remove. The use of glass slides, which then have to be transported to the laboratory, is hazardous as they are frequently broken. Squares of brightly coloured paper are ideal; these may then be carefully folded and secured by a paper clip. The details of the patient, exact site of the lesion and time of sampling should then be clearly written on the outside of the sample. Specially designed commercial transport packs for hair, skin and nail samples are available from several sources. Dermatophytes in skin scrapings may remain viable for months, and yeasts for several weeks.

Hairs

Hairs to be examined for the presence of black or white piedra may be simply cut off at skin level. If dermatophytosis is suspected, the hairs should be removed with the roots intact; cut hairs are unsuitable. In many instances, the affected hairs may be recognized because they are dull and broken but, if not, the fact that they slip out easily with fine forceps may also help in selecting the right material. This is particularly useful in examining scalp or beard kerions caused by *Trichophyton verrucosum*, where relatively little fungus may provoke a severe reaction, and it may be necessary to test many hairs before an infected hair is found. In those instances where the hairs break off very short, as in black-dot infections, a scalp scraping will yield the best material, with the infected roots appearing as tiny stumps among the skin scales. It should be noted that, in cases of steroid-treated tinea corporis or tinea incognito, the examination of vellus hairs may be the easiest method of diagnosis as, although fungi such as *T. rubrum* rarely invade the hair shaft, they may colonize the hair follicle. In addition to collecting scales and hairs, brush samples are an excellent method for the culture of scalp infections, and may also be useful in testing suspected animal sources of infection [2–4]. A sterile plastic scalp massager or disposable toothbrush is brushed firmly through the hair at least 10 times, and is then pressed against the culture medium in a 90-mm Petri dish. This simple technique is an extremely sensitive culture method, and is invaluable when screening large numbers of children. Several hundred children may be examined in a day by performing a Wood's light examination and taking a brush sample from each child, which can then be taken back to the laboratory for culture. Cultures from infected children produce a fungal colony from many of the inoculation points; contacts of infected children usually yield only a few colonies. In cases of kerion, when brush sampling may be unsuitable and painful, a transport swab wiped over the lesion will usually pick up enough conidia to give a positive culture.

Wood's light examination. The discovery by Margarot and Deveze [5] in 1925 that hair infected by certain dermatophytes produced a characteristic fluorescence in ultraviolet (UV) light filtered by Wood's glass was an important advance in medical mycology. Wood's glass, which consists of barium silicate containing about 9% nickel oxide, transmits rays of wavelength above 365 nm. Most sources of UV light are suitable. The nature and source of the fluorescent substances in infected hairs are not fully understood. The hair remains fluorescent after the fungus has ceased to be viable, and the fluorescent material can be extracted from the hair in hot water [6,7] or in a cold solution of sodium bromide [5]. The colour of the fluorescence is influenced by the pH of the solution [8]. Because fungi growing in culture or on hair *in vitro* do not fluoresce in this way, the phenomenon must be attributed to some substance produced by the interaction of the fungus and the growing hair. Its chemical nature has not been defined, and the suggestion that it may be a pteridine has been challenged [7–10].

Only some of the dermatophytes capable of invading hair will induce fluorescence, but these include members of the genus *Microsporum* (e.g. *M. audouinii* and *M. canis*), which are common in a number of densely populated parts of the world. Hairs infected by these species produce a brilliant green fluorescence, easily recognized in a darkened room. Only the fully invaded portions of the shaft develop this property. In recent infections or at the spreading margin of early lesions, the fluorescent part of the hair may not yet have emerged from the follicle, and can be detected only after the hair is plucked. Among other *Microsporum* species and variants, only *M. canis* var. *distortum* and *M. ferrugineum* regularly induce fluorescence, and *M. gypseum* and *M. nanum* occasionally do so. *Trichophyton schoenleinii* causes a paler green fluorescence of infected hair. In favus, the fluorescent hairs tend to be

long, in contrast to the short broken stumps characteristic of *Microsporum* infections.

In areas where *Microsporum* infections are prevalent, the Wood's light is an essential tool in the diagnosis and treatment of the individual patient, and in the control of epidemics. The lamp is easily transportable and can be taken to schools or institutions for the rapid examination of contacts. The most common sources of error are the bluish or purplish fluorescence produced by ointments containing petrolatum, scales, serum, exudates, an insufficiently darkened room, light reflected from the examiner's white coat and the failure to remember that not all fungi cause fluorescence. Correctly performed and interpreted, the test is virtually specific, but the absence of fluorescence in infections with *M. audouinii* and *M. canis* has been reported [11]. The lamp can be used in the detection of subclinical infection, and to assess response to treatment or spontaneous cure. The Wood's lamp is also of value in the diagnosis of pityriasis versicolor, where the scales fluoresce yellow in some cases. A similar yellow fluorescence, presumably because of the presence of yeasts of *Malassezia* species, may be seen in some cases of severe dandruff, in cradle cap in infants and in the follicular orifices of the face and upper trunk in normal subjects.

Nail

The diagnosis of onychomycosis is complicated by the fact that the isolation of the pathogen in culture from nail material is more difficult to achieve than for skin and hair samples. In the majority of nail infections, the material for examination is taken from the distal end of the nail, despite the fact that the infection is advancing proximally. The hyphae at the distal end of the nail are less likely to be viable [12]. Unfortunately, it is usually not practicable to take deep samples from the proximal advancing edge with minimum discomfort to the patient. The full thickness of the nail should be sampled, as most infections start in the hyponychium. Debris from under the nail is a fruitful source of material, which may be scraped out using the flat end of a dental probe. Superficial scrapings are inadequate, except in cases of superficial white onychomycosis or proximal subungual onychomycosis.

In cases of paronychia, the nail fold may be moistened with saline using a wet swab, and the flat end of a dental probe may be gently pushed into the fold to withdraw material for direct examination and culture. After this, a swab should also be taken for culture.

As the isolation of fungi from nail material is difficult, samples should also be taken from any skin lesions that may be present, as these are very likely to be invaded by the same pathogen as the nail, and cultures are more likely to be positive. It is essential when submitting nail material to the laboratory to specify whether the sample is a fingernail or toenail, as some pathogens are more prevalent in one than the other.

Mucous membranes

The mouth or vagina may be sampled using a blunt scalpel or by using swabs. If the specimen is not to be examined immediately, swabs with transport medium are preferable, as yeasts rapidly die in dry conditions. However, delays in processing of transport medium swabs will allow multiplication of yeasts in the samples.

Ear

Scrapings from the external ear canal may be supplemented with swab samples.

Direct examination

For routine examination, specimens are usually mounted in 10–30% potassium hydroxide; the higher the percentage, the faster the specimen will clear. For skin scrapings, warming gently over the pilot light of a bunsen burner will speed up the process, but boiling should be avoided, if possible, as this tends to encourage the formation of artefacts, which may confuse the inexperienced observer. It is impossible to soften skin samples too much, for the thinner the specimen, the easier it will be to observe the fungal elements. Excess potash will etch microscope lenses, so it must be removed using small squares of filter paper, and the cover slip can be pressed down gently, using a needle, to flatten the specimen. A few minutes

spent carefully preparing the specimen in this way are well spent. Nail specimens take longer to clear, but if small pieces and debris are taken, they will usually soften within 10 min. In those instances where the nails do not soften satisfactorily, the slide may be put in a 37°C incubator for 1 h, and the material can then be flattened. In contrast to skin and nail samples, infected hairs are very delicate, and if heated or left in mounting fluid for more than a few minutes tend to disintegrate, obscuring the characteristic arrangement of the arthroconidia. They should therefore be examined as soon as possible after mounting. If examining specimens using bright-field illumination, the lighting is critical; overillumination, particularly when scanning the slide under low power (× 10), will render the fungal elements invisible. The light should therefore be low initially and then raised when the presence of fungus is confirmed by examination with a higher power lens (× 20 or × 40). An alternative clearing agent, which does not require warming of the specimen, is 10% sodium sulphide solution [1,2].

With experience, bright-field examination of specimens cleared in this way is quick and relatively straightforward. However, several authors have recommended a variety of techniques to make observation of the fungal elements easier. Phase-contrast and dark-field microscopy can produce good results [3], but do require that the specimen be really thin, and thus may need a longer period of softening of the material than bright-field microscopy. The addition of 35% dimethylsulfoxide to the potash may speed up softening, but overdigestion is then a problem, and the specimens should be examined within 1–2 h. Dimethylacetamide or dimethylformamide have been suggested as alternatives [4]. Several stains such as Congo red, methylene blue and cotton blue have been recommended to enhance the contrast between fungus and skin, but again these require a fully softened specimen. One stain that has been extremely useful is Parker's stain, made by the mixing of equal volumes of potassium hydroxide and Parker's blue–black Quinck permanent fountain pen ink [5]. Unfortunately, the manufacturers have now changed the formulation of the ink and the new product no longer stains hyphae; when current stocks are finished this stain will become unavailable.

Fluorescence microscopy using either acridine orange [6] or a fluorescent brightener such as Calcofluor white or Blankophor [1,2], which specifically stain polysaccharides in the fungal cell wall, is becoming increasingly popular. A comparative study of different methods used in direct examination [2] concluded that most of the recommended staining procedures for direct microscopic examination were no better than the classic potassium hydroxide method, but that if a fluorescence microscope is available, the use of fluorescent brighteners does give superior results. A more recent study [1] concluded that fluorescence microscopy using Blancophor P flussig in sodium sulphide solution was quicker, and produced significantly fewer direct microscopy negative samples, which subsequently yielded fungus on culture, than bright-field microscopy using sodium sulphide solution alone. In the authors' experience the fluorescent technique is superior to bright-field microscopy and strongly recommended, particularly for nail samples.

Whatever method is used, the ability to find fungi on direct examination of samples is largely a matter of practice. The beginner may well be confused initially by the common artefacts that may be present, such as mosaic fungus—cholesterol-forming polygonal deposits around cells—air bubbles, fibres and crystals, but with practice it becomes progressively easier to find the fungi and distinguish the various infections.

It must be noted that some workers advocate the histopathological processing of nail material and staining with a fungus-specific stain such as periodic acid–Schiff (PAS) as a routine measure [7]. It has been suggested that this not only confirms that the nail plate is actually invaded, but also reduces the number of false-negative direct reports, where fungus is cultured from a microscopically negative nail. However, the facilities for histopathological processing may not be available in a small laboratory.

Culture (Table 31.2)

For some of the superficial mycoses, the appearance of the fungal elements observed on direct examination is so characteristic that culture is not strictly necessary for diagnosis of the infection. This is certainly true of pityriasis versicolor and, to a lesser degree, black piedra, white piedra and tinea nigra. For otomycosis, in contrast, culture is essential, as the range of organisms that can cause infection is enormous, and the specific identification of the pathogen will have a profound effect on the therapy selected. Similarly, differences in the response of the different pathogenic yeasts to some of the newer antifungals, such as fluconazole, necessitates identification down to species level, at least in patients on long-term treatment. The situation with dermatophyte infections is rather different because, although on direct examination of skin and nail samples the different species are indistinguishable, generally all the dermatophyte species have been believed to respond similarly to the major systemic and topical antifungals available, and treatment has been initiated on the basis of the direct examination. However, this may not be true with some of the more recent antifungals developed. In addition, culture will provide valuable information on the possible source of infection and the likelihood of spread of the disease. Culture of specimens with negative direct microscopical results is also desirable, as it will allow the detection of the small percentage of cases where prolonged therapy, or a very inflammatory

Table 31.2 Cultural conditions for isolation of superficial and cutaneous pathogens.

Disease	Causative organisms	Media		Antibiotics		Temperature		Maximum length incubation (days)
		GP	MEA	Cyc	Chlor	26–28°	37°

Candidosis	*Candida* spp.	+	+	–	+	+	+	7
Otomycosis	*Aspergillus* spp. *Candida* spp., etc.	+	+	–	+	+	+	21

Chlor, chloramphenicol 0.05 g/L; Cyc, cycloheximide 0.4 g/L; GP, glucose–peptone agar; MEA, malt extract agar; + recommended; – not recommended.

host reaction, may make the microscopical detection of the fungus in the skin difficult. The non-dermatophytic moulds capable of infecting skin or nail, such as *Scytalidium* species and *Scopulariopsis brevicaulis*, can be diagnosed on the basis of direct microscopy, but this requires considerable expertise, and in addition mixed infections with dermatophytes do occur, so that it is advisable to always perform cultures in these cases.

Fungi grow readily on simple media containing glucose and preferably an organic nitrogen source; they are not particularly fastidious. The primary culture medium used therefore is largely a matter of personal choice. Many laboratories will select a simple glucose/peptone agar, either with 4% sugar, 1% peptone and an acid pH (Sabouraud's dextrose agar) or with 2% sugar, 1% peptone and a neutral pH (Emmon's modification). Antibacterial antibiotics such as gentamycin (0.0025%) and/or chloramphenicol (0.005%) may be added to reduce contamination and, if a dermatophyte infection has been diagnosed, the addition of cycloheximide at 0.04% will inhibit the growth of non-dermatophyte moulds. This antibiotic must be excluded, however, if infection by a non-dermatophyte mould such as *Scytalidium* or candidosis is suspected as, although *C. albicans* is not affected, many of the less common species of *Candida* found, particularly in nail and mucous membrane sites, will be inhibited. For sites where non-dermatophyte moulds such as *Scytalidium dimidiatum* may be significant —palms, soles, toe webs and nails—duplicate cultures with and without cycloheximide are recommended. Sabouraud's dextrose agar is available from a number of different commercial sources. It should be noted, however, that variations in the different makes, particularly the type of peptone included, will affect the overall morphology of the isolates, and cause differences in pigmentation and texture of the fungal colonies, particularly of dermatophytes. It is easiest therefore to become familiar with the morphology of these pathogens on one brand only. One should also note carefully which formulations have cycloheximide and/or chloramphenicol already incorporated (e.g. Mycosel and Mycobiotic agars) and which require their addition. Another medium that is frequently used for primary culture is 3–4% malt extract agar, which is also commercially available.

As incubation is much longer than for bacterial cultures, the medium should be poured relatively thickly to prevent drying out; 30 mL/90-mm Petri dish is adequate. The majority of laboratories now perform their cultures in disposable plastic Petri dishes, but if screw-capped glass bottles or tubes are used, the tops must be left slightly loose to provide adequate aeration. For moulds, the temperature of incubation should be 26–28°C and cultures should be held for a maximum of 3–4 weeks. For *Candida* species, the temperature of incubation should be 37°C, and plates may be discarded after 1 week. As some *Trichosporon* species will not grow at 37°C, incubation should be at 26–28°C for up to 2 weeks.

Identification of isolates

Yeasts

The identification of yeasts requires morphological data together with physiological and biochemical investigations. Examination of the yeast colony should include colour and texture. Microscopic features of note may include the size and shape of the budding cells (blastoconidia), and the presence of pseudohyphae, true hyphae, capsules, arthroconidia and ascospores. In the case of *C. albicans*, the formation of terminal vesicles (chlamydospores) on cornmeal or rice agar supplemented with Tween 80, or the production of germ tubes after incubation in serum at 37°C for 2–3 h, allows specific identification. For speciation of other pathogenic yeasts, physiological tests must be performed. An increasing number of commercially produced yeast identification kits are available and widely used, including the API 20C (bioMerieux) and the Auxacolor (Sanofi Diagnostic Pasteur). Primary isolation media that allow the specific identification of certain species to be made by the production of a characteristic colour are also now available. On Albicans ID medium (bioMerieux), *C. albicans* colonies develop a blue colour; on Chromagar (Becton & Dickinson) *C. tropicalis*, *C. krusei* and *C. albicans* produce blue, pink and green coloured colonies, respectively. These media facilitate the detection of mixed infections, which has become increasingly important because of the relative insensitivity of certain *Candida* species to some of the currently available antifungal drugs.

Moulds

The identification of moulds relies almost entirely on examination of the colonial and microscopical morphology. Examination of the fungal colonies should include noting the colour of the surface and reverse of the culture, and the presence of any pigment diffusing into the medium. The texture of the surface of the colony is also important, and terms such as downy, powdery, granular and glabrous are widely used (see Glossary, p. 31.101). Hyphae that project above the surface of the agar—aerial hyphae—and growth completely submerged in the medium may also be characteristic. Folding may take very characteristic forms, either radial, circular or cerebriform (see Glossary, p. 30.101).

Microscopic features to note include the shape and size of the conidia, their colour, septation and the presence of wall thickenings or other ornamentation. The arrangement of the conidia on the conidiogenous cell and the type of conidiation is of critical importance. Such microscopic features may be observed using a needle mount, a sticky tape strip or a slide culture. The simplest method is a needle mount, when a portion of the growth is removed with a stiff wire needle, and teased out in a drop of a suitable stain, such as lactophenol cotton blue. A cover slip is applied and the sample examined microscopically. The disadvantage of this method is that, as it entails relatively rough handling of the material, it is inevitable that many of the conidia will become detached from the hyphae. A method that will retain more of the conidia in position is to apply a piece of sticky tape, sticky surface down, onto the surface of the colony, and then mount this in a drop of stain and examine the preparation directly through the back of the tape. The sticky tape strip is extremely useful for the examination of colonies with many conidia. The most successful but time-consuming method for examining the details of conidial structure and formation, however, is the slide culture [1]. In this method, the fungus is inoculated onto the four sides of a square of agar, sandwiched between a glass slide and cover slip, and maintained in a sterile Petri dish with a moist atmosphere. The fungus grows out from the agar block directly onto the glass of the cover slip and slide, which may be used to prepare two undisturbed mounts of the growing fungus. When sealed with nail polish, these form permanent preparations.

Pityriasis versicolor

SYN. TINEA VERSICOLOR; DERMATOMYCOSIS FURFURACEA; TINEA FLAVEA; LIVER SPOTS; CHROMOPHYTOSIS

Definition. A mild chronic infection of the skin caused by *Malassezia* yeasts, and characterized by discrete or concrescent, scaly, discolored or depigmented areas mainly on the upper trunk.

Aetiology. The normal flora of the skin includes a number of morphologically distinct lipophilic yeasts. It was thought that a single polymorphic yeast, *Pityrosporum ovale*, or two species, *P. ovale* and *P. orbiculare*, were present, but it is now recognized that this genus name was invalid, and these yeasts were reclassified in the genus

Malassezia as a single species, *M. furfur*. However, genetic analysis has now demonstrated that the situation is far more complex, and at least seven separate species of lipophilic yeasts exist on the human skin. These comprise *M. sympodialis*, *M. globosa*, *M. restricta*, *M. slooffiae*, *M. furfur*, *M. obtusa* [1] and the recently described *M. dermatis* [2] and are all lipid dependent. One lipophilic but not totally lipid-dependent species, *M. pachydermatis*, is more often found on animal skin. The isolates previously known as *M. furfur* therefore probably include a complex of species. Colonization by these species is especially dense in the scalp, the upper trunk and flexures. Various studies have examined the distribution of the different species in normal skin from various sites and in lesional skin in various *Malassezia*-associated dermatoses. Some have included direct microscopical observation or counting of yeasts, some rely on cultures alone. However, as different workers have used different sampling techniques, few of them quantitative, and different culture media, the studies are not directly comparable. The current consensus from these studies is that *M. globosa* is the species most frequently associated with pityriasis versicolor and *M. sympodialis* is that found most commonly on normal skin [3]. Microscopy of the scales of pityriasis versicolor nearly always reveals thick-walled spherical yeast forms budding from a narrow base—compatible with *M. globosa*—and coarse septate mycelium often broken up into short filaments. In some instances, however, more commonly in tropical zones [4–6], mycelium is observed together with oval yeasts budding from a broad base, a morphology more suggestive of *M. furfur* or *M. obtusa* [3]. Initially it was found impossible to demonstrate the mycelial phase of *Malassezia* species *in vitro*, but in 1977 Dorn and Roehnert [7] achieved this using a glycine-containing medium.

Pityriasis versicolor in most cases represents a shift in the relationship between a human and his or her resident yeast flora. Factors contributing to the change are probably multiple. It is known that some *Malassezia* species more readily become mycelial, and have perhaps a slightly greater pathogenic potential. A positive family history among blood relations is found more often than chance would suggest in pityriasis versicolor, but whether this is caused by a genetically determined host-susceptibility factor, or the greater opportunity for heavy colonization by *Malassezia* species, is at present undetermined. Conjugal cases also occur, and it is possible that in some instances infection does not arise from the individual's own autochthonous flora but by transmission from another individual [8]. The relationships between different *Malassezia* species causing pityriasis versicolor and other skin diseases are partly understood. *M. globosa* is associated in particular with pityriasis versicolor, whereas a number of different *Malassezia* species are isolated from seborrhoeic dermatitis [3]. Most attention has been devoted to environmental factors and individual host susceptibility. The sexes are probably equally prone to this condition, but there are certainly differences in susceptibility at different ages [9,10]. In temperate zones, the condition is rare in childhood but becomes more common in the late teens with a peak in the early twenties. Infections in old age are rare. In tropical climates, the condition is more common than in temperate zones, and as many as 40% of some populations may be affected [11]. Although no reliable figures are available for colder climates, the prevalence is almost certainly less than 1%. In temperate zones, among patients who can give a reliable history, the onset is more often in the warmer months of the year [10]. Pityriasis versicolor has been claimed to be more common in various disease states, but only in Cushing's syndrome, spontaneous and iatrogenic [12], and possibly in malnutrition are these suggestions reliably supported by evidence. Pregnancy and oral contraceptives may have some influence in increasing susceptibility, but again firm data are lacking. Pityriasis versicolor does not appear to be more common in acquired immune deficiency syndrome (AIDS) patients [13]. There have been many attempts to explain susceptibility in terms of physical and biochemical abnormalities, but a variety of differing and conflicting results leaves the problem unresolved. Application of oils to the skin may increase susceptibility but is not proven.

There is ample evidence of an antibody response to *Malassezia* species in subjects without pityriasis versicolor. There have been many studies on humoral response to *Malassezia* species in patients with pityriasis versicolor and controls but, prior to the recognition of the new species, antigens used were probably made from a number of different species, making the often conflicting results difficult to interpret. Similarly, studies of cell-mediated responses have also produced conflicting results with a wide range of antigens [14]. One interesting new approach has been to use mycelial-phase antigens and this has shown significantly greater lymphocyte transformation responses in pityriasis versicolor patients compared to controls [15]. The initial views that patients with pityriasis versicolor have a cell-mediated deficiency specific to *Malassezia* species or depletion of specifically reactive T cells from the blood [16,17] have been questioned. The extensive review of the immunology of diseases associated with *Malassezia* species is recommended to those interested in these aspects [18]. T-cell inhibition by a lipid component of the *Malassezia* cell wall has recently been reported [17].

Malassezia species do not attack the hair shaft, nails or mucous membranes, but recently pulmonary infections in infants on long-term intravenous lipid therapy have been attributed to *Malassezia*.

Histology and pathogenesis. In those patients who do produce a cellular response, hyperkeratosis, parakeratosis

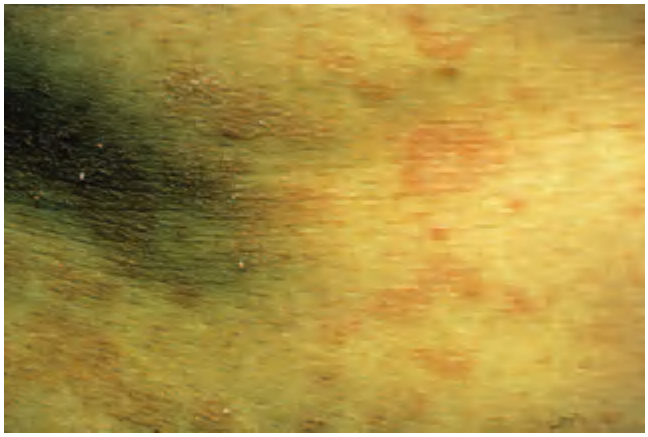

Fig. 31.2 Pityriasis versicolor.

and slight acanthosis, with a mild inflammatory infiltrate in the upper dermis, are the characteristic histological changes. Immunophenotyping of the infiltrates revealed a dominance of memory T cells, an accumulation of macrophages and a lack of B cells [19]. A marked accumulation of Langerhans' cells in the epidermis, reduced expression of cellular activation markers and the presence of suppressor T cells were also demonstrated. The infecting organism is usually present in the upper layers of the stratum corneum, and on electron microscopy may be seen to invade not only between but within the keratinized cells. Corneocyte counts have demonstrated an increased cell turnover in affected skin. Depigmentation has been explained on the basis of dicarboxylic acids produced by *Malassezia* species (e.g. azaleic acid) causing competitive inhibition of tyrosinase and perhaps a direct cytotoxic effect on hyperactive melanocytes [20]. However, these acids had no effect on normal melanocytes in tissue culture. The explanation for the hyperpigmentation seen in fair-skinned subjects remains obscure, although electron microscopy reveals abnormally large melanosomes in hyperpigmented lesions, and smaller-than-normal melanosomes in hypopigmented ones [21,22]. It has also been noted that total epidermal pigmentation is reduced in hypopigmented lesions, and a thicker keratin layer in hyperpigmented lesions may be significant [23].

Clinical features [3,8]. The patient usually complains only of a patchy and varying change of skin colour, but mild irritation is sometimes noticed. The primary lesion is a sharply demarcated macule, sometimes slightly erythematous, but characterized essentially by fine branny scaling (Fig. 31.2). Typically, the eruption shows large confluent areas, scattered oval patches and outlying macules. Where scaling is minimal, it may be emphasized by firm scraping or stretching of the skin, but a sticky tape strip is a better alternative. The site most commonly affected is the upper trunk, but there is often spread to the upper arms, the neck and the abdomen. Lesions in the axillae and groins, and on the thighs and genitalia occur, and extension down the forearms on to the backs of the hands, and into the popliteal fossae is by no means rare. Facial and scalp involvement are well recognized in the tropics, and occasional cases in which only these areas are affected are seen. Palmar lesions have been reported from the tropics, and rarely occur in temperate zones. A few unusual cases have been described where the disorder appears to have been localized by occlusion or pressure, as under the straps of a rucksack or in the groins under a 'T' bandage.

The term versicolor is particularly apt. The colour of the scales may vary from pale ochre to medium brown. In the untanned white skin, the affected areas are darker than normal, but they fail to respond to light exposure; in the suntanned subject, the abnormal skin is commonly paler, as it usually is in black people. The terms pityriasis versicolor alba or achromia parasitica are sometimes used in such cases. In ordinary cases that settle spontaneously or as a result of treatment, the residual depigmentation may remain for many months without any scaling. Under the Wood's lamp, the scaly lesions may show pale yellow fluorescence, and unsuspected macular lesions more widely scattered are often revealed by this technique.

Differential diagnosis. Vitiligo and chloasma are normally distinguishable by their complete absence of scaling. Seborrhoeic dermatitis, pityriasis rosea, secondary syphilis, pinta and tinea corporis show more inflammatory change than pityriasis versicolor, and none of these ever has the even branny scale of the latter condition. Erythrasma may closely mimic pityriasis versicolor with pigmentary change and scaling, but satellite lesions are less common, and pink fluorescence under the Wood's lamp is often present. Erythrasma and pityriasis versicolor may occasionally coexist, sometimes confusingly.

Laboratory diagnosis. The finding on direct examination of coarse mycelium, fragmented to short filaments 2–5 μm wide and up to 25 μm long, together with spherical thick-walled yeasts 2–8 μm in diameter confirms the presence of infection (Fig. 31.3). Occasionally, oval yeasts may be seen. However, it is the mycelium that is the diagnostic feature, and sometimes this predominates to the extent that there are few yeast forms. As they are members of the normal flora, isolation of *Malassezia* species from scrapings is of no diagnostic value, and is not normally undertaken by diagnostic laboratories.

Treatment. There are a number of different methods of treatment [3]. The topical azole antifungals work well in pityriasis versicolor, and there is no significant difference in results achieved by different compounds [24]. The usual time to recovery is 2–3 weeks. However, there is

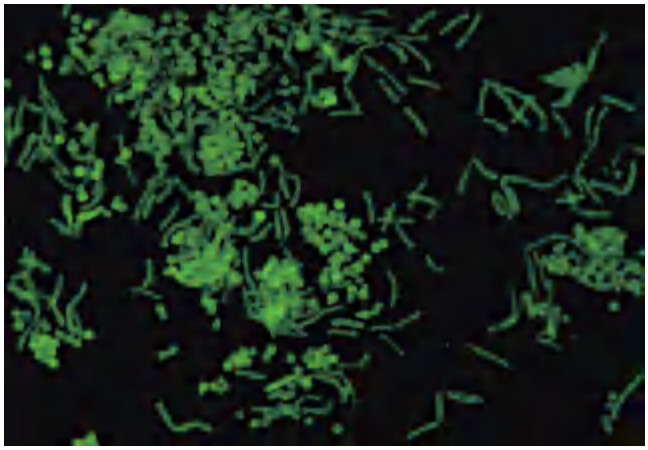

Fig. 31.3 Pityriasis versicolor. Skin scales mounted in KOH and calcofluor white, ultraviolet (UV) illumination. The hyphae diagnostic of the condition have taken up the stain immediately. *Malassezia* yeasts are also present. (Courtesy of the Department of Medical Mycology, St John's Institute of Dermatology, King's College London, London, UK.)

increasing evidence that shorter application periods using appropriate formulations such as lotions may work after only one or two applications. As has been shown with oral itraconazole, the organisms die rapidly after exposure to azoles, but in view of the thickened *Malassezia* cell wall are not rapidly cleared from the epidermis, giving the false impression of a persistent infection [25,26]. Terbinafine 1% cream is also effective in pityriasis versicolor. The main problem with the use of topical antifungals is the difficulty of applying creams to such a wide body surface area. A possible solution to this is provided by the development of a shampoo version of ketoconazole, and although it has not been fully evaluated in pityriasis versicolor, two or three applications of the shampoo appear to clear most infections.

A second cheaper approach is the application of 2.5% selenium sulphide in a detergent base (Selsun® shampoo). It is applied to all the affected areas and left overnight. The liquid is pinkish yellow and is best applied at bedtime and should be washed off the next morning. Estimates vary as to the most appropriate length of treatment, and in many cases it is necessary to apply the material regularly (e.g. every other night over 2 weeks). In some patients, however, one or two applications may be sufficient. The principal advantages of selenium sulphide are its low cost and the convenience of application. On the other hand, it is irritant if inadvertently applied to the face or genitalia, necessitating care in its application. It also stains clothes and bedding. Alternatives include 20% sodium hyposulphite solution, and 50 : 50 propylene glycol in water. The latter has also been used intermittently as long-term suppressive therapy to prevent relapse [27].

Both oral ketoconazole and itraconazole are also very effective in cases of pityriasis versicolor. The dose of ketoconazole recommended varies, but some patients respond to a single 400-mg dose; others may require longer periods of treatment [28,29]. While opinions differ as to the appropriate place for oral therapy, the authors usually reserve oral itraconazole for recalcitrant cases. Itraconazole is active against pityriasis versicolor in a total dosage of 800–1000 mg [9,26], usually given over 5 days.

Relapse is unfortunately very common, whatever the primary treatment; in all but the most resistant cases it is probably simplest to re-treat each episode rather than resort to long-term suppressive therapy. Patients should be warned that repigmentation may take several months, as otherwise they will often report treatment failure, even when the organisms have been destroyed, simply because the hypopigmentation persists.

Other cutaneous disorders associated with *Malassezia* yeasts

Lipophilic yeasts of the genus *Malassezia* are part of the normal skin flora, and therefore any evidence that they are either directly or indirectly implicated in the pathogenesis of skin disease is often difficult to assess.

For many years, it has been known that *Malassezia* yeasts are found in large quantities in the scales of seborrhoeic dermatitis both on the scalp and elsewhere. This has been attributed largely to hyperproliferation of the epidermis, the assumption being that the organisms were merely colonizing this particular site. The same was thought to be the case with skin-surface bacteria [1]. However, it has become apparent that most patients with seborrhoeic dermatitis or scaling of the scalp (dandruff) clear on treatment with azole antifungal agents coincidentally with the disappearance of the yeasts, and that if they relapse after therapy this occurs when the organisms reappear [2,3]. The circumstantial evidence therefore that the two events are causally related is very strong. In animals, it is possible to induce skin scaling that bears some resemblance to seborrhoeic dermatitis after the application of *Malassezia* yeasts [4]. Some but not all authors have reported that patients with seborrhoeic dermatitis have significantly raised levels of antibody to these organisms [5], but do not appear to develop contact sensitization to antigenic extracts. One further intriguing piece of evidence is that seborrhoeic dermatitis is one of the earliest and most consistent abnormalities seen in patients with AIDS not on antiretrovirals [6,7]. Yet, as with seborrhoeic dermatitis in non-AIDS patients, there is no consistent correlation between colonization and primary disease, although numbers of yeasts are higher in those with low CD4 counts. All these observations reinforce the view that adult-type seborrhoeic dermatitis is directly related to *Malassezia* yeasts but not to a single species. The relationship between infant seborrhoeic dermatitis and these organisms is less well established. The mechanisms by which they induce skin changes are not known, and the possibilities of direct lipase activity [8] or antibody-mediated epidermal damage [5] have both been considered. It is also apparent that a small percentage of patients with typical seborrhoeic dermatitis do not respond to azole antifungals, and the exact mode of pathogenesis is not clear. However, it is possible that a number of different stimuli can trigger this common condition of which the most common is *Malassezia*.

A further observation is that certain patients with eczema affecting the head and neck may also respond to topically applied azole antifungals, and also show immediate-type hypersensitivity to extracts of *Malassezia* [9]. Patients have usually had childhood atopic disease or are atopic on family history, and the condition is most often seen in young women.

The second condition associated with *Malassezia* yeasts is a form of folliculitis on the back and upper trunk. *Malassezia* folliculitis is a clinically distinct condition most often seen in teenagers or young adult males [10,11]. Lesions are itchy papules and pustules, which are often diffusely scattered on the shoulders and back. The itching and distribution distinguish them from acne vulgaris. Patients often report the development of lesions following a holiday in the sun. The condition responds well to oral itraconazole or ketoconazole shampoo. Biopsies taken from typical cases show clusters of yeasts within follicles surrounded by inflammatory cells, which are distinguishable from the colonization of follicular openings that can be seen in normal individuals. The exact pathogenesis of this condition is once again unknown, but treatment with appropriate antifungals is highly effective. *Malassezia* yeasts have also been associated with other skin conditions such as confluent and reticulate papillomatosis [12–14]. However, their presence in this condition is not invariable, and their removal with antifungals not necessarily followed by significant changes in the skin lesions. In addition, some patients respond to minocycline. Finally, there is a variant of psoriasis that has been termed 'sebopsoriasis' where, it is speculated, lipophilic yeasts may have a pathogenic role [15]. While clinically this condition shows some features of both psoriasis and seborrhoeic dermatitis, it still needs to be defined more clearly before it is possible to ascribe a role to the yeast flora.

Tinea nigra

SYN. TINEA NIGRA PALMARIS; KERATOMYCOSIS NIGRICANS PALMARIS; PITYRIASIS NIGRA

Definition. Tinea nigra is an asymptomatic superficial fungal infection generally affecting the skin of the palms and characterized by deeply pigmented macular non-scaly patches.

Aetiology. Tinea nigra is generally caused by *Phaeoannellomyces werneckii* (syn. *Exophiala werneckii, Hortaea werneckii*) [1]. A different organism, *Stenella araguata* has been isolated from some cases diagnosed in Venezuela [2]. The disease occurs sporadically in many parts of the world, including the Americas and the Caribbean, South Africa, Australia, Europe and the Far East. It can easily be reproduced experimentally by scarifying the skin and applying a pure culture of *P. werneckii* under a bandage. The incubation period in separate studies was reported to be 10–15 days and 7 weeks, respectively.

Histology. There is thickening of the stratum corneum in which hyphae are present. Inflammatory reaction in the dermis is minimal.

Clinical features [3]. The lesions are asymptomatic, macular, sharply defined and not scaly. The most distinctive feature is the brown or black colour resembling a silver nitrate stain. The palms are most commonly affected [4,5] in cases reported in the western hemisphere, but other areas of the body such as the soles and, more rarely, neck and trunk have been recorded, particularly in Asia. By uneven rate of spread or coalescence of lesions, irregular outlines are produced. Spontaneous clearance is very unusual.

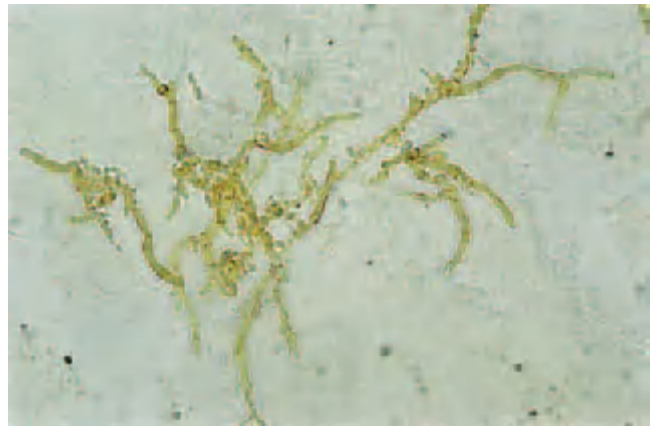

Fig. 31.4 Tinea nigra. Skin scales mounted in 30% potassium hydroxide, bright field. The natural brown colour of the septate hyphae is apparent. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

Differential diagnosis. The black colour and the absence of scaling differentiate the condition from pityriasis versicolor. The pigmented lesions of Addison's disease, syphilis, pinta and junctional naevi of the palm may have to be differentiated, and mycological examination of scales is usually required.

Laboratory diagnosis. Microscopy of infected epidermal scales in potassium hydroxide mounts reveals brown branched closely septate hyphae up to 5 μm in diameter, and elongated budding cells (Fig. 31.4).

Phaeoannellomyces werneckii. Colony: cultures on glucose peptone agar may be relatively slow growing, and initially yield a dirty white to grey moist yeast-like colony, which darkens to black, and over the course of several days becomes more filamentous and velvety. Microscopy: examination of young cultures reveals annellidic yeast-like budding cells, which are often uniseptate, the septum being dark in mature cells. The conidia are initially hyaline but become brown on maturity. Hyphae in older cultures produce intercalary and lateral conidiogenous cells, which are annellidic or sympodial.

Treatment. Topical azole creams such as econazole and ketoconazole [6] are effective. The condition also responds to the topical application of fungicidal preparations such as Benzoic Acid Ointment Compound BPC. Tiabendazole 2% in 90% dimethylsulfoxide once a day for 14 days gives good results, as does the ordinary commercially available 10% tiabendazole suspension.

Black piedra

SYN. TINEA NODOSA; TRICHOMYCOSIS NODULARIS

Definition. A fungal infection confined to hair shafts and resulting in the formation of hard dark superficial nodules thereon.

Aetiology. Black piedra is caused by the fungus *Piedraia hortae*. It occurs in humid wet tropical regions [1] in the Americas and in South-East Asia, and affects monkeys as well as humans [2]. The infection was thought to be more common in males than females, but a study among the Zoro indians of Brazil [3] showed no significant difference between the sexes. The same study showed a prevalence of infection of 57% in subjects over the age of 11 years.

Clinical features. Black piedra is characterized by the presence of firmly adherent black gritty hard nodules on the hairs of the scalp, or less frequently of the beard, moustache or pubic area. The nodules vary in size from microscopic to 1 mm or more in diameter, and their thickness often tapers, either from one end to the other or from the middle to the edge. They are usually multiple, and oval or elongate in shape. Subcuticular fungal growth may rupture the cuticle, and the fungus may then grow on the outside of the cuticle, completely surrounding the hair shaft. Because the fungus grows into the hair shaft, the hair may fracture easily. Untreated, the infection may last for months or years.

Histology. In histological section or in potassium hydroxide mounts, the nodules are observed to be made up of closely packed brown hyphae held in a mass by a viscous or cement-like substance (Fig. 31.5). At the edges of the nodule, regularly aligned hyphal strands and arthroconidia, 4–8 µm in diameter, can be seen, while in the thicker parts club-shaped asci containing eight elongated ascospores may be formed. The ascospores have a polar filament at each end, and can be observed by crushing or sectioning the nodule. *Piedraia hortae* is almost unique among the human pathogenic fungi in producing sexual spores in its parasitic phase.

Fig. 31.5 Black piedra. Hairs mounted in 30% KOH, bright field. The dark nodules are formed of dematiaceous hyphae cemented together to form a hard mass. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

Laboratory diagnosis. The direct examination is so characteristic that culture is not absolutely necessary. If culture is performed, it should be noted that the fungus is not inhibited by cycloheximide.

Piedraia hortae. Colony: the culture is slow growing, compact, domed and black. Microscopy: brown thick-walled septate hyphae and chlamydoconidia are present. Asci and ascospores may be present in the thicker portion of the colony [4], but are not formed by every isolate.

Treatment. Shaving or cutting the hair effects a cure. To prevent recurrence, antifungal preparations such as Benzoic Acid Ointment Compound BPC or a 1 : 2000 solution of mercury perchloride may be applied to the hair after shampooing. The first case treated with terbinafine has been reported [5].

White piedra

SYN. TRICHOSPOROSIS NODOSA

Definition. A fungal infection confined to hair shafts and resulting in the formation of soft, white, grey or brown superficial nodules.

Aetiology. Until 1994, the aetiological agent of white piedra was considered to be the basidiomycetous yeast *Trichosporon beigelii*, but genetic analysis has now determined that this name covered a complex of different species [1], and the agent of capital white piedra is now considered to be *T. ovoides* and those reported from crural white piedra include *T. inkin*, *T. asahii* and *T. mucoides*. The infection occurs in South America, Africa, central and eastern Europe, and Japan [2,3]. The horse and certain species of monkey may be affected. The cases occasionally observed in temperate countries have usually been in visitors from the tropics, but cases have occurred in both Europe and the USA in individuals who have never left these regions [4]. A study in equatorial Africa demonstrated a prevalence of 18% among inguinal specimens from 449 female subjects [2].

Clinical features. White piedra is characterized by the presence of soft white or light brown nodules. The infection is more common on the hairs of the beard, moustache and genital areas than the scalp [5,6]. The fungus grows both within and outside the hair shaft, and the hair shaft may be weakened and break off. The nodules are transparent, easily detached from the hair and vary in size from microscopic to 1 mm in diameter. The underlying skin is not affected and there is no fluorescence under Wood's light.

There have been some new findings relevant to the pathogenesis of this condition. First, there is evidence that some cases may be sexually transmitted [7]. In addition, it has been postulated that the bacteria known to accompany the concretions of the fungi on hair, now identified as a new species of *Brevibacterium*, *B. mcbrellneri* [8], may have a synergistic role in the infection [9]. The strong proteolytic activity of the bacterium may facilitate hair shaft invasion by both yeast and bacterium, while fungal byproducts may stimulate bacterial growth. There is an increased carriage rate of perianal '*T. beigelii*' reported in human immunodeficiency virus (HIV)-positive individuals, suggesting that this region may provide a reservoir for carriage. Interestingly, there does not appear to be an increased incidence of hair shaft infection in these patients.

Histology. The nodules of white piedra are in the form of a sheath, which may extend around the hair shaft. There may be extensive growth within the hair, giving rise to the characteristic nodular swellings on the hair shaft. The hyphae segment into arthroconidia 2–4 μm in diameter, and budding blastoconidia may also be seen (Fig. 31.6).

Differential diagnosis. The presence of pruritus and the distinctive shape of egg cases of pediculi should serve to distinguish pediculosis from piedra, but microscopical examination is desirable.

Fig. 31.6 White piedra. Hair mounted in KOH, bright field. The gelatinous nodules formed by various *Trichosporon* species surround the hair. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

Laboratory diagnosis. Most *Trichosporon* species are inhibited by cycloheximide, so this antibiotic should be excluded from the culture medium. As a few isolates fail to grow at 37°C, it is also advisable to incubate at 28–30°C.

Trichosporon species. Colony: the colonies of *Trichosporon* species develop rapidly and are soft, creamy and wrinkled, and sometimes mucoid [10]. Microscopy: the genus *Trichosporon* is characterized by the presence of hyphae, arthroconidia and budding cells. These are best observed with a deep cut streak on a cornmeal or rice agar supplemented with Tween 80. Physiological tests: the species recently recognized using genetic analyses can be identified in the routine laboratory using their morphological characteristics, together with carbohydrate assimilation patterns determined by the commercial API 32C system (bioMerieux), failure or ability to grow at 37°C and relative sensitivity to cycloheximide [1].

Treatment. As with black piedra, shaving or cutting the hair may effect a cure. Responses to concentrated topical antifungals, azoles and allyamines have been reported but are unpredictable.

Otomycosis

SYN. MYCOTIC OTITIS EXTERNA

Definition and clinical features. A chronic inflammatory condition of the external auditory canal caused by fungal infection (external otitis in general, including the differential diagnosis and the management, is considered in Chapter 65). In some patients with external otitis, fungi may be isolated from swabs or scrapings, and indeed material taken from the normal external ear may on occasions yield a variety of moulds [1]. Such isolates are more common in tropical regions. Very occasionally in external otitis, the fungus isolated appears to be playing a pathogenic part, perhaps even a primary one. The species most commonly accepted as a pathogen in this situation is *Aspergillus niger*. Other species implicated as pathogens include *A. fumigatus* and other *Aspergillus* species [2,3], *Scedosporium apiospermum*, numerous other moulds and *Candida* species.

The inflamed, itchy and sometimes painful external canal usually discharges a little serous fluid. In advanced cases of true mycotic otitis, an overgrowth of fungal hyphae may produce a mass of white material suggesting damp cotton wool, lodged in the external canal. Where *A. niger* is the causative organism, the mat of fungus is often covered by black fruiting heads [4]. In severely immunocompromised patients, the external auditory meatus can be extensively eroded by fungal invasion to produce a necrotic form of otitis externa [5]. This form may spread to involve other sites including the middle ear and the mastoids. The pinna may be the site of several mycotic diseases including chromomycosis [6], sporotrichosis [7] and tinea [4], but such infections usually spare the external auditory meatus.

Laboratory diagnosis. A light growth of a mould from a swab taken from the ear is of little significance. *Rhizopus*, *Absidia*, *Mucor* or *Penicillium*, or indeed *Aspergillus* species, in small amounts mean little. Nor should any great weight be given to a light growth of *Candida*, although this organism can cause external otitis. The criteria for accepting the fungus as having an aetiological role are the absence of any significant bacterial pathogens and the presence of large masses of fungi, such as may sometimes be seen on examination of the patient. If there is a considerable amount of fungal material in specimens taken for direct examination, this may be adequate evidence.

Aspergillus niger. Colony: growing rapidly, the colony initially has a white or cream surface, which becomes black as the conidia are produced. The reverse remains pale cream to celadon green. Microscopy: the conidiophores arise at right angles to the supporting hyphae, and have a swollen globose vesicle at their tip, which is completely covered by a layer of supporting cells or metulae. These metulae support a layer of phialides, which produce chains of dark brown, rough-walled phialoconidia. The bottom end of the conidiophore ends in a foot cell inserted in the supporting hypha.

Treatment [4,8,9]. Careful toilet, with removal of debris and fungal material from the ears, is of paramount importance. Various local applications have been suggested. One routine consists of applying 2% thymol in 70% alcohol during cleansing, followed by 50% metacresyl acetate or olive oil on a pledget of cotton wool left for 24 h. Clotrimazole lotion has been employed with success in both *Aspergillus* and *Candida* infections. Bifonazole lotion and cream were effective in the majority of 35 patients included in a long-term study attempting to correlate the bacterial and fungal flora in patients with symptomatic otomycosis [9]. Oral itraconazole has been used in the aggressive invasive form of otitis externa.

Miscellaneous superficial fungal infections caused by saprophytic moulds

The normal skin, especially the scalp and toe clefts, is commonly contaminated with spores or even short lengths of mycelium of saprophytic species. Where the fungal mycelium is pigmented or where distinctive spores are concerned, they may be recognized in direct examination of skin scrapings. If cycloheximide-free media are used, they may be readily cultured. Usually, such species are present in small amounts, and may without difficulty be dismissed as contaminants that have impacted on the skin, in the same way as the pollen grains occasionally observed. From time to time, however, reports appear in

the dermatological literature of cases in which species such as those of *Aspergillus* [1] appear to colonize damaged tissues, become firmly established and perhaps cause secondary tissue destruction. Most authors wisely counsel caution before accepting any sort of pathogenic role for the moulds in these cases.

Laboratory diagnosis and management. In situations like these, it is important to take repeated scrapings, to use cycloheximide-free media in culture and then to weigh the facts carefully before assuming that the organism is anything more than a contaminant. In many cases, simple correction of local precipitating factors, such as maceration or occlusive dressings, may be all that is needed.

Dermatophytosis

Introduction

Dermatophytes are related fungi [1,2] capable of causing skin changes of the type known as ringworm or dermatophytosis. Thus defined, the ringworm species are all moulds belonging to three asexual genera: *Microsporum*, *Trichophyton* and *Epidermophyton*. Forty years ago, the sexual state of dermatophytes was unknown, and this phase of the life cycle has still not been found for many of the common species. However, in those species where the sexual state has been identified, all the organisms are classified in the single genus *Arthroderma* in the phylum Ascomycota [3]. A list of synonyms of sexual and asexual names is included for reference (Table 31.3). However, as sexual states are not routinely seen in the diagnostic laboratory, the asexual anamorph names will be used throughout this section.

In addition to the recognized pathogens, a number of fungi have been discovered that are keratinophilic and that are clearly close relatives of the ringworm fungi—indeed, some are even classified in the same three anamorph genera—but that are soil dwellers and non-pathogenic. Although some authors include these fungi within the dermatophytes, in the authors' opinion they are better classified in the broader group of keratinophilic fungi, retaining the term dermatophyte for those species that can act as true cutaneous pathogens.

Table 31.3 Asexual–sexual connections of dermatophytes.

Asexual state	Sexual state
Microsporum canis	*Arthroderma otae*
Microsporum fulvum	*Arthroderma fulvum*
Microsporum gypseum	*Arthroderma incurvatum*
Microsporum gypseum	*Arthroderma gypseum*
Microsporum nanum	*Arthroderma obtusum*
Microsporum persicolor	*Arthroderma persicolor*
Trichophyton mentagrophytes	*Arthroderma benhamiae*
Trichophyton mentagrophytes	*Arthroderma vanbreuseghemii*
Trichophyton simii	*Arthroderma simii*

The three asexual dermatophyte genera are distinguished by the morphology of the large multicellular macroconidia that are produced [4]. In the genus *Microsporum*, the macroconidia are rough, usually thick walled and range from fusiform to obovate in shape with 1–12 or more septa. Those of *Trichophyton* species are thin walled, smooth and may be cylindrical, fusiform or clavate in shape, with up to 12 transverse septa. In *Epidermophyton*, the macroconidium is clavate, broadened and rounded at its distal pole, thin walled and has up to five septa; the conidia are smooth when first formed, but as the colony ages discrete wall thickenings may be observed.

Apart from the mycological classification of dermatophytes, it has been traditional for clinical and epidemiological reasons to group dermatophytes that infect humans according to their ecological niche: geophilic species originating in the soil (Table 31.4), zoophilic species having animal origins (Table 31.4) and anthropophilic species, which are largely restricted to human skin (Table 31.5). However, these three groups are not always sharply demarcated. Species that are clearly geophilic may contaminate or infect the coats of animals, especially small rodents, and may thus infect humans through an intermediate animal host. Similarly, animal species may shed infective material on to the soil and, although incapable of multiplying there, fungal elements may survive long enough to be isolated in a soil survey [5]. In the case of species affecting farm animals, their environment, cow sheds and fences may be contaminated by shed keratinocytes or hair containing fungal spores, just as the floors around swimming baths and the air of hospital clinics may be contaminated by anthropophilic species [5].

The distribution of the zoophilic species reflects that of the major animal hosts. Those geographically limited include *Microsporum canis* var. *distortum*, *M. persicolor*, *Trichophyton mentagrophytes* var. *erinacei* and *T. simii* (Table 31.4). Many of the anthropophilic species are also geographically limited and the classic endemic distributions are indicated in Table 31.5. However, to some degree these must reflect the distribution of diagnostic facilities, and data for some areas are slight or outdated. Also, the anthropophilic dermatophytes are spread by population movements. For example, species classically thought of as African, such as *T. soudanense*, have been isolated in the USA and Europe with some regularity. The European infections have not been among immigrants from the endemic areas alone, but also in children born in Europe of African immigrants and, more rarely, among the

Table 31.4 Geophilic and zoophilic dermatophytes.

	Geographical distribution	Major host
Geophilic species		
*Microsporum gypseum**	Worldwide	
Microsporum praecox	USA, western Europe	
Zoophilic species		
Microsporum canis var. *canis*	Worldwide	Cat, dog
var. *distortum*	New Zealand, USA	Cat, dog
Microsporum equinum	Worldwide	Horse
Microsporum gallinae	Worldwide	Fowl
Microsporum nanum	Worldwide	Pigs
Microsporum persicolor	Americas, Europe	Voles
Trichophyton equinum	Worldwide	Horse
Trichophyton mentagrophytes		
var. *mentagrophytes*	Worldwide	Rodents
var. *erinacei*	Europe, New Zealand	Hedgehogs
var. *quinckeanum*	Worldwide	Mice
Trichophyton simii	India	Monkey
Trichophyton verrucosum	Worldwide	Cattle

* This asexual species is a complex of three sexual species.

Table 31.5 Anthropophilic dermatophytes.

Species	Geographical distribution
Epidermophyton floccosum	Worldwide
Microsporum audouinii	Worldwide
var. *rivalieri*	Africa
var. *langeronii*	Africa
Microsporum ferrugineum	Far East, eastern Europe, Africa
Trichophyton concentricum	Pacific, South-East Asia, Latin America
Trichophyton gourvilii	Central Africa
Trichophyton mentagrophytes var. *interdigitale*	Worldwide
Trichophyton megninii	Mediterranean
Trichophyton rubrum	Worldwide
Trichophyton schoenleinii	Worldwide
Trichophyton soudanense	Subsaharan Africa
Trichophyton tonsurans	Worldwide
Trichophyton violaceum	North Africa, India, Middle East
Trichophyton yaoundei	Central Africa

endemic European population. Some of the species that have been regarded as cosmopolitan, including *M. audouinii* and *T. schoenleinii*, are currently rarely isolated in the USA and many parts of western Europe, although in some areas, particularly parts of Africa, they remain endemic.

It must also be appreciated that these distributions are not static, and the range of species in some areas may change dramatically and quickly. For instance, in one central London laboratory during the period between 1980 and 1990, the most common isolate from tinea capitis was the zoophilic organism *M. canis*. In contrast, during 2000 and 2001 *T. tonsurans*, a species that was rarely seen in the 1980s, was responsible for 87% of scalp infections (M.K. Moore, St John's Institute of Dermatology, London, unpublished data). A resurgence of infection by other anthropophilic species, such as *T. soudanense* and *M. audouinii*, has also been noted in London during the period between 1993 and 2002 (M.K. Moore, St John's Institute of Dermatology, London, unpublished data).

From the evolutionary point of view, it is likely that the anthropophilic species represent the end of a line, starting with non-pathogenic keratinophilic soil species, existing as saprophytes on keratinous debris, passing through the geophilic dermatophytes and the zoophilic species. The increased specialization that this evolutionary trend implies seems to be accompanied by a progressive loss of the sexual state and a reduction in the production of conidia, particularly macroconidia, and a loss of certain mating types [6–8]. Virtually all the non-pathogenic keratinophilic species and geophilic dermatophytes have demonstrable sexual states, as do a few of the zoophilic group, particularly those infecting animals living in

burrows or dens and thus soil-associated. However, dermatophytes that infect larger animals, such as *T. verrucosum* from cattle, *T. equinum* from horses and the anthropophilic dermatophytes, have as yet no known sexual state. It has been suggested that this transition from sexual to asexual life cycles had led to an unprecedented level of adaptive radiation among the anthropophilic dermatophytes, resulting in a large number of species and variants. Other factors that may have contributed to the adaptive radiation on humans include the separation of the human skin into distinct areas differing in the distribution of sebaceous glands and hairs, resulting in a marked affinity for particular body sites among the anthropophiles, which is not seen in zoophiles.

Characteristically, zoophilic species tend to produce highly inflammatory reactions in humans and this may lead to a spontaneous cure. Anthropophilic species produce mild but chronic lesions. There are many exceptions to this useful generalization, and the degree of inflammatory response depends in part on the site of infection—large follicles of scalp and beard are associated with an intense reaction—and the immune status of the host [9].

An important characteristic of the dermatophytes as parasites is their restriction to dead keratinized tissue. Although the inflammatory responses of ringworm infection involve the dermis and the Malpighian stratum of the epidermis, the fungus itself is found growing only within the stratum corneum of the epidermis, within and around the fully keratinized hair shaft, and in the nail plate and keratinized nail bed. Within these keratinized tissues, the fungus exists only as mycelium and arthroconidia. In this parasitic phase of fungal growth, there are no micro- or macroconidia and no specialized vegetative structures, such as spiral or pectinate hyphae. For these reasons, precise identification of the species of an infecting dermatophyte is generally impossible on direct microscopy of skin or nail.

In dermatophyte infections involving hair, the fungus invades the follicle from the adjacent stratum corneum and follows one of several precise patterns of growth. In the case of *M. canis* and *M. audouinii*, for example, the fungus penetrates the keratinized hair at about mid-follicular level, having grown down on the hair surface [10]. It then grows downwards within the hair towards the bulb, until the zone of incomplete keratinization is reached. Growth is then arrested, or rather slowed and resisted. An equilibrium is established, the fungal mycelium invading new, fully keratinized hair shaft at the same rate as it is formed, but never growing down into the incompletely keratinized tissue. Further up the shaft, hyphae from the existing mycelium grow outwards from inside the hair and proliferate on its surface. These secondary extrapilary hyphae are tortuous; they fragment into small arthroconidia, which rapidly round up to become spherical structures, and are seen as a packed mosaic of spores coating the surface of the hair. This is the small-spored ectothrix type of hair invasion.

Other species of dermatophytes show different patterns of hair invasion. *T. verrucosum* and *T. mentagrophytes* var. *mentagrophytes*, like the *Microsporum* species, show arthroconidia on the surface of the hair and hyphae within it, but these conidia are larger and are arranged in straight chains. This is known as large-spored ectothrix hair invasion. *T. tonsurans* and *T. violaceum*, among others, produce an endothrix type of hair invasion, with the hyphae inside the hair fragmenting completely into a mass of relatively large arthroconidia, which are retained entirely within the hair shaft. *T. schoenleinii*, the cause of favus, is different again. The hyphae within the hair are fewer in number than in other endothrix infections and do not break up into a mass of arthroconidia but run intact through the hair, forming tunnels within its structure. When mounted in potassium hydroxide, these tunnels around the hyphae, initially filled with air, form the characteristic air spaces seen. While in favus the infected hair commonly grows to normal lengths, in endothrix infections where arthroconidia are formed the hair, being most severely damaged, breaks at the skin surface. In small-spored ectothrix infections the shaft tends to fracture a few millimetres above the surface.

All these parasitic patterns are very different from the mode of growth of dermatophytes on hair *in vitro* [11]. If plucked hair is inoculated with any of the *T. mentagrophytes* varieties, for example, frond-like fungal hyphae develop on the surface and lift the cuticle cells. Conical pits are then formed perpendicular to the surface of the hair as penetration of the keratinized hair cortex occurs. Intrapilary growth follows along the hair shaft in both directions, and micro- and macroconidia may be produced. There are no linear chains of arthroconidia on the surface. Moreover, if a hair, parasitized *in vivo*, is plucked, and then cultured *in vitro*, the specialized growth pattern initially established will cease and the saprophytic phase, with the development of micro- and macroconidia, will rapidly follow.

Pathogenesis of infection

Invasion of the epidermis by dermatophytes follows a common pattern starting with adherence between arthroconidia and keratinocytes, followed by penetration through and between cells and the development of a host response.

Adherence

On the stratum corneum, the first phase of dermatophyte invasion involves the adherence of infectious arthroconidia to keratinocytes. *In vitro*, this process is completed after about 2 h of contact, at which stage germination and penetration of the keratinocyte occurs [1]. Different dermatophytes show similar kinetics, which are also unaffected by the source of the keratinocytes. The germination of arthroconidia and hyphal prolongation which follows adherence proceeds radially, and *in vitro* there is evidence of indentation of keratinocytes beneath the growing hyphae, possibly resulting from enzymic action [2].

