SEVENTH EDITION

Rook's TEXTBOOK OF DERMATOLOGY

VOLUMES 1 - 4

EDITED BY

TONY BURNS • STEPHEN BREATHNACH
NEIL COX • CHRISTOPHER GRIFFITHS

Blackwell Publishing

How to go to your page

In this book, each chapter has its own pagination scheme, consisting of a chapter number and a page number, separated by a period.

For example, to go to page 5 of Chapter 1, type 1.5 in the "page #" box at the top of the screen and click "Go." To go to page 5 of Chapter 2, type 2.5… and so forth.

Please note that the Index is paginated with the prefix I and a Roman numeral page number, separated by a colon. For example, to go to page v of the Index, type I.v in the "page #" box and click "Go."

Rook's

Textbook of Dermatology

The Editors. From l to r, Tony Burns, Stephen Breathnach, Christopher Griffiths and Neil Cox standing in front of a portrait of Arthur Rook, the father of the *Textbook of Dermatology*.

Rook's Textbook of Dermatology

VOLUME 3

VOLUME 4

Contributors

ADRIAANS, Beverley M.
MD, FRCP
Consultant Dermatologist, Department of Dermatology, Gloucestershire Royal Hospital, Great Western Road, Gloucester GL1 3NN
Co-author of
Chapter 27: Bacterial Infections

ANSTEY, Alexander V.
MB, BS, FRCP
Consultant Dermatologist, Royal Gwent Hospital, Cardiff Road, Newport NP20 2UB, and Honorary Senior Lecturer, Academic Department of Dermatology, University of Wales College of Medicine, Heath Park, Cardiff CF14 4XN
Co-author of
Chapter 39: Disorders of Skin Colour

ARCHER, Clive B.
BSc, MB, BS, MD, PhD(Lond), FRCP(Lond & Edin)
Consultant Dermatologist and Clinical Senior Lecturer, Bristol Dermatology Centre, Bristol Royal Infirmary, Marlborough Street, Bristol BS2 8HW
Author of
Chapter 4: Functions of the Skin
Co-author of
Chapter 60: The Skin and the Nervous System

ATHERTON, David J.
MA, MB, BChir, FRCP
Consultant in Paediatric Dermatology, Department of Dermatology, Great Ormond Street Hospital for Children, Great Ormond Street, London WC1N 3JH
Co-author of
Chapter 14: The Neonate
Chapter 15: Naevi and other Developmental Defects

BARAN, Robert
MD
Head of Nail Disease Centre, Le Grand Palais, 42 rue des Serbes, 06400 Cannes, France
Co-author of
Chapter 62: Disorders of Nails

BARHAM, Kelly L.
MD
Resident Physician, Department of Dermatology, Wake Forest University School of Medicine, Medical Center Boulevard, Winston-Salem, NC 27157-1071, USA
Co-author of
Chapter 49: Vasculitis and Neutrophilic Vascular Reactions

BARKER, Jonathan N.W.N.
BSc, MD, FRCP, FRCPath
Professor of Clinical Dermatology, St John's Institute of Dermatology, St Thomas' Hospital, Lambeth Palace Road, London SE1 7EH
Co-author of
Chapter 35: Psoriasis

BARLOW, Richard J.
MD, FRCP
Consultant Dermatologist and Senior Lecturer, Dermatological Surgery and Laser Unit, St John's Institute of Dermatology, St Thomas' Hospital, Lambeth Palace Road, London SE1 7EH
Co-author of
Chapter 77: Physical and Laser Therapies

BECK, Michael H.
MB, ChB, FRCP
Consultant Dermatologist and Director of Contact Dermatitis Investigation Unit, Dermatology Centre, University of Manchester, Hope Hospital, Stott Lane, Salford, Manchester M6 8HD
Co-author of
Chapter 19: Contact Dermatitis: Irritant
Chapter 20: Contact Dermatitis: Allergic

BERTH-JONES, John
FRCP
Consultant Dermatologist, University Hospitals Coventry and Warwickshire NHS Trust, Department of Dermatology, Walsgrave Hospital, Clifford Bridge Road, Coventry CV2 2DX, and Coventry and George Eliot Hospital NHS Trust, Nuneaton
Author of
Chapter 44: Rosacea, Perioral Dermatitis and Similar Dermatoses, Flushing and Flushing Syndromes
Chapter 75: Topical Therapy
Co-author of
Chapter 17: Eczema, Lichenification, Prurigo and Erythroderma

BLACK, Martin M.
MD, FRCP, FRCPath
Consultant Dermatologist, St John's Institute of Dermatology, St Thomas' Hospital, Lambeth Palace Road, London SE1 7EH
Co-author of
Chapter 42: Lichen Planus and Lichenoid Disorders
Chapter 55: Subcutaneous Fat

BLEEHEN, Stanley S.
MA, MB, BChir, FRCP
Emeritus Professor of Dermatology, University of Sheffield, Sheffield, and Honorary Consultant Dermatologist, St John's

Institute of Dermatology, St Thomas' Hospital, Lambeth Palace Road, London SE1 7EH
Co-author of
Chapter 39: Disorders of Skin Colour

BREATHNACH, Stephen M.

MA, MB, BChir, MD, PhD, FRCP
Consultant Dermatologist and Senior Lecturer, St John's Institute of Dermatology, St Thomas' Hospital, Lambeth Palace Road, London SE1 7EH, and Consultant Dermatologist, Epsom and St Helier University NHS Trust, Dorking Road, Epsom, Surrey KT18 7EG
Editor
Author of
Chapter 73: Drug Reactions
Chapter 74: Erythema Multiforme, Stevens–Johnson Syndrome and Toxic Epidermal Necrolysis
Co-author of
Chapter 11: Wound Healing
Chapter 42: Lichen Planus and Lichenoid Disorders
Chapter 57: Metabolic and Nutritional Disorders
Chapter 72: Systemic Therapy

BUNKER, Christopher B.

MA, MD, FRCP
Consultant Dermatologist, Chelsea & Westminster Hospital, Fulham Road, London SW10 9NH, and the Royal Marsden Hospital, Fulham Road, London SW3 6JJ, London, and Honorary Senior Lecturer, Imperial College School of Medicine, London
Co-author of
Chapter 26: AIDS and the Skin
Chapter 68: The Genital, Perianal and Umbilical Regions

BURD, D. Andrew R.

MD, FRCSEd, FHKAM
Chief of Division of Plastic and Reconstructive Surgery, Department of Surgery, Chinese University of Hong Kong, Prince of Wales Hospital, Shatin, Hong Kong
Co-author of
Chapter 22: Mechanical and Thermal Injury

BURGE, Susan M.

BSc, DM, FRCP
Consultant Dermatologist, Department of Dermatology, Churchill Hospital, Old Road, Headington, Oxford OX3 7LJ
Co-author of
Chapter 40: Genetic Blistering Diseases
Chapter 41: Immunobullous Diseases

BURNAND, Kevin G.

MB, BS, FRCS, MS
Professor of Vascular Surgery, Head of Academic Department of Surgery, UMDS, St Thomas' Campus, Lambeth Palace Road, London SE1 7EH
Co-author of
Chapter 50: Diseases of the Veins and Arteries: Leg Ulcers

BURNS, David Anthony

MB, BS, FRCP, FRCP(Edin)
Emeritus Consultant Dermatologist, Leicester Royal Infirmary, Leicester LE1 5WW
Editor
Author of
Chapter 2: Comparative Dermatology
Chapter 33: Diseases Caused by Arthropods and Other Noxious Animals
Chapter 67: The Breast
Co-author of
Chapter 1: Introduction and Historical Bibliography
Chapter 57: Metabolic and Nutritional Disorders

BURROWS, Nigel P.

MD, FRCP
Consultant Dermatologist and Associate Lecturer, Department of Dermatology, Addenbrooke's Hospital, Hills Road, Cambridge CB2 2QQ
Co-author of
Chapter 46: Disorders of Connective Tissue

CALONJE, Eduardo

MD, DipRCPath
Director of Diagnostic Dermatopathology, and Consultant and Honorary Senior Lecturer in Dermatology, St John's Institute of Dermatology, St Thomas' Hospital, Lambeth Palace Road, London SE1 7EH
Co-author of
Chapter 7: Histopathology of the Skin: General Principles
Chapter 37: Tumours of the Skin Appendages
Chapter 53: Soft-Tissue Tumours and Tumour-like Conditions

CAMP, Richard D.R.

PhD, FRCP
Professor of Dermatology, Department of Infection, Immunity and Inflammation, Maurice Shock Medical Sciences Building, University of Leicester, University Road, Leicester LE1 9HN
Co-author of
Chapter 35: Psoriasis

CANT, Andrew J.

BSc, MRCP, MD, FRCP, FRCPCH
Consultant in Paediatric Immunology and Infectious Diseases, and Honorary Clinical Senior Lecturer in Child Health, Newcastle General Hospital, Westgate Road, Newcastle upon Tyne NE4 6BE
Co-author of
Chapter 14: The Neonate

CERIO, Rino

BSc, MB, BS, FRCP, FRCP(Edin), FRCPath
Consultant Dermatologist and Reader in Dermatopathology, Department of Dermatology and Institute of Pathology (QMUL), Bart's and Royal London Medical Schools, Whitechapel Road, London E1 1BB
Co-author of
Chapter 7: Histopathology of the Skin: General Principles

CHALMERS, Robert J.G.

MB, FRCP
Consultant Dermatologist, University of Manchester, Dermatology Centre, Hope Hospital, Stott Lane, Salford, Manchester, M6 8HD
Co-author
Chapter 72: Systemic Therapy

CHU, Anthony C.

FRCP
Senior Lecturer/Honorary Consultant Dermatologist, Imperial College, Hammersmith Campus, Hammersmith Hospital, Du Cane Road, London W12 0HS
Author of
Chapter 52: Histiocytoses

CHURCH, Martin K.
MPharm, PhD, DSc
Professor of Immunopharmacology, Allergy and Inflammation Research, Southampton General Hospital, Tremona Road, Southampton SO16 6YD
Co-author
Chapter 9: Inflammation

COTTERILL, John A.
BSc, MD, FRCP
Formerly Consultant Dermatologist, Department of Dermatology, Leeds General Infirmary, Leeds
Co-author
Chapter 61: Psychocutaneous Disorders
Chapter 71: General Aspects of Treatment

COULSON, Ian H.
BSc, MB, BS, FRCP
Consultant Dermatologist, Dermatology Unit, Burnley General Hospital, Casterton Avenue, Burnley, Lancashire BB10 2PQ
Author of
Chapter 45: Disorders of Sweat Glands
Co-author
Chapter 5: Diagnosis of Skin Disease

COX, Neil H.
BSc, MB, ChB, FRCP(Lond & Edin)
Consultant Dermatologist, Department of Dermatology, Cumberland Infirmary, Carlisle CA2 7HY
Editor
Co-author of
Chapter 1: Introduction and Historical Bibliography
Chapter 5: Diagnosis of Skin Disease
Chapter 48: Purpura and Microvascular Occlusion
Chapter 49: Vasculitis and Neutrophilic Vascular Reactions
Chapter 59: Systemic Disease and the Skin

CUNLIFFE, William J.
MD, FRCP
Professor of Dermatology, Department of Dermatology, Leeds General Infirmary, Great George Street, Leeds LS1 3EX
Co-author
Chapter 43: Disorders of the Sebaceous Glands
Chapter 55: Subcutaneous Fat

DART, John K.G.
MA, DM, FRCS, FRCOphth
Consultant Ophthalmologist, Corneal External Disease and Cataract Services, Moorfields Eye Hospital, City Road, London EC1V 2PD
Co-author
Chapter 64: The Skin and the Eyes

DAWBER, Rodney P.R.
MA, FRCP
Consultant Dermatologist, Department of Dermatology, Churchill Hospital, Old Road, Headington, Oxford OX2 7LJ
Co-author
Chapter 62: Disorders of Nails

de BERKER, David A.R.
BA, MRCP
Consultant Dermatologist and Clinical Senior Lecturer, Bristol Dermatology Centre, Bristol Royal Infirmary, Marlborough Street, Bristol BS2 8HW
Co-author
Chapter 62: Disorders of Nails
Chapter 63: Disorders of Hair

DOWD, Pauline M.
BSc, MD, FRCP
Professor of Dermatology, Department of Dermatology, The Middlesex Hospital, Tottenham Street, London W1T 4NJ
Author of
Chapter 23: Reactions to Cold

EADY, Robin A.J.
DSc, FRCP, FMedSci
Emeritus Professor of Experimental Dermatopathology, Division of Skin Sciences, Guy's, King's and St Thomas' School of Medicine, King's College London, and Honorary Consultant Dermatologist, St John's Institute of Dermatology, St Thomas' Hospital, Lambeth Palace Road, London SE1 7EH
Co-author of
Chapter 3: Anatomy and Organization of Human Skin
Chapter 13: Prenatal Diagnosis of Genetic Skin Disease
Chapter 40: Genetic Blistering Diseases

EEDY, David J.
MD, FRCP
Consultant Dermatologist, Department of Dermatology, Craigavon Area Hospital Group Trust, 68 Lurgan Road, Portadown, Co. Armagh, Northern Ireland BT63 5QQ
Co-author of
Chapter 60: The Skin and the Nervous System

ENGLISH, John S.C.
MB, BS, FRCP
Consultant Dermatologist, Department of Dermatology, Queen's Medical Centre, University Hospital, Clifton Boulevard, Nottingham NG7 2UH
Co-author of
Chapter 21: Occupational Dermatoses

FERGUSON, James
MD, FRCP
Consultant Dermatologist, Photobiology Unit, Department of Dermatology, Ninewells Hospital and Medical School, Dundee DD1 9SY
Co-author of
Chapter 24: Cutaneous Photobiology

FINE, Jo-David
MD, MPH, FACP
Professor of Medicine, University of Kentucky College of Medicine, and Dermatology Associates of Kentucky, PSC, 250 Fountain Court, Lexington, KY 40509, USA
Co-author of
Chapter 40: Genetic Blistering Diseases

FINLAY, Andrew Y.
FRCP(Lond & Glasg)
Professor of Dermatology and Honorary Consultant Dermatologist, Department of Dermatology, University of Wales College of Medicine, Heath Park, Cardiff CF14 4XN
Co-author of
Chapter 71: General Aspects of Treatment

FRIEDMANN, Peter S.
MD, FRCP, FMedSci
Professor of Dermatology, Dermatopharmacology Unit, Southampton General Hospital, Tremona Road, Southampton SO16 6YD
Co-author of
Chapter 18: Atopic Dermatitis

GAWKRODGER, David J.
MD, FRCP, FRCPE
Consultant Dermatologist and Honorary Senior Clinical Lecturer, Department of Dermatology, Royal Hallamshire Hospital, Glossop Road, Sheffield S10 2JF
Author of
Chapter 58: Sarcoidosis
Chapter 69: Racial Influences on Skin Disease

GENNERY, Andrew R.
MD, MRCP, MRCPCH, DCH, DipMedSci
Watson Clinical Senior Lecturer/Honorary Consultant in Paediatric Immunology and Bone Marrow Transplantation, Newcastle General Hospital, Westgate Road, Newcastle upon Tyne NE4 6BE
Co-author of
Chapter 14: The Neonate

GOODFIELD, Mark J.D.
MD, FRCP
Consultant Dermatologist, Department of Dermatology, Leeds General Infirmary, Great George Street, Leeds LS1 3EX
Co-author of
Chapter 56: The 'Connective Tissue Diseases'

GOTCH, Frances
PhD, FRCPath
Professor of Immunology, Head of Department, Department of Immunology, Imperial College School of Medicine, Chelsea & Westminster Campus, Fulham Road, London SW10 9NH
Co-author of
Chapter 26: AIDS and the Skin

GRAHAM, Robert M.
MB, FRCP
Consultant Dermatologist, Department of Dermatology, James Paget Healthcare NHS Trust, Lowestoft Road, Gorleston, Great Yarmouth, Norfolk NR31 6LA
Co-author of
Chapter 59: Systemic Disease and the Skin

GRAHAM-BROWN, Robin A.C.
BSc, MB, BS, FRCP
Consultant and Honorary Senior Lecturer in Dermatology, Department of Dermatology, Leicester Royal Infirmary, Leicester LE1 5WW
Author of
Chapter 70: The Ages of Man and their Dermatoses

GRATTAN, Beth
MD
Resident Physician, Department of Dermatology, Medical University of South Carolina, Charleston, SC 29425, Carolina, USA
Co-author of
Chapter 49: Vasculitis and Neutrophilic Vascular Reactions

GRATTAN, Clive E.H.
MA, MD, FRCP
Consultant Dermatologist, Department of Dermatology, Norfolk and Norwich University Hospital, Colney, Norfolk NR4 7UZ
Co-author of
Chapter 47: Urticaria and Mastocytosis

GREAVES, Malcolm W.
MD, PhD, FRCP
Professor of Dermatology, Department of Dermatology, Singapore General Hospital, Outram Road, Singapore 169608
Author of
Chapter 16: Pruritus

GRIFFITHS, Christopher E.M.
BSc, MD, FRCP, FRCPath
Professor of Dermatology and Consultant Dermatologist, The Dermatology Centre, University of Manchester, Irving Building, Hope Hospital, Salford, Manchester M6 8HD
Editor
Co-author of
Chapter 9: Inflammation
Chapter 35: Psoriasis
Chapter 72: Systemic Therapy

HARPER, John I.
MD, FRCP, FRCPCH
Professor of Paediatric Dermatology, Great Ormond Street Hospital for Children, Great Ormond Street, London WC1N 3JH
Co-author of
Chapter 12: Genetics and Genodermatoses

HAWK, John L.M.
BSc, MD, FRACP, FRCP
Consultant Dermatologist and Head, Department of Environmental Dermatology, St John's Institute of Dermatology, St Thomas' Hospital, Lambeth Palace Road, London SE1 7EH
Co-author of
Chapter 24: Cutaneous Photobiology

HAY, Roderick J.
DM, FRCP, FRCPath
Dean, Faculty of Medicine and Health Sciences, Queen's University Belfast, Whitla Medical Building, 97 Lisburn Road, Belfast BT9 7BL
Co-author of
Chapter 27: Bacterial Infections
Chapter 31: Mycology
Chapter 32: Parasitic Worms and Protozoa
Chapter 72: Systemic Therapy

HOLDEN, Colin A.
BSc, MD, FRCP
Consultant Dermatologist, Epsom and St Helier University Hospitals NHS Trust, St Helier Hospital, Wrythe Lane, Carshalton, Surrey SM5 1AA
Co-author of
Chapter 17: Eczema, Lichenification, Prurigo and Erythroderma
Chapter 18: Atopic Dermatitis

JONES, Stephen K.
BMedSci, BM, BS, MD, FRCP(Lond & Edin)
Consultant Dermatologist, Department of Dermatology, Clatterbridge Hospital, Bebington, Wirral CH63 4JY

Co-author of
Chapter 56: The 'Connective Tissue Diseases'

JORIZZO, Joseph L.
MD
Professor and Former (Founding) Chair, Department of Dermatology, Wake Forest University School of Medicine, Medical Centre Boulevard, Winston-Salem, NC 27157-1071, USA
Co-author of
Chapter 49: Vasculitis and Neutrophilic Vascular Reactions

JUDGE, Mary R.
MD, FRCP, DCH
Consultant Dermatologist, Department of Dermatology, Royal Bolton Hospital, Minerva Road, Farnworth, Bolton BL4 0JR, and Consultant Paediatric Dermatologist, Dermatology Centre, Hope Hospital, Stott Lane, Salford, Manchester M6 8HD
Co-author of
Chapter 34: Disorders of Keratinization

KELLY, Charles G.
MSc, FRCP, FRCR
Consultant Clinical Oncologist, Northern Centre for Cancer Treatment, Newcastle General Hospital, Westgate Road, Newcastle upon Tyne NE4 6BE
Co-author of
Chapter 76: Radiotherapy and Reactions to Ionizing Radiation

KENNEDY, Cameron T.C.
MA, MB, BChir, FRCP
Consultant Dermatologist and Clinical Senior Lecturer, Bristol Dermatology Centre, Bristol Royal Infirmary, Marlborough Street, Bristol BS2 8HW
Author of
Chapter 65: The External Ear
Co-author of
Chapter 22: Mechanical and Thermal Injury

KERDEL-VEGAS, Francisco
CBE, MD, MSc, DSc, FACP
Former Professor of Dermatology, Universidad Central de Venezuela, Caracas, and Fellow of the National Academy of Medicine and the Academy of Sciences of Venezuela, Central University of Venezuela, Apartado 60391, Caracas 1060-A, Venezuela
Co-author of
Chapter 30: The Treponematoses

KINGHORN, George R.
MB, ChB, MD, FRCP
Clinical Director, Department of Genitourinary Medicine, Royal Hallamshire Hospital, Glossop Road, Sheffield S10 2JF
Co-author of
Chapter 30: The Treponematoses

KOBZA BLACK, Anne
MD, FRCP
Consultant Dermatologist, St John's Institute of Dermatology, St Thomas' Hospital, Lambeth Palace Road, London SE1 7EH
Co-author of
Chapter 47: Urticaria and Mastocytosis

LAWRENCE, Clifford M.
MD, FRCP
Consultant Dermatologist, Department of Dermatology, Royal Victoria Infirmary, Queen Victoria Road, Newcastle upon Tyne NE1 4LP
Co-author of
Chapter 77: Physical and Laser Therapies
Chapter 78: Dermatological Surgery

LEONARD, Jonathan N.
BSc, MD, FRCP
Consultant Dermatologist, Department of Dermatology, St Mary's Hospital, Praed Street, London W2 1NY
Co-author of
Chapter 64: The Skin and the Eyes

LOCKWOOD, Diana N.J.
MD, FRCP
Consultant Physician and Leprologist, The Hospital for Tropical Diseases, Capper Street, London WC1E 6AU
Author of
Chapter 29: Leprosy

LOVELL, Christopher R.
MD, FRCP
Department of Dermatology, Royal United Hospital, Coombe Park, Bath BA1 3NG
Co-author of
Chapter 46: Disorders of Connective Tissue

LUGER, Thomas A.
MD
Professor and Chairman, Department of Dermatology, University of Münster, Von-Esmarch-Strasse 58, D-48149 Münster, Germany
Co-author of
Chapter 9: Inflammation

MacKIE, Rona M.
CBE, FRSE, MD, DSc, FRCP, FRCPath
Senior Research Fellow, Public Health and Health Policy, University of Glasgow, 1 Lilybank Gardens, Glasgow G12 8RZ
Author of
Chapter 38: Disorders of the Cutaneous Melanocyte
Co-author of
Chapter 36: Non-Melanoma Skin Cancer and Other Epidermal Skin Tumours
Chapter 37: Tumours of the Skin Appendages
Chapter 53: Soft-Tissue Tumours and Tumour-like Conditions
Chapter 54: Cutaneous Lymphomas and Lymphocytic Infiltrates

McGRATH, John A.
MD, FRCP
Professor of Molecular Dermatology, St John's Institute of Dermatology, St Thomas' Hospital, Lambeth Palace Road, London SE1 7EH
Co-author of
Chapter 3: Anatomy and Organization of Human Skin
Chapter 11: Wound Healing
Chapter 13: Prenatal Diagnosis of Genetic Skin Disease

McLEAN, W.H. Irwin
PhD, DSc
Wellcome Trust Senior Research Fellow and Professor of Human Genetics, Human Genetics Unit, Division of Pathology and Neuroscience, Ninewells Hospital and Medical School, University of Dundee, Dundee DD1 9SY

Co-author of
Chapter 34: Disorders of Keratinization

MESSENGER, Andrew G.
MD, FRCP
Consultant Dermatologist, Department of Dermatology, Royal Hallamshire Hospital, Glossop Road, Sheffield S10 2JF
Co-author of
Chapter 63: Disorders of Hair

MILLARD, Leslie G.
MD, FRCP(Lond & Edin)
Consultant in Dermatology and Cutaneous Surgery, Department of Dermatology and Dermatological Surgery, Queen's Medical Centre, University Hospital NHS Trust, Clifton Boulevard, Nottingham NG7 2UH
Co-author of
Chapter 61: Psychocutaneous Disorders

MOORE, Mary K.
MA, PhD
Lecturer, Mycology Department, St John's Institute of Dermatology, St Thomas' Hospital, Lambeth Palace Road, London SE1 7EH
Co-author of
Chapter 31: Mycology

MORTIMER, Peter S.
MD, FRCP
Professor of Dermatological Medicine, Dermatology Unit, St George's Hospital Medical School, Cranmer Terrace, London SW17 0RE
Author of
Chapter 51: Disorders of Lymphatic Vessels
Co-author of
Chapter 50: Diseases of the Veins and Arteries: Leg Ulcers

MORTON, Robert S. [Deceased]
MBE, MD, FRCP(Edin), DHMSA
Formerly Honorary Lecturer in History of Medicine, University of Sheffield
Co-author of
Chapter 30: The Treponematoses

MOSS, Celia
DM, FRCP, MRCPCH
Consultant Dermatologist, Department of Dermatology, Birmingham Children's Hospital, Steelhouse Lane, Birmingham B4 6NL
Co-author of
Chapter 15: Naevi and other Developmental Defects

MUNRO, Colin S.
MD, FRCP(Glasg)
Consultant Dermatologist and Professor, Department of Dermatology, South Glasgow University Hospitals NHS Trust, Govan Road, Glasgow G51 4TF
Co-author of
Chapter 34: Disorders of Keratinization

NEILL, Sallie M.
FRCP
Consultant Dermatologist, St John's Dermatology Unit, Guy's and St Thomas' NHS Trust, Lambeth Palace Road, London, SE1 7EH, Chelsea and Westminster NHS Trust, Fulham Road, London SW10 9NH and Ashford & St Peter's NHS Trust, Guildford Road, Chertsey, Surrey KT16 0PZ
Co-author of
Chapter 68: The Genital, Perianal and Umbilical Regions

PIETTE, Warren W.
MD
Professor and Vice-Chair, Department of Dermatology, University of Iowa Roy J. and Lucille A. Carver College of Medicine, University of Iowa Hospitals and Clinics, 200 Hawkins Drive, Iowa City, IA 52242-1090, USA
Co-author of
Chapter 48: Purpura and Microvascular Occlusion

POPE, F. Michael
MD, FRCP(Lond, Edin & Glasg)
Consultant Dermatologist, West Middlesex University Hospital, Twickenham Road, Isleworth, Middlesex TW7 6AF, and the Chelsea & Westminster Hospital, Fulham Road, London SW10 9NH, Professor of Medical Genetics and Honorary Consultant Clinical Geneticist, Institute of Medical Genetics, University of Wales College of Medicine and University Hospital of Wales, Heath Park, Cardiff CF14 4XN
Co-author of
Chapter 3: Anatomy and Organization of Human Skin

QUINN, Anthony G.
BMSc, MB, ChB, PhD, FRCP
Director/Senior Principal Scientist, Experimental Medicine, AstraZeneca R&D Charnwood, Bakewell Road, Loughborough, Leicestershire LE11 5RH
Co-author of
Chapter 36: Non-Melanoma Skin Cancer and Other Epidermal Skin Tumours

REES, Jonathan L.
BMedSci, MB, BS, FRCP, FMedSci
Grant Chair of Dermatology, Department of Dermatology, The University of Edinburgh, Lauriston Building, Lauriston Place, Edinburgh EH3 9HA
Author of
Chapter 8: Molecular Biology

ROOK, Graham A.W.
BA, MB, BChir, MD
Professor of Medical Microbiology, Department of Medical Microbiology, Windeyer Institute of Medical Sciences, Royal Free and University College Medical School, 46 Cleveland Street, London W1T 4JF
Co-author of
Chapter 28: Mycobacterial Infections

SARKANY, Robert P.E.
BSc, MRCP, MD
Consultant Dermatologist, Department of Dermatology, St George's Hospital, Blackshaw Road, London SW17 0QT
Co-author of
Chapter 57: Metabolic and Nutritional Disorders

SCHWARZ, Thomas
MD
Professor of Dermatology, Department of Dermatology, University of Münster, Von-Esmarch-Strasse 58, D-48149 Münster, Germany
Co-author of
Chapter 10: Clinical Immunology, Allergy and Photoimmunology

SCULLY, Crispian
CBE, MD, PhD, MDS, MRCS, FDSRCS, FDSRCPS, FFDRCSI, FDSRCSE, FRCPath, FMedSci
President of the European Association of Oral Medicine, and Dean and Director of Studies and Research, Eastman Dental Institute for Oral Health Care Sciences, and International Centres for Excellence in Dentistry, University College London, 256 Gray's Inn Road, London WC1X 8LD
Author of
Chapter 66: The Oral Cavity and Lips

SEYMOUR, Carol A.
MA(Oxon), MA(Cantab), PhD, FRCPath, FRCP
Emeritus Professor of Clinical Biochemistry and Metabolic Medicine, St George's Hospital Medical School, Blackshaw Road, London SW17 0QT
Co-author of
Chapter 57: Metabolic and Nutritional Disorders

SIMPSON, Nicholas B.
MD, FRCP(Lond & Glasg)
Consultant Dermatologist, Department of Dermatology, Royal Victoria Infirmary, Queen Victoria Road, Newcastle upon Tyne NE1 4LP
Co-author of
Chapter 43: Disorders of the Sebaceous Glands

SINCLAIR, Rodney D.
MB, BS, FACD
Senior Lecturer and Consultant Dermatologist, Skin and Cancer Foundation and St Vincent's Hospital Melbourne, Department of Dermatology, 41 Victoria Parade, Fitzroy, Victoria 3065, Australia
Co-author of
Chapter 63: Disorders of Hair

SPICKETT, Gavin P.
MA, DPhil, FRCPath, FRCP(Lond)
Consultant Clinical Immunologist, Regional Department of Immunology, Royal Victoria Infirmary, Queen Victoria Road, Newcastle upon Tyne NE1 4LP
Co-author of
Chapter 10: Clinical Immunology, Allergy and Photoimmunology

SPITTLE, Margaret F.
MSc, FRCP, FRCR, AKC
Consultant Clinical Oncologist, Meyerstein Institute of Oncology, The Middlesex Hospital, Mortimer Street, London W1N 8AA
Co-author of
Chapter 76: Radiotherapy and Reactions to Ionizing Radiation

STEINHOFF, Martin
MD, PhD
Associate Professor, Department of Dermatology and Boltzmann Institute for Immunobiology of the Skin, University of Münster, Von-Esmarch-Strasse 58, D-48149 Münster, Germany
Co-author of
Chapter 9: Inflammation

STERLING, Jane C.

Chapter 24: Cutaneous Photobiology

Preface to the Seventh Edition

Over thirty years have passed since the first edition of *Textbook of Dermatology* was published under the leadership of Arthur Rook, Darrell Wilkinson and John Ebling.

Arthur Rook, a wise clinician with an encyclopaedic knowledge of medical literature, and a man of great linguistic talent and enormous energy, died in 1991 (see Preface to the fifth edition).

John Ebling, who continued as an editor to the fifth edition, died in 1992. He occupied a unique position in British dermatology, as a full-time Professor of Zoology, a distinguished research worker and a man of enormous erudition and editorial skills. His breadth of knowledge covered the whole of biology and we owe him a great debt for his tremendous and untiring work over 25 years on this textbook.

The fifth edition, published in 1992, was edited by Champion, Burton and Ebling, with invaluable advice from Darrell Wilkinson. Bob Champion and John Burton continued to lead the editorial team into the sixth edition, published in 1998, and we are indebted to them for their expertise and dedicated hard work for many years.

For this seventh edition, Tony Burns and Stephen Breathnach have been joined by two new editors, Neil Cox and Christopher Griffiths. As always, we would all like to express our gratitude to the three original editors who laid the foundations and provided a framework upon which this book has developed through subsequent editions.

Our aim is to continue to provide a comprehensive reference guide to all recognized dermatological diseases, and to encourage understanding and development of scientific aspects of dermatology, although the book is not intended to provide details of research in the basic sciences.

For this edition, every chapter has been updated, and several have been completely rewritten. There are several new contributors, and a new chapter on AIDS and the skin is a reflection of the impact this disease has had in recent years. We would like to acknowledge our indebtedness to contributors to earlier editions, who have generously allowed some of their original material to be retained for the present edition.

We are also very grateful to all those colleagues who have donated colour photographs, and the origin of these is given in the legend to each figure. Where no acknowledgement is given the figures have been provided by the authors of that chapter.

Our wives and families deserve our thanks for their forbearance and support over many years.

We should also like to thank the staff of Blackwell Publishing for their efforts throughout the production of this edition, in particular Rupal Malde, Nick Morgan, Katrina Chandler and Stuart Taylor. We are once again extremely grateful to Caroline Sheard for her excellent index. Her index for the sixth edition deservedly won the Wheatley Prize (1998). Our heartfelt thanks also go to the team of copy editors and proof readers who, in deciphering and analysing reams of verbiage, are the ultimate refiners of these four volumes.

D.A. Burns
S.M. Breathnach
N.H. Cox
C.E.M. Griffiths

Preface to the First Edition

No comprehensive reference book on dermatology has been published in the English language for ten years and none in England for over a quarter of a century. The recent literature of dermatology is rich in shorter texts and in specialist monographs but the English-speaking dermatologist has long felt the need for a substantial text for regular reference and as a guide to the immense monographic and periodical literature. The editors have therefore planned the present volume primarily for the dermatologist in practice or in training, but have also considered the requirements of the specialist in other fields of medicine and of the many research workers interested in the skin in relation to toxicology or cosmetic science.

An attempt has been made throughout the book to integrate our growing knowledge of the biology of skin and of fundamental pathological processes with practical clinical problems. Often the gap is still very wide but the trends of basic research at least indicate how it may eventually be bridged. In a clinical textbook the space devoted to the basic sciences must necessarily be restricted but a special effort has been made to ensure that the short accounts which open many chapters are easily understood by the physician whose interests and experience are exclusively clinical.

For the benefit of the student we have encouraged our contributors to make each chapter readable as an independent entity, and have accepted that this must involve the repetition of some material.

The classification employed is conventional and pragmatic. Until our knowledge of the mechanisms of disease is more profound no truly scientific classification is possible. In so many clinical syndromes multiple aetiological factors are implicated. To emphasize one at the expense of others is often misleading. Most diseases are to some extent influenced by genetic factors and a large proportion of common skin reactions are modified by the emotional state of the patient. Our knowledge is in no way advanced by classifying hundreds of diseases as genodermatoses and dozens as psychosomatic.