Penetration

It is widely accepted that dermatophytes are keratinophilic. Evidence for this ranges from the success of hair-baiting techniques for isolating the fungi from the soil, to the ability of many dermatophytes to invade hair and nail *in vitro*, and the presence of evidence of damage around penetrating hyphae in nail, suggesting digestion of keratin. However, many workers have been unable to demonstrate enzymes produced by dermatophytes with keratin-specific proteinase activity [3]. *In vitro*, non-keratin substances extracted from keratinized tissues will support growth of dermatophytes much better than the keratin, which remains after extraction [4]. Dermatophytes produce a variety of proteolytic enzymes, which range in size from 40 to over 200 kDa [5]. There is evidence in *T. mentagrophytes* that both a cell-free and a membrane-bound keratinase are present [6]. One group of workers has demonstrated that keratinase activity from certain dermatophytes is inducible by low-molecular-weight peptides released from the epidermis by the action of other fungal proteinases [7]. From this it can be seen that the precise part that keratin-specific enzymes play in fungal invasion of the stratum corneum is not entirely clear, and that other proteinases and even mechanical forces caused by hyphal growth may have a role. Clinically, there appears to be a certain amount of heterogeneity in substrate preference as, while all dermatophyte species invade the stratum corneum of the skin, different species vary widely in their capacity to invade hair and nail. *T. rubrum* rarely invades hair but frequently invades nail; *Epidermophyton floccosum* never invades hair and only occasionally nail. In addition, other factors, such as those concerned with host resistance (e.g. serum) have a role in limiting the ability of dermatophytes to penetrate further than the stratum corneum [8].

Host resistance and immunology

Defence against the fungi causing ringworm depends on both innate and acquired immune mechanisms [9], the latter requiring the intervention of immunological memory [10]. Serum factors appear to be able to inhibit the growth of dermatophytes *in vitro* and on cultured explants of skin. It is not entirely clear what is responsible for this, but unsaturated transferrin is one candidate, which inhibits the growth of dermatophytes by binding to the hyphae [11]. Its mode of action appears to be independent of iron-binding capacity. In experimental infections of skin grafted on to *nu/nu* mice, there is evidence of increased turnover of epidermis, which occurs in the absence of effective T-lymphocyte-mediated defence [12]. A further, potentially important mode of defence is provided by the presence of fatty acids from sebaceous glands, which inhibit dermatophyte growth *in vitro*. This activity appears to reside in saturated fatty acids with chain lengths of 7, 9, 11 and 13 carbon residues. It has been postulated that their presence on the skin in postpubertal children may account for the spontaneous resolution of tinea capitis after this age, and the rarity of new infections in adults. Undecenoic acid derivatives are a practical example where fatty acids have been used for the treatment of dermatophytosis. Whatever the influence of these factors, it is clear that in experimentally infected mice the initial inflammatory changes occur as early in the process as 4 h after infection. This suggests that endogenous mechanisms may attract leukocytes [13], and the role of inflammatory mediators, such as the eicosanoids, in this respect needs to be investigated.

It has also been found that dermatophytes are chemotactic and that they can activate the alternative pathway of complement activation. This has been demonstrated for *T. rubrum*, *T. mentagrophytes* [13] and fungi causing endothrix scalp infections, such as *T. violaceum*. The production of cytokines, such as interleukin-1 (IL-1), by keratinocytes has not been investigated in the mobilization of neutrophil defences. It has been shown that neutrophils, and to a lesser extent monocytes, can kill dermatophyte conidia [14]. This activity depends both on intra- and extracellular mechanisms, and the generation of the respiratory burst is an important stage in this process [15]. Dermatophytes produce catalase and superoxide dismu-

tase, which may act as defences against the phagocyte myeloperoxidase system.

By contrast, there is little evidence that antibodies to dermatophytes are protective. Patients with widespread infections, such as tinea imbricata, may have high antibody titres [16]. The presence of elevated IgE in particular is associated with chronicity (see below) [17]. Transfer of specific serum containing a high titre of antibody to irradiated mice does not confer immunity on recipients. It is still premature to rule out a role for antibody, as dermatophytes show some cytological changes when grown in the presence of specific antibody *in vitro*. However, there is strong evidence that the development of cellular immunity via sensitized T lymphocytes is a key factor in immunological defence. Lymphocytes bearing T-helper phenotypic markers are responsible for transferring immunity to infection to naïve recipient mice [18]. In humans, the appearance of inflammation in ringworm correlates with the development of delayed-type skin reactivity to trichophytin [19–21] and cytokines such as interferon-γ. Chronic infections are associated with poor T-lymphocyte-mediated response to specific fungal antigens, suggesting that depression of responses is responsible for the poor clinical response [19,22]. Langerhans' cells can act as antigen-presenting cells for dermatophyte antigens [23].

The reason for failure of immunity in persistent infections, and its relationship with chronicity, are still not well understood. There is an association between the presence of atopy and chronic dermatophytosis, with a high proportion of those with persistent disease having atopy (usually asthma or hay fever) as well as immediate-type hypersensitivity and raised IgE levels [19,22]. It has been suggested that modulation of T-lymphocyte activity either locally or systemically may be responsible. Possible mechanisms include activation of a type 2 helper T (Th2) lymphocyte pathway, which might explain the spectrum of antibody responses. It has also been found that dermatophyte antigens, including those that contain mannose residues, can reversibly suppress lymphocyte proliferation, but not the expression of human leukocyte antigen (HLA)-DR [24]. Patients with persistent infection have detectable levels of circulating antigen [25]. Both are possible factors in the regulation of immunity in dermatophytosis.

Patients with dermatophytosis are usually otherwise healthy. However, altered or chronic infections have been noted in a number of patient groups, such as those with chronic mucocutaneous candidosis, AIDS [26] and patients on corticosteroid therapy or with endogenous Cushing's syndrome. In addition to these, there is the raised incidence of atopy in those with chronic infection, suggesting that host factors may well determine the clinical course. However, this is not the only factor, and it has been found that where there is ample facility for the spread of infection (e.g. among coalminers), the incidence of atopy is no different to that seen in uninfected co-workers [27].

Other factors affecting infection

Age, sex, genetic and racial factors

The known differences in the incidence of ringworm infection between the age groups and sexes seem, in general, to reflect differing rates of exposure and of sebum production, differing clothing and fluctuations of immunity with old age. What little evidence there is does not support the suggestion that susceptibility to ringworm infection is linked to any of the ABO blood groups. There may be racial differences of susceptibility, but they are not clearly established [28]. In tinea imbricata, a genetic susceptibility factor inherited as an autosomal recessive has been suggested [29]. It has also been suggested that a genetically determined factor(s) may be wholly or partly responsible for family clusters of cases of infection [30]. The definitive proof awaits the demonstration of appropriate genetic abnormalities by linkage studies.

Endocrine and metabolic factors

There is no reliable evidence that diabetic patients are especially susceptible to dermatophyte infection [31], even though diabetes may affect the course of established infections; for example, diabetic patients with tinea pedis are more likely to develop onychomycosis. In malnutrition and in Cushing's syndrome, the apparently diminished resistance to infection may well have followed depressed cellular immunity.

Temperature and microenvironment

With the exception of *T. verrucosum*, dermatophytes grow poorly at 37°C. This factor alone may be responsible for the lack of deeper penetration of the epidermis and dermis. Raised carbon dioxide tension is known to facilitate arthroconidial formation, and may also aid either adhesion or penetration [32]. Moisture is also important for germination of arthroconidia on keratinocytes.

Competing organisms and co-pathogens

The ability of certain dermatophyte species to produce penicillin-like antibiotics may allow these fungi to regulate the bacterial flora [33]. Although there is some competitive interaction [34], *Staphylococcus aureus* may occasionally act as a co-pathogen, increasing the degree of inflammation in dermatophyte infections [34].

Histopathology

The clinical appearances of the various forms of ringworm infection are the result of the combination of direct damage to the keratinized tissues by the fungus (this

applies mainly in hair and nail infections), and of the inflammatory host response. The latter varies widely. At one extreme there is the simple hyperkeratosis seen, for instance, in dry-type *T. rubrum* infections; at the other is the pustular, highly inflammatory kerion seen most frequently in zoophilic infections, such as those caused by *T. verrucosum*. This subject has been extensively reviewed [35]. *T. rubrum*, for instance, may provoke the epidermal changes seen in chronic dermatitis with hyperkeratosis, patchy parakeratosis, hyper- or hypogranulosis, spongiosis, mononuclear invasion, and mild or moderate acanthosis. The accompanying dermal infiltrate of lymphocytes and histiocytes is largely perivascular. The picture may be more inflammatory with superficial crusting, and the more acute inflammatory changes in the epidermis may at times become vesicular, to the extent of mimicking acute contact dermatitis. Other changes described include an erythema multiforme-like process with subepidermal bullae [35], and dermal blood-vessel changes of an allergic angiitis, accompanied by an infiltrate of lymphocytes, histiocytes, neutrophils and eosinophils. Another further histological pattern is a granuloma faciale type of reaction, in which the epidermis and the upper dermis are substantially normal, but the mid-dermis has an infiltrate of neutrophils, eosinophils, lymphocytes, histiocytes and plasma cells in close proximity to dilated blood vessels.

Pustular reactions may be subcorneal or follicular. The folliculitis and perifolliculitis are normally associated with fungal remnants in the follicles. Inflammatory changes range from spongiosis of the outer root sheath, to deep perifollicular granulomatous inflammation showing areas of necrosis and foreign-body giant cells, perhaps induced by fragments of hair exuded from disrupted follicles. In cases of kerion, the histology is that of a combined subacute dermatitis and a marked folliculitis, with disrupted follicles and a diffuse granulomatous inflammatory response with many foreign-body giant cells, blood-vessel changes and fibrosis [35].

In classical annular ringworm, the rim of the lesion is marked by clear inflammatory changes including a perivascular infiltrate of lymphocytes. By contrast, in the central zone inflammation is usually less, possibly following elimination of the fungus in the stratum corneum. For reasons that are not entirely clear but that may depend on the persistence of immunological surveillance [10], previously infected skin remains free of fungal hyphae compared with uninfected, and fungal growth proceeds centrifugally. The epidermal turnover rate is normal within the ring, but more than four times as rapid in the zone where inflammation is maximal. Central clearance is often partial and, in tinea imbricata caused by *T. concentricum*, successive waves of fungal growth occur in skin previously cleared of infection, but overall mycelial expansion is centrifugal.

Fig. 31.7 Tinea circinata: ringworm.

Clinical forms of ringworm infection

The clinical features of dermatophyte infections result from a combination of keratin destruction and an inflammatory host response. The wide variation in clinical presentation depends upon the species and probably the strain of the fungus concerned, upon the size of the inoculum, upon the site of the body infected and upon the immune status of the host. In the following sections, the traditional division of ringworm into different syndromes according to the site of the body infected is followed because it is of considerable merit in terms of diagnosis and management.

Tinea corporis

SYN. RINGWORM OF THE BODY; TINEA CIRCINATA

Definition. Ringworm of the glabrous skin. The clinical manifestations result from invasion and proliferation of the causal fungi in the stratum corneum. Terminal hair in the affected parts may be invaded. By definition, it includes lesions of the trunk and limbs, excluding ringworm of specialized sites such as the scalp, feet and groins, which are considered below.

Species concerned. All known dermatophytes can produce lesions of the glabrous skin. A comprehensive list of causal species thus corresponds to a complete list of dermatophytes. For any part of the world, the causes of tinea corporis can be assessed by reference to the prevailing dermatophyte flora in the region [1–3]. Some species have predilections for particular parts of the body; for example, *M. audouinii*, classically a cause of tinea capitis, and *T. rubrum*, which usually causes tinea pedis, but these can and on many occasions do cause tinea corporis [4,5].

Pathogenesis. Natural infection is acquired by the deposition of viable arthrospores or hyphae on the surface of the susceptible individual. The source of infection is usually an active lesion on an animal or on another human, although fomite transmission is known to occur, and infection from soil is a well-established if unusual occurrence. In young children infected with *T. rubrum* and *E. floccosum*, half of the infections may come from their parents. In geriatric wards, epidemics may occur [1]. Spread from existing localized infection (e.g. feet, groins, scalp and nails) is not uncommon. Invasion of the skin at the site of infection is followed by centrifugal spread through the horny layer of the epidermis. After this period of establishment (incubation), which lasts 1–3 weeks, the tissue responses to infection become evident. The characteristic annular appearance of many ringworm infections results from the elimination of the fungus from the centre of the lesion, and the subsequent resolution of the inflammatory host response at that site. This area usually becomes resistant to reinfection, although a second wave of centrifugal spread from the original site may occur with the formation of concentric erythematous inflammatory rings. However, many lesions lack any tendency to central clearing. The natural history is very variable. Some inflammatory cases of animal infection resolve spontaneously in a few months, while a typical case of *T. rubrum* tinea corporis may persist for years.

Clinical features. The site of infection is typically on exposed skin, unless the infection represents an extension from a pre-existing infection. In such cases, infection may spread from the scalp, down the neck on to the upper trunk, or from the groins on to the buttocks and lower trunk. Characteristic lesions are circular, usually sharply marginated with a raised edge (Fig. 31.7). Single lesions occur, or there may be multiple plaques. The latter may remain discrete or become confluent. This clinical pattern is often modified in patients with defects in cellular immune responses [6]. The degree of inflammation is very variable. This feature depends not only on the species of the fungus and the immune status of the host, but it is also very roughly proportional to the extent of follicular invasion; thus, tinea corporis is generally less inflammatory

than tinea capitis or tinea barbae. In inflammatory lesions, pustules or vesicles may dominate and even in quiet infections close observation may reveal one or two small pustules. Rarely, frank bullae have been reported as an extreme expression of inflammatory change. In quieter infections, scaling is a common but not constant finding. Central resolution, which, as has already been stated, is a common but not invariable feature of tinea corporis, is perhaps more frequent in inflammatory lesions, but it is by no means confined to them. The process is often incomplete, and the central skin may show postinflammatory pigmentation, a change of texture or residual erythematous dermal nodules.

Special forms and species variations. Lesions of the glabrous skin caused by *M. canis* are not rare. They are as common in adults as in children, and are characteristically annular. *M. audouinii* produces short-lived lesions of tinea corporis in perhaps one-third of cases of scalp infection [7]. *T. equinum* from horses also gives plaques of tinea corporis but, although this may be a fairly common infection among those who work with these animals, the lack of a severe inflammatory response and a tendency to early spontaneous regression explain its rarity in patients attending skin clinics. *T. verrucosum* from cattle, *T. mentagrophytes* var. *erinacei* from hedgehogs, *T. mentagrophytes* var. *mentagrophytes* from small rodents in general and *M. persicolor* from voles are all likely to cause inflammatory lesions of exposed skin. Although classically a cause of kerion, *T. verrucosum* can lead to extensive annular lesions of the upper trunk, especially in children [8]. These often start around the neck.

The ubiquitous anthropophilic species *T. rubrum* may invade the buttocks and lower back, as well as more distant sites of the trunk as an extension from tinea cruris. Similar patterns are seen occasionally with *E. floccosum* and *T. megninii*. In infants, ringworm is rare, but the moist conditions of the napkin area may predispose to *E. floccosum* or *T. rubrum* infections [1].

Tinea corporis resulting from *T. rubrum* is often particularly extensive, and the inflammatory margin difficult to distinguish [9]. On the legs and usually extending from the feet, *T. rubrum* may cause typical lesions with raised margins, but rather psoriasiform lichenified plaques without central clearing may also occur, and a variety of vasculitis-like lesions are recognized. The perifollicular granulomatous papules of the Majocchi type are classical (Fig. 31.8) [10,11], but erythema induratum-like plaques sometimes occur with an almost haemorrhagic appearance.

Tinea imbricata (Tokelau) [12] resulting from *T. concentricum*, an anthropophilic dermatophyte found in southern Asia, the islands of the South Pacific and in Guatemala, southern Mexico and Brazil, causes a distinctive infection. It seems to affect mainly the native peoples

Fig. 31.8 Nodular folliculitis caused by *Trichophyton rubrum*.

of these areas, and although susceptibility may be inherited as an autosomal recessive character [13], it occurs in both sexes and at all ages. Occasional cases may be seen elsewhere in travellers from these regions [14]. The infection begins as a scaling ring; centrifugal spread follows, but within the area of central clearing a second wave of scaling soon arises. The process is repeated to give numerous concentric rings (Fig. 31.9) and, as the natural history is normally extremely prolonged, the whole body may become affected. Pruritus is intense and may lead to lichenification. Hypopigmentation may accompany the lesions [15].

Atypical deep forms of tinea corporis occur. There are some reports of extensive and persistent cases of tinea corporis, in which dermal or subcutaneous involvement has been a feature [16,17]. Occasionally, a specific defect of immune function has been detected, such as a missing plasma factor. In other patients, depression of cellular immune responses is associated with the presence of a serum factor, possibly circulating antigen or immune complexes [6,18]. Such cases may present with dermal nodules, abscesses or draining sinuses [19]. A few particularly bizarre dermatophyte infections with invasion of bone, central nervous system and lymph nodes have been reported [16,20], but no satisfactory explanation for the highly unusual behaviour of otherwise superficial pathogens is as yet forthcoming.

Fig. 31.9 Tinea imbricata affecting the upper arm.

Differential diagnosis. Although tinea corporis can masquerade as any of a vast number of skin diseases, in practice the diagnosis is usually straightforward.

The characteristic lesions seen with infection resulting from *M. canis* are easily diagnosed, but atypical infections caused by the more exotic fungi and by *T. rubrum* can, on occasions, cause great difficulty. Indeed, the possibility that any red scaly rash on the body is a fungus infection should be considered, because the lesions produced by fungi are so curiously variable. Seborrhoeic dermatitis often causes difficulty, but the condition is symmetrical and there is often associated seborrhoeic dermatitis of the scalp and perhaps intertrigo in the body folds. Psoriasis can lead to confusion in those cases in which the distribution is not quite typical. Its presence on the knees, elbows and scalp, and associated psoriasis of the nails, particularly if pitting is present, is helpful. Patches of impetigo are often confused, particularly when of the circinate type. The finding of staphylococci on a skin swab does not, of course, exclude tinea. Lichenification of a patch of tinea (e.g. of the leg) can mimic lichen simplex very closely. Nummular eczema is a common source of error. The plaques of papulovesicles tend to occur symmetrically on the limbs. Pityriasis rosea is also symmetrical and characteristically confined to the trunk and proximal parts of the limbs, but the herald patch, if seen, is almost impossible to differentiate from ringworm without microscopic examination of scales. Candidosis, tertiary syphilis and pityriasis versicolor should be excluded.

Tinea capitis

SYN. RINGWORM OF THE SCALP; TINEA TONSURANS

Definition. Ringworm of the scalp in which the essential feature is invasion of hair shafts by a dermatophyte fungus. Ringworm of the beard area, although essentially similar, is discussed separately. Tinea capitis is predominantly an infection of children, although adult cases are seen particularly with *T. tonsurans* infections. Tinea capitis may also be seen in adults with AIDS.

Species concerned. Most species of dermatophyte are capable of invading hair but some species (e.g. *M. audouinii*, *T. schoenleinii* and *T. violaceum*) have a distinct predilection for the hair shaft. *E. floccosum*, *T. concentricum* and *T. mentagrophytes* var. *interdigitale* are exceptional in apparently never causing tinea capitis. All dermatophytes causing scalp ringworm can invade glabrous skin and

many attack nails as well. Those species of dermatophyte fungi most likely to be causing tinea capitis vary from country to country and from region to region [1–5]. Moreover, in any given location, the species may change with time, particularly as new organisms are introduced by immigration [6,7]. It is of interest that in tinea capitis anthropophilic species predominate.

The principal feature of tinea capitis in recent years has been the rise of *M. canis* as the dominant organism in infections in some parts of Europe [4], and the spread of *T. tonsurans* in urban communities in the USA [3]. A similar rise in the prevalence of *T. tonsurans* has recently been recorded in urban areas of the UK [8,9] and in some other European countries.

Pathogenesis. The principles of hair invasion and the distinctions between *in vitro* and *in vivo* activity have been already outlined. The spores of ringworm fungi causing tinea capitis can be demonstrated in the air in close proximity to patients with the condition. It is highly likely that scalp hair acts as a trapping device, and it is known that contamination of hair without demonstrable clinical findings may occur among classmates of children with tinea capitis [10,11]. From the classical experimental work of Kligman [12,13] on *M. audouinii*, it is clear that if actual hair infection is to occur, invasion of the stratum corneum of the scalp skin must first develop. Trauma assists inoculation, which is followed, after approximately 3 weeks, by clinical evidence of hair shaft infection. Spread to other follicles proceeds, then for a period of variable duration the infection persists but does not spread further. Finally, there is a period of regression with or without an inflammatory phase.

There are several distinct types of hair invasion that are worthy of note.

Microsporum type. This may be a small-spored ectothrix caused by *M. audouinii*, *M. audouinii* var. *rivalieri*, *M. canis*, *M. canis* var. *distortum*, *M. equinum* or *M. ferrugineum*. In this type, the hair shaft is invaded in mid-follicle. The intrapilary hyphae continue to grow inwards towards the bulb of the hair. Secondary extrapilary hyphae burst out and grow in a tortuous manner over the surface of the hair shaft, which is growing outwards continuously. These secondary extrapilary hyphae segment to produce a mass of small arthroconidia (2–3 μm diameter), each one of which becomes rounded off and eventually spherical. The size of these conidia is such that they cannot easily be distinguished as separate structures under the low power of the microscope. Fluorescence under the Wood's lamp is characteristically present in this type of hair invasion.

A similar type of hair invasion occurs with other *Microsporum* species (e.g. *M. gypseum*, *M. fulvum*, *M. nanum* and *M. vanbreuseghemii*). The spores, although similarly arranged, are larger, in this case about 5–8 μm. Fluorescence has been reported in some cases.

Trichophyton types. These may be large-spored ectothrix (in chains) caused by *T. verrucosum*, *T. mentagrophytes* var. *mentagrophytes*, *T. mentagrophytes* var. *erinacei*, *T. megninii* or *T. rubrum* (rarely). The arthroconidia are spherical, arranged in straight chains and again confined to the external surface of the hair shaft. They apparently arise from straight primary extrapilary hyphae, rather than from the hyphae inside the hair. Although size varies with species, up to 10 μm in the case of *T. verrucosum*, they are all larger than those seen in small-spored ectothrix *Microsporum* infection, and individually distinctly visible under the low power of the microscope. There is no fluorescence.

The endothrix type may be caused by *T. tonsurans*, *T. soudanense*, *T. violaceum*, *T. yaoundei*, *T. gourvilii* or *T. rubrum* (rare). Intrapilary hyphae fragment into arthroconidia up to 8 μm in diameter, which are entirely contained within and completely fill the hair shaft. Hair thus affected is especially fragile, and breaks off close to the scalp surface. This type is non-fluorescent.

The favic type is caused by *T. schoenleinii*. Broad, regularly septate hyphae and air spaces are seen in the hair shaft, but disarticulated arthroconidia are absent. The affected hair is less damaged than in other types, and may continue to grow to considerable lengths. Greenish grey fluorescence is present [14]. Air spaces are characteristic and fungal hyphae form clusters in the vicinity of hair follicles.

Clinical features. The clinical appearance of ringworm of the scalp is most variable, depending on the type of hair invasion, the level of host resistance and the degree of inflammatory host response [15,16]. The appearance therefore may vary from a few dull grey, broken-off hairs with a little scaling, detectable only on careful inspection, to a severe painful inflammatory mass covering most of the scalp. Itching is variable. In all types, the cardinal features are partial hair loss with inflammation of some degree (Fig. 31.10). It is useful to recognize several basic clinical pictures, as described below.

Small-spored ectothrix type. In *M. audouinii* [1] and *M. ferrugineum* infections, the basic lesions are patches of partial alopecia, often circular in shape, but showing numerous broken-off hairs, dull grey from their coating of arthrospores. Inflammation is minimal, but fine scaling is characteristic, usually with a fairly sharp margin. There may be several or many such patches arranged more or less randomly. In *M. canis* and in the much rarer *M. canis* var. *distortum* infections, the picture is similar but there is typically more inflammatory change. In infections caused by all these species, green fluorescence under the Wood's

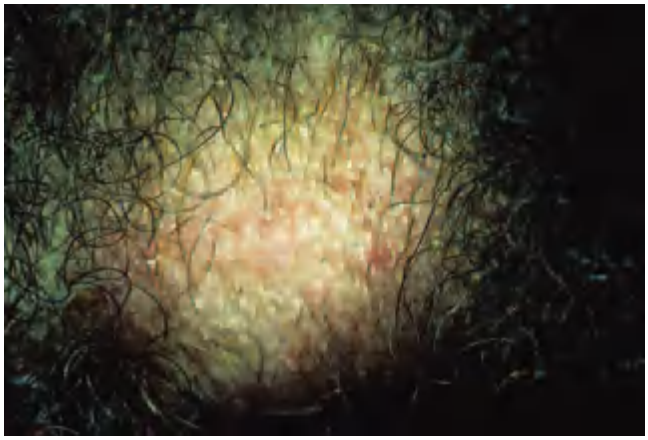

Fig. 31.10 Tinea capitis caused by *Microsporum canis*.

lamp is usual, but occasional non-fluorescent cases have been reported, and may not be rare with *M. ferrugineum* (perhaps as many as 10%) [17]. Children are affected much more frequently than adults, although the occasional case of tinea capitis in older patients must not be forgotten [18,19]. The attack rate for epidemic infections caused by anthropophilic species may be as high as 30%, within a school class for example, but it is commonly lower than that [20]. In the past, infection rates of both *M. audouinii* and *M. canis* have been higher in boys than girls [1], often at least twice as high.

Kerion. The most severe pattern of reaction is known as a kerion. It is a painful inflammatory mass in which such hairs as remain are loose. Follicles may be seen discharging pus, there may be sinus formation, and on rare occasions mycetoma-like grains may be found [21]. Thick crusting with matting of adjacent hairs is common. The area affected may be limited, but multiple plaques are not rare, and occasionally a large confluent lesion may involve much of the scalp. Lymphadenopathy is frequent. Although this violent reaction is usually caused by one of the zoophilic species, typically *T. verrucosum* or *T. mentagrophytes* var. *mentagrophytes*, occasionally a geophilic organism will be isolated, and anthropophilic infections that have been smouldering quietly for weeks may suddenly become inflammatory and develop into kerions if a high degree of hypersensitivity develops [22]. The possibility that a bacterial co-pathogen may be playing some part should not be ignored, and in this type of case a swab sent to the bacterial laboratory is a useful procedure in addition to the plucking of hairs for mycology. Generally, however, pustule formation represents an inflammatory response to the fungus itself [23].

Agminate folliculitis, a somewhat less severe inflammatory ringworm of the scalp consisting of sharply defined, dull red plaques studded with follicular pustules, is also seen in zoophilic infections.

Endothrix infections. In *T. tonsurans* [20,24,25] and *T. violaceum* [25,26] infections, a relatively non-inflammatory type of patchy baldness occurs. Formation of black dots (swollen hair shafts) as the affected hair breaks at the surface of the scalp is classical in this condition, but such findings may be inconspicuous [27]. The patches, which are usually multiple, may show minimal scaling, sometimes mimicking discoid lupus erythematosus, sometimes seborrhoeic dermatitis [28,29]. They are commonly angular in outline rather than round. Other forms include the diffuse and patchy alopecia, even with involvement of single isolated hair shafts and without scales. A low-grade folliculitis is often seen, while sometimes a frank kerion may develop. The three African species, *T. soudanense*, *T. yaoundei* and *T. gourvilii*, induce very similar lesions, in which the inflammatory reaction is usually mild but occasionally violent. Approximately 2 or 3% of patients have some nail involvement [30,31] or lesions on the face.

Favus. Infection with *T. schoenleinii* is seen sporadically in a variety of countries, such as South Africa [32], Ethiopia, where it is still endemic, as well as the Middle East, Pakistan, USA, Canada, the UK and Australia. The classical picture of tinea capitis caused by this organism is characterized by the presence of yellowish cup-shaped crusts known as scutula [33]. Each scutulum develops round a hair, which pierces it centrally. Adjacent crusts enlarge to become confluent and form a mass of yellow crusting. Many patients may show less distinctive changes, in early cases perhaps amounting to no more than perifollicular redness and some matting of the hair. Extensive patchy hair loss with cicatricial alopecia and atrophy among patches of normal hair may be found in long-standing cases, where much of the hair loss is irreversible. In such patients, the glabrous skin is commonly affected by the development of similar yellowish crusts. Although the initial infection is probably a childhood event in nearly all cases, it shows little if any tendency to clear spontaneously at puberty, particularly in women. Families with several generations affected are well recognized [14].

Differential diagnosis. The differential diagnosis of tinea capitis includes all conditions capable of causing patchy baldness with inflammatory changes of the scalp. Alopecia areata may show erythema and, although of itself it is not a scaly condition, it may coexist with seborrhoeic dermatitis. Such cases can be confusing, although careful examination usually shows that the scaling and the hair loss are not co-extensive. Exclamation-mark hairs must be distinguished from broken hairs of tinea capitis. Traumatic alopecia from hairdressing procedures and trichotillomania may also be confused [34]. Seborrhoeic dermatitis is usually more diffuse than tinea capitis, but in tinea amiantacea the changes are often localized. In this

condition, the scaling is adherent to the hair, but breakage of the hair shaft does not normally occur. In psoriasis, hair loss is found only occasionally, and again broken-off hairs are not usually present.

In impetigo, which may be secondary to pediculosis of the scalp, loosening of the hair is not normally present, but matting and crusting may cause confusion with inflammatory ringworm. A carbuncle of the scalp is much more acutely painful, and shedding of loosened hairs much less evident than in kerion. Discoid lupus erythematosus, lichen planus and other causes of cicatricial alopecia may sometimes have to be considered.

Control [35,36]. It is of considerable importance with scalp ringworm to discover the species involved. Clearly, some information may be obtained from the clinical picture, the presence or absence of fluorescence, etc., but culture is required for this to be firmly established. Where animal species are concerned, the source should be proved mycologically; it is not always the expected one. The course of action to be taken clearly depends upon the situation and the value placed upon the animal. A small much-loved domestic pet can often be treated successfully and economically with griseofulvin. Cattle ringworm in calves will normally settle spontaneously. A group of highly infected laboratory mice should probably be destroyed.

With anthropophilic infections, careful investigation of the outbreak or epidemic is recommended, and exclusion of children from school is not recommended [37]. It may also be resented by the parents and lead to non-compliance with treatment. With zoophilic infections such as *M. canis* ringworm, children can normally be allowed to remain at school as infectivity from human to human is small. The main treatments in all these conditions are terbinafine or griseofulvin. Topical therapy has little place, although it is sensible to remove matted crusts and to follow a routine of frequent shampooing.

Tinea barbae

SYN. RINGWORM OF THE BEARD

Definition. Ringworm of the beard and moustache areas of the face with invasion of coarse hairs. It is thus a disease of the adult male. Tinea of the chin and upper lip in females and children are considered as tinea faciei (ringworm of the glabrous skin of the face).

Species concerned. The animal species *T. verrucosum* and *T. mentagrophytes* var. *mentagrophytes* are responsible for

the great majority of cases [1]. *M. canis* is an uncommon cause (eyelashes may be affected in some cases) as is *T. mentagrophytes* var. *erinacei*. The anthropophilic species, *T. violaceum*, *T. schoenleinii*, *T. megninii* and *T. rubrum* [2] are recognized as occasional causes.

Pathogenesis. Although tinea barbae has attracted fewer investigations than tinea capitis, all the available clinical evidence points to a similar pathogenesis. Infections with *T. verrucosum* and *T. mentagrophytes* var. *mentagrophytes* lead to large-spored ectothrix invasion with the spores in chains. The other less commonly involved species produce their own characteristic type of hair invasion.

Clinical features. The affected men are commonly farm workers in cases caused by the two main species, *T. mentagrophytes* var. *mentagrophytes* and *T. verrucosum*. The clinical picture in these is that of a highly inflammatory pustular folliculitis, often showing all the features of a kerion. Hairs of the beard or moustache regions are surrounded by red inflammatory papules or pustules, usually with exudation or crusting. Many hairs within the affected areas are loose and easily removed with the forceps without causing pain. These inflammatory lesions, although tending eventually to settle spontaneously, often persist for some months. A little irritation is commonly present, and at times pain, but this latter symptom is less marked than might be expected from the clinical signs. Some infections are less severe and consist of dry circular reddish scaly lesions enclosing lustreless hair stumps which are either broken off close to the surface of the skin or plug the follicles.

Differential diagnosis. The classical, highly inflammatory lesions are distinguished from boils by their relative lack of pain. Loosened hairs, although present in some bacterial infections, are rarely as obvious as they are in tinea barbae. The quieter cases of tinea must be distinguished from bacterial folliculitis, acne, rosacea and pseudofolliculitis. The presence of *Staphylococcus aureus* on a swab taken from lesions in this area does not exclude ringworm, as bacterial colonization or frank co-infection may occur in tinea barbae. Unfortunately, mycological cultures are often negative.

Control. Cases of tinea barbae are likely to continue to occur sporadically until more satisfactory means of controlling ringworm in cattle are found. Early diagnosis and prompt treatment of the individual patient and the encouragement of high standards of hygiene in the livestock industry are as much as can be expected in the present state of knowledge. A vaccine against *T. verrucosum* in cattle has resulted in a reduced incidence of infection, not only in cows but also among their human contacts in some countries in eastern Europe [3].

Tinea faciei

SYN. RINGWORM OF THE FACE; TINEA FACIALE

Definition. Infection of the glabrous skin of the face with a dermatophyte fungus (the moustache and beard areas of the adult male are excluded).

Species concerned. *T. mentagrophytes* var. *mentagrophytes* and *T. rubrum* predominate but *M. audouinii* and *M. canis* are also common causes worldwide. *T. concentricum* frequently spreads to the face in cases of tinea imbricata and, as with tinea corporis, all dermatophytes must be considered potentially capable of producing this condition.

Pathogenesis. Facial skin may be infected either by direct inoculation of a dermatophyte fungus from an external source (e.g. *T. mentagrophytes* var. *mentagrophytes* from an infected pet mouse) or there may be secondary spread from pre-existing tinea of another body site. The latter pattern is likely to occur with *T. rubrum* as well as with *T. concentricum* infections.

Clinical features. The prime reason for separating tinea faciei from tinea corporis in this account is to draw attention to the frequency of misdiagnosis in facial ringworm [1]. The clinical features vary considerably, but complaints of itching, burning and exacerbation after sun exposure are common. The last mentioned symptom is a frequent source of diagnostic error [2]. There will often be a history of exposure to animals. Erythema is usual, but scaling is present in fewer than two-thirds of cases. A substantial proportion of patients do show annular or circinate lesions, and induration with a raised margin is present in about half (Fig. 31.11). Simple papular lesions, and in some cases completely flat patches of erythema, also occur. A few vesicles or pustules may be found, but these are rarely conspicuous. The application of topical steroids may be expected to modify the appearance still further, and in the authors' experience this complication is as frequent among patients with tinea faciei as it is in those with tinea cruris.

Differential diagnosis. Because of light sensitivity, the frequent absence of scaling and the somewhat nondescript appearance, this condition may be confused with discoid lupus erythematosus (DLE) [1] and polymorphic light eruption. Moreover, tinea faciei coexisting with DLE has

Fig. 31.11 Tinea faciei caused by *Trichophyton rubrum*.

been described [3]. Bowenoid solar keratoses, psoriasis, impetigo, rosacea, seborrhoeic dermatitis [4] and benign lymphocytic infiltrates must also be considered. Reluctance to biopsy the face adds to the problem, but if the possibility of tinea faciei is remembered, careful examination and scrapings taken from the skin surface, even if this is not obviously scaly, should enable a diagnosis to be made. General examination of the skin, particularly the scalp, should not be forgotten. If topical steroids have been applied, a cessation of the therapy may be followed a few days later by a great increase in scaling and by appearances much more readily diagnosable.

Control. Pets and laboratory animals may require treatment or elimination according to their value. It is customary to give short-term oral antifungal treatment, but the authors have seen minimal lesions respond well to topical imidazoles. Long-standing steroid-modified cases, especially those resulting from *T. rubrum*, may require prolonged oral antifungal therapy.

Tinea pedis

SYN. FOOT RINGWORM; ATHLETE'S FOOT

Definition. Infection of the feet or toes with a dermatophyte fungus. The term athlete's foot is used by some to imply any form of toe cleft intertrigo. In this account, we therefore prefer the terms tinea pedis or foot ringworm, which clearly exclude infections caused by bacteria, *Candida* and non-dermatophyte moulds.

Species concerned. Three anthropophilic species, *T. rubrum*, *T. mentagrophytes* var. *interdigitale* and *E. floccosum*, are together responsible for the vast majority of cases of foot ringworm throughout the world. Double infections with any two of these species occur and, for precision, especially in clinical surveys, it is useful to adopt a standard terminology to describe them. Combined infections are those in which different species are present in the same lesion. Concurrent infections are those in which different species are found in different lesions at the same time, and consecutive infections are those in which the same patient has a different organism at the single site on different occasions. Other species, including zoophilic ones, occur occasionally as a cause of tinea pedis. In countries where *T. violaceum* is common, foot involvement with this anthropophilic species is sometimes seen and may be very intractable [1]. The relative numerical importance of the three main species of dermatophyte can be discovered from the extensive published data on foot ringworm seen in dermatological clinics throughout the world. Although minor variations are frequent, an average clinic sample would be: *T. rubrum* infections, 60%; *T. mentagrophytes* var. *interdigitale* infections, 25%; *E. floccosum* infections, less than 10%; mixed infections, 5%. The prevalence of *T. rubrum* infections has been growing over several decades [2]. Prior to 1970, in surveys of populations consisting of subjects in institutions, coal mines [3] or swimming baths [4], the relative frequency of infections with *T. mentagrophytes* var. *interdigitale* was higher than those caused by *T. rubrum*. *T. mentagrophytes* var. *interdigitale* would outnumber *T. rubrum* by as much as eight to one [5,6]. Since 1980, surveys in industry have indicated that this pattern is changing, with over 60% of isolates being *T. rubrum*. A high proportion of patients also have Gram-negative bacterial infection of the web spaces [7,8].

Pathogenesis. Tinea pedis is the most common form of dermatophyte infection in the UK and North America [9], and probably throughout the developed world. Occlusion of toe clefts through wearing shoes predisposes to this condition, which is in most cases initially a lateral web space infection. The condition is more common in adults than children, but may begin to occur in young children aged 6 or more. The mean age of onset was 15 years in one survey [10]. Overall prevalence within the community and including all age groups is not reliably known, but extrapolation from the most useful surveys [4,10] suggests that in the developed world at any one time as many as 10% of the total population may be expected to have dermatophyte infections of the toe clefts. Adult males probably have about a 20% chance of developing tinea pedis, while among women only 5% are likely to become chronically infected. Living in an institution, especially where washing facilities are shared, is likely to increase the chances of infection [10,11]. Prevalence figures as high

as 80% have been reported among German miners, and in some wards of a long-stay hospital more than two-thirds of the patients were infected [11]. Nevertheless, tinea pedis may be equally well transmitted within the family bathroom [12]. Among dermatological outpatients with *T. rubrum* infections there is a significant excess of atopics [13], but in a study of coalminers with recurrent *T. rubrum* tinea pedis this was not so [14], suggesting perhaps that reinfection from the environment is important in their case.

Experimental evidence [15] suggests the importance of maceration in dermatophyte infections of the toe clefts. These moist conditions probably favour growth of the fungus directly, and damage the stratum corneum at the same time. A simultaneous increase in the bacterial flora is likely and may also play a part. There is growing evidence that during some symptomatic episodes in chronic tinea pedis, resident bacteria, such as large-colony coryneforms, may be acting as important co-pathogens, but whether or not they assist in initiating new infections remains, so far, unknown [16].

Although dermatophytes are occasionally isolated from clinically normal toe clefts, and a contrary situation exists in which mildly abnormal toe clefts yield no dermatophytes, it is now generally held that where dermatophytes are present (in perhaps 10% of the population) they do cause abnormalities, and are not in the true sense members of the normal skin flora. The sex differences in the level of tinea pedis may be partly explained by different exposure to the causal fungi. In this context, in one survey the level of infection among men who attended swimming baths was higher than those that did not. In contrast, surveys at a swimming bath showed that the level of infection among girl swimmers was only one-quarter of that among boy swimmers [4]. However, further enquiry showed that the girls swam much less than the boys, so that there was, even in this instance, a true difference in exposure, although both groups went swimming. The sex difference in choice of footwear—men generally wearing more occlusive and heavier footwear throughout the year than women—is probably important and this correlates well with the known rarity of interdigital tinea pedis among those who habitually go barefoot [17].

Clinical features. The most common form of tinea pedis is an intertriginous dermatitis characterized by peeling, maceration and fissuring affecting the lateral toe clefts, and sometimes spreading to involve the undersurface of the toes. This picture may be produced by any of the three species. Itching is a common complaint in warm weather. The condition is highly persistent. In *T. rubrum* infections, a squamous hyperkeratotic variety, which is particularly chronic and resistant to treatment and which affects the soles, heels and sides of the feet, is often found. The affected areas are pink and covered with fine silvery white scales. If the foot is extensively involved, the term 'moccasin foot' or dry-type infection are sometimes applied (Fig. 31.12). The dorsal surfaces of the toes and feet are not often affected (Fig. 31.13), but associated nail infection is very common. If there is hyperhidrosis, the symptoms are more severe. This hyperhidrosis seems on occasions to be secondary to the presence of fungi, because it may improve if the fungus is successfully treated. As well as itching of the feet, the patient may also complain of their smell, and secondary bacterial infection, with fissuring in the toe clefts, may aggravate symptoms [16].

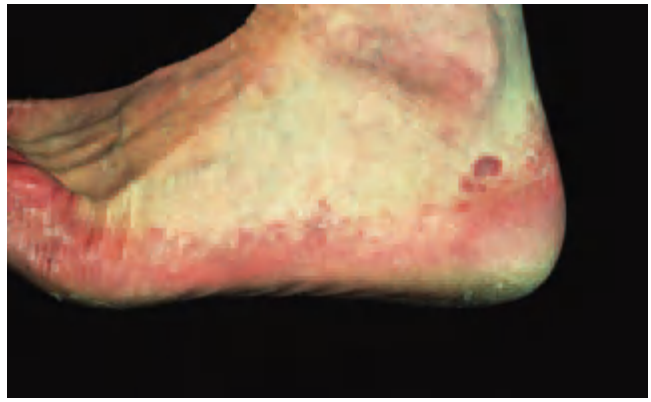

Fig. 31.12 Dry-type *Trichophyton rubrum* infection.

Fig. 31.13 Tinea pedis spreading to the dorsum of the foot.

The changes produced by *T. mentagrophytes* var. *interdigitale* vary from mild insignificant scaling in the toe clefts to severe acute inflammatory reactions affecting all parts of the feet [18]. A vesiculobullous reaction is more likely to be caused by this species than to any other fungus (Fig. 31.14). The reaction may occasionally extend over the whole sole. It may be preceded for months or years by maceration or fissuring in the toe clefts. Vesicles may become pustules, and when they rupture they tend to leave collarettes of scaling with the intervening skin normal, or showing various degrees of scaling and inflammation. This variety of ringworm frequently goes on to

Fig. 31.14 *Trichophyton mentagrophytes* var. *interdigitale* infection: bullous lesion on the sole.

apparent spontaneous cure, but tends to recur in warm weather; indeed, under hot humid conditions the inflammatory reaction may be extremely incapacitating. There is very often associated hyperhidrosis.

Apart from mild toe cleft intertrigo, *E. floccosum* may produce on occasions a vesicular infection of the sole similar to that typically produced by *T. mentagrophytes* var. *interdigitale*, or a dry hyperkeratotic condition resembling infections caused by *T. rubrum*. With *Epidermophyton* infections, there is significantly less toenail involvement than with *T. rubrum* or *T. mentagrophytes* var. *interdigitale*, but chronicity of the skin infection may be just as troublesome.

When the lesions on the feet are acutely vesicular, irrespective of the fungus responsible, a vesicular allergic reaction (ide) may develop on the uninfected hands. This clinical picture, which closely simulates pompholyx, was vastly overdiagnosed in the past but is now known to be quite uncommon, and an ide reaction of this type should not be considered unless the primary foot condition is acutely inflammatory.

Differential diagnosis. Where changes are largely restricted to the toe cleft, erythrasma, which is usually asymptomatic and rarely causes fissures, and candidosis, which is characterized by a build-up of rather more white macerated skin, must both be considered. Other bacterial infections with staphylococci or streptococci or Gram-negative organisms, including *Acinetobacter* species, can produce inflammation and often odour. Any of these organisms may coexist with tinea pedis, contributing to a greater or lesser extent to the abnormalities seen. Apart from swabs and scrapings for bacteria and ringworm organisms, the Wood's lamp, which may show pink fluorescence for erythrasma and a greenish blue for *Pseudomonas* infections, may be useful.

Soft corns or callosities, sometimes with sinus formation, are common in the lateral toe clefts, especially in women. Younger children do not commonly suffer from foot ringworm but frequently have eczema of the foot such as juvenile plantar dermatosis. Where the sole of the foot is affected without obvious involvement of the toe cleft, a diagnosis of pustular psoriasis must be considered. The latter condition more commonly affects the heels than does tinea, but this is not a reliable criterion. Psoriasis, pityriasis rubra pilaris, Reiter's syndrome, contact dermatitis from nylon dyes or shoe materials, and tylosis may all need to be excluded. Scrapings by which a positive diagnosis of tinea pedis may be established should always be taken, and they may need to be repeated if an initial negative result is incompatible with the clinical features.

Control. Clearly, if infected individuals avoided exposing others to their infection by not walking on the floors of communal changing rooms and by avoiding swimming baths, the level of infection in the community would fall. Because such large numbers of people are involved, many of whom are completely asymptomatic, this is usually not feasible. Moreover, eradication of these fungi from the toe clefts is often a long and tedious process, and elimination of the organism may never be achieved. Among industrial workers using communal showers, it is virtually impossible to avoid continual exposure to infection. There are two simple measures that do seem fruitful. Frequent hosing of the floors of shower rooms and the sides of swimming baths does reduce the prevalence of dermatophytes on these surfaces, and probably would lead to a reduction of infection in time. This should certainly be encouraged. Satisfactory antifungal powder is readily available, and encouragement of its use has been demonstrated to be effective in the long-term reduction of tinea pedis at one swimming bath.

Tinea manuum

SYN. RINGWORM OF THE HAND

Definition. Any species of dermatophyte may affect the skin of the hand. Infections of the dorsal surface present no specific features and are considered as ringworm of the glabrous skin under tinea corporis. This section is therefore concerned with ringworm of palmar skin and with infections beginning under rings.

Species concerned. For the most part, the organisms concerned are the three anthropophilic species involved in tinea pedis. *T. rubrum* is, among cases coming to the skin clinics, the most common cause by far. In the authors' experience, *E. floccosum* and *T. mentagrophytes* var. *interdigitale* are involved in a small minority of cases.

The anthropophilic species *T. violaceum* may also produce this clinical picture and animal species may occasionally infect the palmar skin. *T. mentagrophytes* var. *erinacei* from contact with hedgehogs has been notable in this regard.

Pathogenesis. In most cases, apart from animal infections, there is pre-existing foot infection with or without toenail involvement. A special mention should be made of ringworm beginning under rings, wrist watches, and where anatomical deformities or occupational usage predispose to maceration between the fingers. Here, there may be a particular susceptibility to *T. mentagrophytes* var. *interdigitale* infections, and in such cases infection may occur without obvious foot involvement [1]. Poor peripheral circulation and palmar keratoderma are other possible predisposing factors [2].

Clinical features. *T. rubrum* infection may take several different clinical forms. Hyperkeratosis of the palms and fingers affecting the skin diffusely is the most common variety, and is unilateral in about half of cases. The accentuation of the flexural creases is a characteristic feature. Other clinical variants include crescentic exfoliating scales, circumscribed vesicular patches, discrete red papular and follicular scaly patches, and erythematous scaly sheets on the dorsal surface of the hand. The latter forms are more likely to be zoophilic infections.

Differential diagnosis. Dermatophyte infections of the palm are often quiet and chronic, commonly passing unnoticed or misdiagnosed. Contact dermatitis, especially the primary irritant variety, psoriasis, pityriasis rubra pilaris, constitutional eczemas, keratoderma, syphilis and post-streptococcal peeling must all be considered. In ring infections and web space cases with anatomical deformity, candidosis and bacterial intertrigo should be excluded.

Unilateral scaling should always alert the clinician to the necessity of taking scrapings. Nail changes may help: pitting suggests psoriasis, but subungual hyperkeratosis if present should always be scraped. If the palmar infection spreads to the dorsal surface, a more classical picture of tinea circinata may be seen, although this happens relatively infrequently. Tinea manuum, like tinea cruris and tinea faciei, is sometimes modified by inappropriate treatment with topical steroids leading to further diagnostic difficulties.

Control. The prevalence of tinea manuum is directly related to the level of tinea pedis in the population. Prompt treatment of tinea pedis and the use of separate towels are sensible measures that can be recommended, but it is likely that tinea manuum will continue to occur sporadically and a greater awareness of this condition, so that it may be recognized promptly, is of prime importance.

Tinea cruris

SYN. RINGWORM OF THE GROIN; DHOBIE ITCH; ECZEMA MARGINATUM

Definition. Infection of the groins by a species of dermatophyte.

Species concerned. The causal species are those implicated in foot ringworm but in different proportions. *T. rubrum* is the main cause [1]; *T. mentagrophytes* var. *interdigitale* and *E. floccosum* also account for some cases.

Pathogenesis. Ringworm of the groins is a common condition throughout the world, and is probably more prevalent in tropical zones and particularly among migrants from temperate countries. The warm humid conditions in this site seem important [2]. This condition has always been much more common in men than in women [3].

Apart from the numerous cases of autoinfection from the foot to the groin [4], the sharing of towels and sports

clothing is undoubtedly important [5]. In cases thus contracted, the toe clefts may be normal.

Clinical features. Whatever the causal species, itching is a predominant feature. The lesions in the early stages are erythematous plaques, curved with sharp margins extending from the groin down the thighs. Scaling is variable, and occasionally may mask the inflammatory changes. Vesiculation is rare, but dermal nodules forming beading along the edge are commonly found in older lesions. One or two minute pustules are often detected if sought with care. Some central clearance is usually present, but is often incomplete with nodules scattered throughout the affected area.

Satellite lesions, if present, are few in number and relatively large. Spread to the scrotum is common, but scaling is minimal and inflammation inconspicuous against a background that is normally rugose and erythematous [6]. *E. floccosum* infections are clinically indistinguishable from *T. rubrum* infections, but are often not associated with tinea pedis. *T. rubrum* cases are classically chronic and sometimes more nodular. The rarer *T. mentagrophytes* var. *interdigitale* infections may be vesicular and inflammatory. Extension of infection from the groins to other sites is common, in *T. rubrum* classically to the buttocks, the lower back and the abdomen. The penis is occasionally affected.

Differential diagnosis. Candidosis, which is more common in women, does not have a distinct raised margin. White pustules are often found, satellite lesions are numerous and small, and the frayed peeling edge that occurs as the tiny pustules rupture is characteristic. Pityriasis versicolor may be localized to the groin but is usually non-inflammatory and asymptomatic, as is erythrasma. Central clearing is rarely found in either of these infections.

Intertrigo with heavy bacterial colonization is common in the obese subject of either sex. It may show a sharp margin, but this edge is usually a simple curve where the opposed skin surfaces meet. In many cases, extension upwards from the groin is as prominent as that down the thigh, a feature usually absent in tinea cruris. The central skin is often macerated and the submammary, periumbilical and axillary skin may also be affected, resembling flexural seborrhoeic dermatitis. However, this feature is not a completely reliable distinguishing criterion, as *E. floccosum* in particular may involve the axillae and the submammary areas. Psoriasis and mycosis fungoides may occasionally mimic tinea cruris, but characteristic lesions in other sites can usually be found. In atopic eczema there may be lichenification, but these changes usually extend up towards the hip. Contact dermatitis from clothing or deodorants may confuse, and Hailey–Hailey disease and flexural Darier's disease require consideration.

Topical steroids lead to suppression of the physical signs of tinea cruris.

Control. Greater control of foot ringworm might lead to fewer cases of tinea cruris. A person suffering from tinea pedis or cruris should not lend towels to others, even if they have been laundered. In the tropics, sensible clothing and prompt treatment of tinea pedis are probably of considerable importance. Topical therapy is often sufficient to control early cases, but long-established *T. rubrum* infection will require terbinafine or itraconazole.

Onychomycosis caused by dermatophytes

SYN. RINGWORM OF THE NAILS; TINEA UNGUIUM

Definition. Invasion of the nail plates by species of dermatophytes. A different category of onychomycosis is associated with certain other species of filamentous fungi that are frequently found in dystrophic nails; these are considered separately [1,2].

Species concerned. The principal dermatophytes concerned are: (i) with associated foot and hand infections—*T. rubrum*, *T. mentagrophytes* var. *interdigitale* and *E. floccosum*; (ii) with associated scalp infections—*T. tonsurans*, *T. violaceum* and *T. soudanensei.*

Pathogenesis. Ringworm of the nails occurs in all parts of the world, and almost all dermatophytes have been reported to infect nails at one time or another [3]. Although nail infections may be the only manifestation of fungus disease in a patient, in the great majority of cases they are associated with tinea pedis or tinea manuum, and the three dermatophytes most commonly implicated are therefore *T. rubrum*, *T. mentagrophytes* var. *interdigitale* and, rarely, *E. floccosum* [4–6].

T. soudanense has been reported as a cause of onychomycosis, and other dermatophytes usually encountered as a cause of tinea capitis, such as *T. tonsurans* and *T. violaceum*, not infrequently infect fingernails. In regions or populations where tinea pedis is uncommon and tinea capitis caused by these fungi is frequent, they are likely to predominate as a cause of onychomycosis.

It is likely that *T. rubrum* and *T. mentagrophytes* var. *interdigitale* both invade the nail plate with relative ease [3]. *T. rubrum* predominates in fingernail infections, owing no doubt to the prevalence of that species in tinea manuum. It is also the main cause of infection of the toenails. *T. mentagrophytes* var. *interdigitale* is a less common cause, and often only affects the great toenail. Invasion of the nail plate usually occurs either from the lateral nail fold or from the free edge and, as Alkiewicz [7] has shown, an elaborate network of channels and lacunae is formed, leading to opacity and eventually destruction and crumbling of the nail plate. Subungual hyperkeratosis, sometimes difficult to distinguish from softening of the nail plate proper, frequently occurs, but the mechanism of its production is obscure. As might be expected from the age distribution of tinea pedis, onychomycosis is largely a disease of adults [8], but children, especially those in institutions and in households where the adults are infected with *T. rubrum*, may be infected from time to time. A poor peripheral circulation is frequently blamed for resistance to treatment [9]. It may also be a factor in susceptibility. Nails that have been traumatized and nails of elderly people, where the linear growth is slow, are both unduly susceptible to infection.

Clinical features [2]. Four distinct patterns of tinea unguium have been described.

Distal and lateral subungual onychomycosis. Distal and lateral subungual onychomycosis (DLSO) is the most common pattern of infection, and usually presents as a streak or a patch of discoloration, white or yellow at the free edge of the nail plate, often near the lateral nail fold. The initial invasion of the hyponychium shows through a relatively normal dorsal nail plate. It commonly spreads towards the base of the nail and may occasionally become darker brown or black (Fig. 31.15). The nail plate becomes obviously thickened, and may crack as it is lifted up by the accumulation of soft subungual hyperkeratosis. A later phase of invasion may lead to massive destruction of the nail plate (total dystrophic onychomycosis; TDO). Although commonly starting with a single affected nail, other digits later become invaded. The variation in the severity of damage is sometimes marked, so that minor changes, a little discoloration or just fraying of the nails, may be all that is seen. Indeed, nail clippings may reveal fungus mycelium in nails that appear completely normal [10].

Superficial white onychomycosis. Superficial white onychomycosis (SWO) is a less common presentation and can produce a distinct form of nail invasion in which the dorsal surface of the nail plate is eroded in well-circumscribed powdery white patches, often away from the free edge [11]. It is distinguishable from other causes of leukonychia by the powdery nature of the white material, which can easily be scraped away. The whole surface of the nail plate may be thus affected, and occasionally this picture may also coexist with deep invasion of the nail plate of the ordinary type starting at the free edge. Although more common with *T. mentagrophytes* var. *interdigitale*, it can occasionally be seen in *T. rubrum* infections and also occurs with certain non-dermatophytes. Toenails are usually affected, but in AIDS patients SWO of both toe- and fingernails has been reported [12]. In AIDS patients, superficial infection may coexist with proximal nail plate invasion (see below).

Fig. 31.15 Onychomycosis caused by *Trichophyton rubrum.*

Proximal subungual onychomycosis. This is a pattern that was very uncommon, but in the last 10 years has become particularly associated with AIDS patients. Rapid invasion of the nail plate from the posterior nail fold may develop to produce a white nail with only marginal increase in thickness [12]. The most common cause is currently *T. rubrum*, although in the past more unusual species such as *T. megninii* were associated with this picture.

Endonyx onychomycosis. This is seen with infection caused by dermatophytes that cause endothrix scalp infections, notably *T. soudanense*. The nail plate is scarred with pits and lamellar splits. The invasion occurs from the top surface, but penetrates deeply into the nail plate.

On occasions, patients with onycholysis alone may have positive cultures of dermatophytes, suggesting that carriage of dermatophytes without invasion is possible [13].

Differential diagnosis. The destructive changes of the nail plate and nail bed produced by dermatophytes can be mimicked closely by psoriasis. Fine pitting of the dorsal nail plate is never produced by fungal infections and strongly suggests psoriasis, as does the oil-drop sign away from the free edge. The irregularly buckled nail of eczema

and the ridged or dysplastic nail of lichen planus must be distinguished. Paronychia, caused either by bacteria or by *Candida*, usually affects the nail plate proximally and laterally, while the free edge is often spared, at least initially. Conversely, swelling of the nail fold is rare in dermatophyte infections, and purulent discharge is never a feature of uncomplicated tinea unguium. Onycholysis and other nail dystrophies must be considered. Ringworm of the nails is rarely symmetrical, and it is common to find the nails of only one hand affected. The skin of the feet and of the palms should always be examined carefully. Nail clippings or scrapings are essential, and direct microscopy should be carried out with great care, as culture often fails with nail plate material [10,14]. For this reason, it is wise to sample any obvious skin lesions present, as these are usually infected with the same organism and will be more likely to yield a positive culture [15]. It must be remembered that double pathologies do occur and a nail, dystrophic from some other cause, may become invaded by a dermatophyte fungus. This is not uncommon with onychogryphosis.

Control. Proper early treatment of tinea pedis and manuum would almost certainly reduce the prevalence of tinea unguium.

Steroid-modified tinea

SYN. TINEA INCOGNITO

Definition. Ringworm infections modified by corticosteroids, systemic or topical, prescribed for some pre-existing pathology or given mistakenly for the treatment of misdiagnosed tinea.

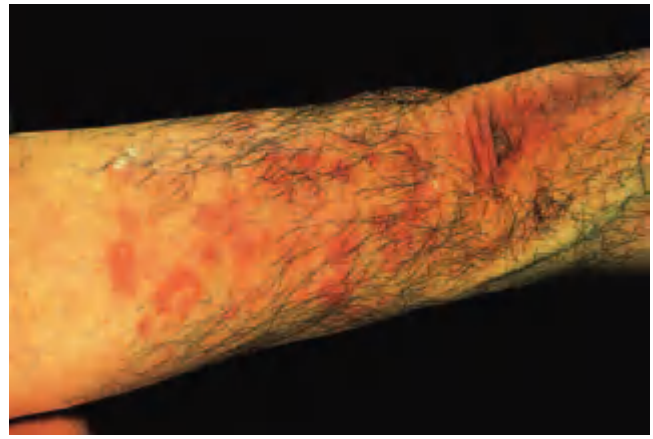

Fig. 31.16 Tinea corporis in a patient on systemic corticosteroids.

Pathogenesis and clinical features [1–3]. Normally, the clinical diagnosis of tinea depends heavily on the inflammatory changes involved. This inflammatory response may be almost totally suppressed by corticosteroids, systemic or topical. At the same time, it is probable that the resistance to infection mediated by the immune response, especially the cell-mediated response, is diminished by corticosteroids. In this situation, the patient suffers doubly: the infection is less likely to be diagnosed, and the patient has been rendered more susceptible to that infection.