The true prevalence of a disease may throw light on its aetiology but reported incidence figures are often unreliable and incorrectly interpreted. The scientific approach to the evaluation of racial and environmental factors has therefore been considered in some detail.

The effectiveness of any physician in practice must ultimately depend on his ability to make an accurate clinical diagnosis. Clinical descriptions are detailed and differential diagnosis is fully discussed. Histopathology is here considered mainly as an aid to diagnosis but references to fuller accounts are provided.

The approach to treatment is critical but practical. Many empirical measures are of proven value and should not be abandoned merely because their efficacy cannot yet be scientifically explained. However, many familiar remedies old and new have been omitted either because properly controlled clinical trials have shown them to be of no value or because they have been supplanted by more effective and safer preparations.

There are over nine hundred photographs but no attempt has been made to provide an illustration of every disease. To have done so would have increased the bulk and price of the book without increasing proportionately its practical value. The conditions selected for illustrations are those in which a photograph significantly enhances the verbal description. There are a few conditions we wished to illustrate, but of which we could not obtain unpublished photographs of satisfactory quality.

The lists of references have been selected to provide a guide to the literature. Important articles now of largely historical interest have usually been omitted, except where a knowledge of the history of a disease simplifies the understanding of present concepts and terminology. Books and articles provided with a substantial bibliography are marked with an asterisk.

Many of the chapters have been read and criticized by several members of the team and by other colleagues. Professor Wilson Jones, Dr R.S. Wells and Dr W.E. Parish have given valuable assistance with histopathological, genetic and immunological problems respectively. Many advisers, whose services are acknowledged in the following pages, have helped us with individual chapters. Any errors which have not been eliminated are, however, the responsibility of the editors and authors.

The editors hope that this book will prove of value to all those who are interested in the skin either as physicians or as research workers. They will welcome readers' criticisms and suggestions which may help them to make the second edition the book they hope to produce.

Chapter 1

Introduction and Historical Bibliography

D.A. Burns & N.H. Cox

What is dermatology?

Dermatology is defined in the *New Oxford Dictionary of English* as 'The branch of medicine concerned with the diagnosis and treatment of skin disorders' [1]. However, dermatologists do not confine themselves merely to a study of intrinsic disorders of the skin, but must also study internal medicine and the many environmental and occupational factors that so frequently cause skin problems.

A plethora of external factors, including numerous chemicals, can adversely affect the skin in some circumstances. The clinical dermatologist must be knowledgeable about these potential hazards, and this will often require a detailed study of the multiplicity of chemicals, plants, animals, parasites, microorganisms, radiation, climatic conditions, etc., to which the skin is exposed. In many cases, the dermatologist will need to obtain exact details of what is involved in the patient's occupation and hobbies, and many dermatologists build up a considerable knowledge of the different jobs involved in their local industries.

The dermatologist must also have a good knowledge of internal medicine, as most systemic diseases can occasionally affect the skin, either directly or as a result of a complication of the disease or its treatment. Drugs taken by the patient have to be considered by the dermatologist, because the unwanted effects of many drugs include provocation of rashes. This applies not only to prescribed medication, but also to over-the-counter and 'complementary' remedies.

A dermatologist must also pay attention to the psyche, as psychological factors play an important part in dermatology. The skin is of major importance in our 'body image', and the fact that skin diseases are often regarded with revulsion by the general population adds to the distress they cause, so that the psychological disturbance induced by skin problems may be out of all proportion to their 'medical' significance. Sometimes, these psychological problems are exacerbated by the reactions of the patient's relatives, friends or colleagues, and in other cases they are partly accounted for by feelings of guilt or despondency, induced by the belief that skin diseases are due to 'uncleanliness' of some kind (with or without sexual overtones). In recent years, there has been increasing awareness of the impact of skin diseases on social and leisure activities, work and sexual relationships, and questionnaires such as the Dermatology Life Quality Index (DLQI) have been employed to measure the impairment of quality of life (see Chapter 71). In addition, skin diseases not only cause stress or depression, but psychological stress from another cause can exacerbate, or even be involved in causation of, some skin diseases.

Whatever the complexity of these psychological nuances, the dermatologist must be aware of their existence and try to deal with them accordingly. As described later (Chapter 61), some patients have 'skin problems' that are imagined or self-inflicted, and the presentation to the dermatologist seems to be a 'cry for help' with marital or other social problems. In other cases, the dermatological consultation may be a manifestation of an underlying psychological disease such as depression or schizophrenia.

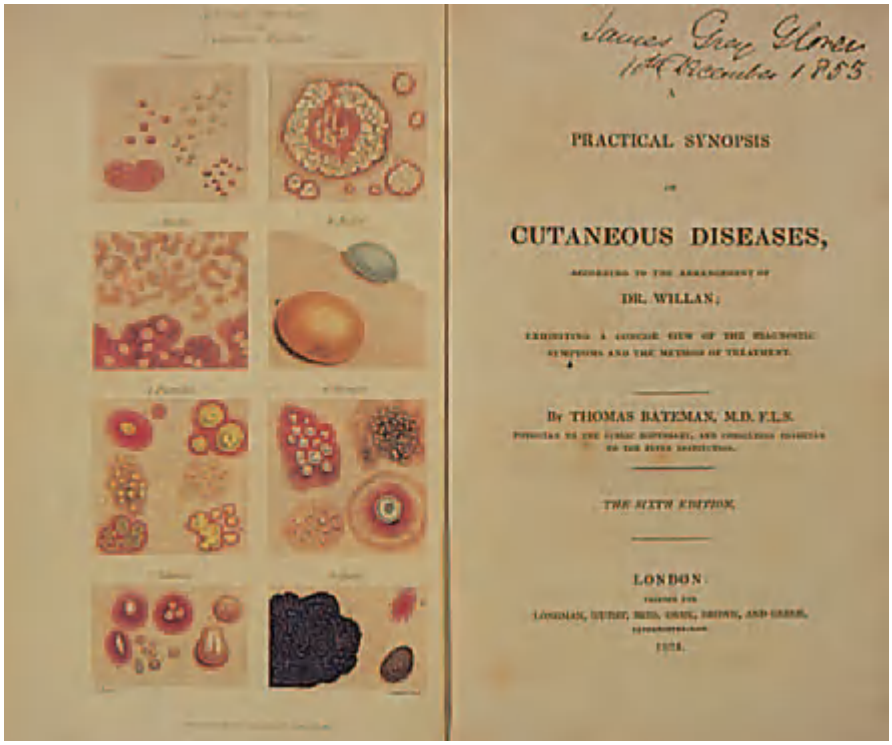
The evolution of dermatology

Skin diseases predate written records, and many of the earliest medical writings deal with dermatological subjects. The history of dermatology is too large a subject to be covered in this book, although a selected historical bibliography is given at the end of this chapter. The development of modern dermatology is briefly outlined below.



PRACTICAL SYNOPSIS

OF

CUTANEOUS DISEASES,

ARRANGED ACCORDING TO THE ARRANGEMENT OF

DR. WILLAN;

EXHIBITING A CONCISE VIEW OF THE DIAGNOSTIC SYMPTOMS AND THE METHOD OF TREATMENT.

By THOMAS BATEMAN, M.D. F.L.S.

THE SIXTH EDITION.

LONDON:

Fig. 1.1 The title page and facing plate from the 6th edition (1824) of Thomas Bateman's *Practical Synopsis of Cutaneous Diseases, According to the Arrangement of Dr Willan*. The plate shows the eight orders of cutaneous eruption in Willan's classification.

Dermatology evolved as a branch of internal medicine during the 19th century. Previously, many diseases of the skin had fallen within the province of the quack or the surgeon, and indeed many of the older surgical textbooks devote much attention to the treatment of skin disease. The physicians of that time were little concerned with the skin, apart from the eruptions of the acute infectious fevers. In the early 18th century, individuals such as Daniel Turner advocated use of preparations applied to the skin as treatment for internal diseases. During the last decades of the 18th century, however, many of the great physicians began to record their observations on the diseases of the skin, and this continued throughout the 19th century. Towards the end of that century, skin diseases, particularly the chronic infections such as syphilis and tuberculosis, formed a significant part of the general physician's practice, and by the beginning of the 20th century some physicians were beginning to specialize in dermatology. This trend towards increasing specialization has continued ever since.

In the first half of the 20th century, dermatology was slow to develop along scientific lines. The emphasis was very much on the clinical description, naming and classification of the numerous skin disorders, and this led to a profusion of synonyms, which are daunting to those attempting to get to grips with dermatological nomenclature. Only empirical treatment was available, and it was often ineffective, messy and malodorous. Dermatology certainly lagged behind some of the other medical specialties in its understanding of basic disease processes. In retrospect, this seems to have been due to two main factors. The first was that most skin diseases could be identified by external examination alone, and therefore seemed to need no further investigation. The second and perhaps more important factor was that most skin diseases could not be investigated by the relatively crude tests that were available at that time. It was only when skin biopsy became a standard technique, with the plethora of pathological knowledge that followed, that an understanding of the pathogenesis of many skin diseases began to emerge.

In the second half of the 20th century, there was an explosion of dermatological knowledge, mainly as a result of the introduction of sophisticated research techniques which not only led to a better knowledge of the pathogenesis and treatment of skin disorders, but also facilitated the development of more targeted treatments. More recently, the techniques of molecular biology have also been applied (Chapter 8), leading to, amongst other things, important developments in genetics and the understanding of mechanisms underlying cancer. As a result, increasing numbers of non-medical scientists are studying the skin, and its accessibility, which paradoxically inhibited investigation in the first half of the 20th century, is now of course very helpful to the research worker.

Dermatological treatment patterns have changed over the last 50 years, and will no doubt continue to do so. Recent advances in treatment include topical immunosuppressants, immune response modifiers and biological therapies for psoriasis. Further sophistication in treatment

Fig. 1.2 Impetigo contagiosa, from the *Portfolio of Dermochromes* by Professor Jacobi (1903). The English adaptation of the text was performed by J.J. Pringle of the Middlesex Hospital. The majority of the illustrations were of models in the Breslau Clinic.

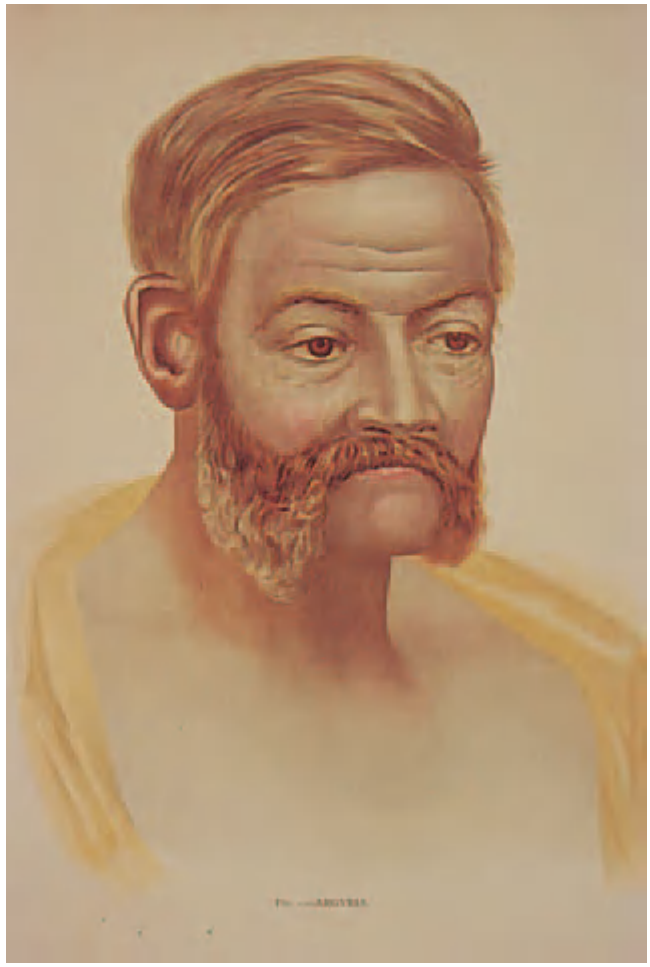


Fig. 1.3 Argyria, from Radcliffe Crocker's *Atlas of Diseases of the Skin*. Henry Radcliffe Crocker (1845–1909), physician to the skin department of University College Hospital, London, made a number of important contributions to clinical dermatology, and was also a pioneer in skin microscopy and the therapeutic use of radium. His textbook *Diseases of the Skin* and the *Atlas of Diseases of the Skin* contributed to his reputation as one of the leading dermatologists of his day.

should parallel increasing knowledge of the roles of inflammatory mediators in disease. Some older treatment modalities, such as radiotherapy, are used much less.

Dermatology is thus changing at an ever-accelerating pace, both in the amount of scientific knowledge and treatments available, and with regard to disease patterns and patients' expectations. Increasing specialization within dermatology is becoming more common, with the expansion of expertise in dermatological surgery, laser therapy, chemosurgery, photobiology, contact allergy, genetic counselling, histopathology, etc. Certainly, dermatologists can no longer be regarded only as general physicians with an interest in the skin, although some training in internal medicine is still regarded as desirable in most countries. In the UK, trainee dermatologists are expected to have completed a minimum of 2 years of general professional training and to have passed a postgraduate examination in general medicine (Membership of the Royal College of Physicians, MRCP) before they can start their specialist training in dermatology. The specialist training entails 4 years in an approved training post, with an annual assessment of progress, on satisfactory completion of which the trainee is awarded a Certificate of Completion of Specialist Training (CCST).

It seems possible that the days of the generalist dermatologist are numbered. Future dermatologists will perhaps regard themselves as dermatological physicians, surgeons or researchers and train accordingly. The future cannot be predicted, but it seems certain that with the increasing sophistication of populations throughout the world, the demand for dermatological expertise is likely to increase.

The dermatologist's work

There are probably at least 2000 different skin conditions that might present to the dermatologist, and most dermatologists treat patients of all ages, from the neonate to the very old.

Fig. 1.4 Lupus vulgaris with epithelioma, from Crocker's *Atlas*.

The conditions seen vary enormously in severity. They range from cosmetic problems, such as dry skin or wrinkles, through a huge variety of acute or chronic diseases, which may be disfiguring, itchy or painful, but are rarely fatal, to life-threatening conditions, which, if untreated, may prove fatal within days (e.g. toxic epidermal necrolysis), weeks (e.g. pemphigus), months (e.g. malignant melanoma) or years (e.g. cutaneous lymphoma). In the UK, about 70% of consultations for dermatological problems are related to skin cancer, acne, psoriasis, viral warts and other infections, benign tumours, leg ulcers and various forms of dermatitis [1].

Obviously, the pattern of disease varies from one country to another, and even in the same city the work of dermatologists will differ, depending on their particular interests and expertise and on the social mix of their patients. Involvement with cosmetic procedures, in particular, varies according to the constraints of the health care system in which the dermatologist works.

Space precludes any detailed consideration of the work of dermatologists throughout the world, but in the British system patients are normally first seen by a primary care physician (general practitioner, GP) who refers the patient to the hospital consultant if he or she thinks it necessary or advisable. It has been estimated that around one in seven primary care consultations relates to a dermatological problem [2]. In a semirural practice in Cornwall, England, 21% of patients seen in a 5-year period by one GP had a dermatological diagnosis [3], and the most common skin diseases seen were viral warts, eczema and benign tumours. In another survey of GPs in the Bristol area of the UK, 47% of those replying to a questionnaire managed nearly all skin problems themselves in primary care [4]. The hospital dermatology services are provided by consultant dermatologists and their supporting staff. In the UK at present, each consultant is responsible for a population of around 200 000 persons, although the British Association of Dermatologists recommends a ratio of one consultant per 85–100 000 to cope with the need for specialist advice. About 12.5 people/1000 population are referred to a hospital dermatology department annually [1].

Other countries have different systems and services. In the USA, there is a ratio of 3.3 dermatologists for every 100 000 persons, although there is considerable interstate and intrastate variation in this ratio [5]. For example, it is 1/100 000 in Alaska and 3.9/100 000 in California, and within California varies from 1.26/100 000 in Fresno to 7.66/100 000 in San Francisco. There is continuing concern about provision of an adequate number of trained dermatologists to satisfy increasing demand, and that an increase in the number of dermatologists specializing in surgical and cosmetic procedures might lead to a shortage of those dealing with 'medical' dermatology patients [5–8]. It is also important that planning should take account of the high proportion of women in dermatology, and of the changing roles of nursing staff [9]. There are, of course, other countries from which dermatologists are conspicuously absent.

Many skin diseases, for example warts, acne vulgaris or psoriasis, can be quickly diagnosed by their clinical features, and need little or no further investigation. At the other extreme, there are some patients—for example, those with lymphoma—who need detailed and time-consuming investigations both to confirm the diagnosis and as a basis for treatment.

The most common investigations performed in a dermatology clinic, other than simple blood tests or swabs for microbiology, are skin biopsies. Other investigations include the extraction and identification of scabies mites, the microscopic examination of hairs, patch testing and photo-patch testing (Chapter 20). In occasional cases, special procedures may be needed, such as the examination of pets for animal parasites, or a visit to the patient's workplace or home to search for possible allergens.

The management of this infinite variety of skin disorders ranges from simple reassurance and explanation

Fig. 1.5 Discoid lupus, from Crocker's *Atlas*.

through the gamut of topical and systemic remedies, to the performance or supervision of numerous physical procedures such as ultraviolet irradiation, photochemotherapy, curettage and cautery, surgical excision and laser treatment. Some dermatologists will also undertake complicated and specialized techniques such as prenatal investigation and Mohs micrographic surgery, which may require close collaboration with other specialists, and newer techniques such as photodynamic therapy are finding a niche in the dermatologist's armamentarium.

In addition to this clinical workload in the hospital, UK dermatologists also sometimes undertake 'domiciliary' visits to assess and treat at home patients who for one reason or another cannot attend hospital. All consultant dermatologists in the UK are also involved in administrative and managerial work, audit and continuing medical education. All dermatologists, and not just those few employed by a university, are involved in teaching, whether of nurses, undergraduate medical students, GPs or trainee dermatologists, and a surprising number of National Health Service consultants (i.e. 'non-academics') manage to undertake other commitments such as writing and research.

Chapter 2

Comparative Dermatology

D.A. Burns

The evolutionary sources of the skin components [1–5]

All organisms have an outer layer that delimits the body and separates it from the environment. Its main functions include protection of the animal against physical damage, including that from radiation, defence against biological invasion, the regulation of the inward and outward passage of materials, and the receipt and transmission of signals to other organisms.

Dermatologists may consider matters relating to other animals unimportant, but an appreciation that many of the structures and much of the biochemistry of skin has an evolutionary history that antedates the origin of the vertebrates not only gives perspective to the human condition but also may provide clues to its understanding and models for its investigation.

Although the anatomy of skin differs greatly between animal classes and shows considerable variety in relation to the exigencies of lifestyle even within groups, it is nevertheless possible to recognize various long-standing elements. Structural materials, such as cross-linked proteins similar to collagen, are found in the most primitive animals. For example, supporting structures of aromatically cross-linked proteins associated with polysaccharides are found in coelenterate polyps, and the cuticles of parasitic worms such as *Ascaris* are composed of collagen proteins linked by disulphide bonds. Among the vertebrates, keratin first seems to have occurred in the lips and in the breeding tubercles of some fish, but similar materials are found in invertebrates.

Glands and pigment cells have an equally long history. The simplest glands are the unicellular goblet cells, which secrete mucus in coelenterates and fish alike. Multicellular glands of various degrees of complexity are ubiquitous.

Melanins, which are pigments produced by the oxidation of tyrosine, are equally widespread and are found, for example, in worms, molluscs, arthropods and echinoderms, as well as throughout the vertebrates.

The questions of most interest in dermatology concern the skin changes, including loss of long hair on the body, which have occurred in hominid evolution. However, the appreciation that the biochemical machinery of human skin was established much earlier makes it relevant first to review briefly the integument in the more primitive forms of life.

The epidermis and the dermis and their derivatives

Invertebrates

Life began in the sea, just as the human fetus develops bathed in the amniotic fluid. Among the simplest and most archaic animals are the coelenterates, namely the

corals, jellyfish and their allies. Such forms have only two layers of cells: an ectoderm in contact with the aquatic environment and an endoderm lining the gut cavity. The ectoderm may, nevertheless, contain gland cells, stinging cells, pigment cells and sensory cells, and its outer surface may bear microvilli, suggesting an absorptive function [1]. Microvilli are similarly found on the outside of the integument of flukes and tapeworms, which are internal parasites [2,3], and on the amniotic border of periderm of the human embryo.

Marine worms and their relatives in fresh water and on land have a thick cuticle outside their epidermis [4,5]. Arthropods, animals with jointed limbs of which crustacea and insects are examples, have a tough exoskeleton, which has helped some of their forms to colonize land. In crabs and lobsters this cuticle is hardened by the inclusion of calcareous material. Insect cuticle is composed of chitin, a polysaccharide containing amino groups, and protein, which may be tanned or otherwise cross-linked to form a hard natural plastic [6,7]. A coat of wax prevents desiccation of the animals. An obvious disadvantage of the exoskeleton is that growth can only occur if it is periodically shed, a procedure that leaves its owner vulnerable to predation or other damage [8].

One interesting feature of annelid worms is that they bear stiff bristles or chaetae, made of a keratin-like material with properties similar to that of human hair. Although of epidermal origin, chaetae are not composed of aggregated cells produced by an active matrix. Lateral cells may add substance or provide tanning agents, but the bulk of each chaeta is secreted by only a single basal cell [9,10].

Vertebrates

Origins and trends

A continuous evolutionary narrative starts with the vertebrates—animals with a backbone, which is preceded in embryonic development by an elastic rod known as a notochord. The simplest known chordates, which have only notochords and no vertebral column, are the planktonic larvae of sea squirts and a small, bottom-living marine animal known as the lancelet or *Amphioxus*.

Amphioxus has no more than a single layer of epidermal cells, but this is attached to a basal lamina below which is a cutis made up of a jelly-like zone sandwiched between two layers of collagen [11]. This appears to be a simple version, perhaps the forerunner, of the thick dermis that gives support and instruction to the complex epidermis and its elaborate derivatives, scale, feather and fur, in the various vertebrate classes, fish, amphibia, reptiles, birds and mammals.

In all vertebrates, the skin is characterized by an outer stratified epidermis and an underlying dermis, also known as the corium or cutis. The epidermis consists of closely packed cells, which are renewed from the basal layer and which constitute a barrier. The dermis is a connective tissue of mesodermal origin and is made up mainly of extracellular ground substance and collagen fibres manufactured by scattered cells.

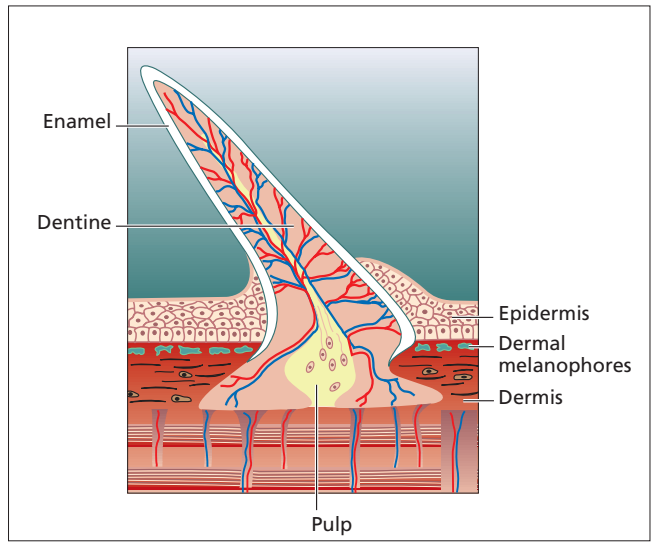

Fig. 2.1 Placoid scale of a shark.

The evolution of the vertebrates and their successful colonization of land are associated with a variety of structures, such as glands, scales, feathers and hair, as well as horns, claws and nails. Some of these, notably the scales of fish, are derived from the dermis or have substantial dermal components. Most, however, are epidermal, although their formation is orchestrated by interactions with the dermis.

Fish [12–14]

With few exceptions, such as eels and some catfish, fish have scales of one type or another. Sharks have placoid scales or denticles, which project from the skin. It is their presence that gives shark leather, or shagreen, its characteristic rough feel. In essence, the placoid scale has the same structure as a mammalian tooth, of which it is regarded as a forerunner (Fig. 2.1). Its bulk is formed by a cone of dentine, of dermal origin, which during its formation becomes capped with enamel deposited by an epidermal enamel organ.

Bony fish have elasmoid scales, consisting of plates of collagen with superficial mineralization. There are two main types. The more primitive cycloid scales found, for example, in the cod and the carp, are thin, large, round or oval, and have smooth, free edges, which overlap and show growth rings (Fig. 2.2). Ctenoid scales, found in perches and sunfishes, differ in having stiff spines on their posterior borders. All elasmoid scales remain covered by a thin layer of dermis and epidermis.

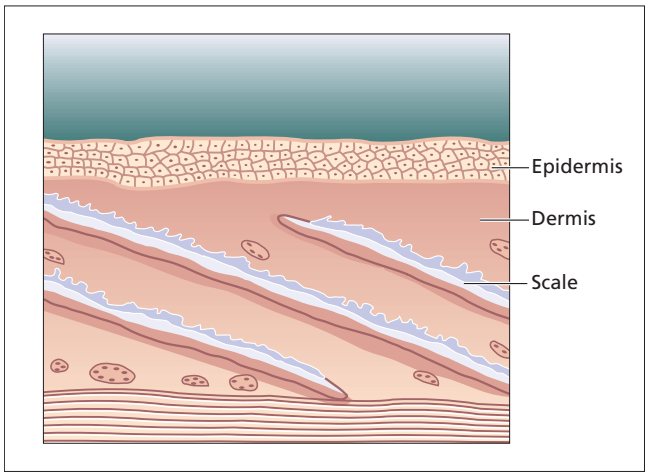

Fig. 2.2 Section of skin of bony fish. The cycloid scales lie below the epidermis.

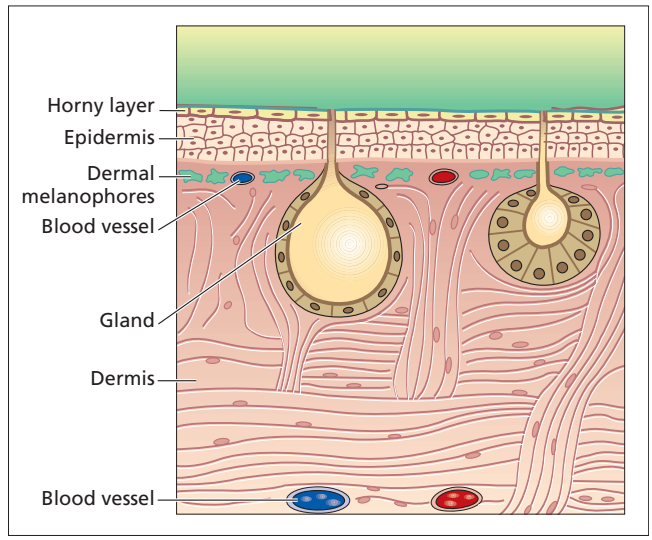

Fig. 2.3 Section of frog skin. Note the flattened superficial horny layer, only one cell deep, which is periodically sloughed as the 'scarf skin', the dermal chromatophores and the multicellular glands.

Unlike mammals or birds, fish do not reach a definitive size at maturity but go on growing throughout life. The problem of increasing the area of the integument is met by cartilaginous fish and bony fish in different ways. In sharks, completed denticles do not increase in size, but denticles continue to be formed *de novo*. Elasmoid scales of bony fish cannot be generated in this fashion but grow throughout life by the addition of step-like rings.

Amphibia [15–18]

Amphibians were the first vertebrates to emerge from the water, although they still depend on it for reproduction. Their epidermis has several layers of cells, which are formed by a basal stratum germinativum and ultimately become keratinized to form a very thin horny layer, only one cell deep in most species, which is intermittently sloughed (Fig. 2.3). Although the amphibia have lungs, they also respire through their moist skin.

Reptiles [19,20]

Reptiles are truly terrestrial, in that they do not need an aqueous environment for the development of their larvae. Their chief problem, prevention of desiccation, is solved by possession of scales, which in essence are overlapping folds of skin. An additional property of scales is that they allow the passage of infrared radiation from the sun. All modern reptiles are dependent on this external source of heat to achieve and maintain a constant body temperature similar to that of mammals.

Reptile scales contain a thick stratum corneum in which waxes are sandwiched between keratinized cells. Snakes and lizards do not, like mammals, renew their epidermis by continuous proliferation and exfoliation of cells. The vertically stratified epidermis is periodically shed as a whole, subsequent to the formation of a complete new generation of epidermal cells below it [21]. Only in rattlesnakes are several generations of scale retained at the tip of the tail.

Birds [22]

The most obvious integumental feature of birds is the possession of feathers of three kinds. The small, almost hair-like filoplumes and the downy plumules provide insulation to conserve metabolically produced body heat, whereas the larger contour feathers, which include those of the wings and tail, have aerodynamic functions.

Feathers are considered to have evolved from reptile scales [23,24] and, like scales, they are periodically moulted and replaced.

The legs and feet of birds bear scales, and some other areas, such as the comb and wattles of the domestic cockerel, are naked. The epidermis of birds, as distinct from its derivatives, is thin, and so is the dermis in most species, although ostrich skin is thick enough to be processable into leather.

Mammals [25–27]

Mammals, in general, are characterized by hair, but not all possess it. The epidermis also produces a range of other derivatives such as quills, claws, nails, hooves and horns. Antlers are made of bone, but they are covered with epidermis, the velvet, when newly grown, and the bony plates of the armadillo are similarly of dermal origin.

2.4 Chapter 2: Comparative Dermatology

Hair, wool and quill are all produced by follicles that are ingrowths of epidermis enclosing a papilla of mesodermal cells in their bases. Hair is not considered to be the homologue of scale or feather. It is more likely that the first hairs to arise in evolution were part of sensory structures between the scales of some ancestral reptile [23,28].

Reptiles with ancestral mammalian features appear in the fossil record over 200 million years ago (Ma) in the Carboniferous period, long before the first dinosaurs. Skin, unfortunately, usually leaves no fossil record. However, the existence of pits in the outer surface of the maxillary bones of some later mammal-like reptiles suggests that these creatures had tactile vibrissae, as similar pits also occur in living mammals.

The fact that groups of three or four primary hair follicles are found in the hinge regions of the reptile-like scales on the tails of modern marsupials and rodents possibly lends support to this view. It is undoubtedly of interest that the keratinization of the tail scales is similar to that in reptiles and birds, whereas typical mammalian keratinization with a granular layer occurs only in the hinge regions [12,23,24]. The evolution of the mammalian pelage may have involved the appearance of numbers of secondary hair follicles and an increase of the hinge accompanied by the loss of scales.

Antlers, as already noted, are formed from bone and are shed annually. The horns of cattle, goats, sheep and antelopes also have a bony core, but this is covered by a layer of dense horn formed by a non-hairy epidermis. Except in the American pronghorn, horns are never shed [25].

Claws, nails and hooves are tough, keratinized derivatives, which develop dorsally on the ends of the digits. They are all formed from an active matrix within a fold of epidermis; the various shapes are produced by differential growth. Nails are found only in primates, but the dorsal skin of the scaly anteater or pangolin is covered with horny scales that are surprisingly similar to nails in structure [12,25].

As distinct from the appendages, mammalian epidermis is of several types. Most furry species, from rodents to sheep, have a thin epidermis, which is only two or three cells deep. Human epidermis lacks a protective pelt and, perhaps in compensation, is somewhat thicker. The epidermis of the palms and soles has a much thicker stratum corneum than skin that bears hair follicles.

The elephant, rhinoceros and hippopotamus all have skins with very thick hyperkeratotic horny layers. Whales, which lack hair, also have a very thick epidermis, although the cells remain parakeratotic, i.e. they retain their nuclei. Whale skin has a highly indented dermal–epidermal junction, which suggests a very high rate of epidermal cell production. The whole epidermis bears a remarkable and striking histological similarity to that of psoriasis.

Glands

Evolution of glands

Glands are organs that manufacture and discharge their products either by extrusion (*merocrine*) or by complete disintegration (*holocrine*) of their cells.

Simple unicellular glands are found throughout the animal phyla. Primitive examples, in the evolutionary sense, are the mucus glands of coelenterates [1] and the considerable variety of glands in the simple epidermis of annelid worms [2]. Unicellular glands are also plentiful within the stratified epithelium of lampreys and fish [3].

The simplest type of multicellular gland is no more than an aggregation of glandular cells. Many segmented worms, for example, have glandular fields. In earthworms there is a region known as the clitellum (Latin for 'saddle'), which not only secretes a cocoon that can be slipped off like an arm band and sealed but also fills it with a fluid which is of nutritive value in some species [2].

Glands of greater productive capacity can be produced by proliferation of nests of epidermal cells and their growth downwards into the dermis. Such an occurrence can be observed in the larval development of amphibia, providing a model for the evolutionary process, if not a literal recapitulation of it [4].

Glands of vertebrates

Amphibia

Amphibian glands are of a number of types and have various functions, including the production of mucus, poison and even courtship stimulants. The flask-shaped gland of the frog skin is a typical structure (see Fig. 2.3). It is globular, lined with secretory cells, sunk into the dermis, and opens by a neck to the skin surface [5].

Reptiles

Multicellular glands, both holocrine and merocrine, are found in reptiles, although they are usually small and inconspicuous [6]. So-called 'generation glands' in lizards and snakes are connected with the shedding and sloughing cycle [7,8]. Odour-producing glands, used in both courtship and aggression, are present in most reptiles, including turtles and crocodiles as well as lizards and snakes [9]. For example, turtles have chin glands [10] and paired inguinal and axillary musk glands [11], and snakes have sac-like glands at the base of the tail.

Birds

In birds, the only conspicuous glands are the large uropygial or preen glands, although there are also some small tubular glands in the vent region [12]. The uropygial gland is holocrine and secretes an oily material by way of ducts, usually two, which open on a papilla. Histologically, it closely resembles both the mammalian sebaceous glands and the holocrine glands of reptiles. The product of the uropygial gland is transferred by the beak of the bird to the feathers, and is important for their maintenance. It may also serve to regulate the fungal and microbial species on the plumage, contain a scent for intraspecific communication, and perhaps distribute ergosterol for conversion to vitamin D, which is then ingested or absorbed. The gland is hormonally controlled and appears to be sensitive to progesterone [13] and androgens [14].

Mammals

Nearly all mammals have both holocrine and merocrine glands. Only whales lack sebaceous glands, and only whales, elephants, sea cows and scaly anteaters have no tubular glands in their skin.

Merocrine glands occur in many different sites and serve several functions. The tubular glands associated with hair follicles were designated by Schiefferdecker [15] as 'apocrine', on the grounds that secretion involved decapitation of at least some of the cells, as distinguished from 'eccrine' glands in which the cells remain intact. Although electron microscopy has cast doubt on these criteria, the terms remain useful. Alternative designations of 'epitrichial' and 'atrichial' have been proposed, but apocrine glands do not invariably open into hair ducts. In primates, most tubular glands can, in fact, be clearly assigned to one type or the other on histochemical grounds.

A major function of sebaceous and apocrine glands is the production of scent for intraspecific communication. Although sebaceous units occur throughout hairy skin and so, in some species, do apocrine units, they also occur in batteries to form discrete scent organs [16,17]. Such structures are found in most mammalian orders and can occur in almost any area of the body. Some, such as the chin gland of the rabbit, contain only tubular units; there are those, such as the supracaudal gland of the guinea pig, that are purely sebaceous; and others, such as the side glands of shrews, contain units of both kinds. The human axilla contains large hair follicles with functional holocrine and apocrine glands, which constitute a scent organ of this type [18].

Eccrine glands are found in two sites. On footpads, including human soles and palms, they occur in many different mammals, and their main function appears to be to increase surface friction by moistening the keratin. On hairy skin, however, where they function to cool the body by sweating, they occur only in primates and are most abundant in humans.

Pigment cells

Animal colours [1–3]

Colours abound throughout the animal kingdom. Some, such as the metallic sheen of beetles and the gleam of the feathers in the peacock's tail, are produced by *interference*, i.e. by the reflection of light from both the outer and inner surfaces of a film. So-called structural colours can also be produced by *diffraction*, which accounts for the iridescence of the wet bristles of the 'sea mouse' (*Aphrodita*), or by *scattering* of the shorter waves of white light by very small particles, a phenomenon that produces the pale blue of the clear sky or the bright blue on the mandrill's face. The blue colour of the human Mongolian spot is a similar optical effect (Chapter 38).

Most colours are, however, due to pigments. The most widespread and the most important in humans is *melanin*, which also gives colour to the feathers of blackbirds, black beetles and slugs, and fills the ink sacs of the octopus and the squid. Melanin exists in two forms: black or dark-brown *eumelanin* and reddish or yellow *phaeomelanin*. Both are oxidation products of tyrosine.

Not all brown or black pigments are melanin. Insects and crustacea have *ommochromes*, synthesized from the amino acid tryptophan. A third group are the white, yellow and orange *pterins*, which give colour to the wings of butterflies and to spotted salamanders. Fourth, there are the widespread *carotenoids*, imparting colour to red sponges, goldfish and pink flamingos, for example, as well as to human skin. None can be synthesized by animals; all are acquired by eating plants. Fifth, of particular importance in human skin colouration, is the oxygen-carrying pigment of the blood, *haemoglobin*, which is responsible for the pink tint of white people and the bright red of human lips and baboons' buttocks. This list is not exhaustive. For example, some marine worms contain a green respiratory pigment known as *chlorocruorin*, and a red pigment, *echinochrome*, is found only in sea urchins and in the bones and teeth of the Pacific sea otter which feeds on them. This last material may seem of little interest to dermatologists, except to remind them that human skin colour may be similarly acquired, for carotenaemia is caused by the ingestion of excessive amounts of food rich in carotenoids.

Chromatophores and melanocytes

In many animals, pigment is formed in specialized cells. Pigment cells start their evolutionary history in coelenterates and appear to reach the peak of their variety in each of two unrelated groups: the molluscs and the vertebrates.

Molluscs

Molluscs contain not only melanins and ommochromes but also porphyrins and bilichromes. The squid, cuttlefish and octopus have assemblages of differently coloured pigment cells, or chromatophores, containing yellow, orange, red, red–brown, blue, violet–black or black ommochromes. Underlying these are so-called iridiophores and leukophores, which absorb, reflect and scatter light [4,5]. The chromatophores can be expanded rapidly or

contracted by smooth muscle fibres that are attached to the periphery of each cell. Contraction of the muscle pulls out the cell and its pigment into a flat plate, and relaxation causes the cell and pigment to concentrate into a small dot. The animals are thus able to change colour and pattern to match their backgrounds extremely rapidly. The information about background is obtained through the eye and mediated through colour centres in the brain [6].

Vertebrates in general

The pigment cells of vertebrates differ from those of molluscs in that their size is not controlled by muscle fibres [7]. There are two mechanisms of colour change, each involving a distinctive cell. Short-term *physiological* colour change is brought about by active redistribution of pigment-containing organelles within the boundaries of relatively large cells, which are collectively known as *chromatophores*. Long-term *morphological* colour change results from alterations in the numbers of smaller pigment cells known as *melanocytes*, or in the amount of pigment each produces. The dendritic pigment cell of the human epidermis is an example.

Fish

Fish contain chromatophores in both the dermis and the epidermis, but in most species the dermal chromatophores are the more important [8]. Several types can be distinguished, namely black or brown melanophores, red erythrophores and yellow xanthophores. In each, the pigments, namely melanins, carotenoids and pteridines are contained within organelles. In addition, there are leukophores and iridiophores containing colourless pigments, mainly guanine. Iridiophores cannot translocate the pigment-containing organelles; the guanine is deposited in crystalline platelets. Their function is to produce physical colours by reflection, scattering or diffraction.

There are two modes of regulation: hormonal and nervous. Hormones, in particular the melanocyte-stimulating hormone (MSH) of the pituitary, appear to provide the more primitive mechanism. It is the only one present in lampreys, the prevailing means of control in sharks, and it is retained in the evolution of amphibia, reptiles and mammals. Only in some bony fish does nervous control take over, making it possible, for example, for flatfish such as the flounder to mimic a chequerboard bottom on which it is placed.

Amphibia and reptiles

Amphibia also have both dermal chromatophores, of similar types to those found in fish (Fig. 2.4), and dendritic epidermal melanocytes [9].

The pattern is continued in reptiles [10]. Lizards have a layer of melanophores in the dermis, with two to four layers of iridiophores above them and, more superficially, xanthophores and erythrophores [11,12]. In addition, melanocytes occur in the basal layer of the epidermis and transfer melanosomes into the keratinocytes.

Birds

In birds [13], melanocytes are responsible for transferring eumelanin and phaeomelanin into the feather germ to produce black, grey, brown and related tints, and also to form the dark background for structural blue and interference colours. Carotenoids, also, may be responsible for yellow and red, and sometimes even for green, violet and blue. It is of interest that the pelican can produce cosmetic colouration of the plumage by a rose-coloured secretion from the preen gland.

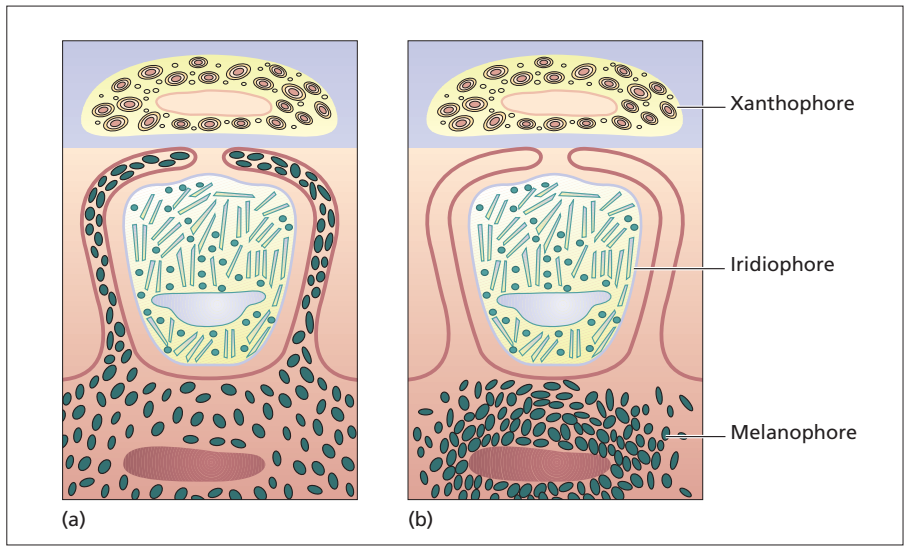

Fig. 2.4 The dermal chromatophore unit of amphibia. Uppermost, just below the basement membrane, is a layer of yellow pigment cells (xanthophores). Immediately beneath are reflecting iridiophores lying over melanophores, which engulf them with dendrites. In adaptation to dark backgrounds, melanosomes fill the dendrites to obscure the reflecting surface (a). When the melanosomes retreat, the dark pigment becomes almost completely obscured by the xanthophores and iridiophores and the animal appears light (b).

The striking white colour of many aquatic birds, for example, the albatross, seagull and swan, is entirely structural. Pigment-free feathers contain irregularly distributed air-filled cavities, which equally reflect all wavelengths of light. Some blue, green and violet colouration, for example that of kingfishers and parrots, is produced by scattering or interference.

Mammals

In comparison with their vertebrate relatives—fish, amphibia, reptiles and birds—and, indeed, many invertebrates, mammals are drab animals. Even the power to perceive colours has been lost in most mammalian orders. Animals as diverse as crabs, octopuses, insects, fish and birds all have colour vision, but dogs are colour blind, and the bull remains indifferent to the redness of the rag even if enraged by the antics of the matador. The evolutionary explanation is that for many millions of years our ancestors were small, insect-eating, nocturnal mammals for which colour vision had no adaptive advantage.

All was not lost forever. Something was retained and something was regained. All mammals retain epidermal melanocytes, and monkeys, apes and humans share with some species of squirrel the power to appreciate colours. The return of colour as an item of social commerce is symbolized, for example, by the rump of the sexually receptive female macaque or the bright-blue scrotum of the vervet monkey.

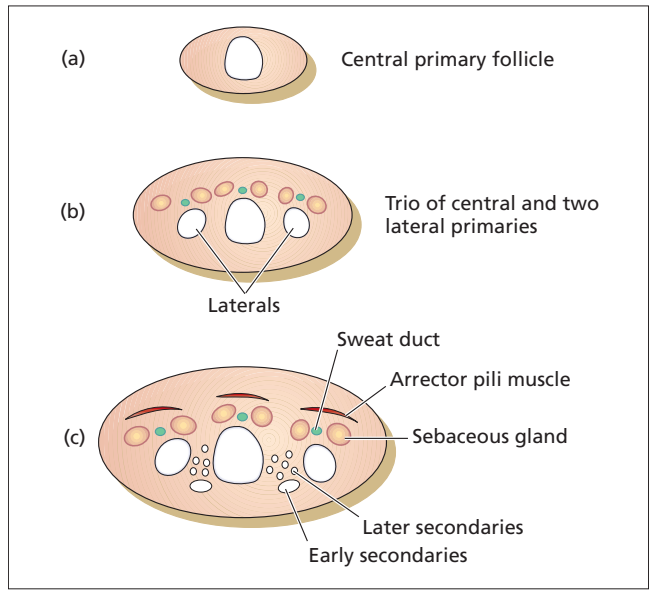

Fig. 2.5 Stages in the development of a follicle group in the sheep.

The skin of mammals

Mammals owe their evolutionary success to many features, and changes in the skin were critical factors. The development of a tough, flexible but impermeable integument enhanced the capacity for movement, especially on land, and the evolution of the hair follicle and its associated structures not only provided the essential insulation against heat loss, but also the glands for suckling the young.

How did the first hairs arise? In the virtual absence of fossil evidence, only speculative answers can be suggested. The most favoured idea [1,2] is that the first hairs were sensory structures, perhaps similar to the tylotrichs of living mammals, between the scales of reptilian ancestors. A model may be provided by the tails of many mammals in which groups of three follicles occur between epidermal scales, as first noted by De Meijere in 1894 [3]. Embryological evidence is certainly consonant with this view. In many mammalian families, the first follicles to develop are those of the whiskers, and in humans, similarly, follicles form on the upper lip, chin and eyebrows long before they take shape elsewhere. Moreover, the development of all follicles in many different mammals involves the formation of trio groups at an early stage, even though the ultimate patterns may greatly vary.

Sheep are the most widely studied and described species [4]. The first central primary follicles appear on the flank of lambs at about 60 days of fetal age (Fig. 2.5). Subsequently, a lateral primary follicle forms on each side of the central to form the trio group. Each of the three follicles has a sebaceous and an apocrine gland, as well as an arrector muscle. After 90 days of gestation, secondary

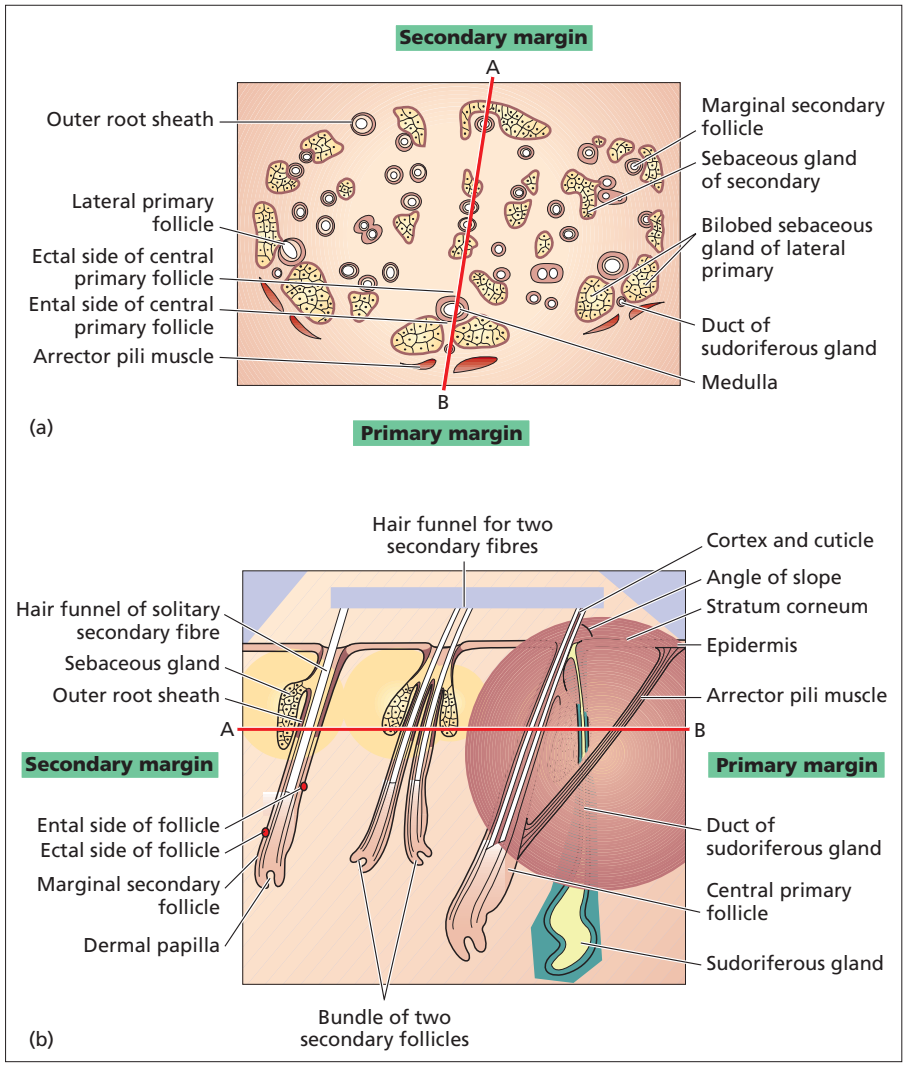

Fig. 2.6 Diagram of a sheep follicle group (a) in transverse section and (b) in longitudinal section. (From Hardy and Lyne [5].)

follicles, lacking apocrine glands and arrector muscles, develop in between the primaries, on the side opposite to that with the glands, to form a group of five follicles, three primary and two secondary. The maturation of these secondary follicles is complete by birth. However, further groups of smaller secondary follicles mature after birth, and these may not have fibres for 2 or 3 months (Fig. 2.6). Primary follicles produce the coarse hairs of the outer coat, whereas secondary follicles form the fine underwool.

Although similar features can be recognized in many other mammals, it has to be admitted that the density and arrangement of follicle types varies greatly between species and between regions of the body. Thus, for example, the duck-billed platypus (*Ornithorhynchus*) an egg-laying mammal considered to be of the most primitive type, has, according to Carter [6], over 600 follicles per square millimetre of skin, with over 30 secondaries to each primary. The mole (*Talpa*) of the order Insectivora, which are considered to be the most primitive of placental mammals, similarly has a high density of follicles, which produce a thick coat of fine hairs. The mouse (*Mus*) has 50–150 follicles per square millimetre, with a ratio of secondaries to primaries of two to five. Four types of fibre have been described in mice and rats [7,8]. The larger monotrichs, awls and auchenes are produced by primary follicles; the finer zig-zags of the underfur grow from secondary follicles. This order of decreasing length is also probably the order of follicle initiation and fibre emergence. Only the vibrissae have emerged by birth (Fig. 2.7).

The coat shows wide variations, related to size and to lifestyle, throughout the mammalian orders. Larger animals in general have a lower density of follicles than the familiar rodents and fur species. For example, horses have 10–15 follicles per square millimetre and use apocrine glands for thermoregulation. Pigs have less than one [6]. The hippopotamus, one of the largest living terrestrial mammals, is hairless except for sparse bristles on the tail, ears and muzzle. This remarkable animal immerses itself in water during the day, but emerges to graze on land at night. The skin is adapted for this habit; thermoregulatory

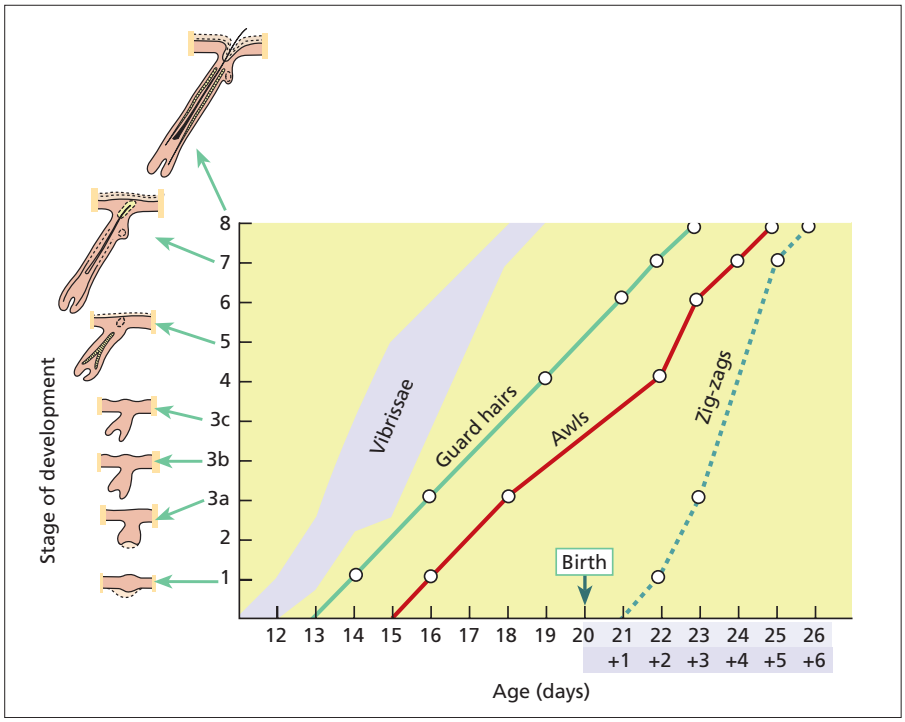

Fig. 2.7 Development of hair follicles in the mouse. Rudiments become evident on the 12th day of gestation, and Hardy [9] recognized 11 stages of development (1–8, with three subdivided). The presumptive dermal papilla, shown by a broken line in stages 1 and 3a, becomes engulfed in stages 3b and 3c. Hardening of the inner root sheath is seen in stages 4 and 5, and keratinization of the growing hair in stages 6 and 7. Eruption occurs at stage 8. At birth, the vibrissae but not the guard hairs or awls have emerged. Rudiments of the zig-zag follicles do not appear until the day after birth.

sweating is not required, but the apocrine glands produce a pink, sticky secretion that dries to form a protective and possibly antiseptic lacquer when the animal is on land.

The skin of primates

Origins and classification of primates [1–4]

The human species, *Homo sapiens*, is a member of the primates, an order of the class Mammalia. The traditional classification of primates is in two suborders—the Prosimii or so-called 'lower' primates (lemurs, lorises and tarsiers) and the Anthropoidea or 'higher' primates (monkeys and apes). The higher primates are composed of two groups, which had a common ancestor, but evolved separately in the New World and the Old World. A superfamily of the Anthropoidea, the Hominoidea, includes the apes and humans. All primates have a typical mammalian skin. Hair follicles occur over most of the body, and are lacking only on the footpads and other friction surfaces such as the contact areas of the prehensile tails of some New World monkeys or the knuckle pads of gorillas.

The evolution of Hominoidea [1–6]

Apes and men

The superfamily Hominoidea has traditionally been divided into the Pongidae, to include all the apes, and the Hominidae, to include humans and their recognizable antecedents. Now that the evidence for taxonomic relationships comes not only from fossil history and comparative anatomy but from biochemical analyses such as aminoacid and DNA sequencing, it is generally

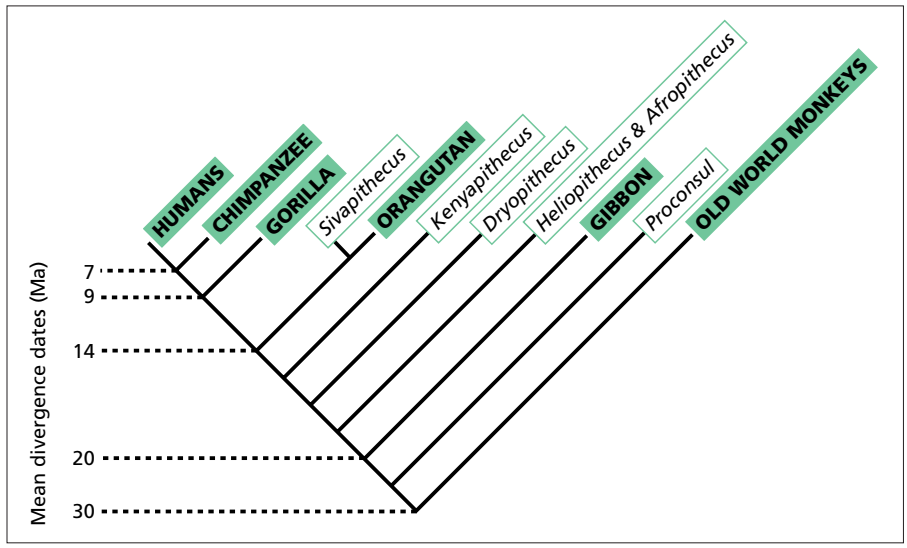

Fig. 2.8 A cladogram showing relationships within the Hominoidea and the divergence dates. Fossil forms are shown in lower case. (From Tattersall *et al*. [2].)

acknowledged that some modern apes are more closely allied to humans than to other apes.

The fossil evidence suggests that the hominids originated in Africa. Among the fossil apes of the Early Miocene, the most favoured candidate as the last common ancestor of both apes and humans is *Proconsul*, of which jaws, skulls and limb bones, assigned to more than one species, have been discovered in Kenya. The genus was named in 1933, and the name refers to a chimpanzee named Consul who then lived at London Zoo [3]. They are dated to around 22–17 Ma. Between 22 and 18 Ma, the gibbons (family Hylobatidae), which are the most primitive of living apes, diverged (Fig. 2.8).

The remaining genera are now put into a single family, the Hominidae, from which one subfamily, the Ponginae, including only the orangutan, diverged some 16–13 Ma, when it left Africa for Asia.

The other subfamily, the Homininae, embraces gorillas, chimpanzees, humans and their fossil relatives. This split also marks the development of different modes of locomotion, from a generalized tree-climbing ancestor. The orangutans suspended themselves in the trees by their arms (brachiation) and the African great apes specialized in terrestrial quadrupedalism (chimp, gorilla) and bipedalism (humans). The mean date for divergence of gorillas was 9 Ma and for the chimpanzee about 7 Ma.

The Australopithecines, which are recognized as human ancestors, and of whom there were several species, occur as fossils from around 4 Ma, but the molecular clock suggests they may be rather older.

Homo: the human genus

The genus to which modern human beings belong was given its title by Linnaeus in 1758, and the line to modern humans is considered to include several species of australopiths and *Homo*. Neanderthal Man is considered to be a variety of *Homo sapiens*.

Homo sapiens

The species now embraces not only the whole variety of human beings in the world today, and closely related forms, but also a range of archaic fossils, including Neanderthals.

'Neanderthal Man' was the name given to parts of a skeleton found in 1856 in a cave in a valley near Düsseldorf, the first indisputable example of a fossil man to be discovered [7].

The Neanderthals had many distinct anatomical features, and the stereotype is well known. They appear to date from the middle Pleistocene and to have spread widely over Europe and western Asia. Their evolutionary position is disputable, for, although in some respects they seem to be an intermediate between archaic and modern *Homo sapiens*, they had many unique characters that are not found in modern peoples. Neanderthals seem to have disappeared about 35 000 years ago, and the reasons for this are not clear—they may have been killed off by more modern *Homo sapiens*, or have interbred with them.

The early populations of modern *Homo sapiens* in Europe are known collectively as 'Cro-Magnons' after the site near Les Eyzies in the Dordogne, France, where what appeared to be a deliberately buried skeleton was disinterred in 1868. The association of the bones with flint tools of the Aurignacean type, and the stratigraphic evidence, dated them to the fourth glaciation period of the upper Pleistocene, overlapping the Neanderthals.

Genetic data support the view that all existing races of *Homo sapiens* arose from a single, relatively recent ancestor, in Africa—the 'single origin model' of human evolution [3–9]. By assuming a constancy of molecular

mutation, it has been estimated that European and Asian populations shared a last common ancestor about 40 000 years ago and, in turn, had common ancestry with an African population about 110 000 years ago. It is probable therefore that modern *Homo sapiens* originated from southern African ancestors during the African middle Stone Age from 120 000 to 40 000 years ago. Asian populations probably reached Australia as early as 40 000 years ago.

The three major geographical varieties of humans—Negroid, Caucasoid and Mongoloid—each with distinctive characteristics of skin and hair, have all become established within this relatively recent era.

From *Tupaia* to *Homo*: a variety of skins

Tupaioidea

Tree shrews have a thin skin that resembles that of the Insectivora, which are regarded as among the most primitive of living mammals [1]. The hair follicles are arranged in rows rather than in groups and have small but typically mammalian sebaceous glands opening into the pilary canals. Apocrine glands are widespread throughout the hairy skin and are borne by almost every follicle in some regions, although only on every second or third follicle on the scalp, arms and back. Of particular interest is that eccrine sweat glands are found not only in clusters in the soles, palms, fingers, toes, rhinarium and genital skin, but also, in fewer numbers, throughout the hairy skin. In this respect, *Tupaia* appears nearer to the Anthropoidea than the Prosimii.

Tarsiidae

The Philippine tarsier (*Tarsier syrichta*) [2] one of the three existing species, has a thin epidermis, only one or two cells thick, except on the friction surfaces. The dense, woolly pelage is made up of fine hairs similar to those of the Lorisidae. Hair follicles are in groups of six to nine, and each has a sebaceous gland but no arrector muscles. There is one apocrine gland to each hair group, with the duct opening directly to the surface. The friction surfaces have glands that appear to be of the eccrine type. On the lateral sides of the upper lip there are gigantic sebaceous 'labial' glands. Tarsiers have opposable thumbs and big toes, and bear nails on their digits, except for the second and third of the hind limb, which bear grooming claws.

Lorisidae

Varieties of bushbaby [3–5] have similar skins. The epidermis is relatively thin except over the lips, face and scrotum, and for the most part lacks demonstrable melanocytes. The fur is soft and very dense, and the hair follicles are arranged in groups of three or four in the pigmy bushbaby, and four to 26, but usually eight or nine, in the great bushbaby. Sebaceous glands open into the pilary canals. In the pigmy bushbaby, each hair group has one associated apocrine gland; in the great bushbaby there is only one gland in every three to five follicle groups. The ducts open independently of the pilary canals.

The skin of the potto (*Periodicticus potto*) [6,7] resembles that of bushbabies in most respects. The fur is dense and woolly, with sparse coarse hairs projecting 2 cm or more beyond the fur in the cheek, eyebrow and scapular regions. Hair follicles occur in groups of four to 20. Most sebaceous glands are small and open directly to the pilary canals, but they are larger and have ducts in the face, scalp and scrotum. There is usually only one tubular gland to each group of follicles, with the duct opening directly to the skin surface. Eccrine glands are confined to the palms, soles and digital pads.

The slender loris (*Loris tardigradus*) [8] and the slow loris (*Nycticebus coucang*) are similar to other members of the family. The hairy skin of the slender loris is very thin and lacks melanocytes. Hair follicles occur in clusters of four to 20, with small sebaceous glands, which open directly into each pilary canal. There are one or two tubular glands to each hair group and they open directly to the surface. 'Eccrine' glands occur on the palms and soles. Of particular interest is the existence of large apocrine scent glands, the brachial organs, on the medial side of each arm.

Lemuridae

The skin of lemurs has many similarities to that of lorises. In the black lemur (*Lemur macaco*) [9], the ring-tailed lemur (*Lemur catta* [10]), *Lemur mongoz* [11] and *Lemur fulvus* [12], the hair follicles occur in groups of various sizes, and most of the hair groups contain only a single apocrine gland. Both this and the sebaceous glands open directly to the skin surface.

In the black lemur, for example, the hair follicles are in islands of six to 14 and lack arrector muscles. The skin within each island is glabrous, and the sweat and sebaceous glands open directly between the orifices of the

pilary canals. The hairs are of two types, wool and guard hairs, in the ratio of three or four to one. The sebaceous glands are of two types: multiple acinar on the face, lips, scrotum and perianal region, and single acinar elsewhere. There are numerous melanocytes in the sebaceous glands as well as in the epidermis, and the sebum is yellow, brown or black.

Ceboidea

The skins of New World monkeys show considerable variety. Hanson and Montagna [13] considered that of the owl monkey (*Aotus trivirgatus*) to resemble that of prosimians in that it has a thin, fairly unpigmented epidermis. The hair follicles are arranged in elongated clusters of four to 20. Apocrine glands occur over the general body surface and open into the pilary canals, but eccrine glands are confined to the friction surfaces of the hands and feet. Large aggregations of sebaceous and apocrine glands occur in the sternal and subcaudal fields.

In contrast, the woolly monkey (*Lagothrix lagotricha*) [14] has a heavily pigmented epidermis and a near absence of dermal melanocytes, and thus appears to resemble the Old World lutong. At the same time, the hair follicles are formed in clustered groups as in the owl monkey and prosimians. Apocrine glands occur only in the tail and external genitalia.

The red-mantled tamarin (*Saguinus oedipus*) [15] appears to have characteristics of both Prosimii and Catarrhini. The epidermis, like that of the black lemur, is moderately pigmented, but the hair follicles are arranged in linear perfect sets, with one apocrine gland per hair group. Eccrine glands are confined to the friction surfaces, except for some in the brow and pubic region. A similar arrangement of hair follicles and a comparable distribution of apocrine and eccrine glands are found in the pigmy marmoset (*Callithrix pygmaea*) [16].

The glabrous skin of the prehensile-tailed, woolly, golden, spider and howler monkeys resembles that of their palms and soles in possessing eccrine glands. However, in the woolly monkey the glands are restricted to the tail and external genitalia; in the spider monkey they occur in the chest, axilla and back; and in the howler monkey they are present throughout the hairy skin.

The red uacari (*Cacajao rubicundus*) [17] is another New World monkey in which the skin shows many primitive features. Nevertheless, the hair follicles are arranged in independent perfect lines, just as are those of the Old World macaques and baboons. Uacaries are notable because, like the stump-tailed macaque and man, they undergo progressive balding of the scalp (Fig. 2.9). The process starts on the forehead and gradually extends to the frontal, parietal and occipital regions [18]. The follicles do not disappear, but become smaller and produce only vellus hairs. Baldness occurs in both sexes.

Fig. 2.9 *Cacajao calvus*, the white uacari. Uacaris are notable because both sexes undergo progressive balding of the scalp in which the follicles produce only vellus hairs. (Courtesy of Edward Parker, Oxford Scientific Films Ltd.)

Cercopithecoidea

The skins of the various members of the family Cercopithecidae, which include the rhesus monkey [19], the anubis baboon [20] and the lutong [21], have many features in common.

The epidermis is moderately thick in all species. In the rhesus monkey, for example, the stratum germinativum is three or four cells thick, there is a discontinuous stratum granulosum, which is especially well developed on the friction surfaces, and a compact stratum corneum, which becomes deep and dense in the ischial callosities.

The dermis varies with region. The papillary layer is most pronounced in the friction surfaces, the anogenital areas and the scalp.

Melanocytes occur in both epidermis and dermis, but they are not ubiquitous. The rhesus monkey, for example, appears to lack epidermal melanocytes except in the face, eyelids and friction surfaces. The skin is, nevertheless, pigmented in piebald fashion, the colour being derived entirely from melanocytes in the dermis.

In all species the hair follicles occur in linear groups. Each one has one or two large follicles flanked by smaller ones, usually making a total of three or four, although there may be up to seven. The stump-tailed macaque (Fig. 2.10) is of particular interest because all adult males,

Fig. 2.10 *Macaca arctoides*. Adult males of the stump-tailed macaque, but not females, become progressively bald from the forehead backwards. (Courtesy of Mikaail Kavanagh, Oxford Scientific Films Ltd.)

but not females, become progressively bald from the forehead backwards [22].

Sebaceous glands with one or two lobules occur generally, and multilobular glands are found in sites such as the eyelids, lips and external genitalia.

Apocrine glands with their ducts opening into the pilary canals are found throughout the hairy skin. In the anubis baboon [20] there are large apocrine glands sparsely distributed over the body, but forming large fields, which resemble the axillary organs of humans and apes on the chest.