With patients on systemic steroids (perhaps treated with additional immunosuppressive agents or irradiation [4]), the degree of modification is often minor, but even in these cases it may be sufficient to mislead (Fig. 31.16), especially on the face. With topical steroids, the degree of modification can be profound. The usual sites where this problem occurs are the groins, lower legs, face and hands, but tinea circinata elsewhere may be steroid treated.

The history is characteristic. The patient is often satisfied initially with the treatment. Itching is controlled and the inflammatory signs settle. He or she stops applying the cream, the eruption relapses, with varying rapidity. Further applications bring renewed relief and the cycles are repeated. In the groins, the patient may develop few persistent nodules, which become unsuppressible by the steroid preparation.

Typically, the raised margin is diminished. Scaling is lost and the inflammation is reduced to a few nondescript nodules. Often, a bruise-like brownish discoloration is seen, especially in the groins. On the face, the picture may be modified by a superimposed perioral dermatitis with papules and tiny pustules. Steroid-modified eyelid infection may closely resemble a sty. With chronic use, atrophy, telangiectasia and, in the groins and axillae, striae are likely to be observed. In some cases, concentric rings of erythema are seen among the atrophy and telangiectasia. Presumably, these represent waves of fungal growth. The eruption remains localized but, especially in

E. floccosum infections, it spreads more widely than one would expect in the unmodified case. Accumulation of fungal hyphae may lead to cross-infection, as has been reported with steroid-modified *T. violaceum* infection in a dermatology ward [1]. Strong fluorinated steroids seem most likely to produce this syndrome, but even 1% hydrocortisone cream can, on occasions, modify tinea to a confusing extent.

Diagnosis. The differential diagnosis of other steroid-modified infections in the groin, particularly candidosis, must be considered, and these may be indistinguishable without cessation of therapy and mycological investigations. A ready awareness that the face, groins and the hands are sites of diagnostic error is important in alerting the physician, and the history is usually extremely suggestive. Scrapings may be difficult to obtain in a patient who is currently applying a steroid cream, but if he or she stops it for a few days an upsurge of inflammation with marked scaling often occurs, making clinical diagnosis easier and facilitating the taking of scrapings. In such samples, fungal mycelium is usually abundant but scrapings taken while steroids are still being applied may show very few fungal elements, unless a fluorescent whitener is used [5].

Dermatophytide reactions

SYN. MICROSPORIDE; TRICHOPHYTIDE OR EPIDERMOPHYTIDE (ACCORDING TO GENUS)

Definition. A non-infective cutaneous eruption representing an allergic response to a distant focus of dermatophyte infection.

Pathogenesis and criteria. Jadassohn in 1918 first described a dermatophytide reaction in a patient with a kerion. Since then a great many cutaneous eruptions have been labelled unconvincingly as dermatophytides. It is now clear [1] that the essential criteria required for the diagnosis of an ide reaction to a dermatophyte infection are:

1 Proven dermatophyte infection, which usually becomes highly inflamed before the appearance of the secondary rash.

2 A distant eruption, which is demonstrably free of ringworm fungus.

3 Spontaneous disappearance of the rash when the ringworm infection settles, with or without treatment.

Even with these criteria, ide reactions may be overdiagnosed. An additional criterion has been recommended; the morphology of the ide eruption should match one of the well-recognized types.

Clinical features. The focus of infection is often a kerion, for instance caused by *T. verrucosum*, but the species is not important as long as it provokes inflammation. Highly inflammatory tinea pedis may be insufficient. The main ide reactions are well established.

1 A widespread eruption of small follicular papules grouped or diffusely scattered. The eruption is symmetrical, usually pronounced on the trunk, but in severe cases extending down limbs, even at times covering the face. Sometimes the follicular papules are topped by horny spines. The common cause of this type of ide reaction is a scalp ringworm kerion, typically caused by *T. verrucosum*. On occasions, *T. tonsurans* and *M. audouinii* may be responsible, when they produce inflamed ringworm. Treatment of the original ringworm lesion may play a part in initiating the process.

2 A pompholyx-like ide affecting the web spaces and palmar surfaces of the fingers, the palms and sometimes the dorsal surfaces of the hands. This eruption is characteristically associated with an acutely inflammatory tinea pedis, which may have arisen spontaneously or as a result of inappropriate treatment. The palmar and web space skin may be covered with papules or vesicles. On occasions, bullae or pustules may occur. Clinically, this is indistinguishable from a constitutional eczema of the pompholyx variety, and the diagnosis of a dermatophytide in this clinical situation demands rigorous application of the criteria outlined above. In the past, failure to adhere to these criteria has led to inordinate overdiagnosis of this uncommon syndrome.

Of the many other suggested morphologies for ide reactions, erythema nodosum seems most acceptable [2]. There are a few published accounts of this, and the authors are aware of other cases that fit the above criteria.

It is possible that erythema multiforme, erythema annulare and urticaria may, on occasions, be manifestations of an allergic reaction to the ringworm infection, but such instances must be extremely rare and the clinician is cautioned to apply critical judgement vigorously before accepting new examples of such associations in his or her own practice, or indeed in new published accounts.

Laboratory diagnosis

The isolation and identification of dermatophytes is a relatively simple process and needs only basic laboratory facilities. The features of the most common species will therefore be outlined and illustrated grown on 2% glucose, 1% mycological peptone (Oxoid) agar supplemented with 0.04% cycloheximide and 0.005% chloramphenicol at 26°C. Illustrations of the more unusual species are beyond the scope of this chapter and the reader is referred to more specialized texts [1–3].

All the dermatophyte species appear identical in skin and nail samples. Septate hyphae are observed, which may branch without constriction at the branching point and which display an even diameter along their length (Fig. 31.17a). In some specimens, the hyphae fragment into arthroconidia, which disarticulate when mature, and may then round up and increase notably in size (Fig. 31.17b). These germinate to produce true hyphae. Hair invasion results in four distinct patterns: small-spored ectothrix, large-spored ectothrix, arthrosporic endothrix and favus endothrix (Fig. 31.17c–f) and these are readily distinguishable by the arrangement and the size of the fungal elements. When trying to determine whether infection is endothrix or ectothrix, it is useful to note that the pigment in the hair clearly delineates the edge of the hair shaft, and can be used as a marker to judge whether the fungus is entirely confined within the hair, or has formed an ectothrix sheath of arthroconidia on the surface.

Most isolates can be identified directly from the primary culture, but if sporulation is poor, a number of media may be used to encourage the production of conidia, including potato dextrose agar and lactritmel agar [4]. A few simple physiological tests, such as growth on polished rice grains, the production of urease, the ability to penetrate human hair *in vitro* and specific vitamin requirements, may be used to confirm the identification of certain species (Table 31.6).

In recent years there have been numerous molecular studies of dermatophyte taxonomy. As a result various changes have been recommended to the nomenclature and separation of the classically recognized species. These include the merging of some anthropophilic and zoophilic species (e.g. *T. equinum* and *T. tonsurans*) and of some morphologically very distinct species, such as *T. soudanense* and *T. violaceum* [1]. In the authors' opinion, although these results may show taxonomic relationships among this still evolving and comparatively young group of fungi, they are not helpful and would probably be epidemiologically confusing in clinical diagnosis. The changes have certainly not been universally accepted and in this text the classic species are retained. In cases where cultures are completely atypical morphologically, however, molecular methods such as polymerase chain reaction patterns and ribosomal DNA analysis will allow species identification. Whether the cost can be justified in all but the most exceptional cases is questionable.

Genus Microsporum

When present, macroconidia are species specific; their production is enhanced by subculture on to lactritmel agar. Microconidia are similar in most species, clavate to elongate and borne along the sides of the hyphae, and thus not useful in species identification. The presence of specialized hyphae, such as racquet hyphae, where the cells are swollen at one end, and pectinate hyphae, which bear unilateral flattened comb-like protrusions, may be helpful.

Table 31.6 Physiological tests used in the identification of dermatophytes.

Production of urease Filter-sterilized urea agar base (Difco) is mixed with sterile molten agar and allowed to set. The medium is then inoculated with the test organism. After incubation at 26°C for 7 days, if urea is degraded the colour turns from yellow to magenta red
Penetration of human hair in vitro Sterile human hair is suspended in sterile distilled water supplemented with yeast extract. The test organism is inoculated onto the hairs. After 2 weeks' incubation at 26°C, hairs are mounted to look for wedge-shaped penetrations perpendicular to the hair axis
Vitamin tests Trichophyton agars 1–7 (Difco) are used to determine vitamin requirements. Agar 1 is a casein-based, vitamin-free control; agar 2 is supplemented with inositol; agar 3 with thiamine and inositol; and agar 4 with thiamine alone. Agar 5 contains nicotinic acid. Agar 6 is an ammonium nitrate vitamin-free control for Agar 7, which is supplemented with histidine. Small, agar-free inocula are transferred from Sabouraud's agar plates and incubated for 2–3 weeks at 26°C
Growth on rice grains Ordinary white rice is covered with distilled water and autoclaved. The test organisms are then inoculated straight onto the surface, and growth is assessed after 2–3 weeks' incubation at 26°C
Growth on 1% peptone agar On this sugar-free medium *Microsporum persicolor* will produce a pink surface colour, in contrast to *Trichophyton mentagrophytes* var. *mentagrophytes*, which remains white

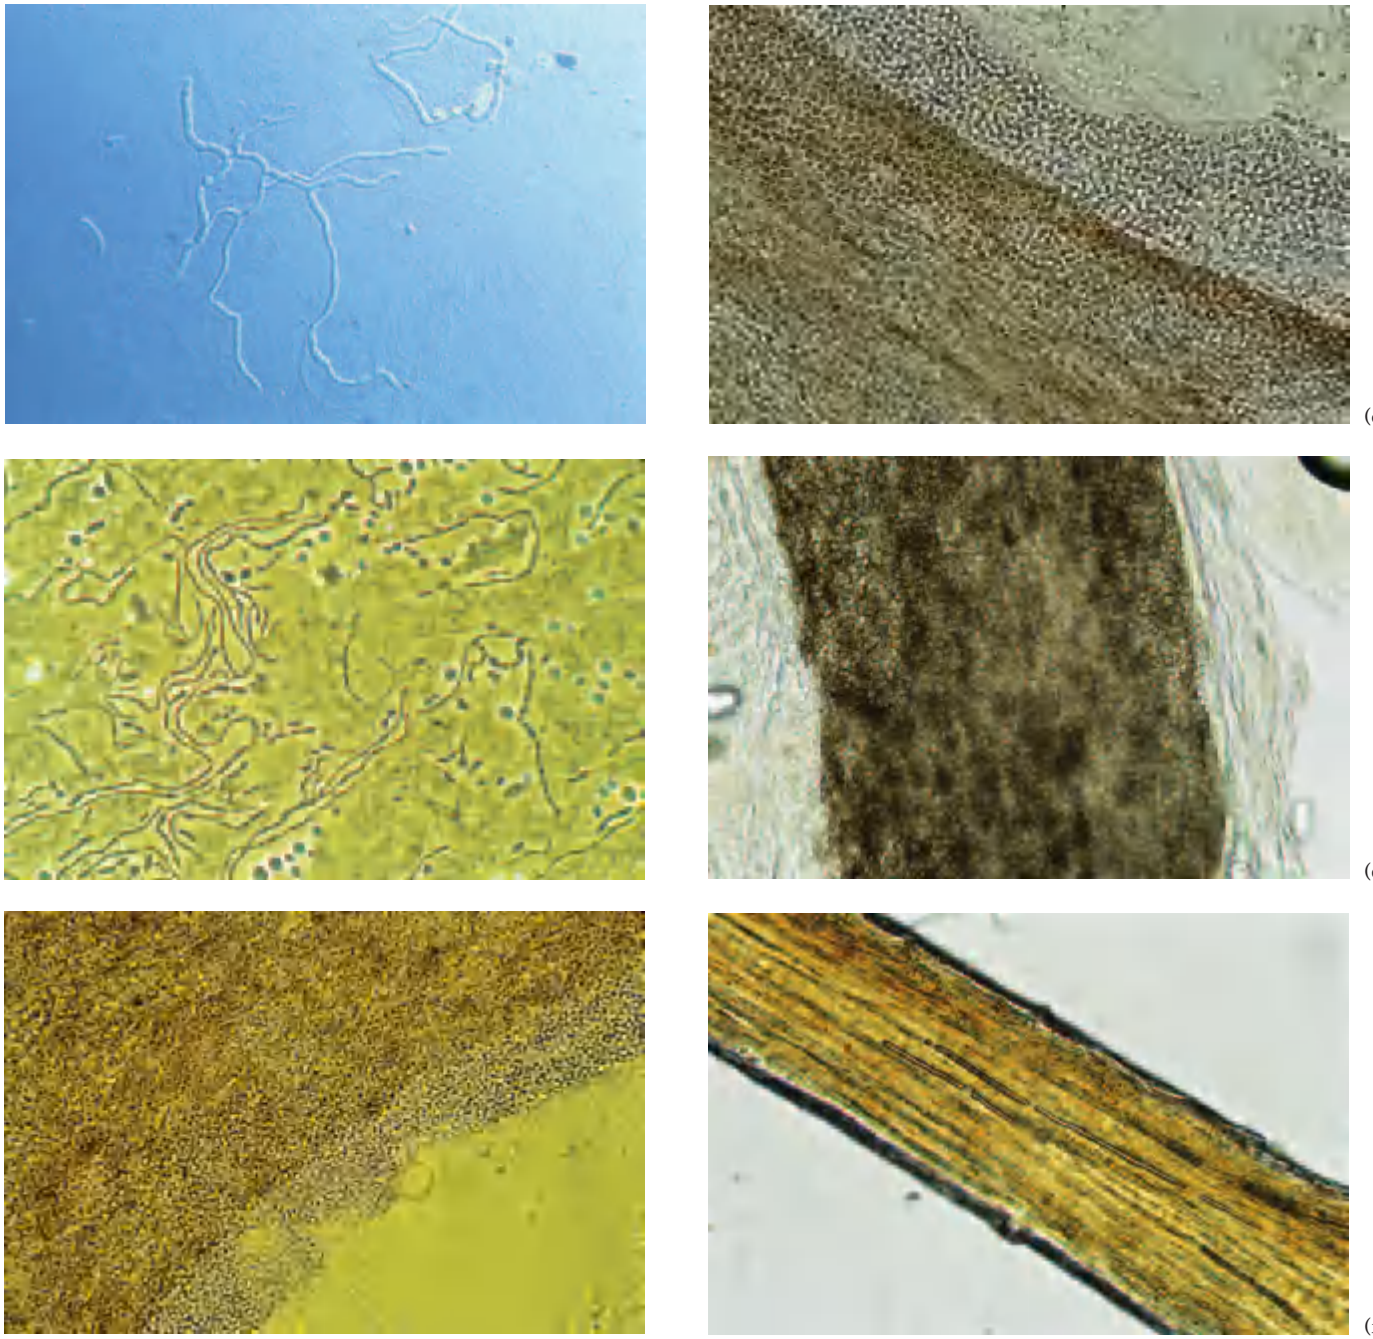

Fig. 31.17 Dermatophytosis. (a) Skin scales mounted in 30% KOH, Nomarski illumination. The hyphae are very even in diameter and regularly septate. (b) Skin scales mounted in 30% KOH, phase contrast. The hyphae are fragmenting to form arthroconidia, which may increase notably in size and round up as they mature. (c) Small-spored ectothrix hair invasion, 30% KOH bright field. The brown pigment delimits the edge of the hair, and the sheath of small arthroconidia that has formed on the surface of the hair is clearly visible. (d) Large-spored ectothrix hair invasion, 30% KOH, bright field. The sheath surrounding the hair is formed of arthroconidia, which are significantly larger than those seen in small-spored ectothrix infections. (e) Endothrix hair invasion, 30% KOH, bright field. The fungus inside the hair has broken up into a mass of large arthroconidia. These are retained entirely within the hair shaft. (f) Favus hair. The fungus is entirely confined within the hair shaft but does not fragment into arthroconidia. When first immersed in KOH, air is trapped around the hyphae forming the characteristic, long air spaces. These rapidly fill in with KOH, when the hyphae themselves become visible. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

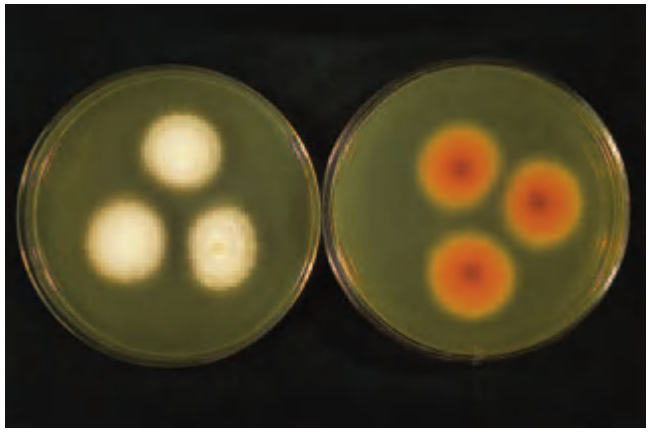
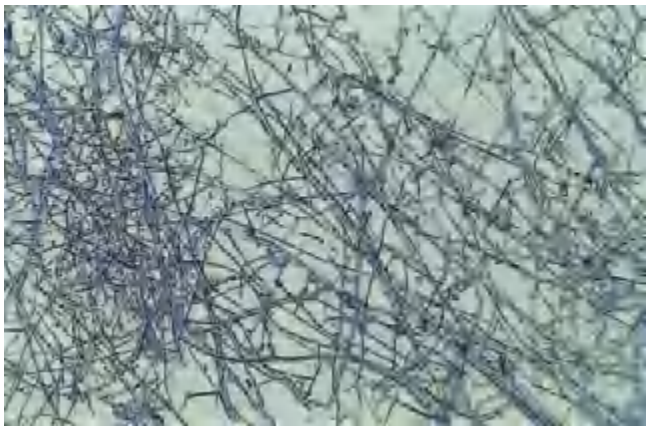
(a)



(b)



(c)

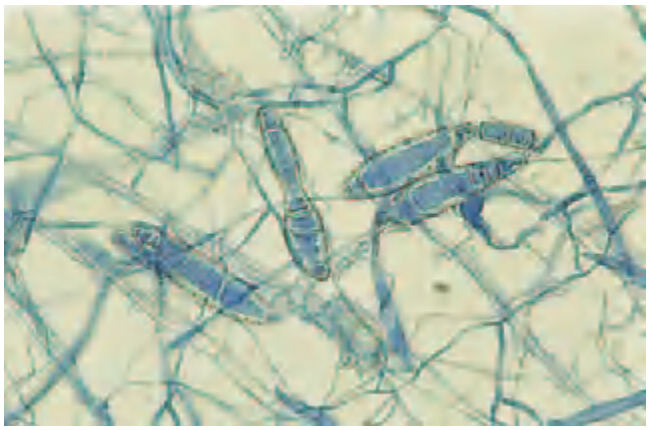


Fig. 31.18 (a) *Microsporum audouinii* colony: reverse of colony shown on right. (b) *Microsporum audouinii* microscopy, bright field. In many isolates chlamydoconidia, raquet hyphae and microconidia may be the only features of note. (c) *Microsporum audouinii* microscopy, bright field. In some isolates, macroconidia are observed. These are large, unevenly septate and may have a waisted appearance. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

M. audouinii (Fig. 31.18a–c). Colony: in many isolates the surface is white to tan with thin, sometimes silky growth, which has been compared to mouse fur. Other strains may have a thicker, downy white surface. The colour on the reverse of the colony is salmon pink to tan. Microscopy: in most isolates macroconidia are absent and the most characteristic features may be the presence of terminal and intercalary chlamydoconidia and racquet hyphae. However, in isolates where macroconidia are present, they are large, unevenly septate, variably rough and thick-walled, and often have a constricted centre and irregular shape. Physiological tests: *M. audouinii* grows poorly on polished rice grains.

M. audouinii var. *rivalieri* is a variant found mainly in Africa, but also reported from North America and Europe. The colony surface is white, with a distinctive ground-glass texture and radial or more complex cerebriform folding. Microscopically, macroconidia may be present, but the most characteristic feature is the presence of numerous pectinate hyphae. On primary culture, some isolates produce well-developed antler hyphae, which may cause confusion with *T. schoenleinii*. Subculture on to lactritmel agar may stimulate macroconidial production in these isolates and the characteristic small-spored ectothrix mode of *in vivo* hair infection will also aid in their correct identification.

M. canis (Fig. 31.19a,b). Colony: the surface is white, thinning towards the edge to reveal the yellow or orange reverse pigment. The texture may be cottony, with a buff centre caused by the abundant production of macroconidia; alternatively, the surface may be thinner, silky or patchily cottony and entirely white. Radial folds may be present. Microscopy: macroconidia are rough, particularly at the tip, with thick outer walls and up to 16 cells. They are spindle-shaped and may show a slightly bent apical beak. Physiological tests: *M. canis* grows well on polished rice grains. This medium also encourages macroconidial production.

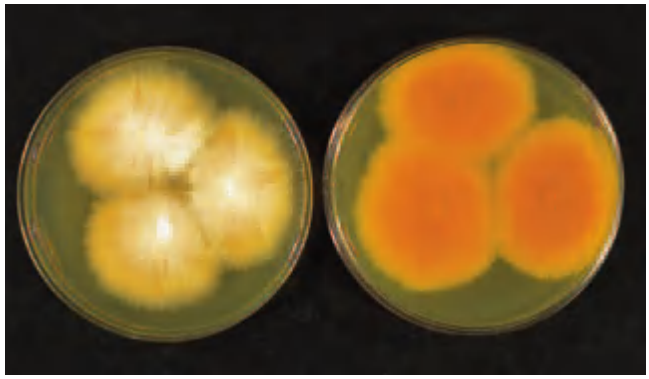
A glabrous variant (Fig. 31.20) has been described with heaped, leathery yellow or orange–brown colonies with feathery edges [5]; this mutant quickly reverts to the normal colonial form and produces typical macroconidia if cultured on rice grains.

M. canis var. *distortum* is a variety found in Australia, New Zealand and the Americas. The rough, thick-walled macroconidia are grossly distorted and bent.

M. equinum. Colony: the short surface mycelium is white to pale buff with regular deep radial grooves. The reverse is pink or salmon. Microscopy: the macroconidia are characteristic. They are rough and thick-walled but shorter and wider than those of *M. canis*, usually with one to four cells.

M. ferrugineum. Colony: restricted glabrous heaped colonies, yellow to rust in colour or more spreading, downy colonies similar to *M. audouinii*. Microscopy: thick 'bamboo' hyphae with prominent septa may be the only notable feature.

(a)



(b)

Fig. 31.19 (a) *Microsporum canis* colony; reverse of colony shown on right. (b) *Microsporum canis* microscopy, bright field. The macroconidia are characteristic, thick-walled and fusiform, often with a tilted, apical beak. They are rough with the most pronounced thickenings at the apical tip. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

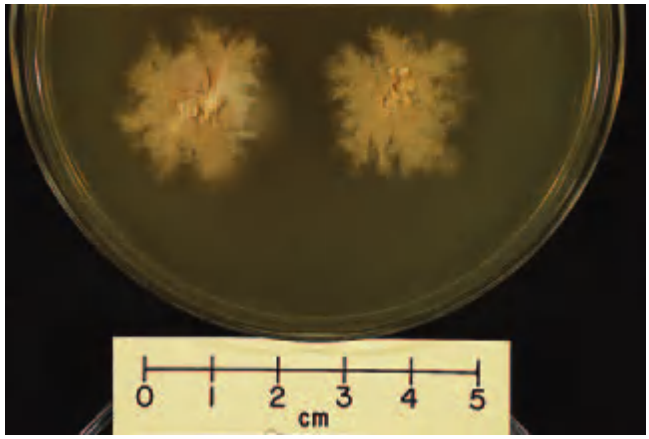


Fig. 31.20 *Microsporum canis* glabrous form colony. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

M. gypseum (Fig. 31.21a,b). Mating studies have demonstrated that the fungus traditionally known as *M. gypseum* is actually a complex containing three separate species: *A. fulvum* (Anamorph *M. fulvum*), *A. incurvatum* (Anamorph

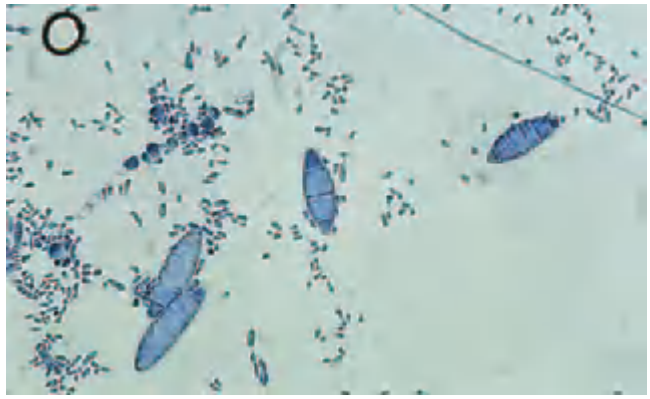

Fig. 31.21 (a) *Microsporum gypseum* colony. (b) *Microsporum gypseum* microscopy, bright field, the macroconidia are abundant and characteristic, with a symmetrical cigar shape and thin, finely roughened cell walls. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

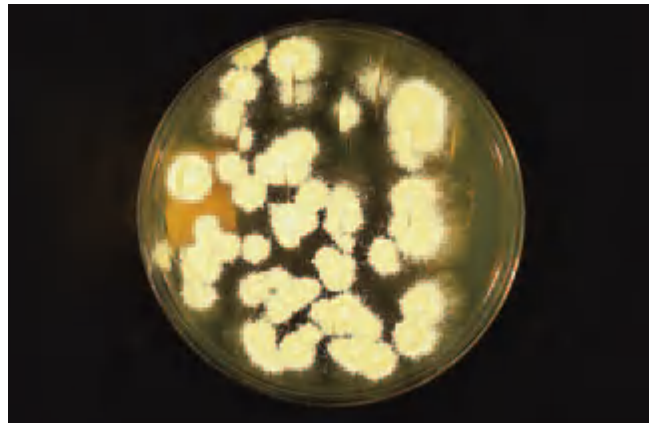
M. gypseum) and *A. gypseum* (Anamorph *M. gypseum*). Colony: all the species produce rapidly growing colonies with a cinnamon or brown powdery surface. *M. fulvum* typically has a much thicker, more floccose surface texture; in *M. gypseum* the surface is almost completely flat. The reverse is yellow-buff to brown or may have red overtones. Microscopy: the numerous macroconidia are thin-walled, finely roughened over their entire surface and have up to six septa. The shape is very symmetrical, broadly fusiform with rounded ends, and has variously been described as cigar- or boat-shaped.

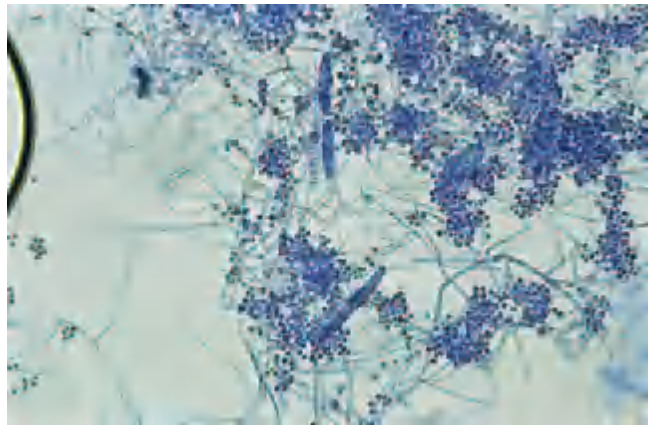
M. nanum. Colony: rapidly growing, flat powdery colonies with a buff surface and red-brown reverse. Microscopy: characteristic thin-walled rough obovate macroconidia with a single septum are abundantly produced.

M. persicolor. Colony: the surface of the colony is creamy buff, sometimes with pale pink tones. The texture is noticably thicker than that seen in *T. mentagrophytes* var. *mentagrophytes*. The reverse is buff to brown and may also

develop pink or reddish tones. Microscopy: very similar to *T. mentagrophytes* var. *mentagrophytes*. Many clavate to spherical microconidia are present, and arranged in grape-like clusters and along the hyphae. Young microconidia are pyriform and match-stick hyphae with an elongated basal cell carrying a microconidium at its tip may be observed. Tightly coiled, spiral hyphae are usually present. Thin-walled elongated macroconidia appear smooth on primary isolation media and usually contain six cells. Physiological tests: on medium free of sugar (1% peptone agar), *M. persicolor* colonies produce a pink surface colour; *T. mentagrophytes* var. *mentagrophytes* retains a white surface on this medium. On 3% salt agar, macroconidia are more obviously rough.



(a)



(b)

Fig. 31.22 *Trichophyton mentagrophytes* var. *mentagrophytes*. (a) Colony. (b) Microscopy, bright field. Round microconidia are arranged in clusters. Spiral hyphae and thin-walled, smooth, cylindrical macroconidia may also be present. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

Genus Trichophyton

Macroconidia are rarely formed by most of the anthropophilic species, and may not be particularly distinctive when they are. They are smooth and thin-walled. The size, shape and arrangement of the microconidia is useful in species identification, together with the presence of features such as coiled spiral hyphae, abundant chlamydospore production and special physiological requirements.

T. concentricum. Colony: the compact, heaped, folded colonies have a grey, tan or brown surface; initially glabrous, a thin short surface mycelium may develop. The reverse may be tan, brown or have reddish tones. Microscopy: conidia are absent. The hyphae may be swollen and distorted with numerous chlamydospores and occasional antler hyphae, or unremarkable. Physiological tests: 50% of isolates are stimulated by thiamine.

As the morphological features of this fungus are not very distinctive, it may be confused with other glabrous anthropophilic *Trichophyton* species, such as *T. yaoundei* or unpigmented isolates of *T. violaceum*. However, the clinical features of infection are so characteristic that they will aid in the identification.

T. equinum. Colony: in young cultures, the surface is very thin, revealing the reverse brown pigment. The reverse is initially brown in the centre with an outer yellow edge. As the culture matures, the surface texture thickens and becomes uniformly white and the reverse uniformly deep reddish brown. Microscopy: elongate to pyriform microconidia are arranged along the sides of the hyphae. Cylindrical smooth thin-walled macroconidia are rarely observed. Physiological tests: with the exception of some isolates from New Zealand and Australia, this fungus has a specific vitamin requirement for nicotinic acid.

T. gourvilii. Colony: the centre of the colony is garnet red to lavender, waxy, heaped, folded and surrounded by a flat white silky edge with an eyelash fringe. The reverse is cream to buff. Microscopy: clavate or pyriform microconidia are arranged along the sides of the hyphae.

T. megninii. Colony: the colony is very similar to downy *T. rubrum* isolates. The surface is white, developing pink or rose tones. The texture is velvety or downy, often with radial folds. The reverse is reddish brown to wine red. Microscopy: as in *T. rubrum*, pyriform microconidia are arranged along the sides of the hyphae. Physiological tests: when grown on a medium with an inorganic nitrogen source, this fungus has a specific requirement for L-histidine. Unlike *T. rubrum* it is urease positive.

T. mentagrophytes var. *mentagrophytes* (Fig. 31.22a,b). Colony: the colonies are fast growing with an intensely granular surface, which may be entirely white or develop a cream centre. The edge of the colony is thinner and may be spiky or stellate. The reverse is yellow, tan or red to brown. Microscopy: the spherical microconidia are

arranged in grape-like bunches and to a lesser extent along the hyphae. Coiled spiral hyphae are usually present, and in many isolates thin-walled, cylindrical macroconidia with up to eight cells may be present. Physiological tests: the fungus is urease positive and penetrates human hair *in vitro*.

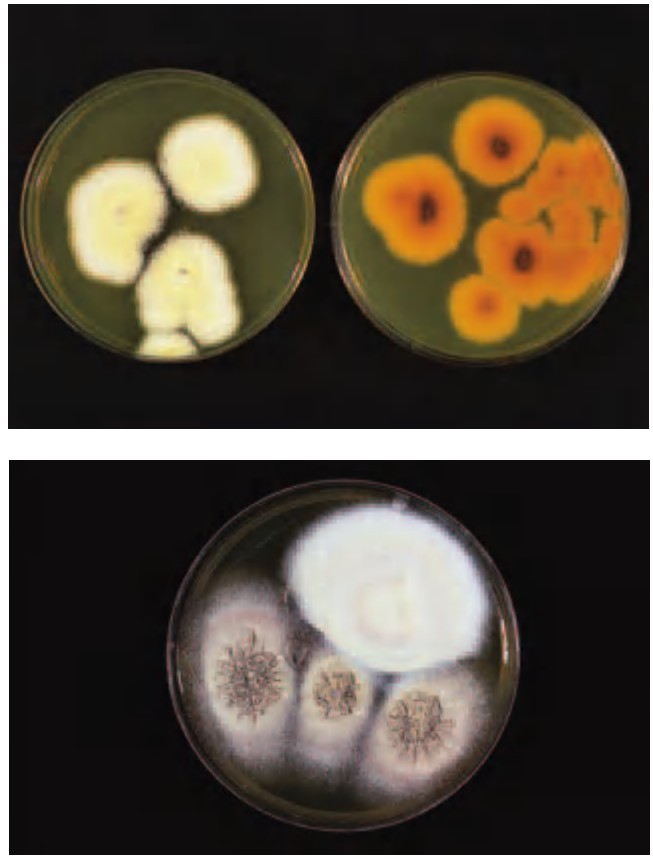
T. mentagrophytes var. *erinacei*. Colony: the rapidly growing colonies have a flat white intensely granular surface. The reverse is a bright canary yellow. Microscopy: elongate microconidia, even longer than those of *T. rubrum*, are arranged along the sides of the hyphae. Spiral hyphae and smooth thin-walled macroconidia may be present in some isolates. Physiological tests: unlike other variants of *T. mentagrophytes*, the fungus is urease negative, but will penetrate human hair *in vitro*. Some workers believe that this fungus should be regarded as a separate species, *T. erinacei*.

T. mentagrophytes var. *quinckeanum*. Colony: the surface is white, velvety or downy and often folded in the centre. The reverse is buff to cream. The colony has been reported to have a distinctive sour smell. Microscopy: pyriform microconidia are arranged along the sides of the hyphae. Physiological tests: produces a Wood's light-positive hair infection in mice with characteristic scutula.

T. mentagrophytes var. *interdigitale* (Fig. 31.23). Colony: the most typical isolates are rapidly growing with a white powdery surface, which develops a cream centre (Fig. 31.23a). A few isolates may develop a pinkish surface. The reverse is tan or reddish brown, often with a paler edge. Less typical downy forms have a fluffier white surface, sometimes slightly cream in the centre and folded (Fig. 31.23b). The reverse is pale cream to buff. Microscopy: powdery isolates may be very similar to *T. mentagrophytes* var. *mentagrophytes* with spherical microconidia arranged in bunches; spiral hyphae and macroconidia are present in some isolates. The fluffier downy isolates have pyriform microconidia arranged along the sides of the hyphae. Physiological tests: the fungus is urease positive and penetrates human hair *in vitro*.

The 'nodulare' form of *T. mentagrophytes* var. *interdigitale* has a predominantly glabrous, waxy surface devoid of aerial hyphae and feathery subsurface growth. Both the surface and reverse of the colony are orange–red in colour. Small areas of more typical white growth may be present. Nodular bodies are present on microscopical examination. This variety is relatively unstable, and may quickly sector out into a powdery or downy colonial form.

T. rubrum. This is probably the most morphologically variable dermatophyte species and several distinct colonial forms are regularly isolated. Only the most common will be described here.



(a)

(b)

Fig. 31.23 *Trichophyton mentagrophytes* var. *interdigitale*. (a) Typical colony form; reverse of colony is shown on right. (b) More unusual colony forms. The upper colony is of the downy white form and the lower colonies show an intricately folded, beige form. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

1 *Downy form*. The most commonly isolated form in temperate zones (Fig. 31.24a,b). Colony: the surface of the colony is white, downy or cottony, and domed. The reverse of the colony is initially dark brown, usually with a paler cream border, but after incubation for 3–4 weeks produces the typical deep red pigment characteristic of this species. Microscopy: small tear-shaped, clavate or elongate microconidia are arranged along the sides of the hyphae. In some isolates microconidia may be scanty. Physiological tests: the fungus is urease negative and does not perforate human hair *in vitro*.

2 *Melanoid form* (Fig. 31.24c). Colony: similar to the downy form, but characterized by producing a brown melanoid pigment that diffuses into the medium and masks any red pigment on the reverse of the colony. Microscopy: small tear-shaped microconidia are arranged along the sides of the hyphae.

3 *Dysgonic form* (Fig. 31.24d). Colony: slow-growing tiny deep-red colonies with a brittle texture. This form is

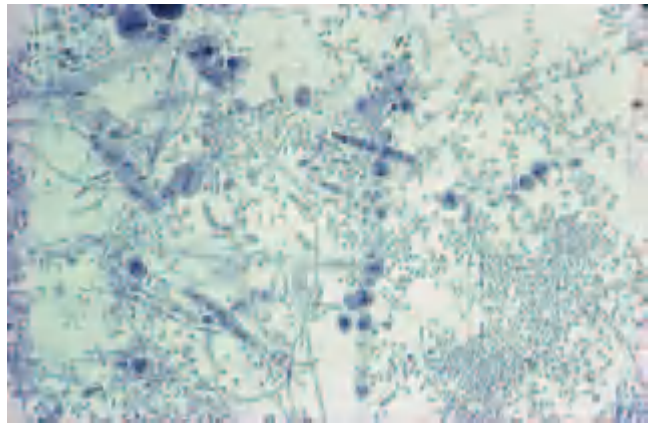
(e)

(c)



(f)

Fig. 31.24 *Trichophyton rubrum*. (a) Downy colony; reverse of colony shown on right. (b) Downy form microscopy, bright field. Clavate to elongate microconidia are arranged along the sides of the hyphae. They may be scanty in some isolates. (c) Melanoid colony form. A brown pigment diffuses into the agar medium. (d) Dysgonic colony form. Growth is initially very restricted and the tiny colonies a deep red. They usually revert to a more typical downy form within 2–3 weeks. (e) Granular form colony, with a powdery pink surface often raised and folded in the centre. (f) Granular form microscopy, bright field. Cylindrical, smooth-walled macroconidia are abundant and may become swollen as they mature with constricted septa. Microconidia and chlamydoconidia may also be abundant. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

relatively unstable and will quickly revert to the more typical downy form.

4 *Granular form* (Figs 31.24e,f). Colony: the surface is powdery or granular, cream to pink and often raised and folded in the centre. The reverse is red-brown. Microscopy: numerous smooth thin-walled cylindrical or pencil-shaped macroconidia are produced; some macroconidia may have constricted septa. Typical tear-shaped

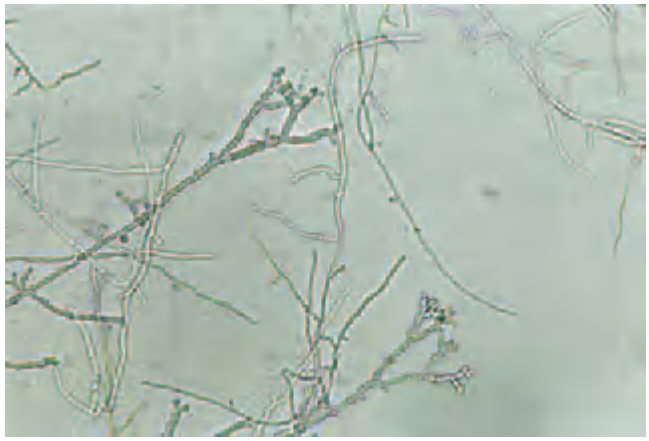

Fig. 31.25 *Trichophyton schoenleinii*. (a) Colony. (b) Microscopy, bright field. Typical antler hyphae may be observed by examining through the back of the culture plate with a × 10 or × 20 objective. The antlers branch dichotomously and have flattened tips. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

(a)

(b)

Fig. 31.26 *Trichophyton soudanense*. (a) Colony forms. A typical apricot yellow and a red isolate are illustrated. (b) Microscopy, bright field. The stiff hyphae with many arthroconidia and reflexive branching may be observed directly through the back of the culture plate. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

microconidia are also present. Physiological tests: this form is urease positive and may penetrate human hair *in vitro*.

5 *Yellow form.* The surface may be similar to the more usual downy form or it may be smooth, leathery and yellow. The reverse is yellow; the red pigment characteristic of *T. rubrum* is completely absent. In instances where microconidia are not observed it may be difficult to show that this is indeed a dermatophyte. However, pigmentation and sporulation may be enhanced on lactritmel agar.

T. schoenleinii (Fig. 31.25a,b). Colony: on primary isolation, the colonies may be glabrous or velvety, usually heaped and folded, and often with a fringe of hyphae at the edge submerged in the culture medium. The surface is white to cream and reverse pale. On repeated subculture, most isolates become downy. Microscopy: conidia are usually absent. Characteristic dichotomously branching hyphae with flattened tips, termed chandelier or antler hyphae, are present in fresh cultures. These may be readily observed by focusing on the back of the primary culture plate with a × 10 objective. Swollen distorted hyphae with many chlamydoconidia are also usually present.

T. simii. Colony: the surface is flat and granular, pale at the edges and buff or sometimes pink in the centre. The reverse is usually yellow to red-brown. Microscopy: many smooth-walled macroconidia are produced, often outnumbering the number of clavate to pyriform microconidia. The macroconidia are thin-walled, cylindrical or torpedo-shaped and are characterized by the development of constricted septa, and the fact that certain of the cells swell to produce endochlamydoconidia as they age.

T. soudanense (Fig. 31.26a,b). Colony: the colony is relatively slow growing, glabrous and leathery or brittle in texture, with a characteristic stellate or eyelash fringe around the edge. The colour is typically apricot, but

(a)

(b)

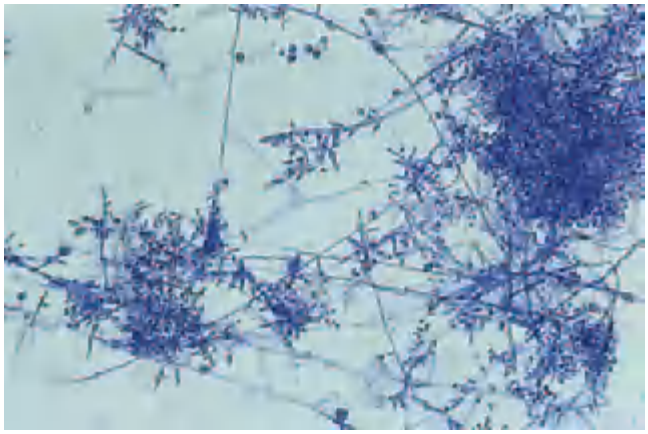

Fig. 31.27 *Trichophyton tonsurans*. (a) Colony; reverse of colony shown on right. (b) Microscopy, bright field. The microconidia are large and vary considerably in their shape. Chlamydoconidia are often abundant. Macroconidia and spiral hyphae are occasionally seen. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

isolates producing purple or red colonies are also common. Microscopy: when examined through the back of the primary culture plate using a × 10 objective, the hyphae appear stiff and 'brush-like'. They are very regularly septate, and the formation of arthroconidia produces a zig-zag appearance. Reflexive branching back towards the centre of the colony is a characteristic feature. Pyriform microconidia may be present.

T. tonsurans (Fig. 31.27a,b). Colony: the colony surface is velvety or powdery and may be grey, cream or yellow in colour, more rarely brown in the centre. Some isolates produce very sparse surface mycelium, so that the reverse brown pigmentation shows through. Circular or radial folds are often present. The reverse is typically chocolate brown, mahogany or yellow. Microscopy: the most characteristic feature is that the microconidia are noticeably larger than those of *T. mentagrophytes* or *T. rubrum* and very variable in shape. They range from clavate to elongate, and swollen 'balloon' microconidia and stalked, match-stick microconidia are also observed. In the majority of isolates, chlamydoconidia are numerous and in some isolates spiral hyphae and macroconidia are present. Physiological tests: this fungus has a specific vitamin requirement for thiamine.

T. verrucosum (Fig. 31.28a–c). Colony: this is a very slow-growing fungus, and after 2 weeks of incubation at 26°C the white or grey waxy colonies may still be barely visible. Growth is better at 37°C so, if cattle ringworm is suspected, incubation at both temperatures is recommended. Microscopy: examining the reverse of the primary plate under a × 10 objective, colonies incubated at 26°C show short hyphae with terminal chlamydoconidia. In contrast, colonies incubated at 37°C produce very characteristic long chains of chlamydoconidia. Clavate or elongate microconidia may be present along the sides of the hyphae. Rat-tailed macroconidia may be produced on depleted media. Physiological tests: most isolates have a requirement for thiamine and inositol. In a few, growth is enhanced by thiamine alone.

T. violaceum (Fig. 31.29). Colony: the slow-growing glabrous colonies have a waxy or leathery texture. Characteristically they are deep red in colour, but some isolates take several weeks to pigment, or retain unpigmented sectors. Occasionally, isolates fail to pigment at all. Microscopy: microconidia and macroconidia are usually absent. Chlamydoconidia and distorted hyphae may be present. Physiological tests: growth is stimulated by thiamine.

T. yaoundei. Colony: the colonies are initially glabrous, white to cream. As they age, the surface may develop a velvety texture and tan to brown colour; a diffusable brown pigment may be produced. Microscopy: irregular hyphae and chlamydoconidia may be present; clavate microconidia are rare. Physiological tests: the lack of vitamin requirements will distinguish this species from *T. verrucosum* and unpigmented isolates of *T. violaceum*.

Genus Epidermophyton

Identified by the characteristic macroconidia and lack of microconidia.

E. floccosum (Fig. 31.30a,b). Colony: this species grows rapidly to form velvety or suede-like colonies, which may remain flat or develop central or radial folds. The colour is typically khaki or olive green and some isolates produce tufts of floccose sterile white mycelium on the surface of the colony. Microscopy: large clavate macroconidia with a rounded apical end and up to six cells are rapidly formed. They are thin-walled and initially smooth, but may develop a few discrete thickenings as they age. Microconidia are absent. Chlamydoconidia are abundant and predominate in older cultures.

Therapy and management of ringworm infections

The treatment of fungal infection is now comparatively straightforward, and cure rates for many forms of dermatophytosis over 90%. In addition to treatment, some other management measures are generally helpful.

The identification of the causative agent is useful, particularly in tinea corporis and tinea capitis where treatment of an infected animal source is important in order to prevent other infections. In the case of tinea capitis, it will also provide information on the risk of spread to other children at home or in the school.

Prevention of dermatophytosis is not practicable except in situations where there is a high risk of spread to other individuals. These include shower rooms in industry or in the armed forces or schools. In the case of tinea pedis, improvement of hygiene in swimming baths may result in lower levels of infection. Frequent washing of changing room floors and walkways will remove infective material in skin scales. The provision of tolnaftate powder at a swimming bath and encouragement to use it prophylactically has been shown to reduce levels of toe cleft tinea pedis caused by *T. mentagrophytes* var. *interdigitale*, although it had little effect on *T. rubrum*. Clearly, infected individuals using these facilities should be encouraged to seek treatment. In industry or in schools, prompt treatment of infection combined with simple hygienic measures such as washing shower room floors with an antiseptic will be useful. It is less easy to prevent spread of tinea pedis in households; treatment of infection and care in keeping to personal towels are both sensible measures. Even with less care, family members often remain free of infection in spite of persistent cases of tinea pedis in their midst.

In the case of tinea capitis, it may be necessary to take preventative action [1]. This is particularly important if there is any evidence of an increasing number of cases of tinea capitis in schools. It is important to establish the nature of the infections, and whether the organisms are anthropophilic. There are no proven methods of ensuring eradication of infection in schools, but early identification of infected children and prompt treatment are probably the best approaches to adopt. An additional precaution is the use of a topical antifungal, which is likely to reduce spread while having little effect on the infection itself [1]. There is evidence that selenium sulphide shampoo may reduce the incidence of positive cultures in children receiving griseofulvin. The issue of keeping children off school remains controversial. The value of this measure in limiting spread has to be weighed carefully against its possible effect on compliance with surveillance and treatment. Therefore, this issue has to be considered in conjunction with the local situation. In one such outbreak in London, the policy adopted was to advise treatment for all infected children with griseofulvin plus selenium sulphide or ketoconazole shampoo, to allow them to attend school once on treatment, and to screen classes with scalp brushes if there were more than two children infected.

Therapeutic agents

The treatment of dermatophyte infections usually involves the use of oral terbinafine, fluconazole itraconazole, griseofulvin or one of several well-tried topical preparations (Table 31.7). All those noted have been shown to be effective in a substantial majority of patients, provided they are used regularly.

Terbinafine [2,3]. Terbinafine is a member of the allylamine antifungals, a newly developed group of drugs, which act by the inhibition of squalene epoxidase in the formation of the fungal cell membrane. This enzyme acts at an early stage in membrane biosynthesis, and the accumulation of squalene is thought to destabilize the cell membrane. The two main antifungal compounds are naftifine and terbinafine. Both are active *in vitro* against dermatophytes in addition to other fungi; terbinafine is also active against *Sporothrix schenckii*, some *Aspergillus* species and *Histoplasma capsulatum*, in addition to other fungi. *In vitro* there is little difference between the dosage at which the drug inhibits cell growth and that at which the fungal cell is killed (the drug is fungicidal rather than fungistatic). Terbinafine can be given topically or orally. When given orally, it is rapidly taken up into the stratum corneum and it persists in nails at high concentrations for several months. These may exceed the minimum inhibitory concentration 80 days after the end of therapy [4]. Terbinafine is given orally in a dosage of 250 mg/day. It has produced rapid and long-lasting remissions in both nail disease [5,6] and persistent tinea pedis, as well as tinea corporis. A smaller tablet form of 125 mg is available in some countries for treatment of children. The frequency of relapse is much lower than with griseofulvin. It also has activity against most of the agents of tinea capitis, particularly *Trichophyton* species, although it is not licensed for this indication in many countries [7]. There are few drug interactions reported for terbinafine, and side effects are uncommon. Some patients describe abdominal fullness and nausea. Taste loss may occur occasionally but is

Table 31.7 Topical antifungal agents used in dermatophyte infections.

Compound	Available as	Comments
Benzoic acid compound (Whitfield's ointment)	Ointment	Cheap
Undecenoates—various brands available	Ointment, powder	Cheap
Tolnaftate	Cream, powder, lotion	Cheap
Imidazoles		
Miconazole, clotrimazole, econazole, sulconazole,* ketoconazole, bifonazole*	Cream, powder, lotion, spray, shampoo (ketoconazole)	Broad spectrum including antibacterial (not ketoconazole)
Tioconazole nail solution*	Nail treatment	Expensive
Bifonazole urea*	Nail treatment	Expensive
Allylamines	Cream	Very rapid
Terbinafine, naftifine*		Expensive
Amorolfine*	Cream, nail lacquer	Can be used on nails Expensive
Cyclopyroxolamine*	Cream	Broad spectrum

* Availability varies in different countries.

reversible. Hepatic reactions, although reported, are exceptionally rare. Skin rashes including erythema multiforme or toxic epidermal necrolysis are also seen on occasion.

Itraconazole [8,9]. This is an orally active azole of the triazole series. It has similar activity to ketoconazole, but without the risk of hepatotoxicity. Its mode of action is through the inhibition of the cytochrome P-450-dependent demethylation stage in the formation of ergosterol on the fungal cell membrane. It is active *in vitro* against all the main superficial fungal pathogens including *Candida albicans*, as well as a wide range of fungi that cause deep infections from *Histoplasma capsulatum* to *Penicillium marneffei*. Itraconazole rapidly penetrates to the outer stratum corneum and is also found in sebum. It is avidly bound to keratin-containing tissues, and in nail, for instance, may persist long after cessation of therapy. It has been shown that after 3 months of 200 mg/day itraconazole, levels in the toenail persist for up to 6 months [10]. This feature allows a range of different dose regimens. These have evolved so that the initial treatments first described involving 100 mg/day itraconazole have been superseded by higher or intermittent (pulsed) therapy. It is active against a wide range of dermatophytes and is effective in regimens of 100 mg for 15 days in tinea cruris and corporis, or 30 days in tinea pedis. The currently preferred regimen uses 400 mg/day, given as two daily doses of 200 mg. In tinea corporis, 1 week of therapy is sufficient, and in tinea pedis 2 weeks. For onychomycosis, a regimen of 400 mg/day for 1 week every month for 3 months is usually given. Occasionally, longer periods of treatment are needed [11]. Although it is not licensed yet in many countries for the treatment of tinea capitis [12], it is effective in this indication. Side effects are not common but include nausea and headache. There is some evidence that its absorption is impaired in the presence of phenobarbital. It also interacts with coumarin anticoagulants, ciclosporin, rifampicin, digoxin, statins and astemizole and terfenadine. It should not be given together with the latter antihistamines, as they may cause cardiac arrythmias. Side effects are not common and mainly consist of nausea and abdominal discomfort. Hepatic reactions are exceptional.

Griseofulvin [13]. This is a metabolic product derived from several species of *Penicillium*, which was first isolated from *P. griseofulvum*. Its activity, which is fungistatic, is largely restricted to dermatophyte infections. The mode of action appears to be in part through inhibition of the formation of intracellular microtubules. Resistance to griseofulvin among dermatophytes is rare. The smaller particle size microcrystalline preparations of griseofulvin are better absorbed than those with larger particles, and the micronized form is now the standard preparation. Unlike itraconazole, griseofulvin is not firmly bound to keratin.

The usual human regimen is 10 mg/kg/day given in tablet form, or solution form for children. Treatment duration varies between 2 and 4 weeks for tinea corporis to over 1 year for onychomycosis of toenails. In tinea capitis, a single dose of 1–2 g griseofulvin has been reported to be effective in some patients with tinea capitis [14]. Drug interaction with phenobarbital and coumarin anticoagulants occur [13]. Headaches and nausea are common complaints on griseofulvin; however, serious side effects have been extremely rare. There are a few reports of apparent precipitation or exacerbation of systemic lupus erythematosus (SLE) and porphyrias by griseofulvin. Occasionally, urticarial rashes are seen and light sensitivity eruptions (distinct from lupus erythematosus and porphyria) have occasionally been reported.

The use of griseofulvin has largely been superseded in many countries by terbinafine or itraconazole, except in tinea capitis.

Ketoconazole [15]. This orally active imidazole is a broad-spectrum antifungal agent. In ringworm infections requiring systemic treatment, it offers an alternative agent and is given in a 200–400 mg/day regimen with food (for adults). Hepatitis is a proven complication, occurring in 1 in 10 000 patients. Because of this, ketoconazole is reserved for second-line therapy. At high doses, ketoconazole may also inhibit androgen biosynthesis [15].

Fluconazole [16]. Fluconazole is an orally active triazole antifungal used for the treatment of *Candida* infections and systemic mycoses. However, it also has activity against dermatophyte fungi. It is given in a regimen of 150 mg/week for 2–3 weeks for tinea corporis and tinea cruris, and somewhat longer for dry-type tinea pedis. It is also reported to be effective given in weekly doses in onychomycosis, although the exact length of treatment necessary is not clear as yet. There are fewer interactions than with itraconazole but, like the latter, side effects are rare and mainly confined to gastrointestinal discomfort. However, drug resistance in *Candida* species, particularly *C. krusei* and *C. glabrata*, have been described. There is *C. albicans* resistance in AIDS patients [17].

Topical applications. A great variety of topical applications have been used for the treatment of ringworm infections. The short list includes a few preferred preparations (Table 31.7), which have been soundly tested, and which in the authors' clinical experience and the published controlled trials are of very comparable effectiveness [18–22]. In all cases, allergic contact dermatitis is rare. Irritant effects may occur with any of them, especially on raw skin and in fissures between the toes. Benzoic acid compound ointment (Whitfield's ointment), full strength, is not advised for tender skin, such as the scrotum or the groins, and in such sites should only be used diluted to half-strength with its vehicle (emulsifying ointment). Magenta paint (Castellani's paint) is still used in some cases of inflammatory tinea pedis, particularly when bacterial infection coexists, although potassium permanganate followed by a topical antifungal is preferred. Imidazoles for topical use, such as clotrimazole, econazole and ketoconazole, are now well established as effective remedies in ringworm infections with an extremely low incidence of adverse reactions; other drugs in this group, miconazole, isoconazole, tioconazole and sulconazole are equally effective [23,24]. Alternatives include topical terbinafine and amorolfine. Terbinafine applied topically has been shown to produce responses in some dermatophyte infections in very short periods. For instance, 1 week of topical terbinafine was found to be more effective than 4 weeks of clotrimazole in tinea pedis. Amorolfine, a morpholine, is mainly used as a treatment for onychomycosis in the form of a 5% nail lacquer [25] applied after abrading the nail once or twice weekly.

Treatment regimen

The different syndromes of ringworm infections require different treatment regimens. The evidence base has only recently been reviewed in the case of some infections and among published clinical trials there are very few with long-term follow-up. Generally, topical therapies are used for localized or mild infections, oral antifungals for the more extensive infections. The newer oral azoles, such as fluconazole or itraconazole and terbinafine, are now the preferred oral treatments for extensive or severe dermatophytosis rather than griseofulvin. Although cheaper than the alternatives, griseofulvin is usually slower and, in many studies, less effective.

Tinea corporis. Localized tinea corporis, especially of recent origin, commonly responds to topical therapy applied twice daily, usually for about a month. Topical terbinafine often works in a shorter time (e.g. 2 weeks). In more widespread infections of recent onset, oral terbinafine or itraconazole will generally be preferred, and may be expected to clear the condition in about 2–3 weeks, depending on the dosage used. With griseofulvin, much longer term treatment is needed, for up to several months with extensive infections. With *T. concentricum*, treatment failures may occur with griseofulvin. Both terbinafine and itraconazole are effective in tinea imbricata, but the most appropriate regimen is not clear.

Tinea capitis. Topical therapy has little place in the management of this condition except as an adjunct to oral therapy. Griseofulvin should therefore be given. Although massive single-dose therapy and intermittent dose regimens (25 mg/kg twice a week) have had some success, in general, conventional continuous daily therapy is advisable (10 mg/kg). In small-spored ectothrix infections, griseofulvin for at least 6 weeks is usually adequate. In some *T. tonsurans* and *T. schoenleinii* infections, much longer courses and sometimes higher dosage (20 mg/kg/day) of griseofulvin therapy may be needed. With scalp kerions, careful removal of crusts using wet compresses should not be neglected, and the possibility of coexisting bacterial infection should be considered. If confirmed by swabs, systemic antibacterial chemotherapy should be instituted. In general, the kerions are less painful than their inflammatory appearance suggests, but analgesics may be needed. Occasionally, in children with extensive kerions, frequent attendance at the outpatient clinic where

skilled nursing is available may be of great value, and is much appreciated by the worried parents. Permanent hair loss from scarring is usually less than would be expected.

Both itraconazole and terbinafine are now licensed in a few countries for use in children, and are alternatives for certain infections such as those caused by *Trichophyton* species, although there are fewer data and, in some cases—particularly with terbinafine—they have appeared to be less effective in disease caused by *Microsporum* species. The best length of treatment for *T. tonsurans* and *T. violaceum* infections with terbinafine appears to be 1 month. There is some evidence that higher doses of terbinafine may be more effective for *Microsporum*. The appropriate length of treatment with either itraconazole or fluconazole is not established, although both appear to be effective against *T. tonsurans*. Ketoconazole shampoo or selenium sulphide can be used to prevent spread in the early phases of therapy, when used in combination with an oral treatment. In severely inflammatory forms, there has been some argument in favour of using oral steroids to inhibit the inflammatory response. While this view has its supporters, we tend to review all cases early after the institution of antifungal therapy, and only use oral steroids in severe cases with widespread ide reactions.

Tinea barbae. Beard infections usually respond satisfactorily to itraconazole or terbinafine, sometimes in combination with topical therapy over a period of 4–6 weeks. Fairly long-term follow-up is recommended, and late recurrences undoubtedly occur.

Tinea faciei. In localized cases, promptly diagnosed topical therapy seems to work well, especially with tolnaftate or one of the imidazoles. Where delay has occurred before the diagnosis is established, and especially when steroid therapy has modified the condition, terbinafine or itraconazole is generally preferred. Most cases will clear in 3 or 4 weeks, certainly in 6 weeks, but long-standing infections may occasionally need longer periods of treatment.