Eccrine glands occur generally on the friction surfaces. However, they are also found throughout the hairy skin.

Hylobatidae

Only in females of the white-browed gibbon (*Hylobates hoolock*) does the skin appear to have been fully described. The epidermis is very thin throughout the general body surface, and when shorn of its black hairs the skin appears pink without apparent pigmentation. However, in the lips, vulva, eyelids, perianal region and pressure surfaces the epidermis is thick and has a good population of melanocytes.

Hair follicles are arranged in groups of three. Sebaceous glands are generally small, but they are larger in the lips, eyelids, vulvar and perianal regions. Most, but not all, open into the pilary canals. Both apocrine and eccrine glands occur throughout the hairy skin, but the apocrine are the more numerous. Unlike humans and the other apes, the gibbon has no axillary organs.

Homininae

Apart from humans, only the skin of the chimpanzee seems to have been described in detail. A study of the gorilla was confined to the male.

The gorilla (*Gorilla gorilla*) [23] has an entirely black skin, with pigment cells crowded into the epidermal ridges, where these are present, and elsewhere distributed uniformly along the basal layer and extending into the pilary canals. The pelage is in general sparse and formed by coarse, deeply pigmented hairs about 4 cm long, except on the cheeks and brow, which are covered mainly by vellus hair. Both the large and small hair follicles are grouped in clusters of two to five.

The sebaceous glands are generally small, but are larger on the cheek and upper lip. Small apocrine glands are sparsely distributed throughout the hairy skin and are always associated with hair follicles. Larger glands occur on the chest, areola, cheek and perianal region, and very large and numerous glands contribute to axillary organs, which closely resemble the human structures. Eccrine glands are found over the entire body, in hair and in glabrous skin.

One other interesting feature of the gorilla is the occurrence of friction pads on the knuckles, an adaptation for their use in walking. These pads resemble the palms and soles in their possession of dermatoglyphic configurations, a thick stratum corneum, an abundance of eccrine glands and numerous tactile end-organs.

The skin of the chimpanzee (*Pan troglodytes*) [24] resembles that of the gorilla and humans (Fig. 2.11). The epidermis is pigmented, with the greater concentrations of melanin in the ridges. The pelage of young animals is fairly dense, but that of adults is usually sparse. In adults, the forehead becomes denuded and animals may go bald. The hair follicles are in groups of two or three, but these become less obvious in the adult.

Sebaceous glands appear, in general, to be smaller than those of humans, although large ones associated with small hair follicles occur on the face. Apocrine glands are widely but sparsely distributed, except in the axillae, where they contribute to axillary organs, the exterior meatus, the upper throat region and the mons. They are surrounded by nerves that contain cholinesterases, and they show phosphorylase activity. Eccrine glands occur throughout the hairy as well as the glabrous skin. Their secretory epithelium is composed of characteristic dark, clear cells.

The skin of *Homo sapiens* will be described in detail elsewhere, principally in Chapters 3 and 4. It is, however, appropriate here to note that in its essentials human skin is similar to that of the gorilla and the chimpanzee. The epidermis is pigmented, but to various extents in different geographical races. The most important evolutionary development is the loss or great diminution in hair, except for that on the scalp, axillary and perineal areas. The scalp may become progressively bald with age, especially in males. Except for the friction surfaces, however, hair

Fig. 2.11 The chimpanzee (*Pan troglodytes*)—the nearest living relative of *Homo sapiens*. (Courtesy of Mike Hill, Oxford Scientific Films Ltd.)

follicles are present. Apocrine gland rudiments form, but they remain vestigial and effectively disappear, except in the axilla, areola and perineum. Eccrine glands occur throughout the body. Both types of tubular gland contribute to axillary organs.

Comparative anatomy

Eight different patterns of hair-follicle configuration have been discerned (Fig. 2.12), each one characteristic of one or a number of species [1]. Only in gibbons and gorillas have two arrangements, each in different areas of the body, been recognized.

The linear arrangement of repeating subunits of three or more follicles (linear perfect) occurs in tarsiers, the New World Ceboidea and the Old World Cercopithecoidea. Independent perfect lines and imperfect lines are found in a wide range of Old World monkeys and in some apes.

Independent circular clusters appear to be generally characteristic of lemurs, and clustered circular sets of lorises, supporting the conclusion that these Prosimians have deviated early from the main evolutionary line. The elongated clusters of the owl monkey (*Aotus*) add weight to the view that this is one of the most primitive of New World monkeys.

Random and paired groupings occur largely (but not exclusively) in the Hominoidea, suggesting that the hair groupings become less organized with phylogenetic advancement.

Changes in the skin glands are of the utmost importance in the evolution of the Hominoidea. No difficulties arise in relation to the sebaceous glands; they are present in all species of primate just as in nearly all other mammals. Small glands open into hair follicles throughout the hairy skin, and larger, multiacinar glands frequently

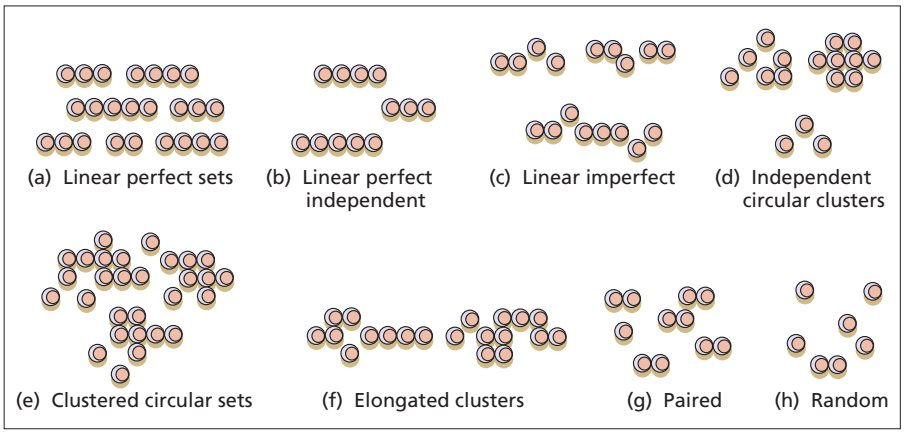

Fig. 2.12 Hair-follicle configurations as discerned by Perkins *et al*. [1].

occur in limited areas or as discrete glands, sometimes in association with tubular units.

The comparative anatomy and evolution of the merocrine glands is less clear-cut. Schiefferdecker's division into apocrine, in which secretion involves decapitation of the apical cytoplasm, and eccrine, in which the cells remain intact, is not entirely satisfactory, as evidence of necrobiotic secretory cycles is often lacking (Chapter 45). In the primates, at least, it is equally unsatisfactory to distinguish between 'epitrichial' glands, which normally develop from the external root sheath and remain attached to the hair follicle, and 'atrichial' glands, which develop from the superficial epidermis and remain independent, because Prosimians have glands which develop from the hair follicle but, in the adult, open separately to the skin surface. Moreover, as in the ring-tailed lemur, similar glands open directly on to the glabrous surfaces.

Broad distinctions can, nevertheless, be made between two types of gland. In humans, apocrine glands are much the larger. They contain cuboidal secretory cells with prominent nuclei and apical caps projecting into the lumen, as well as myoepithelial cells next to the basement membrane. In eccrine glands, three types of cell can be identified: myoepithelial cells, serous or clear cells, and mucous or dark cells. Apocrine glands rarely contain glycogen, lack phosphorylase, are low in succinic dehydrogenase and are not surrounded by cholinergic nerve fibres. Eccrine glands, in contrast, abound in glycogen, phosphorylase and succinic dehydrogenase activity, and are always wrapped with nerve fibres containing cholinesterase.

Montagna and Yun [2] have used these histological and histochemical criteria to describe the tubular glands throughout the primates. The distinctions are fairly clear-cut in Cercopithecidae, but less so in the lower primates. In the anubis baboon [2], for example, the large apocrine glands have thick, coiled secretory segments, rich in alkaline phosphatase but lacking phosphorylase; the eccrine glands have both clear and dark cells and are rich in succinic dehydrogenase and amylophosphorylase. However, there are regional differences. In the white-crowned mangabey, for example, the larger apocrine glands of the external genitalia show greater phosphorylase activity than do those of the hairy skin [3]. In the potto [4], the skin of the scrotum and vulva contains large apocrine glands, which, unlike those of the body surface, are surrounded by nerves rich in acetylcholinesterase.

It is therefore perhaps not surprising that Grant and Hoff [5] found that a dendrogram plot of sweat gland characters separated ceboids from non-ceboids (prosimians plus catarrhines) but otherwise did not correlate with groupings determined by other taxonomic criteria. It seems probable that apocrine glands are of more than one type, and that histochemistry may reveal more about their function than their phylogenetic history.

Eccrine glands should clearly be put into two categories. Those of the friction surfaces are present in many mammalian orders as well as in all species of primates. The fact that in humans the friction surface glands develop at about 3.5 months of gestation, 2 months before those elsewhere, reinforces the view that these are the more archaic. This does not, however, imply that the eccrine glands of the hairy skin are structures only recently acquired by the Hominoidea, for they are also present in *Tupaia* and in all the Old World monkeys. Only the New World monkeys and the Prosimii have diverged from this tradition.

The trend to nudity

Fossils cannot help in establishing when and why hair was lost in the course of human evolution, and there has been much speculation about the reasons for denudation, including an assumption that the reduction of body hair was a gradual process. It is, moreover, necessary to explain why humans have more highly developed eccrine sweat glands than any other mammal and a dermal blood vasculature far in excess of its own metabolic needs [1,2].

Physical anthropologists have generally neglected skin; for example, a famous book in which Wood Jones [3] documented the anatomical evidence for human arboreal ancestry does not mention it. Darwin [4], however, proposed the hypothesis of *sexual selection*, which was admirably designed to explain why body hair had virtually disappeared in the human species. The idea was, in essence, simple. As mating, in humans at least, and probably in many animals, was a matter of choice for both parties, each would select a partner with pleasing features.

Darwin first argues that from the presence of woolly hair, or *lanugo*, on the human fetus, and of rudimentary hairs scattered over the body in maturity, it could be inferred that humans are descended from some animal which was born hairy and remained so during life. He believed that this loss of hair was an inconvenience and probably an injury 'even in a hot climate, for he is thus exposed to the scorching of the sun, and to sudden chills, especially during wet weather. No one supposes that the nakedness of the skin is any direct advantage to man; his body therefore cannot have been divested of hair through natural selection' [4]. The absence of hair on the body was to a certain extent a secondary sexual character for, in all parts of the world, women are less hairy than men, 'therefore, we may reasonably suspect that this character has been gained through sexual selection'.

A more feasible argument, that hair loss was related to the descent from the trees and the adoption of a bipedal stance, has been advanced by several authors. Morris [5] regarded the achievement of nakedness as a major factor in human evolution. He puts the view that somewhere around 15 Ma a climatic change caused a diminution in the forest strongholds of the early apes. The ancestors of chimpanzees, gorillas, gibbons and orang-utans held on—and their numbers have been diminishing ever since. Human ancestors struck out, and left the forest for the savannah. Their diet changed; insects, eggs, tree frog-utans and small reptiles were added to fruit and nuts. Then they started to hunt mammals. The development of humans as hunters depended on a bipedal stance, which allowed sprinting, and the hands were freed for the making and use of tools and weapons. In parallel with this development of manual skill was enlargement of the brain and increase of mental ability.

Why should nudity have any selective advantage? Morris mentions several proposed explanations, such as a reduction in infestation with ectoparasites and, with particular regard to the female, a role in sexual attraction. He also refers to the suggestion of Hardy [6] that the ancestral hominid went through an aquatic phase, conceding that this nicely explained the existence of the thick layer of subcutaneous fat. Finally, he discusses the most commonly held view that the hairless condition is a cooling device. Although simply removing a hairy coat may not reduce body temperature, as heat can be gained as well as lost, the loss of the heavy coat of hair coupled with a great increase in sweat glands could be a cooling mechanism, not for minute-by-minute living in an intensely hot climate, but for the supreme movements of the chase in more moderate environmental temperatures. In short, hunting was a major factor in bringing about the skin changes.

A similar view is expressed by Brace and Montagu [7], who suggest that, by virtue of their hairlessness and sweat glands, human beings became the only major predators which could function exclusively in broad daylight. Until their advent as a serious menace, the big-game quadrupeds had less to fear from predators during the mid-day heat than at any other time.

Ardrey [8] developed the argument even further. In his view, the expansion of the brain depended on the eating of meat. After claiming that the association of fossil animal bones with hominid remains proved that butchering sites existed almost 2 Ma, long before the development of the brain to human capacity, he cites the statement of Crawford and Sinclair [9] that certain structural fats are essential for the development of the brain and nervous system. The necessary unsaturated fatty acids—linoleic and linolenic—originate in plants, and are concentrated and synthesized into chains by herbivores. Only carnivores, however, can acquire a whole season's storage from a single kill.

The evidence quoted in favour of an aquatic phase in the evolution of the ancestral hominid is that, alone among all primates, the hairs on the human body show precisely the pattern which would be followed by the flow of water over a swimmer. Moreover, *Homo sapiens* resembles other aquatic mammals in its layer of subcutaneous fat, and the erect walk might also be related to wading. The aquatic hypothesis undoubtedly has some attractions. In particular, it must have been easier for hominid ancestors to obtain food from the resources of the sea or even fresh water than by hunting animals larger and faster than themselves. A serious objection, if one is needed, is that the human's heavy endowment of eccrine sweat glands would appear to be utterly superfluous for aquatic life.

Whatever the doubts about the hunting hypothesis, it seems undeniable that the reduction in hair density and

the development of eccrine glands provides a mechanism for keeping cool, perhaps especially for the dispersal of metabolic heat produced by short bursts of muscular activity. These evolutionary events were not, however, recent. Both the gorilla and the chimpanzee have relatively sparse hair in adult life, which suggests that the trend towards hairlessness existed before their divergence 9–7 Ma. Such sparsity could result from a reduction in hair density as well as in hair size, and may simply be related to body size. Thus, Schwartz and Rosenblum [10] concluded from an examination of hair densities in 23 primate species, ranging from the marmoset to the gorilla, that increasingly massive primates have substantially fewer hairs per equal unit of body surface. As the 'equal units' referred to were 'relative hair densities' for which the actual density of hairs per square centimetre had already been divided by the body surface area, the extent of the claimed allometric trend is difficult to assess. However, by estimating the weight of australopithecines from the skeletal remains, the authors conclude that substantial depilation of hominids probably occurred prior to and not after their migration from forest to grassland.

Similarly, eccrine glands did not suddenly replace allegedly more primitive apocrine glands. It may be true that apocrine units function as sweat glands in some large mammals, such as horses, cattle and other ungulates, in which the hairy skin lacks eccrine glands. But the most primitive extant primate, the tree shrew, has both apocrine and eccrine glands in the hairy regions, as do Old World monkeys and apes. The evolutionary change in primates is thus simply a vestigialization of the apocrine glands accompanying that of the hair follicles.

Increase in body size does not explain everything. Viewed by hindsight at least, evolving hominids were preparing to move out of the tropical forests, first to the savannah, and ultimately to fan out globally, even to the edges of the polar seas. This change was accompanied by the adoption of bipedalism. In relation to gain or loss of heat and protection from solar radiation, an upright organism has completely different properties from one on all fours. Thus, Lee [11] has pointed out that a standing human receives on average only two-thirds as much solar radiation as a sheep of equivalent size and less than one-quarter at the noontime peak, and Wheeler [12] has calculated that a quadruped hominid would expose 17% of its total body surface area to direct radiation when the sun is at its zenith, whereas a bipedal hominid would expose only 7%.

Wheeler [12] points out that many mammals are able to keep the brain at a lower temperature than the rest of the body by dissipating heat through a counter-current system. It is exchanged between a carotid rete and the venous blood system, which drains the mucosal linings of the nasal chamber and turbinates, where cooling by evaporation occurs. Primates lack this system, and can only protect the brain from thermal damage by restricting rises in overall body temperature. The thermoregulatory advances in the evolution of *Homo* removed the physiological restraint and made the rapid expansion of the brain possible.

Why does hair persist in certain areas? The male beard is undoubtedly a sexual character, as its production requires high levels of male hormone. Whether as a visual signal it is directed towards females, or other males, or both, is unclear; ethologists have conveniently invented the term 'socio-sexual' to cover such ambiguous situations. Hair on the trunk of males is similarly androgen dependent and must be put in the same category. Pubic and axillary hair also clearly serves a socio-sexual purpose, as it develops, in both sexes, only after puberty. It is probably part of scent-disseminating systems.

Little controversy surrounds the assumption that scalp hair remains to protect bipedal animals from radiation in the mid-day sun. Long hair would similarly protect the shoulders and could, indeed, provide a complete shield for both mother and infant. However, the fact that long, straight scalp hair is generally characteristic only of the Caucasoid and Mongoloid geographical races and Negroids more often have curved or crimped hair would seem to invalidate any sweeping generalizations.

The loss of scalp hair in some adults, particularly males, is not entirely a human propensity, as it is presaged in the uacari, the stump-tailed macaque and the chimpanzee. Montagna [1] has regarded scalp baldness simply as part of the evolutionary trend to complete denudation. But what is important is that baldness, although hereditary, is androgen dependent. It is thus manifested principally in males, notwithstanding that less obvious diffuse hair loss in women probably has a similar aetiology. Does baldness therefore have a direct selective advantage to males alone? Or could its cosmetic disadvantage be linked with some other unidentified benefit?

Chapter 3

Anatomy and Organization of Human Skin

J.A. McGrath, R.A.J. Eady & F.M. Pope

Components of normal human skin

Human skin consists of a stratified, cellular epidermis and an underlying dermis of connective tissue [1–5]. The dermal–epidermal junction is undulating in section; ridges of the epidermis, known as rete ridges, project into the dermis. The junction provides mechanical support for the epidermis and acts as a partial barrier against exchange of cells and large molecules. Below the dermis is a fatty layer, the panniculus adiposus, usually designated as 'subcutaneous'. This is separated from the rest of the body by a vestigial layer of striated muscle, the panniculus carnosus.

There are two main kinds of human skin. Glabrous skin (non-hairy skin), found on the palms and soles, is grooved on its surface by continuously alternating ridges and sulci, in individually unique configurations known as dermatoglyphics. It is characterized by a thick epidermis divided into several well-marked layers, including a compact stratum corneum, by the presence of encapsulated sense organs within the dermis, and by a lack of hair follicles and sebaceous glands. Hair-bearing skin (Fig. 3.1), on the other hand, has both hair follicles and sebaceous glands but lacks encapsulated sense organs. There is also wide variation between different body sites. For example, the scalp with its large hair follicles may be contrasted with the forehead, which has only small vellus-producing follicles, albeit associated with large sebaceous glands. The axilla is notable because it has apocrine glands in addition to the eccrine sweat glands, which are found throughout the body. Regional variation is further considered below.

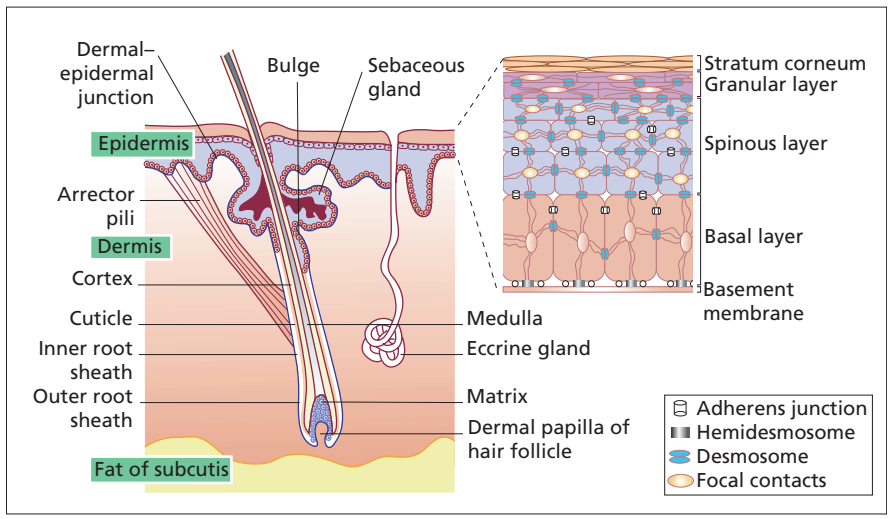

Fig. 3.1 The skin and its appendages.

The superficial epidermis is a stratified epithelium largely composed of keratinocytes that are formed by division of cells in the basal layer, and give rise to several distinguishable layers as they move outwards and progressively differentiate. Within the epidermis, there are several other cell populations, namely melanocytes, which donate pigment to the keratinocytes (Chapter 39), Langerhans' cells, which have immunological functions (Chapter 10) and Merkel cells.

The hair follicles comprise pockets of epithelium that are continuous with the superficial epidermis. They undergo intermittent activity throughout life. During the active phase, the follicle envelops at its base a small papilla of dermis. A bundle of smooth muscle, the arrector pili, extends at an angle between the surface of the dermis and a point in the follicle wall. Above the insertion, the holocrine sebaceous gland opens by a short neck into the pilary canal, and some follicles in certain areas of the body, notably the axilla, have, in addition, an apocrine gland. Also derived from the epidermis, and opening directly to the skin surface, are the eccrine sweat glands, present in every region of the body in densities of 100–600/cm^2.

The basis of the dermis is a supporting matrix or ground substance in which polysaccharides and protein are linked to produce macromolecules with a remarkable capacity for retaining water. Within and associated with this matrix are two kinds of protein fibre: collagen, which has great tensile strength and forms the major constituent of the dermis, and elastin, which makes up only a small proportion of the bulk. The cellular constituents of the dermis include fibroblasts, mast cells and histiocytes (monocyte/macrophages). The dermis has a very rich blood supply, although no vessels pass through the dermal–epidermal junction.

The motor innervation of the skin is autonomic, and includes a cholinergic component to the eccrine sweat glands and adrenergic components to both the eccrine and apocrine glands, to the smooth muscle and the arterioles and to the arrector pili muscle. The sensory nerve endings are of several kinds: some are free, some terminate in hair follicles and others have expanded tips. Only in glabrous skin are some nerve endings encapsulated. Sense organs are described later in this chapter.

Embryology [1,2]

Origin of the skin

The skin arises by the juxtaposition of two major embryological elements: the prospective epidermis, which originates from a surface area of the early gastrula, and the prospective mesoderm, which is brought into contact with the inner surface of the epidermis during gastrulation [3,4]. The mesoderm not only provides the dermis but is essential for inducing differentiation of the epidermal structures, such as the hair follicle in mammals [5]. Indeed, an influence from the dermis is essential for the maintenance of adult epidermis [6], although organized dermis is not in this instance mandatory, the property also residing in powdered dermis or tendon [7].

The neural crest also makes an important contribution to the skin, namely the pigment cells, although their bulk is small.

The timing of the events during development is summarized in Table 3.1.

Epidermis

The development of the epidermis (and its appendages) relies on specific initiation signals. Although complex, critical events appear to be governed by opposing interplay between the Notch and Wnt (wingless-related) signalling pathways, with β-catenin, Lef1 and Notch peptide all having key roles [9]. Signals from the Sonic hedgehog pathway and bone morphogenetic proteins (BMPs) also are important in early embryogenesis, notably in determining whether cells have an ectodermal or neural fate. Specifically, BMP signalling promotes ectodermal development, while Sonic hedgehog promotes neural tube and

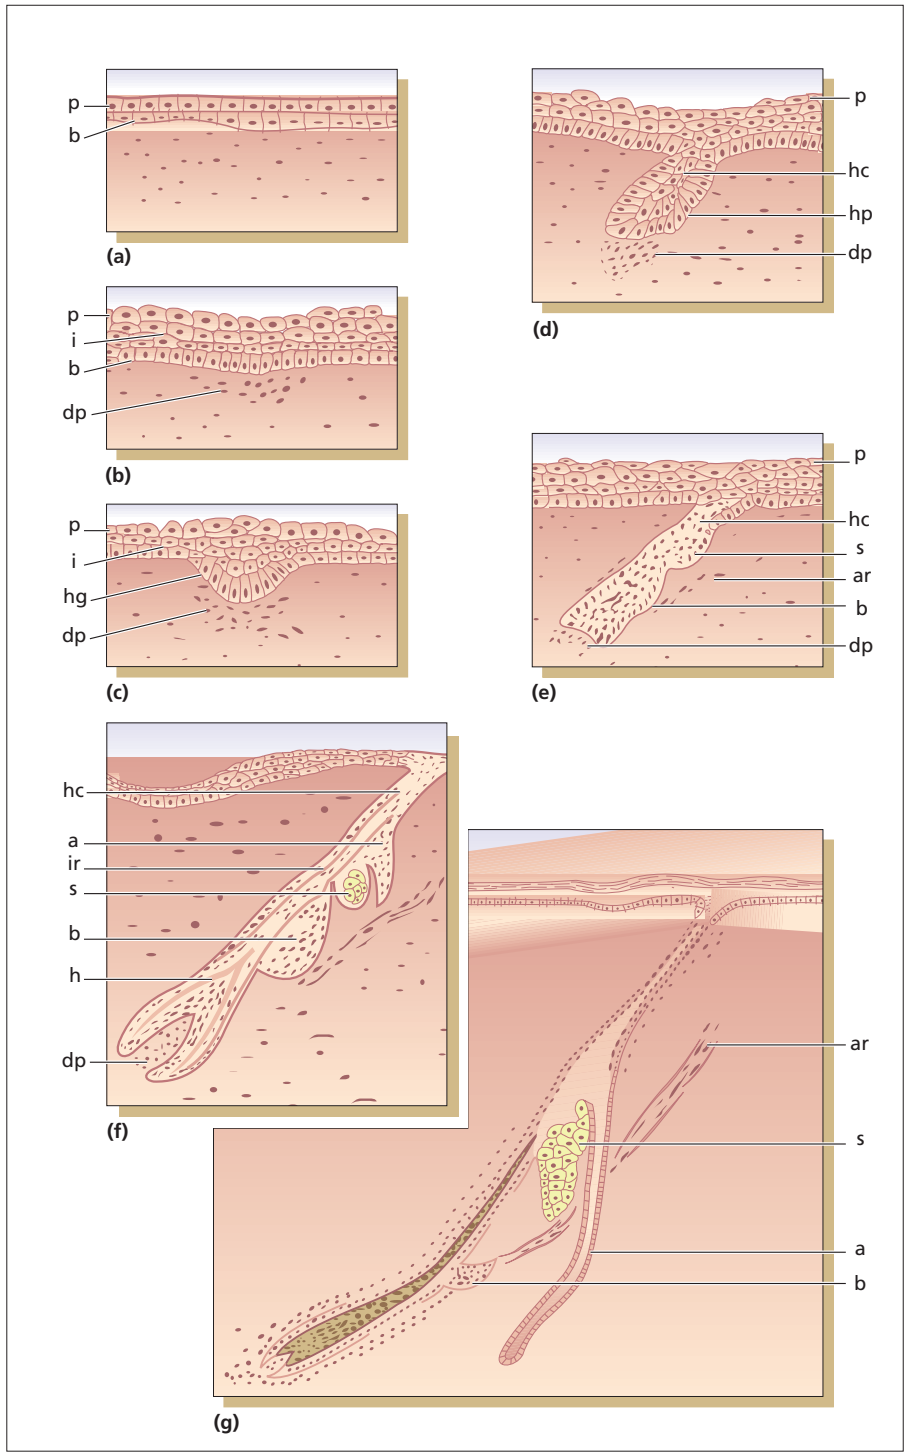

Fig. 3.2 Development of epidermis, hair follicle and associated structures. (a) Section of skin of embryo at about 4 weeks. The periderm (p) is clearly seen, and a basal or germinative layer (b) appears in some areas. (b) Skin at about 11 weeks. The epidermis is made up of basal cells, cuboidal in shape (b), and cells of the stratum intermedium (i) are beginning to appear above them. The periderm (p) consists of a single cell layer. Mesenchyme cells (dp) are beginning to aggregate below a presumptive hair follicle. (c) Hair germ (hg) stage. Basal cells are now columnar and starting to grow downwards. (d) Hair peg (hp) stage. Cells of the so-called 'hair canal' (hc) form a solid strand. (e) Bulbous hair peg. Note the solid 'hair canal' (hc), sebaceous gland rudiment (s), bulge (b) for attachment of developing arrector muscle (ar). (f) Later stage showing apocrine rudiment (a), sebaceous gland (s) now partly differentiated, and bulge (b). The dermal papilla (dp) has been enclosed and a hair (h) is starting to form, with an inner root sheath (ir). (g) Complete pilosebaceous unit of axillary skin from a 26-week-old fetus. The sebaceous gland (s) is well differentiated and the apocrine gland (a) is canalized.

central nervous system (CNS) development [10]. Thus, a complex interaction between these two components, as well as signals from fibroblast growth factors (FGFs) and additional regulatory control mechanisms from the Wnt pathway, underlies the preliminary stages of epidermal development.

In about the third week of fetal life, the epidermis consists of no more than a single layer of undifferentiated, glycogen-filled cells [8]. In a 4- to 6-week-old fetus [2], however, two layers of cells can be distinguished, the periderm or epitrichial layer and a stratum germinativum (Fig. 3.2). The periderm [8] is a purely embryonic structure (Fig. 3.3), which is unique to primates: it is ultimately lost *in utero* as the true epidermis keratinizes beneath it.

Between 8 and 11 weeks (crown to rump length 26–50 mm) a middle layer starts to form (Fig. 3.2). Glycogen is

Fig. 3.3 Scanning electron micrograph of an 85–110 day (estimated gestation age) human embryo. Single globular blebs project from the periderm cells. (Courtesy of Professor K.A. Holbrook, University of Florida, Gainesville, FL, USA.)

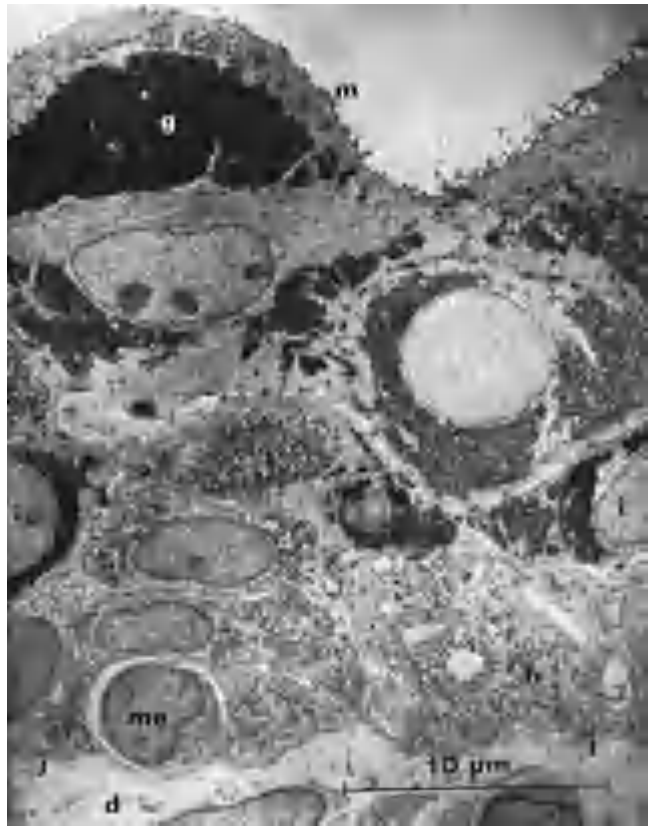

Fig. 3.4 Electron micrograph of the full-thickness epidermis from the back of a 14-week human fetus. Osmium fixation and lead staining. The periderm cells are full of glycogen (g) and have microvilli (m) at their amniotic border. Cells of the intermediate layer (i) also contain glycogen. Basal-layer cells (b) have lost glycogen by this stage. Just above the dermal–epidermal junction (j) is seen a melanocyte (me); the surrounding space indicates that it is a recent immigrant from the dermis (d). (Courtesy of Professor A.S. Breathnach, St John's Institute of Dermatology, London, UK.)

abundant in all layers, and a few microvillous projections occur at the surface of the periderm. The surface cells, as viewed by the scanning electron microscope, are flat and polygonal [11].

By 12–16 weeks (crown to rump length 69–102 mm), there are one or more intermediate layers. These cells contain mitochondria, Golgi complexes and a few tonofilaments, as well as abundant glycogen both within and between the cells (Fig. 3.4). Microvilli become much more numerous.

From this stage onwards, dome-shaped blebs start to project from the centres of the periderm cells (Fig. 3.3). At first the blebs are simple (Fig. 3.4), but later their surface becomes dimpled and infolded. Between 16 and 26 weeks, the intermediate layers increase in number, and by 21 weeks keratohyalin granules appear in the uppermost layer. The elevations of the periderm become cast off into the amniotic fluid, and by 24 weeks the periderm cells start to separate from the embryo. Together with shed lanugo, sebum and other materials, they form the vernix caseosa.

Hemidesmosomal and desmosomal proteins are already demonstrable in the basal keratinocytes at 10 weeks. By 14 weeks, basal keratins are expressed by the basal cells and skin-differentiation keratins are expressed by cells of the middle layer. Filaggrin, the protein of the granular layer, is first detectable at 15 weeks.

The periderm may be no more than a protective investment for the fetus before keratinization of the epidermis. On the other hand, features such as the abundant microvilli, raised blebs, coated- and smooth-membrane vesicles and increasing cell size, suggest it may have an important embryonic function. The microvilli with their 'fuzz' coat of mucopolysaccharide are similar to the modifications of the luminal border of the intestinal mucosa cell. All these considerations suggest that the periderm might be concerned with the uptake of carbohydrate from the amniotic fluid [11].

Hair follicles and apocrine glands

The earliest development of the hair rudiments [12–14] occurs at about 9 weeks in the regions of the eyebrow, upper lip and chin. This represents an initial response to the first of three discrete mesenchymal-epithelial exchanges that orchestrate hair follicle formation [15]. The first sign of a hair follicle is a crowding of nuclei in the basal layer of the epidermis, the so-called primitive hair germ or pregerm stage (Fig. 3.2b). This occurs in response to a primary message from the subjacent mesenchyme. The pregerm passes rapidly into the hair germ stage, the

basal cells become high; the nuclei become elongated and the structure starts to grow downward into the dermis. At the same time, mesenchymal cells and fibroblasts increase in number to form the rudiment of the hair papilla beneath the hair germ. These events are mediated by a second series of signals from the expanding epithelial cells. At this stage it is known as the hair peg (Fig. 3.2d). The outer cells of the hair peg are arranged radially to the long axis, and are columnar in shape, those at the advancing matrix end being conspicuously tall and narrow. As the germ develops, it grows obliquely downwards, and the advancing extremity becomes bulbous, gradually enveloping the mesodermal papilla. Proliferation and differentiation are then enhanced by a third series of signals emanating from the dermal papillae. At this bulbous hair-peg stage, two epithelial swellings appear on the posterior wall of the follicle. The lower one is the bulge to which the arrector muscle becomes attached, and the upper is the rudiment of the sebaceous gland. In many follicles, a third bud later appears above the sebaceous gland; this is the rudiment of the apocrine gland. Such rudiments develop in a large number of the follicles, including some on the scalp, face, chest, abdomen, back and legs, as well as in the axilla, mons pubis, external auditory meatus, eyelids, circumanal area, areola region of the breast, labia minora, prepuce and scrotum, where they survive in the adult.

As the bulbous hair peg grows downwards and differentiates, the first cells of the inner root sheath (IRS) begin to form above the region of the matrix. The matrix continues to burrow deeper, and above the root sheath the inner cells of the follicle grow upwards into the epidermis, to form the hair canal.

The different mesenchymal-epithelial cues involve several signalling pathways including Notch, Sonic hedgehog and Wnt, as well as contributions from FGFs and BMPs. There are also marked changes in certain cell adhesion proteins, notably E-cadherin and P-cadherin [15].

The hair follicles are arranged in patterns, usually in groups of three. It appears that the first follicles develop over the surface at fixed intervals of between 274 and 350 μm. As the skin grows, these first germs become separated, and new rudiments develop between them when a critical distance, dependent on the region of the body, has been reached. Commonly, follicles occur in groups of three, with the hairs arranged on a straight, short line, more or less transverse to the grain or slant of the hair. There is no large-scale destruction of follicles during postnatal development, only a decrease in actual density as the body surface increases; nor do any new follicles develop in adult skin.

Sebaceous glands [16,17]

These are, at first, solid, hemispherical protuberances on the posterior surfaces of the hair pegs. The cells contain moderate amounts of glycogen, but soon the cells in the centre lose this, and become larger and foamy as they accumulate droplets of lipid. The sebaceous glands become differentiated at 13–15 weeks, and are then large and functional. The sebum forms a part of the vernix caseosa. At the end of fetal life, sebaceous glands are well developed and generally large. After birth, the size is rapidly reduced, and they enlarge to become functional again only after puberty.

Eccrine glands [18,19]

These start to develop on the palms and soles at about 3 months, but not over the rest of the body until the fifth month. In embryos of 12 weeks, the rudiments of eccrine sweat glands are first identifiable as regularly spaced undulations of the stratum germinativum. Cells that form the anlagen are oblong, palisading and lie closely together, but otherwise they do not differ from the rest of the stratum germinativum. By 14–15 weeks, the tips of the eccrine sweat gland rudiments have penetrated deeply into the dermis, and have begun to form the coils. In the overlying epidermis, columns of cells that are destined to form the intraepidermal sweat ducts are recognizable. Each column is composed of two distinct cylindrical layers, comprising two inner cells that are elongated and curved so that they embrace the inner cylinder.

The intraepidermal duct appears to form by the coalescence of groups of intracytoplasmic cavities formed within two adjacent inner cells. In the intradermal segment, on the other hand, the lumen appears to form by dissolution of the desmosomal attachment plaques between the cells that compose the inner core of the eccrine duct germ.

Nails [20,21]

Nails begin to develop in the third month. In fetuses at 16–18 weeks (crown to rump length 120–150 mm) keratinizing cells from both dorsal and ventral matrices can be distinguished.

Melanocytes [22]

Melanocytes take their origin from the neural crest. This can be identified in early human embryos, but the elements arising from it soon lose themselves in the mesenchyme, and pigmented melanocytes cannot be identified, even in black skin fetuses, before 4–6 months of gestation. However, dopa-positive melanocytes can be demonstrated earlier.

Langerhans' cells [22,23]

These are derived from the monocyte–macrophage–histiocyte lineage and enter the epidermis at about 12 weeks.

Merkel cells [24]

These appear in the glabrous skin of the fingertips, lip, gingiva and nail bed, and in several other regions, around 16 weeks.

Dermis

It was at one time believed that the mesenchymal cells forming the dermis came from the ventrolateral part of the somite, which for that reason was named the dermatome. Although some cells may migrate from the dermatome and take part in the formation of the skin, most of the dermis is formed by mesenchymal cells that migrate from other mesodermal areas. These mesenchymal cells give rise to the whole range of blood and connective tissue cells, including the fibroblasts and mast cells of the dermis and the fat cells of the subcutis. Nevertheless, a new type of stem cell from the dermis, called skin-derived precursor (SKP) cells, has been identified [25]. Such cells are capable of being converted into several different cell types *in vitro* (e.g. neurones, smooth muscle cells or adipocytes) and might constitute a highly accessible source of pluripotential autologous stem cells.

The embryonic dermis is at first very cellular, and in the second month the dermis and subcutis are not distinguishable from each other. Fibrillar components shortly make their appearance, and regular bundles of collagen fibres are evident by the end of the third month. Later, the papillary and reticular layers become distinct and, at the fifth month, the connective tissue sheaths are formed around the hair follicles. Elastic fibres are first detectable at 22 weeks [26]. Beneath the dermis is a looser tissue characterized by fat islands that begin to form in definite places.

In embryos of 6–14 weeks, three types of cell have been described in the dermis: stellate cells, phagocytic macrophages and a granule-secretory cell, either a melanoblast or a mast cell [27]. From weeks 14–21, fibroblasts are numerous and active, and perineurial cells, pericytes, melanoblasts, Merkel cells and mast cells [28] can be individually identified. Another cell, of bone marrow origin, may be ancestral to the Langerhans' cell and the histiocyte [27].

At first, the undersurface of the epidermis is smooth, but during the fourth month, at the same time as the hair follicle starts to develop, it becomes irregular.

Touch pads become recognizable on the hands and fingers, and on the feet and toes, by the sixth week, and reach their greatest development at the 15th week. After this, they flatten and become indistinct. It is these areas, however, that determine the pattern of dermatoglyphs —the systems of papillary ridges—that take their place [29].

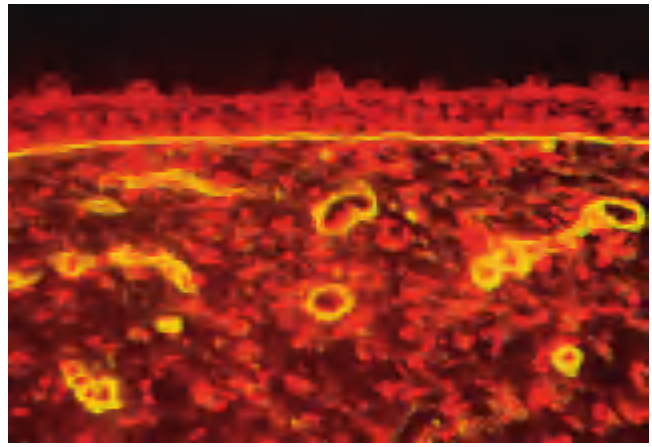

Fig. 3.5 Immunofluorescence photomicrograph showing staining with antitype IV collagen antibody of a section of the skin of a fetus of 15 weeks' gestational age. Note the surface periderm and the bright fluorescence at the dermal–epidermal junction and around the blood vessels. × 250.

Dermal–epidermal junction

A continuous lamina densa of the basement membrane becomes evident in the second month of gestation (Fig. 3.5), and hemidesmosomes appear in the third month [30].

Epidermis

Structure and ultrastructure [1,2]

The normal epidermis is a terminally differentiated, stratified squamous epithelium (Fig. 3.6). The major cell, making up 95% of the total, is the *keratinocyte*, which moves progressively from attachment to the epidermal basement membrane towards the skin surface, forming several well-defined layers during its transit. Thus, on simple morphological grounds, the epidermis can be divided into four distinct layers: *stratum basale* or *stratum germinativum*, *stratum spinosum*, *stratum granulosum* and *stratum corneum*. The term *Malpighian* layer includes both the basal and spinous cells. Other cells resident within the epidermis include melanocytes, Langerhans' cells and Merkel cells.

The stratum basale (Fig. 3.7) is a continuous layer that is generally described as only one cell thick, but may be two to three cells thick in glabrous skin and hyperproliferative epidermis. The basal cells are small and cuboidal (10–14 nm) and have large, dark-staining nuclei, dense cytoplasm containing many ribosomes and dense tonofilament bundles. Immediately above the basal cell layer,

In the dermis, collagen fibres (Co), histiocytes (Hi), monocytes (Mo) and mast cells (Ma) can be identified. ×1400. (Courtesy of Professor A.S. Breathnach, St John's Institute of Dermatology, London, UK.)

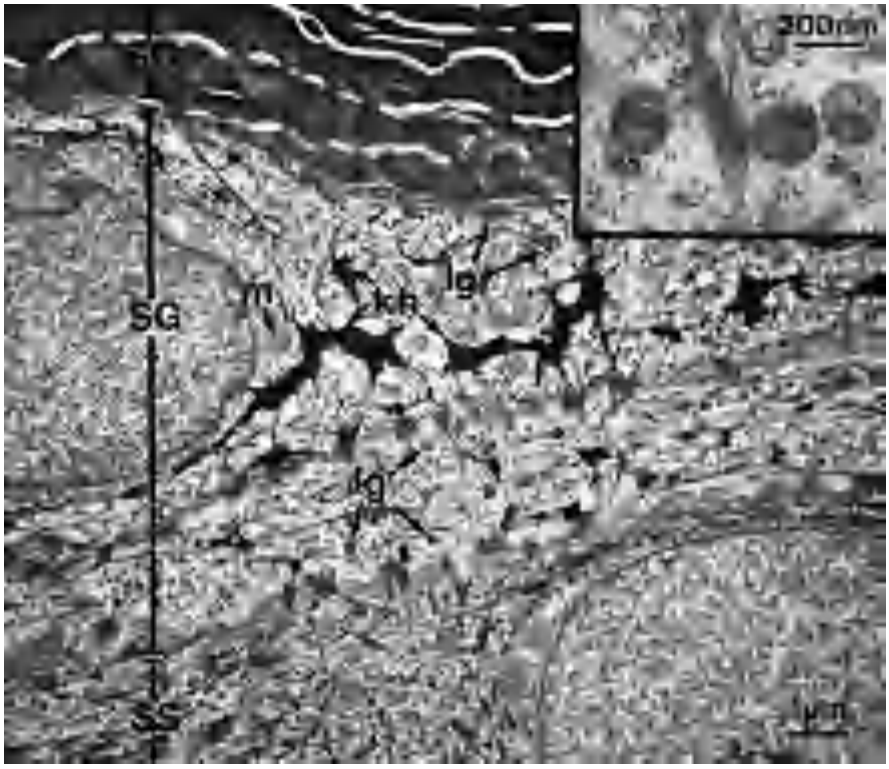

Fig. 3.8 Electron micrograph showing details of upper part of epidermis including stratum corneum (SC), stratum granulosum (SG) and the most superficial cell layer of stratum spinosum (SS). Note the irregularly shaped keratohyalin granules (kh) and the small, round lamellar granules (lg). The latter are present in both SS and SG and are smaller than mitochondria (m). Inset shows details of lamellar granules. See also Figs 3.19 and 3.20. Scale bar = 1 µm.

the epibasal keratinocytes enlarge to form the spinous/prickle-cell layer or *stratum spinosum* (Fig. 3.8).

The stratum spinosum is succeeded by the *stratum granulosum* or granular layer (see Fig. 3.8) because of the intracellular granules of keratohyalin. At high magnification, the dense mass of keratohyalin granules from human epidermis has a particulate substructure, with particles of irregular shape on average 2 nm length and occurring randomly in rows or lattices [3]. The cytoplasm of cells of the upper, spinous layer and granular cell layer also contains smaller lamellated granules averaging 100–300 nm in size, which are known as lamellar granules or bodies, membrane-coating granules or Odland bodies [2] (see Fig. 3.8). These are numerous within the uppermost cells of the spinous layer and migrate towards the periphery of the cells as they enter the granular cell layer. They discharge their lipid components into the intercellular space, playing important roles in barrier function and intercellular cohesion within the stratum corneum.

The outermost layer of epidermis is the stratum corneum (see Fig. 3.8) where cells (now corneocytes) have lost nuclei and cytoplasmic organelles. The cells become flattened and the keratin filaments align into disulphide cross-linked macrofibres, under the influence of *filaggrin*, the protein component of the keratohyalin granule, responsible for keratin filament aggregation [4]. The corneocyte has a highly insoluble cornified envelope within the plasma membrane, formed by cross-linking of the soluble protein precursor, *involucrin* [5], following the action of a specific epidermal transglutaminase also synthesized in the high stratum spinosum [6]. The process of desquamation involves degradation of the lamellated lipid in the intercellular spaces and loss of the residual intercellular desmosomal interconnections. In palmoplantar skin there is an additional zone, also electronlucent, the *stratum lucidum* between the granulosum and corneum. These cells are still nucleated, and may be referred to as 'transitional' cells.

Intercellular junctions

Several types of cellular junction exist that link adjacent keratinocytes and which are responsible for mechanical,

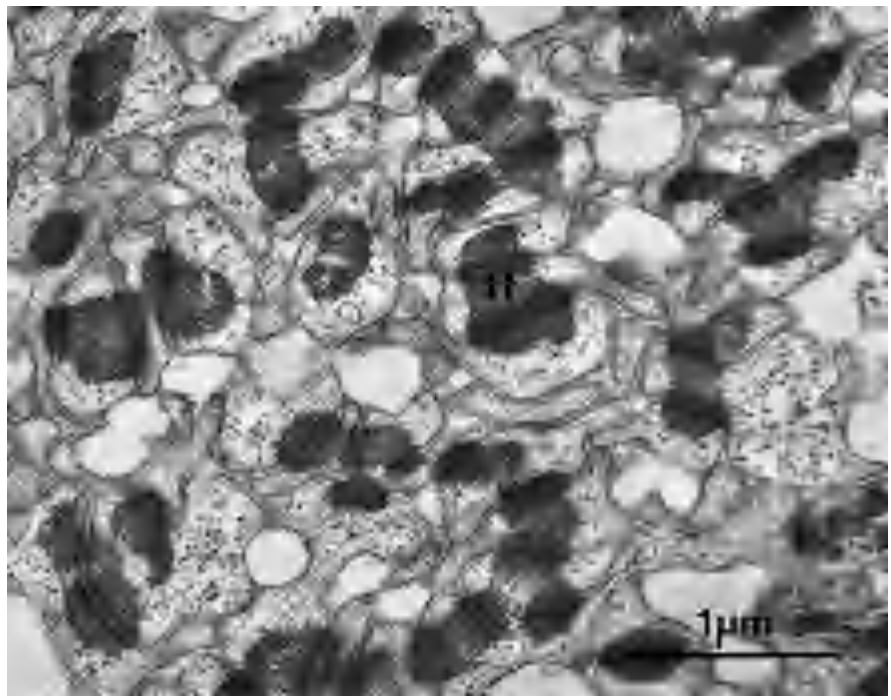

Fig. 3.9 Electron micrograph of desmosomes in spinous layer. These intercellular junctions are closely associated with tonofilaments (tf), many of which, in this view, are cross-sectioned. Scale bar = 1 μm.

biochemical and signalling interactions between cells. These include desmosomes, adherens junctions, gap junctions and tight junctions.

Desmosomes

Desmosomes are the major adhesion complex in epidermis, anchoring keratin intermediate filaments (IFs) to the cell membrane and bridging adjacent keratinocytes, and allowing cells to withstand trauma. The desmosome has a characteristic ultrastructure, in which the cell membrane of two adjacent cells forms a symmetrical junction with a central intercellular space of 30 nm containing a dense line (Fig. 3.9). Plaques of electron-dense material run along the cytoplasm parallel to the junctional region, in which three ultrastructural bands can be distinguished: an electron-dense band next to the plasma membrane, a less dense band, then a fibrillar area. Intermediate filaments loop through this region, and traversing filaments extending between the IFs and globular elements in the cell membrane may be unravelling IF protofilaments or associated proteins [1].

The main components of desmosomes consist of the products of three gene superfamilies: the desmosomal cadherins, the armadillo family of nuclear and junctional proteins, and the plakins [2]. The transmembranous cadherins comprise heterophilic associations of desmogleins and desmocollins. There are three main epidermis-specific desmogleins (Dsg1–3) and likewise for the desmocollins (Dsc1–3), all of which show differentiation-specific expression. For example, Dsg1 and Dsc1 are preferentially expressed in the superficial layers of the epidermis whereas Dsg3 and Dsc3 show greater expression in basal keratinocytes. The intracellular parts of these glycoproteins are attached to the keratin filament network via desmoplakin, plakoglobin and other macromolecules, the nature of which has been gleaned from a combination of yeast two hybrid, coimmunoprecipitation, recruitment assays in cultured cells and immunoelectron microscopy studies [2,3]. These have identified the armadillo protein, plakophilin 1, as an important stabilizer of keratinocyte adhesion in differentiated keratinocytes [4], as well as other site-specific plakin cell envelope proteins, such as envoplakin and periplakin [5,6]. The network of the major interactive desmosomal proteins is depicted in Fig. 3.10.

Further clues to the biological function and *in vivo* contribution to keratinocyte adhesion of these desmosomal components have arisen from various mouse models and human diseases, both inherited and acquired [2]. A summary of recent findings is represented in Table 3.2.

Adherens junctions

Adherens junctions are electron dense transmembrane structures that associate with the actin skeleton, part of the keratinocyte filament network concerned with cell motility, changes in cell shape and cell interactions. The transmembrane component of adherens junctions is E-cadherin, which forms calcium-dependent homophilic adhesive interactions with E-cadherin on opposing cells. The main linkage to the actin cytoskeleton is through α-catenin, although other adherens junction components

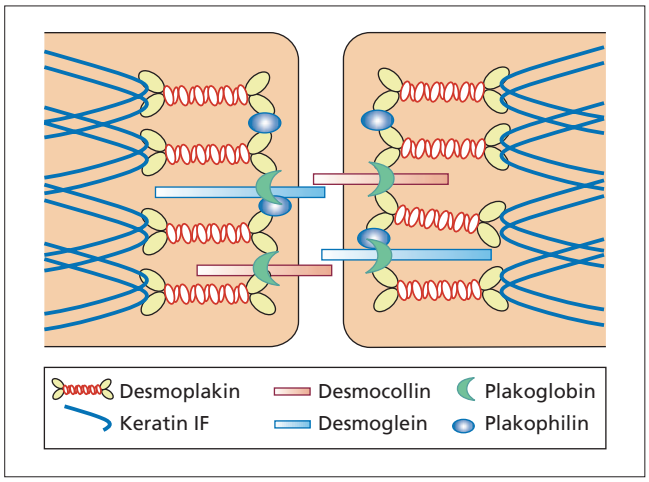

Fig. 3.10 Macromolecular composition of desmosomes linking adjacent keratinocytes. Cells are connected via transmembranous cadherin glycoproteins (desmogleins and desmocollins). Attachment of these molecules to the keratin filament cytoskeleton occurs via a network of desmosomal plaque proteins (desmoplakin, plakoglobin and plakophilin).

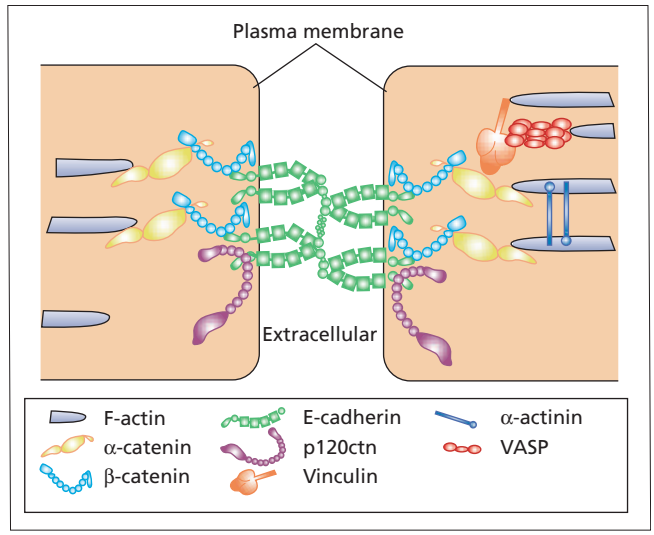

Fig. 3.11 Macromolecular composition of adherens junctions linking adjacent keratinocytes. Cells are connected via transmembranous E-cadherin and linked to the actin cytoskeleton via a network of adhesive proteins including β-catenin, α-catenin and p120ctn.

include p120ctn, β-catenin, plakoglobin (also present in desmosomes), α-actinin, vinculin, VASP (vasodilator-stimulated phosphoprotein), Mena and ZO1 (Fig. 3.11). Apart from forming E-cadherin–catenin complexes, α-catenin also appears to have a role in organizing the entire multiprotein complexity of adherens junctions and in determining the actin-binding and polymerization activities [7]. Clues to the precise function of individual components are gradually being realized through extensive conditional gene targeting and cultured cell

Table 3.2 Mouse models and human diseases related to desmosome genes/proteins.

Mutation/target antigen	Phenotype
Mouse models	
Plakoglobin knock-out	Lethal in early embryonic development (cardiac defects) Later survivors show epidermal fragility
Desmoglein-3 knock-out	Hair loss and epithelial fragility
Epidermally targeted truncated desmoglein-3 transgenic	Flakiness of back skin and paw swelling within 2 days of birth Desmosomes are reduced in number Hyperproliferation and inflammation in some areas
Desmoplakin knock-out	Lethal in early embryos
Desmocollin-1 knock-out	Flaky skin, defective epidermal barrier, hair loss
Inherited human diseases (autosomal recessive)	
Plakoglobin carboxy-terminal truncation	Naxos disease (arrhythmogenic right ventricular cardiomyopathy, keratoderma and woolly hair)
Desmoplakin carboxy-terminal truncation	Cardiomyopathy, keratoderma and woolly hair
Desmoplakin nonsense/missense combination of mutations	Skin fragility, keratoderma, woolly hair
Plakophilin-1 ablation	Skin fragility—ectodermal dysplasia syndrome
Desmoglein-4 ablation	Congenital hypotrichosis
Inherited human diseases (autosomal dominant)	
Desmoplakin haploinsufficiency	Striate palmoplantar keratoderma
Desmoglein-1 haploinsufficiency or dominant-negative mutations	Striate palmoplantar keratoderma
Autoimmune human diseases	
Desmoglein-3	Pemphigus vulgaris
Desmoglein-1*	Pemphigus foliaceus
Desmocollin-1	IgA pemphigus (subcorneal pustular dermatosis subtype)

* Desmoglein-1 is also the target/cleavage site of bacterial toxins in staphylococcal scalded skin syndrome and bullous impetigo.

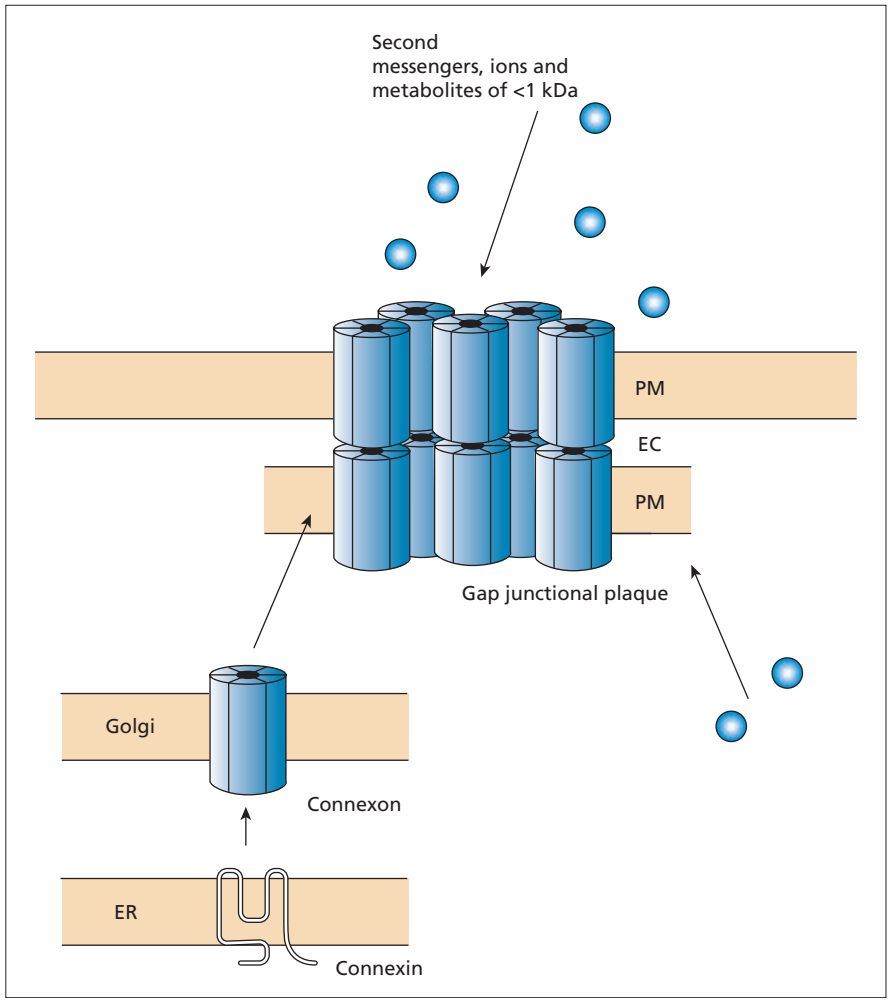

Fig. 3.12 Formation of gap junctions in human skin. In the Golgi network six connexin subunits assemble to form a connexon. The connexon is then transported to the plasma membrane. Other connexons then coaggregate and, in combination with aggregates of connexons on adjacent keratinocytes, a gap junction is formed that allows for the transfer of low-molecular-weight molecules (< 1 kDa) between cells. EC, extracellular; ER, endoplasmic reticulum; PM, plasma membrane.

reconstitution experiments, although the mechanisms regulating the dynamics of adherens junction formation are not yet clear. Nevertheless, the small GTPases of the Rho family appear to be important [8]. Likewise, VASP/Mena proteins have been implicated in the reorganization and polymerization of actin filaments [9]. Aside from actin polymerization, the myosin family of actin motor proteins may also contribute to generating the cellular movement necessary for intercellular adhesion by inducing contraction of actin filaments akin to pulling on a purse string [10]. The dynamics of the actin filament network allow for the extension, protrusion, embedding and anchorage of filipodia into neighbouring keratinocytes. This then encourages formation of adherens junctions and, in turn, permits other cell–cell junctions such as desmosomes to form, thus sealing adhesion between adjacent keratinocytes.

No human skin disorders have been linked to primary abnormalities in the structural components of adherens junctions, although plakoglobin—which may be mutated in Naxos disease (see Table 3.2)—is a component of both desmosomes and adherens junctions.

Gap junctions

Gap junctions comprise clusters of intercellular channels, known as connexons, that directly form connections between the cytoplasm of adjacent keratinocytes (and other cells) [11,12]. Thirteen different human connexins have been described [11]. Connexons originate following assembly of six connexin subunits within the Golgi network that are then transported to the plasma membrane. Here, connexons associate with other connexons to form a gap junction (Fig. 3.12). Homotypic or heterotypic connexins (formed from one or more than one type of connexin, respectively) are possible and the formation and stability of gap junctions can be regulated by protein kinase C, Src kinase, calcium concentration, calmodulin, adenosine 3′,5′-cyclic monophosphate (cAMP) and local pH. The function of gap junctions is to permit sharing of low-molecular-mass metabolites (< 1000 Da) and ion exchange between neighbouring cells, thus allowing intercellular coordination and uniformity [13].

Inherited abnormalities in genes encoding four different connexins (Cx26, 31, 30.3 and 30) have been detected in

several forms of keratoderma and/or hearing loss [12]. Specific connexin-associated genodermatoses include Vohwinkel's syndrome, autosomal dominant and recessive forms of erythrokeratoderma, Clouston's syndrome and *k*eratitis–*i*chthyosis–*d*eafness (KID) syndrome [14].

Tight junctions

Intercellular (tight) junctions are the major regulators of permeability in simple epithelia, but they are also present in skin, with a key role in skin barrier integrity [15]. Tight junctions, including those linking keratinocytes, are composed of transmembrane and intracellular molecules that include occludin, junction adhesion molecule and claudins [16]. As well as controlling permeability, tight junctions also have a role in maintaining cell polarity. Claudins may regulate epidermal permeability either through formation of tight junctions or via direct binding to certain transcription factors. However, a direct link to other transcription factors (e.g. Kruppel-like factor 4, Klf4) or enzymes (e.g. transglutaminase 1), that are known to be involved in regulating epidermal permeability through cross-linking of cornified cell envelope proteins, has yet to be established. Nevertheless, genetic ablation of claudin-1, or Klf4, or transglutaminase 1, in mice has been shown to cause similar patterns of epidermal barrier disruption [15,17,18]. This suggests that both the correct organization of tight junctions in the stratum granulosum and of cornified cell envelopes in the stratum corneum are required for full control of skin permeability.

No human skin disease has been associated with primary abnormalities in tight junction proteins, although abnormal expression of tight junction components, such as occludin, has been noted in a variety of inflammatory dermatoses, including psoriasis [19].

Organization and kinetics

In adult life, cell division maintains differentiated tissues and replaces lost cells. There are three broad categories of tissues according to proliferative potential. In nerve and skeletal muscle there is no cell division. In other tissues, such as liver, cell division can occur in response to injury—'conditional renewal', which occurs little in normal states. In many tissues including skin and mucosa (stratified squamous epithelia) and gastrointestinal tract (simple epithelia), permanently renewing populations are produced by rapid and continuous cell turnover from a small population of 'stem' cells into differentiated cells having short lifespan. The epidermis has classically been viewed as a stratified squamous epithelium maintained by cell division within the basal layer, which is attached to the epidermal basement membrane. Differentiating cells are gradually displaced outwards through the stratum spinosum to the stratum corneum. The anucleate corneal cells (squames), corneocytes or cornified cells, which protect the viable cell layers, are continually shed from the skin surface, and the rate of production of cells in the basal layer must match the rate of loss from the surface to produce the normal skin thickness, although increased rates of loss and cell division occur in pathological states.

Dynamics of epidermis

Stem cells

Stem cells can be defined as cells that have an unlimited capacity for self-renewal and the ability to generate daughter cells that undergo terminal differentiation [1,2]. However, not all dividing basal keratinocytes are stem cells [2]. It is evident that a stem cell daughter cell that is

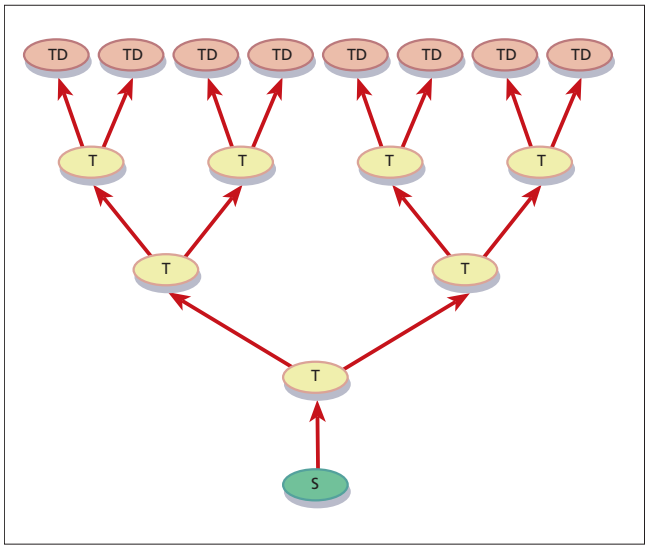

Fig. 3.13 Keratinocyte stem cell and transient amplifying cell division in human skin. Transient amplifying cells (T) are capable of increasing the number of keratinocytes that undergo terminal differentiation (TD) following a single stem cell (S) division. In this example, one stem cell division has resulted in eight terminally differentiated cells.

destined to undergo terminal differentiation can first proliferate and divide a small number of times (perhaps 5–6 mitoses): such cells are known as transient amplifying cells (Fig. 3.13). This expansion of proliferation therefore increases the number of terminally differentiating keratinocytes generated from each original stem cell division. Thus stem cells in the epidermis have a large capacity for proliferation but actually divide infrequently.

Stem cells are located in small clusters in the basal interfollicular epidermis and, in particular, in the bulge region of follicles. Although morphologically similar to other keratinocytes, stem cells are, to some extent, associated with a profile of particular chemical, molecular and biological characteristics. For example, stem cells retain labelling with injected ^{3}H-thymidine or Brdu after repeated cell division. In culture, actively growing clones present after serial passaging are considered to indicate origins from stem cells. Stem cells have also been shown to display increased β1 integrin expression as well as high levels of Notch ligand Delta 1. Other markers with altered expression in epidermal stem cells include the transferrin receptor, the nuclear-export protein 14-3-3σ, and the cytoskeletal keratins, K19 and K15.

Some putative stem cell markers, such as the c-Myc-regulated protein or the psoriasis-associated fatty acid binding protein (PA-FABP), are also expressed in the transient amplifying compartment. The same is true for the transcription factor p63.

Stem cells in the bulge region have the capacity to migrate (e.g. to the base of the hair follicle in follicular regeneration), as well as to differentiate into diverse lineages (e.g. outer root sheath [ORS], IRS, hair shaft, sebocytes and interfollicular epidermis). The precise lineage of terminal differentiation is governed by several local environmental cues. For example, Sonic hedgehog, Wnt and BMP are important in both embryonic and postnatal hair follicle development. Indeed, overexpression of the Wnt signalling component, β-catenin, leads to *de novo* follicle formation in skin. Thus, Wnt signalling appears to be important in making a follicle and Sonic hedgehog in maintaining it. Bone morphogenetic protein signalling influences differentiation of the hair shaft but not the IRS. However, little is known about the control of other adnexal differentiation, although Myc activation may be relevant for sebocyte differentiation.

The mechanisms that control exit from the stem cell compartment are incompletely understood, but clearly several molecular networks and signalling pathways are important in balancing epidermal growth and differentiation. Key components include NF-κB, Wnt/β-catenin, Sonic hedgehog/Patched, p63, 14-3-3σ, α-catenin and β1 integrin.