Tinea pedis. For very mild toe cleft changes and for prophylaxis at swimming baths, one of the topical preparations is recommended. Tolnaftate powder, for instance, has proven value, and the imidazoles are likely to be equally effective. For toe cleft changes that are more than trivial, a cream is generally preferred and any of the listed preparations can be confidently recommended for minor forms of tinea pedis. Azole preparations are cheap and are usually effective in up to 30 days, but topical terbinafine can be used for 1–7 days; it is more expensive. If the toe clefts are very inflamed and secondary bacterial infection is likely, a brief period with rest and bland applications may be necessary. Magenta paint initially used at half strength, potassium permanganate solution or aluminium chloride solution 20–30% twice daily have considerable advantages. Clearly, if there is any evidence of serious bacterial infection, swabs should be taken; if there is clinical evidence of cellulitis, patients should receive a systemic antibacterial antibiotic.

In dry-type tinea pedis, usually caused by *T. rubrum*, terbinafine or itraconazole are of great value. Speed of recovery is faster and relapse rates less than with griseofulvin. Treatments using terbinafine 250 mg/day for 2 weeks or itraconazole 400 mg/day for 1–2 weeks are usually given.

Tinea cruris. In cases of recent onset, topical therapy can be expected to be curative within 2–4 weeks. Any of the local applications listed is satisfactory, but benzoic acid compound ointment (Whitfield's ointment) should be prescribed at half strength. Tolnaftate, terbinafine and the imidazoles are better tolerated in the flexural areas, and if the diagnosis is in doubt terbinafine and the imidazoles have the advantage of being effective against *Candida* as well. Where the condition has been present for many months, or has spread to the pubic area, the natal cleft or the buttocks, and where topical steroids have been used, systemic treatment is strongly recommended. Terbinafine and itraconazole usually produce a remission in 1–2 weeks [26]. Some patients relapse even after this therapy, although it appears less likely to occur than with griseofulvin. A longer course of therapy may work in these recalcitrant cases.

Tinea manuum. Chronic ringworm infections of the palm are not easily cleared, and oral therapy is always needed. Itraconazole and terbinafine are both effective in this condition. Most cases clear with 2–4 weeks of treatment although it may be advisable to review the results a few months after the end of treatment. With griseofulvin, longer periods of treatment are necessary. Many patients will require 3 months of therapy and may even relapse after that.

Onychomycosis caused by dermatophytes. In general, fingernail infections with ringworm fungi respond satisfactorily to oral terbinafine 250 mg/day for 6 weeks or itraconazole 400 mg/day for 1 week, given monthly for 2–3 months. With griseofulvin [27], clearance may be expected in about 4 months, but longer treatment regimen, up to 8 months or even 1 year, are often needed. In the case of toenails, longer periods of treatment may be necessary; for example, terbinafine 250 mg/day for 3 months or itraconazole 400 mg/day for 1 week given monthly for 3–4 months. One large clinical trial has shown better efficacy with terbinafine than itraconazole [28]. Some, possibly 15% of patients, fail to respond to these drugs, and there is a strong clinical impression that results are much better

in younger patients in whom faster linear nail growth and relative absence of coexisting ischaemic or traumatic dystrophy are probably important factors. Poor peripheral circulation seems to have an adverse effect on treatment.

Avulsion of the nail or removal of the infected areas with a drill or burr as adjuncts to antifungals are occasionally valuable. The use of 40% urea cream under occlusive dressing is an alternative approach to treatment [29], particularly in oral treatment failures. The addition of the imidazole, 1% bifonazole, to the urea paste has produced good responses in some patients with involvement of the entire nail plate [30]. When a single great toenail is infected, these procedures are worthy of serious consideration. Unfortunately, there has been no reliable controlled evaluation of their worth, and avulsion is certainly not without its drawbacks. Topical therapy for nail infections has been used in the past with poor results, except in SWO caused by ringworm infection, where it may well be effective. Other topical agents reported to be effective —28% tioconazole, ciclopyroxolamine and amorolfine nail paint—have all produced remissions in some studies, although these are seldom frequent enough to encourage sole use of these preparations, except in early or superficial infections or as adjuncts to oral therapy. The use of combined treatment with either terbinafine or itraconazole with amorolfine may be more effective than oral therapy alone [31].

Steroid-modified ringworm. Whatever site is affected, it is often best to treat steroid-modified ringworm with oral therapy, allowing a few applications of topical steroid to continue until the terbinafine or itraconazole has begun to take effect. It is wise to use 1% hydrocortisone cream or at least a weaker steroid than that originally prescribed, and also to warn the patient about a possible rebound in spite of these measures. Follow-up to ensure steroid cream has been stopped and cure obtained is mandatory.

Treatment failures

Failure of topical therapy. Most failures of topical therapy are caused by inaccurate diagnosis or by inappropriate use of topical therapy (e.g. in hairy areas), or because the treatment is not used. Once or twice daily application for several weeks is usually required for success, and many patients, particularly if their symptoms are minor, will not achieve this unless they are carefully supervised and enthusiastically encouraged. Paradoxically, some non-fungal conditions may be improved considerably by one of the antidermatophyte preparations, and these remedies should not be used empirically to establish the diagnosis of ringworm infection. Many dermatoses respond, at least temporarily, to any bland application, and imidazole compounds in particular have considerable antibacterial properties.

Failure of oral therapy. When a patient fails to respond to terbinafine, fluconazole or itraconazole, the following points should be checked:

1 Is the diagnosis correct? If necessary repeat scrapings.

2 Has the patient been taking the tablets regularly?

3 Is the patient taking any potentially competitive drugs?

4 In spite of taking them correctly, is the patient failing to absorb the antibiotic? Estimation of itraconazole levels, which is sometimes poorly absorbed, may be helpful.

5 In some patients with onychomycosis, poor penetration of drugs into defined linear or nail edge areas of nail plate infection may account for treatment failure.

6 Is there coexisting pathology such as arterial disease?

7 Is a co-pathogen or secondary infection present? This should be considered in feet and in the case of kerions, and perhaps in groin infections too. In nails, the coexistence of non-dermatophyte fungus should be considered. *Scopulariopsis brevicaulis*, apart from causing infections of the toenails in its own right, may coexist with *T. rubrum* or *T. mentagrophytes* var. *interdigitale* and seems, at least on occasions, to cause failure of treatment. Nail removal may be indicated in this instance.

8 Antifungal resistance. This phenomenon is sufficiently uncommon among dermatophytes to make routine testing unnecessary [30], but where treatment failure occurs without other explanation, it is possible to estimate the sensitivity of the causal organism. This should be performed by a specialist laboratory. Apart from true resistance, tolerance, in which the organism apparently becomes clinically resistant to drug in the tissues but is sensitive *in vitro*, may also be important.

9 Reinfection. As ringworm fungi can frequently be isolated from the environment, when there are cases of ringworm of the scalp, and from clothing after laundering, it is highly likely that patients whose infection has been eradicated may be reinfected from these sources. Unfortunately, there is no proven way to avoid this.

Despite running through this checklist, dermatologists may not come up with an adequate explanation for treatment failure. In these situations, the use of one of the alternatives is a logical further step.

Infections caused by *Scytalidium* species

Aetiology. *Scytalidium dimidiatum*, previously known as *Hendersonula toruloidea*, is a weak secondary pathogen of higher plants, found mainly in tropical areas, but also in the USA and the Mediterranean region. This grey to black mould is now recognized as the cause of ringworm-like infections of the palms, soles, toe webs and nails [1–4]. *S. hyalinum*, a variant non-pigmented form of *S. dimidiatum*, can also mimic tinea pedis and manuum and invade the nail plate [5]. These two moulds evoke the same clinical picture.

Fig. 31.31 Onychomycosis caused by *Scytalidium dimidiatum*: early onycholysis.

Although these infections were first diagnosed in the UK in patients who were immigrants from the West Indies, East Africa and the Indian subcontinent, reports from areas where they may be truly endemic, such as the Caribbean [6], West Africa [7–9] and Thailand [10], have shown that infection by *Scytalidium* species is extremely common. Infection has also been seen in Europeans who have merely visited an endemic area for a vacation.

Clinical features. These fungi are capable of producing toe cleft changes and involvement of the palms and soles. In this, they closely resemble the dry-type infection caused by *Trichophyton rubrum* affecting the palms or soles [5]. Lesions are often asymptomatic and only discovered on routine inspection. In fingernails, the nail changes start at the lateral and distal edges, and there may be extensive undermining of the nail without corresponding thickening of the nail plate (Fig. 31.31). The nails may fracture transversely in due course. Paronychia often accompanies these changes. Usually, yeasts are not present under the nail fold, suggesting that the changes are caused by *Scytalidium* alone. In the toenails, the changes are usually identical to those seen in dermatophyte infections. Occasionally, there may be increased pigmentation in the nail plate, but this should not be confused with idiopathic longitudinal pigmented streaking of the nail. This change is most prominent in white people with nail infections [11]. The infection is confined to areas of thickly keratinized skin, and involvement of less heavily keratinized areas, such as the groins, or dorsum of the hand or foot, is not found.

Laboratory diagnosis. Although pigmented brown hyphae have occasionally been observed in skin and nail

Fig. 31.32 Infection by *Scytalidium* species. Skin scales mounted in 30% KOH, bright field. The hyaline hyphae superficially resemble those of dermatophytes, but are very uneven in diameter. One- to two-celled arthroconidia may be observed. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

Fig. 31.33 *Scytalidium dimidiatum* colony forms. The fast-growing form (right) fills a 90-mm Petri dish in a few days and develops profuse aerial mycelium. The velvety, slow-growing form grows at the same rate as a dermatophyte. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

samples infected by *S. dimidiatum*, in the vast majority of cases the hyphae are hyaline and appear very similar to those of dermatophytes. Typically, however, they are more irregular, varying noticeably in width along the length of a single hypha [12] (Fig. 31.32). With experience, a preliminary diagnosis of *Scytalidium* infection may be made on the basis of direct microscopy alone.

Both *S. dimidiatum* and *S. hyalinum* are sensitive to cycloheximide, and this antibiotic must be excluded from the culture medium. As mixed infections by *Scytalidium* species and dermatophytes have been recorded, duplicate cultures with and without cycloheximide are ideal, and will allow the isolation of both dermatophyte and non-dermatophyte. Mixed infections of dermatophytes and *S. dimidiatum* and *S. hyalinum* have also been reported.

S. dimidiatum. Colony: variable colonial morphology [13] (Fig. 31.33). One form grows very rapidly and produces a high aerial mycelium, which completely fills a 90-mm Petri dish in a few days. The other common form grows more slowly, at about the same rate as a dermatophyte and does not produce aerial hyphae, but has a velvety surface texture. Both are pale initially, but darken to black and mouse grey, respectively, as they mature. Microscopy: branching chains of one- to two-celled brown arthroconidia are observed (Fig. 31.34). These are abundant in the fast-growing cultures, but may be scanty in the slow-growing form. Coiled hyphae and rough-walled hyphae are usually present in the slow-growing cultures.

S. hyalinum. Colony: the fungus grows rapidly, and in a few days produces a white to cream colony with a moderately high aerial mycelium and buff reverse (Fig. 31.35).

Fig. 31.34 *Scytalidium dimidiatum* microscopy, bright field. Chains of brown, one- to two-celled arthroconidia are characteristic. They may be scanty in the slow-growing form. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

Fig. 31.35 *Scytalidium hyalinum* colony. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

Microscopy: chains of hyaline one- to two-celled arthroconidia are produced.

Treatment. There is no reproducibly effective therapy, although individual patients may respond to treatment with tioconazole or econazole. For scaling sole lesions, the use of Whitfield's ointment may be very effective. Although both organisms may be sensitive *in vitro* to itraconazole or terbinafine infections seldom respond to these drugs clinically.

Onychomycosis caused by other non-dermatophyte moulds

Definition. Broadly, the term onychomycosis describes any fungal infection of the nail plate. Ringworm infections, *Candida* infections and *Scytalidium* infections are considered separately, and these organisms are considered to be primary pathogens. However, a wide variety of other non-dermatophyte moulds have been reported from abnormal nails, most often toenails, and in such cases their significance needs very careful assessment [1]. Many of these putative pathogens are common in the environment, and may be isolated as contaminants, particularly on media free of cycloheximide. It is therefore essential in cases where such moulds are implicated in onychomycosis to correlate the morphological findings on direct microscopy with those of the isolate. A considerable proportion of dermatophyte infected nails with typical hyphae present on direct microscopy will fail to yield a dermatophyte on culture. In these instances, the isolation of a few colonies of a contaminating mould may be misinterpreted. In other instances, a non-dermatophyte mould may be isolated in addition to a dermatophyte, and once more, unless evidence suggestive of a mixed infection has been obtained on direct microscopy [2], in most instances this will represent simple contamination. Before the isolation of a non-dermatophyte can be considered significant, re-examination of the patient is essential in order to confirm the infection. A second direct examination will allow any unusual features of the fungus in the nail to be assessed. Atypical morphology, such as the presence of large numbers of fronding hyphae or even the production of characteristic conidia within the nail, may be present. In such instances, a second culture on medium free of cycloheximide may allow reisolation of the same mould and confirm the infection. Concurrent culture with cycloheximide is also recommended to confirm the absence of a dermatophyte, or it may in some instances prove the presence of a mixed infection, for nails rendered abnormal by a primary dermatophyte infection may occasionally be secondarily invaded by moulds. It is noteworthy that in unmixed infections, these non-dermatophytes, unlike *Scytalidium* species, are incapable of producing concurrent skin infection.

Using reliable criteria, one survey in Canada [3] of over 2500 isolates from infected nail samples found that *Scopulariopsis brevicaulis* made up 1.6% of the total, and that species of *Aspergillus* and *Fusarium* comprised a further 0.3% of the total. Similarly, a working group of the British Society for Medical Mycology [4] has estimated that approximately 5% of cases of onychomycosis are caused by non-dermatophyte moulds. Such data confirm the view that a few moulds are fairly regularly reported from a small percentage of the total cases of onychomycosis, and their isolation may suggest that they are playing some part in the pathology, although whether their removal with antifungal therapy will result in clinical recovery remains to be established. By far the most common of these isolates is *Scopulariopsis brevicaulis*, which does appear capable of attacking undamaged nails or ones showing only trivial abnormalities. In cases of superficial white onychomycosis, species of *Acremonium*, *Fusarium* and *Aspergillus* may be isolated rather than *Trichophyton mentagrophytes* var. *interdigitale*. Since 1990, *Onychocola canadensis* has been recognized as a cause of onychomycosis in nine subjects from Canada and New Zealand [5,6].

Scopulariopsis infections [2]

Scopulariopsis brevicaulis is a common saprophytic mould that does not attack the skin. When it causes nail dystrophy, the clinical features may be indistinguishable from those of a ringworm infection, but where there is heavy

Fig. 31.36 Onychomycosis caused by *Scopulariopsis brevicaulis*.

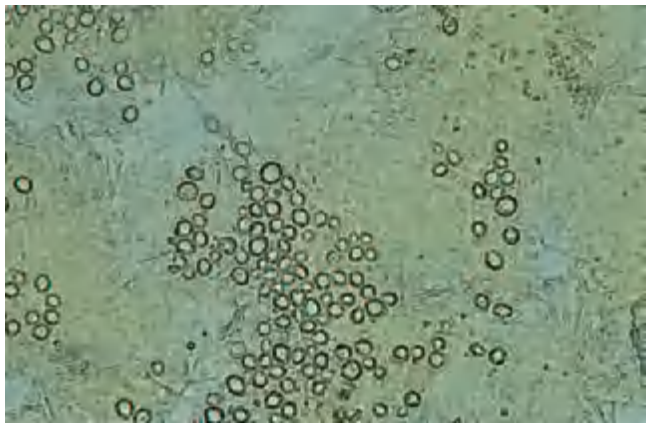

Fig. 31.37 Onychomycosis caused by *Scopulariopsis brevicaulis*. Nail mounted in KOH, bright field. The characteristic conidia are relatively thick-walled, oval or lemon-shaped with a truncate base. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

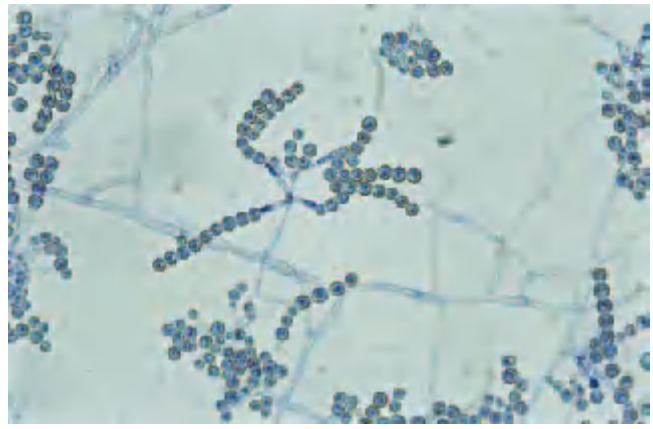
(a)



(b)

Fig. 31.38 *Scopulariopsis brevicaulis*. (a) Colony. On media free of cycloheximide, the colonies are initially waxy and deeply folded, but production of conidia rapidly produces a brown colour on the colony surface. (b) Microscopy, bright field. Chains of rough-walled conidia are formed from annellides. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

invasion its brown spores may discolour the nail, producing a cinnamon colour (Fig. 31.36), best seen end-on in the area of subungual hyperkeratosis. The great toenails are most often affected, but other toenails and, very occasionally, fingernails are involved. Dermatophyte infections of the skin and of the *Scopulariopsis*-infected nail plate itself may coexist.

Laboratory diagnosis. The distribution of the fungus in the infected nail material is often patchy, but where conidia are found they are quite distinctive, being approximately spherical or lemon-shaped with one flat basal facet. The thick cell walls and truncate bases of the conidia distinguish them from the arthroconidia of dermatophytes. The surfaces of the conidia appear smooth (Fig. 31.37). The mould is partially sensitive to cycloheximide and, in most instances, if cycloheximide-containing medium is used for isolation, the fungus will grow but remain compact, pale and intricately folded, producing few conidia.

Scopulariosis brevicaulis (Fig. 31.38a,b). Colony: on cycloheximide-free medium, the fungus grows rapidly to produce a powdery cinnamon brown surface, often with radial or cerebriform folds. The reverse is cream to brown. Microscopy: chains of basipetal conidia are formed from annellides. The conidia are rough, lemon-shaped or obovoidal with a truncate base.

Management. It is essential to search carefully for a coexisting dermatophyte infection, particularly if there are cutaneous changes. Treatment of pure *Scopulariopsis* infections is difficult. Occasionally, patients may respond to a topically applied lotion such as econazole. However, the most commonly used approach is to use 40% urea paste as a method of chemical nail avulsion and, following removal of the infected plate, an azole antifungal cream or lotion is applied daily to the nail bed until the new nail has completely formed. Itraconazole 400 mg/day for 1 week monthly for 3–4 months may be of help [7].

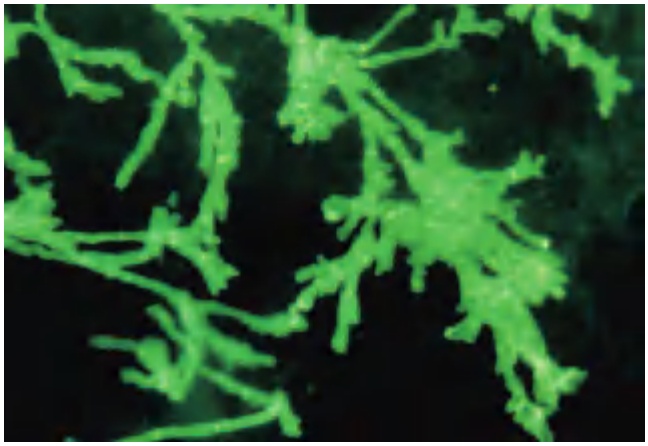


Fig. 31.39 Superficial white onychomycosis caused by non-dermatophyte moulds. Nail mounted in KOH and Calcofluor white, UV illumination. Bizarre, fronding hyphae may be observed (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

Superficial white onychomycosis

Non-dermatophyte moulds that cause SWO produce a clinical picture identical to that seen in SWO caused by *Trichophyton mentagrophytes* var. *interdigitale*. However, one distinguishing feature is the lack of accompanying skin lesions.

Laboratory diagnosis. Direct examination of the nail material often reveals bizarre atypical hyphal forms (Fig. 31.39) and extensive fronding hyphae. However, some degree of fronding may be seen in dermatophyte infections. The most commonly isolated species, which include *Acremonium strictum*, *Aspergillus terreus* and *Fusarium* species [8], grow rapidly if cycloheximide is omitted from the culture medium.

Acremonium strictum. Colony: the rapidly growing colonies are slimy to waxy with a few central tufts of aerial mycelium and are pink, beige or orange in colour. Microscopy: elongate narrow phialides arise at right angles from the slender hyphae. The ellipsoidal conidia collect as a slimy ball at the apex of the phialide.

Aspergillus terreus. Colony: colonies are rapidly growing, powdery with a cinnamon brown surface and pale yellow reverse. Microscopy: the vesicle at the apex of the stout conidiophore bears metulae and phialides only on the upper two-thirds of its surface. Long chains of small smooth brown phialoconidia are produced, which form a columnar head.

Fusarium species. Colony: rapidly growing woolly colonies may have a pink, purple or pale brown surface and reverse. Microscopy: the genus *Fusarium* is characterized by the production from phialides of curved multicellular macroconidia, with a distinct foot cell at the base. Microconidia are also formed and are unicellular or bicellular, ovoid to ellipsoidal. They collect as slimy balls or chains at the apices of the phialides. Chlamydoconidia may also be present.

Management. Results of treatment are unpredictable, but a trial of therapy with amorolfine 5%, tioconazole 28% or removal of the nail with 40% urea is worth attempting.

Onychomycosis caused by Onychocola canadensis

This fungus was only recognized as a pathogen in 1990. Nails display yellow or grey discoloration and hyperkeratosis with a build-up of subungual debris. Direct microscopy reveals irregular hyaline, sometimes golden or brown hyphae, together with barrel-shaped or round arthroconidia. The fungus grows in the presence of cycloheximide as a very slowly developing, restricted, glabrous, pale-grey mould, which after 5–6 weeks eventually produces delicate chains of hyaline, waisted arthroconidia.

Management. A single patient treated with griseofulvin showed some clinical improvement after 6 months, but the direct microscopy remained positive.

Miscellaneous mould infections

In contrast to the fungi described above, an enormous variety of other moulds have been implicated in one or only very few cases of onychomycosis. These include *Pseudeurotium ovalis*, *Pyrenochaeta unguius hominis*, *Lasiodiploidea theobromae*, *Curvularia lunata* and many others [9]. Investigations of abnormal toenails, especially in elderly people, have shown that an appreciable minority are colonized by non-dermatophyte fungi, usually moulds, often *Aspergillus* species. Fingernails are much less often invaded. These moulds are generally accepted as existing purely saprophytically. Although they may conceivably add to the primary damage caused by ischaemia, trauma or a dermatosis, they are, in general, of little practical importance to the patient. For the dermatologist, their significance lies in the fact that they must be distinguished from dermatophytes. Moreover, a dystrophic nail caused by ischaemia, secondarily colonized by *Aspergillus* species, is likely to regrow abnormally even if the fungus is eliminated by avulsion. Unlike *Scopulariopsis* infections, secondary mould invasion often affects several nails and indeed all may be invaded.

In addition to causing SWO, *Fusarium* species may also cause proximal subungual onychomycosis and rarely can be isolated from interdigital tinea pedis.

Candidosis

SYN. CANDIDIASIS; MONILIASIS; THRUSH

Definition. Candidosis is an infection caused by the yeast *Candida albicans*, or occasionally by other species of *Candida*. Superficial infections of the mucous membranes and skin are numerically most important, but more serious involvement of internal organs as in septicaemia, endocarditis and meningitis can also occur and these are considered in the section on systemic mycoses.

Aetiology [1]. *C. albicans* is an oval yeast 2–6 × 3–9 μm in size, which can produce budding cells, pseudohyphae and true hyphae. This ability to simultaneously display several morphological forms is known as polymorphism. Although hyphae are likely to be produced during the process of tissue invasion, yeasts without hyphae may also occur in invasive disease, particularly in infections caused by non-*albicans Candida* species. Apart from *C. albicans*, the genus *Candida* includes over 100 species, most of which are neither commensals nor parasites on humans. A few other species of *Candida*, for example *C. tropicalis*, *C. dubliniensis*, *C. parapsilosis*, *C. guilliermondii*, *C. krusei*, *C. pseudotropicalis*, *C. lusitaniae*, *C. zeylanoides* and *C. glabrata* (formerly *Torulopsis glabrata*) are occasional causes of human candidosis, particularly in AIDS patients and in patients in intensive care units.

Candida ecology and the commensal or parasite role [2]

Gastrointestinal tract carriage

Many species of animals and birds carry yeasts, often species of *Candida*, in their gut as part of the normal commensal flora and the human is no exception. *C. albicans* is a frequent, but not invariable inhabitant of the gastrointestinal tract. Colonization with *C. albicans*, or another species, may occur during birth directly from the birth canal, at some time during infancy or perhaps later in life. We lack good information on carriage rates at different ages. Very early colonization of the mouth seems more likely to be followed by frank pathological changes, but if the organism is acquired later it is usually established asymptomatically.

The literature on oral carriage rates is extensive and confusing, but in his review Odds [1] concludes that fewer than 26% of normal subjects carry yeasts in the mouth, and that the figure for *C. albicans* carriage is about 18%. Surveys of the oral flora of hospital patients tend always to give higher figures. Isolation rates of yeasts from faecal specimens and rectal swabs are also higher than those from oral samples. Odds suggests figures of nearly 47% for yeast carriage, and just under 41% for *C. albicans* on the basis of published studies.

If specialized techniques or repeated sampling are used, the proportion of healthy adults carrying *Candida* in the gastrointestinal tract may be demonstrably higher, even rising to two-thirds. Moreover, if antibacterial antibiotics effective against the resident gastrointestinal bacterial flora are given by mouth, the percentage of *Candida* carriers rises—as demonstrated by a single oral or rectal swab [3]. However, even then there remain some from whom *Candida* cannot be isolated. Clearly, the density of the gastrointestinal yeast flora varies from individual to individual, and influences the chances of isolation. Presumably, there is a spectrum from those with high levels through moderate carriers to those whose gut has no yeasts, or at least very low levels.

Studies of *Candida* serology and skin testing suggest that a substantial proportion of those not colonized by yeasts may have been exposed to *Candida* in the past. The practical implication of this is that normal individuals show a wide range in the density of carriage of *Candida* species as assessed, for instance, by mouth swabs. Extraneous factors such as oral antibiotic therapy are likely to increase not only the incidence of carriage, but also the number of organisms present and the chances of invasion of tissue.

Because the mouth and rectum are easily accessible for swabbing, gastrointestinal tract carriage of *Candida* is generally considered in these terms, but there is considerable evidence that the yeast colonizes other parts of the gastrointestinal tract.

Vaginal carriage [4]

The healthy vagina may be colonized by yeasts—most commonly *C. albicans*, sometimes *C. glabrata*—but only in a minority of women [5]. The percentage of vaginal carriers differs widely in different surveys, but a figure of 12.7% for *C. albicans* is probably accurate. Higher rates are found in hospital patients, even without vaginal disease [1].

Pregnancy and oral contraception have both been associated with elevated carrier rates, but so is the use of intrauterine devices [6].

Cutaneous carriage

Generally, neither *C. albicans* nor any other species of *Candida* is a permanent member of the normal flora of the skin. At the same time, it is clear from numerous surveys that skin adjacent to the body orifices and the skin of the fingers, which are in frequent contact with the mouth, often yield *C. albicans* and sometimes other species, particularly *C. parapsilosis* and *C. guilliermondii* [7]. In moist intertriginous sites, *Candida* may be a persistent colonizer in a few individuals [8]. Age and climate are important in this connection. Samples from the very young and the very old are more likely to yield *Candida*.

Carriage in other sites

The bronchial tree is not normally colonized by *Candida*, and where the organism is isolated from sputum specimens, at least in low amounts, it can be assumed that it has come from the mouth or oropharynx. It is apparent that swallowing a massive quantity of *Candida* cells will result in the transfer of these yeasts rapidly through the gut wall into the circulation, presumably via the portal vein and the liver [9]. Whether such passage of *Candida* cells occurs in normal situations is not known, but it may be an important portal of entry in the neutropenic patient.

C. albicans can occasionally be cultured from the environment, usually in situations where there are heavily infected subjects [1], human or animal; for example, it has been isolated from a nursery where there was an epidemic of oral thrush, from hospital bed linen, and from the air of dermatology clinics. Normally, however, *Candida* is not part of the air-borne microflora. Except for neonatal and conjugal infections, most cases of candidosis probably result from infection of the host by his or her own commensal yeasts. Further experience with typing [10] have tended to confirm the view that most infections are endogenous, and generally infection seems to follow a shift in the existing host–yeast relationship. This shift from commensal to parasite results from a variety of influences. To date, an increase in yeast virulence has not been shown to be important. Theoretically, different isolates of *C. albicans* might be expected to differ to a minor degree at least in their capacity to cause damage in the human host [11]. In practice, such variations are hard to demonstrate.

Genetic methods of typing *Candida* strains have provided a means of investigating the spread of organisms within individual patients, groups or hospital wards [12]. They have indicated that spread of predominant strains can occur either between individuals or in hospitals. In one well-documented outbreak, an isolate that resisted normal hand-washing procedures was the cause of a number of infections in an intensive care unit [13]. This indicates that strains carried by patients may be replaced by others with different biological characteristics. These techniques can now be used to determine important issues, such as the acquisition of drug resistance [14]. *C. albicans* may also demonstrate an unusual phenomenon known as phenotypic switching, whereby a strain may change morphology or another phenotypic character such as drug sensitivity in response to a change in growth conditions; such changes are reversible and not associated with genetic variation [15].

Pathogenesis

Fungal virulence

In animal experiments, some *Candida* species have been shown to be less virulent than *C. albicans*, a finding that conforms well with clinical experience. Generally, the most common pathogen in skin disease is *C. albicans*, although increasingly other species are isolated in vaginal infections and from AIDS patients.

Enzymes and toxins

Factors such as the production of an acid proteinase by certain strains of *C. albicans* are also known to affect pathogenicity. Proteinase-negative strains are known to be less virulent [1]; laboratory-generated gene defective strains have not been shown to be less virulent.

Yeast–mycelial shift [2]

In oral and cutaneous candidosis, scrapings examined microscopically usually show *Candida* in both budding and mycelial forms. In histopathology of invasive candidosis, hyphae are usually present. This suggests that the production of hyphae may contribute to fungal virulence.

Adherence

The ability of yeast forms to adhere to the underlying epithelium is also an important prerequisite for tissue invasion [3–5]. Adherence of *Candida* to epithelial surfaces is mediated through a number of receptor interactions. *Candida* adhesins are either based on cell-wall mannan or protein components. Among the latter is a *Candida* surface C3d-binding protein [6]. It has also been shown that proteinase production is necessary for adherence.

Other factors

In vivo, a wide variety of factors have at various times been claimed to be important in stimulating mycelium formation [7]. Temperatures above 35°C, low oxygen tension, liquid media, non-sulphur-containing amino acids, a polysaccharide carbon source, serum and a pH of 7.5 are the most convincing factors in experimental studies [8]. However, it is difficult to relate these experimental results to the *in vivo* situation.

The effects of ecological pressures from other organisms are of considerable importance [9]. Both in the gastrointestinal tract and on the skin, removal of competing bacteria leads to an increase in yeast numbers, an important prerequisite to invasion. Work on the competition between *Candida* and bacteria in saliva suggests that a crucial factor is the amount of available glucose [9,10], and that if this is elevated and plentiful, as in diabetes, the bacterial flora will not inhibit the yeast [11]. Mechanisms other than nutrient depletion may possibly apply. In other situations (e.g. the finger web), bacteria, especially Gram-negatives, may act as co-pathogens rather than competitors, their presence enhancing the pathogenicity of the yeast. Once again the presence of bacteria may impair the ability of *Candida* to adhere to the underlying substrate [12].

Host factors

Host factors involved in mucocutaneous candidosis are numerous. It has long been recognized that the very old, the very young and the very ill are susceptible to oral thrush. However, a variety of other factors are also involved, and many patients have more than one predisposing factor. In the mouth, carbohydrate levels are important; food debris, likely to be present in the mouth of the severely ill patient with inadequate oral hygiene, should not be ignored and may be as significant as diabetic saliva. In Sjögren's syndrome, *Candida* carriage and probable susceptibility to candidosis are high, a fact attributed to low saliva flow rates. Whether this correlates with changes in pH as has been suggested, or with IgA levels, or whether it simply leads to poor oral hygiene as the mouth is inadequately washed by saliva, is not known. High glucose levels in urine, general tissue fluids and sweat may make diabetics more susceptible to candidosis [1]. Phagocytosis is also impaired in diabetics. In practice, this feature is largely confined to *Candida* vulvovaginitis and balanitis.

Any form of local tissue damage may be important in the pathogenesis of candidosis [2]. Experimental removal of the stratum corneum facilitates the establishment of cutaneous candidosis, and with a given inoculum increases the severity of the response [3]. In the mouth, the wearing of dentures undoubtedly increases susceptibility, but whether this is primarily because of trauma, food debris

or the restriction in saliva flow is not clear. On the skin, maceration is of fundamental importance, and in experimental candidosis high moisture levels, usually provided by occlusion, are a prerequisite. Although several surveys have shown higher levels of *Candida* carriage on psoriatic and eczematous skin, and one other study [4] has claimed that *Candida* paronychia is more common in psoriatics, in general candidosis is not a common complication of either psoriasis or eczema. Indeed, Rebora *et al*. [3] found difficulty in colonizing such diseased skin with *Candida* without prior removal of the bacteria.

Furthermore, in experimentally infected guinea pigs there is increased epidermal cell turnover, which develops after *Candida* infection, possibly through a cellular immune mechanism. In this case, increased shedding of stratum corneum correlates well with recovery from infection [5].

Higgs and Wells [6] showed that some cases of chronic mucocutaneous candidosis had iron deficiency. With iron replacement therapy, their resistance to *Candida* infection increased. On the other hand, *in vitro* experiments indicate that unsaturated transferrin acts as an inhibitor to *C. albicans*. Iron reverses this effect.

Serum factors

Apart from transferrin, other serum factors affecting *C. albicans*, such as clumping factor, have been described [7]. Short of actual clumping, even the well-known effect of serum in encouraging *C. albicans* to produce germ tubes and mycelium may be disadvantageous. Davies and Denning [8] have shown that hyphae longer than 200 μm are poorly phagocytosed, and not readily killed by leukocytes. The presence of heavy persistent *Candida* infection has on some occasions led to the appearance of factors present in serum that, far from being advantageous, resulted in the inhibition of T-cell function; an effect demonstrable with other leukocytes *in vitro*, and that was reversed by anticandidal therapy [9]. It is likely that this is a circulating antigenic product of *Candida* such as mannan, which is known to affect immune responsiveness, blocking antibody or an immune complex.

Endocrine factors [10]

Apart from diabetes, a variety of endocrinopathies have been mentioned as susceptibility factors in candidosis. There is little doubt that Cushing's syndrome, whether spontaneous or iatrogenic, increases susceptibility to a wide range of infections including candidosis. The mechanism seems to be a direct suppression of immune mechanisms, especially T-cell function. In addition to these two conditions, familial endocrinopathy presenting with Addison's disease, hypoparathyroidism and hypothyroidism have all been found to occur in association with some cases of chronic mucocutaneous candidosis. Mutations on the *AIRE* (autoimmune regulator) gene have been identified in some patients [11]. Treatment of the endocrine abnormality does not improve the *Candida* infection and other factors are probably involved.

Immunological factors

Intensive investigation of patients with the syndrome of chronic mucocutaneous candidosis, and studies of a wide range of patients with primary immune defects, indicate clearly that in the defence against *Candida* infection, both superficial and deep-seated, cell-mediated immunity is of paramount importance, coupled with normal phagocytosis and killing by polymorphs and macrophages [12,13]. Circulating humoral antibodies or secretory IgA may have some role [14]. Absence of specific anti-*Candida* IgA salivary antibody in cases of chronic mucocutaneous candidosis was subsequently shown to be associated with depressed T-cell function, a factor now thought to be more important. However, in children wearing orthodontic appliances, the risk of candidosis is higher in those with low salivary IgA levels.

While systemic corticosteroids act to increase the susceptibility to candidosis by diminishing immune functions, the practical importance of topical steroids in this connection is not so well understood. However, there is evidence that an inflammatory response to *Candida*, which can be produced experimentally in humans [15] but not in the rat [2], by dead disintegrated *Candida* cells, as well as by living organisms, can be suppressed by topical steroids. The description of large granulomatous lesions in the napkin area of infants with candidosis treated with steroids suggests that it may also enhance the real susceptibility to the organisms, as might be expected if fewer lymphocytes and phagocytic cells are present.

The susceptibility of elderly and severely ill people, especially those with leukaemia, lymphomas and carcinomatosis, probably lies, in large measure, in the depression of cell-mediated immunity. In AIDS this is clearly the case.

Patients with defective T-lymphocyte function, such as those with AIDS, appear to be particularly susceptible to mucosal or cutaneous candidosis, but not systemic infections [16]. Congenitally T-cell-deficient mice (*nu/nu*) do not show reproducible increased susceptibility to systemic infection by *Candida*. In fact, some investigators have found heightened resistance, suggesting that T-lymphocyte activity alone does not account for resistance to systemic invasion [17]. By contrast, in patients with chronic mucocutaneous candidosis, the most consistent abnormalities have been those of T-lymphocyte function, particularly cytokine expression [9], even though some of

these are now thought to be secondary to immunoregulation induced by the infection.

Patients with defective neutrophil or macrophage function are susceptible to both superficial and systemic candidosis. The activity of neutrophils and macrophages in phagocytosis and killing of *Candida in vitro* has been demonstrated [18,19]. In addition, some cytokines such as interferon-γ appear to interact with these cells to enhance killing of the organism. It appears that there is therefore substantial interplay between different immune mechanisms in defence against candidosis.

Candidosis and AIDS

In the untreated HIV-positive population, oral *Candida* carriage rates are generally high, and this has been confirmed by the finding that carriage rates are, for instance, higher in HIV-positive homosexual males than in a control group of HIV-negative homosexual men [1]. Another study of HIV-positive patients without clinical evidence of oral candidosis showed that 24% of 261 individuals were carrying *C. albicans* on the tongue or buccal mucosa. Colonization rates were higher in intravenous drug abusers, Center for Disease Control (CDC) group IV and in those with lymphopenia. In addition, patients with CD4 cell depletion and those with elevated β_2-microglobulin levels were more likely to be carriers [2].

The relationship between CD4 counts, as a guide to disease progression, and oral candidosis in AIDS patients has been studied by a number of authors. Oral thrush does appear to reflect viral load [3]. Both hairy leukoplakia and oral candidosis are markers for increased rate of progression to AIDS [4]. The presence of oral candidosis may also be a marker of survival in some patients. For instance, HIV-positive patients with oral candidosis but who have no other features of AIDS have a poorer survival rate than those without [5]. However, it is important to remember that immunologically related factors such as CD4 counts are not the only determinants of oral candidosis. Another factor implicated as a possible predisposing cause of oral *Candida* infection in AIDS patients is the salivary flow rate.

The evidence that persistent vaginal candidosis is associated with AIDS is less convincing.

Histology [1,2]

The range of clinical manifestations caused by *C. albicans* and other *Candida* species is paralleled by the variety of pathological changes seen in inflamed tissues. However, there are certain generalizations that can usefully be made about histology of candidosis of epithelial surfaces. Fungal elements are almost always restricted to the outer layers of epithelium, including the stratum corneum. On the skin, particularly in acute infections, mycelium may be very sparse, and indeed yeast forms may be present in only small numbers. There seems also to be less likelihood of finding mycelium in infectious species other than *C. albicans*.

Apart from the presence of the fungus, acute oral candidosis is characterized by inflammatory changes with the formation of a pseudomembrane of epithelial and inflammatory cells [1]. In the oral epithelium and in the cutaneous epidermis, the inflammatory infiltrate consists predominantly of polymorphs, which may form microabscesses or subcorneal pustules. Splitting of the epidermis often follows. In the dermis, the inflammatory infiltrate is a mixture of lymphocytes, plasma cells (especially in the mouth) and histiocytes. In chronic cases, hyperplasia with parakeratosis and acanthosis of the epithelium is associated with a mixed chronic inflammatory infiltrate. In chronic cutaneous lesions, hyperkeratosis with acanthosis may be seen, and in *Candida* granuloma of the skin, a dense mixed cell infiltrate may include giant cells [3]. Although the matter is still somewhat controversial, it seems probable that in chronic oral cases, neoplastic change secondary to candidosis may develop as a late feature [4].

Clinical syndromes of candidosis

Oral candidosis [1]

Acute pseudomembranous candidosis (oral thrush; acute pseudomembranous candidiasis) [2,3]. The characteristic sign of this condition is a sharply defined patch of creamy, crumbly, curd-like white pseudomembrane, which, when removed, leaves an underlying erythematous base. This membrane consists of desquamated epithelial cells, fibrin, leukocytes and fungal mycelium that attaches it to the inflamed epithelium. There may be one or many patches. The buccal epithelium on the cheeks, the gums or the palate may be affected. In immunocompromised patients, the tongue may be affected as well. In severe cases, extension to the pharynx or the oesophagus may occur, and erosion and ulceration are occasional complications.

The condition occurs most commonly in the first weeks of life, and the preterm infant may be especially susceptible. Apart from in neonatal oral candidosis (as distinct from *Candida* carriage), acute pseudomembranous candidosis is usually secondary to local or general predisposing factors. For instance, it may present in the neutropenic patient or those with AIDS [4–6]. In both cases, the clinical changes are often erosive with severe symptoms resulting in inadequate food intake because of pain. Extension of lesions to the buccal mucosa, tongue and oesophagus is common in these groups. Coincident oral infection with herpes simplex virus may occur in both groups [7]. Oral candidosis is the most common secondary infection in those with AIDS, and recurrent or more prolonged episodes are to be expected in these patients [8].

Acute erythematous candidosis (acute atrophic oral candidiasis) [9]. In this condition, there is marked soreness and denuded atrophic erythematous mucous membranes, particularly on the dorsum of the tongue. It may follow pseudomembranous candidosis, when traces of the residual membrane will often be found. It is especially associated with antibacterial antibiotic therapy, but may also develop in HIV-positive subjects. In these cases, the tongue is often markedly affected.

Chronic pseudomembranous candidosis. This does not differ clinically from the acute pseudomembranous variety but, as the name suggests, lesions are very persistent. It occurs principally in immunocompromised patients.

Chronic erythematous candidosis (chronic atrophic candidiasis; denture sore mouth; denture stomatitis) [10]. Some soreness in the epithelium in the denture-bearing area is said to affect nearly one-quarter of all denture wearers and most, if not all cases appear to be caused by candidosis. A similar problem may also occur in children wearing orthodontic appliances.

Elimination of *Candida* alone does not usually result in complete recovery, and it is likely that other factors such as chronic mechanical irritation and bacterial colonization have a role in the pathogenesis of this condition.

The condition is normally confined to the upper denture-bearing area, the palate and gums. The affected mucous membranes show a variable bright red or dusky erythema, fairly sharply defined at the margin of the denture. The epithelium is often shiny and atrophic, and there may be marked oedema, in some areas at least. In late cases, secondary papillomatosis may occur. There is often an associated angular cheilitis, and that is the feature that frequently brings the patient to seek dental or medical advice, for the symptoms from the palatal area are often minimal. The excess of female patients over males remains unexplained. The vast majority of patients of either sex are otherwise fit. Underlying defects of immunity are not to be expected in this syndrome. However, AIDS patients with erythematous candidosis may enter a chronic phase.

Chronic plaque-like candidosis (chronic hyperplastic candidiasis; Candida leukoplakia) [11]. Very persistent, firm, irregular white plaques occur in the mouth, commonly on the cheek or the tongue. Most patients are male and generally over the age of 30 years but the onset of the disorder is difficult to date, as symptoms are mild, only slight soreness and roughness being noticed. Around the hyperplastic

area, there may be a margin of erythema. Unlike the pseudomembrane of oral thrush, this plaque cannot be easily removed. In most cases, serious predisposing factors are not present, although this appearance, particularly an extensive form, may occur in patients with chronic mucocutaneous candidosis. Smokers appear to be particularly prone to develop this form of oral candidosis [12].

The significance of this condition lies in the fact that it must be differentiated from other types of leukoplakia as, although the affected areas may undergo malignant change [13,14], it may eventually clear with prolonged anti-*Candida* therapy.

Chronic nodular candidosis. This is a rare form, where the clinical appearance that usually affects the tongue is of a cobbled appearance. It is most often seen in certain patients with chronic mucocutaneous candidosis.

Angular cheilitis (angular stomatitis; perleche) [15]. Soreness at the angles of the mouth extending outwards in the folds of the facial skin is a well-known syndrome, not always associated with *Candida* infection. It is perhaps best considered as an intertrigo in which different organisms may play a part, *Candida* being the most common. Nutritional status and mechanical factors (e.g. the depth of the fold), the presence of moisture from persistent salivation or licking the lips may also be important. The yeasts involved clearly come from the mouth, and the association with denture stomatitis is important. Although the condition may present acutely, it is common to find a long history of soreness and cracking at the angles of the mouth and a fluctuating course is typical. Obviously, the oral cavity should be examined carefully in such cases and swabs taken from that site to establish the presence of *Candida* carriage, as well as from the affected skin at the angles.

Median rhomboid glossitis [16]. This condition, characterized by a more-or-less diamond-shaped area on the dorsum of the tongue with loss of papillae, occurs as an acquired condition. It has been regarded in the past as a developmental abnormality, but current opinion suggests that it is simply a variant of chronic plaque-like candidosis.

Candidosis, steroids and the mouth. Apart from systemic steroid therapy, local applications of steroids in the form of steroid creams, mouthwashes and lozenges for the treatment of aphthosis or lichen planus of the mouth may predispose to candidosis, sometimes occurring as a secondary invasion of the primary pathology. Similarly, steroid aerosols for asthma must be considered as at least a potential cause of diminished local immunity in this area.

Other conditions associated with Candida in the mouth. *Candida* can secondarily invade other oral conditions such as ulcerative lichen planus [17], leukokeratosis and white-sponge naevus. On the lips, invasion of traumatic cheilitis may complicate management. In all cases, the removal of *Candida* often speeds the recovery even though the yeast is only a contributory cause.

Fig. 31.40 *Candida* infection of the groins.

Candidosis of the skin and genital mucous membranes

Most cases of cutaneous candidosis occur in the skin folds or where occlusion from clothing or medical dressings produces abnormally moist conditions. Areas close to the body orifices [18] and the fingers, which are frequently contaminated with saliva, are also at risk.

Candida intertrigo (flexural candidosis). Any skin fold may be affected, especially in the obese subject. Signs are typically erythema and a little moist exudation starting deep in the fold (Fig. 31.40). As the condition develops, it spreads beyond the area of contact, usually developing the typical features of candidosis with a fringed irregular edge and subcorneal pustules rupturing to give tiny erosions, and then further peeling of the stratum corneum. Satellite lesions, pustular or papular, are classical. Soreness, and itching, which may on occasions be intense, is usual. Topical steroids, prescribed for relief of the latter symptoms, may modify the inflammatory signs and cause diagnostic confusion. Where the web spaces of the toes or the fingers are affected, marked maceration with a thick white horny layer is usually prominent. In the case of the hands, some abnormality, including wide fat fingers, appears to predispose to infection. In this particular syndrome, often known as erosio interdigitalis blastomycetica or interdigital candidosis, *Candida* and Gram-negative bacteria are often co-pathogens [19]. Apart from skin folds, macerated skin under rings and dressings may become infected with *Candida*.

The differential diagnosis of intertriginous candidosis includes tinea, seborrhoeic dermatitis, bacterial intertrigo,

flexural psoriasis, Hailey–Hailey disease and flexural Darier's disease. It is important to establish that the *Candida* species are present by taking a scraping or swab. Although it is useful to find mycelium, its absence does not exclude the diagnosis, and the culture of *Candida* from an inflamed lesion of a skin fold usually justifies instigation of anti-*Candida* treatment. Bacterial co-pathogens should be considered.

Vulvovaginitis (vulvovaginal thrush) [18,20]. This common condition presents with itching and soreness, and with a thick creamy white discharge. Most women with vaginal candidosis have no evidence of underlying disease.

It is more common in pregnancy. In the non-pregnant, it is said to be more prevalent in the premenstruum, but a fluctuating course not clearly related to the menstrual cycle is frequent. Although largely confined to sexually active subjects, it has been described in childhood, sexually inexperienced and elderly people. Typically, there is dusky red erythema of the vaginal mucosa and the vulval skin, with curdy white flecks of discharge, but on occasions the only sign is erythema. The rash may extend onto the perineum and into the groins. The perianal area is often affected. In extensive cases, subcorneal pustules may be seen peripherally. In pregnancy, the picture is modified by marked physiological leukorrhoea.

Candida vulvovaginitis may recur and in some it appears to be a chronic condition [21]. In chronic cases, the vaginal mucosa may become glazed and atrophic. There may be considerable vaginal soreness or irritation as well as dyspareunia. Management of the recurrent or chronic case is difficult; the condition causes considerable distress. It is important in such patients to evaluate the presence of *Candida* during repeated episodes where there are symptoms, to establish that recurrence of signs of disease is associated with recurrence of *Candida*. Although vaginal candidosis has been reported to occur with an increased frequency in women with AIDS, and in some cases the infection is resistant to therapy, this is not always the case; many patients present with an acute and treatable episode. In this it seems to differ from the situation seen with oral candidosis.

Candida balanitis [22]. The skin of the glans penis, especially in the uncircumcised, may sometimes be colonized by *Candida* asymptomatically [23]. When *Candida* balanitis develops, it is usual to find either abundant vaginal *Candida* carriage or frank vulvovaginitis in the sexual partner, although this is variable. In the mildest cases, transient tiny papules or pustules develop on the glans penis a few hours after intercourse, and rupture, leaving a peeling edge. Some may settle spontaneously without going through the full evolution. This mild form is usually associated with a little soreness and irritation. In some men, the condition continues in this intermittent form. In more severe and chronic cases, the inflammatory changes become persistent over the glans and the prepuce. Involvement of the groins sometimes coexists, especially in hot weather.

Trichomonas infection, although it usually produces watery brown discharge, and bacterial vulvovaginitis should both be considered in the differential diagnosis, and in pregnancy physiological leukorrhoea. Dermatoses affecting the vulva may mimic this condition (e.g. psoriasis, contact dermatitis, lichen sclerosus). In the case of balanitis, bacteria and herpes simplex require consideration, but few of the common venereal diseases are episodic like candidosis. Psoriasis and lichen planus, although sometimes fluctuating, should not be a cause of confusion, except with the chronic established lesion, in which case plasma-cell balanitis and erythroplasia must be excluded as must lichen sclerosus. The diagnosis in both sexes is confirmed by finding the organism, preferably in large numbers. However, even scanty amounts of *Candida* isolated from cases with typical clinical features demand active and sometimes prolonged therapy. In the male, it must be stated that failure to find the organism does not exclude the diagnosis if swabs or scrapings were not taken during the acute phase. It is wise to consider diabetes in cases of genital yeast infections, but florid persistent lesions spreading beyond the genitalia seem most likely to be associated with that condition. Although the large majority of patients with genital candidosis will not have diabetes, it is appropriate to test for glycosuria in persistent or recurrent cases.

Perianal and scrotal candidosis. Perianal and scrotal candidosis may occur with or independently of genital involvement. Although usually starting around the anal margin with non-specific erythema, soreness and irritation, subsequent spread along the natal cleft is common, with classical features developing as it extends. Involvement of the scrotum is usually in the form of a nondescript erythema and subcorneal pustules are rarely seen. Candidosis must be included in the differential diagnosis of unexplained erythema of scrotal skin. Secondary infection of flexural psoriasis with *Candida* may have to be considered.

It has been suggested that a more objective assessment can be provided by taking quantitative cultures to determine the density of *Candida* more accurately [24]. For practical purposes this is not necessary, and dense growth of organisms on swab culture or the presence of diagnostic clinical features such as satellite pustules are usually taken as indications for treatment.

Napkin candidosis (diaper candidiasis). C. albicans is commonly isolated from the moist skin of the buttocks and genitalia of the infant but is more prevalent where the skin is affected by napkin rash [24]. In some instances, the classical subcorneal pustules, a fringed irregular border

and satellite lesions are found. In these cases, there is little doubt that the organism is playing a pathogenic part, and it is likely to be found in the faeces [10,24]. In other nondescript cases of napkin eruption from which the organism is isolated, the role of the yeast is in doubt. Steroid creams applied to this site not only modify the clinical features but they are probably advantageous to *Candida*. Moreover, if the bacterial flora has been suppressed by a topical antibiotic, this will also favour the yeast. All these factors should be considered in any napkin rash.

In acrodermatitis enteropathica in which zinc deficiency has a central role, there may be a secondary *Candida* infection, particularly of the napkin area.

In all but the most trivial cases of napkin eruption, a moistened swab or a scraping should be taken to discover whether or not *Candida* is present on the affected skin. Some estimate of the density of colonization is also helpful. If *Candida* is present, particularly in large numbers, even if the features are non-specific, a trial of anti-*Candida* therapy is generally indicated.

Nodular or granulomatous candidosis of the napkin area (granuloma gluteale infantum) [25,26]. The clinical picture is that of a napkin eruption over the buttocks, genitalia, upper thighs and pubis, within which develop nodules, sometimes as large as 2 cm across, bluish or brownish in colour, reminiscent of Kaposi's sarcoma [25]. The primary napkin dermatitis may clear leaving only the nodules. Some examples have marked scaling and hyperkeratosis over the lesions, in others the epidermis appears to be normal. Histological changes are those of an intense dermal infiltrate with lymphocytes, eosinophils and histiocytes.

The natural history of this condition has not been elucidated. Successful management involves removal of microorganisms, avoidance of topical steroids and general measures to ensure adequate dryness in the region.

Candida paronychia

Candida species, not always *C. albicans*, can be isolated from the majority of cases of chronic paronychia [27,28]. The yeast is thought to have an aetiological role in this condition, but bacteria and irritant or allergic contact dermatitis also play a part, although the contribution of each varies from patient to patient.

This condition is chiefly found among those whose hands are frequently immersed in water, but in chefs and pastrycooks the presence of organic debris such as flour and other carbohydrates may be equally important. The condition is less common in the UK than formerly. Toenail folds are not usually affected. Some experimental confirmation of the role of *Candida* has been achieved by occluding the nail fold in the presence of the yeast, but fully developed chronic paronychia has not been produced experimentally.

Clinical features. Typically, several fingers are chronically infected, but one or all may be involved. The nail fold is red and swollen, and there is loss of the cuticle, and detachment of the nail fold from the dorsal surface of the nail plate, leading to pocketing. Occasionally, thick white pus may discharge; often force is needed to express it. The patient usually has marked tenderness, and spontaneous pain is an occasional feature. Nail dystrophy with buckling of the nail plate and some discoloration and onycholysis around the lateral nail fold frequently occur, but massive destruction of the nail plate is rare. Many patients, particularly those who are resistant to treatment, appear to have a poor peripheral circulation. A link with psoriasis has been reported [29].

Onychomycosis resulting from Candida

There are three main manifestations of *Candida* infection of the nail apparatus [30]. The most common is onycholysis (DLSO) associated with paronychia. Complete destruction of the nail plate is also seen in some patients with chronic mucocutaneous candidosis. In addition to these conditions, erosion (DLSO) of the distal and lateral nail plate of the fingernails, not usually progressing to total nail dystrophy, has been associated with *C. albicans* invasion of the nail [31]. This is not common, but when it occurs it is most often seen in women. Two important predisposing conditions are Raynaud's phenomenon or disease and Cushing's syndrome. The main clues that the yeast is a significant pathogen are erosion of the distal nail plate, presence of yeasts and hyphae in nail on direct microscopy and the isolation of *C. albicans*. Such cases respond well and completely to oral antifungals such as itraconazole. Very rarely, *Candida* may invade the nail plate in the neonatal period, sometimes causing an isolated nail dystrophy with evidence of penetration of the superior aspect of the nail plate (SWO). In addition to these conditions, *Candida* is not infrequently isolated from the undersurface of the nail plate in patients with onycholysis resulting from other causes. Antifungal therapy in these circumstances does not produce any improvement.

Differential diagnosis. It is usual in chronic paronychia to establish which organisms are present, and a platinum loop introduced into the nail fold may be more valuable than a swab for this. It must be plated out promptly. When nail plate involvement is suspected, clippings should be taken.

Congenital candidosis [32]

This, as the name implies, represents established candidosis, usually of the skin and birth membranes present at the time of birth, and following intrauterine infection. It is

quite distinct from oral thrush of the neonate in which the organism is acquired, at the very earliest, from the birth canal during delivery.

Factors associated with this condition have included prematurity, although this has not been noted in some cases, and the presence of an intrauterine foreign body, usually a contraceptive device. The amniotic fluid is often turbid at delivery [32,33]. The skin is the most common site for lesions, which are usually present at birth. The lesions are typically discrete vesicles or pustules on an erythematous base. The face and chest are first affected by the rash, which generally spreads over the next few days after delivery. In over 10% there is evidence of spread to deep sites such as the lungs. Although there has been a high level of mortality reported with such cases, the cause of death is usually related to other complications of prematurity rather than candidosis *per se*.

Such widespread skin infections are believed to follow contamination of the skin surface during birth, and the high incidence of intrauterine infection or vaginal candidosis associated with this disease would support this contention. Such cases are distinct from the more common neonatal systemic candidosis, a septicaemic illness associated with extreme prematurity, where skin involvement is not common.

Candida allergy [23]

There is no doubt that in normal subjects skin testing with *Candida* antigens and serological studies reveal evidence of antibodies, humoral and cellular, to *C. albicans* and to other *Candida* species. A variety of clinical features attributed to *Candida* allergy have been described and include urticaria, ordinary annular erythema, bullous annular erythema and generalized pruritus. Even palmoplantar pustulosis has been linked to delayed hypersensitivity to *Candida* antigen. In the case of urticaria, some association, not necessarily mediated by immune mechanisms, may exist between yeast carriage in the gut (or frank candidosis) and the wealing of the skin. Unfortunately, the fluctuating nature of urticaria, and the fact that *Candida* is difficult if not impossible to eliminate from the gut, make the response to anti-*Candida* therapy difficult to evaluate. The candidide situation in general is even more perplexing than that of dermatophytide, in that the cutaneous reactions have often been ascribed to normal gut carriage. The so-called ide eruptions are not specific morphologically, and even the enthusiast for *Candida* allergy claims only a small percentage of cases of annular erythema, for example, is causally associated with *Candida*. Observant open-mindedness with a hint of scepticism would seem to be the right approach in this difficult area.

The term *Candida* allergy or *Candida* syndrome is also used to describe a constellation of symptoms ranging from headache to malaise and depression, allegedly secondary to colonization of the gastrointestinal tract with yeasts. However, there is no objective evidence to connect these symptoms with the presence or absence of *Candida*.

Fig. 31.41 Chronic oral candidosis.

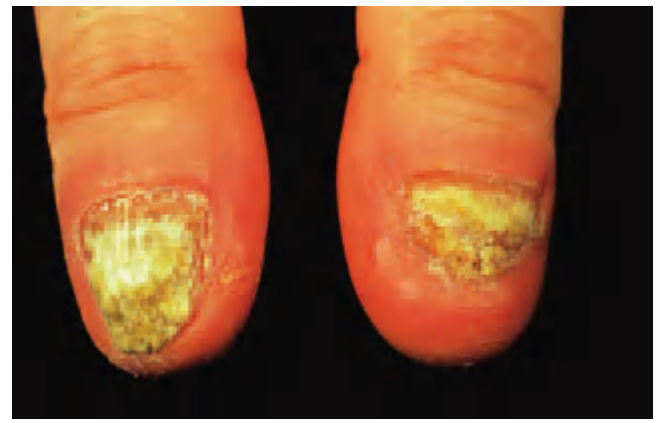

Fig. 31.42 *Candida* onychomycosis in a patient with chronic mucocutaneous candidosis.

Chronic mucocutaneous candidosis

Persistent *Candida* infection of the mouth, the skin and the nails, refractory to conventional topical therapy, is a distinct syndrome occurring as a more-or-less isolated feature. Sometimes it is associated with a variety of other infections, both cutaneous and systemic [1,2]. In the latter case, it may represent a manifestation of a primary defect in immune function, for example severe combined deficiency (Swiss-type agammaglobulinaemia).