Epidermal kinetics

Cell kinetics are complicated in the epidermis by the balance between growth with differentiation and cell death. A differentiated cell may have no proliferative capacity but may be extensively metabolically active, and can increase tissue volume or mass without an increase in cell number. There are a number of kinetic concepts that underly skin biology.

A major concept is that of *turnover time*, which is the amount of time for the whole cell population to replace itself (regeneration time or replacement time). This depends both on the time taken for individual cells to divide, *cell cycle*, and the proportion of basal cells dividing the *growth fraction*.

The *cell cycle* or intermitotic time (Tc) represents the interval between two successive mitoses (M). On histopathology of skin, dividing cells can be recognized by mitotic figures, but a longer period of time is spent between mitoses in interphase. Radiolabelled thymidine is incorporated into DNA, because of the salvage pathway for DNA, only during a specific period of DNA synthesis, the 'S' phase. All proliferating cells go through a cycle (Fig. 3.14), in which mitosis (M) is followed by the interphase or post-mitotic growth phase (G1), a period of active DNA synthesis (S) and a short resting or premitotic

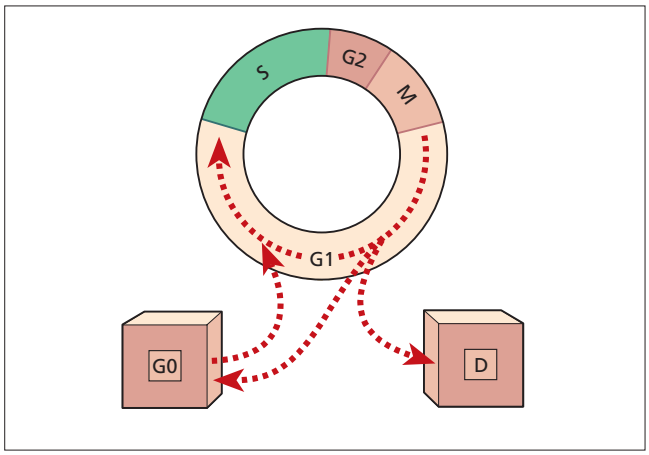

Fig. 3.14 Compartments of a cell proliferation system: M, mitosis, G1, interphase or post-mitotic growth phase; S, DNA synthesis; G2, resting or premitotic phase; G0, stem cells not proliferating; D, cells differentiating.

growth phase (G2). Some basal cells may remain quiescent in the so-called G0 phase, which permits them to re-enter the cell cycle and continue proliferation when required to do so by various stimuli. The balance of cell loss, from death, desquamation and apoptosis, and cell birth, decides the rate of increase or decrease of a cell population.

The *growth fraction* is the proportion of basal cells that are proliferative at any one time: in normal mouse skin this is estimated to be 60% of cells [1]. High proliferative rates can be achieved by a shorter cell cycle, or a higher proportion of proliferating cells, or both.

The proliferative index is familiar as the mitotic index and the flash-labelling index. The *mitotic index* is the fraction of basal or viable cells that is in mitosis at any point, and the *labelling index* is the fraction of basal cells in DNA synthesis. The labelling index is measured by exposing the skin to tritiated thymidine (^{3}HTdR), by intradermal or systemic injection, which is selectively taken up in DNA synthesis or rapidly broken down. This 'flash' labels the cells in S phase, which can then be detected by high-resolution autoradiography. Flash labelling the normal human epidermis labels about 30% of suprabasal cells, so this has to be included in some calculations [2].

These indices are referred to as state parameters, as they reflect the state of a particular component. However, rate parameters reflect the rate at which cells enter any phase. The rate of entry into mitosis is referred to as the *birth rate* in cells per 1000 cells per hour and can be measured by the accumulation of arrested metaphases after application of a stathmokinetic agent such as vincristine or colcemid [3]. The rate of entry into S phase is measured by double labelling, and is equivalent to the birth rate if all cells entering the S phase eventually divide, which is often not the case for keratinocytes in hyperproliferation. It is not known when cells leave the cycle to enter differentiation, as cells expressing involucrin as late markers of proliferation can still undergo scheduled DNA synthesis.

The *epidermal turnover time*, or transit time, has been used to represent the time taken for a cell to pass from basal layer to the surface of the skin, comprising passage through the living compartment to the upper stratum Malpighi and on through the non-viable compartment to the surface. Epidermal transit through stratum corneum can be estimated by injecting radioactive label or fluorescent dye, and measuring their appearance or disappearance at the surface of the skin. In normal skin, the total time is 52–75 days, but this is greatly reduced for psoriatic epidermis.

The best way of measuring the epidermal cell cycle and its component phases is the fraction of labelled mitoses technique, which involves determining the proportion of labelled mitoses after flash labelling with tritiated thymidine. From plotting the curve of the percentage of labelled mitoses with time, the duration of different phases of the cell cycle can be determined. Most cell populations show a distribution of cell-cycle times. *In vitro* studies, including explant cultures and cultures of disaggregated keratinocytes, have now been extensively used to analyse parameters of proliferation. Time-lapse photography can be used to directly measure intermitotic time *in vitro*. Initial colony formation is not dependent on multiplication, as keratinocytes appear to reassociate to colonies of four to six cells before replication, which occurs after 24–48 h. The kinetic parameters also illustrate a diversity of cell-cycle time *in vitro*. Scintillation counting is often used to measure incorporation of tritiated thymidine into DNA, but errors can be introduced by the size of the endogenous thymidine pool, and activity of thymidine-incorporating enzymes.

There are few direct measures of the cell-cycle time in normal skin, but they vary from 50 h (flow cytometry) to 457 h (turnover time). In psoriatic skin, the labelling index is greatly increased; the cell-cycle time is consistently reported to be reduced to around 50 h, and the growth fraction increased to 100% [4]. Keratinocytes *in vitro* have a mean intermitotic time of 22–24 h.

The regulation of epidermal differentiation

Recent years have seen considerable progress in our

understanding of the patterns of expression of different structural genes in the epidermis and its appendages. However, just how the specific programmes of terminal differentiation are orchestrated at the transcriptional level remains poorly understood.

In skin development, several signalling pathways such as Hedgehog, Wnt and transforming growth factor-β (TGF-β) have been implicated. Indeed, many of these pathways show evolutionary conservation in aspects of epithelial differentiation, proliferation and tumourigenesis. These pathways may be variably activated, both spatially and temporally, leading to a diverse series of transcribed genes. In keratinocyte differentiation, three main classes of transcription factors, AP1, AP2 and Sp1, appear to be relevant, although gene-targeting experiments have shown evidence for functional redundancy. Nevertheless, key elements include the Fos/Jun family of *AP1* genes. *In vitro* studies have also identified several other relevant transcription factors such as basonuclin, C/EBP, Oct6 and Oct11 (POU domain transcription factors), ESE2 (ELF5), Klf4 and retinoic acid receptors (RARs).

Regulation of the nuclear transcription factor NF-κB also appears to be significant in the process of terminal differentiation in epidermis. I kappa kinase alpha (IKKα) is a kinase that, along with IKKγ, phosphorylates and destroys IκB, a cytoplasmic inhibitor of NF-κB. Targeted inactivation of the gene encoding IKKα results in impaired terminal differentiation, although actual levels of NF-κB are normal. It is thought that the defects result from loss of an unknown secreted factor normally dependent on IKKα activity. However, NF-κB activity is abnormal if IKKβ is compromised. IKKβ usually increases NF-κB activity but *IKKβ* gene-targeted heterozygous mice (X-linked gene) display signs of keratinocyte proliferation, skin inflammation and increased apoptosis. The *IKKβ* gene is clearly important in human epidermal physiology too since mutations underlie most cases of incontinentia pigmenti. Overall these *in vitro* data, mouse models and human gene mutations demonstrate that compromising NF-κB perturbs the balance between growth and differentiation in the epidermis (and perhaps also in certain immune response cells).

Terminal differentiation is also influenced by retinoids that act at the mRNA level to inhibit aspects of differentiation and to promote proliferation. These changes are mediated by nuclear RARs and their heterodimeric binding partners, retinoid X receptors (RXRs). Transgenic mice with disrupted RARs have impaired epidermal barrier function and suppressed epidermal differentiation. In addition, targeted disruption of RXRα leads to further changes in epidermal hyperplasia and aberrant terminal differentiation. These mice also have alopecia, indicating a further role for these receptors in hair follicle morphogenesis and cycling.

Growth stimulatory signals [1,2]

Epidermal growth factor (EGF) family

Human EGF is a 6-kDa polypeptide with 53 amino acids that stimulates cell proliferation and differentiation in a wide range of tissues. Transcripts are not found in the epidermis but in the salivary glands and intestinal tract. EGF has been shown to increase the growth and persistence of epidermal keratinocytes *in vitro* via binding to specific cell-surface receptors (170-kDa EGFr1), that have been detected in the basal layer of human epidermis and throughout the epidermis in psoriasis [3]. The EGFr has a large cytoplasmic domain with tyrosine kinase activity stimulating protein phosphorylation, and the cerB1 oncogene encoding truncated receptors acts by mimicking receptor activation [4].

In contrast to EGF, TGF-α, a single-chain 26-kDa polypeptide, is synthesized by epidermal keratinocytes and stimulates keratinocyte growth in an autocrine fashion following binding to the EGFr [5], although keratinocyte lifespan *in vitro* is mainly enhanced by stimulation of lateral migration of dividing colonies [6]. TGF-α can up-regulate its own production, as well as that of EGFr1. Overexpression of TGF-α has been found in suprabasal psoriatic epidermis [7].

Amphiregulin is a unique member of the EGF family of growth factors, with binding affinity for heparin-like glycosaminoglycans (GAGs) [8]. The amphiregulin gene maps to chromosome 4q, and encodes a transmembrane precursor protein, cleaved proteolytically to the active form, which binds to the EGFr. Amphiregulin appears to be a major autocrine keratinocyte growth factor, regulated by cellular GAGs and up-regulated by exogenous EGF and TGF-α, being overexpressed in hyperproliferative skin disease and squamous carcinomas [8,9].

More than 90% of autocrine growth of keratinocytes is mediated through the EGFr [8], but other cytokines synthesized by keratinocytes including interleukin-1 (IL-1), IL-6 and granulocyte–macrophage colony-stimulating factor (GM-CSF) can also stimulate growth [10–12]. Paracrine factors may be produced by dermal fibroblasts and microvascular endothelial cells. Some members of the FGF family stimulate keratinocyte growth, including acidic and basic FGF (bFGF). *Keratinocyte growth factor* (KGF: FGF7), in particular, has a high specificity for keratinocytes and is induced in dermal fibroblasts within 24 h of wounding [13]. Factors produced by leukocytes and macrophages—platelet-derived growth factor (PDGF) [14], TGF-α, IL-1β and tumour necrosis factor (TNF)—induce the *KGF* gene and may induce this rapid response.

Growth inhibitors for keratinocytes

It has long been suggested that epidermal growth is under the influence of a negative-feedback mechanism. Bullough *et al*. and Elgio *et al*. proposed the existence of growth inhibitors or *chalones* produced by suprabasal cells that slow basal mitosis [1,2]. Recent studies have purified a number of defined growth-inhibitory substances that are produced in skin and may have contributed to activities within the previous crude biological extracts. It is likely that further cytokines with growth-inhibitory activity towards keratinocytes remain to be found, some of which may be site or cell specific.

TGF-β comprises a family of closely related two-chain polypeptides present in normal cells and malignant cell lines [3]. TGF-β1 stimulates fibroblast growth and increases fibrosis, but inhibits growth of keratinocytes [4]. TGF-β receptors are ubiquitous and are likely to be important regulatory molecules in inflammation and repair and in epithelial–mesenchymal interactions.

Interferon-α (IFN-α) and IFN-γ have cytostatic effects on keratinocytes both *in vivo*, following systemic administration, and *in vitro* [5]. Following stimulation with IFN-γ, keratinocytes express class II antigens, predominantly human leukocyte antigen (HLA)-DR, in a dose-dependent manner, but higher doses are cytotoxic to keratinocytes.

TNF-α, a macrophage cytokine, induces neutrophil activation [6], endothelial activation, fibroblast stimulation, endotoxic shock and acute phase protein release, but is also secreted by keratinocytes, especially after UV radiation. TNF is reversibly cytostatic to keratinocytes, but stimulates fibroblast proliferation and cytokine production.

Apoptosis [1]

Selective cell death is a means of eliminating unwanted cells during normal differentiation, or when cells are damaged [2]. There are two pathways: necrosis, when cells are passively damaged with membrane damage, cell swelling and rupture; and apoptosis, an active process. Apoptosis, a term first introduced in 1972 [3], and also known as programmed cell death, is characterized by nuclear fragmentation and shrinkage of the cells into small fragments that are then phagocytosed by surrounding cells. Intricate control of apoptosis is vital since insufficient cell death will lead to uncontrolled growth, whereas too much apoptosis will result in degeneration or developmental defects. The final pathway leading to cell death often results from mitochondrial permeabilization and activation of caspases and other proteases, but these events can be triggered through numerous mechanisms including signalling induced by DNA damage, responses from the ubiquitin/proteasome pathway, the pro-apoptotic molecule Fas and proapoptotic mediators such as ganglioside GD3. Moreover, these signals can by modified by tumour suppressor genes including p53, p63 and the retinoblastoma tumour suppressor protein, the inhibitor of apoptosis (IAP) gene family, and Fas-ligand.

Alterations in the regulation of apoptosis are relevant to several developmental and malignant skin disorders. For example, mutations in the *p63* gene result in ectodermal dysplasia syndromes and altered responses to UV irradiation. In melanoma, resistance to chemotherapy in some cases may be due to increased antiapoptotic activity [4].

For example, several natural defence processes induced by granzyme B or interactions with TNF family members (e.g. TNF-related apoptosis-inducing ligand, TRAIL) normally function to kill melanoma cells, but melanomas that express high levels of the oncogene bcl-2 may override these protective pathways, making them more resistant to treatment.

Differentiation

Terminal differentiation of the epidermis *in vivo*

As the epidermal keratinocytes move through the epidermis after losing their attachment to the basal lamina, they undergo the complex process of terminal differentiation to produce the stratum corneum. Most suprabasal cells in the stratum spinosum have lost this ability to divide, and are inevitably committed to differentiation, although they remain metabolically active. The stratum corneum cells (squames or corneocytes) have lost their nuclei and other recognizable organelles, and comprise 65% insoluble cysteine-rich, disulphide cross-linked, fibrous proteins or keratins (Greek *keras* = horn). The series of changes whereby keratin filaments aggregate into bundles through the action of the histidine-rich basic protein filaggrin is the process of *keratinization*. However, keratin IFs characterize all epithelial cells. In addition, epidermal differentiation involves the synthesis of a highly insoluble cornified envelope whose cross-linking is catalysed by a keratinocyte-specific transglutaminase from a precursor protein called involucrin (Greek = envelope).

In addition to formation of keratin macrofilaments and the cornified envelope, changes also occur during terminal differentiation in the expression of intercellular lipids and membrane glycoproteins, including growth-factor receptors, intercellular adhesion proteins (integrins), cell-matrix adhesion proteins and blood-group antigens.

Aside from changes in these structural proteins, terminal differentiation is also influenced by several other factors including expression of desmosome proteins and signalling pathways such as Notch [1] or phosphatidylinositol 3 kinase [2], extracellular matrix protein 1 (ECM1) [3], vitamin D receptors [4], FGF10 [5], cyclo-oxygenase enzymes [6], calcium-sensing receptors [7], sodium channels [8] and small heat shock protein [9].

Keratin biochemistry, synthesis and changes in epidermis

The filamentous cytoskeleton of all mammalian cells, including epidermal keratinocytes, comprises actin-containing microfilaments approximately 7 nm in diameter; tubulin containing microtubules 20–25 nm in diameter; and filaments of intermediate size, 7–10 nm in diameter (IFs). There are six types of IFs: vimentin within mesenchymal cells; glial filament acidic protein (GFAP) in glial cells; neurofilaments in neurones; desmin in muscle cells; and peripherin in peripheral nerves [1]. The nuclear matrix proteins, nuclear lamins A, B and C, are also IFs. The keratins are the IFs characteristic of all epithelial cells. The polypeptide building blocks of all IFs have a similar backbone structure of a classical α-helical region with heptad repeats, having four separate helical zones with interhelical linker sequences, and non-helical carboxy- and amino-terminals.

Keratins form a family of proteins with more than 30 individual and distinct members, each the product of a distinct and separate gene. The molecular weight of keratins varies between 40 kDa and 67 kDa, and they can be resolved on two-dimensional gel electrophoresis into individually numbered polypeptides: the basic keratins (numbered 1–8) and the acidic keratins (numbered 9–19) [2]. The genes encoding individual keratins fall into two gene families: type I (basic) and type II (acidic) [3]. Keratin expression within cells and tissues can be determined by a variety of techniques: immunohistochemistry using polyclonal antisera and monoclonal antibodies (Fig. 3.15) and *in situ* hybridization probes to analyse the cellular

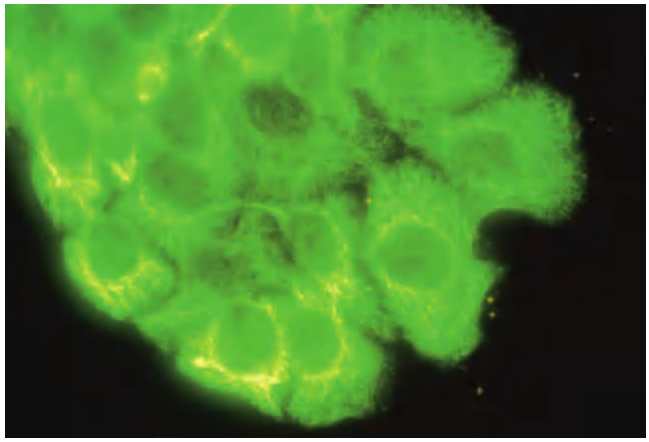

Fig. 3.15 Cells in tissue culture stained by immunofluorescence with monoclonal antibody to keratin intermediate filaments (IFs).

expression of mRNA for the individual keratin genes [4,5]. Synthetic peptides to carboxy-terminal sequences can be used to develop highly specific antibodies [4]. Mapping the tissue distribution of keratins shows co-expression of particular acidic–basic pairs in a cell- and tissue-specific manner [5,6]. Heterodimers are assembled into higher-order protofibrils and protofilaments by an antiparallel stagger of some complexity [7,8]. Simple epithelia are characterized by the keratin pair K8/K18, and the stratified squamous epithelia by K5/K14. In addition, stratified squamous epithelia express up to four other keratin pairs during epithelial differentiation (Fig. 3.16). In skin, suprabasal keratins K1/K10 are characteristic of epidermal differentiation [4]. In the stratum granulosum, release of filaggrin from the keratohyalin granules forms macrofibres. Retinoid levels, growth factors and hormones may regulate keratin gene expression. Mesenchymal signals may also direct or permit intrinsic patterns of keratinocyte differentiation. K19 is expressed in basal keratinocytes of the hair-follicle bulge region at the site of pluripotential stem cells [9]. K9 and K2e expression are site restricted in skin: K9 to palmoplantar epidermis and K2e to superficial interfollicular epidermis. Apart from their structural properties, keratins may also have direct roles in cell signalling, the stress response and apoptosis [10].

In epidermal hyperproliferation, as in wound healing and psoriasis, expression of suprabasal keratins K6/K16/K17 is rapidly induced suprabasally, probably due to previous expression of their mRNAs with post-transcriptional regulation [5]. Mutations in epithelial keratins underly an increasing number of human skin diseases with good correlation of genotype and phenotype, as lesions tend to occur at sites of expression of particular keratins [11,12].

Hair and nail differentiation

The pilosebaceous units develop from epidermal downgrowths under the influence of specific mesenchymal cell condensations between the 10th and 14th week estimated gestational age. They have complex groups of specialized cell layers with distinctive pathways of differentiation. There are four classes of pilosebaceous unit: terminal on the scalp and beard; apopilosebaceous in axilla and groin; vellus on the majority of skin; and sebaceous on the chest, back and face. The dermal papilla is located at the base of the hair follicle with a rich ECM. Around the papilla are germinative (matrix) cells that have a very high rate of division, and give rise to spindle-shaped central cortex cells of the hair fibre, and the single outer layer of flattened overlapping cuticle cells. In animals, a paracortex and orthocortex can be distinguished, with nuclear remnants distinguishable in the paracortex. A central medulla is seen in some hairs, with regularly stacked condensed cells interspersed with air spaces or low-density cores [1]. The cortical cells are filled with keratin IFs orientated along the long axis of the cell, interspersed with a dense interfilamentous protein matrix. Terminal differentiation of cortical cells is associated with the appearance of a continuous laminated intercellular layer, which appears critical for filament integrity. The cuticular cells are morphologically distinct, with flattened outward-facing cells, with three layers inside the cuticle of condensed, flattened protein granules: endocuticle, exocuticle and 'a' layer.

Around the cuticle is the IRS, which is composed of three distinct layers of cells that undergo keratinization: the IRS cuticle, the Huxley layer and the outermost Henle layer. Differentiation in the IRS involves the development of trichohyalin granules, with 8–10-nm filaments orientated in the direction of hair growth. The IRS moves up the follicle, forming a support for the hair fibre, and degenerates above the sebaceous gland. The outermost layer is the ORS, which is continuous with the epidermis and expresses epithelial keratins, K5/K14, K1/K10 and K6/K16 in the upper ORS and K5/K14/K17 in the deeper ORS (Fig. 3.17).

Normal growth of the hair fibre is 300–400 μm/day, generated by the high rate of proliferation of progenitor cells in the follicle bulb. Compartmentalization within the bulb gives rise to the different layers within the follicle, with the majority of bulb cells forming the IRS. There are three phases of cyclical hair growth: anagen, when growth occurs; catagen, a regressing phase; and telogen, a resting phase (Fig. 3.18). The follicle re-enters anagen, and the old hair is replaced by a new one [2]. It had been assumed that

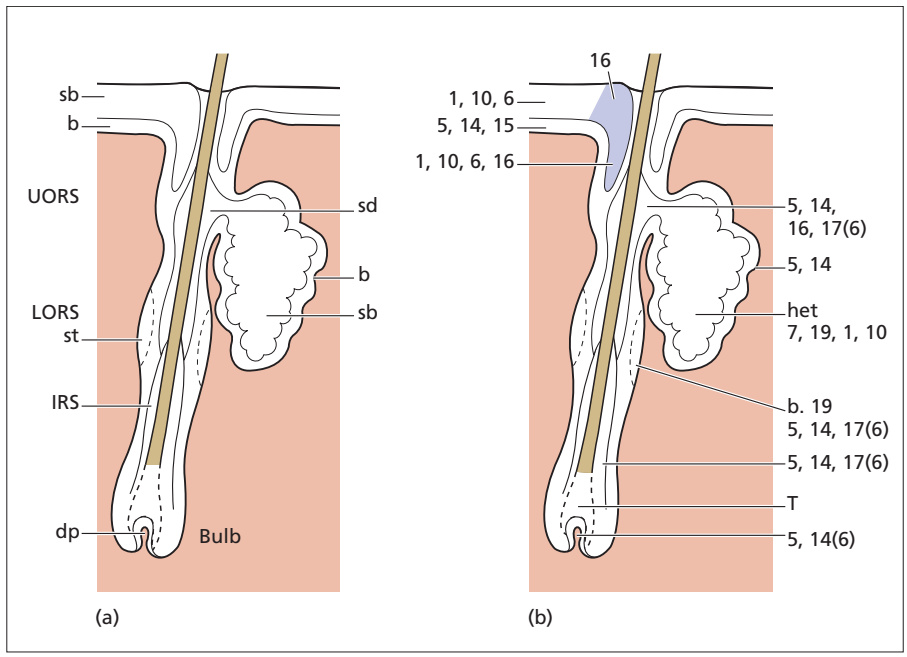

Fig. 3.17 Hair follicle: (a) structure and (b) expression of epithelial keratins (Moll number). b, basal; dp, dermal papilla; IRS, inner root sheath; LORS, lower outer root sheath; sb, suprabasal; sd, sebaceous duct; st, stem cell region; UORS, upper outer root sheath.

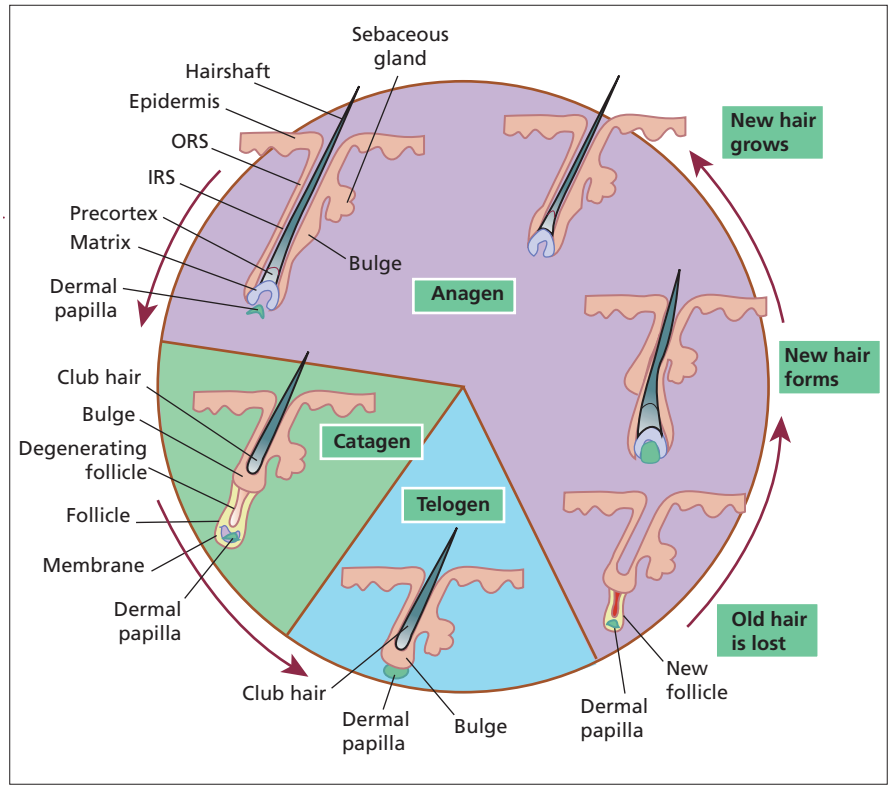

Fig. 3.18 The hair cycle. There are three components to the hair cycle: anagen (where new hair forms and grows), followed by catagen and telogen, and then loss of old hair. The hair cycle is associated with discrete changes in hair follicle anatomy, both in the shape of the follicle and in the subjacent dermal papilla. IRS, inner root sheath; ORS, outer root sheath.

stem cells for the follicle lay in the highly proliferative matrix [3], but recently a slow-cycling (label-retaining) population of basal keratinocytes at the level of arrector pili muscle has been suggested as the pluripotential stem-cell region. Cells in this region express keratin K19 and high levels of β1 integrin [4].

Immediately above the basal layer in the hair bulb, cells undergo a secondary pathway of 'trichocyte' or hair differentiation, and express a further complex group of keratins, the hard keratins [5,6]. Two families of hair keratins, types I and II, are present in mammals, which have distinctive amino- and carboxy-terminals with high levels of cysteine residues, and lack the extended glycine residues of epidermal keratins. The proteins differ from epithelial keratins in position on two-dimensional gels, but form acidic and basic groups: on gel electrophoresis, there are four major proteins in each family and several minor proteins, Ha 1–4 and Hb 1–4 [7]. Recent cloning of the hair keratin genes, which cluster on chromosomes 12 and 17, has shown a greater number of hair keratin genes, *HaKRT1–6* (including 3.1 and 3.2) and *HbKRT1–6*. Mutations in hair keratin genes have been found to be causative for the human disease monilethrix [8]. In addition, keratin 17 null mice also demonstrate varying degrees of alopecia, depending on the age and strain of the mice [9].

The hair keratin-associated proteins are cysteine-rich and glycine tyrosine-rich families [10]. Cysteine-rich proteins were originally called the high sulphur group, but protein fractions with even higher amounts of cysteine were noted and called the ultra-high sulphur keratin proteins, at least five families occurring in both cortical and cuticular cells [4].

A similar pathway of differentiation occurs in nail formation, when hard keratin expression occurs following a pattern of adjacent epithelial keratin expression, in the nail matrix [11]. The nail cells mature from a deep layer at the proximal nail, with cells moving forward and outward, filling up with a complex, hair-like cortex of filaments embedded in an electron-dense interfilament matrix. Nail keratinocytes show marked interdigitations with laminated intercellular cement. The expression of significant amounts of epithelial keratins in nail matrix explains the nail findings in some diseases caused by keratin gene mutations.

Keratohyalin granules

Keratohyalin granules are highly distinctive cellular inclusions in differentiating epidermis forming the characteristic granules of the stratum granulosum, which disappear in the formation of cornified squames. They are also found in other cornifying epithelia, such as palate and gingiva, but not in non-cornified squamous epithelia. Filaggrin provides the interfilamentous material between keratin filaments in the lower stratum corneum cells; it contributes towards the cornified envelope [1]. Two types of granule can be distinguished in rodent skin by staining characteristics, differential incorporation of radioactive probes and microanalysis. The PF granule is phosphate rich and contains the filaggrin precursor, profilaggrin, and the L granule, which is found at the periphery of the PF granule or independently in the cytoplasm, contains the sulphur-rich protein loricrin [2]. In human interfollicular epidermis, keratohyalin forms dense, irregular, stellate globules of amorphous material along keratin filament bundles and at intersections of such bundles.

Filaggrin is a cationic protein originally isolated from rat epidermis [3–5], and has an unusual amino-acid composition, being rich in arginine, glutamine, glycine, serine and histidine, but lacking non-polar residues. The name results from the recognition that filaggrin was a *fil*ament *aggr*egating prote*in*. Antibodies to filaggrin react with stratum corneum and keratohyalin granules. Filaggrin is derived from a high-molecular-weight precursor profilaggrin, which is insoluble, cannot aggregate filaments and is highly phosphorylated. It comprises of multiple repeats of filaggrin joined by linker peptides. Profilaggrin is dephosphorylated, cleaved by proteases [6], which remove the linker peptides to generate the filaggrin, and which associates with keratin filaments. The degradation of filaggrin produces amino acids that help to retain stratum corneum water [7].

The cornified envelope

The cornified envelope [1] is rendered highly insoluble by the formation of glutamyl-lysysl isodipeptide bonds between envelope proteins, catalysed by transglutaminases [2]. There are three distinct transglutaminases, but TG1 (keratinocyte transglutaminase) can cross-link envelope proteins in the absence of other enzymes. An increasing number of envelope precursor proteins have been identified.

Involucrin is the best-established envelope precursor, as a preferred substrate of TGk. The protein can be found decorating the cytoplasmic face of envelopes from human plantar epidermis [3]. The involucrin gene has been located on chromosome 1q21–22 in the epidermal differentiation gene complex. Twenty-six per cent of the residues in involucrin are glutamine, but preferential labelling of residue 496 suggests this site initiates cross-linking [4]. The protein is expressed in stratified squamous epithelia, accumulating in the upper stratum spinosum, but is detected in the lower stratum spinosum in benign epidermal hyperplasia, and epibasally in cultured keratinocytes. Regulation of expression appears relatively retinoid insensitive. Involucrin is not always associated with cornification, as it occurs in cornea and is therefore a good marker of epithelial differentiation. Other cytosolic envelope precursors include the family of small proline-rich proteins (SPR1) including *cornifin* [5] or SPR1 and *pancornulins*. There are three closely related subfamilies SPRr1, SPRr2 and SPRr3, originally isolated by differential screening as UV-inducible genes [6]. They all contain internal peptide repeating units of eight or nine amino acids, up to 40% proline. Other envelope proteins include *SKALP/elafin* and *keratolinin/cystatin*, a 36-kDa protein cross-linked by transglutaminase into a 150-kDa multimer [7].