Clinical features [1]. With minor variations, the syndrome consists of the following features, usually starting in infancy or early childhood:

1 Persistent oral thrush, responding only partially to conventional therapy, or relapsing promptly after apparently successful treatment. Chronic hypertrophic changes may follow (Fig. 31.41).

2 Cutaneous candidosis. Often intertriginous skin is involved, but also the face and the hands, and sometimes it is widespread over the trunk and limbs. In long-standing lesions, the cutaneous changes are often atypical, suggesting ringworm. In some patients, markedly thickened areas with gross hyperkeratosis may form. However, lesions may also develop as deep dermal nodules or small macules. Scalp involvement is not rare in this syndrome. Dermatophytosis in such patients may present in a similar manner.

3 Paronychia is commonly a feature, often with serious nail plate invasion and total dystrophic onychomycosis [3]. The important findings are nail invasion at an early age often proceeding to complete nail involvement (Fig. 31.42). Here, the nail plate is thickened and the whole terminal phalanx may become encased in hyperkeratotic infected skin.

Patients with this syndrome comprise a heterogeneous group, which was originally classified by Higgs and Wells [2,4] into several distinct categories using genetic and clinical criteria. It is probably best to exclude from the syndrome of chronic mucocutaneous candidosis those patients who present with a well-documented underlying immune defect, such as severe combined immunodeficiency or agammaglobulinaemia, where severe candidosis may form a minor part of the secondary infectious complications. In these patients, mucosal candidosis is usually overshadowed by other serious infections, such as recurrent pneumonia or aspergillosis. In contrast, in patients with chronic mucocutaneous candidosis (CMC), the skin and mucous membrane infections dominate the clinical pattern [1].

However, it is important to recognize that all patients with this syndrome may develop other infections, most commonly human papillomavirus infections (warts) and dermatophytosis, in addition to other features, such as recurrent aphthous ulcers, seborrhoeic dermatitis and alopecia areata.

The main body of CMC patients develop signs in early childhood, and usually *Candida* infection is the presenting feature [5]. While a number of different forms of immune defect have been described in these patients [6], the abnormalities are neither constant nor diagnostic and may reverse with antifungal therapy. Within the childhood-onset group, there are a number of different variants that show features in common. Such features should not be taken as inflexible markers of a particular type, as there is probably considerable overlap in clinical expression between the different groups. The different types are as follows:

1 *Autosomal recessive CMC* [7]. This usually starts in the first decade with persistent oral and nail plate infections. Generally, the health of these patients is good and they do not develop endocrine defects. They also tend to improve with increasing age.

2 *Autosomal dominant CMC* [8]. There are now a number of well-documented pedigrees of families with the dominant form of CMC. Generally, they are more severely affected than those with the recessive variety, and other

infections, such as dermatophytosis, may be particularly troublesome.

3 *Idopathic CMC* [4]. This form was named diffuse CMC by Higgs and Wells in children who had no evidence of genetic predisposition. Some of the original group have now produced affected offspring, and it is likely that some of these patients belong to the autosomal dominant group. Indeed, it is not possible to exclude the possibility that all may eventually be classified with these. However, it remains a useful subgroup to describe the most severely affected patients, who may have other infections and often develop bronchiectasis and pulmonary bullae. Their candidosis is also very severe with oesophageal involvement and the appearance of 'granulomas'. The term *Candida* granuloma was originally used to describe these severely affected patients, who may produce sheets of hyperkeratosis caused by *Candida* infection on the skin and scalp. It has been suggested that this appearance follows attraction of neutrophils into an area of infection, but because of defective function these are unable to destroy the invading yeasts. In practice, the main histological features are hyperkeratosis with only the occasional granuloma in the dermis. Rarely, patients have been reported from this group who develop other systemic diseases, such as cryptococcosis or miliary tuberculosis. Survival into adult life is still not universal in these children.

4 *CMC associated with endocrinopathy*. The majority of these patients appear to have the familial polyendocrinopathy syndrome [9,10]. Mutations of the autoimmune regulator gene appear to be correlated with this syndrome in many cases [10]. This is usually seen in early childhood, and occasionally the onset of *Candida* infection may predate the appearance of endocrine disease by as much as 10 years. The main cluster of endocrine abnormalities is hypoparathyroidism with hypoadrenocorticalism. In addition, other autoimmune abnormalities can occur, such as pernicious anaemia, vitiligo [11] and ovarian failure. This condition is also inherited as an autosomal recessive condition [12]. The severity of the patient's candidosis is very variable, and it is not uncommon to find that one affected sibling has extensive infection while another has only mild but chronic oral candidiasis.

A further group of CMC patients have CMC with associated hypothyroidism [13]. The inheritance of this abnormality is vertical, suggesting autosomal dominant transmission. Their clinical features are similar to other patients with endocrinopathy. It is important to recognize this group in view of their different genetic risk. A mutation has recently been mapped to chromosome 2p [14].

5 *Late onset CMC* [15,16]. Occasionally, adult patients are found to have the syndrome of CMC. The best-documented cases have been associated with a thymoma, but the occasional sporadic infection in a patient with no detectable abnormality may be recognized [3]. Patients with SLE occasionally develop the severe nail changes and oral manifestations of this condition. The sudden onset of chronic oral candidosis in an adult should be investigated as it may be the initial presentation of another condition such as HIV infection.

Immunological classification [1]. It is still not possible to correlate precisely defects of immune function with different clinical variants of the CMC syndrome, and indeed, with current investigative techniques, a substantial minority of cases have no demonstrable defect of immune function at all [5]. To date, a variety of defects of delayed hypersensitivity has been shown to be important [6]. Defects of phagocytosis or killing both in macrophages and polymorphs must be considered, but the much publicized myeloperoxidase deficiency, found in a few cases of systemic candidosis, has not been present in any patient with the chronic mucocutaneous syndrome.

In addition, it is known that certain antigenic components of *C. albicans*, such as mannan as well as some glycoproteins, are immunomodulatory [17]. Reversal of immune defects, such as absent delayed-type hypersensitivity to *Candida* antigens, has been seen with successful clearance of candidosis in CMC patients. It is therefore possible that some of the immunological changes may be secondary to the infection itself.

Diagnosis. The diagnosis of this condition normally requires the elapse of time and repeated failure to respond to conservative treatment. Confusion may occur with persistent ringworm infections, and indeed in some reported cases candidosis and dermatophytosis have coexisted. A family history is of obvious importance, and special note should be taken of other infections, cutaneous or systemic. Full endocrine investigation is also indicated.

Laboratory diagnosis

As *C. albicans* is a common commensal, the interpretation of cultural findings has to be related to the clinical appearances. A scanty growth of *C. albicans* from the skin or from a mucocutaneous site may be meaningless without evidence of infection from a positive direct microscopy.

On direct examination of skin or nail material, the oval thin-walled yeasts bud on a narrow base, and are usually accompanied by filaments, either true hyphae or pseudohyphae (Fig. 31.43). Occasionally, particularly when a non-*albicans* yeast is present, filaments may be absent. The size and shape of the yeasts observed may also suggest the presence of a non-*albicans* yeast; for example, the budding cells of *C. krusei* are noticeably larger and more elongate than those of *C. albicans*. Isolation and identification of *C. albicans* is simple. At 37°C, on media free of cycloheximide, colonies from swabs and skin samples usually appear within 1–3 days. However, growth from thicker skin and nail material can be slower, so plates should be held for a week before reporting as negative. Chromogenic agars have now been developed that allow the identification of *C. albicans* on primary culture. On Albicans ID agar (bioMerieux), the colonies of *C. albicans* are blue and all other yeasts cream or white. On Chromagar (Becton & Dickinson), colonies of *C. albicans*, *C. tropicalis* and *C. krusei* are green, blue and pink, respectively.

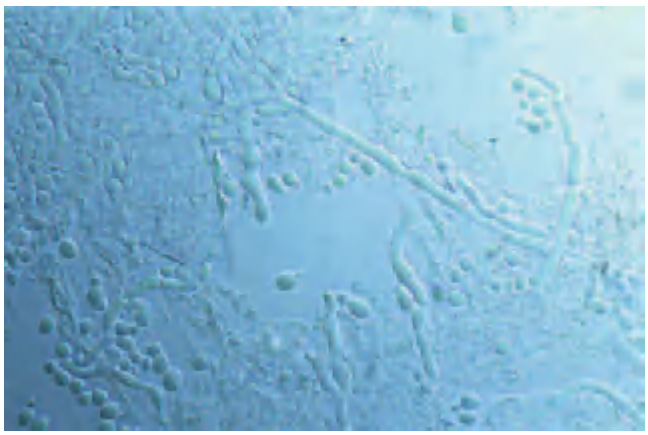

Fig. 31.43 Candidosis. Skin scales mounted in 30% KOH, Nomarski illumination, oil. Budding yeasts and slender filaments are observed. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

Candida albicans. Colony: the colonies on glucose–peptone agar are white to cream and soft in texture (Fig. 31.44). Some isolates may produce wrinkled 'rough' colonies and some may produce an obvious fringe of pseudohyphae around the edge of the colony. Microscopy: mounts from primary culture plates will reveal predominantly budding yeast cells. The production of filaments is best examined on depleted media, such as cornmeal agar, or rice extract agar supplemented with Tween 80. The morphology of *C. albicans* on these media allows identification, for in addition to filaments and budding yeasts, *C. albicans* produces rounded refractile vesicles, usually erroneously termed chlamydospores (8–12 µm diameter), at the sides and ends of the filaments (Fig. 31.45). These are produced within 24–96 h of incubation at 26°C. *C. albicans* also differs from most other species of *Candida* by the production of rudimentary true hyphae—germ tubes—when lightly inoculated into serum and incubated at 37°C for 2–4 h (Fig. 31.46). The only other species that is germ-tube positive and produces vesicles on depleted media is *C. dubliniensis*, a yeast associated predominantly with oral infections in HIV-positive patients.

Other Candida species. Colony: the different species produce colonies that vary slightly in texture, colour and production of obvious pseudohyphae. With experience,

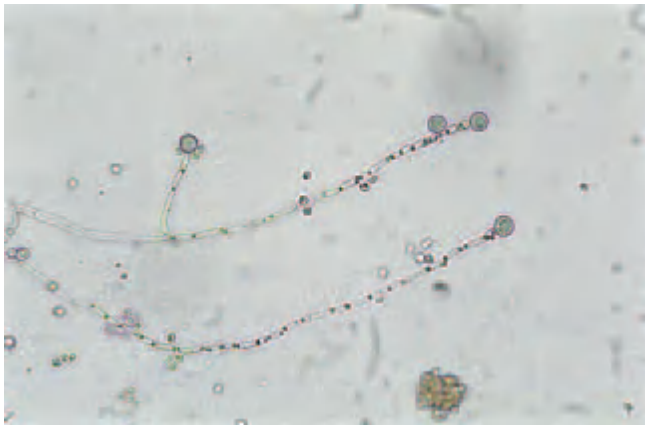

Fig. 31.45 Specific identification of *Candida albicans* can be made by the observation of filaments with thick-walled terminal vesicles when cultured on a depleted medium such as rice–agar supplemented with Tween. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

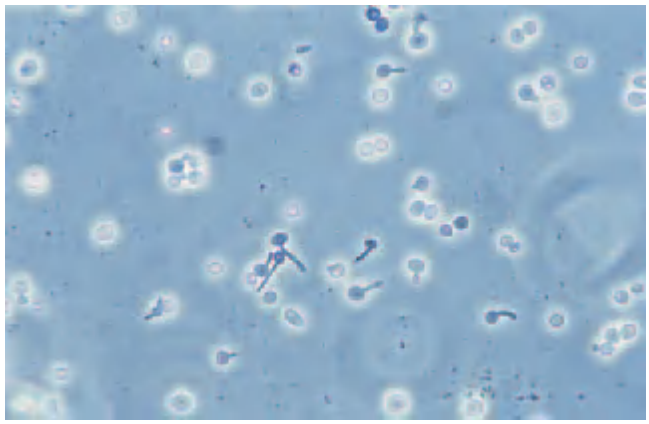

Fig. 31.46 A second method for specific identification of *Candida albicans* is the observation of germ tubes in serum after incubation at 37°C for 2–4 h (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

these differences may be recognized on the primary culture plates, but specific identification always requires study both of the morphology and physiology of each isolate. Microscopy: the majority of pathogenic *Candida* species—*C. glabrata* is a notable exception—will produce filaments and budding yeasts, but not chlamydospores, on depleted media, and the appearance of these filaments and yeasts is subtly different and characteristic for each species. The presence or absence of filaments is a key characteristic that is necessary for the identification of all *Candida* yeasts. Physiological tests: a battery of physiological tests, such as sugar and nitrogen source assimilations, and determination of the presence or absence of urease, are used. The development of commercial yeast identification systems, such as the API 20C (bioMerieux) and the Auxacolour (Sanofi), have greatly facilitated this task, and such kits are widely used. It has become particularly necessary to speciate non-*albicans* yeasts, because of the realization that some of these species may show innate resistance to some antifungals; for example, *C. glabrata* and *C. krusei* are often resistant to fluconazole.

Treatment of candidosis

General principles [1]

In the treatment of candidosis, it is important to be aware of the necessity of altering both localized and general susceptibility factors. In the mouth, for instance, this involves frequent toilet in the seriously ill, and denture hygiene in other patients, whereas in *Candida* infections affecting the skin, careful drying of affected sites is important. In many cases, topical antifungal therapy alone is sufficient to produce a response, but in immunocompromised patients with oropharyngeal candidosis, oral systemic therapy may be necessary to treat concomitant oesophageal infection, as well as being the most effective treatment for oral candidosis in AIDS patients. In addition, oral antifungals are used to prevent systemic candidosis in neutropenic patients. Although the success of this approach is often contested, it is nonetheless a common practice. Apart from these indications, and CMC and onychomycosis, the main indications for systemic anti-*Candida* therapy are *Candida* septicaemia and deep-seated candidosis.

Therapeutic agents

The polyene antibiotics amphotericin, nystatin and natamycin are all highly effective against *Candida* species and most other yeast pathogens. Even though the polyenes have been used over many years, resistance by *C. albicans* and other *Candida* species, with the possible exception of *C. lusitaniae*, to these antibiotics is very rare. They are all safe to use topically, and contact dermatitis is rare. Of these drugs, only amphotericin is used systemically, and this must be given by intravenous infusion. Recently, intravenous lipid-associated amphotericin B compounds including a liposomal formulation (AmBisome), a colloidal dispersion (ABCD) and a lipid complex (ABLC) have been introduced. These compounds have the advantage of producing reduced renal toxicity. Gastrointestinal absorption of all the polyenes is limited; after oral administration, only 5–10% is taken up. The other important group of agents effective against *Candida* are the imidazoles. Clotrimazole, miconazole and econazole are the best known and, after a decade or so of topical use, significant resistance to them has not developed in *Candida* species [2]. Contact allergy, although reported, seems to be almost

as rare as reactions to the polyenes. The most useful treatments are with the two triazoles, fluconazole [3] and itraconazole [4], that are also effective in these conditions and have the additional advantage that hepatotoxicity, seen with ketoconazole, an alternative treatment, is exceptionally rare with both drugs. The usual daily doses are itraconazole 100–200 mg and fluconazole 100–400 mg or ketoconazole 200 mg. In addition, fluconazole can be given for systemic candidosis as an intravenous compound. A formulation of itraconazole in cyclodextrin solution provides better absorption in severely immunocompromised patients. Resistance to ketoconazole has been reported in CMC patients receiving long-term therapy with the drug. Similarly, primary resistance to fluconazole has been recorded with some *C. albicans* isolates, and particularly with *C. krusei*, *C. dubliniensis* and *C. glabrata*. Secondary drug resistance in *C. albicans* can occur in AIDS patients receiving fluconazole for long-term management of oropharyngeal candidosis [5]. However, *Candida* infection and resistance is less common in patients receiving highly active antiretroviral (HAART) therapy [6].

Flucytosine is an agent that is absorbed from the gut, is relatively safe and very potent against those strains of *Candida* that retain their sensitivity. Unfortunately, resistance developing during treatment is not uncommon, and this drug is now only occasionally used for systemic candidosis, usually in combination with intravenous amphotericin B.

Treatment of the different clinical forms

Oral candidosis. In infants, suspensions of nystatin, amphotericin or miconazole gel applied several times a day are usually adequate for treating oral thrush. In the adult patient, removal of the dentures with careful hygiene at night is important. Regular amphotericin lozenges, nystatin or amphotericin tablets or oral nystatin suspension are effective in non-immunocompromised patients. The duration of the treatment varies with the condition: 10–14 days may be enough in acute cases. For treatment of unresponsive and chronic cases, such as those with hyperplastic candidosis, the responses to topical therapy are often poor, and either fluconazole (100–200 mg/day) or itraconazole (100–200 mg/day) are more effective. Ketoconazole 200–400 mg/day is an alternative. In patients with chronic oral candidosis, a biopsy may be justified to exclude leukoplakia. Angular stomatitis usually responds to treatment of the primary oral condition, although a topical antifungal applied to the area may speed recovery.

Oral candidosis in patients with AIDS or CMC, by contrast, frequently fails to respond to topical polyene therapy. In these conditions, the best approach is to use oral ketoconazole [7,8], itraconazole [9] or fluconazole [10,11]. If possible, therapy should be given intermittently if there is a recurrence, because of the risk of resistance developing with continuous therapy. Treatment is usually given until there is symptomatic recovery, which is usually quicker with fluconazole than the capsule formulation of itraconazole. A new cyclodextrin solution of itraconazole is also quicker than the capsule form.

Genital candidosis. Acute vulvovaginitis is best treated with a single-dose topical preparation (pessary, ovule), such as clotrimazole, econazole or isoconazole. Longer courses of these compounds (e.g. 14 days), as well as the polyenes, such as nystatin, are also available. If there is coexistent involvement of the skin, a topically applied cream should also be used. Single-day oral therapy with either fluconazole 150 mg or itraconazole 600 mg have recently been introduced; both are more convenient but more expensive. Efficacy seems to be similar to that seen with topical drugs. There is no reliable method of curing recurrent vaginal candidosis.

Balanitis usually responds satisfactorily to topical antifungals applied several times a day, but if there is a source of infection in the sexual partner this should be treated appropriately, and diabetes, if discovered, obviously requires management. Conjugal cases need simultaneous and often prolonged therapy.

Flexural candidosis. Candida intertrigo requires specific topical therapy (azole or polyene creams) usually continued for about 2 weeks, but treatment may be required for longer periods, and is likely to fail if attention is not given to drying the affected area. In some patients with moist *Candida* intertrigo, potassium permanganate soaks are more effective. Attention should be given to treating concomitant bacteria; once again, potassium permanganate is useful for this purpose. In finger or toe web infections, topical antifungal therapy, combined with use of open footwear in the case of infections of the feet, is appropriate.

Napkin candidosis. In infants, rashes in the napkin area should be investigated for *Candida* and, if present, this can be treated topically. The antifungal should be combined with a general regimen for napkin dermatitis, with frequent napkin changes. In seborrhoeic dermatitis, a weak topical steroid is appropriate for the disseminated dry lesions, but steroids should be avoided on the napkin area itself.

Paronychia and onychomycosis. Candida paronychia requires prolonged topical therapy with frequent applications of polyenes, imidazoles or non-specific remedies, such as 4% thymol in chloroform. Lotions are probably preferable

to creams. There have been too few studies of either itraconazole or fluconazole to comment on their effectiveness in paronychia. Whatever anti-*Candida* regimen is chosen, it must be followed by general measures, such as ensuring adequate drying of the hands. The hands should be kept warm and a poor peripheral circulation improved if at all possible. In many patients, particularly in the chronic phases of paronychia, the role of *Candida* is more contentious and other factors such as irritant or allergic contact dermatitis may have a role. For this reason, in chronic cases, concomitant use of a topical corticosteroid is a logical approach. In proven *Candida* onychomycosis, fluconazole or itraconazole [9] offer a real hope of success.

Congenital candidosis. In congenital candidosis of the skin, topical therapy alone is required, but where there is systemic involvement, clearly amphotericin B or fluconazole should be considered.

Chronic mucocutaneous candidosis. Treatment of this condition depends critically on antifungal chemotherapy [12]. Attempts have been made to restore T-cell function, usually by the use of transfer factor [13], or thymosin, or grafting compatible lymphocytes from blood or marrow, or fetal thymic tissue [14], and non-specific measures such as restoration of normal iron stores when these are defective. Systemic anti-*Candida* therapy with fluconazole, itraconazole or ketoconazole is likely to be necessary, and may need to be prolonged and repeated.

Once a remission has been induced, maintenance therapy should not be used in view of the risk of antifungal resistance. In a few patients, reduction of the load of *Candida* antigen seems to result in restoration of normal immunological responses, such as delayed hypersensitivity. Attention must be given to any endocrine factors as, although such treatment is not likely to lead to improvement in the candidosis, it may have considerable importance on the child's health and development. Endocrine screening tests should be repeated, even if initially negative, as patients with endocrinopathy may develop endocrine disease years after the first appearance of candidosis. Where appropriate, parents should be given genetic counselling. The possibility of coexisting dermatophytosis should not be forgotten, but it should respond satisfactorily to itraconazole or terbinafine.

Subcutaneous mycoses

Subcutaneous mycoses, or mycoses of implantation, are sporadically occurring infections caused by fungi present in the natural environment, which are directly inoculated into the dermis or subcutaneous tissue through a penetrating injury. They are seldom common even in endemic areas, and are mainly seen in the tropics, although, as many have long incubation periods, they may be seen in countries outside these endemic areas in patients who were originally infected elsewhere. The most common of these infections are sporotrichosis, mycetoma and chromoblastomycosis; rarer infections are phaeohyphomycosis, lobomycosis, rhinosporidiosis and subcutaneous zygomycosis.

The diagnosis of the subcutaneous mycoses is made initially by direct examination and examination of histopathological sections. Culture is not necessarily difficult, but identification of the more unusual pathogens may require the help of a reference mycological laboratory, as, with the rise in the number of immunocompromised patients in the population, an ever-increasing number of organisms have now been recognized as opportunistic pathogens. Additionally, some isolates, particularly from cases of eumycotic mycetoma and phaeohyphomycosis, may fail to sporulate on primary isolation, and special media or conditions of incubation may be required to encourage conidial production. The description of all the potential pathogens is outside the scope of this chapter, although brief descriptions of the most common isolates are included.

Laboratory methods

Collection of samples

Materials from patients thought to have subcutaneous mycoses are obtained from a variety of sources. Occasionally, superficial scrapings from a lesion may be useful, but generally pus or exudates discharging or obtained by aspiration, and samples of biopsied tissue, ideally both from the edge and from the centre of the lesion, are required for satisfactory diagnosis. All samples are placed in sterile containers for immediate despatch to the laboratory. To prevent drying out of the material tissue, biopsy specimens intended for culture must be placed in sterile saline or wrapped in moistened sterile gauze if they cannot be processed immediately. Delays in processing samples will increase the likelihood of bacteria or saprophytic fungi contaminating the samples.

Direct examination and histopathology

A simple potassium hydroxide mount may be enough to give a preliminary diagnosis in some cases. For example, typical organisms may be observed in superficial crusts from chromoblastomycosis lesions, and pus containing grains from mycetoma patients can be used to immediately differentiate eumycotic and actinomycotic disease. Small fragments of biopsy tissue may be similarly examined, but generally histopathological processing will be more informative. Of the specific fungal stains, the silver impregnation procedure (Grocott, Gomori) and PAS are most commonly used and give excellent results, but in some instances examination without a specific fungal stain may also be valuable to determine whether the infecting fungus is naturally pigmented (dematiaceous). Details of the appearances of individual mycoses are dealt with more fully in the relevant sections of this chapter and are well reviewed in standard textbooks [1–4].

Culture and identification of isolates

Generally, tissue samples should be finely divided, either by grinding or cutting into small pieces using sterile scalpel blades. The exception to this is material suspected of being infected with a zygomycete, where the largely aseptate hyphae are particularly fragile and will not survive such fine division. Although glucose–peptone agar alone can be used for primary isolation of the subcutaneous pathogens, a number of other media are also commonly used, including inhibitory mould agar (BBL) and brain–heart infusion agar (Difco), with or without the addition of 5–10% sheeps' blood. Antibacterial antibiotics, such as chloramphenicol (0.005%) and gentamicin (0.0025%) are usually incorporated into the agar, and cycloheximide may be added for the culture of *Sporothrix schenckii* and the agents of chromoblastomycosis. If sufficient material is available, incubation at 26–30°C and 37°C on a variety of media is recommended. Although many organisms will grow quite quickly, cultures should be held for 6 weeks before being reported negative. If isolates fail to sporulate on the primary culture plate, subculture on to potato dextrose agar (Oxoid) or half-strength cornmeal agar (Oxoid) and incubation in the light may be necessary to encourage conidial production.

Sporotrichosis

Definition. An acute or chronic fungal infection caused by *Sporothrix schenckii* [1]. There are both cutaneous and systemic forms of sporotrichosis.

Aetiology. Sporotrichosis is caused by a single species, the dimorphic fungus *S. schenckii* [2]. It occurs in both temperate and tropical zones. Less than 20 cases of sporotrichosis diagnosed in the UK have been published. The disease was common in France between 1905 and 1920, and occasional cases are reported from other European countries. It occurs sporadically in North, South and Central America, Egypt, Japan and Australia [3] and has been particularly prominent in the mining areas of South Africa. The incidence, and possibly the geographical distribution, are dependent on climate.

In Uruguay, it has been shown that the incidence is highest in the autumn and first half of the winter (high humidity and temperatures between 16 and 22°C) [4]. These conditions favour saprophytic growth of *S. schenckii*. Sporotrichosis is rare in semiarid areas. The fungus grows on decaying vegetable matter, for example the timber in mines. It has been shown that the timber harbours the fungus before being taken underground [5], and that the source is probably the soil in the vicinity of the mines. *S. schenckii* could be recovered from the feet of mine workers who did not have sporotrichosis.

The disease may also occur in other groups occupationally exposed to the organism, such as workers using straw as packing material, forestry workers, florists or gardeners [6].

In most cases of cutaneous sporotrichosis, the fungus is introduced into the skin or mucous membrane by trauma, as in a minor puncture wound caused by a thorn or to a splinter, or perhaps an insect bite. Sporotrichosis is not

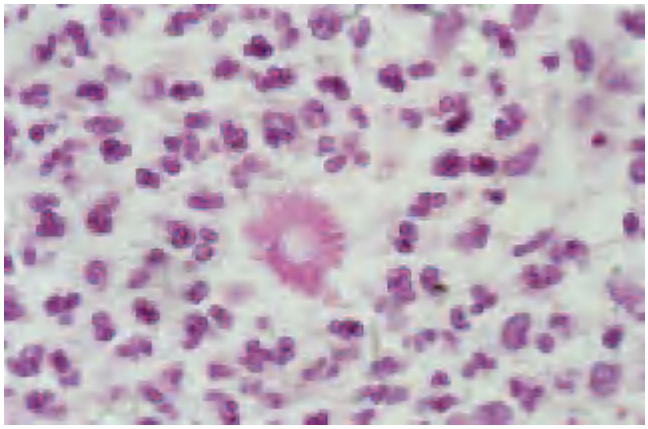

Fig. 31.47 Sporotrichosis: tissue section stained with haematoxylin and eosin. Organisms are usually very scanty but asteroid bodies, representing a foreign body tissue reaction, may be observed. Fig. 31.48 Lymphangitic sporotrichosis.

contagious, although transmission has been recorded in a family from a cat, which also affected veterinary personnel. Adult males are, by their occupation, most exposed to the risk of infection. Systemic sporotrichosis is rare, and the portal of entry is thought to be the lung in these cases.

Unexplained areas of hyperendemicity have been described in certain countries, where unexpectedly high numbers of the local population develop cutaneous lesions of sporotrichosis and appear to be sensitized on skin testing with sporotrichin [7].

A family epidemic of cutaneous sporotrichosis was described among four children who became infected after playing in hay. On rare occasions it has been seen in young children. The incubation period is variable, but is usually 8–30 days.

Histology. *S. schenckii* may remain localized in the subcutaneous tissue, may spread locally in the subcutaneous lymphatics or, rarely, may be widely disseminated in the bloodstream after pulmonary infection. The immunological response of the host probably determines the form that the infection assumes [8]. The fungus provokes a mixed granulomatous reaction with neutrophil foci. The fungus is present in the tissue, usually in the form of small (3–5 μm) cigar-shaped or oval yeasts, and these may, on occasion, be surrounded by a thick radiate eosinophilic substance, which forms the distinctive asteroid bodies (Fig. 31.47) [9]. A mycelial form of the fungus in tissue has occasionally been reported [10].

Clinical features. The main clinical varieties of sporotrichosis are the cutaneous and the sytemic forms. In turn, cutaneous sporotrichosis is normally divided into two main types, the lymphangitic and fixed forms, but occasionally atypical varieties such as mycetoma-like or cellulitic forms may occur [2].

The most common type of sporotrichosis is the localized lymphatic variety, which follows the implantation of spores in a wound. This therefore usually occurs on exposed skin, often on the upper extremity [2,11], and is known as lymphangitic sporotrichosis. A nodule or pustule forms, which may break down into a small ulcer. Untreated, the disease usually follows a chronic course, which is characterized by involvement of lymphatics from the draining area and a chain of lymphatic nodules develops (Fig. 31.48). New nodules appear at intervals of a few days. These soften and ulcerate, and are connected by tender lymphatic cords [12]. A thin purulent discharge may come from the primary lesion and the earliest lymphatic nodules. As the disease becomes chronic, the regional lymph nodes become swollen and may break down. The primary lesion may heal spontaneously leaving the lymphatic nodes enlarged. The general health of the patient may not be affected.

The fixed variety, where the pathogen remains more or less localized at the point of inoculation, is less common [2,13]. The lesions may be acneiform, nodular, ulcerated or verrucous; the latter form is occasionally very extensive. Less commonly, there may be infiltrated plaques or red scaly patches. An ulcer may be gummatous or may simulate an epithelioma. The plaques may suggest leishmaniasis or tuberculosis. It is thought that this variety may reflect a high degree of immunity on the part of the patient. The variable morphology of this type is notable.

The reason for the difference in clinical behaviour of the two principal forms of cutaneous sporotrichosis is unknown, although changes in temperature sensitivity of the organisms [14] or in the host's immune response [2] have both been suggested. It is possible that some sporotrichosis infections are self-healing. Others are chronic and may mimic mycetoma or stasis ulcers. In

AIDS patients, multiple cutaneous lesions may develop, suggesting cutaneous spread.

The less common systemic form probably follows inhalation, and presents either with local pulmonary disease or focal or widely disseminated lesions in the joints, meninges and skin [15]. There is some evidence that systemic sporotrichosis occurs in patients with some defect in host defence, such as alcoholics. This is in contrast to the cutaneous variety, which occurs in perfectly healthy individuals. Where sporotrichosis has been reported in AIDS patients, the lesions have usually been widespread and have affected internal organs as well as the skin [16].

In the systemic type, which is rare, ulcerated nodules may develop anywhere on the body or mucous membranes, and visceral lesions may occur. No organ is immune and bones or joints may be involved. Occasionally, vascular lesions resembling polyarteritis nodosa may be found. If untreated, this type is fatal but systemic sporotrichosis is exceedingly rare.

Differential diagnosis. Sporotrichosis can simulate granulomatous lesions of almost any other origin, and the diagnosis must be considered in all cases when the initial lesions have followed an injury.

The main conditions that may resemble sporotrichosis are mycobacterial infections and leishmaniasis. The mycobacterial infection caused by *Mycobacterium marinum* (fish-tank granuloma) may closely resemble lymphangitic sporotrichosis.

Laboratory diagnosis. *S. schenckii* is very rarely present in quantity in infected tissues, and direct microscopy of clinical material is of little or no value in confirming a diagnosis because its presence may easily be overlooked. Fluorescent antibody techniques have been successfully employed in locating the pathogenic phase *in vivo* [17]. The fungus grows readily on common agar media.

S. schenckii. Colony: the colonies are leathery, moist and initially white or cream with a wrinkled surface. As the colonies age, they may become progressively darker until they are brown or black. Microscopy: the slender (2-µm) hyphae bear small, oval to pyriform, hyaline conidia produced along the sides of the hyphae and sympodially at the ends of delicate conidiophores arising at right angles from the hyphae. The arrangement of the conidia at the apex of the conidiogenous cell is often described as palmate or flower-like, with each conidium attached by a denticle to the small vesicle. In many strains, particularly when freshly isolated, oval, round or triangular dark brown thick-walled conidia are also produced, and it is partly the production of these conidia that results in the development of darkly pigmented colonies. However, pigmentation has also been reported to vary according to the culture medium and to increase with the addition of thiamine. Physiological tests: to confirm the identification, it is essential to convert this thermally dimorphic fungus to the yeast phase, as fungi that are non-pathogenic and morphologically very similar may be isolated as contaminants. This is best achieved on brain–heart infusion agar supplemented with sheeps' blood and incubated at 37°C. The yeasts are typically oval or cigar-shaped.

Treatment. While cases have been described where spontaneous remission has been seen to occur [18], it is the usual practice to treat patients with sporotrichosis. Potassium iodide in large oral doses is effective in the localized types, and should be continued for 3–4 weeks after clinical cure. It is cheap and effective, although side effects are common. A recommended schedule is five drops initially, increasing to 4–6 mL of saturated potassium iodide three times daily. Patient tolerance may require a lower maximum dose [19].

The alternatives are itraconazole 100–200 mg/day or terbinafine 250 mg/day. However, at these dosages the length of treatment is not significantly different to that used with potassium iodide [20]. However, it may be useful in patients who do not respond to the latter or in systemic cases. In the latter, treatment with intravenous amphotericin B or miconazole may also be helpful. As with chromoblastomycosis, the local application of heat may produce recoveries in some patients.

Mycetoma

SYN. MADUROMYCOSIS; MADURA FOOT

Definition. A localized chronic infection caused by various species of fungi or actinomycetes, and characterized by the formation of aggregates of the causative organisms (grains) within abscesses. This results in severe damage to skin, subcutaneous tissues and bones of the feet, hands and other parts of the body, and grains are discharged to the surface through draining sinuses.

Aetiology [1]. Mycetoma may be caused by various species of fungi (eumycetoma) and aerobic actinomycetes (actinomycetoma), which occur as saprophytes in soil or on plants [2]. From these sources, they are implanted subcutaneously, usually after a penetrating injury [3,4]. The disease is largely confined to tropical and subtropical climates, usually among agricultural workers. Adult males are therefore most often infected. A few cases have occurred in Europe and North America, but in many such cases the patients have originated from the tropics and the infection was imported. These cases also illustrate clearly that the disease may not become troublesome until many years (20–30 years) after the initial injury. The condition, which is not contagious, is characterized by the presence of different coloured grains, which represent microcolonies of the organisms. The aetiological agents listed in Table 31.8 include only the most commonly isolated fungi.

The relative frequency with which the different species are encountered varies from country to country [5,6]. Actinomycetomas caused by *Nocardia* species are most common in Central America and Mexico. In other parts of the world, the most common organism is a eumycetoma agent, *Madurella mycetomatis*. The actinomycete, *Streptomyces somaliensis*, is most often isolated from patients originating from Sudan and the Middle East [7]. The causative organisms have been isolated from either soil or plant material, including thorns from *Acacia* bushes in endemic areas. It is unusual to find a clinically distinct predisposing abnormality in patients with mycetoma, although in the UK there is a striking preponderance of diabetics among mycetoma patients, although this has not been noticed elsewhere. It is thought that the implanted organisms survive in subcutaneous tissue because they are able to develop a number of adaptive changes—from cell-wall thickening to extracellular melanin deposition—which allow them to resist neutrophil attack.

Table 31.8 Aetiological agents of mycetoma.

Fungi	Actinomycetes
Dark grain	
Madurella mycetomatis	*Actinomadura madurae*
Madurella grisea	*Actinomadura pelletieri*
Leptosphaeria senegalensis	*Streptomyces somaliensis*
Curvularia lunata	*Nocardia brasiliensis*
	Nocardia otitidis-caviarum
	Nocardia asteroides
Pale grain	
Scedosporium apiospermum	
Neotestudina rosatii	
Acremonium spp.	
Fusarium spp.	

Histology [4,8]. The causal organisms produce a chronic inflammatory reaction leading to focal neutrophil abscess formation, with scattered giant cells and fibrosis. Grains in the form of white, yellow, red or black granules are found in the centre of the inflammatory response [9], and may be discharged in pus through multiple sinuses on to the skin surface. Secondary bacterial infection may occur but this is not common [10]. The destructive process slowly extends deeply into the underlying tissues, and invades muscle and bones. A haematoxylin and eosin preparation is sufficient to distinguish between eumycetoma and actinomycetoma.

Clinical features. The clinical features are essentially the same no matter which fungus or actinomycete is concerned [11,12]. Because trauma favours infection, most lesions are on the foot and lower leg, but they may occur anywhere on the body [13]. The earliest stage is a firm painless nodule but, with time, papules, pustules which break down to form draining sinuses, appear on the skin surface (Fig. 31.49). The whole area becomes hard and swollen, often without significant pain [14]. Extension to underlying bones and joints gives rise to periostitis, osteomyelitis and arthritis (Fig. 31.50). In advanced cases, destruction of bone within an infected area may be almost complete, and gross deformity may result [15]. There are usually multiple sinus tracts draining pus. These may remain open for months or may close and reopen, or may be replaced by new sinuses. The discharge may be purulent or seropurulent. The condition is comparatively painless and usually develops slowly (Fig. 31.51), but eventually results in gross swelling of the affected foot or other parts with serious deformity. Lymph node involvement is rare [16].

Imaging techniques contribute greatly to assessment of the destruction. Magnetic resonance imaging (MRI) provides the most comprehensive method [17].

Fig. 31.49 Mycetoma caused by *Madurella grisea*.

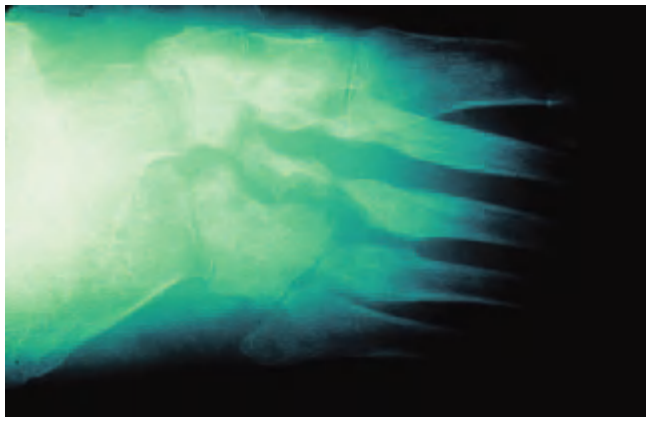

Fig. 31.50 Erosive X-ray changes in a mycetoma.

Fig. 31.51 Eumycetoma affecting the foot.

Differential diagnosis. Chronic osteomyelitis of bacterial or tuberculous aetiology may resemble mycetoma, particularly in the early stages. In early mycetoma, it may be necessary to incise pustules that represent foci of inflammation, necrosis and sinuses that have not yet ruptured through the skin; they often contain grains. Pus should be examined under the microscope for the presence of grains, which may then be processed for histology or examined directly in potassium hydroxide. If the infection is eumycotic, when crushed under the cover slip the grains will be seen to consist of masses of fungal mycelium with hyphae 2–6 µm in diameter. Chlamydoconidia are frequently formed at the periphery or in the centre of the grains. Actinomycotic grains will be seen to consist of masses of much narrower bacterial filaments 0.5–1.0 µm in diameter. If there are no discharging sinuses, biopsy may be required. In elephantiasis there are no sinus tracts.

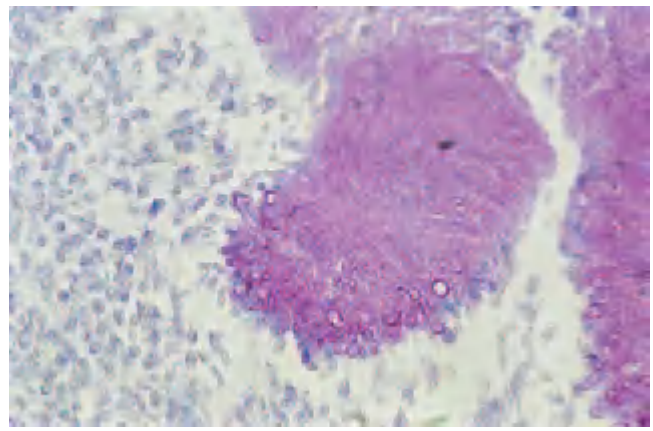

Fig. 31.52 Mycetoma: tissue section. Distinct hyphal filaments, stained pink with periodic acid–Schiff (PAS), are clearly visible in a pale-grained eumycetoma. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

Laboratory diagnosis. A tentative diagnosis sufficient to initiate treatment may be made on the basis of grain colour, texture and direct microscopic appearance [4]. For instance, black grains are always caused by fungi and red grains by an actinomycete. Eumycetomas with black grains are termed dark grain eumycetomas, and many of the fungal species responsible produce hard or brittle grains with a brown cement-like substance surrounding the hyphae. Eumycetomas with white or yellow grains are termed pale grain eumycetomas and most contain no cement and have a soft texture (Fig. 31.52).

In eumycotic disease, the final identification of the infecting fungus requires the isolation of the causal agent in culture. As the surfaces of the grains are frequently contaminated by bacteria, washing with saline containing antibacterials is recommended prior to inoculating the culture medium. Many of the grains may be non-viable. Primary isolates may require subculture on to nutritionally depleted media, such as half-strength cornmeal agar, to induce sporulation, and may fail to sporulate completely. Referral to a reference mycology laboratory for identification is recommended. Serology is helpful in some cases [18].

Only the two most frequently isolated species are described.

Madurella mycetomatis. Colony: the colonial form shows great variation. Colonies are initially pale and leathery, but after a few days become olive, ochre brown or grey in colour and may produce a diffusible brown pigment. Growth is faster at 37°C than 28°C. Microscopy: on nutrionally poor media, spherical conidia may be formed from flask-shaped phialides. Primary cultures may produce large chlamydoconidia but are otherwise usually sterile.

Scedosporium apiospermum. Colony: the colony grows rapidly with a floccose grey or brown–grey surface and white to dark grey reverse. Microscopy: oval, light brown, relatively thick-walled conidia with a truncate base are formed singly along the hyphae or in small groups from annellides. A second form of conidiation is seen in some isolates with the production of coremia—tufts of hyphae held together—which produce smaller hyaline annelloconidia at their tips. This is a homothallic species and the sexual phase with ascospores may be formed on primary culture. In these instances, the teleomorph is reported as *Pseudallescheria boydii*.

Treatment. Localized lesions that can be excised without residual disability are best so treated. In other cases, medical treatment should first be attempted, although chemotherapy of mycetomas caused by fungi has, so far, been found to be quite unsatisfactory in most cases, despite the fact that certain fungi have been found to be relatively sensitive *in vitro* to therapeutic agents such as amphotericin B.

Infection by species of actinomycetes may be susceptible to chemotherapeutic agents. The combination of dapsone with streptomycin or co-trimoxazole plus streptomycin has been reported to give good results [19]. An alternative second drug is rifampicin. Amikacin may also be used in recalcitrant *Nocardia* infections.

Among the fungal causes of mycetoma, *M. mycetomatis* is the most sensitive to therapy, as it responds to ketoconazole in about 60% of cases [1]. For the others, a trial of therapy with griseofulvin, terbinafine or itraconazole is worth attempting as, even though it may not be curative, the progress of the infection may be slowed [19]. Radical surgery, usually amputation, should be considered carefully. Removal of a limb may deprive the patient of livelihood in many countries and this will need to be taken into consideration. However, it remains the only effective means of removing the infection in some patients.

Chromoblastomycosis

SYN. CHROMOMYCOSIS; VERRUCOUS DERMATITIS

Definition. A chronic fungal infection of the skin and subcutaneous tissues caused by pigmented fungi, which produce thick-walled single- or multicelled clusters (sclerotic or muriform bodies) in tissue, and which are characterized by the production of slow-growing exophytic lesions, usually on the feet and legs [1].

Aetiology. Chromoblastomycosis is caused by several fungi, the most common of which are *Phialophora verrucosa*, *Fonsecaea pedrosoi*, *F. compacta* and *Cladophialophora carrionii* (recent syn. *Cladosporium carrionii*) [2]. Other rare causes include *Rhinocladiella aquaspersa*. The nomenclature of these fungi has been reviewed by McGinnis [3].

The causal fungi have been isolated from wood and soil, and the infection usually results from trauma, such as a puncture from a splinter of wood [4]. The condition is usually found in rural communities [5]. It has been reported from Central, South and North America [6], Cuba, Jamaica, Martinique, and also from many other

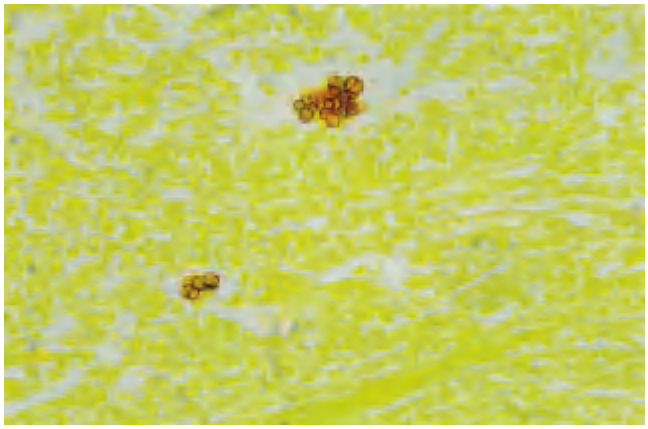

Fig. 31.53 Chromoblastomycosis: tissue section. The natural brown pigment of the fungal muriform cells is clearly visible. The cells divide by fission and may form septa in more than one plane of division. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

countries including India, South Africa, Madagascar, Australia and northern Europe. It is occasionally seen as an imported infection in the UK.

Adult male agricultural workers are most often affected, but the condition has been reported in children.

Histology. The histology is that of a foreign-body granuloma, with isolated areas of microabscess formation. In the organized granuloma, mainly within giant cells, groups of fungal cells may be seen. Because the cells are chestnut or golden brown in colour, they are easily distinguished in the infiltrate. The cells are characteristically divided in several planes of division by thick septa and are termed muriform or sclerotic cells (Fig. 31.53). There is marked pseudoepitheliomatous hyperplasia in the epidermis, and in some areas apparent transepidermal elimination of fungal cells, which can be found in the stratum corneum. The tissue between the granulomatous nodules shows chronic fibrosis. When ulceration has occurred there is usually secondary bacterial infection.

Clinical features [7,8]. The lesions are usually found on exposed sites (Fig. 31.54), particularly the feet, legs, arms, face and neck. A warty papule slowly enlarges to form a hypertrophic plaque [9,10]. In some lesions, the plaque is flat and expands slowly with central scarring. The early lesion may occasionally be an ulcer. Eventually, after months or many years, large hyperkeratotic masses are formed, and these may be as large as 3 cm thick (Fig. 31.55). Secondary ulceration may occur. The lesion is usually painless unless the presence of secondary infection causes itching and pain. Satellite lesions are produced by scratching, and there may be lymphatic spread to adjacent areas. Haematogenous spread has occurred but is rare, and brain abscesses have been described. Secondary infection may eventually lead after several years to lymphatic stasis with the production of elephantiasis. Some forms of the infection produce psoriasiform lesions. Squamous carcinomas may develop in chronic lesions.

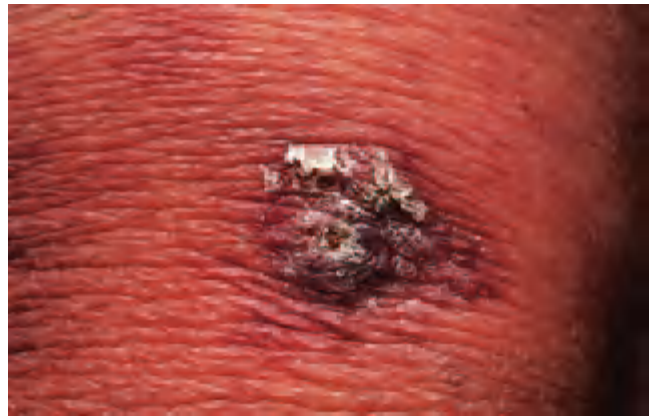

Fig. 31.54 Early lesion of chromoblastomycosis.

Fig. 31.55 Plaque-type chromoblastomycosis.

Differential diagnosis. The disease must be differentiated from blastomycosis (by the absence of a sharp border containing minute abscesses) and also the absence of pulmonary lesions, cutaneous tuberculosis, leishmaniasis, syphilis and yaws. Biopsy and culture of material for the associated fungi will establish the diagnosis.

Laboratory diagnosis. Irrespective of species, the pathogen can be seen in biopsy sections as deeply pigmented, thick-walled muriform or sclerotic cells. Occasionally, in superficial skin scrapings from the surface of the lesions, pigmented hyphae rather than sclerotic cells are seen. Multiplication *in vivo* is by splitting rather than budding, and this results in the production of single, two- or multiple-celled clusters.

In culture, the colonies of all species are dark grey–green to black and velvety or downy, with a black reverse. Three forms of conidial production are observed in the

most common agents of infection: acropetal budding, production of phialides and sympodial conidiation. Some agents are polymorphic, demonstrating more than one type of conidiation simultaneously, and this has caused some confusion in the nomenclature of these agents. They are named according to the dominant form of conidiation.

Phialophora verrucosa. Microscopy: the dominant form of conidiation is the production of flask-shaped phialides with a pronounced dark collarette at the apex. These are produced laterally or terminally. The hyaline thin-walled elliptical conidia are produced at the tip of the phialide in basipetal succession and collect as balls. On nutritionally weak media, a few sympodial or acropetal conidiogenous cells may also be observed.

Fonsecaea pedrosoi. Microscopy: the dominant form of conidiation is sympodial with the conidia confined to the upper part of the cell. The brown single-celled conidia are produced on short denticles and may in turn produce secondary conidia in a similar manner. Conidia produced by acropetal budding are also present in the majority of isolates, and some isolates will produce scanty phialides.

Cladophialophora carrionii. Microscopy: acropetal budding is dominant, producing long chains of pale, oval or lemon-shaped conidia. The chains branch at frequent intervals. On starvation media, such as half-strength cornmeal agar, bulbous phialides may be produced by the conversion of some of the cells within the branched chains.

Treatment. The main treatment of chromoblastomycosis involves the use of antifungal chemotherapy. Itraconazole with or without flucytosine is often successful, although responses to itraconazole alone are thought to be better if the causative organism is *C. carrionii* [1,11]. Flucytosine used on its own or combined with amphotericin B [12] may also be effective, but resistance to flucytosine may develop if it is used on its own. There is also evidence that terbinafine 250 mg/day may also be effective [13]. Tiabendazole is a further alternative, but is not well tolerated by patients because of gastrointestinal side effects. Other approaches to treatment have included the use of cryotherapy or the local application of heat [14]. The use of surgery is contentious; in larger plaques there is a risk in pursuing this approach as satellite lesions may develop around the excision site. Surgery is really only indicated in very small lesions, and even in these should be combined with chemotherapy.

Phaeohyphomycosis

SYN. PHAEOMYCOTIC SUBCUTANEOUS CYST

Definition. Phaeohyphomycosis is a rare, and generally localized, subcutaneous or intramuscular infection, usually a cyst or abscess caused by a range of brown-pigmented (dematiaceous) fungi including *Exophiala jeanselmei*, *Exophiala dermatitidis*, *Bipolaris* species, *Alternaria alternata* and others that form pigmented hyphae in tissue [1]. Systemic forms of phaeohyphomycosis also exist.

Aetiology. The pathogen probably originates by implantation from an exogenous source, and occasionally fragments of plant tissue can be found in lesions. Infection begins with a firm, sometimes tender nodule, which may develop into a large cyst up to several centimetres in diameter. The overlying epidermis is not conspicuously thickened. There is no tendency towards lymphatic spread, and dissemination is exceedingly uncommon. Some patients are immunocompromised, usually through steroid therapy. An ever-increasing number of fungi have been reported as agents of phaeohyphomycosis: a review lists 104 species [2]. The most common causative organisms are shown in Table 31.9.

Table 31.9 Major aetiological agents of phaeohyphomycosis.

Exophiala jeanselmei	*Bipolaris* spp.
Exophiala dermatitidis	*Exserohilum* spp.
Cladophialopora bantiana	*Curvularia* spp.
Phialophora spp.	*Alternaria* spp.

Histopathology. The diagnosis should be confirmed by biopsy, and it is important to exclude other cystic structures such as Baker's cysts. The fungi can be seen in the inflammatory lining of the cyst wall. Specific fungal stains such as Grocott or PAS will mask the natural colour of the hyphae, but in haematoxylin and eosin sections the brown colour may be obvious. In some cases, however, the hyphae appear unpigmented and a specific stain for melanin, the Masson Fontana stain, must be used to reveal the presence of the fungal pigment. Beaded or moniliform hyphae are frequently reported, and sections through these structures may give the appearance of yeast-like structures.

Laboratory diagnosis. The organisms are not usually difficult to grow from the lesions, but the fact that so many different species may be involved, together with the failure of some primary isolates to sporulate, means that their identification may require the help of a specialist laboratory. The major dematiaceous pathogens are well illustrated and described in the review by Dixon and Polak-Wyss [3].

Exophiala jeanselmei. Colony: this fungus belongs to the group sometimes termed 'black yeasts'. The colony is initially glabrous or moist, and black in colour. As the culture matures, it becomes more filamentous and eventually is covered with a grey velvety mycelium. Microscopy: initially, the culture is made up of single cells, which are annellides reproducing by budding. When the filamentous stage has developed, the septate brown hyphae bear slender annellides producing elliptical conidia, which collect in a mass at the tip of the conidiogenous cell or slide down to form a row along the side of the annellide. Physiological tests: will not grow at 40°C.

Bipolaris species. Colony: the colonies grow rapidly. Initially downy and pale grey, the colour darkens to olive grey or black on both surface and reverse. Microscopy: the conidiogenous cells are geniculate, producing the brown multicellular phragmoconidia in a sympodial sequence. The hilum at the base of the conidium is only slightly protuberant.

Treatment. The usual treatment is excision, and although there are no published studies to establish efficacy, an appropriate antifungal such as itraconazole is often given after surgery.

Lobomycosis

SYN. KELOIDAL BLASTOMYCOSIS; LOBO'S DISEASE

Definition. This rare disease is characterized by keloidal skin lesions that remain fairly well localized and apparently do not affect the general health of the patient [1].

Aetiology. The disease was first observed in 1931 in a patient from the Amazon valley and other cases have been seen there [2] and throughout Central and northern South America.

The causal fungus, which has never been isolated in culture, is *Lacazia loboi*. It is thought that the agent might be associated with water and gain entry through a wound [3]. In most cases studied, the disease has been present for periods of many years. Infections have been reported in fresh-water dolphins [4].

Histology. Fungi and giant cells are abundant in the lesions, which are granulomatous and apparently devoid of collagenous fibrosis. The fungus cells are usually round or lemon-shaped, sometimes joined one to the other with a narrow tubular neck. They measure about 8 μm in diameter and have a thick wall [5].

Clinical features [1,6]. Lesions may be found anywhere on the body, but are usually on exposed parts: legs, arms and face. They can, in most instances, be associated with injuries to the skin, and spread from one site to another is thought to be by autoinoculation following injury. There is no marked lymphangitis and no visceral dissemination. Old chronic lesions present as elevated crusted fungoid plaques. Squamous carcinomas may occasionally develop in chronic lesions [1].

Differential diagnosis. Clinically, the disease most closely resembles chromoblastomycosis. Microscopic examination of biopsy material will establish the diagnosis.

Laboratory diagnosis. The fungus has not been isolated in culture, and mycological confirmation depends on recognition of the characteristic cells of *Loboa loboi* in tissue. This is easily performed with potassium hydroxide mounts of epidermal crusts or sections, which need not be specially stained.

Treatment. There is no effective medical therapy for lobomycosis and where possible lesions are excised surgically.

Rhinosporidiosis

Definition and aetiology. A chronic granulomatous mycosis caused by *Rhinosporidium seeberi*, inducing polyps of the mucous membrane. As the organism has never been isolated *in vitro*, its taxonomic position is not clear, nor can it be established that the organism is a fungus.

Rhinosporidiosis has occurred in many parts of the world on rare occasions, but is endemic in India and Sri Lanka [1]. In one review, 51 cases were described from Uganda [2]. Adult male workers are the persons most likely to be infected.

Histology. The histology is superficially like that of a nasal polyp but with conspicuous sharply defined globular cysts up to 0.5 mm in diameter. Occasionally, microabscesses may be found.

Clinical features. Vascular polyps, which may be pedunculated, occur on any mucosal surface [3]. The mucous membrane of the nose, the nasopharynx or the soft palate is involved in three-quarters of cases, and the conjunctiva or the lacrimal sac in a proportion of the others. Lesions are also found on other mucous membrane surfaces, such as the larynx, penis, vagina, rectum and sometimes also on the skin, where it is presumed to have spread from a primary site on the nearby mucous membrane [4]. They become hyperplastic and may reach an enormous size, extending from the nostrils to the pharynx or outwards over the lip [5]. The pink or red surface is lobulated and cauliflower-like. Close examination of the surface reveals small white spots, which represent mature sporangia of the fungus. The disease may last for many years. Spontaneous resolution has been observed rarely. It is not contagious. Obstruction to breathing is usually the chief complaint. On the genitalia, the lesions look like condylomas. If the eye is involved there is conjunctivitis and photophobia, and the weight of the polyps may cause eversion of the lid.

Differential diagnosis. Typical lesions are easily recognized by their pink–purple colour, friable consistency and the presence of the white sporangia within the polyp itself. Atypical lesions should be differentiated from warts, condylomas and haemorrhoids.

Laboratory diagnosis. The causative organisms cannot be cultured, and the diagnosis depends on histopathology —recognition of the sporangia seen on the surface of the polyp or in tissue sections. Depending on maturity, these may attain diameters of 0.5 mm, and can be readily seen by the naked eye as firm white cysts on or just below the surface. Microscopically, these are single, thick-walled and spherical, and when fully differentiated are packed with numerous rounded endospores, 6–7 μm in diameter. Immature and collapsed discharged sporangia are also present [6].

Treatment. Surgical removal resulting in complete eradication of the disease is the treatment of choice.

Subcutaneous zygomycosis

SYN. BASIDIOBOLOMYCOSIS; SUBCUTANEOUS PHYCOMYCOSIS; CONIDIOBOLOMYCOSIS; RHINOENTOMOPHTHOROMYCOSIS

Definition. A localized subcutaneous and predominantly tropical mycosis characterized by chronic, woody swelling of subcutaneous tissue.

Aetiology. Subcutaneous zygomycosis caused by *Basidiobolus ranarum* was initially described in Indonesia [1,2], but cases have since been reported in Africa and South-East Asian countries. Subcutaneous zygomycosis caused by *Conidiobolus coronatus* (rhinoentomophthoromycosis) is another localized zygomycotic infection affecting animals and humans [3]. Reported from the West Indies, Africa, India and South America, infection may result in gross but non-painful facial swelling originating from the nasal mucosae or sinuses. In their natural environment, both fungi are associated with decaying vegetation and the gastrointestinal tracts of frogs.

Histology. The lesion is an eosinophilic granuloma lying deep in the subcutaneous tissue and largely replacing fat. Wide, sparsely septate hyphae, branching at right angles, are scattered throughout the granuloma [4,5] (Fig. 31.56) and there is often dense fibrosis.

Fig. 31.56 Subcutaneous zygomycosis: tissue section. Wide, aseptate hyphae stained black with Grocott methenamine silver (GMS) are characteristic of infection by a zygomycete. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

Clinical features. There is a slowly spreading, painless subcutaneous swelling without other obvious clinical signs [6–8]. It may be single, or there may be multiple satellite lesions. The disc-shaped masses have a uniform hard consistency [9], and they do not pit.

The smooth rounded edge, which may be lobulated, can be raised up by inserting the fingers underneath it. Pain and tenderness may be absent or, less often, pronounced. The overlying skin may be tense, oedematous, desquamating, hyperpigmented or normal. Ulceration does not occur, and the regional lymph glands are not often enlarged [10].

In *Basidiobolus* infections, the lesion usually involves the limbs or limb-girdle areas and the infection is most often seen in children. The clinical features of *Conidiobolus* infections (rhinoentomophthoromycosis) are similar but affect the face, apparently spreading from the region of the inferior turbinates to involve the central facial tissues. It is mainly seen in young adults. Both subcutaneous infections are very disfiguring.

Differential diagnosis. Histological and mycological examinations are required for accurate diagnosis, but lymphatic oedema, which lacks the distinctive edge, subcutaneous malignant lymphoma, which grows more rapidly, and induration round an infection site, where there is pain and tenderness, have to be considered [11].

Laboratory diagnosis. The diagnosis is usually established histologically by biopsy, but culture is not difficult.

Basidiobolus ranarum. Colony: on cycloheximide-free media at 30°C, *B. ranarum* grows very rapidly as waxy cream or yellow colonies with many radial folds. Microscopy: the hyphae are broad, 8–20 µm in diameter and have few septa. After 10–14 days, sexual zygospores with a prominent beak may be produced. In addition, unicellular sporangia—sporangiola—are formed, which are forcibly ejected into the air from the tip of the sporangiophore.

Conidiobolus coronatus. Colony: the colonies are waxy white to grey, becoming more powdery and beige as a short aerial mycelium develops. Microscopy: wide, sparsely septate hyphae are present. Sporangiola are forcibly discharged, and impact on the sides and lid of the Petri dish. Some sporangiola may form small protuberances or villi all over their surfaces.

Treatment. Lesions usually respond to oral treatment with potassium iodides. These are given in similar doses to those used in sporotrichosis. There is some evidence that co-trimoxazole can be used in addition in conidiobolomycosis, and that itraconazole is also useful in this condition.

Systemic mycoses

The systemic mycoses are fungal infections that involve deep structures, and that have the propensity to disseminate, usually via the bloodstream, from the original focus of infection. They include two main groups of disease: the endemic respiratory mycoses and the opportunistic systemic mycoses.

Infections caused by any of the respiratory mycoses usually follow inhalation of organisms. They therefore have a common mode of pathogenesis. In many cases, infections are asymptomatic and the primary infection

can only be detected in retrospect by a positive skin test, as in tuberculosis. These mycoses have defined endemic areas, which may have a characteristic climate or flora and fauna. The main endemic mycoses are histoplasmosis (classical and African types), blastomycosis, coccidioidomycosis, paracoccidioidomycosis and infection caused by *Penicillium marneffei*. The clinical manifestations of these infections are affected by the underlying state of the patient, and many of them develop in the presence of particular immunodeficiency states, notably AIDS. Cryptococcosis shares features of both respiratory mycoses and the second group, the opportunistic infections. However, as it can affect the healthy and is a primary respiratory infection caused by a fungus that occupies a specific ecological niche, it will be considered here with the respiratory infections.

The opportunistic systemic mycoses are those systemic infections that only occur in patients with some underlying predisposition. In contrast to the endemic mycoses, they may occur in any geographical area and their clinical manifestations are very variable, depending on the predisposition and mode of entry of the fungus.

Laboratory methods

The dimorphic fungi causing the respiratory mycoses are extremely hazardous to the laboratory worker, and must be handled in containment level 3 conditions. Laboratory infections and fatalities have been recorded. These organisms should never be cultured in Petri dishes, which pose too great a threat of aerosol dissemination. Cultures should be performed in capped bottles or tubes. The laboratory must be alerted to the possibility of a dimorphic pathogen when the specimen is submitted for examination.

Serological tests

Serological tests are of considerable value in the diagnosis of the systemic mycoses. In the endemic respiratory infections, immunodiffusion tests may demonstrate the presence of specific precipitin bands, for example, the H and M bands in histoplasmosis, and complement fixation tests are also routinely performed in suspected cases of histoplasmosis, coccidioidomycosis and paracoccidioidomycosis. The cross-reactivity of fungal antigens can be a problem, however, and this is true of antigens of *Blastomyces dermatitidis*, which cross-react with those of other dimorphic pathogens. In the opportunistic systemic mycoses, serology is also useful but may be more difficult to interpret. Many normal individuals will have detectable antibodies to *Candida* species, resulting from exposure in the environment, so that changes in titre have more significance than a single positive test. Additionally, many patients with opportunistic infections caused by *Candida* species or *Aspergillus* species will be unable to raise any antibody responses. For this reason, methods attempting the detection of antigen or fungal metabolites are currently of most interest, and are being developed in specialist laboratories. However, antigenaemia is transient and detection may require serial samples. These tests are not yet widely available. The situation is reversed in cryptococcosis, however, where the detection of antigen rather than antibody has proved to be virtually diagnostic, and commercial latex particle agglutination or enzyme-linked immunosorbent assay (ELISA) tests for cryptococcal antigen are routinely used.

Direct examination and histopathology

As with the subcutaneous infections, in some instances a simple wet mount of samples such as sputum or bronchoalveolar lavage fluid can show characteristic fungal structures. For example, observation of encapsulated yeasts in cerebrospinal fluid is diagnostic of cryptococcosis, and spherules of *C. immitis* may be detected in sputum. Histopathological investigations may allow the recognition of all the dimorphic mycoses, zygomycetes and *Cryptococcus*, but cannot distinguish some of the rarer pathogens such as *Fusarium* species and *Scedosporium apiospermum* reliably from *Aspergillus*.

Culture and identification of isolates

Suitable media are similar to those described for the subcutaneous fungi. Incubation should be performed at around 30°C and also at 37°C if sufficient material is available. Many of the opportunistic pathogens will grow in a few days, but some of the dimorphic fungi grow relatively slowly, and cultures should be held for a minimum of 4–6 weeks.

Isolation of any of the dimorphic pathogens is always considered significant. The identification of the five major dimorphic agents may, however, be complicated by the fact that in some cases they can be morphologically atypical or sterile. Exoantigen tests and nucleic acid probes for specific identification of these pathogens have now been developed. These techniques involve less handling of these pathogens and are far quicker than the traditionally used methods for converting the organisms to their parasitic phase *in vitro*.

The situation is rather different with the opportunistic infections, where the pathogens are widespread in the environment. The isolation of a few colonies of *Aspergillus* from a non-sterile site such as sputum may be difficult to interpret. However, the isolation of an opportunistic pathogen from a normally sterile site should always be taken seriously. The use of molecular diagnostic methods is beginning to increase, although all are still only available in specialist laboratories.

Histoplasmosis

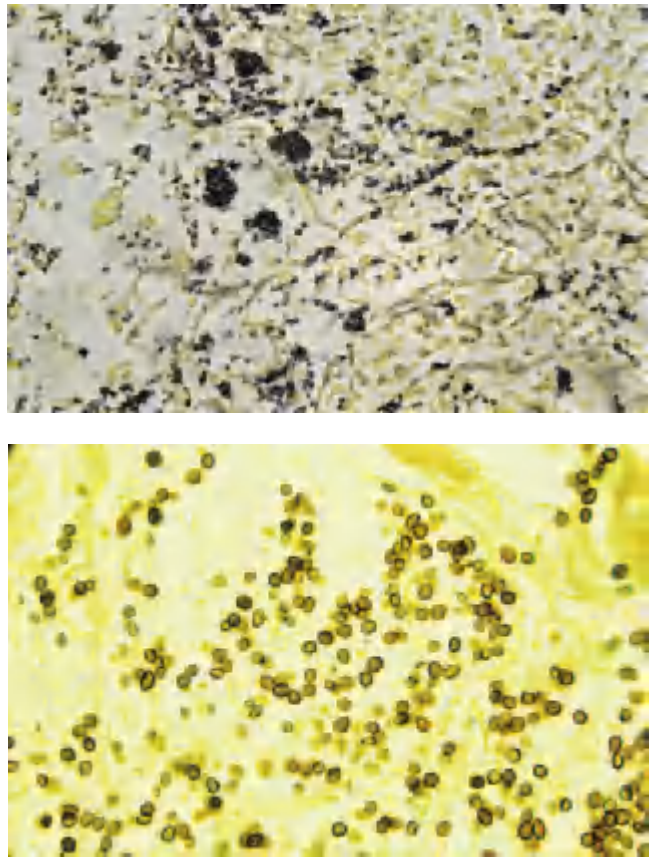
SYN. DARLING'S DISEASE; HISTOPLASMOSIS CAPSULATI

Definition. A highly infectious mycosis caused by *Histoplasma capsulatum* and affecting primarily the lungs, where it is generally asymptomatic. The fungus is intracellular, parasitizing the reticuloendothelial system and involving the spleen, liver, kidney, central nervous system and other organs. Rarely, the disease may become chronic, progressive and fatal.

Aetiology. Histoplasmosis results from infection with the dimorphic fungus, *H. capsulatum* var. *capsulatum*, or the closely related *H. capsulatum* var. *duboisii*. The two varieties differ in that in yeast phase they have different sizes, the *capsulatum* variety producing cells from 2 to 5 µm in diameter, the *duboisii* form 10–15 µm. The other important differences are in their epidemiology and clinical manifestations (see below). They show some subtle antigenic differences but their mycelial phases are identical.

The disease caused by *H. capsulatum* var. *capsulatum*, referred to here as histoplasmosis (small-form histoplasmosis), is widely distributed throughout the world, occurring in some 60 temperate and tropical countries in the Americas, Africa and Australasia [1]. It has been widely studied in the USA, where the number of human infections has been estimated at 30 million. It is highly endemic in the Mississippi and the Ohio valleys of the USA. In certain areas, more than 80% of the population are known to have acquired the infection, as revealed by cutaneous reactivity to histoplasmin [2]. Infections with the *duboisii* form, known as African histoplasmosis or large-form histoplasmosis, have been reported only from Africa. Infants and children are frequently infected, and among adults the rate is highest in male agricultural workers.

H. capsulatum exists as a saprophyte in nature, and has often been isolated from soil, particularly when contaminated with chicken feathers or droppings. Other birds, such as starlings, and bats have also been implicated in the establishment of saprophytic reservoirs of infection. The fungus has been demonstrated in the soil of caves inhabited by bats, and in endemic areas histoplasmosis is recognized as a hazard to speleologists. *H. capsulatum* var. *capsulatum* has been isolated from the organs and faeces of house-dwellings bats in Panama. Its spores are infectious not only to humans, but also to small animals such as dogs, cats and rats. The disease is not transmitted from human to human or from animal to human, but by the inhalation of air-borne conidia. Epidemics have occurred from time to time among people exposed to spore-charged atmospheres when exploring caves or cleaning out sites rich in the excrement of birds. Infection may follow introduction of spores through skin and mucous membranes, as in laboratory workers. Lymphoma appears to favour the development of the infection [3]. In addition, histoplasmosis is an important complicating infection in patients with AIDS [4,5].



(a)

(b)

Fig. 31.57 Histoplasmosis var. *capsulatum*. (a) Tissue section. The tiny yeasts, stained black with GMS are largely intracellular. (b) Oil immersion. The typical budding yeasts are clearly visible. Compare with *Penicillium marneffei* infection, Fig. 31.62. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

A sexual state (*Ajellomyces capsulatus*) has been described [6].

Histology. *Histoplasma* is predominantly an intracellular parasite, growing within the cells of the reticuloendothelial system as an oval yeast (Fig. 31.57). All phagocytic cells of the reticuloendothelial system are involved, including those in the liver, spleen, lymph nodes and bone marrow, so that the cytoplasm is swollen with masses of fungal cells. There is at first little tissue reaction; later, necrosis takes place to be followed by granulomatous changes and fibrosis. *H. duboisii* is usually distinctive in having a much larger tissue form, and it often elicits an inflammatory response in which giant cells predominate.

Clinical features [1]. Benign forms of the disease, which heal by calcification, are indistinguishable on X-ray from

tuberculosis. The spectrum of disease includes asymptomatic as well as symptomatic and benign infections, and the progressive disseminated variety with blood spread to all organs. Primary coin lesions have been demonstrated as well as areas of cavitation. All varieties are reminiscent of tuberculosis.

Skin lesions are more common with *H. duboisii* than with *H. capsulatum*. Indeed, whereas the skin is rarely affected in histoplasmosis, it is often involved in African histoplasmosis.

Although primary inoculation can rarely produce a local granuloma or ulcer, most skin lesions in histoplasmosis arise following dissemination from the primary pulmonary focus. Papules, ulcers, nodules, granulomas, abscesses, fistulae, scars and pigmentary changes may be seen, and there may be secondary involvement of the skin with osteomyelitis [3]. Involvement of the skin in some immunosuppressed patients may produce a condition resembling cellulitis [7].

Asymptomatic forms of histoplasmosis, indicated by the presence of positive skin-test reactivity without evidence of infection, are common in endemic areas [3]. It is likely that this form of exposure is the dominant pattern, unless other factors such as a massive inoculum (exposure in a bat-infested cave) or defective host defence are present.

The four main clinical varieties of histoplasmosis are acute pulmonary, acute disseminated, and chronic disseminated and pulmonary forms.

Acute pulmonary histoplasmosis. The patient has the usual symptoms of acute infection of the lungs, and X-ray examination of the chest reveals diffuse mottling or localized infiltration. However, this acute pulmonary form must be considered uncommon, as a great majority of people in endemic areas who have shown reactions to histoplasmin testing and are assumed to have acquired their infection by the pulmonary route have done so without developing recognizable signs and symptoms. Even in such cases, the organism is not limited to the lungs but is disseminated throughout all parts of the reticuloendothelial system. Associated erythema multiforme or erythema nodosum have been observed. This skin reaction occurs very early in the disease, but the association with histoplasmosis may not be apparent for several weeks.

Acute disseminated form. In this uncommon type, the lungs may be consolidated as a result of inhalation of many spores of *Histoplasma* and, although the pulmonary signs are prominent, there are also enlargement of the liver and spleen, fever, anaemia, loss of appetite and generalized enlargement of lymph glands. In such circumstances, any of the manifestations listed may be prominent, and the clinical features can be infinitely variable. Pulmonary manifestations may simulate miliary tuberculosis. Indurated granulomatous ulcers of the mouth, nose and larynx are often present and are distinctive [8]. Progressive emaciation, induced by gastrointestinal involvement, contributes to a fatal outcome after a course of weeks or months. Cutaneous or mucocutaneous granulomas are often seen in association with disseminated disease [9,10]. This is the form seen in patients with AIDS [11]. In AIDS patients, multiple small skin nodules may develop, the skin being more often involved than in other patient groups [4,5]. Often, papules have central softening.

Chronic pulmonary histoplasmosis. This usually occurs in adults, and also closely resembles tuberculosis with pulmonary involvement.

Chronic disseminated forms. These may appear months or years after a patient has left an endemic area. The most common clinical presenting features are oral ulceration and Addison's disease caused by adrenal infiltration. Mouth ulcers are large and may be chronic [8]; laryngeal involvement, ulceration or granuloma formation may also occur. Patients should be investigated for adrenal insufficiency, as this may appear for the first time during treatment. Ultrasound scans are useful for screening for adrenal enlargement [12].

Primary cutaneous histoplasmosis. This is very rare and appears after inoculation of the organism into the skin. The primary lesion is a nodule or indurated ulcer and there is often local lymphadenopathy [1].

Other forms of histoplasmosis. Other forms can be recognized. Dissemination may occur shortly after infection, or there may be a latent period of many years. Moreover, the severity of the condition may be influenced by various predisposing causes, including leukaemia, corticosteroid treatment, lymphoma, diabetes, carcinoma, AIDS and systemic collagen disease [11,13].

Diagnosis. The diagnosis of histoplasmosis is established by identifying the small intracellular yeast cells (2–5 μm) of *Histoplasma* in sputum, peripheral blood, bone marrow or in biopsy specimens. Lymph node aspiration may also be employed. Care should be taken in areas endemic for *Penicillium marneffei*, as the two organisms are of a similar size, although the latter shows characteristic septal formation rather than budding. The identity of the organism should be confirmed by culture. Some workers consider that cultures should be continued for up to 12 weeks before reporting negative results.

H. capsulatum. Colony: at 30°C the growth may initially be waxy, but surface mycelium usually develops to produce white or tan cottony colonies. Microscopy: two types of conidia are formed: large (8–15 μm), rounded or occasionally pear-shaped unicellular tuberculate macroconidia;

and small, oval, smooth or roughened microconidia. Physiological tests: ideally, cultural identification should be confirmed by demonstrating eluted *Histoplasma*-specific antigens, by using an exoantigen test or a nucleic acid hybridization test. However, if these techniques are not available, a suitable medium for conversion to the yeast phase is brain–heart infusion agar supplemented with 10% sheeps' blood, 1% glucose and 0.1% cysteine. Serological tests: the intradermal histoplasmin skin test is an epidemiological tool that is of no help in diagnosis because it is negative in many patients with disseminated histoplasmosis. A rising complement fixation titre indicates dissemination. Precipitins are also valuable because some antigens, designated H and M, correlate well with active or recent infection [14]. The histoplasmin skin test should not be performed before the serological test, as it may produce a rise in the serological titre. Several serological kits are now sold commercially for both complement fixation and double diffusion tests.

A significant development has been the use of a serological test for the detection of circulating *Histoplasma* antigens [15], which is particularly helpful in AIDS patients.

African histoplasmosis. The clinical appearances of African forms of histoplasmosis are variable, and the disease is sporadic and uncommon [16]. It is confined to the areas south of the Sahara and north of the Zambezi river. The most common sites clinically involved in African histoplasmosis are the skin and bone, although lymph nodes and other areas including the lungs may be affected [17]. Skin lesions range from small papules resembling molluscum contagiosum, to abscesses or ulcers [18]. It is useful to screen patients with a bone scan or X-rays to exclude bone foci of infection [19]. The course of the disease is usually chronic, although some patients appear to develop a more rapidly progressive disseminated type of infection. However, this form of histoplasmosis has only rarely been seen in AIDS patients. The diagnosis is confirmed by microscopy (direct or histopathology) and culture. Serology, using conventional tests, is often negative in African histoplasmosis.

Treatment. The choice of therapy for histoplasmosis has become considerably wider in recent years. For many disseminated or localized forms of the disease, oral itraconazole is highly effective [20], including the treatment of the disease in AIDS patients, where long-term suppressive therapy is usually needed. It appears that the use of HAART may reduce the requirement for maintenance therapy in some cases. Ketoconazole and fluconazole are alternatives [20]. Amphotericin B is useful and is used in those with widespread and severe infections, particularly where an intravenous drug is needed [3]. The acute pulmonary forms of histoplasmosis require no specific antifungal therapy.

In African histoplasmosis, there is some evidence that itraconazole or ketoconazole are effective. An alternative in severe cases is amphotericin B [18]. Some patients with solitary skin lesions may simply respond to excision without chemotherapy, although antifungals should be given where possible.

Blastomycosis

SYN. NORTH AMERICAN BLASTOMYCOSIS; GILCHRIST'S DISEASE

Definition. A chronic granulomatous and suppurative mycosis caused by *Blastomyces dermatitidis*, affecting primarily the lungs but with disseminating forms affecting skin, bones, central nervous system and other sites.

Aetiology. The condition was originally thought to be restricted to the North American continent where it ex-

tends from Canada, particularly Quebec, through the USA with occasional cases in Mexico and Central America. The largest number of cases is seen in the Mississippi valley. Central Kentucky is an endemic area [1]. Blastomycosis, however, is now known to be widely distributed in Africa, with the largest numbers of cases coming from Zimbabwe [2,3], and cases have been reported from the Middle East [4], India [5] and Poland.

B. dermatitidis has only rarely been isolated from the environment. Studies suggest that its natural substrate may be wood debris or soil close to rivers or subject to flooding [6,7]. The fungus can grow in sterile soil in the laboratory, and it is believed that humans are infected by the inhalation of spores from a saprophytic source. However, primary skin infection also occurs, particularly in laboratory workers or pathologists. The incidence of infections tends to be highest in rural areas [1] and in agricultural workers. Human–human transmission does not normally take place. As with most of the systemic mycoses, adult males are most commonly affected, the majority being between the ages of 30 and 50 years. Indeed, some 86% of recorded cases are males. The fungus has also been recovered from domestic animals (e.g. the dog).

Histology. *B. dermatitidis* produces budding yeasts with a characteristic broad base to the bud in the tissues. The tissue reaction, and ultimately the course and prognosis, are determined by the immunological response of the patient. Primary lesions, usually pulmonary, sometimes cutaneous, develop 1–3 weeks after infection and are associated with regional lymphadenopathy. The skin lesions that follow bloodstream dissemination show marked epidermal hyperplasia, which may be pseudoepitheliomatous in degree. Intra- and subepidermal polymorphonuclear abscesses and a granulomatous infiltrate are found in the dermis. These include giant cells of Langhans' type, which contain the round or oval organisms with thick refractile walls. Disseminated skin lesions may also take the form of abscesses with organisms in their walls or within giant cells, and a non-specific granulomatous infiltrate.

Clinical features [8]. There are three forms of blastomycosis: primary cutaneous, pulmonary and disseminated.

Primary cutaneous blastomycosis. This is very rare and follows trauma to the skin and the introduction of fungus. The condition has been seen mainly in laboratory workers (e.g. pathologists carrying out necropsy examinations) [9]. After inoculation, an erythematous indurated area with a chancre appears in 1–2 weeks with associated lymphangitis and lymphadenopathy. There may be some constitutional reaction. There is a strong tendency towards spontaneous recovery.

Fig. 31.58 Cutaneous blastomycosis. (Courtesy of Dr M. James, Royal Berkshire Hospital, Reading, UK.)

Pulmonary blastomycosis. This is very similar to pulmonary tuberculosis. There may be no symptoms, or there may be low-grade fever, chest pain, cough and haemoptysis. Occasionally, erythema nodosum develops [8]. The pulmonary lesion may resolve, or there may be cavity formation with lung abscess. In most cases, other organs are also affected [10]. The disease, if untreated, may frequently disseminate and often progresses to death. Mild asymptomatic self-limiting infections, common in histoplasmosis and coccidioidomycosis, may occur [11], but are probably uncommon.

Disseminated blastomycosis. When the infection spreads from the chest, lesions develop in many organs, commonly the skin, bones and central nervous system [12]. Mucous membranes are rarely involved. One or many skin lesions may be present [13]. These are often symmetrical and usually on the trunk rather than on the exposed parts. Each consists of a papule or nodule that may ulcerate and discharge pus. The lesions enlarge at the periphery, and tend to show central scarring, which may be dense. Eventually, after a relentless progress for months, the lesion is serpiginous in outline, the borders are raised and warty (Fig. 31.58) and have a violaceous margin studded with miliary abscesses containing the organisms [8].

Other patients may present with nodules and abscesses. African patients with blastomycosis have a higher frequency of skin and bone involvement [2].

Differential diagnosis. The microabscesses are the distinctive clinical feature, but the chronic granulomas of the skin must be differentiated from tuberculosis, syphilis, leprosy, pyoderma gangrenosum and drug reactions resulting from bromides and iodides. Pulmonary lesions, which are invariably present, necessitate X-ray examinations of the chest and differentiation from tuberculosis

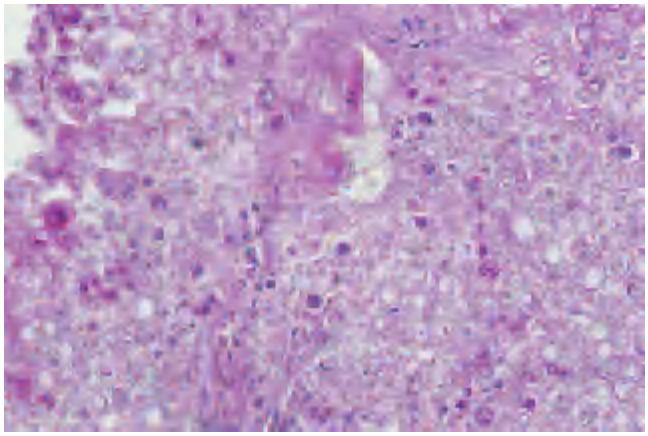

Fig. 31.59 North American blastomycosis tissue section. The large yeasts, stained pink with PAS, are characterized by the broad base of the buds. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

and other infections, and from neoplasia. The diagnosis of the skin lesions is established by direct microscopy of pus in 10% potassium hydroxide and confirmed by culture or biopsy.

Laboratory diagnosis. The fungus can be observed in potassium hydroxide mounts of pus or scrapings as rather thick-walled, rounded, refractile, spherical yeasts with broad-based buds. In tissue, sections must be scanned carefully to identify organisms with the characteristic broad bud (Fig. 31.59).

B. dermatitidis. Colony: in culture at 30°C, mycelium is developed, the colonies being initially waxy, then cottony and white to tan. Microscopy: small, rounded or pear-shaped conidia (2–5 µm) are produced on short stalks arising at right angles from the hyphae. Physiological tests: exoantigen tests or nucleic acid probes are available for safe and rapid identification of the organism. Alternatively, conversion to the yeast phase can be achieved on blood–glucose–cysteine agar. Serological tests: precipitating antibodies to *B. dermatitidis* are often present in the serum of infected subjects and a characteristic precipitin line, the E band, has been described in a high proportion of established cases [8].

Treatment. Amphotericin B is still widely used for the treatment of widespread disseminated forms of blastomycosis [8]. However, in most cases, itraconazole appears to be effective and has the advantage that it can be given orally [14]. The best regimen is not clear, but at least 400 mg should be given initially. Ketoconazole is an alternative therapy [15].

Coccidioidomycosis

SYN. COCCIDIOIDAL GRANULOMA; VALLEY FEVER; SAN JOAQUIN VALLEY FEVER; DESERT RHEUMATISM

Definition. A (primary) respiratory fungal infection caused by *Coccidioides immitis*, which may become progressive and disseminated, with severe or fatal forms.

Aetiology [1]. Coccidioidomycosis, caused by *C. immitis*, is endemic in desert areas of the south-western states of the USA, and in parts of Central and South America [2]. Cases described outside this area are imported infections. The climate in endemic areas is characterized by high mean January and July temperatures and an annual rainfall of 12–50 cm. There is clear evidence that human infection may develop from very short residence in, or even a journey through, an endemic area, so that with increasing travel, cases of coccidioidomycosis are found in many parts of the world. Skin tests have shown that the incidence in endemic areas may be as high as 95%. It is a widespread and important disease only within these regions, affecting individuals of all ages. The fungus is a soil inhabitant; infection of humans and a wide variety of domestic and wild animals is acquired by inhalation of fungus-laden dust particles. The control of dust therefore

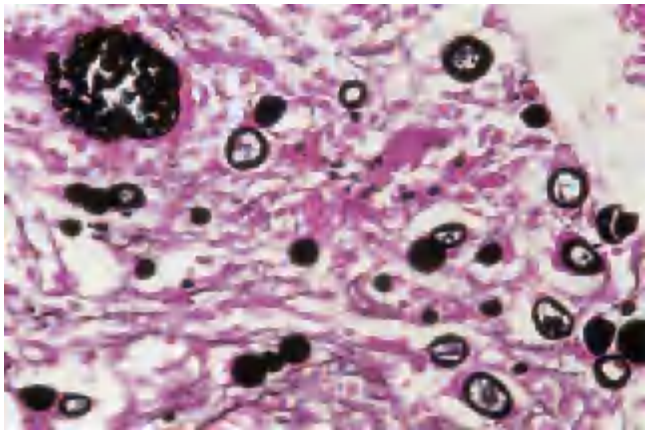

Fig. 31.60 Coccidioidomycosis tissue section. Spherules of various sizes are stained black with GMS. In the top left-hand part of the slide, freshly released endospores are visible. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

becomes important in prevention of the disease [3]. Primary infection of the skin is rare but is known to occur [4].

Histology. The inhaled spores (arthroconidia of the saprophytic mycelial phase) develop in the lung tissue to form spherules—large, round, endospore-containing structures, which when mature are usually 30–80 µm in diameter (Fig. 31.60). Between 2 and 6 weeks after exposure, the patient becomes sensitive to an intradermal skin test using the fungal antigen, coccidioidin. The primary lesion is associated with regional lymphadenopathy, but usually there is no further spread. If secondary dissemination occurs, granulomatous lesions with giant cells and epithelioid cells are produced. Usually in active lesions, spherules with endospores can be demonstrated with routine staining, but in lesions with immature, empty or degenerate fungal spherules this may be difficult or impossible. Spherules may be seen within the cytoplasm of histiocytes and in giant cells of the foreign-body type. The fungus can be easily demonstrated by the use of special fungus stains such as PAS or silver impregnation stains.

Clinical features [1]. The severity of coccidioidomycosis varies from a very mild, inapparent, upper respiratory tract infection to an acute, disseminated fatal disease. The primary pulmonary form, which is the most common form, is sometimes asymptomatic, but may simulate influenza or, occasionally, pulmonary tuberculosis. Erythema multiforme or erythema nodosum occurs from the third to the seventh week in some 3–25% of patients, particularly in females. In endemic areas, coccidioidomycosis is often the most common cause of erythema nodosum. There may be accompanying uveitis and arthralgia.

Pulmonary symptoms, when present, include pain resembling pleurisy, and often very sudden and acute shortness of breath, cough and associated pyrexia. Generalized aches, malaise and lassitude may occur, and there may be severe headache. An early generalized macular erythematous rash is seen in 10% of patients. The exceedingly rare primary skin lesions are painless, firm, indurated nodules often occurring 1–3 weeks after some form of local trauma. Regional lymphadenopathy develops but spontaneous healing follows after a few weeks [5].

Disseminated coccidioidomycosis is very uncommon and develops in fewer than 0.5% of infected individuals, usually in black, Filipino or immunosuppressed patients [6]. It may develop rapidly by blood spread of endospores to all organs, or insidiously from a pulmonary lesion after a period of quiescence. The death rate in acute disseminated disease, or with meningitis, is very high [7]. Disseminated lesions may occur in the skin, subcutaneous tissues, bones, joints and all organs. The skin lesions may appear as abscesses, granulomas, ulcers or discharging sinuses, particularly if there is underlying bone or joint disease [4].

Persistent and progressive pulmonary involvement and dissemination of infection are seen, including the appearance of multiple skin lesions in patients with AIDS [8]. Prolonged and progressive pulmonary infection may also occur in AIDS patients.

Differential diagnosis. The clinical manifestations of the disease are so varied that the condition must be differentiated from most chronic infectious conditions. Residence in, or travel through an endemic area might suggest the diagnosis.

Prognosis. The prognosis for the primary form is excellent; for the acute disseminated forms it is very poor indeed, with all stages in between.

Laboratory diagnosis. The large (usually 30–80 µm, exceptionally larger) globular spherules may be seen in potassium hydroxide mounts of sputum, cerebrospinal fluid or pus. Confirmation depends on the isolation of the fungus in culture.

C. immitis. Colony: cultures of *C. immitis* are mycelial, fast-growing, initially waxy then cottony and white to tan [9]. Microscopy: characteristic thick-walled arthroconidia separated from each other by alternate empty cells are observed. Physiological tests: exoantigen testing and nucleic acid probes are available for identification. If necessary, conversion can be achieved using modified Converse medium [10]. Serological tests: these are of value in diagnosis and prognosis of the disease. Thus, precipitins develop in some 90% of infected individuals within 2–4 weeks, but are short lived; complement fixing

(CF) antibodies are characteristic of more severe infections and increase to a maximum after 6 months. A rise of CF antibodies indicates dissemination while a decrease parallels clinical improvement.

Skin tests with coccidioidin are of little value in diagnosing infections. Positive reactions are of no diagnostic value in individuals from endemic areas, but may be helpful in subjects whose visits have been recent and brief [2]. Patients with coccidioidomycosis may cross-react to histoplasmin, but responses are usually much milder, and seldom cause confusion with the specific reaction to coccidioidin. Spherulin, derived from the tissue form of *C. immitis*, is reported to be superior to coccidioidin in detecting cutaneous hypersensitivity in both epidemiological and clinical settings [11]. In severe infections, cutaneous anergy is common [12].

Treatment. In the primary pulmonary infection, no specific therapy apart from rest is necessary. There is little evidence that the use of an oral azole, such as itraconazole, in patients with erythema nodosum is helpful in reducing symptoms, and it may aggravate the situation. For disseminated disease, the approach depends on the form of disease. Intravenous amphotericin B is used for many of the clinical forms of coccidioidomycosis [13], but alternatives are now becoming available. Oral ketoconazole, fluconazole and itraconazole [5] are effective in some forms of localized infection such as solitary disseminated skin lesions. Itraconazole may be effective in other disseminated forms of disease [14]. The most difficult to treat at present are meningitis and joint infections. Neither of these responds well even to newer therapies, although temporary improvements may be achieved. The use of lipid-associated amphotericin B preparations in coccidioidomycosis has not been widely assessed at present.

Paracoccidioidomycosis

SYN. SOUTH AMERICAN BLASTOMYCOSIS; PARACOCCIDIOIDAL GRANULOMA

Definition. A chronic granulomatous fungal infection caused by *Paracoccidioides brasiliensis*, affecting the skin, mucous membranes, lymph nodes and internal organs [1].

Aetiology. Paracoccidioidomycosis has been reported from most Latin American countries, but the infection is most commonly found in Brazil, particularly in the state of Sao Paulo [2], Colombia and Argentina. The infection is not known in other continents. Adult males between the ages of 20 and 50 years are most frequently infected, although exposure rates are equal across the two sexes [3]. It is thought that the fungus occurs as a saprophyte on vegetation or in soil [4]. The disease is not transmitted directly from person to person. The condition is much more frequent in rural areas.

P. brasiliensis is likely to gain entry to the body after inhalation via the respiratory tract, as with the other dimorphic fungal infections. Susceptibility to *P. brasiliensis* may be related to HLA-A9. This antigen has been found more frequently in progressive pulmonary forms of the disease than in patients with extrapulmonary involvement. The inhibition of the yeast phase, the form seen in human infections, is at least partially dependent on the binding of oestrogen by the fungus, which may account for the marked sex difference in susceptibility.

Histology [5]. The reaction resembles that seen in blastomycosis, namely granulomas with pyogenic inflammation; giant cells are conspicuous and these frequently contain the rounded budding cells. Exceptionally, these may attain diameters of 60 μm. The tendency to produce many multilateral buds in tissue sections is diagnostic (Fig. 31.61). In the skin and mucous membranes, there is pseudoepitheliomatous hyperplasia with severe granulomatous inflammation; intraepithelial abscesses occur and these frequently communicate with the surface.

Clinical features. The most common site of infection is the lung (pulmonary form), although skin and mucous membranes (mucocutaneous form) or lymph nodes (lymphatic form) are also often involved. Many patients have a mixed type of infection with involvement of different

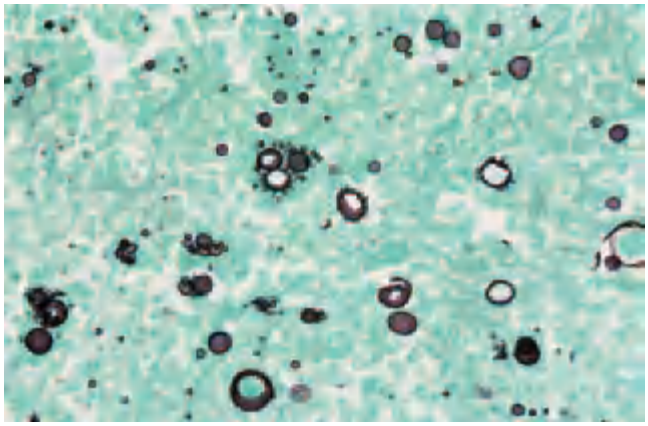

Fig. 31.61 Paracoccidioidomycosis. The yeasts, stained black with GMS, are characterized by the numerous peripheral buds produced. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

organ systems. In most patients, the disease is only slowly progressive.

Patients with pulmonary lesions present with weight loss and chronic cough. The lesions may be bilateral and nodular on X-ray, and there is often extensive fibrosis [6]. Mucocutaneous lesions may be present in patients with lung disease, or occur on their own. Oral or circumoral lesions are common in the mucocutaneous forms of paracoccidioidomycosis, although they may also occur in the nose, conjunctivae or anus. Lesions may be localized or diffuse. If in the mouth, a severe painful ulcerating stomatitis occurs. The ulcers become granulomatous and spread over the mucous membranes (the so-called 'mulberry-like erosion'). Lesions of the gums are common: they loosen the teeth, which are usually lost. The tongue may be involved. The skin lesions may begin at the mucocutaneous junction by direct extension from the mouth, or there may be satellite lesions from autoinoculation. Haematogenous or lymphatic spread results in subcutaneous abscesses. The cervical lymph nodes are sometimes enlarged early. They are palpable, painful, adherent to the overlying skin and may eventually suppurate with chronic sinus formation. If systemic spread occurs, the spleen, intestines, lungs and liver are involved; it is said that the intestines are often affected, with lesions eroding into the lumen [7]. Bone lesions have been seen and the adrenals may be destroyed. The central nervous system may also be affected [1]. Untreated, the disease was fatal in a few months to a few years in 43% of proved cases [6,7]. The extensive painful mouth lesions with loss of teeth interfere with feeding, and the patient becomes cachectic. Paracoccidioidomycosis is uncommon in AIDS patients, and widespread infections may develop in young adults or older children without recognizable predisposition.

Differential diagnosis. The frequency with which the mouth and gums are involved with loss of teeth, the fact that there is no central scar formation, and the presence of marked lymphadenitis and lymphadenopathy differentiates paracoccidioidomycosis from blastomycosis. Other conditions to be considered are tuberculosis, syphilis, histoplasmosis, actinomycosis, sporotrichosis, rhinoscleroma and leishmaniasis. The organisms are readily found in biopsy specimens or in scrapings from the mucous membrane lesions. Aspiration of pus from lymph nodes will also provide material for microscopic examination and culture.

Laboratory diagnosis. Pus, exudates and scrapings examined in potassium hydroxide mounts may show rounded refractile cells, which can be distinguished from *Blastomyces dermatitidis* when the characteristic multiple budding is seen. Yeasts range from 2 to 30 μm in diameter.

P. brasiliensis. Colony: growth is much slower and more restricted than that of *B. dermatitidis*. Initially flat or wrinkled and leathery, the colonies develop tufts of white to tan aerial mycelium. Microscopy: the hyaline unicellular pear-shaped conidia (3–4 μm) are borne directly on the hyphae or on short stalks. Very few conidia are produced. Physiological tests: an exoantigen test is available to identify the isolates; alternatively, conversion can be achieved on brain–heart infusion agar supplemented with 10% sheeps' blood. Serological tests: both complement fixation and immunodiffusion assays are useful in the diagnosis of this condition. A new antigen detection test is useful in monitoring therapy [8].

Treatment. The treatment of choice in most cases is itraconazole, which can produce remissions in 3–6 months [9]. Ketoconazole is an alternative [10]. Relapse is common, and long-term surveillance should be carried out. Some patients, particularly those with more rapidly progressive and extensive infections, may require amphotericin B [1].

Paracoccidioidomycosis is often associated with severe fibrosis, and in oropharyngeal lesions contractures or laryngeal strictures can occur during or after therapy.

Infections caused by *Penicillium marneffei*

SYN. PENICILLIOSIS

Definition. *Penicillium marneffei* is a recently recognized fungal pathogen that causes a disseminated mycosis in both healthy and immunocompromised patients [1]. There is a strong association with AIDS.

Aetiology. Although the causative organism is thought to originate from soil, it has not been isolated from this source. *P. marneffei* infections in humans are confined to South-East Asia, particularly Thailand, South China and Vietnam [2,3]. However, there are reports in other Asian countries, and imported cases have been seen in Europe and the USA [4]. Natural infections occur in bamboo rats, which are large, underground-dwelling rodents. Infections can occur in apparently healthy individuals, but it is a particular problem in severely immunocompromised patients in the endemic area.

Clinical features. It is not known if there is a subclinical form of *Penicillium* infection (cf. histoplasmosis). However, patients may present with respiratory symptoms, such as cough, chest pain and fever, or with signs of dissemination such as anaemia, multiple skin papules and hepatosplenomegaly. Skin lesions occur in over 50% of cases. They are small papules, ulcers or molluscum-like lesions. They are usually widely scattered on the face and trunk. *P. marneffei* infections are also seen in travellers to the endemic area. Left untreated, this infection is fatal.

Differential diagnosis. The main differential is with other disseminated mycoses, such as histoplasmosis and cryptococcosis, which can also be found in the endemic area in AIDS patients. Biopsy and, where necessary, culture will distinguish between the different causes.

Diagnosis. *Penicillium marneffei* forms characteristic cells which are divided by a septum in tissue (Fig. 31.62). It does not produce buds. However, most cells in biopsy material are small oval structures similar in size to *Histoplasma capsulatum*. Occasionally, larger banana-shaped cells are seen. The diagnosis can be made from appropriately stained biopsies, smears and blood films, although with experience the typical cells can be distinguished on simple stains such as leishmanin.

(b)

Fig. 31.62 Infection by *Penicillium marneffei*. (a) Tissue section. The tiny organisms are largely intracellular and look very similar to histoplasmosis at this magnification. (b) Oil immersion. The organisms divide by a central septum, rather than by budding. Sausage-shaped cells are also clearly visible. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

P. marneffei. Colony: in culture, *P. marneffei* grows rapidly on glucose–peptone agar as a green or greyish mould. It produces a diffusible red pigment. Microscopy: typical *Penicillium* conidiophores and phialoconidia are produced. Physiological tests: on glucose–peptone agar after incubation for 14 days at 37°C, the organism produces dry yeast-like colonies. The cells are oval to elliptical and reproduce by fission. Serological tests such as western blot are still only available in specialized centres.

Treatment. In severe cases, amphotericin B is necessary. However, there is usually a good response to itraconazole 200–400 mg/day, but this may have to be given for a long period to prevent relapse.

Cryptococcosis

Definition. An acute, subacute or chronic infection caused by the encapsulated yeast *Cryptococcus neoformans*. There is a marked predilection for the brain and meninges, although the lungs and occasionally the skin and other parts of the body may be involved.

Aetiology. Cryptococcosis, unlike many other systemic mycoses, occurs throughout the world [1]. The condition is not excessively rare, and the diagnosis is frequently unsuspected. It is particularly associated with AIDS and is now seen regularly in these patients. Cryptococcosis is caused by a single species of fungus *C. neoformans*, which comprises two variants: *C. neoformans* var. *neoformans* and *C. neoformans* var. *gattii*. These correspond to cryptococcal serotypes known as A, D, AD and B and C, respectively [2]. Interest has been stimulated by the observation that in Europe and much of the USA the *neoformans* variety was dominant, whereas in much of the tropics including Africa the *gattii* form was more common [3]. With the spread of HIV infection, the *neoformans* variety is overwhelmingly found in AIDS patients. The *neoformans* variety exists as a saprophyte in nature, being particularly abundant in soils enriched with pigeon droppings. By contrast, the *gattii* variant has been isolated from leaf and bark debris from red gum trees. Under certain conditions sexual stages are formed. These have been named *Filobasidiella neoformans* and *Filobasidiella bacillispora*, corresponding to the *neoformans* and *gattii* varieties, respectively. Unusual among pathogenic fungi, the sexual stage is a basidiomycete. It is not known if spores produced by the sexual phase (basidiospores) constitute infectious propagules. Studies *in vitro* have shown that yeast cells of *C. neoformans* are susceptible to soil microorganisms, including bacteria and amoebae.

Animal–human, or human–human transmission of the disease has not been reported. Bird droppings act as an excellent culture medium, and probably play an important part in promoting multiplication of the fungus in contaminated soil and the provision of a significant reservoir of infection in the case of var. *neoformans*. The inhalation of small yeast forms which have been aerosolized is likely to be the main route of infection. It is assumed that var. *gattii* infections follow a similar route of infection, although the exact mode of pathogenesis is still not known.

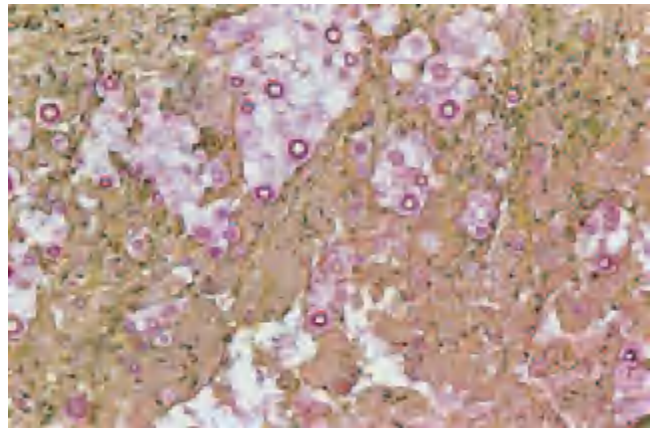

Fig. 31.63 Cryptococcosis tissue section. The mucicarmine stains the capsule specifically. The radiate spiny appearance is caused by shrinkage during processing. (Courtesy of the Department of Medical Mycology, King's College London, St John's Institute of Dermatology, London, UK.)

The disease usually occurs between the ages of 30 and 60 years, and is uncommon in childhood. Susceptibility is greatly increased by immunodeficiency states and neoplastic diseases, especially Hodgkin's disease. Recognizable predispositions include AIDS, malignant lymphomas, sarcoidosis, collagen disease, carcinoma and systemic corticosteroid therapy [4]. Cryptococcosis has also been associated with immunosuppression in patients following renal transplantation. However, the main underlying disease is AIDS [5]. The incidence of cryptococcosis in patients with established AIDS varies in different countries from 3–5% in the USA to 4% in the UK and over 12% in parts of Africa (e.g. Zaire) and of Thailand. This has resulted in an increase in the numbers of patients presenting with cryptococcal infection in many countries.

The respiratory tract is the usual portal of entry, but primary cutaneous lesions may occur. *C. neoformans* is unusual among pathogenic fungi in its predilection for invasion of the central nervous system. Strains of serotype D are more likely to be found in skin lesions which occur in 10–15% of cases of disseminated cryptococcosis.

Histology. There may be minimal inflammatory reaction. The characteristic lesion consists of encapsulated budding cells mixed with a network of connective tissue, which enlarges and compresses the surrounding tissues [6]. A specific stain for the capsule—mucicarmine—is available (Fig. 31.63). Alternatively, a granulomatous reaction without caseation may be seen [7]. These clusters of cells are

seen in most tissues of the body, but particularly in the central nervous system. In rare instances, cryptococci may proliferate in infected tissues in a non-encapsulated form. An acute inflammatory or granulomatous reaction is then seen, with overall resemblances to blastomycosis or histoplasmosis.

Clinical features [7]. Systemic involvement is usual, and the central nervous system manifestations often predominate, presenting as a chronic meningitis or as focal brain lesions simulating a tumour. There is low-grade fever and general decline in health, ending in coma and death, usually within a year but sometimes after a fluctuating course with periods of remission over many years. Pulmonary or urinary tract cryptococcosis may occur without involvement of the central nervous system when the prognosis is believed to be favourable, as it is in the rare cutaneous forms. In the disseminated disease, cutaneous lesions may precede or follow the signs of involvement of the central nervous system and lungs. These cutaneous and mucous membrane lesions, which occur in about 10 and 3% of cases, respectively, are seldom pathognomonic [8–10]. Most frequent are firm or cystic, slow-growing, subcutaneous, erythema nodosum-like swellings. Acneiform papules or pustules are characteristic of widespread systemic infection. They often occur around the nose and mouth. Any of these lesions may ulcerate or ulcers may develop in primarily unaffected skin, when they are often punched out with a rather distinctive rolled edge, or are multiple and resemble molluscum contagiosum. Direct extension of infection to the skin from bony lesions may occur, and mucosal lesions have been reported.

Often, the term primary cutaneous cryptococcosis is used erroneously to describe a solitary lesion of *Cryptococcus* on the skin, as in many such cases there is evidence of systemic spread, implying that the skin lesion has developed after bloodstream spread from a primary lung focus [4]. Documented cases of primary cutaneous infection by inoculation are exceptional.

In AIDS patients, the manifestations of cryptococcosis are not greatly different to those seen in other groups. However, often the symptoms of meningitis are minimal and there is evidence of wide dissemination, such as positive blood cultures or multiple skin lesions [1,11]. The skin lesions are often papules with central softening.

Differential diagnosis. Cryptococci may be recognized in smears of pus and of cerebrospinal fluid. When there is cutaneous involvement, cryptococci may be seen readily in and cultured from biopsy material. Their identity should be confirmed by culture. The diagnosis should particularly be considered when inflammatory nodules or ulcers develop in AIDS patients. However, similar lesions occur with other systemic mycoses, notably histoplasmosis and infections caused by *Penicillium marneffei*.

Laboratory diagnosis. The large (5–15 μm) budding cells with their characteristic capsules are best observed by direct microscopy of cerebrospinal fluid or pus in India ink or nigrosin mounts. Material suspected of containing *C. neoformans* should not be inoculated on to media containing cycloheximide, which inhibits growth. Incubation at 30°C for up to 4 weeks is sufficient.

C. neoformans. Colony: the growth is soft, cream to pale brown and usually mucoid. Isolation of *C. neoformans* is facilitated by its tendency to form brown colonies on media made selective by the addition of various melanin precursors (e.g. *Guizotia* seed or caffeic acid media). Microscopy: yeasts alone are formed; no filaments are produced. Physiological tests: identification is based on such cultural characteristics as the ability to grow at 37°C, urease production, phenoloxidase production, and ability to assimilate creatinine and various carbohydrates. As with the identification of *Candida* species, commercial kits are widely used to identify *Cryptococcus neoformans*. Serological tests: these are rapid, specific and useful, particularly in disseminated or central nervous system infections. Serodiagnosis is dependent on the detection of cryptococcal capsular antigen, using either a latex agglutination test or an ELISA assay. High titres are found in AIDS patients in serum and cerebrospinal fluid. However, non-AIDS patients with single, localized skin lesions are often antigen negative.

Treatment. The mainstay of treatment in the non-AIDS patient is intravenous amphotericin B combined with flucytosine [5]. This should be used in most cases, except in the occasional patient without serious underlying disease, who has focal infections, such as a skin lesion, and in whom there is no evidence of systemic spread, where fluconazole 400–600 mg/day may be used. In AIDS patients, the situation is more complicated as it is virtually impossible to induce complete remissions, necessitating maintenance therapy, although some patients on HAART appear to achieve remission [12]. The current strategy adopted by most units is to use amphotericin B with or without flucytosine for 7–14 days to induce remission, and this is followed by long-term oral maintenance with fluconazole 200–400 mg/day given as outpatient therapy. Itraconazole is an alternative for long-term therapy. The use of higher doses of fluconazole, triazoles combined with flucytosine or lipid-associated amphotericin B formulations as alternative initial treatments is being evaluated.

Systemic candidosis

A general account of systemic candidosis is outside the scope of this text, but certain aspects do impinge upon the dermatologist, and are therefore considered [1,2].

In most cases of systemic candidosis, the causal organism originates in the patient's own gastrointestinal tract, and in patients with leukaemia or other serious illness a history of mucocutaneous candidiasis in the past is the indication for vigilance, and perhaps for prophylaxis with oral anti-*Candida* agents. Invasion by *Candida* along intravenous infusion lines is also important, and maceration or signs suggestive of cutaneous candidosis on adjacent skin should not be ignored. Drug addicts are particularly at risk.

Typical lesions start as macules, become papular or nodular, and may show a pale centre. Some are likely to be haemorrhagic and may break down to form ecthyma gangrenosum-like lesions. Subcorneal pustules are not a feature, but follicular invasion by *Candida* leading to pustules and nodules in the coarse hair-bearing areas of the scalp, beard, axilla and pubis may be characteristic of *Candida* septicaemia in heroin abusers [3]. Fever, diffuse muscle tenderness and an erythematous macular rash are regarded as an indication for prompt skin biopsy in any compromised patient. Histology of a skin lesion showing *Candida* cells in the dermis provides a rapid diagnosis, often before blood culture is positive. Unfortunately, only a minority of patients with *Candida* septicaemia manifest skin lesions, but when present they should not be ignored.

The treatment of systemic candidosis with intravenous amphotericin B or fluconazole drugs is beyond the scope of this volume. Satisfactory management may demand facilities for the measurement of blood levels of some of these agents (e.g. flucytosine) and a careful watch should be kept on renal function. With flucytosine or fluconazole, isolates of the *Candida* strain should be tested for sensitivity if the patient fails to respond. Wherever possible, the predisposing pathology should be treated, and where immunosuppression has been used this should be reduced to minimum levels if possible.

Zygomycosis

SYN. MUCORMYCOSIS; PHYCOMYCOSIS

Zygomycosis is caused predominantly by species of *Rhizomucor*, *Absidia* and *Rhizopus*. *Cunnighamella bertholletiae* and *Saksenaea vasiformis* are less common causes. Although they are frequent in the natural environment, they are rare causes of invasive disease in patients made susceptible by poorly controlled diabetes, neutropenia or renal disease [1,2]. Fatal infections have been reported in patients with burns. Apart from invasion of necrotic burned areas, zygomycosis of the skin is uncommon.

Necrotizing infections of the skin associated with the application of dressings contaminated with *Rhizopus rhizopodiformis* [3] and *R. microsporus* from wooden spatulae have been described [4]. Cutaneous lesions have been described in patients with lymphoma and kidney transplants [2]. Zygomycosis is usually diagnosed in autopsy or biopsy sections, based on the recognition of the broad and generally non-septate hyphae. However, provided adequate samples are taken, they can be grown from tissue. Infections may respond to intravenous amphotericin, and recent results with lipid-associated amphotericin B formulations have been encouraging.

Unusual causes of skin lesions among opportunistic systemic mycoses

Most of the organisms that can invade the immunocompromised patient may cause skin lesions. Some of these

infections, such as candidosis, zygomycosis and cryptococcosis, have been described previously. However, other organisms that can cause skin disease include *Aspergillus* [1,2], *Trichosporon* [3] and *Fusarium* [4]; all of these may affect the neutropenic patient.

Aspergillus and *Trichosporon* usually produce large, scattered necrotic lesions, although with the latter, smaller papules and pustules have been seen. *Fusarium* and, more rarely, *Acremonium* infection may produce target-like lesions, which may undergo central necrosis. In some cases of *Fusarium* infection, scattered skin lesions have been accompanied by digital cellulitis and SWO caused by the same organism.

Skin involvement has also been described in a variety of invasive infections affecting the paranasal sinuses such as those caused by *Exophiala dermatidis*. Skin lesions in these infections develop in severely sick patients. However, skin biopsy will sometimes reveal the true diagnosis. Treatment for these infections is usually amphotericin B. The response rates in both *Fusarium* and *Trichosporon* infections are low, and a lipid-associated amphotericin B formulation is often used instead.

Cutaneous infection caused by *Pneumocystis jiroveci*

Pneumocystis jiroveci is an opportunistic fungal pathogen that is found in immunocompromised patients, including neonates, solid-organ transplant recipients and AIDS patients. *Pneumocystis* was previously regarded as a protozoan, but more recent DNA analysis has shown that it is best regarded as a fungus, although in certain structural features, such as its cell membrane, it differs from the fungal norm. Usually a pulmonary infection, it has rarely been found to cause skin lesions in AIDS patients [1]. The organisms stain with methenamine silver and appear as round, non-budding structures 5–10 µm in diameter. Treatment is with co-trimoxazole or pentamidine.

REFERENCE

Infections caused by *Pythium insidiosum*

Infections caused by *Pythium* species (swamp cancer, Florida horse leech) were first recognized in animals in 1884, affecting mainly horses and mules. Since 1987, a number of cases of human infection have been reported, nearly all of them from Thailand and in farmers exposed to swampy areas. Affected patients have usually had severe infections with ascending gangrene of the lower limbs. Most have had an underlying haemoglobinopathy such as thalassaemia [1]. The organisms appear to invade blood vessels with large, sparsely septate hyphae, 3–20 µm in diameter, similar to those seen in zygomycosis. It is now recognized, however, that the organism is not a true fungus and is probably more closely related to the algae. It is possible to isolate *P. insidiosum* on glucose–peptone agar, but production of the characteristic motile biflagellate zoospores, necessary to speciate the isolate, requires special media and expertise [2].

There is no known effective treatment, apart from high doses of amphotericin B and amputation.

Protothecosis

Prototheca is generally accepted as a genus of achloric algae embracing three species of worldwide distribution: *P. wickerhamii*, *P. zopfii* and *P. stagnora*. The first two species are established as rare and opportunistic pathogens in humans [1]. Infections with green and blue-green algae, although recorded, are rarer still. Lesions confined to skin and subcutaneous tissues are generally located on exposed sites, and may be associated with trauma [2,3]. Papules, nodules, ulcers and multiple granulomatous lesions have all been described. In such cases, the organisms may be found in the dermis and epidermis. Protothecal bursitis, particularly of the olecranon bursa after injury, is also well documented, as are a few examples of widespread cutaneous, subcutaneous or deep infection in immunocompromised hosts including AIDS patients [4]. Colonization of nails has been reported, and *Prototheca* may occur as transients on the skin. Spontaneous recovery has occurred in one cutaneous infection. However, surgical excision is recommended for localized lesions, and systemic amphotericin B, ketoconazole [5] or itraconazole have proved effective on occasions.

Glossary

anamorph an asexual state.
anthropophilic adapted to humans.
arthroconidium a spore resulting from the breaking up of a hypha into separate cells; characteristic of parasitic form of ringworm fungi.
asexual reproduction not involving prior union of two nuclei.
blastospore a spore formed by budding.
cerebriform complex folding similar to the brain surface.
chlamydospore a thick-walled cell, intercalary or terminal, containing stored food and able to function as a spore.
clavate club-shaped.
cleistothecium a reproductive structure associated with the sexual state of ringworm fungi.
conidiophore a specialized structure of varying complexity that bears conidiogenous cells.
conidium an asexual spore.
dermatophyte a ringworm fungus.
dimorphic having two distinct forms, which often correspond to saprophytic and parasitic phases, respectively.
downy fluffy.
ectothrix dermatophyte hair infection with hyphae inside the hair and a sheath of spores outside the hair.
endospore spore formed internally (e.g. a sporangiospore).
endothrix dermatophyte hair infection with fungus confined to the inside of a hair.
faviform waxy, restricted honeycomb-like growth of certain dermatophytes.
floccose cottony.
fusiform spindle-shaped.
geophilic soil-inhabiting.
glabrous smooth, leathery.
grain compact agglomeration of fungal or actinomycete elements formed *in vivo*.
granular texture similar to icing sugar.
hypha one of the branching filaments, septate or nonseptate, that make up the vegetative mycelium (q.v.) of moulds.
intercalary not terminal.
kerion an intensely inflammatory ringworm lesion.
macroconidium the larger of the two types of conidia in those fungi that bear large and small (microconidia) spores.
microconidium the smaller of the two types of conidia in those fungi that bear large and small conidia
mycelium the collective name for a mass of hyphae.
mycosis a fungal disease.
obovate inverted egg-shape.
pleomorphic strictly having two or more forms; used frequently to describe non-sporing (sterile) cultures of dermatophytes.
powdery with a texture like face powder.
pseudohyphae hypha-like structure produced by elongation of budding yeasts lying end to end.
pyriform pear-shaped.
sessile without a stalk.
spiral vegetative hypha assuming spiral forms.
sporangium asexual reproductive body in *Zygomycetes*.
spore a reproductive unit; formed sexually or asexually, sometimes multicellular.
sporophore a spore-bearing structure.
tuberculate covered with peg-like outgrowths.
zoophilic adapted to an animal host.

Chapter 32

Parasitic Worms and Protozoa

F. Vega-Lopez & R.J. Hay

Introduction

A parasite is conveniently defined as an organism that depends upon a living host for one or more of its essential metabolic requirements. Such a definition does not imply that the host must inevitably suffer in the process; indeed, the situation where two organisms benefit mutually from a close association represents one extreme of a wide range of relationships.

Many terms have been used to describe the relationships between parasites and their hosts, and a number are useful; but few can be given an exact or exclusive definition. It is not, for example, possible to draw a sharp line between so-called endoparasites living within the body, which, like some intestinal worms, may not invade the tissues, and ectoparasites living on the body surface, which, like the scabies mite, may in fact burrow into it. Similarly, when more than one species of host is successively infected during the life history of a parasite, they are not described in consistent terms. The definitive or final host is usually designated as the one in which the parasite reaches sexual maturity, and an intermediate host is one in which it undergoes larval development or an asexual phase. Thus, the human is definitive host for the so-called pork tapeworm *Taenia solium*, but may also act as an intermediate host in harbouring the bladder worm or cysticercus stage, which normally occurs in the pig. On the other hand, the human—as well as the sheep, the cow and the pig—is the intermediate host for *Echinococcus granulosus*, the hydatid cyst, and the dog, which harbours the tapeworm stage in its gut, is the definitive host. This logic is not ruthlessly applied. The human is usually regarded as the definitive host of the malarial parasite of the genus *Plasmodium*, though sexual maturity is reached only within the mosquito. In practice, the anthropocentric view usually prevails: when the life history of a parasite involves alternations of human and arthropod hosts, the human is designated the definitive host and the arthropod becomes the intermediate host or vector. A consequence of such illogicality is that the parasite now appears to be host specific only in respect of the vector, and not in respect of the so-designated definitive host. Humans share hospitality for *Plasmodium* spp. with other mammalian species, which are relegated to the status of reservoirs.