Some precursors of the cornified envelope are delivered by granules. Small, smooth, sulphur-rich L granules were suggested to contain the 315 amino acid, cysteine-rich protein *loricrin*, and accumulate in the stratum granulosum [8]. Loricrin appears to be the major component of the cornified envelope, cross-linked by isodipeptide bonds by the action of epidermal transglutaminase. The human

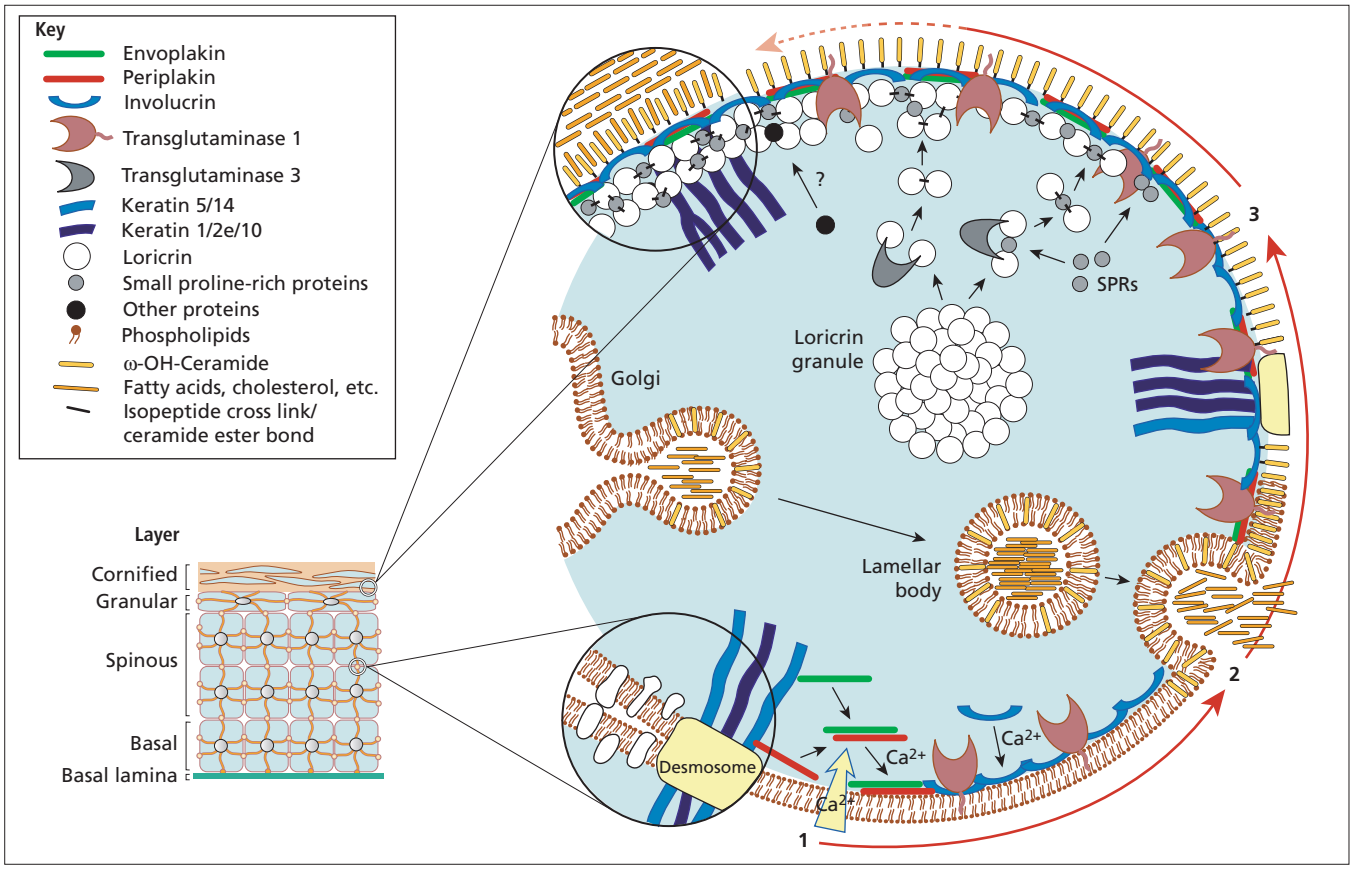

Fig. 3.19 Assembly of the epidermal cornified cell envelope. In response to increasing intracellular calcium, an internal scaffold of desmosomal proteins is made along the plasma membrane. The contents of lamellar bodies (ceramides and other fatty acids, cholesterol and cholesterol esters) are released into the extracellular milieu to form a lipid membrane. The developing envelope is then added to and reinforced by recruitment of various proteins including loricrin, small proline-rich proteins (SPR1), other desmosomal remnants and attached keratin filaments. The resulting cornified cell envelope is durable and flexible and provides important mechanical and barrier functions.

loricrin gene is also located on chromosome 1q21. Expression depends on a high calcium concentration, is associated with keratinocyte differentiation and is down-regulated by retinoids. Profilaggrin in F granules may make a minor contribution to the envelope.

At least three membrane-associated proteins are also envelope precursors: a 210-kDa protein (envoplakin) and a 195-kDa protein (periplakin) detected in human keratinocytes [9]; and a 61-kDa protein found in transformed cells. Envoplakin has recently been cloned and sequenced [10,11], has some homologies with desmoplakin and plectin, and thus may serve as an organizing linker protein.

Transglutaminases [2] catalyse isopeptide bonding between γ-amide of donor glutamine and ε-amino group of acceptor lysine to produce a stable insoluble macromolecule. The transglutaminases consist of a family of distinct enzymes, TGase 1 membrane-associated enzyme in many epithelial tissues, a ubiquitous TGase 2, and TGase 3, which is restricted to epidermal and hair keratinocytes. Both TGase 1 and 3 are thought to be important in constructing the cornified cell envelope during terminal differentiation, although TGase 3 is thought to account for 75% of activity in epidermis.

Formation of the cornified cell envelope (Fig. 3.19) is triggered by a rise in intracellular calcium levels [12]. This leads to cross-link formation between plakins and involucrin catalysed by transglutaminase. Other desmosomal proteins are then also cross-linked, forming a scaffold along the entire inner surface of the plasma membrane. Ceramides from the secreted contents of lamellar bodies are then esterified onto glutamine residues of the scaffold proteins. The cornified cell envelope is reinforced by the addition of a variable amount of SPRs, repetin, trichohyalin, cystostatin α, elafin and LEP/XP-5 (skin-specific protein) [12]. Although most desmosomal components are degraded, keratin IFs (mostly K1, K10 and K2e) may be cross-linked to desmoplakin and envoplakin remnants. Together these assembly and degradation events result in durable, flexible but dead cells that have vital mechanical and water-permeability barrier functions.

Lipid biosynthesis and barrier function

During epidermal differentiation, there are profound changes in the composition of lipids: in the viable layers phospholipids, cholesterol and triglycerides predominate, but in the upper stratum spinosum and stratum granulosum lipid is synthesized and packaged into lamellated membrane-bound organelles known as *membrane-coating granules*, lamellar granules or Odland bodies (Fig. 3.20). They are found adjacent to the cell membrane with alternating thick and thin dense lines separated by lighter lamellae of equal width, consistent with packing of flattened discs within a membrane boundary. Immunochemistry has confirmed the presence of phospholipids, glycolipids and free sterols. The organelles move towards the plasma membrane as the cells move through the granular layer and cluster at the cell membrane. They fuse with the plasma membrane dispersing their contents into the intercellular space. Polar lipids from the lamellar granules are remodelled into neutral lipids in the intercellular space between corneocytes, forming an important barrier to permeability [1]. The lamellar granules also contain hydrolytic enzymes, lipases and glycosidases, which are responsible for this remodelling [2,3].

Thus, the stratum corneum is rich in ceramides, free sterols and free fatty acids [4]. Linoleate appears to be essential for proper barrier function as an ester-linked residue in acyl ceramides, so in essential fatty acid deficiency substitution of this linoleate by oleate causes a defect in barrier function [5]. The skin is an active lipid-synthesizing tissue, with a daily rate of 100 mg/day. Keratinocytes *in vitro* can synthesize all lipids except essential fatty acids, which have to be obtained from the circulation, so epidermal lipogenesis can be studied in culture.

In human epidermis, nearly all sterol is present as cholesterol. In many cells, cholesterol biosynthesis may be modulated by uptake of exogenous cholesterol, mediated by low-density lipoprotein (LDL) receptors, but these are only present on the plasma membrane of basal keratinocytes, and are rapidly down-regulated on epidermal differentiation [6]. Sterol synthesis is higher in the stratum granulosum, and is thus relatively autonomous and uninfluenced by dietary or circulating sterol levels. Cholesterol sulphate is highest in the stratum granulosum

and corneum, where it is thought to play a role in cell cohesion. In X-linked recessive ichthyosis vulgaris due to steroid sulphatase deficiency, scales contain high levels of cholesterol sulphate giving increased intercellular adhesion [2].

Keratinocyte integrins

Integrins are a 'superfamily' of cell-surface glycoproteins forming receptors, which mediate adhesion, in both intercellular and cell–substrate interactions. Each integrin consists of a heterodimer of an α (95–130 kDa) and a β (130–210 kDa) subunit; they are transmembrane glycoproteins that interact with actin on the intracellular surface, and the extracellular domains form the ligand binding sites [1]. There are at least 14 α subunits and eight β subunits, ligand specificity being dependent on heterodimer composition. The predominant integrin subunits found in the epidermis are α1, α3, α6, β1 and β4 [2,3], expressed as α2β1, α3β1 and α6β4, predominantly expressed on basal keratinocytes. Other integrins that can be expressed by keratinocytes are αv and α5. Many integrins bind to ECM proteins at sites encompassing the arginine–glycine–aspartate (RGD) sequence and many bind to a specific matrix protein. α2β1 mediates keratinocyte adhesion to types I and IV collagen, α3β1 and α6β4 to laminins and α5β1 to fibronectin. α6β4 is a component of the hemidesmosome complex, and is the receptor for laminins [4,5]. β4 integrin can only combine with the α6 integrin, whereas the α6 subunit can also combine with β1. β4 integrin has a large intracellular domain that includes a connecting segment capable of binding plectin. Other intracellular parts of the molecule bind type XVII collagen and there is a tyrosine activation motif that is necessary for the incorporation of β4 integrin into hemidesmosomes.

When keratinocytes differentiate, they lose adhesion to matrix by loss of integrin expression. Most adherent keratinocytes with high levels of surface β1 integrin expression are thought to contain stem cell populations [6]. There are changes in integrin expression during epidermal morphogenesis and wound healing [7,8], with expression of α1, α3, α6 and β1 in all suprabasal layers. Changes have been noted in basal cell cancer [9]. Suprabasal α6 and β1 have been reported in psoriasis, with variable increased and decreased expression in epidermal tumours [1,3].

Keratinocytes *in vitro*

The ability to grow keratinocytes through multiple generations has added considerably to our understanding of keratinocyte biology (Fig. 3.21). Initial attempts to grow skin centred on the use of organ cultures and explant cultures, where whole pieces of skin where kept alive and growth was confined to the epibole around the piece or to the plastic around the explant. These cultures have a short life and limited application, as mixed cultures of keratinocytes and fibroblasts are obtained. In 1975, Rheinwald and Green [1] reported the ability to grow pure cultures of keratinocytes from single cell suspension of epidermal cells, using a mesenchymal feeder cell (irradiated mouse 3T3 cells) and serum containing medium. These cells could then be passaged through multiple generations. The technique of keratinocyte culture was improved by added mitogens (EGF and CAMP-elevating agents, including cholera enterotoxin) [1,2]. In the cultures, keratinocytes attach as single cells or small clusters, and then grow at the periphery of the colony while stratifying in the centre. The cells form intercellular desmosomes, and so grow as coherent colonies until confluent stratifying multilayered sheets are obtained. These have poorly formed squames and do not show normal skin morphology, with cells being flattened, attenuated and

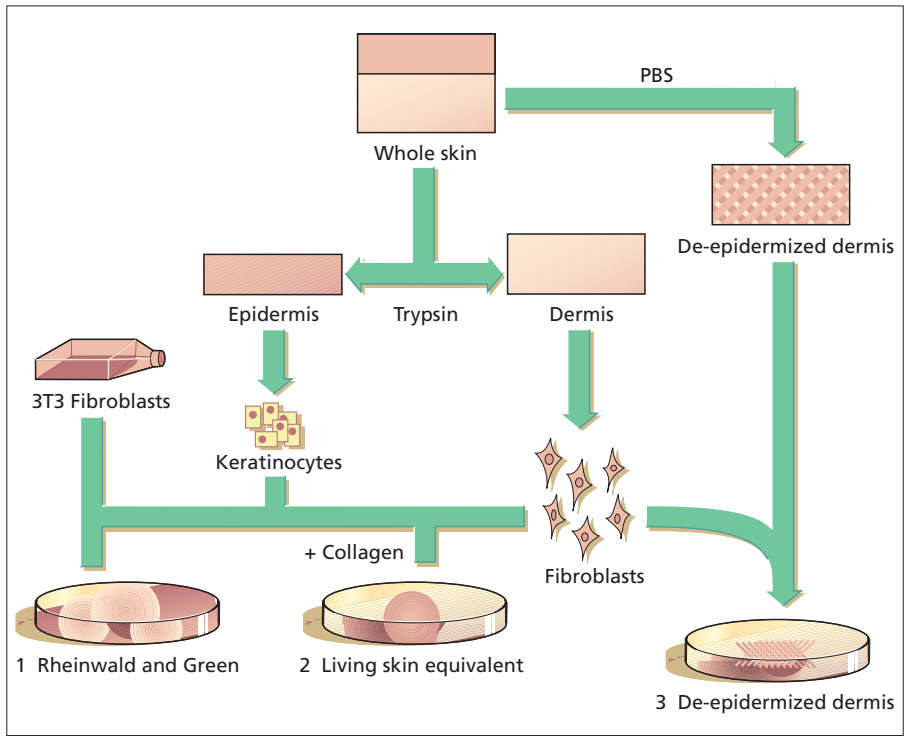

Fig. 3.21 Different methods of culturing skin. PBS, phosphate-buffered saline.

forming no stratum granulosum or stratum corneum. Membrane coating granules and keratohyaline granules are sparse, and the cultures show the same phenotype as regenerating epidermis [3].

Since the fundamental breakthrough of keratinocyte culture, other ways of growing keratinocytes have been developed. The search for a defined serum-free medium has resulted in a low-calcium medium containing many growth factors, which is now commercially available [4]. In a low-calcium (< 0.06 mmol/L) medium the cells fail to form desmosomal interconnections and are spaced out as a monolayer [5]. Although the keratinocytes fail to stratify, they commence terminal differentiation with the expression of involucrin in the larger cells, which move suprabasally when calcium levels are restored (to 1.2 mmol/L). There is no difference in cell proliferation between low-calcium and high-calcium medium. The cell cycle is around 22 h with a growth fraction of 60–70% [6]. These systems are therefore heavily weighted towards hyperproliferation.

The desire to produce a more normal epidermis for experimental purposes has led to the development of complex cultures involving a dermal equivalent or substrate of collagenous gels, including fibroblasts and ECM components [7–9] or de-epidermized dermis [10]. These form organotypical cultures—also termed skin equivalents—sometimes also containing cultured fibroblasts [11]. The cells tend to form a more differentiated epidermis, with stratum corneum and granulosum including keratohyaline and membrane-coating granules. These complex cultures are useful for pharmacological experiments, but they provide little tissue expansion, whereas with the Rheinwald–Green technique 1 cm^2 of skin can generate 1-m^2 culture areas within 6 weeks. This huge population expansion enables application of keratinocyte culture for skin grafting—keratinocyte grafting [12]. The technique has been applied to the treatment of burns and other skin defects, including leg ulcers [13]. Both autologous keratinocytes and allogeneic keratinocytes have been used—keratinocyte autografting and keratinocyte allografting. Although allografts do not survive transplantation [14], they provide a biological dressing and produce wound healing via cytokine release.

In addition to direct clinical application, the development of keratinocyte culture systems has contributed greatly to an increased understanding of factors influencing keratinocyte growth and differentiation, and the release of peptide growth factors and immunological cytokines. The keratinocyte has been shown to play an active part in the skin immune system or SALT (skin-associated lymphoid tissue), both in cellular interactions with Langerhans' cells and epidermotropic T lymphocytes, and in the production of cytokines (Chapter 10). Keratinocytes have been transformed by virus exposure, particularly SV40 [15] and human papillomaviruses, and by oncogene transfections, which have illuminated the processes of skin carcinogenesis. The effects of pharmaceutical agents, particularly retinoids, has been studied *in vitro*. Keratinocytes which have been transfected with human growth hormone genes can release human growth

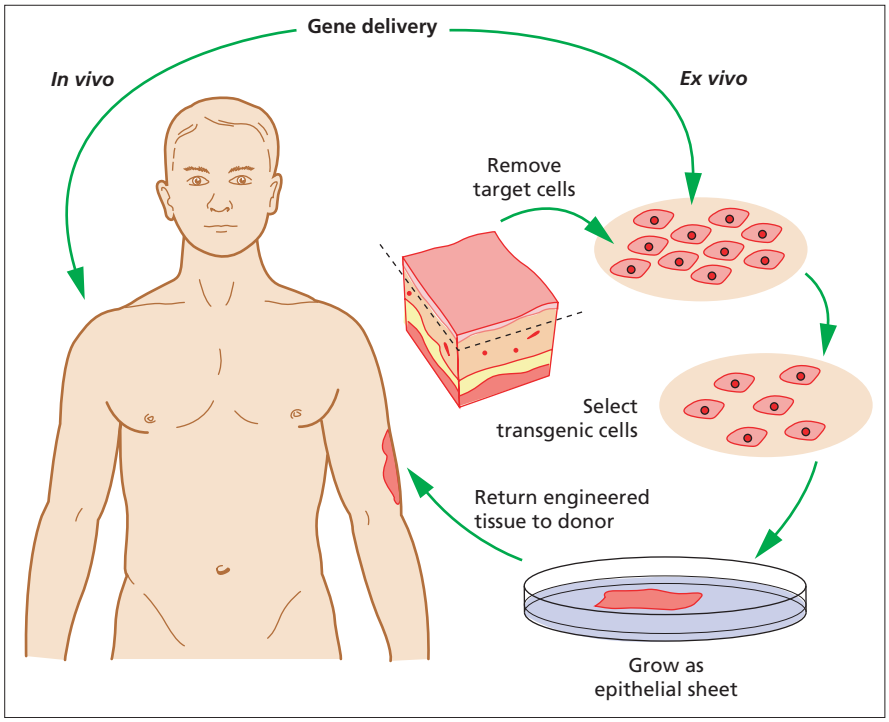

Fig. 3.22 Possible approaches to keratinocyte gene therapy for inherited skin disorders. One approach is direct transfer of genes into skin (*in vivo*) using direct injection of naked DNA or 'gene guns' (ballistic microprojectile accelerators) with the new genes being coated onto small particles of ice or gold. The alternative approach (*ex vivo*), and relevant to most strategies aimed at somatic gene therapy in skin, involves taking a biopsy from a patient, selecting transgenic cells, keratinocyte culture, and grafting of autologous engineered skin back onto the patient.

hormone [16], laying a basis for the use of keratinocytes in gene therapy, perhaps eventually to correct genetic defects such as type VII collagen abnormalities in recessive dystrophic epidermolysis bullosa or laminin 5 pathology in junctional epidermolysis bullosa (Fig. 3.22) [17]. The concept of keratinocyte function has changed over the last 10 years, from a passive cell awaiting terminal differentiation to an active secretory cell having important biochemical and immune functions.

The dermal–epidermal junction [1]

The dermal–epidermal junction is one of the largest epithelial–mesenchymal junctions in the body. It forms an extensive interface between the dermis and epidermis, and is continuous with the junction between dermis and epidermal appendages. By virtue of its anatomical location and highly complex composition, the dermal–epidermal junction and its major constituent, the basement membrane, have a key role in a wide range of epithelial–mesenchymal interactions including epidermal cell anchorage, adhesion, migration and differentiation. It is also involved in signalling between the ECM and basal cells, and serves as a barrier and filter.

Ultrastructure of the dermal–epidermal junction

The dermal–epidermal junction encompasses the basal plasma membrane of keratinocytes, melanocytes and Merkel cells and closely related structures, including hemidesmosomes. Hemidesmosomes [1–4] superficially resemble focal thickenings of the basal plasma membrane of keratinocytes. At high magnification, hemidesmosomes (Fig. 3.23) can be seen to have a complicated ultrastructure [1]. The most cytoplasmic portion of the hemidesmosome plaque, or inner plaque, associates with tonofilaments or IFs comprising keratin 14 and keratin 5. The outer plaque is closely associated with the basal plasma membrane. An extracellular component, known as the subbasal dense plate, lies parallel to and just beneath the outer plaque and associated plasma membrane.

Hemidesmosomes have an important role in maintaining adhesion between dermis and epidermis. Hemidesmosome numbers are consistent among individuals, and are not influenced by age, sex or body region [5]. They are similar in skin, gingiva, epidermal cell cultures and cornea.

Immediately beneath the basal plasma membrane is the basement membrane, which consists of three layers: the lamina lucida, the lamina densa and the lamina fibroreticularis [2,6,7]. Distributed throughout the lamina lucida are anchoring filaments, which are often difficult to resolve in electron micrographs, but are most conspicuous in the region of the hemidesmosomes. Anchoring filaments are very fine structures (approximately 3–4 nm in diameter) that are orientated perpendicularly between the lamina densa and basal plasma membrane. The lamina densa is an electron-dense layer that lies parallel to and below the lamina lucida. It usually appears amorphous in skin, although a filamentous substructure has been resolved in other tissues [6]. Anchoring fibrils are the major constituent of the fibroreticular layer of the basement membrane [2,5,8]. These are curved structures, with an irregularly spaced central cross-banding, that insert into the lamina densa and extend into the upper part of the dermis. They may also insert into amorphous bodies in the superficial dermis known as anchoring plaques [8], or, more typically, curve back to have a second insertion in the lamina densa [8,9]. Anchoring fibril numbers vary widely among individuals. Fewer have been found in the arm compared with the leg [5].

Another component of the lamina fibroreticularis is the elastic microfibril [2]. This may occur singly, but is best recognized in a 'bundle' consisting of many microfibrils that extends into the dermis and may enmesh with the microfibrillar system that surround dermal elastin [2]. The main elastic microfibril at the dermal–epidermal junction is fibrillin.

Molecular components of the epidermal basement-membrane zone [1–3]

Our understanding of the nature and function of the different components of the dermal–epidermal junction has progressed enormously over the past few years. This progress has resulted from studies incorporating recombinant DNA strategies, applied both *in vitro* and in transgenic and knock-out mouse experiments, from the production of highly specific monoclonal and polyclonal antibodies, and from improvements in immunocytochemistry enabling precise immunolocalization of antigens at the subcellular level. Important biological functions for many components of the dermal–epidermal junction have also been derived from mutation analysis in DNA from patients with inherited blistering skin diseases. The epidermal basement membrane, in common with other basement membranes, consists of a number of collagenous and non-collagenous macromolecules [1] (Table 3.3). These components have unique capabilities to interact and bind to one another, and to form a matrix that subserves the main functions of the basement membrane, including cell attachment, differentiation and movement.

Type IV collagen is the main structural constituent of the basement membrane (Figs 3.24 & 3.25), and has been immunolocalized mainly to the lamina densa [4]. The two major polypeptides are α1(IV) and α2(IV) with a molecular weight of 180–200 kDa for the α(IV) chains and of 550–600 kDa for the monomeric collagen type IV. The molecule is thought to have heterotrimeric composition of [α1(IV) α2(IV)]. The type IV collagen molecule has a large C-terminal globular domain at one end (Fig. 3.24), and an aminoterminal triple-helical region at the other, through which four molecules are able to bind covalently and form tetramers or 'spiders'. The point of overlap has been referred to as the 7s domain. The spiders are linked by covalent interactions between the C-terminal globular domains (Fig. 3.24). The type IV collagen molecule is able to interact with laminin, nidogen, heparan sulphate proteoglycan (PG), BM-40/SPARC and β1 integrin. Immunolabelling of normal human skin with an antitype IV collagen antibody is shown in Fig. 3.25.

Table 3.3 Molecular components of epidermal basement membrane.

Intermediate filament (IF) components
Keratin 14
Keratin 5
Hemidesmosomal plaque components
Bullous pemphigoid 230-kDa antigen (BP230; BPAG1)
Plectin
Transmembrane components
α6β4 integrin
Type XVII collagen (180-kDa bullous pemphigoid antigen 2 [BPAG2])
α3β1 integrin
Type XIII collagen
Syndecans 1 and 4
Lamina lucida/lamina densa components
Laminin 5
Laminin 6
Laminin 10
Laminin 2
Laminin 1
Lamina densa components
Type IV collagen
Nidogen
BM-40/SPARC
Perlecan
Anchoring fibril components
Type VII collagen
GDA-J/F3 antigen

Type VII collagen (Fig. 3.24) is described elsewhere. Initially, it was recognized that crystallites of SLS collagen were similar to anchoring fibrils [5], and more recently type VII collagen has been immunolocalized to anchoring fibrils (Fig. 3.26).

Of the non-collagenous basement-membrane components, the laminin family of glycoproteins is the best characterized [1,2,6]. The laminins are heterotrimeric molecules, each consisting of an α chain, β chain, and γ chain. More than 10 different laminin isoforms have been described [6], and laminins 1, 2, 5, 6 and 10 are known to occur in epidermal basement membrane.

Nidogen is a ubiquitous 150 kDa glycoprotein comprising three globular domains and a central rod [7]. It acts as a key stabilizer of basement membrane, binding to type IV collagen, perlecan and fibulins [8]. It also has calcium-dependent binding to the γ1 laminin chain. Thus, ligands for nidogen at the dermal–epidermal junction include laminins 1, 2, 6 and 10.

Perlecan is the main PG of basement membranes. It comprises a 500-kDa core domain with heparan sulphate attached to the amino terminus [9]. Perlecan binds to nidogen, dystroglycan and ECM1 [10]. Its functions include stabilization of basement membrane and regulating basement membrane synthesis and turnover through binding cytokines and growth factors.

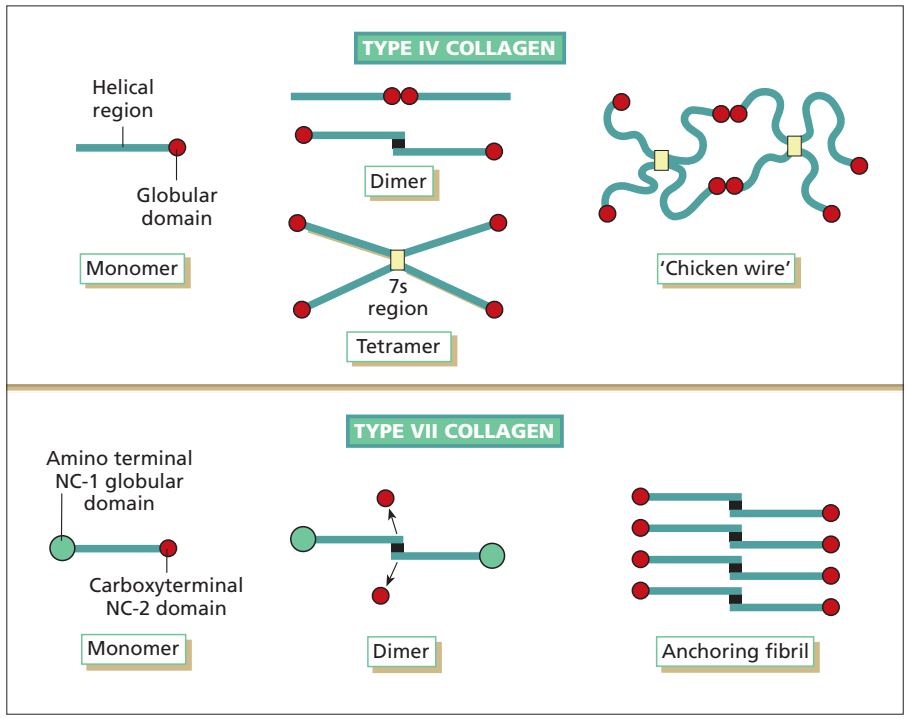

Fig. 3.24 Diagrammatic representation of the molecular organization of types IV and VII collagen.

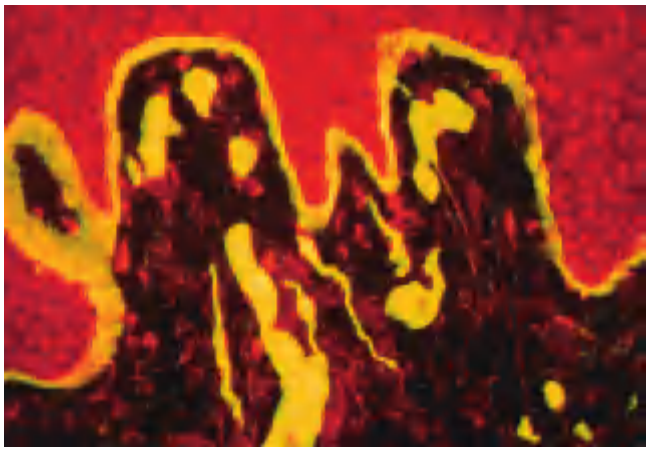

Fig. 3.25 Immunofluorescence micrograph showing staining for type IV collagen in the dermal–epidermal junction and around dermal vessels. × 250.

The major component involved in adhesion between basal cells and ECM is the hemidesmosome-anchoring filament-anchoring fibril adhesion complex (see below).

The hemidesmosome-anchoring filament-anchoring fibril adhesion complex [1–3]

Hemidesmosomes are thought to form a continuous link between the intracellular keratin filament network and the extracellular basement membrane. Further links are possible with elements in the superficial dermis via the anchoring fibril network. Because of the nature of the different molecules comprising this highly specialized complex, it now seems likely that hemidesmosomes are important not only in adhesion but also as a pathway for signal transduction between the extracellular and intracellular compartments [4,5; reviewed in 3]. Major intracellular (plaque) components of the hemidesmosome include the 230 kDa bullous pemphigoid antigen (BP230

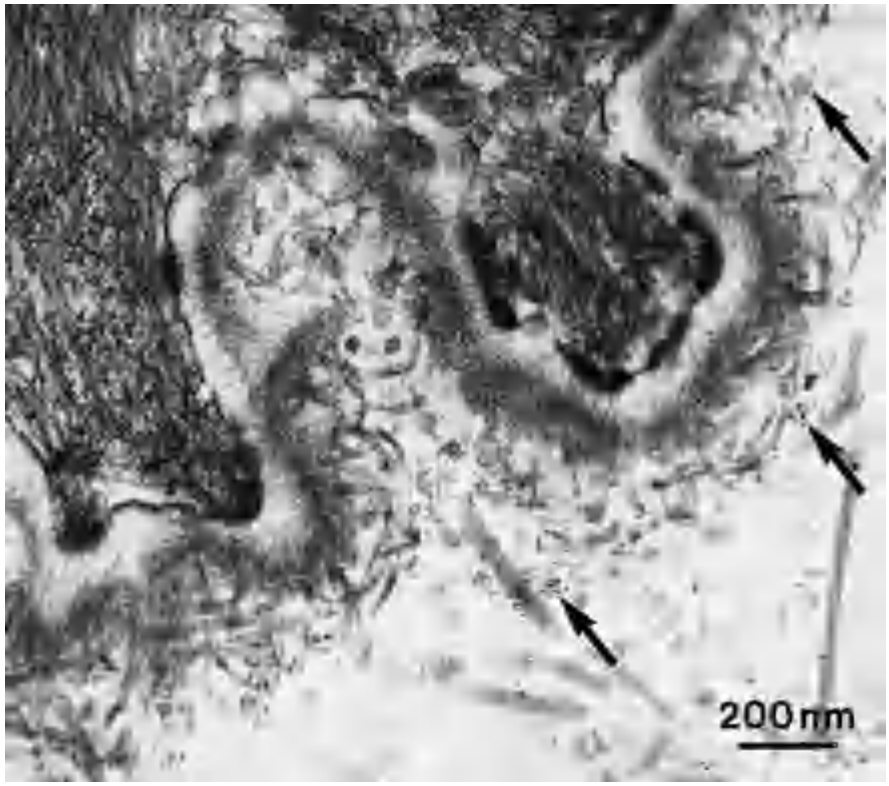

Fig. 3.26 Immunoelectron micrograph showing 5-mm gold labelling of epidermolysis bullosa acquisita antigen (N terminus of type VII collagen) associated with the ends of anchoring fibrils (arrows). (Courtesy of Dr H. Shimizu, Hokkaido University, Japan.)

or BPAG1) [6] and plectin [7] (Fig. 3.27). At least part of these molecules (the C termini) extend into the inner plaque, in a region of the hemidesmosome that would seem, at least spatially, well suited to interact with the keratin filament network. The possibility of such an interaction is strengthened by sequence homology between BP230 and plectin, and with another putative IF-associated protein, desmoplakin [2,8], which is a component of desmosomes but not hemidesmosomes. Plectin has a molecular mass of around 500 kDa. It is widely distributed among different cell types in various tissues, and its localization is not restricted to hemidesmosomes. It has the potential to form links with a variety of cytoskeleton components, including IF-forming proteins, microtubules and microfilaments [7]. HD1 and IFAP300 have also been described as components of the inner hemidesmosomal plaque. However, it appears that these represent either specific variants of plectin that are expressed only in hemidesmosomal inner plaques or unique plectin epitopes expressed only in the context of hemidesmosomes [9,10].

The α6β4 integrin and the 180-kDa bullous pemphigoid antigen (BP180, BPAG2 or collagen type XVII) are both transmembrane components of hemidesmosomes [11–13]. The region spanned by this combination of molecules is quite extensive. The cytoplasmic tail of the β4-integrin subunit contains over 1000 amino acids, and is thought to extend to the inner plaque of the hemidesmosome [14]. It also may have the potential to bind to keratin filaments, perhaps the end domain of keratin 5 (Fig. 3.28).

Immunoelectron microscopy has been used to localize epitopes of different proteins to anchoring filaments, which straddle the lamina lucida between hemidesmosomes and the lamina densa. These anchoring filament-associated proteins include laminin 5 [15,16], laminin 6 [17], the extracellular segment of type XVII collagen [18,19], the linear IgA antigen, LAD-1 (which constitutes part of the extracellular domain of type XVII collagen [20]) and the as yet unknown antigen recognized by 19-DEJ-1 monoclonal antibody [21].