Parasites that affect humans exemplify a variety of life histories [1–10]. At one extreme are species that need not leave the host even from one generation to the next; *Sarcoptes scabiei* is an example of dermatological interest. At the other extreme are species that are only dependent on the host for the briefest contact, such as the female mosquito, which needs only a single meal of human blood before she can reproduce. In between these limits, there is a range of types of contact between parasite and hosts. Some forms spend part of their life history free, and only part as ectoparasites or endoparasites. Ticks, for example, while remaining for most of the time on their hosts, may drop off to lay eggs in the soil, and the larvae of hookworms hatch from the egg in the soil before burrowing their way through the skin to become gut parasites. Another category may be the many parasites that spend

all of their lives in the host, except for an egg or cyst stage that is transferred to another host without the intervention of any free-living phase; the roundworm, *Ascaris lumbricoides*, is such a form. Lastly, there are those parasites with one or more intermediate hosts or vectors. Examples of dermatological interest are the guinea-worm *Dracunculus medinensis*, for which the fresh-water crustacea of the genus *Cyclops* act as intermediate hosts, and *Loa loa*, a roundworm causing Calabar swellings, which is transmitted by flies of the genus *Chrysops*.

A number of biological considerations are of relevance to dermatological diagnosis and treatment. Cutaneous lesions may result from direct damage by or presence of the parasite, or occur in sites that are not themselves infected. In scabies, for example, extensive inflammatory lesions are found in regions other than those that actually harbour *Sarcoptes* spp. Skin disease due to parasites may be localized, or it may be only one manifestation of wider systemic infection. A parasite may make its first contact with the body via the skin, and may sometimes get no further, or the parasite may be ingested, when the skin lesions are either fortuitous, such as those caused by bladder worms, or serve as escape channels for propagation of the parasite, as are the ulcers caused by *Dracunculus* spp.

The principal groups of parasitic animals that cause skin disease are the protozoa, the helminth worms, which include the class Nematoda (roundworms) belonging to the phylum Nemathelminthes, the classes Trematoda (flukes) and Cestoda (tapeworms), both belonging to the phylum Platyhelminthes (Table 32.1), and the classes Insecta and Arachnida, both of the phylum Arthropoda.

The parasitic protozoa of dermatological interest include members of three classes. Belonging to the class Sarcodina is *Entamoeba histolytica*, an amoeba that infects the intestine causing amoebic dysentery, but which may occasionally invade the skin where it causes ulcers. Among the Flagellata (or Mastigophora) are classed the species of *Trypanosoma* that cause Chagas' disease, transmitted by species of 'kissing bugs', and African sleeping sickness, transmitted by tsetse flies: all these diseases have cutaneous manifestations. Other important flagellate parasites are the species of *Leishmania*, some responsible for systemic and others for superficial infections, which are also transmitted by insect vectors.

The Nematoda embrace both parasitic roundworms and forms that live free in water or soil. Both free-living and parasitic forms go through a similar series of moults during their life cycle, but in soil-living forms all these stages take place in a single environment. In comparing the life histories of parasitic species, it is convenient first to consider species such as *Ancylostoma*, *Necator* and *Strongyloides* in which the eggs hatch in the soil to produce free-living larvae. *Strongyloides stercoralis* is an example of particular interest, because it is capable either of undergoing a complete life cycle free in the soil, or of infecting humans or other animals. Female worms living in the soil produce partially developed eggs, which soon hatch into rhabditiform larvae. These larvae undergo a series of four moults while growing into adults, and this free-living cycle is essentially similar to that of any non-parasitic soil nematode. When environmental conditions become unfavourable, however, the rhabditiform larvae develop into more slender filariform larvae, which are non-feeding but infective to mammalian hosts. These larvae can infect cats and dogs by being eaten, but in humans they usually penetrate by way of the skin, where they cause a transitory 'ground' itch. They enter the bloodstream and are carried to the lungs, whence after penetrating the alveoli they pass up the bronchi and the trachea to the buccal cavity. Thus, they are swallowed, eventually reaching the intestine where they develop to adults. A third type of life cycle, which is completely parasitic, can occur by the hatching and development of the larvae in the gut lumen. At the filariform stage, the larvae burrow through the mucosa into the blood vessels, and hence make their way via the lungs back to the intestine, where they mature.

The life histories of *Strongyloides* spp. provide some of the models for other species. In the hookworm, *Ancylostoma duodenale*, for example, eggs that pass out with the faeces hatch, within 24 h in moist warm soil, to rhabditiform larvae. These larvae grow rapidly, moult twice and in about a week become filariform, the stage that is infective to humans. The young worms crawl to a high point of moist vegetation and wait for a new host. They penetrate the skin, enter blood or lymph vessels where they are

Table 32.1 Worms commonly causing cutaneous disease.

Nematodes (roundworms)
Necator americanus
Ancylostoma duodenale
Ancylostoma spp.
Strongyloides stercoralis
Enterobius vermicularis
Gnathostoma spinigerum
Trichinella spiralis
Dracunculus medinensis

Loa loa
Dirofilaria spp.
Wuchereria bancrofti
Brugia malayi and *B. timori*
Cestodes (flatworms)
Taenia solium
Echinococcus granulosus and *E. multilocularis*
Spirometra spp.
Trematodes (flukes)
Schistosoma mansoni
S. haematobium
S. japonicum
Schistosoma spp.
Paragonimus spp.

carried to the lungs, and undergo a migratory journey by way of alveoli, bronchi, trachea and buccal cavity to the small intestine. Here, a final moult occurs, and the young worm attaches itself to the intestinal wall, where it feeds and matures to an adult: by about 5 weeks after the original penetration of the skin it can produce new eggs. The American hookworm, *Necator americanus*, has a similar life history, and filariform larvae of other species, which do not infect the gut of humans, can nevertheless penetrate the skin and cause local 'creeping eruption'.

The problem of host infection has been solved in other ways by different species of nematodes. In the species *Ascaris*, the human roundworm, pairing of male and female worms occurs in the intestine of the host, and the eggs, each in a highly resistant capsule, pass out with the faeces. Growth and moulting of the embryo takes place within the egg, but the larvae do not hatch into the soil: the process is delayed until the eggs are ingested by a new host. After hatching in the intestine, the larvae burrow through the intestinal wall to reach the lymphatic or blood vessels and make the same tour through the body as species of *Strongyloides* or hookworm larvae. The threadworm or pinworm, *Enterobius vermicularis*, another intestinal parasite of humans, differs from *Ascaris* spp. in that the eggs are not deposited in the intestine, but discharged by the female after it has crawled out through the anus of the host, and in that the larvae undergo no migratory journey after ingestion by a new host.

In species of *Dracunculus*, the guinea-worm, the problem of reinfection is solved by the role of an intermediate host, *Cyclops* spp., which is ingested by the definitive host. The adult worms live in the connective tissue of humans and other vertebrates, especially the tissue just under the skin, and they can migrate from one site to another. The cutaneous lesion is a hole in the host skin through which a part of the female worm projects and, when the infected host skin gets in contact with water, sets free large numbers of larval worms. *Trichinella spiralis* is an intestinal parasite of the human and a number of other mammals. The young larvae are shed from the female and burrow through the host tissues to the blood vessels, where they are carried to all parts of the body. The vast majority of the larvae encyst in striated muscles, where they gradually become encapsulated. The life cycle can continue only if the infected muscle is eaten by another host: humans usually become infected by eating undercooked pork. The human parasites, *Wuchereria bancrofti*, which lives in the lymphatic vessels, and *Onchocerca volvulus* and *Loa loa*, which live in connective tissue, all produce microfilarial larvae in the host. Infection of new hosts is by blood-sucking or tissue-feeding insects, respectively, mosquitoes (*Anopheles* spp.), coffee flies (*Simulium* spp.) and deer flies (*Chrysops* spp.).

Trematoda that infect humans all belong to the order Digenea. Flukes are parasites of various cavities of the body, such as the intestine, the ducts associated with the alimentary canal, the bladder or the lungs. Eggs are discharged to pass out of the body, where their further development requires water and a mollusc. The egg is either eaten by a snail or it hatches into a free-swimming, ciliated larva, known as a miracidium, which finds its way into a snail. In the snail, the miracidium gives rise to a sporocyst, and an asexual reproductive cycle takes place, producing a number of larvae known as rediae. Within each redia, there may develop either a further generation of rediae or a number of motile larvae known as cercariae. Cercariae can enter a new host in a number of ways. In the sheep liver fluke, *Fasciola hepatica*, they form cysts on blades of grass and are ingested by the host. In the human liver fluke, *Clonorchis sinensis*, the cercariae penetrate the skin of fish, where they encyst as metacercariae. Humans are infected by eating uncooked, infected fish. In the various species of *Schistosoma*, however, the cercariae enter the human host by way of the skin. Of particular interest is the fact that cercariae of flukes parasitic in various birds and mammals, which cannot fully infect humans, can actually enter the skin and cause cutaneous symptoms known as cercarial dermatitis or swimmer's itch.

The Cestoda, or tapeworms, are entirely parasitic throughout their life histories, and have at least two hosts, one of which harbours the adult stage in the gut, and a second that harbours the bladder worm stage in the body cavity or tissues. Humans may, for example, become infected with the tapeworm stage of *Taenia solium*, of which the bladder-worm stage normally occurs in the pig, or by the bladder worm of *Echinococcus* spp., of which the tapeworm stage occurs in the dog and other mammals. Cysticercosis, which may affect the human skin, can occur also from *Taenia solium*. Cestodes belonging to the family Diphyllobothriidae, parasites of humans, other mammals and birds, have a so-called plerocercoid larva stage in copepod crustacea, fish or other aquatic animals. Larvae of this kind from intermediate hosts, such as frogs or snakes, may sometimes infect the skin of humans, causing a condition known as sparganosis.

Parasitic worms and protozoa cause a high proportion of the world's transmissible diseases, particularly in the tropics and subtropics, and they are responsible for some of the most dramatic and serious of the affections of the skin. Worms commonly causing cutaneous disease are shown in Table 32.1. In many instances, simple and effective preventive measures are available, which, when fully applied, should greatly reduce the world incidence.

Infection with human nematodes

In these infections, the human is an obligatory host at some stage of the life cycle of the parasite. Helminths, including nematodes, may be long lived—up to 30 years for *Schistosoma* spp. and 17 years for *Onchocerca* spp. for example—and constant reinfection in endemic countries gives rise to heavy worm burdens. All nematodes must spend part of their life cycle outside the human body, either on soil or in water, or in an insect, crustacean or vertebrate intermediate host. *Strongyloides stercoralis* is the exception to this rule: autoinfection with this worm permits lifelong infections in humans. With some species of nematode, the worm is masked from immune recognition, and large worm burdens may be tolerated with remarkably little clinical effect. With others, inflammation, often in response to naturally dying worms or their progeny, causes severe disease. By contrast, some helminths make excessive demands on the body's nutritional reserves.

Onchocerciasis

SYN. BLINDING FILARIASIS; RIVER BLINDNESS; COASTAL ERYSIPELAS; MAL MORADO

Aetiology and epidemiology. Onchocerciasis is a filarial disease caused by *Onchocerca volvulus*. The worm affects inhabitants of certain areas in tropical Africa, from Senegal right across to Tanzania, and in Yemen, Central America, southern Mexico, Guatemala, Colombia, Ecuador and Venezuela [1]. The clinical manifestations of onchocerciasis in the New World show subtle differences in appearance and distribution, but the infection is otherwise the same [2–4]. The disease has been estimated to affect over 19 million people, of whom the vast majority live in Africa. The male adult worms measure 20–45 mm, and the female 230–700 mm in length; much longer than any other insect-borne filariae. Their progeny are sheathless microfilariae occurring in two sizes approximately 200 μm and 300 μm long.

The vectors of the disease are tiny, humpbacked black flies of the family Simuliidae (buffalo gnats). In Africa, the species *Simulium damnosum* is mainly, but not exclusively, responsible, causing very itchy bites as it transmits the disease. The larvae develop in the thoracic muscles of the flies, and 7 days after infection are fully developed in the labium of the proboscis.

Human infections with zoonotic onchocerca have been reported in the Crimean region, Illinois and Switzerland [5].

Pathology [6,7]. Mature worms and microfilariae are found in granulomatous dermal nodules (onchocercal nodules), often situated on the scalp of their hosts in Central America, but in Africa near bony prominences on the trunk and limbs or in the natal cleft. The nodules measure some 3–35 mm in diameter, and consist of an outer layer of fibroblasts, which contains the parasites in an organized, fibrinous exudate. Inflammatory cells and, sometimes, giant cells, tend to accumulate around the worms. Calcification may also occur.

Microfilariae migrate mainly in the dermis. Their death causes an inflammatory response. The longer the disease lasts, the more these changes are replaced by fibrosis and atrophy of dermis and epidermis [7,8].

The numbers of microfilariae vary greatly. In some instances, there is a dense, predominantly perivascular, reaction with mononuclear cells and eosinophils, but few microfilariae [9]. At its severest, this is accompanied by marked acanthosis and hyperkeratosis. The reason for this extreme reaction is unknown, but serum from patients with this form of onchocerciasis recognize a collagen antigen expressed by a specific nematode gene, suggesting that cross-reaction between antibodies to *Onchocerca* and human collagen might play a role in the pathogenesis of this condition [10]. Often in individuals with minimal clinical lesions and dermal inflammation, there is the highest density of dermal microfilariae (Fig. 32.1). In these patients, there is evidence of defective T-lymphocyte stimulation by certain filarial antigens, which can be reversed by treatment [11]. Conversely activation of T-cell-mediated pathways are associated with the highly inflammatory forms such as lichenified onchodermatitis (LOD) (see below)

Microfilariae also invade the eye, where they cause keratitis, posterior choroiditis, uveitis and optic neuritis, which can lead to blindness. Reports of microfilariae in blood have been rare and sporadic, and this finding is

Fig. 32.1 Microfilaria of *Onchocerca volvulus* in the upper dermis. Note the absence of inflammation around the live organism. (Courtesy of Dr C. McDougall, Slade Hospital, Oxford, UK.)

Fig. 32.2 Acute papular onchodermatitis in a Nigerian. Early in the disease the papules are usually urticarial.

Fig. 32.3 Chronic papular onchodermatitis. Lesions are starting to lichenify.

usually associated with diethylcarbamazine (DEC) therapy [12]. In others, it is difficult to exclude the possibility of concomitant infection with other filarial worms.

Free microfilariae also penetrate superficial lymphatic vessels, and may be found in the urine, tears, sputum, cerebrospinal fluid (CSF) and, occasionally, in vaginal smears or irrigation sediment.

Clinical features [1,4,7,13]. The commonest symptoms and signs are pruritus, onchocercal dermatitis, nodules and, in areas of high endemicity, blindness. The disease may be detectable as early as 6 months of age, and presents with pruritus and a non-specific papular rash worsened by scratching.

In many patients, however, the skin may appear clinically normal, even when microfilarial counts in skin snips are found to be high. The skin changes seen in onchocerciasis vary with the age of the patient, the location of the infection on the skin surface and the geographical and climatic region where the infection occurs. Nonetheless, it is possible to define certain changes that are common features in onchodermatitis, although their prevalence varies from area to area. These changes have been classified as acute papular onchodermatitis (APOD) (Fig. 32.2), chronic papular onchodermatitis (CPOD) (Fig. 32.3), LOD, atrophy and hypopigmentation [13]. In children and in the earliest cases in endemic areas, the skin has an infiltrated appearance, with obliteration of surface markings. This is confined to one skin area and is often accompanied by the appearance of small, itching papules or pustules (APOD). The oedematous features are often more pronounced in Europeans with the disease, when it may appear as localized oedema [14]. In Europeans, blotchy erythema and urticated papules are common early signs. The early rash is usually seen on exposed sites, such as

Fig. 32.4 Late lichenified onchodermatitis (pachyderma).

the shoulders and around the pelvis. In Central America, acute swelling on the face and cheeks with erythema and itching, known as erisipela de la costa, is also a manifestation of this acute phase. Patients may continue to present with this pattern over months and years in the early phases of the disease.

As the infection evolves, localized areas of scarring and CPOD (Fig. 32.3) are seen. These may coexist with the acute papular eruption, but chronic lesions are excoriated papules and flat-topped scars with hyperpigmentation and some lichenification. The buttocks and shoulders are common sites for this rash.

Lichenified onchodermatitis may well represent an extreme form of the last clinical pattern. When fully developed, it is a lichenified itchy rash confined to one limb (Fig. 32.4), commonly the leg, although sometimes two or more areas are affected [9,11]. The rash is composed of itchy papules and nodules, which become confluent. The lesion is characteristically hyperpigmented, and it is known in Arabic-speaking areas as Sowda. Gross enlargement of the regional lymph nodes is an important feature. Interestingly, it is found mainly in East Africa (Sudan [15], Ethiopia) and Yemen. It is less common in West Africa or South America. There is some evidence that this pattern of skin change is associated with very low microfilarial loads; it may also improve symptomatically over time with loss of itching and lichenification, but increasing microfilarial loads. LOD is mainly seen in teenagers and young adults.

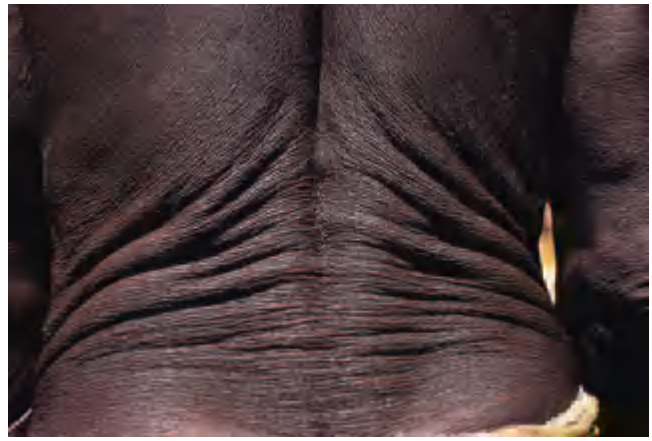

Fig. 32.5 Late onchocerciasis. Atrophy of skin and damage to supporting tissue cause the skin to sag in folds (lizard skin).

Atrophy (Fig. 32.5) is probably a consequence of long-standing onchocerciasis. It may develop after any of the patterns described previously, or arise from apparently normal but infected skin sites. The commonest sites to detect early atrophic changes are over the buttocks, shoulders or lower limbs. The skin becomes dry and shiny, with fine wrinkles resembling tissue paper. An extreme form of this secondary ichthyosis is known as lizard skin. It is believed that degenerative changes leading to loss of dermal elastic fibres, combined with other factors, such as massive inguinal lymphadenopathy, may give rise to the hanging groin, which is an apron-like fold of skin in the inguinal region [16] containing lymph nodes. Depigmentation is a common feature of late-stage onchodermatitis [17]. It is most commonly seen bilaterally over the pretibial region, but may affect the inguinal regions, bony prominences and the shoulders (Fig. 32.6). The patches of hypopigmentation are spotty, with islands of normal-appearing skin, but large coalescent sheets of depigmentation are present in late-stage disease. The name leopard skin is used to describe this change. While it is important to recognize that other causes of hypopigmentation, such as amyloid deposition, may also produce such changes in certain endemic areas, the presence of leopard skin in the community is used as an indicator of the prevalence of onchocerciasis in the population.

In many, if not most, patients with chronic onchocerciasis, it is possible to feel nodules containing the adult worms (Fig. 32.7). They are usually found over the pelvic or pectoral regions, although the top of the natal cleft is often a good site to find them. In South and Central American cases, the nodules are often found on the head.

Fig. 32.6 Depigmentation over the shin in late onchocerciasis (leopard skin). This is common in African endemic areas. Note the stick for the blind.

Fig. 32.7 Cutaneous oedema and cutaneous and subcutaneous nodules in a Nigerian with onchocerciasis.

Other clinical variants of onchocerciasis may occur. These include an acute urticarial eruption seen in Zaire and, in Central America, an inflammatory rash accompanied by hyperpigmentation known as 'mal morado'.

In endemic areas where onchocerciasis is found, the majority of the population may be affected; they will also have other skin diseases. There is little evidence that the presence of onchocerciasis affects the clinical appearances of these. However, it has been suggested that lepromatous leprosy [18] and widespread tinea corporis [4] are commoner in certain patients with onchocerciasis.

The major complication of onchocerciasis is severe visual impairment and blindness. It is the commonest cause of blindness in endemic areas. Ocular manifestations range from punctate and sclerosing keratitis, associated with the presence of microfilariae in the cornea and anterior chamber, to retinal pigmentation, optic atrophy, scarring and blindness. Onchocerciasis may result in blindness rates in endemic communities of 5–10% [19].

Prognosis. In endemic areas, the rate of infection increases up to the age of 50 years and no relative immunity is acquired. Symptoms increase in severity without treatment until atrophic changes are complete.

Diagnosis. Clinically, the diagnosis is usually evident, but other causes of prolonged pruritus and lichenification must be excluded, particularly scabies. Typical burrows may be hard to find in patients with scabies, and great tenacity is needed to demonstrate an acarus. Skin snips for active microfilariae are taken with the corneoscleral punch or by raising a little 'tent' of skin with a needle. This is then shaved off with a very sharp blade without bleeding, placed in normal saline in a microtitre well covered with transparent adhesive tape, or placed under a cover slip and examined microscopically 1–4 h later. The buttocks and legs are often most heavily infected, and are most likely to yield microfilariae. Nodules may be excised and examined histologically for adult worms and microfilariae. The white-cell count shows a leukocytosis with relative eosinophilia. The filarial immunofluorescence test or enzyme-linked immunosorbent assay (ELISA) is positive in 60–90% of cases.

Treatment. The treatment of onchocerciasis has been improved significantly by the development of the microfilaricide, ivermectin. This drug is given orally in a single dose of 100–200 μg/kg [20]. This results in a prolonged suppression of microfilarial counts in skin snips, and improvement in skin symptoms and reversible eye changes [21]. Microfilarial counts remain very low for 6 months, then rise slowly but do not reach pretreatment levels within 1 year. Patients may be retreated after 6–12 months. In patients with low parasite loads, such as travellers returning from an endemic country, about 30%

Fig. 32.8 Acute papular onchodermatitis in a European. Exacerbation and oedema are characteristic of the Mazzotti reaction following a dose of diethylcarbamazine.

will *not* relapse after each treatment [22]. The drug is well tolerated and side effects are seldom severe. Side effects that are seen include pruritus, skin oedema, arthralgia, malaise and fever. In particular, no acute eye changes accompany therapy [23].

The alternative drug regimen, now rarely used, involves the use of DEC, which may cause severe exacerbation of skin (Fig. 32.8) and eye disease, even blindness [24]. DEC kills the microfilariae and is given as follows:

1 first 3 days 1 mg/kg body weight once;
2 second 4 days 2 mg/kg body weight once;
3 second week 4 mg/kg body weight three times a day;
4 third week 4 mg/kg body weight three times a day.

In heavily infected patients, or in those with severe dermatitis or with eye involvement, prednisone should be given at a daily dose in adults of 40 mg, starting the day before DEC and continuing for a few days until the reaction has settled. Collapse and death have occurred in heavily infected patients during treatment. The sharp accentuation of symptoms after a single 50-mg dose of DEC may be used as a diagnostic test where skin snips are negative (Mazzotti's test). Repeated courses are usually necessary until the patient is symptom-free.

Ocular reactions need treatment with corticosteroid eye drops and mydriatics.

Suramin is a drug that kills adult worms (macrofilaricide). However, it can cause severe adverse reactions and is now seldom used.

There is still considerable controversy over the use of nodulectomy, usually combined with a microfilaricide. In South America, some studies have shown that nodulectomy alone without drugs may reduce microfilarial levels by over 60% by 5 months after surgery [25]. It may reduce the burden of eye disease but it does not cure the disease, nor reduce transmission.

Streptocerciasis

Streptocerciasis in an infection caused by the filarial nematode, *Mansonella streptocerca*. The disease is seen mainly in parts of West and Central Africa in rainforest

Fig. 32.9 Streptocerciasis. Pigmentary changes and nodules in a patient from Zaire. (Courtesy of the Armed Forces Institute of Pathology, Washington, DC, USA.)

areas, where it may be found in the majority of the population [1]. Chimpanzees in the endemic area may also be infected.

Adult worms of *M. streptocerca* can be found in the dermis, particularly around the upper trunk; microfilariae are also seen in the dermis.

The skin rash is rather similar to that seen with onchocerciasis, with acute or lichenified itching papules (Fig. 32.9). More widespread lichenification may also occur, and hypopigmented macules are common. Secondary enlargement of the local lymph nodes is seen in many patients. The diagnosis can be made by finding microfilariae in skin snips. These are less active than those of onchocerciasis, and the microfilarial tip may curl in a typical 'shepherd's crook' appearance. The main therapy is DEC.

Infections caused by two other *Mansonella* spp., *M. ozzardi* and *M. perstans*, are seen in Latin America and Africa, respectively, where the parasites are a cause of microfilaraemia; patients, however, are symptomless.

Lymphatic filariasis

SYN. TROPICAL ELEPHANTIASIS

Aetiology and epidemiology [1]. This is a disease due to infection with the filarial worms *Wuchereria bancrofti*, *Brugia malayi* or *B. timori*, of which the first is the commonest. Most authorities agree that clinically the diseases caused by the two genera of filariae are indistinguishable. Infections due to *W. bancrofti* are more widespread than the others [2]. They occur between the latitudes of 40° north and 30° south. The areas with the highest incidence of infection are South-East Asia and sub-Saharan Africa. In the New World, there are fewer endemic foci: Guyana, Haiti and parts of Brazil. Control has been achieved in some other countries such as Taiwan and Japan. It is estimated that about 250 million people are infected. *Brugia malayi* is mainly confined to South-East Asia and as far north as Korea, particularly in rural rainforest areas [3]. The most restricted of this group is *B. timori*, which is found in certain of the Indonesian Islands [4].

Transmission and pathology [4]. The disease is transmitted by many species of anthropophilic mosquitoes of the genera *Culex*, *Aedes*, *Mansonia* and *Anopheles*. In ingested human blood in which microfilariae are present, the organisms lose their sheaths in the mosquito's stomach, and in less than 24 h have entered the thoracic muscles. Metamorphosis proceeds, and mature larvae migrate to the labella 10 days after infection of the insect. Here they are ready to be transmitted to the next human by biting.

In humans, larvae pass through peripheral lymphatics, develop and migrate centrally and eventually grow into adults, which mate in lymphatics proximal to lymph nodes. Fertilized females discharge their microfilariae, which may be found in peripheral blood 12 months after the initial infection. The discharge is cyclical and occurs principally at night. These microfilariae can pass the placental barrier. The adults are found coiled up in dilated lymphatics.

Immunity to filarial infections is complex. Otherwise healthy individuals from within the endemic area have both antibody and T-lymphocyte-mediated immune responses. By contrast, those with active infections and episodic microfilaraemia may show reduced cellular immunity, suggesting that antigens from the organisms may modulate immunity. The worms may also carry symbiotic bacteria of the genus *Wolbachia*. These are antigenic, although their contribution to inflammatory reactions is unknown.

Pathology. The presence of adult worms in the lymphatics with the resulting inflammatory response is the cause of the main pathological feature—lymphatic obstruction (Fig. 32.10). Leakage of lymph may contribute to tissue damage. Circulation of microfilariae in the bloodstream has remarkably little effect, although their entrapment in the lungs may cause tropical pulmonary eosinophilia.

Clinical features. Many of those infected do not appear to develop signs of infection, and such signs that occur vary considerably from patient to patient [5–7]. The first signs are often swelling, tenderness and erythema on the arms, legs or scrotum. Swellings may be firm, and fixed nodules and urticaria have also been described at this stage.

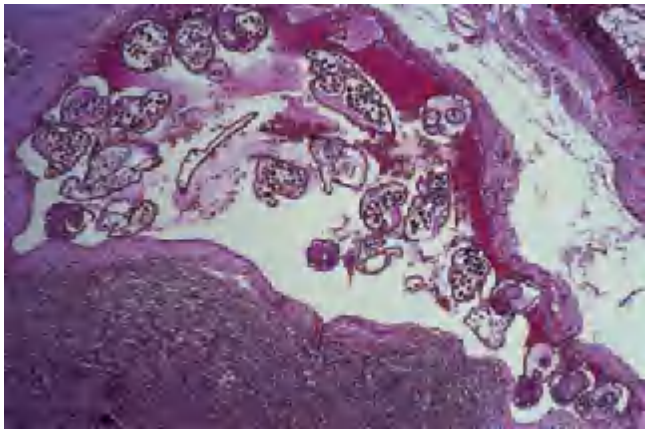

Fig. 32.10 Lymphatic filariasis (low power, H&E). Female adult *Wuchereria bancrofti* within lymph node sinus. Multiple cross-sections of worm are seen. (Courtesy of Professor S.B. Lucas, King's College, London, UK.)

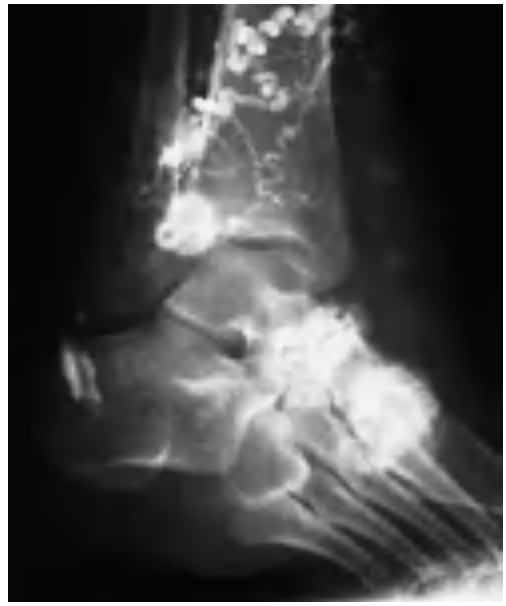

Fig. 32.11 Lymphangiogram showing tortuous dilated lymphatic vessels in the leg of a patient with lymphatic filariasis from Mauritius.

Cellulitis, which is common, may be mild or severe and is recurrent. In the severest form it presents with fever and sweats and the painful enlargement of lymph nodes, particularly the inguinal group. Lymphangitis can accompany some attacks. Milder forms of cellulitis with more localized erythema and tender swellings also occur repeatedly. Other complications include orchitis, which is commonly followed by hydrocoele and scrotal oedema, and recurrent epididymitis. Abscesses deep in the limb muscles, or more superficially located in lymphatics, occur.

Repeated attacks of oedema and cellulitis may be followed over a number of years by evidence of lymphatic obstruction (Fig. 32.11). In males, these commonly present as hydrocoeles, but lower leg oedema and elephantiasis may also develop. Hydrocoele or thickening of the scrotal skin is common in many endemic areas, and may affect up to 25% of the adult male population [8]. Limb oedema of a varying extent and nature is also common and passes through several grades of severity before becoming gross elephantiasis. This may be followed by recurrent episodes of secondary infection, and the appearance of warty thickening of the skin. The legs are usually affected, but arms, breast and genitalia may also be involved. A further complication is rupture of dilated abdominal lymphatics into the urinary tract, to produce episodic chyluria.

Diagnosis. In an endemic area, it may be possible to make the diagnosis on clinical grounds, before the stage at which microfilariae appear in the blood, as well as in the chronic condition. Biopsy of an enlarged lymph node may be diagnostic.

Microfilariae are demonstrated in the blood especially in acute cases, either in a thick blood film or by passing heparinized blood through a millipore filter, which retains the microfilariae, which can then be seen easily under the microscope. In the periodic form of filariasis, blood should be sampled between midnight and 02.00 hours.

An alternative procedure is to repeat blood films 1 h after a single dose of DEC 100 mg. This releases more microfilariae into the circulation. However, some cases of filariasis do not appear to develop detectable filaraemia.

Another approach to diagnosis is the use of serology, where an indirect immunofluorescence or ELISA is positive in a high percentage of those affected, although it is not specific for each organism. An antigen detection system is also used. A polymerase chain reaction (PCR)-based test has been applied to the detection of *W. bancrofti* genomic DNA in blood [9]. It is important to recognize the current deficiencies in the laboratory confirmation of this disease as no single test is even 90% accurate.

Filarial lymphangitis must be distinguished from bacterial lymphadenitis, with its signs of a portal of entry. Genital lesions may resemble lymphogranuloma venereum with adenopathy and oedema. The Frei test will be negative.

Treatment. The management and elimination of lymphatic filariasis has become the focus of a group of research units, governmental organizations, non-governmental organizations (NGOs) and charities collectively known as the Global Alliance for the Elimination of Lymphatic Filariasis. Two phases of their programme have been developed: parasite elimination and morbidity control. Parasite elimination depends on the use of chemotherapy, which is also used for the treatment of individual patients. DEC has long been the main treatment [10,11]. The dosage is the

same as for the treatment of onchocerciasis (see above), although higher doses at monthly intervals have also been given. The predominant effect of the drug is on the viability of microfilariae, but it has relatively little impact on adult worms. It may be necessary to repeat the course after a few months if microfilariae reappear in the blood.

No fatal complication has ever been reported from this use of DEC, but side effects occur, notably anorexia, nausea, vomiting, giddiness, headache, drowsiness and acute allergic reactions due to destruction of microfilariae and adult filariae.

Special care should be taken in areas where both lymphatic filariasis and onchocerciasis coexist, in view of the potentially serious nature of DEC reactions in the latter [8].

There is also experience with ivermectin, and it is effective in lymphatic filariasis. The drug works more rapidly than DEC, and microfilaraemia is reduced to 14–30% of pretreatment levels 6 months after therapy. There are also similar adverse reactions to ivermectin in patients with this condition. The dose is usually 400 µg/kg. Ivermectin does not kill adult worms, so recurrence of microfilaremia is common and further treatments are often necessary [12].

Morbidity control is approached through a combination of lower limb exercise and regular cleansing, combined with treatment of potential portals of entry of bacteria, such as infected web spaces. There is evidence that this can reduce limb swelling considerably, even in late stages. These approaches are being developed across a range of endemic areas. Surgical approaches may improve the appearance of affected limbs either in the early stages by creating a lymph node–venous shunt, or by removing subcutaneous tissue and grafting of split-skin onto a muscle bed (Charle's operation) [13] in established elephantiasis. Repeated drainage and surgery may be required for severe hydrocoeles.

Loiasis

SYN. CALABAR SWELLINGS; FUGITIVE SWELLINGS; *LOA LOA* FILARIASIS; AFRICAN EYE WORM

Aetiology [1,2]. Human loiasis is restricted to the damp forest areas of West and Central Africa from 8° north to 5° south of the Equator, from the Gulf of Guinea across to the Great Lakes. It is particularly prevalent in the Cameroons and on the Ogowe River. Its distribution includes the coastal plain, and follows the Zaire River 500 miles inland. It is also found in southern Sudan. *Loa loa*, the eye worm, is transmitted to humans by blood-sucking tabanid flies of the genus *Chrysops* (deer fly, horse fly and mangrove fly), which bite by day, principally *C. silacea* and *C. dimidiata*. Infection is transmitted by the fly from person to person, and hill houses built at the level of the forest canopy or in cleared plantations are especially susceptible sites for the acquisition of the disease.

Pathology and clinical features [1,3]. Larvae are liberated from *Chrysops* spp. when it presses the labella against the skin to take a blood meal. They then enter the tissues through the puncture made by the proboscis. About 1 year after infection of the host, adult worms may appear under the skin or in the conjunctiva, but microfilariae in the blood are not discoverable until 5 months later [4]. The parasite moves about in fascial planes, from which microfilariae are released and travel up lymphatics to the bloodstream to be lodged in the lungs. The adult makes frequent journeys through the skin connective tissues, and has often been seen on the fingers, trunk, scalp, lingual frenulum, loose penile skin, eyelids, beneath the conjunctiva and in the anterior chamber of the eye [5]. These migrations may cause a pricking, itching, creeping sensation or may be symptomless, although when the parasite appears in the conjunctiva, considerable irritation is usual. When the eye is involved, unilateral palpebral oedema may develop and the worm may be seen actually crossing the eye (Fig. 32.12).

In certain patients, including expatriates who come to live in an endemic area, these wanderings cause temporary, shifting, oedematous swellings—Calabar swellings. These affect mainly the arm and hand (Fig. 32.13), although they may appear on any part of the body. They develop rapidly and may be painful or itchy, lasting for several days.

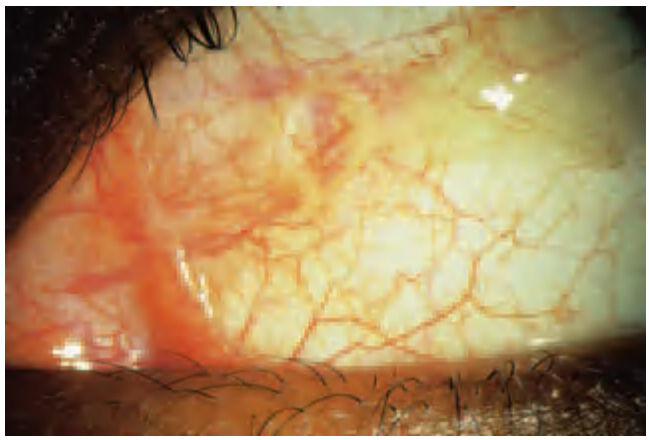

Fig. 32.12 *Loa loa*. Creamy white adult worm crossing the conjunctiva of a Nigerian patient.

Fig. 32.13 Calabar swelling of dorsum of left hand in a European patient with loaiasis. In this case no microfilariae were seen in the blood.

Allergic manifestations, such as eosinophilia and angio-oedema, are often more severe in visitors who originate from a non-endemic area. They have been correlated with high IgG and IgE levels, and increased lymphocyte blastogenesis to filarial antigens [6].

Adult worms may die and calcify. Additional complications reported in loiasis include encephalitis, meningitis and glomerulonephritis [7].

The life expectancy of adult worms is at least 4 years, and may be as much as 15 years. Cases in immigrants have been reported in Australia, Zimbabwe and in North America [5,8].

Diagnosis [3,4]. Clinical diagnosis, based on the presence of Calabar swellings, the sighting of adult worms and eosinophilia in a patient from an endemic area, is usually reliable. Microfilariae may be demonstrated in a sample of daytime blood as for *Bancroftian filariasis* (Fig. 32.14).

Fig. 32.14 Microfilaria of *Loa loa* stained with Giemsa on a micropore filter, after filtration of 10 mL blood taken at 12.00 hours. (Courtesy of Mr A.H. Moody, Hospital for Tropical Diseases, London, UK.)

Filarial serology by immunofluorescence or ELISA is usually positive, but not genus specific. It is particularly helpful in patients without microfilaraemia.

Treatment. One course of treatment with DEC is usually curative. Side effects are few and mild, although there may be an allergic reaction with one or more large Calabar swellings, fever, malaise, swelling of joints, joint pains and pruritus. There is a risk of encephalitis in heavy infections with headache, giddiness, vomiting, purpura and eosinophilia. Steroid therapy starting 1 day before DEC will prevent severe reactions as in onchocerciasis (see above) and is recommended for all microfilaraemic patients. After DEC therapy, elongated subcutaneous nodules, indicating the presence of adult worms, may appear [8].

Ivermectin has been recorded as producing good responses in loiasis, and reduces microfilaraemia [9]. It is given in doses of 200 µg/kg. While it is generally well tolerated, adverse events, such as impaired conscious state and arthralgia, can be seen in those with high levels of microfilaraemia [10]. Ivermectin does not kill adult worms, however.

Adult worms can sometimes be removed from the conjunctiva surgically.

Dracunculiasis

SYN. DRACONTIASIS; GUINEA-WORM; MEDINA WORM; DRAGON WORM

Aetiology and epidemiology. Dracunculiasis is a chronic infection of humans due to the nematode, *Dracunculus medinensis* [1]. The disease occurs in India and West Africa as well as areas in East and Central Africa [2], Saudi Arabia, Yemen, Iran, Pakistan and the West Pacific. The disease was estimated to infect over 50 million people [3]. In some areas, it was particularly common: in Oyo state in Nigeria, for instance, it was found to infect 32% of a large survey population [4]. However, over the past 10 years there has been a highly successful campaign to eliminate this infestation, and the incidence of this disease has been reduced enormously

Pathology [5]. The adult female worm matures over a 1-year period in humans and discharges larvae through an ulcerated skin lesion. Millions of these larvae are produced, particularly on contact with water; these survive for 3–4 days and can develop further in copepods or water fleas (*Cyclops* spp. such as *C. leukarti*). After ingestion by the *Cyclops*, they pass through two developmental stages before reaching the infective third stage (L3) after 2 weeks. Humans are infected via drinking water containing infected *Cyclops* spp.; the larvae are released and penetrate the intestine. Further maturation occurs in the retroperitoneal space or other sites; mating occurs after about 3 months, and the males subsequently die. The females grow and migrate downwards, usually to the lower limbs. Aberrant migration can, however, occur [6]. The female penetrates the skin of the leg and can then discharge larvae after exposure to water. Each female contains 2–3 million larvae. Migration of the worm and larval forms is largely subclinical. Disease is associated with the presence of the adult female in subcutaneous tissue in the lower limbs.

Dracunculiasis is a disease found in poor rural populations. It can be spread in and around communal drinking or washing areas or wells.

Clinical features [1]. Immediately before the appearance of part of the adult female through the skin, there may be generalized symptoms such as fever, pruritus, urticaria and oedema [7]. Dyspnoea and diarrhoea may also occur. Usually, however, the first sign of the infection is the appearance of a small papule or vesicle, which expands and bursts over 4–5 days. When this occurs, commonly on the lower limb, there is intense localized itching. This is often followed by the emergence of part of the female worm through the skin (Fig. 32.15). The surrounding ulcer is covered with slough, which usually becomes secondarily infected. The worm itself is often palpable. Infections with two or more worms may also occur. Eventually, the worms may be resorbed or calcify.

Fig. 32.15 Guinea-worm. Adult female *Dracunculus medinensis* emerging from the skin of a Nigerian patient. (Courtesy of Dr R. Muller, CAB International Institute of Parasitology, St Albans, UK.)

Secondary infection is very common, and may incapacitate the patient. It is a major cause of morbidity [7]. The common infecting organism is *Staphylococcus aureus*, but the open wound may also serve as a portal of entry for tetanus. Sometimes, *Dracunculus* may find its way into other sites [8], such as the knee joint, and cause intra-articular infection.

Diagnosis. The appearance of the worm under the skin is typical. However, the adult can be induced to shed larvae onto a glass slide, which can be examined microscopically, by applying water to the extruded segment. Worms may also calcify in tissue and can be visualized on X-ray [2]. There is usually an eosinophilia.

Treatment. The object of treatment is the removal of the worm. This is now facilitated by oral treatment with an oral benzimidazole, such as metronidazole or thiabendazole. After a few days, the inflammation lessens and it may be possible to extract the worm gently. It may be difficult to extract the worm if mebendazole is used [9]. The more traditional approach is to induce the worm to discharge larvae by applying water or ethyl chloride and to wind the free end around a matchstick. By gradually winding more and more of the worm onto the spool, the whole nematode can be recovered. It is important not to exert tension or the worm will break and cause severe allergic cellulitis. The procedure is therefore carried out slowly over a few days.

In addition, all cases should be treated with local antiseptics, tetanus toxoid and, if necessary, broad-spectrum antibiotics [7]. The drug treatment described above does not affect the larvae or prevent transmission. The latter is best accomplished by public health programmes designed to provide clean drinking water, by sieving or filtration to remove *Cyclops*. Chemical control of *Cyclops* using larvicides such as Temefos is also possible. Considerable progress has been made in the past decade in instituting effective public health measures for the control of dracunculiasis. Since 1986, the estimated prevalence has been reduced by 98% from an initial figure of 3.5 million [10].

Enterobiasis

SYN. THREADWORM; PINWORM; SEATWORM; OXYURIASIS

Aetiology. *Enterobius vermicularis* is the commonest human intestinal worm, with a worldwide distribution. It is more prevalent in cold climates, and is associated with crowding and poverty. Children are most commonly affected, and females more than males. Whole families and communities, notably schools, may be infected [1]. Male and female worms develop in the caecum, becoming mature 2–8 weeks after ingestion of fertile eggs. Gravid female worms migrate to the anus, and at night crawl on the perianal skin where they lay up to 16 000 eggs and expire. The eggs mature within a few hours. Transmission is by ingestion of eggs, most commonly carried by fingernails, because of the itching during sleep. Hands may also become contaminated through sharing a bed or bedroom. Occasionally, transmission is airborne from infected dust, in which eggs may survive for up to 13 days. Adult worms live for 6–12 weeks.

Pathogenesis. Gravid female worms migrating on the skin cause intense itching, although not in all infected people. It is not known whether an allergic reaction is involved. Adult worms may burrow into the submucosa of the appendix or bowel and be associated with inflammation, although causation has not been clearly established. Female worms may migrate from the anus to the vagina, causing irritation and inflammation, and from there to the fallopian tubes or even peritoneal cavity, causing salpingitis and occasionally peritoneal nodules.

Clinical features. Anal and perineal pruritus at night, with sleeplessness and irritability, are the leading symptoms. Perineal intertrigo, nocturia, secondarily infected excoriations, localized urticaria [2], vulval irritation and mucoid discharge may occur [3]. Peritonitis and salpingitis [4,5] are described. It is important to realize, however, that a large number of infected children are asymptomatic.

Diagnosis. This may sometimes be made by seeing the 10-mm long female worms on the perineum at night, on toilet paper or in the stools. If possible, worms should be positively identified in a laboratory, to avoid confusion with proglotids of *Dipylidium caninum*. However, the best procedure is to wind a 6-cm strip of adhesive cellulose tape over the butt end of a test tube or a wooden spatula, sticky side outward. This is then rubbed over the perianal skin (preferably on waking) and the diagnostic eggs and adults stick to it. A drop of toluene is placed on a microscope slide and the tape is spread on it and examined microscopically.

Treatment. Of the several anthelminthic drugs available, mebendazole is probably the most effective, acting against all stages of the worm. In mass treatment campaigns, a single dose of 100-mg mebendazole cures over 90% of infections [6], but reinfection is common. More efficient is 100 mg twice daily for 3 days, repeated after 2 weeks. The whole family should be treated. In the interval, scrupulous attention should be paid to cleanliness of hands and nails on rising, after defaecation and before eating. After each dosing, the bed linen is changed, and the bedroom vacuum cleaned. Even so, relapses may occur and periodic retreatment may be needed. Pyrvinium 5 mg/kg,

piperazine 100 mg/kg and pyrantel pamoate 10 mg/kg are also effective.

Ancylostomiasis

SYN. HOOKWORM DISEASE

'Ground itch', 'dew itch' and 'uncinarial dermatitis' all describe a variable and transient eruption due to skin penetration by larvae of the hookworms *Ancylostoma duodenale* and *Necator americanus*, and the roundworm *Strongyloides stercoralis*.

Aetiology. *Necator americanus* and *A. duodenale* are human hookworms very widely distributed in the tropics and subtropics. *Necator americanus* predominates in Central and South Africa, southern Asia and Melanesia, and is almost the sole hookworm in the New World and Polynesia. It rivals malaria in the store of misery and ill health that it creates [1]. *Ancylostoma duodenale* is the only human hookworm in Europe, the Mediterranean coast, central and northern Asia, and is more prevalent than *Necator* spp. in China, Japan and some parts of Indonesia.

Pathogenesis. The adult worms live in the jejunum with the head firmly attached to the mucosa and cause bleeding: *Necator americanus* 0.03 mL of blood per worm per day and *A. duodenale* 0.2 mL of blood per worm per day. They live for up to 5 years [2]. Bleeding leads to anaemia, hypoproteinaemia, digestive disturbances and retarded development [3]. Thousands of eggs are passed in the faeces. Eggs can survive varying periods of cold or drought, but under favourable conditions of warmth and humidity, hatch into motile rhabditiform larvae. After 5 days and further moults, the infective filariform larvae form. They migrate upwards through soil and grass and, after a period of contact of 5–10 min, can penetrate intact human skin. Walking barefoot is the commonest way of getting infected. Favourable places for transmission include soil around houses, places of work such as plantations and cultivated fields, and mines. Exceptionally, transmission occurs in England during a long hot summer, in playgrounds or picnic sites frequented by immigrants, and formerly in mines where temperatures are maintained above 20°C [4].

After penetrating the skin, larvae migrate within a day or two via the bloodstream to the lungs, pass up the bronchial tree, are swallowed and pass down the oesophagus, reaching the duodenum and jejunum, where they mature in 4–6 weeks. In passing through the lungs they cause acute alveolitis or pneumonitis.

Clinical features. Larvae penetrating the skin cause ground itch: severe pruritus accompanied by erythema and often a papular or papulovesicular rash [5]. The rash is most commonly on the feet, and may be accompanied by a generalized urticaria. The rash is more common with *Necator* infections, and may become secondarily infected as a result of scratching. Larvae passing through the lungs cause a syndrome of cough, wheeze and dyspnoea, which lasts for several days. Adult worms in the gut cause abdominal pain, diarrhoea and, occasionally, melaena. Later, features of iron-deficiency anaemia, with haemoglobin levels as low as 5 g/dL, and hypoproteinaemia develop with pallor, oedema, puffy face and listlessness. Changes in the texture of skin and hair resemble those seen in kwashiorkor [6].

Diagnosis. Clinical and circumstantial evidence point to a diagnosis of ground itch. Löeffler's syndrome is characterized by eosinophilia and patchy pneumonitis seen radiologically. Established infections are diagnosed by demonstrating characteristic eggs in the faeces.

Treatment. Ground itch is treated symptomatically with an antipruritic cream, such as crotamiton with 1% hydrocortisone, or oral antihistamines. Pulmonary symptoms, if severe, respond to a few days' corticosteroids. Established infections respond to a 3-day course of albendazole or mebendazole. Oral iron is given for iron deficiency.

Strongyloidiasis

SYN. STRONGYLOIDAL GROUND ITCH; LARVA CURRENS

Strongyloides stercoralis is a widespread parasitic roundworm with a life cycle and distribution similar to that of the hookworm, but with important differences [1]. It

occurs in warm, especially damp, climates and is especially prevalent in South-East Asia.

Aetiology. Adult male and female worms, 3 mm long, live in the mucosal crypts of the duodenum and jejunum; eggs hatch quickly and rhabditiform larvae are passed in the faeces. In soil, they may either moult into infective filariform larvae, or set up a free-living cycle, with the production of more infective larvae. Infective larvae penetrate human skin, to establish new infections or augment existing ones. Alternatively, larvae mature in the gut and reinfect the patient by penetrating the mucosa or the perianal skin. This autoinfection is capable of maintaining the infection indefinitely, and predisposes to the syndrome of hyperinfection, in which extremely heavy worm loads build up and leave the confines of the gut, in patients who are immunosuppressed by corticosteroid drugs or Hodgkin's disease, or debilitated by advanced age, tuberculosis or other severe infection, ketoacidosis or burns [2].

Pathology [3]. Penetration of the skin by filariform larvae may cause dermatitis. Adult worms give rise to duodenitis and jejunitis, which may cause diarrhoea and malabsorption. Migrating larvae in the skin give rise to a weal-and-flare response, which follows the path of the larva. Hyperinfection causes severe enteritis with fluid loss, and paralytic ileus, pneumonia, meningoencephalitis and secondary Gram-negative bacterial septicaemia with shock and disseminated intravascular coagulation.

Clinical features. Ground itch of initial infection is similar to that seen in hookworm disease. Intestinal infection causes abdominal pain, diarrhoea and, if severe, weight loss or stunting of growth in children [4]. Associated allergic phenomena are common. Urticaria occurs in 66% of cases of strongyloidiasis among ex-Far-East prisoners of war, who have had the infection for over 45 years [5]: IgE levels are raised. Thirty per cent of these individuals also suffer from larva currens, the urticarial weal and flare of migrating subcutaneous larvae. Tracks are seen anywhere on the skin between knees and nipples (Fig. 32.16), but especially around the anus and buttocks. They move at a rate of several centimetres an hour and can traverse the abdomen in a single day, to be gone the next day: features that distinguish the rash from that of larva migrans (see below). Tracks may be several centimetres long or consist simply of one or more urticarial papules. Tracks may be linear or serpiginous [6].

Heavy infection causes severe diarrhoea, with fluid and electrolyte loss; signs of ileus may develop. Fever, abdominal distension, cough, dyspnoea, mental changes and unconsciousness may develop, and the patient may become shocked. Shock commonly indicates a complicating Gram-negative septicaemia. Cough, dyspnoea and chest signs suggest pneumonia. A widespread petechial or purpuric rash may be seen [7].

Fig. 32.16 Larva currens rash of *Strongyloides stercoralis*. The weal and flare will have disappeared in a few hours.

Diagnosis [8]. Larvae of *Strongyloides* spp. are demonstrated in the faeces, by one of several concentration or culture techniques. Diagnostic yield is increased by examining samples of jejunal juice, most conveniently obtained by a 'string test' (Enterotest capsule) or jejunal biopsy. In a few centres, a strongyloides antibody test is available. Except in the hyperinfection syndrome, eosinophilia is common and tests for malabsorption may be positive.

Treatment. Until recently, thiabendazole has been the drug of choice, given in a dose of 25 mg/kg body weight orally twice daily for 3 days, and repeated after 2 and 4 weeks. In unconscious patients or those with vomiting, the drug is given every 6 h by nasogastric tube. Side effects are common, and include headache, malaise, nausea and vomiting. Albendazole is also effective in a dose of 400 mg/day for 3 days, and is free of toxicity. Ivermectin in a single oral dose of 200 μg/kg body weight, to be repeated on day 7, is the currently recommended treatment at the Hospital for Tropical Diseases in London. Faecal and jejunal samples should be examined for larvae after 3 and 6 months. Mebendazole is an alternative.

Infection with nematodes of other animals

Nematodes that do not normally parasitize humans are often unable to mature or develop fully, or to home to their normal site in the body. Biologically, the human is a dead-end host. The infective larvae tend to wander, causing one of several forms of larva migrans, or the adult worm migrates, causing migratory allergic phenomena. Worms reach unusual sites and give rise to eosinophilic granulomas, occasionally in important sites, such as the eye, causing blindness, or the lungs, causing radiological confusion. In other infections, full development may take place and humans act as accidental intermediate hosts.

Cutaneous larva migrans

SYN. CREEPING ERUPTION; SAND-WORM ERUPTION; PLUMBER'S ITCH; DUCK-HUNTER'S ITCH

Cutaneous larva migrans in a clinical term for a distinctive cutaneous eruption that has numerous causes. The prime features, as the name suggests, are that the lesions creep or migrate, and that they are due to the presence of moving parasites in the skin. Visceral larva migrans also occurs (see below).

Aetiology [1]. Causes of creeping eruption include *Ancylostoma brasiliense*, *A. caninum*, *A. ceylonicum*, *Uncinaria stenocephala* and *Bubostomum phlebotomum*. These are all hookworms of various animals, of which the first, the dog hookworm, is the commonest cause of creeping eruption in humans. *Anatrichosoma cutaneum*, a parasite of monkeys in the Far East, is a rare cause. *Strongyloides stercoralis* causes a distinctive form of cutaneous larva migrans. *Dirofilaria repens* and *Spirometra* spp. cause a subcutaneous granuloma that may migrate very slowly. *Gnathostoma* spp. and *Loa loa* cause migratory evanescent subcutaneous swellings. Cutaneous myiasis due to larvae of flies of the genera *Gasterophilus* and *Hypoderma* may cause a creeping eruption similar to that caused by the animal hookworms. Only the helminths that cause creeping eruption are considered further here.

Adult hookworms live in the intestines of dogs and cats, and their ova are deposited in the animals' faeces. Under favourable conditions of humidity and temperature, the ova hatch into infective larvae, which will penetrate human skin. Sandy, warm, moist, shaded areas are particularly favourable, and numerous infections are acquired by children in sandpits, plumbers under houses, farmworkers under outbuildings, hunters in hides, gardeners from the soil and seabathers from the sandy shore above the ebb and flow of the tides. The condition is common in all warm climates, and may occur in northern Europe during a hot summer. A case series in 44 travellers who mostly acquired the condition by direct skin contact with infested sand while on tropical beach holidays has recently been described [2].

Fig. 32.17 Cutaneous larva migrans (creeping eruption). There are several tortuous indurated inflamed worm tracks, in some of which may be seen a blister that marks the head of the track.

Clinical [3]. The larvae may cause a non-specific dermatitis at the site of penetration where the skin has been in contact with infected soil. This is commonly the feet, hands and buttocks. They can then lie quiet for weeks or months, or immediately begin creeping activity with the production of a wandering thread-like line about 3 mm wide. This is exceedingly itchy, slightly raised, flesh-coloured or pink, and forms bizarre, serpentine patterns. Large numbers of larvae may be active at the same time, with the formation of a disorganized series of loops and tortuous tracks (Fig. 32.17).

The larvae advance at a rate of a few millimetres to a few centimetres daily, and are somewhat in front of the head of the track. The wanderings of an individual larva are usually confined to a relatively small area, but exceptionally it travels much further. Itching leads to scratching and secondary changes of dermatitis and bacterial infection. In later stages, these tracks are difficult to see, the path being marked by small itchy and discontinuous nodules.

The disease is self-limiting. Estimates for the natural duration of the disease vary considerably. This variation almost certainly depends on the species of larva observed,

and this is usually unknown. In one study, 25–33% of larvae died every 4 weeks, whereas in another (presumed due to *Ancylostoma brasiliense*) 81% of lesions disappeared in 4 weeks [4]. Some persist for many months.

Larva migrans can be accompanied by Löeffler's syndrome of pulmonary eosinophilia, particularly in severe infestations [5].

Diagnosis. The classic clinical picture of wandering, advancing, serpentine and itchy lesions is easily recognized, but may be atypical, hidden by vesicles and scaling, or spoiled by scratching and secondary infection.

Larva currens and migratory myiasis must be distinguished and, in the Orient, gnathostomiasis.

Biopsy in larva migrans is of little value, as the larvae have advanced beyond the clinical lesions.

Treatment. Ivermectin in a single dose of 200 µg/kg body weight seems best [6]. Albendazole 400 mg/day by mouth for 3 days is also effective. An alternative choice of treatment is the topical application of 10% thiabendazole. Either the commercially available oral preparation may be used directly [7], or two 0.5-g tablets of thiabendazole are triturated in 10-g petrolatum and applied twice daily. Well over 95% of the tracks clear within a week. Oral thiabendazole is less effective and more toxic.

Visceral larva migrans: toxocariasis

Many non-human and human helminths may be found migrating in human organs at some stage of their life cycle, but the syndrome of visceral larva migrans is synonymous with the severe form of toxocariasis.

Aetiology. This infection is caused by *Toxocara canis*, *T. cati* and *T. leonensis*, the common roundworms of dogs, cats and wild carnivores. The domestic dog is the most important source of human infection, and the prevalence of infection in dogs may be high, reaching 73% in New York State and 100% in puppies in Brisbane [1]. Infection is intense in puppies because of transplacental infection, which is augmented by infection from breast milk and contaminated bed litter [2]. Eggs are passed in dog faeces. Humans are most commonly infected by ingesting eggs in soil, or in contaminated food or water. Children are especially at risk when playing in parks or other areas frequented by dogs, or from domestic puppies that have not been regularly wormed. Ova remain infective on soil for many months.

The incidence of human infections is not finally established, but skin tests on apparently healthy subjects suggest that at least 2% of the general population of the UK acquire the infection [2]. The incidence is higher in those in close contact with animals, especially under primitive living conditions. Of a rural population in Pennsylvania, 54% were infected [3].

Pathogenesis. In humans, the second-stage larvae migrate from the intestine to most parts of the body, but notably to liver, lungs, muscles and brain where they eventually die in eosinophilic granulomas.

Clinical features. Most human infections are asymptomatic, or at least unrecognized. Persistent eosinophilia is, however, probably invariably present [4]; counts of over 25×10^9/L are common. In a proportion of infected children, the full syndrome of visceral larva migrans develops. The essential features, apart from eosinophilia, are cough and dyspnoea, failure to gain weight, muscle pains and sometimes fever. The liver is enlarged. Hyperglobulinaemia is frequent. The syndrome is self-limiting after a few months if reinfection is prevented.

Since so many cases are undiagnosed, the incidence of cutaneous manifestations is unknown. Generalized pruritus and urticarial or papular eruptions of the trunk and legs are most frequently reported. Migrating panniculitis, although rarely reported, is distinctive and perhaps pathognomonic: substantial, tender, subcutaneous nodules vanish after 1 or 2 weeks [3,5].

In a minority of infected individuals, who have never experienced visceral larva migrans, a wandering larva causes an ocular granuloma simulating a neoplasm [6].

Diagnosis. This is reliably confirmed by biopsy of the liver or of a cutaneous nodule. Fluorescent antibody and ELISA techniques are helpful [7].

Treatment. Albendazole may prove to be the best treatment [8]. Cure rates are low with DEC or thiabendazole [9].

Gnathostomiasis

Gnathostomiasis is an infection caused by *Gnathostoma spinigerum*, *G. hispidium* and *G. nipponicum*, the definitive host of which are cats, wild felines, dogs and certain other animals that eat fish, snakes and frogs. Human gnathostomiasis occurs throughout South-East Asia, east of and including Bangladesh, China, Japan, Indonesia and the Philippines. The greatest number of cases is in Thailand. There are also reports from Mexico [1].

Aetiology. Adult worms live in tumours in the stomach of the carnivore. Eggs are passed in the faeces, hatch in water and are ingested by a species of *Cyclops*, in which they transform further. When *Cyclops* is ingested by frogs, snakes or fish the larvae develop to the third stage in the flesh of the animals, which in turn are eaten by the definitive host, thus completing the cycle. Humans are infected either by ingesting *Cyclops* in water or by eating inadequately cooked flesh of an intermediate host. Worms removed from a person are most commonly third-stage larvae or immature adults, which measure 2–4 mm long and are rust brown in colour due to ingested blood. The head of the worm is crowned by 4–8 rows of hooklets (Fig. 32.18) and the anterior half of the body is covered in leaf-like spines. Rarely, a mature male worm, up to 12 mm long, has been found [2].

Pathogenesis. Larvae ingested by humans wander, mainly in subcutaneous tissues and muscles, causing deep tunnels, which form the sites of episodes of inflammation or abscess formation. Histology shows intense infiltration with neutrophils, plasma cells, chronic inflammatory cells and especially eosinophils. Less common sites of infection include the brain and eye.

Clinical features. The commonest presentation is of intermittent migratory subcutaneous swellings, several centimetres in diameter. They are firm, warm, red, painful and last up to 4 weeks, before disappearing and returning nearby. They occur most commonly on the upper parts of the body, including the orbit. Abscesses may develop subcutaneously or in muscle [3].

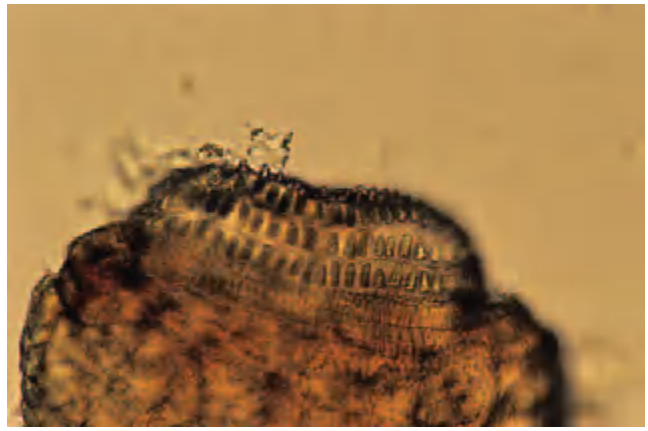

Fig. 32.18 *Gnathostoma spinigerum*. Head of adult worm that was extruded from a subcutaneous swelling in a patient from Bangladesh. The crown of hooklets is characteristic. (Courtesy of Dr P.L. Chiodini, Hospital for Tropical Diseases, London, UK.)

Fatal encephalomyelitis has also been described [4]. Isolated swellings may simulate inflammatory or neoplastic disease of other internal organs.

Diagnosis. Geographical history, clinical features and a peripheral eosinophilia suggest the diagnosis, which is confirmed by surgical extraction of the worm. Occasionally, a worm is expelled through the skin. A reliable serological test is available through some specialist centres.

Differential diagnosis. Other nematodes that may cause similar clinical pictures include *Lagochilascaris minor*, a cause of subcutaneous abscesses in Surinam and Central America, *Thelazia callipaeda*, which parasitizes the conjunctival sac in the Far East, and *Gongylonema pulchrum*, a cosmopolitan parasite of pigs, bears, hedgehogs and monkeys that causes migratory lesions in the oropharyngeal submucosa of humans [5].

Treatment. Albendazole in a dose of 400 mg/day is effective if given for 6 months. The shortest effective course has not been determined [6]. Other anthelmintics have not proven useful. Worms may be removed surgically. Treatment of worms of the face is important, to prevent ocular involvement [7].

Dirofilariasis

Aetiology. Dirofilariasis is an infection by filarial nematodes of the genus *Dirofilaria*. There are two forms of the disease:
1 subcutaneous dirofilariasis caused by *D. tenuis* (*D. conjunctivae*), *D. ursi*, *D. subdermata* and *D. repens*;
2 pulmonary dirofilariasis caused by *D. immitis*, the dog heart worm.

Dirofilaria ursi and the related *D. subdermata* are natural parasites of bears and porcupines, respectively.

Subcutaneous dirofilariasis

Geographical distribution and life cycle. Most cases are reported from the southern USA, but there are occasional reports from Africa, Asia and South America. *Dirofilaria repens* is a subcutaneous parasite of dogs and cats and *D. tenuis* of raccoons in the USA. Transmission to humans is thought to be by mosquitoes.

Clinical features [1–3]. The lesion is usually a tender, occasionally migratory, subcutaneous nodule which develops over a few weeks. Common sites are eyelid, scrotum, breast, arm and leg. The worm may also be seen in the conjunctiva and is present within a foreign-body granulomatous reaction in the nodule (Fig. 32.19). Microfilariae are not found in the blood.

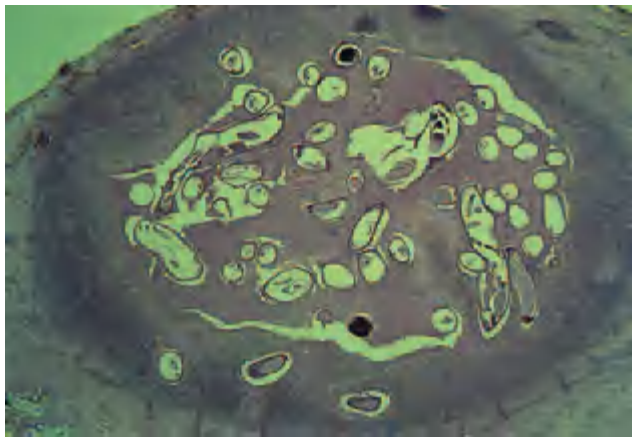

Fig. 32.19 Dirofilariasis. Low-power view of cold abscess from the cheek. It shows degenerate coiled *Dirofilaria* worm within an abscess, and surrounding lymphocytic infiltrate and fibrosis. (Courtesy of Professor S.B. Lucas, King's College, London, UK.)

Diagnosis and treatment [4]. This is made by extracting the worm from the lesion, or by identifying it in an excised specimen. Treatment is by surgical removal.

Trichinosis

SYN. TRICHINIASIS; TRICHINELLIASIS

Trichinosis is an infection of intestine and muscle, with *Trichinella spiralis*, a natural parasite of a wide range of carnivores. The human is normally an end host. A variety of allergic phenomena characterize human infection. Trichinosis is distributed worldwide. It is an important disease both in Europe and in the USA and has been found in Africa, south of the Sahara.

Aetiology. Encysted larvae of *Trichinella spiralis* are ingested in meat, hatch in the duodenum, penetrate the submucosa, and within 5 days have matured and mated and started producing 200–2000 invasive larvae, which reach muscles where they become encysted and infective to a fresh host within 21 days. The adult worms live less than 2 months. Cysts may calcify, but the larvae remain viable for many years and can outlive their dead host by 10 days [1].

Humans acquire the disease by eating raw or undercooked meat infected by *Trichinella spiralis*—usually pork sausages in Germany and areas to which Germans have emigrated, bush pig in Africa, polar and black bear meat in Alaska and the Arctic. Entire polar expeditions have died of the infection after eating polar bear.

Pathogenesis. Intestinal infection causes partial villous atrophy and mucosal and submucosal inflammation. The deposition of larvae in muscles is associated with oedema, loss of cross-striations and basophilic degeneration (Fig. 32.20). The coiled larvae are surrounded by an inflammatory infiltrate of lymphocytes and macrophages until they become encapsulated.

Clinical features [2,3]. The disease may be symptomless or mild, but generally, after a moderate infection with the 'muscle worms', severe symptoms resembling acute food poisoning ensue rapidly. These are followed within a week by an acute illness with fever, generalized muscle pain and tenderness, sweating, periorbital oedema, conjunctivitis, some paralysis of the muscles of the tongue, jaw and

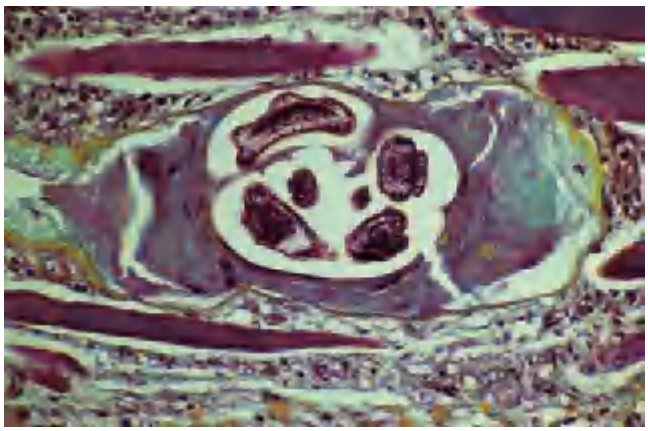

Fig. 32.20 Trichinosis. Medium-power view, Movat stain, showing *Trichinella* worm within a 'nurse cell' in skeletal muscle. There is surrounding oedema, muscle disruption and lymphocytic infiltrate. (Courtesy of Professor S.B. Lucas, King's College, London, UK.)

respiration, with a transient maculopapular rash of the extremities, and splinter haemorrhages beneath the nails.

In severe infections, there is involvement of the heart and central nervous system (CNS). A necrotizing vasculopathy equivalent to classic polyarteritis nodosa is described [4].

Diagnosis. Within a week of eating inadequately cooked meat, especially pork, clinical features suggest the diagnosis. Worms may be found in faeces in the second to fourth week of the infection, and after 4 weeks in biopsied muscle. The eosinophil count, erythrocyte sedimentation rate and serum creatine phosphokinase are all raised. After 3 weeks, antibodies become detectable. Bentonite flocculation and ELISA [5] are the tests most commonly used.

Treatment. Corticosteroids are life saving in suppressing allergic reaction at the height of larval spread. Mebendazole and thiabendazole reduce the severity of infection if given early enough in the acute disease, but albendazole is possibly more effective [6].

Infection with trematodes

SYN. FLUKES; FLATWORMS

Trematodes are non-segmented, single-sex worms, flattened like a leaf and without a formal organ of attachment. Pairs of adult worms live in a hollow viscus (vein, gut, bile duct, lung), from whence eggs make their way into faeces, urine or sputum. The eggs must enter water, hatch and infect a species of snail, in which a cycle of development and multiplication occurs, resulting in the release of motile cercariae. These either penetrate human skin or enter a resting stage in aquatic plants, fish or crustacea, and are later eaten. Trematodes are important and common parasites of humans, especially in Africa and the Far East. They cause skin disease either as a result of cercarial penetration, by the ectopic deposition of adult worms or their eggs, or by causing allergic phenomena.

Schistosomiasis

SYN. BILHARZIASIS

Schistosomiasis or bilharziasis is a serious systemic disease due to different species of human schistosomes or blood flukes [1]. Rashes may occur during the invasive stage of this disease, when the skin is being penetrated by cercariae, and later there may be skin involvement at or near mucocutaneous surfaces, and less commonly at more distant sites on the trunk, following dissemination of ova.

A second group of non-human schistosomes cause cutaneous symptoms only. This situation follows penetration of cercariae into the skin, but further development of the flukes in humans is arrested and there are no sequelae. The condition 'swimmer's itch' or cercarial dermatitis is an example of this process.

Skin manifestations of this common disease of tropical and subtropical distribution are incidental features of the underlying disease. They may be grouped as follows [2]:

1 schistosomal dermatitis;
2 urticarial reactions in the early weeks of the disease;
3 paragenital granulomas and fistulous tracts;
4 ectopic cutaneous schistosomiasis.

Ectopic sites of egg deposition probably arise through migration of adults via the paravertebral venous plexus.

Aetiology [3]. Schistosomiasis is caused by the human blood flukes *Schistosoma mansoni*, *S. japonicum* and *S. haematobium*. Two other species, *S. mekongi* and *S. intercalatum*, are more rarely associated with infection in humans.

Humans infected with *S. mansoni* and *S. japonicum* excrete eggs in the faeces, and with *S. haematobium* excrete eggs in the urine. On contact with water, these eggs develop into miracidia, which undergo further development in certain aquatic snails. From these, free-swimming cercariae are released, which are capable of penetrating

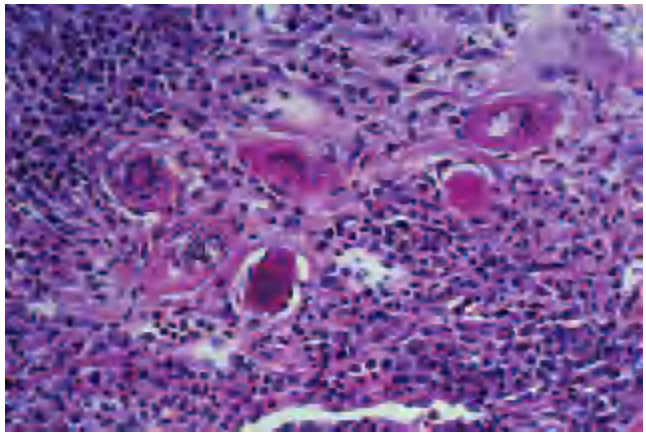

Fig. 32.21 Schistosomiasis of the vulva (medium power, H&E) showing six schistosome eggs with surrounding lymphoplasmocytic infiltration. (Courtesy of Professor S.B. Lucas, King's College, London, UK.)

human skin to produce the infection [4]. The organisms can pass rapidly through the epidermis, and enter the venous blood within 24 h of contact with human skin. The larvae are then carried through the heart and lungs, and mature into flukes in the intrahepatic portion of the portal system.

Finally, the mature flukes pass from the portal system into pelvic veins, where eggs are laid. *Schistosoma mansoni* and *S. japonicum* localize primarily in the veins around the rectum and colon, while *S. haematobium* invades vesical and, sometimes, rectal veins with the production of haematuria and other urinary symptoms. Ova work their way out of the veins into the tissues, where they cause the formation of granulomas in which there is a pseudotubercle arrangement of inflammatory cells rich in eosinophils and histiocytes, and occasional giant cells, surrounding the diagnostic ova [5]. Lesions occurring away from the characteristic sites of egg deposition are termed 'ectopic' (Fig. 32.21). Disease due to the commonest agent, *S. mansoni*, is endemic in Africa and South America (especially the Nile delta and North-East Brazil). *Schistosoma japonicum* occurs in the Far East, and *S. haematobium* extensively in Africa (especially in the Nile and Rift Valleys), Arabia, Malagasy and South-West India [6].

High prevalence rates in workers immigrant to temperate climates [1,7], outbreaks among foreign personnel employed in endemic areas and occasional case reports of the disease in individuals who have left those areas, reflect the frequency with which infections such as schistosomiasis are encountered outside their endemic area. Infections may also be seen in short-term visitors to an endemic zone, particularly if they have swum in an infected lake or river.

Clinical features. Skin involvement may occur either as a result of the initial penetration of the skin by water-borne, free-living cercariae (an intermediate stage in the life cycle), during an immune-complex-mediated phase of the infection, Katayama fever [8], or in the later stages of infection following ectopic localization of worms or ova [9].

1 *Schistosomal dermatitis.* Penetration by cercariae of parts of the epidermis in contact with water may pass unnoticed, or cause an itchy papular eruption indistinguishable from swimmer's itch (cercarial dermatitis due to non-human flukes). The symptoms of itching usually last only for a few hours after leaving the water, although mild erythema may persist for longer. In sensitized individuals, however, papules and itching persist for about a week [2].

2 *Urticarial reactions.* Four to eight weeks after penetration of the skin by cercariae, urticaria may occur. This is particularly severe in *S. japonicum* infection, together with fever, purpura, malaise, arthralgia, abdominal cramps, diarrhoea and enlargement of liver and spleen. In some areas, for example China and Japan, this feature is so prominent that the disease is called 'urticarial fever' or Katayama disease. Eosinophilia is also typical. The symptoms resolve in about 4–6 weeks.

3 *Paragenital granulomas and fistulous tracts.* In areas of high endemicity, cutaneous bilharziasis of the perineum and external genital regions is not uncommon [10,11]. This follows direct spread of adult flukes to adjacent vasculature. Granulomatous genital condylomas occur, and fistulous tracts with extensive firm masses, honeycombed by sinuses, are characteristically found on the perineum, groins or buttocks (Fig. 32.22).

4 *Ectopic cutaneous schistosomiasis* [12–14]. Ova may become deposited in the skin as well as in other ectopic sites, such as conjunctiva, lungs and CNS. They arise following embolism of ova from adults, which are localized in abnormal sites, such as the paravertebral plexus [2]. The trunk is almost invariably the site of ectopic cutaneous involvement. The primary lesion is a flesh-coloured, firm papule reaching a size of 2–3 mm, and ovoid in shape. These papules agglomerate to form slightly raised plaques with irregular contours. Later still, some plaques develop a mammillated surface, and deepen in colour but retain their irregular, ovoid contours. The skin over old nodules may be deeply pigmented and scaly, and may later ulcerate. The para-umbilical area is a common site [12] but other areas may be involved (Fig. 32.22) and, in some cases, the lesions have a segmental or zosteriform distribution [7,14]. With treatment, these lesions slowly disappear in about 5 months. A facial hypopigmented plaque is described.

The major complications of schistosomiasis are due to infections affecting the liver (fibrosis), intestinal involvement and bladder infection, which may lead to carcinoma of the bladder. Other sites of involvement include the kidneys, heart, CNS and retina [4].

Fig. 32.23 *Schistosoma haematobium* ovum in urine. (Courtesy of Mr A.H. Moody, Hospital for Tropical Diseases, London, UK.)

Diagnosis. The characteristic ova may be found in stools or urine (Fig. 32.23). On occasions, rectal biopsy is an alternative method of finding ova. The latter have a characteristic morphology. Serological methods are useful for screening. Immunofluorescence and ELISA are commonly used. Ectopic cutaneous schistosomiasis is diagnosed by biopsy. Histology shows epithelioid cell granulomas containing degenerate ova (Fig. 32.21).

Treatment. Praziquantel is given as a single dose of 20 mg/kg twice in 1 day, except in infections due to *S. japonicum*, where 20 mg/kg three times in 1 day is administered [15]. Cure rates are high with this regimen, and there are few side effects such as abdominal discomfort and headache. Other drugs that are available include metrifonate for *S. haematobium* and oxamniquinine for *S. mansoni*. In early infections, the results of therapy are excellent, although reinfection is a continuing risk. Cercarial dermatitis resolves spontaneously. However, many of the complications of the infection such as hepatic fibrosis, portal hypertension and ureteric stenosis are irreversible, due to scar formation.

Cercarial dermatitis

Cercarial dermatitis is the name given to a group of skin disorders having a common aetiology—penetration of the skin by free-living cercarial stages of non-human schistosomes [1]. There are a number of local names for these conditions, such as swimmer's itch, clam digger's itch, sedge pool itch, koganbyo and sawah itch. While the clinical features of the condition are similar whatever the aetiology, there are three main types of cercarial dermatitis.

1 *Fresh-water avian cercarial dermatitis* [2,3]. This follows penetration of the skin by cercariae of avian blood flukes. The intermediate hosts are fresh-water molluscs. The flukes belong to the genera *Trichobilharzia*, *Gigantobilharzia* and *Ornithobilharzia*. The condition has been described from many different parts of the world including North America, particularly the lakes region of the USA, Canada, Europe, Africa and the Far East [2,4]. In some countries, it affects patients with particular occupations such as rice farmers working in the paddyfields.

2 *Sea-water avian cercarial dermatitis* [5]. This follows invasion of the skin by blood flukes whose definitive hosts are sea birds. While it is recorded less frequently than infections caused by fresh-water species, it accounts for the condition, seen in the Atlantic seaboard of the USA, known as clam-digger's itch. The intermediate hosts are marine molluscs. The term 'sea bather's eruption' is used to describe a variety of different rashes that may develop after sea bathing. It is likely that it includes a number of different conditions from jellyfish dermatitis to eruptions due to toxic algae. A sea water form of cercarial dermatitis is therefore one cause of sea bather's eruption [1].

3 *Fresh-water mammalian cercarial dermatitis* [4]. This has been reported mainly from the Far East, and the definitive hosts for the schistosomes in this condition are mammals such as water buffaloes.

Attempts to find common features connecting the likely locations for cercarial infections have not been entirely successful. It is apparent, however, that areas endemic for cercarial dermatitis usually have abundant submerged vegetation harbouring the intermediate hosts. Hot spells of weather have also been associated with a higher risk of the development of symptoms [6].

Pathogenesis. The pathogenesis of cercarial dermatitis is not completely understood, although the kinetics of the clinical response suggest that sensitization is involved. The first phase of epidermal penetration is accompanied by dermal oedema, which is followed by a brisk neutrophil reaction.

Clinical features. Most forms of cercarial dermatitis have common features, although their intensity varies between different individuals [2]. The first sign of an infection is the development of a tingling sensation after contact with water. This lasts for about 1 h and there may be a fine macular erythema. After 10–15 h, there is usually a second phase with the appearance of multiple itchy papules with surrounding erythema. These may evolve into vesicles or oedematous lesions. The whole reaction takes about a week to resolve. The papules closely resemble small insect bites. There are no long-term sequelae.

Treatment. Treatment is entirely symptomatic. Although brisk rubbing with a dry towel seems sensible advice, there is no evidence that it prevents the second phase of responses [1]. Patients can be treated with antihistamines or topical applications such as crotamiton. Preventative measures are seldom called for as infections tend to be sporadic. Control of vegetation in endemic areas or of the snail population are possibilities, but seldom practised unless the more serious problem of schistosomiasis is also present.

Paragonimiasis

Infections caused by the lung fluke, *Paragonimus westermani*, are found in the Far East, West Pacific and in parts of India and Central Africa [1]. Similar species, *P. africanus* and *P. peruviana*, cause disease in the Cameroons and Central and South America, respectively [2]. In China, two rare species, *P. szechuanensis* and *P. hueitungensis*, have been recorded as causes of migratory subcutaneous nodules in humans. The adult worms are found in the respiratory tract, from which eggs are coughed up and swallowed, thus entering the faeces. Miracidia are released on contact with water and seek and penetrate snails. These in turn are the first intermediate hosts, and liberate cercaria, which then enter the muscles of fresh-water crustaceans such as crayfish. Human infection results from ingestion of inadequately cooked crabs and crayfish. Ingested metacercaria penetrate the intestinal wall and make their way through the diaphragm to the lungs. Adult worms encyst in the lungs (Fig. 32.24) and cause a chronic cough with fever and sweats. Brown-stained sputum is characteristic. Flukes may also reach ectopic sites such as the peritoneum, brain or skin.

Skin lesions of paragonimiasis are large, mobile subcutaneous lesions, which develop into cold abscesses [3]. They can occur at any site including the conjunctiva, and may enlarge rapidly to reach a diameter of 10 cm or more. The larger lesions are often painful but they may rupture spontaneously.

The diagnosis can be confirmed by demonstrating the characteristic ova in sputum or in aspirates from cutaneous lesions.

This infection responds well to praziquantel in a dose of 25 mg/kg three times in a single day [4].

Infection with cestodes

SYN. TAPEWORMS

Tapeworms are flat, ribbon-like worms composed of a variable number of segments called proglottids. The anterior segment or scolex comprises the head, which carries hooks or suckers for attachment to the intestinal mucosa, and a narrow neck from which the proglottids develop. As the hermaphroditic proglottids mature, they become motile sacs full of eggs, which separate from the worm and pass in the faeces or wriggle through the anus. Adult tapeworms inhabit the intestinal lumen of a wide range of natural hosts. Eggs are taken up by an intermediate host and undergo often complex larval development; in some species, there may be two or more intermediate hosts, each supporting a different phase of larval development. The human is a natural host to certain tapeworms, and may be an accidental host to others. Generally speaking, infection with adult worms causes little or no disease, but infection with the larval stages may be serious [1].

Tapeworms that infect humans may be divided into two orders, Cyclophyllidea and Pseudophyllidea, within each of which certain species may cause skin disease.

Cyclophyllidea

Echinococcus granulosus and E. multilocularis. Tapeworms, respectively, of dogs and foxes. Larval stages cause echinococcosis, or hydatid disease in humans.

Taenia saginata. The beef tapeworm of humans. Causes taeniasis. No skin parasitization.

Taenia solium. The pork tapeworm of humans. Causes (i) taeniasis; and (ii) cysticercosis.

Multiceps multiceps. A tapeworm of dogs and wolves. Its larval stage (coenurus) may parasitize human brain and other organs [2].

Multiceps serialis. A tapeworm of dogs, wolves and foxes, whose larval stages may parasitize human muscle or subcutaneous tissue [3].

Multiceps brauni. A tapeworm of dogs whose coenurus may parasitize subcutaneous tissue and the eye in humans [2,4,5].

Pseudophyllidea

Spirometra spp. Tapeworms of carnivores. The larval forms (spargana) cause sparganosis in humans.

Diphyllobothrium latum. The fish tapeworm of humans. Causes diphyllobothriasis.

Echinococcosis

SYN. HYDATID DISEASE

Two species in the genus *Echinococcus* parasitize humans with the formation of hydatids, namely *E. granulosus* and *E. multilocularis* [6]. Adult *E. granulosus* lives in the intestine of the dog and, if ova are accidentally swallowed by humans or other animals, hydatid cysts develop. Sheep are the commonest intermediate hosts. Similarly, adult *E. multilocularis* lives in the bowel of red fox and arctic fox. Mice, voles and lemmings are the intermediate hosts.

Pathogenesis. Humans become infected by ingesting eggs in food or water that has been contaminated by, usually, dog faeces. In endemic countries, especially those where sheep rearing is not accompanied by strict regulations, children's hands readily pick up the eggs from the coats of dogs. Eggs hatch in gastric acid and penetrate the wall of the duodenum, and are distributed via the bloodstream, mainly to liver and lungs, but bones and any other organ may also be infected. The larvae develop into fluid-filled cysts whose germinal layer produces numerous protoscolices, capable of becoming the scolices of adult worms after ingestion by the definitive host.

Cysts of *E. granulosus* tend to grow slowly and bud inwards, producing daughter cysts. Those of *E. multilocularis* may bud outwards, and thus spread through the tissues like a cancer.

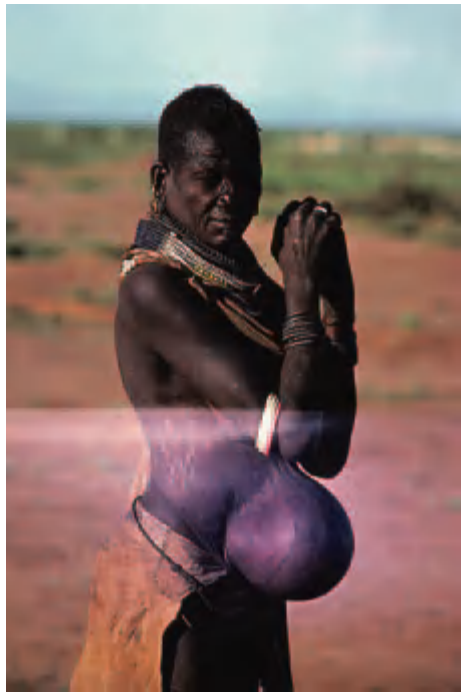

Fig. 32.25 Hydatid disease. Subcutaneous hydatid cyst presenting as a hernia, in a woman from Turkana, Kenya. (Courtesy of Dr C.N.L. MacPherson, Liverpool School of Tropical Medicine, Liverpool, UK.)

Clinical features. The commonest manifestation is an enlarged liver. Leakage of antigenic fluid from the cyst may cause wheeze, urticaria and eosinophilia. Rupture of the cyst may cause local signs and anaphylaxis. Hydatid cysts (Fig. 32.25) may be palpable in muscle or subcutaneous tissues as firm, painless swellings, often up to the size of an orange. They may be fluctuant. The overlying skin is normal.

Diagnosis. Clinical diagnosis is aided by X-ray or computed tomography (CT) examination of the lungs and sonographic ultrasound of the liver.

Excision of a subcutaneous cyst is conclusive. Great care must be taken not to spill any cyst fluid, which may give rise to further cysts. Complement fixation and ELISA are useful serological tests.

Treatment. This is essentially surgical. Formalin 2% or silver nitrate 0.5% should be used as a scolicidal adjunct [7]. Albendazole [8] is used in conservative management.

Cysticercosis

SYN. LARVAL TAENIASIS

Aetiology. *Taenia solium*, the pork tapeworm, is responsible for producing human intestinal infection with the tapeworm (taeniasis), and the lodging of the larval stage (*Cysticercus cellulosae*) in numerous organs, especially subcutaneous tissue, muscle and brain, with the production of the disease cysticercosis.

In taeniasis, the adult *T. solium* lives attached to the wall of the small intestine and may reach a length of 7 m. Inadequately heated or frozen pork is the sole source of human infection with the adult worm, but humans and other primates may harbour the cysticercus stage.

Human infections with *Cysticercus cellulosae* are due to: ingestion of eggs in contaminated food or drink; eggs from their own intestinal infection being introduced into the mouth on dirty hands; or internal autoinfection as a result of vomiting—eggs must be digested in gastric acid.

Taenia solium is an important human parasite with a wide, although shrinking, distribution. It is most frequent in Eastern Europe, China, Manchuria, Pakistan, India, Mexico and Central and South America. Its prevalence depends upon insanitary human faeces disposal and the eating of undercooked pork.

Pathology. The cysticerci are found most frequently in subcutaneous tissue and muscle, but may occur in any organ of the body, especially the brain. The growing cyst provokes a non-specific inflammatory reaction, which may be followed by fibrosis and eventual calcification.

Clinical features. Adult worms in the intestine cause little or no reaction, although the passing of writhing fragments is distressing. The cysticerci form nodules in subcutaneous tissue muscles (rarely with widespread muscular enlargement), eye [1], eyelid [2], lungs and brain and other organs, which may seriously interfere with function depending on their position. Major exacerbation of symptoms, such as epilepsy or intracranial obstruction, coincides with death of the larvae. The disease in the skin is known as cysticercosis cellulosae cutis, and the subcutaneous nodules formed are 1–2 cm in diameter (Fig. 32.26). They are rubbery and firm, rounded and painless and may remain unchanged for many years. Their numbers

Fig. 32.26 Cysticercosis in a man from North India. A subcutaneous cyst is seen over the sternum. (Courtesy of Dr A.P. Hall, Hospital for Tropical Diseases, London, UK.)

Fig. 32.27 Calcified cysticercal cysts in muscles of thighs and pelvis.

vary from one to hundreds, and when the diagnosis is entertained, search must be made for other lesions.

Diagnosis. *Taeniasis*: eggs in the stool cannot be differentiated morphologically from those of *T. saginata*, but examination of gravid proglottids allows exact identification. *Cysticercosis*: the histology of an excised cyst is diagnostic. Serology is helpful, but cross-reactions occur with hydatid disease.

X-ray examination frequently shows calcification in muscle (Fig. 32.27), although rarely in brain. CT shows typical appearances in brain and muscle.

Treatment. Subcutaneous cysticerci are important only in as much as they point to the possibility of more serious cerebral infection, which should be looked for. Individual subcutaneous cysts may be removed surgically if desired. Cerebral disease is treated with praziquantel 25 mg/kg daily for 10 days, under steroid cover. Adult tapeworms are treated with praziquantel in a dose of 10 mg/kg once. Obstructive lesions of the brain require surgical relief.

Prognosis is good in taeniasis, but in cysticercosis it is serious when vital organs are involved.

Sparganosis

Sparganosis is a tissue infection with plerocercoid larvae or spargana of a number of species of pseudophyllidean tapeworms of the genus *Spirometra*. Patric Manson described the first case, in Amoy China in 1882. The Greek word sparganon means swaddling clothes, and describes the slender ribbon-like character of the larval worm. The infection is common throughout Asia, especially the Far East, but also occurs in Australia, the Americas and southern Europe.

Aetiology. Adult spirometra parasitize the gut of canines and felines. Eggs passed into water develop into procercoid larvae in copepod hosts of the genera *Diaptomus* and *Cyclops*. These are eaten by frogs, lizards, snakes, birds and some mammals, including mice and monkeys, in which the plerocercoid larvae develop, in muscle sheaths. Humans are infected either by the application of raw flesh to the skin or eye, usually as a medicinal poultice, or through eating uncooked flesh or drinking water containing infected copepods.

Pathogenesis and clinical features [1]. Ingestion sparganosis occurs a variable time after eating infected flesh, or drinking infected copepods. The larvae penetrate the intestine and develop into spargana, particularly in subcutaneous tissues and muscle. The invaded areas become oedematous and form painful lumps, in the centres of which the white, ribbon-like spargana move. Their death results in very intense inflammation with destruction of tissue and massive eosinophilia [2]. Clinically, the lesions can assume a more nodular consistency with an insidious onset; they may last for several years and can also migrate. Localized elephantiasis also results due to lymphatic invasion.

Application sparganosis. The spargana migrate into the inflamed part causing an immediate severe local pruritus.

Fig. 32.28 (a) Fibrous, encapsulated, cold abscess from the groin, which contained (b) a 22-cm long sparganum. (Courtesy of Professor S.B. Lucas, King's College, London, UK.)

Subsequently, signs of sparganosis may be very hard to differentiate from those of the primary inflammation for which the flesh poultice was applied. Redness, pain and swelling increase in severity over a few days or very few weeks, and the worms become localized in small nodules surrounded by pus (Fig. 32.28). Ocular sparganosis frequently results in panophthalmitis and loss of the globe.

Sparganum proliferum. This is a rare form in which the sparganum branches and divides, producing thousands of mainly subcutaneous spargana, which form subcutaneous nodules and itchy papules [3]. There may be a severe systemic illness with fever and eosinophilia.

Diagnosis. This is made from the history and by recovery of spargana after incision.

Treatment. This is by surgical removal and drainage.

Infection with protozoa

Of the protozoa that give rise to skin disease or may cause changes in the skin indirectly, only *Leishmania* are natural parasites of the skin, in the sense that part of their life cycle must be spent in it. Even so, humans are often simply an accidental host in a zoonotic infection. *Entamoeba histolytica* may occasionally invade the skin, usually as an extension of an existing visceral lesion. Free-living amoebae, of the genus *Acanthamoeba*, may cause a primary lesion in skin, eye or ear, before invading the brain [1]. *Trypanosoma*, of the species that infect humans in Africa and America, may cause florid chancres soon after inoculation, but thereafter cause rashes indirectly. *Toxoplasma* causes an exanthem as part of the secondary stage of the infection, and *Trichomonas*, a mucosal parasite, causes inflammation of skin adjacent to the infected mucosa. Cutaneous manifestations of malaria, due to several species of *Plasmodium*, are simply a reflection of the severity of the systemic infection, or of drug toxicity.

Malaria

Malaria is caused by parasites of the genus *Plasmodium*, and is transmitted to humans by the bites of numerous species of mosquito belonging to the genus *Anopheles*. It causes a febrile systemic illness, which may be fatal in expatriates and in children in endemic areas in the tropics, and is a major cause of chronic ill health [2].

The mosquito bite can give rise to considerable skin reaction, and the disease itself to numerous cutaneous manifestations. In the early cold stage of benign tertian malaria (*P. vivax*) there is vasoconstriction and gooseflesh; in the hot stage, flushing of the face and to a less extent other parts of the skin, and in the sweating stage very profuse sweating. These manifestations are common to all diseases characterized by rigors caused by release of endotoxin or 'endotoxin-like' substances. Malaria commonly causes jaundice, and the skin in Europeans and Asians may have a curious grey or greenish hue. In severe malaria, there may be bleeding from the gums or gastrointestinal tract, and conjunctival petechiae may be seen, but cutaneous petechiae are rare. Herpes simplex and, occasionally, herpes zoster may develop.

Several of the drugs used in treatment of chemoprophylaxis cause skin problems. Chloroquine causes pruritus, especially in black people's skins, often severe enough to arrest treatment [3]. It responds to antihistamines, although the cause is unknown and there is never a rash. Various skin eruptions may occur, and psoriasis may be aggravated. Fansidar contains pyrimethamine and sul-

fadoxine. Epidermal necrolysis and Stevens–Johnson syndrome occur, sometimes fatally [4]. Quinine may cause rashes, notably toxic erythema and urticaria.

Amoebiasis

Amoebiasis due to *Entamoeba histolytica* is arguably the third most important human parasitic infection, after malaria and schistosomiasis, being especially prevalent in South-East Asia and Central America, but the organism is found in all warm and temperate parts of the world where hygiene is inadequate [1,2].

Aetiology. *Entamoeba histolytica* inhabits the lumen of the human caecum, colon and rectum. Free-living trophozoites 10–60 μm in diameter, encyst and divide. Cysts passed in the faeces may survive up to 30 days, depending upon conditions of humidity and temperature, and survive chlorination. They are transmitted in contaminated water or food, especially salads, or by hands or flies, or by male homosexual intercourse. Ingested cysts that survive gastric acid complete the cycle. Isoenzyme electrophoretic analysis of cultured isolates suggest that pathogenic and non-pathogenic strains (zymodemes) of *E. histolytica* exist, but these cannot be distinguished morphologically [3].

Pathogenesis. Trophozoites of a pathogenic zymodeme may, under conditions that have not been determined, invade the mucosa of the large bowel, causing amoebic dysentery [4]. Amoebae that escape the bowel into the bloodstream may set up metastatic lesions, which develop into abscesses, most commonly in the liver. Cutaneous amoebiasis (Fig. 32.29) [5] develops when invasive amoebiasis escapes from the bowel to contiguous skin, usually around the anus or a colostomy, or after appendicectomy, or when amoebae are implanted in another mucosa, most commonly the vagina, cervix uteri or glans penis, and rarely in the mouth. Rupture or surgical intervention of an amoebic abscess is a less common source of cutaneous infection. Amoebae lyse the skin and subcutaneous tissues and mucosae involved, producing necrosis and gangrenous sloughing. *Entamoeba histolytica* is one of the most powerful organisms in terms of its lytic capacity, and this is mediated through amoebapores following the binding to the host's tissue in a lectin-like manner [6].

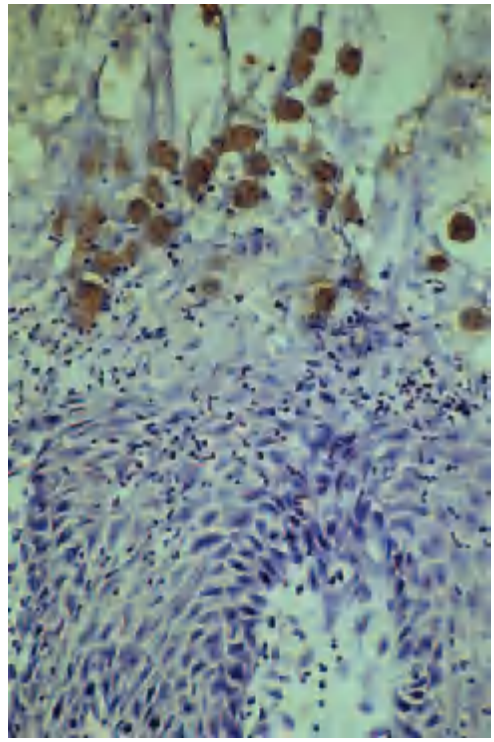

Fig. 32.29 Cutaneous amoebiasis. High-power view of skin biopsy, showing *Entamoeba histolytica* trophozoites on the epidermis, causing necrosis. The amoeba are stained with immunoperoxidase and are brown. (Courtesy of Professor S.B. Lucas, King's College, London, UK.)

Fig. 32.30 Cutaneous amoebiasis. Rapidly spreading ulcer around a colostomy in a patient with intestinal amoebiasis. (Courtesy of Meddia, Amsterdam.)

Clinical features [5,7]. Commonly, one or more lesions appear at the anus or on the buttocks and spread as sloughing, coalescing ulcers [8] (Fig. 32.30). The course of the disease varies from less than 2 weeks to as long as 2 years, the more rapid and destructive lesions tending to occur in the young. The skin lesion itself is not diagnostic and is either a deeply invading ulcer or an ulcerated granuloma (amoeboma). It is usually seen as a serpiginous

ulcer with distinct, raised, thickened, often undermined, edges and with an erythematous rim about 2 cm wide, haemopurulent exudate and necrotic slough. It is intensely painful. Regional adenitis is usual.

All ages are affected. The vulva is particularly likely to be invaded in the infant with amoebic dysentery. Penile amoebiasis may occur in homosexual men [9], but invasive amoebiasis is not especially common in homosexual men or in patients with human immunodeficiency virus (HIV) infection [10].

Diagnosis. Cutaneous amoebiasis can spread very rapidly and terminate fatally, so early diagnosis is important. A solitary lesion may be mistaken for an epithelioma or for tuberculosis verrucosa cutis. On the penis when regional lymphadenopathy is present, syphilis or lymphogranuloma venereum may be confused. Examination of fresh material from the cutaneous lesion regularly discloses amoebae. Material should be taken from the edge of the ulcer avoiding necrotic tissue and examined at once under the microscope. The demonstration of motile trophozoites containing red blood cells is diagnostic. Histology of the ulcer edge will reveal amoebae, but the identification of the parasite in sections stained by haematoxylin and eosin may be difficult (Fig. 32.29). Amoebic trophozoites in faeces, biopsy, necropsy or abscess aspirate are revealed with much greater accuracy by immunofluorescence or immunoperoxidase staining. Serological tests are helpful, and the indirect immunofluorescent antibody test is positive in the serum of near 100% of patients with amoebic liver abscess, and in about 70% of patients with intestinal amoebiasis. Serial stool examinations should be performed.

The prognosis is serious in the neglected case, particularly in infants, but with early diagnosis and treatment it is good. It is important to appreciate that a history of dysentery is not essential to the diagnosis of amoebiasis of the skin.

Treatment. Treatment of invasive amoebiasis is with metronidazole [11]. The recommended adult dose is 800 mg orally three times a day for 10 days. This may be combined with diloxanide furoate 500 mg three times a day, or be followed by oral diiodohydroxyquin 650 mg three times a day for 21 days, to eliminate intestinal cysts.

Local cleaning of cutaneous ulcers with antiseptic solutions may be necessary.

Where a hepatic abscess needs to be drained, this is most safely done by needle aspiration.

Effective treatment is usually followed by complete healing of the skin without the need for plastic surgery.

Trichomonads

Three trichomonads occur in humans. *Trichomonas vaginalis* invades the vagina, urethra and prostate and is pathogenic, causing trichomoniasis. *Trichomonas hominis* is found in the intestine and *T. tenax* in the mouth and occasionally the lung: neither is considered pathogenic [1].

Trichomoniasis

Trichomonas vaginalis is found worldwide affecting all races, but is eight times commoner in black people than in white people [2]. It invades the vagina and urethra in women, causing vaginitis and vulvitis with a characteristic pale-yellow, frothy discharge [3,4]. Vulval soreness and pruritus with inflammation of the surrounding skin are common, whereas infection of Skene's or Bartholin's glands with abscess formation rarely occurs.

Trichomoniasis characteristically causes a copious discharge with vaginal soreness or irritation and urinary frequency. The odour of the discharge is often unpleasant, although this feature is not specific. In many cases, bubbles can be seen in the discharge and the vaginal mucosal and cervical surfaces are infected and sometimes covered with punctate haemorrhages. The pH of the discharge is usually higher than the normal 4.5.

Although commonest in the second and third decades, the infection may occur at any age and has been reported in nearly 17% of babies aged from 1 day to 11 months. Many adults are asymptomatic carriers, particularly males. It can be isolated from up to 15% of men with non-specific urethritis. Discharge in males is scant.

The condition is frequently associated with gonorrhoea [5]. Transmission is usually by sexual intercourse, with an incubation period of 4–21 days. Occasional non-sexual transmission has been reported. In males, the condition occurs with non-specific urethritis in up to 5% of cases,

and balanitis may also occur [6]. The organism may be harboured in the prostate without symptoms.

Diagnosis. In women, diagnosis is usually easily confirmed by examination of a wet film by phase contrast or dark-field microscopy [7], but culture, usually in Feinberg–Whittington medium, gives the most reliable results. On the other hand, in males, examination of centrifuged urine or prostatic fluid following massage is only occasionally positive, and in many men it is not possible to confirm a clinical diagnosis. Examination of a stained dry film is neither easy nor reliable.

Sexual partners should always be examined, and in both sexes specimens taken to exclude other causes of sexually transmitted disease.

Treatment. Standard treatment is with metronidazole 400 mg twice a day for 5 days [8,9]. Alcohol should be avoided during treatment. Single-dose treatments have been advocated with this drug. Gastrointestinal disturbances are common. Benzimidazole drugs should be avoided in the first 3 months of pregnancy.

Clotrimazole has been shown to have some activity [6] and one 100-mg pessary daily for 6 days may be tried. Older remedies such as acetarsol pessaries or hydrargarphen pessaries, two a night for 3 weeks, are still valuable. Simple douching may relieve vaginal symptoms (20 mL of vinegar to 1 L of warm water).

Trypanosomiasis

Protozoa of the genus *Trypanosoma* cause the widespread tropical disease trypanosomiasis. There are African and American forms.

African trypanosomiasis

SYN. SLEEPING SICKNESS

Aetiology and epidemiology. The disease is endemic in a belt running across Africa, limited approximately by lat. 15°N and lat. 15°S. *Trypanosoma gambiense* is the cause in West Africa, and the more virulent *T. rhodesiense* in East Africa to the east and south of Lake Victoria [1]. Occasional cases are imported into countries where the parasite is not endemic [2].

The human is the main natural host of *T. gambiense*, and the disease is transmitted by blood-sucking tsetse flies of the genus *Glossina*, the intermediate hosts *G. palpalis* and other related species are the most important. On the other hand, *T. rhodesiense* (which morphologically resembles *T. gambiense* but is biologically very different) is transmitted by *G. morsitans* and related species. The natural hosts are wild animals, notably antelope, and the human is a 'dead-end' host.

Age, sex, race and occupation have no influence on susceptibility to trypanosomiasis, except in so far as they affect exposure to tsetse flies. *Trypanosoma gambiense* sleeping sickness tends to be an endemic disease, affecting rural communities, with localized outbreaks, while *T. rhodesiense* sleeping sickness causes sporadic infections in herdsmen, hunters and tourists. In some parts of the 'tsetse fly belt' the incidence is high, and, as the same flies transmit bovine trypanosomiasis to livestock, farmers cannot keep cattle and poverty and malnutrition are rife.

Intrauterine transmission has been recorded infrequently. Preventive measures involved removal of entire villages to tsetse-free land. Mass survey and treatment were very successful in reducing the infection rate in Nigeria from 10.9% (1931–40) to 0.14% (1958) [1].

Pathogenesis. Trypanosomes develop, at the site of inoculation by the tsetse fly, from metacyclic forms to mature forms in about 10 days, and then enter the bloodstream. Within this time, the patient starts to develop an antibody response to the infection. The recognition of the trypanosomes in the skin causes the chancre. The systemic clinical illness coincides with invasion of the bloodstream. The early pathology is, thereafter, mainly in the lymph nodes, at first those draining the sore and then generally, with an increase in lymphocytes and plasma cells, but the appearances are not specific, and trypanosomes are not easily seen histologically. In *T. rhodesiense* infections, the lymphoplasmocytic infiltrate is also found in the myocardium, and this myocarditis may be fatal. In late trypanosomiasis, the meninges become invaded with the same infiltrate, and then the brain, especially around the basal ganglia. Gliosis and cerebral atrophy follow. The cause of these pathological changes is poorly understood, although it is known that there is a polyclonal B-lymphocyte activation with the production of very high levels of IgM, and circulating immune complexes [3].

Clinical features [4,5]. Within a few days of the infected bite, a trypanosomal chancre starts to develop (Fig. 32.31).

Fig. 32.31 Trypanosomal chancre due to *Trypanosoma rhodesiense* infection, appearing 6 days after the bite of the tsetse fly. The lesion is swollen, inflamed and haemorrhagic.

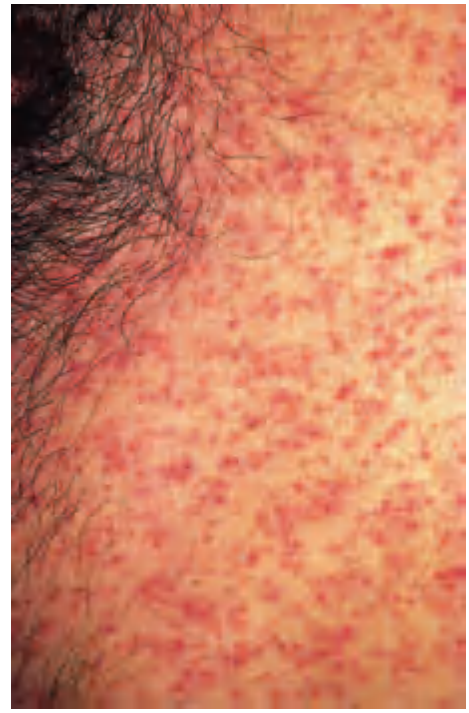

Fig. 32.32 Trypanosomal rash (same patient as Fig. 32.31). The maculopapular rash is becoming haemorrhagic.

It is a round, raised, red, hot, tender lesion, 2–5 cm or more in diameter, spreading to cover, for example, the entire surface of the forearm over the ensuing few days. There may be a tiny central punctum, and a blister with fluid rich in trypanosomes may appear on its surface. The chancre is present in 70–90% of people infected with *T. rhodesiense*, less regularly with *T. gambiense*, but fades within a few weeks. It is usually accompanied by local lymphadenopathy. The chancre heralds the onset of fever and systemic illness and generalized lymphadenopathy, which characterize the second phase of the illness. This is rapid and severe in *T. rhodesiense* infections, but gradual, mild, intermittent or even absent clinically in *T. gambiense* infections [6].

During this phase of the illness, there may be oedema of hands, feet and face, and transient erythematous or urticarial rashes, which are often circinate or annular, poorly defined, pale centrally, and commonest on the trunk. The rash may be haemorrhagic (Fig. 32.32). They are difficult to see in African skins. When the CNS is invaded, the patient experiences behavioural changes, alterations in sleep patterns, extrapyramidal signs and finally coma. These occur months after the onset of *T. rhodesiense* infections, if the patient has not died in the secondary phase, and 1–3 years after the onset of *T. gambiense* infections. At this stage, pruritus and excoriations from scratching are common, and the patient is emaciated.

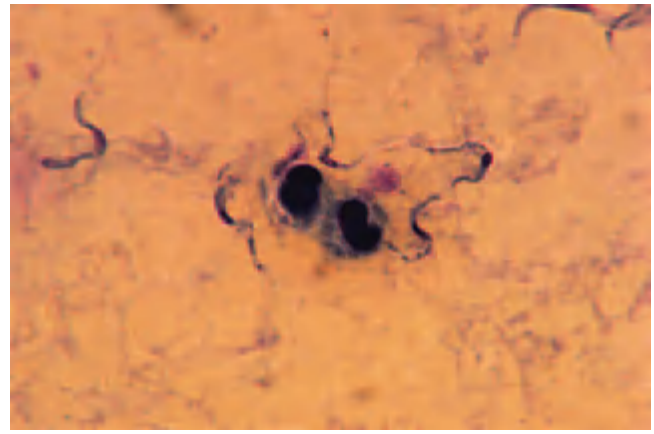

Fig. 32.33 Trypanosomes in a thick blood film, stained with Giemsa. (Courtesy of Dr P.L. Chiodini, Hospital for Tropical Diseases, London, UK.)

Death is often due to intercurrent infection due to the immune suppression.

Diagnosis. Within a few days of the onset of fever, trypanosomes may be demonstrated in simple thin blood films in *T. rhodesiense* infections. However, in *T. gambiense* infections, thick films (Fig. 32.33) or concentration techniques [7] may be necessary. A more profitable approach is puncture and aspiration of the enlarged posterior cervical lymph nodes. Trypanosomes are seen undulating

between the lymphocytes in the wet preparation, or well defined in a Giemsa-stained preparation. Cerebral involvement is characterized by raised protein in the CSF, containing IgM, and a raised cell count comprising lymphocytes and morula cells (plasma cells distorted by vesicles of IgM). Serological tests, including ELISA and immunofluorescence, may be helpful. Serum IgM levels are often grossly elevated, and there may be an anaemia. On diagnosis, a lumbar puncture is mandatory to establish whether the CNS has been invaded.

Treatment. A single course of suramin, preferably, or pentamidine isethionate is usually sufficient, if given before CNS invasion. Dosages are: suramin sodium 200 mg (test dose) i.v., followed by 1 g/week for five doses; pentamidine isethionate 4 mg/kg i.m. on alternate days for five doses. Both drugs are seriously toxic [8].

After CNS invasion melarsoprol is used [7,8], often with corticosteroids [9].

American trypanosomiasis

SYN. CHAGAS' DISEASE; SOUTH-AMERICAN TRYPANOSOMIASIS; TRYPANOSOMIASIS CRUZI; CHAGAS–MAZZA DISEASE; SCHIZOTRYPANOSOMIASIS; OPILACAO

Definition. Chagas' disease is a parasitic disease of the tissues and blood caused by the flagellate *Trypanosoma* (*Schyzotrypanum*) *cruzi* and transmitted to humans and other mammals by blood-sucking bugs of the family *Triatomidae*. It occurs predominantly in rural areas in the tropical zones of the American continent.

Incidence. The insect vectors are widely distributed in the American continent from lat. 42°N in the USA to lat. 43°S in Argentina [1]. *Trypanosoma cruzi* attacks humans and other mammals, and the disease it produces can be regarded as a zoonosis. The area of distribution of the disease is more limited than the range of the reduviid bugs that transmit it, since those found at the two extremes of the continent are wild species, while the domestic types, concerned in the transmission of the infection to humans, occur between lat. 25°N in Mexico and lat. 28°S in Argentina [1].

Age does not influence the incidence of infection, although the acute forms are more frequently observed in children. The sexes are equally affected and there is no evidence of a racial factor. Occupation plays an important role because it is a rural disease and the vectors are found in rural dwellings, especially in huts or shacks with palm leaf roofs [2].

Aetiology. The disease is caused by *T. cruzi*, which bears some resemblance morphologically to the trypanosomes causing sleeping sickness in Africa. In the blood, the organism is 15–20 μm in length and of variable width, and has the typical undulant membrane and flagellum in an anterior position. The nucleus is central, the kinetoplast rod-shaped or oval and situated posteriorly. After transformation into the amastigote stage, *T. cruzi* multiplies only in tissue cells, being an obligatory tissue-cell parasite.

Vector. The disease is transmitted by blood-sucking insects of large size: Hemipteran, reduviid bugs (assassin or kissing bugs), belonging to the family *Triatomidae*, particularly *Panstrongylus megistus* (Brazil), *Triatoma infestans* (Southern Brazil, Uruguay, Paraguay, Bolivia, Southern Peru, Chile and Argentina) [1] and *Rhodnius proxlixus* (Venezuela, Colombia, Guianas and Central America). The larva, nymph and the adult insect can transmit the infection. They are active during the night. After ingestion, the trypanosomes multiply in the vector's intestine by longitudinal division, and within 3 or 4 weeks transform into the metacyclic form, which is infective to humans. Once the insect has been infected, it remains so for the rest of its life. The disease has many non-human reservoirs, including cats, dogs, monkeys, pigs, squirrels, rats, skunks, racoons, opossums, porcupines and armadillos. Transmission occurs by contamination through small cuts and abrasions on the skin, or through the normal mucous membranes of the eyes and lips when the vector, at the moment of biting, deposits its stools containing the infective metacyclic trypanosome [2]. The bite wound itself may provide the portal of entry [3].

Pathology. The tissues react almost immediately to the penetration of the metacyclic trypanosomes, producing oedema and cellular infiltration, which cause subcutaneous swelling. The infection spreads rapidly to the lymphatics, and the regional glands become oedematous and

Fig. 32.34 Chagas' disease. Unilateral oedema of the eyelids and orbit (Chagas–Mazza–Romaña's sign). (Courtesy of Professor M. Miles, London School of Hygiene and Tropical Medicine, London, UK.)

infiltrated with plasma cells and lymphocytes. The spleen and liver enlarge. The trypanosomes penetrate immediately into the cells of the reticuloendothelial system at the site of the inoculation and transform into the leishmania form, later returning to the interstitial spaces and blood in the form of trypanosomes, penetrating again into the cells to repeat the cycle in different organs and systems. The most striking invasion is that of the spleen macrophages, the Kupffer cells of the liver and the cells of the striated muscles [4]. The inflammation and scarring that follows invasion of the myocardium may have serious consequences.

Clinical features. The great majority of infections do not present any clinical manifestations in the early phase. Signs of early disease appear on the fifth day after inoculation: these are both local and general. Eighty per cent of the acute cases show the portal of entry in the conjunctiva, as evidenced by the 'eye sign' or 'Romaña's sign', also known as the 'ophthalmoganglionar complex' (oculoglandular complex), characterized by unilateral oedema of the eyelids and inflammation of the lacrimal gland (Fig. 32.34). Cutaneous inoculation results in the 'cutaneous adenopathy complex' or 'inoculation chagoma' and is less common. The general manifestations consist of moderate to high fever accompanied by headache, myalgia, weakness, particularly pronounced in children, in whom the disease may end fatally from acute meningoencephalitis or myocarditis. Hepatosplenomegaly, oedema and various forms of exanthem ('schizotripanides') are frequent [1]. Forms called oedematous, neuropsychiatric, meningoencephalitic, respiratory, gastrointestinal and pseudotyphoid have been described [2]. The subacute and chronic forms almost always present with heart manifestations—chagasic myocarditis—and digestive manifestations, such as mega-colon and mega-oesophagus. Megasyndromes are common in Brazil but absent in Venezuela. Congenital forms transmitted transplacentally or by the mother's milk are rare.

Prognosis. This is serious in acute cases in children, especially in the meningoencephalitic form, and when the myocardium is extensively involved. In the subacute and chronic forms it depends entirely on the degree of involvement of the heart. Sudden death by thromboembolic accidents and by blockage of the conduction system of the heart may occur. Chronic heart failure is frequently observed in the advanced cases.

Diagnosis. In the acute phase, the diagnosis is made by finding the parasite in the blood by direct examination, or by means of stained thick and thin smears, lymph-gland biopsy, blood culture, animal inoculation and by the so-called xenodiagnosis of Brumpt: the reduviid bugs grown in the laboratory and free from infection are allowed to bite the forearm of the subject under suspicion and feed on the blood, after which the faeces of these insects are examined for metacyclic forms between 30 and 60 days later [2]. In the subacute and chronic forms, laboratory tests are of great help, particularly those based on the complement-fixation test using antigen from culture forms of *T. cruzi* (Machado–Guerreiro's test).

Treatment. The acute stage (including congenital Chagas' disease and transfusion acute disease) should be treated with a trypanocidal drug, either nifurtimox (Lampit) given by mouth (8 mg/kg) for 60 or 90 days, or benznidazole (Rochagan), oral dose (6 mg/kg) for 30 or 60 days. A rare side effect is an exfoliative dermatitis. Both drugs produce anorexia, weight loss, headache and dizziness, gastric irritation and, occasionally, peripheral neuritis (12–30%). Allopurinol has recently been used [5].

Control. Improvement of environmental conditions should be attempted, especially those of the dwellings, eliminating palm leaf roofs. The insects can be destroyed with dieldrin and gamma benzene hexachloride. Chemotherapy of the infective cases may help to break the natural cycle of the disease.