Laminin 5 (previously known as nicein, kalinin or epiligrin) is a member of the laminin family of glycoproteins, of which over 10 distinct isoforms have been described [22]. Each is a heterotrimeric macromolecule with a cruciate structure, consisting of an α chain in part alignment with β and γ chains. Classical laminin, which is ubiquitous in basement membranes, is now known as laminin 1, with the composition of α1, β1 and γ1 chains. Laminin 5 has a more restricted distribution and comprises α3, β3 and γ2 chains. The α3 and γ2 chains undergo post-synthetic processing involving the enzyme BMP-1, leading to a reduction in their molecular weights from around 200 to 165 kDa and from 155 to 105 kDa, respectively. To maintain adhesion, specific interactions between the various structural components of the hemidesmosome-anchoring filament complex, including α6β4 integrin, type XVII

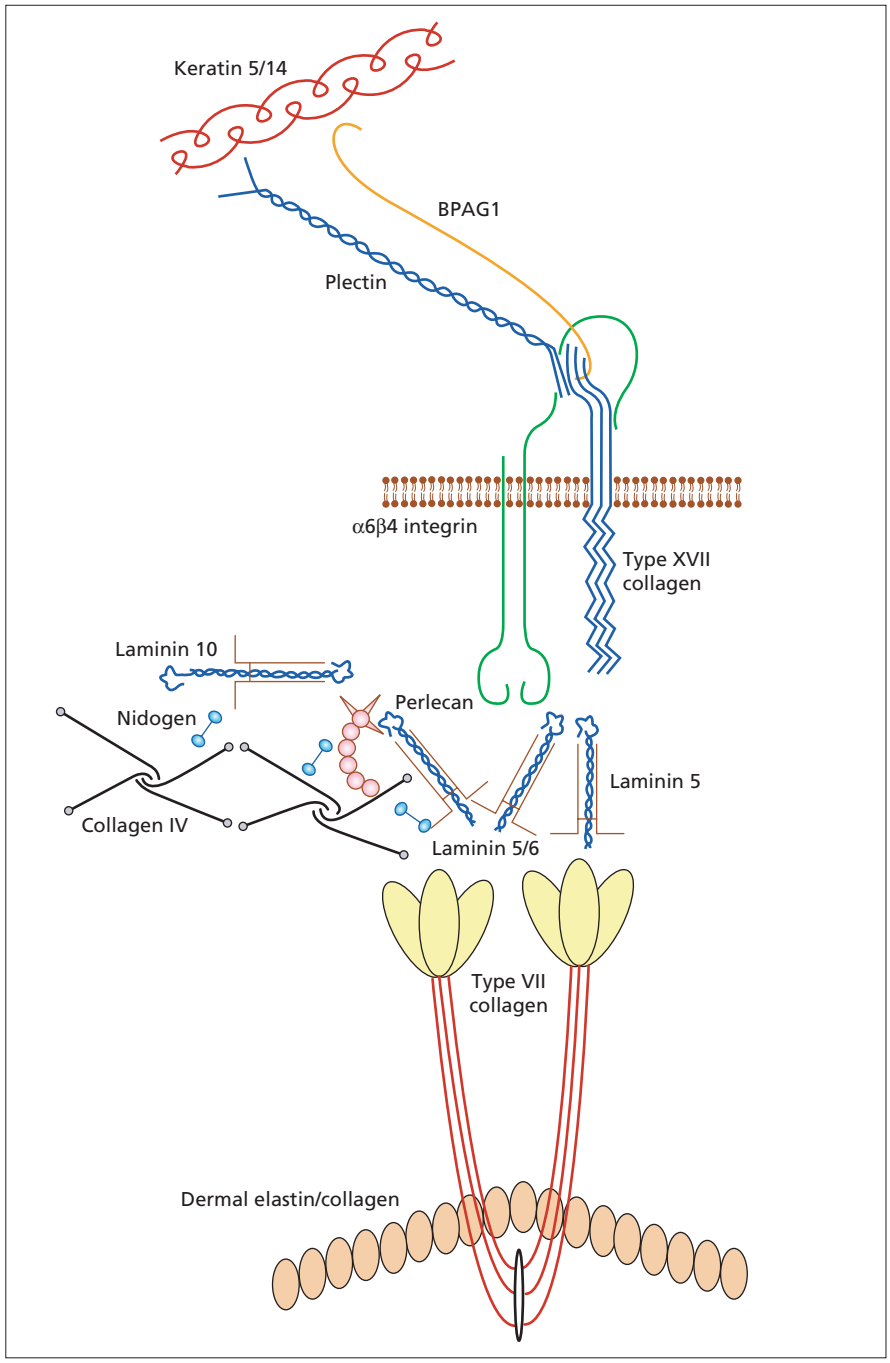

Fig. 3.27 Protein organization and interaction at the dermal–epidermal junction. Keratin filaments in basal keratinocytes are attached to the basal cell plasma membrane through plectin and BPAG1 within hemidesmosomes. Connections between these proteins and α6β4 integrin and type XVII collagen then provide a link to the epidermal basement membrane and bind to laminin 5. Laminin 5 may complex with laminin 6 and secure further adhesion to type IV and VII collagen. Additional protein complexes involving laminin 10, nidogen and perlecan provide further stability to the dermal–epidermal junction.

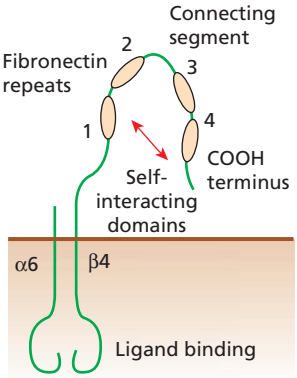
collagen, laminin 5 and laminin 6, must occur. For example, the intracellular part of β4 integrin binds to both plectin and type XVII collagen; the extracellular part of α6 integrin binds to type XVII collagen; laminin 5 binds to type XVII collagen, type VII collagen and laminin 6; laminin 6 binds to nidogen. Thus, a complex and coordinated meshwork of adhesive proteins (Fig. 3.27) is responsible for maintaining adhesion between the epidermis and the dermis [23].

Type VII collagen is the major, if not sole, component of anchoring fibrils [24]. Type VII collagen molecules are homotrimers consisting of three identical pro-α1(VII) chains. During extracellular assembly of anchoring fibrils, two type VII collagen molecules form an antiparallel dimer through an intermolecular interaction at the overlapping C-terminal ends of the molecule. There is also extracellular processing by BMP-1. Formation of anchoring fibrils comes about through lateral aggregation of multiple type VII collagen dimers [25] (Fig. 3.24).

Cloning of cDNA corresponding to overlapping α1(VII) sequences has shown a complex structure, comprising a central collagenous segment flanked by two globular



Domain	Function

domains of unequal size [26,27]. The larger N-terminal NC-1 (non-collagenous) domain is about 145 kDa, and contains sequences with homology to cartilage matrix protein (CMP) and to the A domain of von Willebrand factor [28]. In addition, there are nine consecutive fibronectin type III-like domains. Protein modelling predicts that these fibronectin type III-like domains have suction cup-like morphology and represent the main part of type VII collagen responsible for anchoring fibril adhesion. The smaller C-terminal NC-2 domain is about 17 kDa and contains a segment with homology to the Kunitz proteinase inhibitor [29]. The triple helical collagenous domain contains Gly-X-Y repeat sequences, with a 39-amino-acid non-helical interruption. Binding assays suggest a relatively strong affinity between the NC-1 domain of type VII collagen with type IV collagen with a weaker interaction with laminin 5 [25].

Dermis

[F.M. Pope, pp. 3.33–3.72]

Components of the dermis [1–3]

The dermis, which is bounded externally by its junction with the epidermis and internally by subcutaneous fat, contributes 15–20% of the total weight of the human body. It varies in thickness from about 5 mm on the back and thighs to 1 mm on the eyelids. It is tough and resilient, providing nutriment to the epidermis and cutaneous appendages and cushioning the body against mechanical injury.

It largely consists of a supporting matrix or ground substance, in which polysaccharides and protein coexist and interact to produce hygroscopic proteoglycan (PG) macromolecules, which strongly attract and retain water. Running through and attached to this matrix are several kinds of protein fibre, such as interstitial *collagen*, with great tensile strength, *elastin*, with considerable elasticity, and various other microfibrillar components such as fibrillin (types I and II), microfibril-associated glycoprotein (MAGP), microfibril-associated fibrillar protein (MAFP), collagen type VI and lysyl oxidase. Collagen (see below) represents 75% of the dry weight and 18–30% of the volume of dermis, of which more than 70% is type I collagen and 15% type III collagen. The ratios are reversed in arteries, while bone is composed of almost exclusively collagen type I. Collagen/connective tissue matrix is very complex, and also contains various PGs and adhesive glycoproteins. All interact with various other matrix components and cellular elements to produce a cohesive but variable tissue mix of ECM with differing combinations in tissues such as dermis, bone, blood vessels, etc. Embryonic dermis is a fine, three-dimensional network of collagen and elastic fibres interlaced with abundant PG-rich ground substance; in adults, collagen fills most of the dermal space [4] (Fig. 3.29). The size and arrangement of the collagen fibres distinguishes two main regions. The thin, superficial *papillary dermis* interdigitates with the ridged underside of the epidermis, from which it is separated by a basement membrane. Collagen fibril diameter (in transverse section) increases progressively from the superficial dermis through the mid and lower dermis, increasing from approximately 20 to 70 nm in this interval.

The underlying nine-tenths is called the *reticular dermis*: it blends with the subcutaneous fat. In regions such as the nipple, penis, scrotum or perineum, there are also stress-orientated smooth muscle fibres in the reticular dermis.

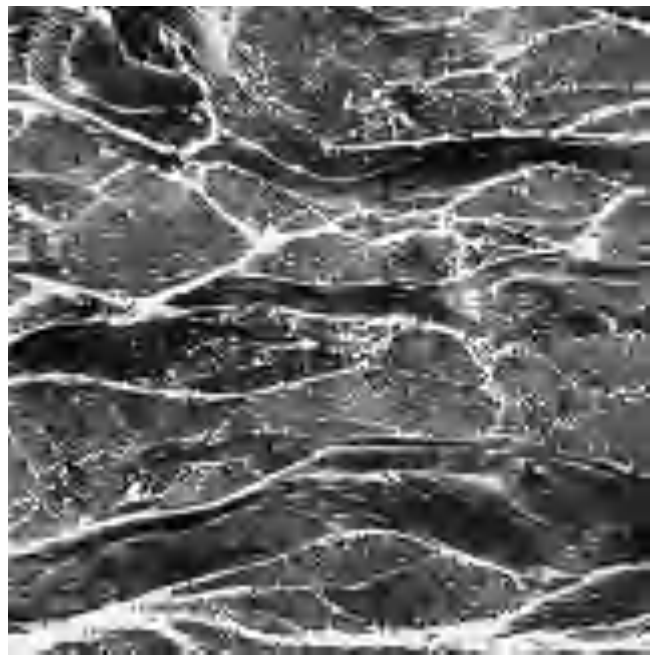

Fig. 3.29 Transmission electron micrograph of a section of dermis from the human forearm showing bundles of collagen fibres sectioned both transversely and longitudinally. × 4900. (Courtesy of Professor A.S. Breathnach, St John's Institute of Dermatology, London, UK.)

Abnormalities of collagen include fibril depletion, and disorganization, as in the hieroglyphic pattern of procollagen peptidase deficiency, the variability of fibrillar diameters in collagen type III deficiency, and highly disorganized fibrillar packing with cauliflower fibrils in type V collagen mutations.

Elastic fibres also form an extensive network, which intermeshes with collagen fibres. They are a complex mixture of proteins; by electron microscopy the central (striped) amorphous material consists of elastin whilst the peripheral microfibrils are more heterogeneous and are formed of components, such as fibrillins 1 and 2, certain microfibril-associated glycoproteins, such as MAGP-1 and -2, microfibril-associated proteins, such as MFAP types 1–3, lysyl oxidase and collagen types VI α1–3. Recently, in 2000, the gene for pseudoxanthoma elasticum (PXE) unexpectedly proved to be an ion transporter related both to the cystic fibrosis sodium CFTR (cystic fibrosis-transmembrane conductance regulator) transporter gene and certain drug resistance phenotypes. The gene contains three distinctive membrane spanning sequences, together with distinctive Walker A and B motifs and nucleotide binding folds (Fig. 3.30). Paradoxically, *ABCC6* mRNA is especially rich in renal and hepatic tissue, whilst homozygous or doubly heterozygous mutations of the gene cause fragmentation of elastic fibres

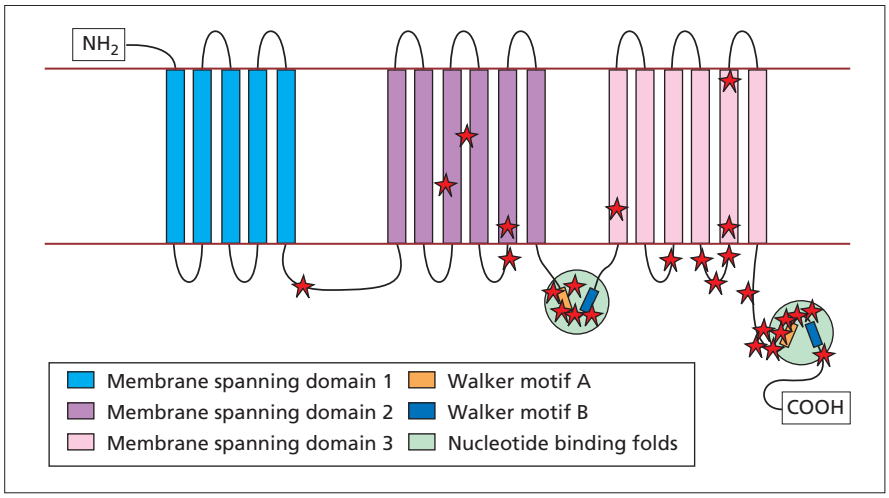

Fig. 3.30 Structure of the *ABCC6* gene showing the characteristic three membrane spanning domains, Walker A and B motifs and the nucleotide binding regions. Many of the starred mutations occur in the transmembrane sequences, or the loops that connect them.

in tissues such as skin, arterial medial walls and the retroretinal Bruch's membarane of the eye. Somehow, errors of *ABCC6* indirectly misassemble elastic fibres, which consequently fragment and bind calcium in skin eyes and arteries [5,6]. This produces the typical flexural rash, premature arteriopathy and early macular degeneration with premature visual loss of PXE. In embryos, the microfibrillar elements precede and act as a scaffold for the more mature elastic fibres. Mature elastic fibres are restricted to the reticular dermis. *Oxytalin* fibres, which probably anchor the basement membrane, extend as small bundles of microfibrils into the papillary dermis [7]. Oxytalin fibres also branch to form a horizontal plexus in the upper reticular dermis; small amounts of stainable elastic matrix are then secreted, to produce so-called *elaunin fibres* [7].

The *fibrillins* are microfibrillar proteins first isolated in 1986, with two or more genes isolated 5 years later. Antifibrillin antibodies detect dermal and vascular elastic fibrils, the ciliary zonules of the lens cornea, vitreous, articular and fibro-cartilage. The anatomical distribution of fibrillin closely parallels that of elastin in the dermis, vasculature, tendons, myotendinous junctions, ligaments, cartilage and lungs. Inherited abnormalities of fibrillin 1 cause Marfan's syndrome, while fibrillin 2 defects have a subtly different distribution, cause congenital contractural arachnodactyly (CCA) (Beals' syndrome), in which the ciliary zonules are normal, whilst impressive tendinous fibrosis causes finger contactures, with accompanying crumpling of the fibrosed external ear cartilage. Unlike Marfan's syndrome, aortic dilatation and rupture is virtually absent.

Other adhesive ECM glycoproteins include fibronectin [8], vitronectin, thrombospondins 1–5 [9,10], tenascins C, R, X and Y [11,12], osteopontin, and the highly diverse α, β and γ laminins [13,14]. The latter not only have mechanical adhesive properties, but also function in embryogenesis, organogenesis, differentiation and cell adhesion, by interactions with integrins, basement membrane collagens and PGs. Fibronectin (cold insoluble globulin), has variably spliced, soluble (in serum) and insoluble (in ECM) forms, of 500 kDa. The multidomain organization and splicing differ in the insoluble and soluble subtypes and a typical RGD binding sequence [8,15] common to most adhesive components. There are interactions with other homologous proteins and certain cellular components via certain integrin receptors [16,17]. The variably spliced domains bind to fibrin, heparin, factor XIIIa, collagen, etc. Fibulins 1 and 2 [18,19] also bind calcium and fibronectin, with distributions in ECM (fibulin 1), and heart, placenta and ovaries (fibulin 2). The fibulin 1 gene is located at chromosome 22, with the fibulin 2 gene on chromosome 3.

Many collagens also contain similar RGD sequences, while some (e.g. collagen type VII) have homologous fibronectin repeats. Vitronectin, thrombospondin and laminin all share RGD sequences but also have sequences with varying combinations of other elements, with EGF, TGF-β and von Willebrand factor homologies. Fibrillin has similar elements, as do some of the PG core proteins.

Proteins such as laminin [13,14], tenascin, vitronectin, nidogen (entactin) and von Willebrand factor share with fibronectin the capacity to modulate cell migration, ECM modelling and skeletal morphogenesis. They may also participate in connective tissue maturation, embryogenesis, wound healing and tumour metastasis, as do many other of the components mentioned earlier.

The predominant dermal cellular elements are fibroblasts, which secrete the ECM proteins mentioned above. Others include mast cells, histiocytes, macrophages, lymphocytes and other leukocytes, and melanocytes. The dermis also contains capillaries, arterioles, venules and lymphatics, as well as peripheral, sensory and motor nerve endings.

Elastic tissue

Elastic fibres are mixed collections of various distinctive microfibrillar structural glycoproteins, at least one of which is an enzyme, whilst elastin forms the central amorphous centre of the compound elastic fibres. By electron microscopy, they have central amorphous and peripheral microfibrils of 10–13 nm [1], whilst light microscopy shows darkly stained unbranched fibrils which are intermingled and separate from collagen and other matrix elements. Microfibrils either decorate amorphous elastin or occur between individual collagen fibres. Elastin-associated microfibrils include glycoproteins such as fibrillin 1 and 2, MAGP-1, -2 and -3, MFAP-1, -2 and -3, and fibulin 1 and 2 with molecular weights of 25–340 kDa [1–4]. Quite clearly, elastin and elastic fibres differ from other ECM components such as collagen (except type VI) and PGs (see below). They stain with elastic-specific stains such as orcein, and are widespread in tissues such as skin, lungs, alveoli, arteries, veins, the urinary tract, eye (both cornea and suspensory ligament), fibrillar and articular cartilage, and specialized tendons such as the ligamentum nuchae.

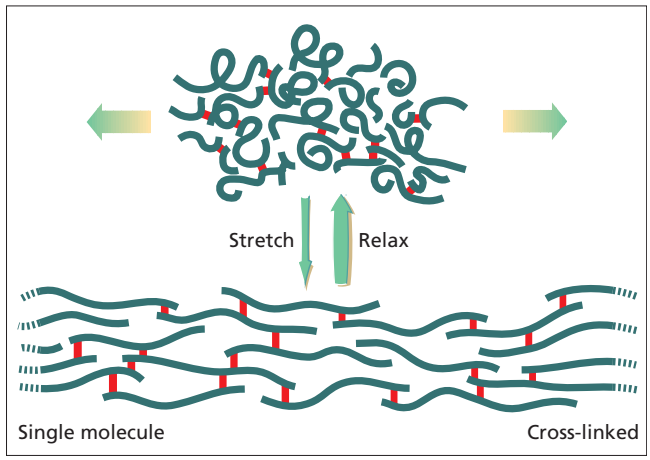

Fig. 3.31 Schematic representation of elastic fibrils in contracted and stretched modes. Cross-linked random coils confer the capacity for extensibility.

Biophysical properties

Elastin possesses a rubbery recoil, allowing the function of expansile tissues such as the aortic arch, which in a lifetime undergoes 1000 million contractions and relaxations. Entropy increases on relaxation but decreases on stretching or expansion. Elastic fibres accommodate these desirable requirements (Fig. 3.31).

Histology and electron microscopy

Elastic fibres have certain characteristic features, on both light and electron microscopy.

Light microscopy [5–7]

On light microscopy with stains such as Weigert's resorcin–fuchsin, Verhoeff's or orcein, elastic fibres are coloured black or dark brown. In contrast, collagen and other connective tissue elements are stained either red or yellow. Oxytalin and elaunin subepidermal microfibrils are closely associated with elastic fibrils in the reticular dermis.

Transmission electron microscopy

Transmission electron microscopy of elastic fibres shows distinctive sheet-like agglomerates, which are several hundred nanometers wide (Fig. 3.32). The peripheral microfibrils include proteins such as MAGP-1, -2 and -3, MFAP-1, -2 and -3, fibulins 1 and 2, and fibrillins 1 and 2, while the central speckled amorphous element contains only elastin. Other proteins, such as collagen type VI α1–3 chains, and lysyl oxidase are also microfibrillar. In the developing embryo, microfibrils precede elastin forming a scaffold upon which mature elastin protein is later

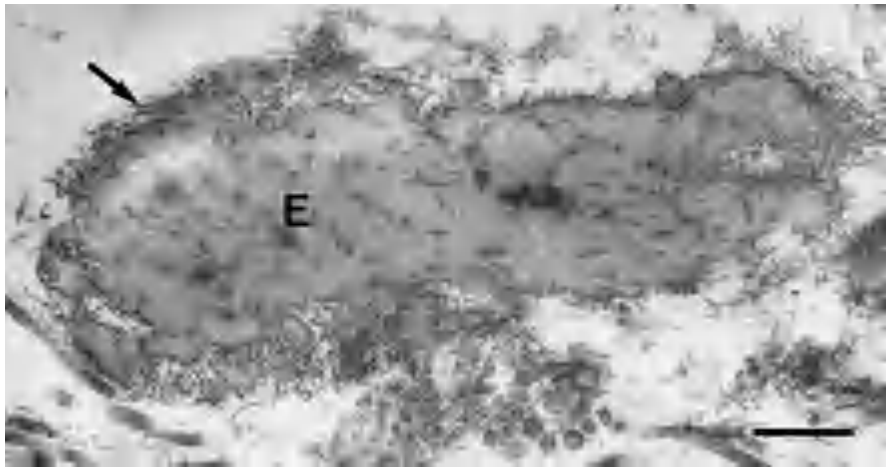

Fig. 3.32 Electron micrograph of an elastic fibre in reticular dermis. The central, mottled component (E) contains elastin, and the microfibrillar network can be seen at the periphery of the fibre (arrow). Scale bar = 0.5 μm.

deposited [1]. Some fibrils behave differently; for example, fibrillin 2 has a subtly different tissue distribution, appears later in fetal development and fulfils a different and non-load-bearing function of elastic fibres [8,9].

Biochemistry and molecular pathology

Since 1984, when the first elastin sequence appeared, all of the other elastin-associated microfibrillar components have also been cloned and sequenced [10–24]. Thus MAGP-1, -2 and -3 and fibrillins 1 and 2 were sequenced between 1991 and 1994 [1,12], closely followed by other constituents, such as the fibulins, the MFAP proteins, lysyl oxidase, lysyl hydroxylase, etc. [13–24]. All are important constituents of mature elastic fibrils. MAGP was first recognized as an ECM component [1]. It formed microfilaments ranging from 3 to 20 nm, which, after denaturing, formed strings of beaded microfilaments on rotary shadowing [4]. Components such as the 340-, 78-, 70-, 31- and 25-kDa proteins were subsequently purified. Other workers identified 128-, 115-, 58- and 36-kDa proteins [12,13]. Fibrillin was then identified as the 340-kDa element and is also microfibrillar. Bressan *et al*. [15] named the 115-kDa component emilin, while Kobayashi *et al*. [16] identified a 58-kDa component of elastin-associated fibrillin. Kielty *et al*. [17–19] showed that fibrillin forms the connecting elements of beaded filaments. The separate, but related, genes (*Fib1* and *Fib2*) were both cloned in 1991 [8,9]. Although MAGP-like glycoproteins are homologous to fibrillin, they are also distinctive and unique. Thus, antibodies to the 31- or 78-kDa proteins both detect part of the 340-kDa fibrillin protein, but do not cross-react [1,13]. Cloning of the relevant genes has clarified this paradox, clearly showing that the protein families have both homologous and non-homologous sequences, which distinguish one from another. More recently, the PXE *ABCC6* gene, rather unexpectedly, has been shown to encode for an ion transporter molecule, analagous to the cystic fibrosis gene. Homozygous or doubly heterozygous muatations somehow disrupt elastic fibril assembly, with consequent fragmention and calcium binding, in tissues such as skin, arterial media and the subretinal Bruch's membrane of the eye, causing the typical PXE clinical phenotype.

Microfibril-associated glycoprotein (MAGP)

Gibson *et al*. [1] first affinity purified and then cloned bovine MAGP, and showed that the 31-kDa protein was not a degradation product of the 340-kDa (fibrillin) protein. Cloning of fibrillins 1 and 2 [11,12] confirmed their distinction from human MAGP [10,20,22], although the latter forms 12-nm microfibrils, which decorate the beaded filaments of fibrillin. Mouse MAGP has two distinctive domains [18]. The N terminus is rich in glutamine, proline and aspartic acid, while the C terminus is cysteine cross-linked, resembling the equivalent fibrillin sequences. The gene has eight introns distributed over 10 kb. It is expressed in lung, pulmonary arteries and heart [11,22]. MAGP-2 and -3 proteins have also been cloned and sequenced. MAGP-1 lies on chromosome 19p36.1–p35, MAGP-2 lies at 12p12.3–13.1, whilst MAGP-3 is located at 15q15–q21, close to the fibrillin 1 (*FBN1*) gene. The microfibril-associated proteins MFAP-1 and -3 are co-associated with, but molecularly distinct from, the MAGP proteins [20–22]. The three MAFP genes have now been sequenced and are located, respectively, close to fibrillin 1 on chromosome 15q15–q21 [10] (*MFAP-1*), and close to fibrillin 2 (*FBN2*) at 5q21–q31, and subsequently, MFAP-2 and -4 [21–24], and mouse MAGP [21] have been sequenced. The deduced protein sequence of MFAP-3 is partially homologous to MAGP-1 and MAGP-2 [23]. Antibodies to MFAP-3 stain ciliary zonules (as does fibrillin 1). Other microfibrillar proteins such as the 78-, 36- and 25-kDa elements have yet to be sequenced, although MFAP-2 may be analogous to the 25-kDa protein. The tissue

distributions of MFAP-1 and -2 also differ substantially. Thus, while MFAP-1 antibodies stain renal glomerulus and mesangium, antibodies to MAFP-2 detect only renal tubular renal basement membrane, implying important functional differences.

Fibrillins 1 and 2

Whilst Gibson *et al*. [1,13] cloned MAGP-1, Sakai *et al*. [25] identified the 350-kDa glycoprotein, fibrillin. Fibrillin antibodies stain elastic fibres in skin and blood vessels and other ECM [26]. Rotary shadowing electron microscopy of fibrillin-containing microfibrils formed from post-confluent Marfan's syndrome fibroblasts showed that they were severely disaggregated [19]. The fibrillin 1 gene [11] and the Marfan's syndrome loci were at 15q15 [12,27,28]. Maslen *et al*. [11] and Lee *et al*. [12] independently cloned a fibrillin cDNA of 10 kb, which was rich in 6- and 8-cysteine repeats. The 6-cysteine repeats resemble EGF [11,12], whilst certain 8-cysteine elements resemble TGF-β. Fibrillin 2 on chromosome 5q causes CCA (Beals' syndrome) [11]. The fibrillin 1 gene has 11 kb of coding sequence spread over 110 kb of genomic sequence split into 65 exons. These include 43 EGF-like calcium-binding regions, four similar but non-calcium-binding repeats and seven TGF-β subunits. Marfan's syndrome mutations frequently cluster in the EGF (calcium-binding) and TGF-β domains. Subsequently Lee *et al*. [12] identified the first mutations and various others quickly followed [29,30]. Nijbroek *et al*. [31] documented 53 mutations including various cysteine substitutions in EGF and TGF-β regions, but also premature stop codons and null alleles. Infantile Marfan's syndrome has mutations clustered between exons 24 and 31. The most structurally disruptive mutations produce the least distorted microfibrils, implying that defective protein structure is more damaging than missing protein. A putative Marfan's syndrome locus at 3p24 is highly controversial [32–34]. Antibodies to fibrillin 1 and 2 differentially stain elastic-containing tissues such as skin, aorta and cartilage. Fibrillin 2 is more widespread than fibrillin 1. In skin, fibrillin 2 is concentrated around hair follicles and sweat glands, and forms connections between the dermis and the overlying basement membrane. Based upon the differential morphological distribution of fibrillin 1 and 2, it has been postulated that fibrillin 1 is load-bearing, and therefore appears early in blood vessels and ciliary zonules. Fibrillin 2, which only appears later in embryogenesis, mainly regulates elastic fibril assembly, but lacks any load-bearing function [9].

Biochemistry and gene structure of elastin

Elastin is highly insoluble and chemically inert [35]. It remains after boiling ligamentum nuchae or aorta in 0.1 mol/L sodium hydroxide at 98°C. Removal of soluble collagen or PG, with 4 mol/L urea or 5 mol/L guanidine, followed by pepsinization and precipitation of microfibrillar proteins, leaves a protein that is rich in glycine, aniline, valine and proline. This suggests an ancient homology with the fibrillar collagens. Both collagen and insoluble elastin have soluble precursors (tropoelastin and preprocollagen). Lysyl 6 oxidase cross-links certain lysines to compounds such as desmosine, isodesmosine, dihydrolysinonorleucine, allylsine and dihydromerodesmosine, with elastin polypeptides cross-linked to form rubbery elastic fibres. Experimental animals fed lysyl oxidase inhibitors produce soluble uncross-linked tropoelastin protein of 72–74 kDa. There are also non-triple-helical Gly-X-Y collagenous homologies which, unlike collagen, are not cross-striated. Instead, elastin monomers cross-link to a deformable rubbery elastomer, distributed in organs such as tendons, lungs and arteries [35].

The elastin gene

Chick, bovine and human tropoelastin/elastin genes have 34 and 36 exons [36–39]. The human gene maps to chromosome 7q11.23 [35,36], coding for a 730 amino acid protein with distinctive hydrophobic and cross-linking cassettes, reminiscent of the fibrillar collagens. As in collagen, each exon ends in a perfect codon, and is followed by the first codon of the next exon. The human gene has 34, rather than the 36, exons of its bovine analogue [39]. Elastin exons are generally small, usually ranging between 27 and 160 bp, and there are similarities to collagen organization [35]. Some intronic sequences also have elastin homologues. In humans, there is alternative splicing of exons 23 and 23a, which significantly alters the geometry and cross-linking of adjacent hydroxylysines to deaminated lysines [32,36]. Elastin mutations cause autosomal dominant and recessive cutis laxa (CL) or PXE [7], Williams syndrome and supravalvular aortic stenosis (SVAS) [40–42]. Both disorders arise from haplo-insufficiency where one copy of the elastin gene has been mutated or deleted [42–45]. The clinical phenotype of Williams syndrome includes generalized ECM features, such as SVAS, mandibular hypoplasia, blubber lips and mental retardation [40,41,45]. Isolated SVAS without Williams syndrome is linked to the elastin locus at 7q11–23 [40,41]. While simple hemizygosity of the elastin gene from small or large intragenic deletions causes SVAS [40,42], those causing Williams syndrome are much larger [43–45]. It is probable that a contiguous deletion syndrome affects adjacent genes, while the defect in SVAS is localized to the elastin gene. The larger Williams syndrome deletions (more than 500 kb) may also affect the contiguous Lim kinase 1 gene, which probably directly influences CNS development and visuospatial capabilities [44,45]. Similarly, more focused elastin mutations cause SVAS, many of which are caused by premature termination

mutations, with nonsense-mediated mRNA decay. SVAS mutations range from clinically benign and undetectable to severe multivessel degeneration [46]. Amongst the various mutational patterns are certain small inframe insertions or deletions, often with duplication or deletion of elastin sequences [47,48]. Contrastingly, single base deletions in exons 32 or 33 cause autosomal dominant CL [49,50], whilst we have recently identified a 24 exon inframe duplication of the elastin gene in a British family with autosomal dominant CL and premature emphysema. This produces an elongated but matrix-incorporated, mutant tropoelastin protein over 55 kDa larger than the normal 72 kDa product. Consequently, there is elastic fragmentation, CL and pulmonary emphysema [51–53]. Furthermore, elastin products are potent chemotactic, proliferative and chemotactic agents, which affect cell proliferation, attachment and migration, and which are potently up-regulated in, and promote the growth of, certain breast and cerebral tumours, especially cerebral astrocytomas.

Ground substance

Proteoglycan (PG) chemistry

PG families have variable core proteins with attached polymers of unbranched disaccharides (Figs 3.33–3.35). Disaccharide units are usually linked by *O*-linked serine–xylose–galactose–galactose sequences [1–4]. The attached disaccharide polymers vary from few to hundreds in number, making chemical separation by electrophoresis difficult to interpret. Glycosaminoglycans (GAGs) link cell-surface receptors with ECM proteins, such as collagen, fibronectin or fibrin. Biochemically, the GAG chains cluster otherwise unrelated proteins into subsets, which separate similarly by column chromatography. Consequently, the functions of such varied proteins are unusually diverse.

Rules for GAG composition

These may be summarized as follows [1,4].
1 Glycosaminoglycans are linear polymers with alternating pairs of different monosaccharides, such as glucose or galactose, joined in 1–3 or 1–4 linkage.
2 Three common disaccharide combinations are the commonest building blocks from which most GAG sequences are derived.
3 Variably sized polymers have particular post-assembly modifications.
4 Modifications are unpredictable, variable in number, and are catalysed by specific sulphatases or epimerases. They include sulphation, the replacement of *N*-acetyl by *N*-sulphate and the epimerization of D-glucuronic to L-iduronic acid.
5 Individual polysaccharide combinations may have any or none of these changes.
6 In contrast to DNA or protein sequence, such combinations have no information content.

Differences between PG polymers

The derivation and chemical structure of heparin, heparan sulphate, chondroitin, dermatan sulphate, keratan sulphate and hyaluronic acid are shown in Table 3.4 and Fig. 3.33. The differences between constituent polymers are chemically minor [1,4]; they have subtle implications for three-dimensional conformation and molecular interactions [5–9]. For example:
1 Chondroitin/dermatan differ from heparin/heparan only by the substitution of *N*-acetyl galactosamine for *N*-acetyl glucosamine; i.e. essentially by the orientation of a single H-C-OH bond at position 1.
2 Hyaluronic acid differs from keratan both by changing glucuronic acid to galactose and by substituting β1–3-linked glucosamine to β1–4 glucosamine.
3 Similarly, hyluronan (1–3-D-*N*-acetyl glucosamine)$_n$ differs from dermatan and chondroitin sulphate (1–3-D-*N*-acetyl galactosamine) only by the orientation of a H bond.

Relationship of disaccharide side-chains to the various PG core proteins

Aggrecan, a large aggregating cartilage PG, is a good model of PG protein organization [2]. It has a central protein core with certain additional structural motifs and domains (Fig. 3.35). Binding to hyaluronate occurs via link and G1 sequences, with homologous G2 sequences nearby at the N terminus. The C terminus possesses a non-homologous globular sequence with lectin-like properties. Lying between G2 and G3 is the bulk of the core protein, containing near to the N terminus keratan sulphate-rich sequences, which in humans and cattle are attached to certain proline-rich hexapeptide repeats. Keratan sulphation increases with age. Most of the remaining link protein (LP) has serine–glycine sequences for attachment of chondroitin sulphate disaccharide polymers. Of the N terminal 428 amino acids, 117 are serine–glycines. In contrast, only 68 of the 628 C-terminal amino acids have this important combination of attachment sequences. The serine–glycines lie within longer 10 amino-acid motifs. The major part of the core has 1000 chondroitin sulphates (D-glucuronic acid β1–3-*N*-acetyl galactosamine)$_n$ compared with only 30 keratan sulphates (D-galactose β1–3-glucosamine)$_n$. There are also 40 oligosaccharides, most of which are *O*-linked with a few *N*-linked ones. The G1 domain binds hyaluronate (D-glucuronic acid β1–3-D-*N*-acetyl glucosamine β1–4)$_n$, which forms very long disaccharide polymers. Hyaluronate also binds various other PGs through their hyluronate binding domains,

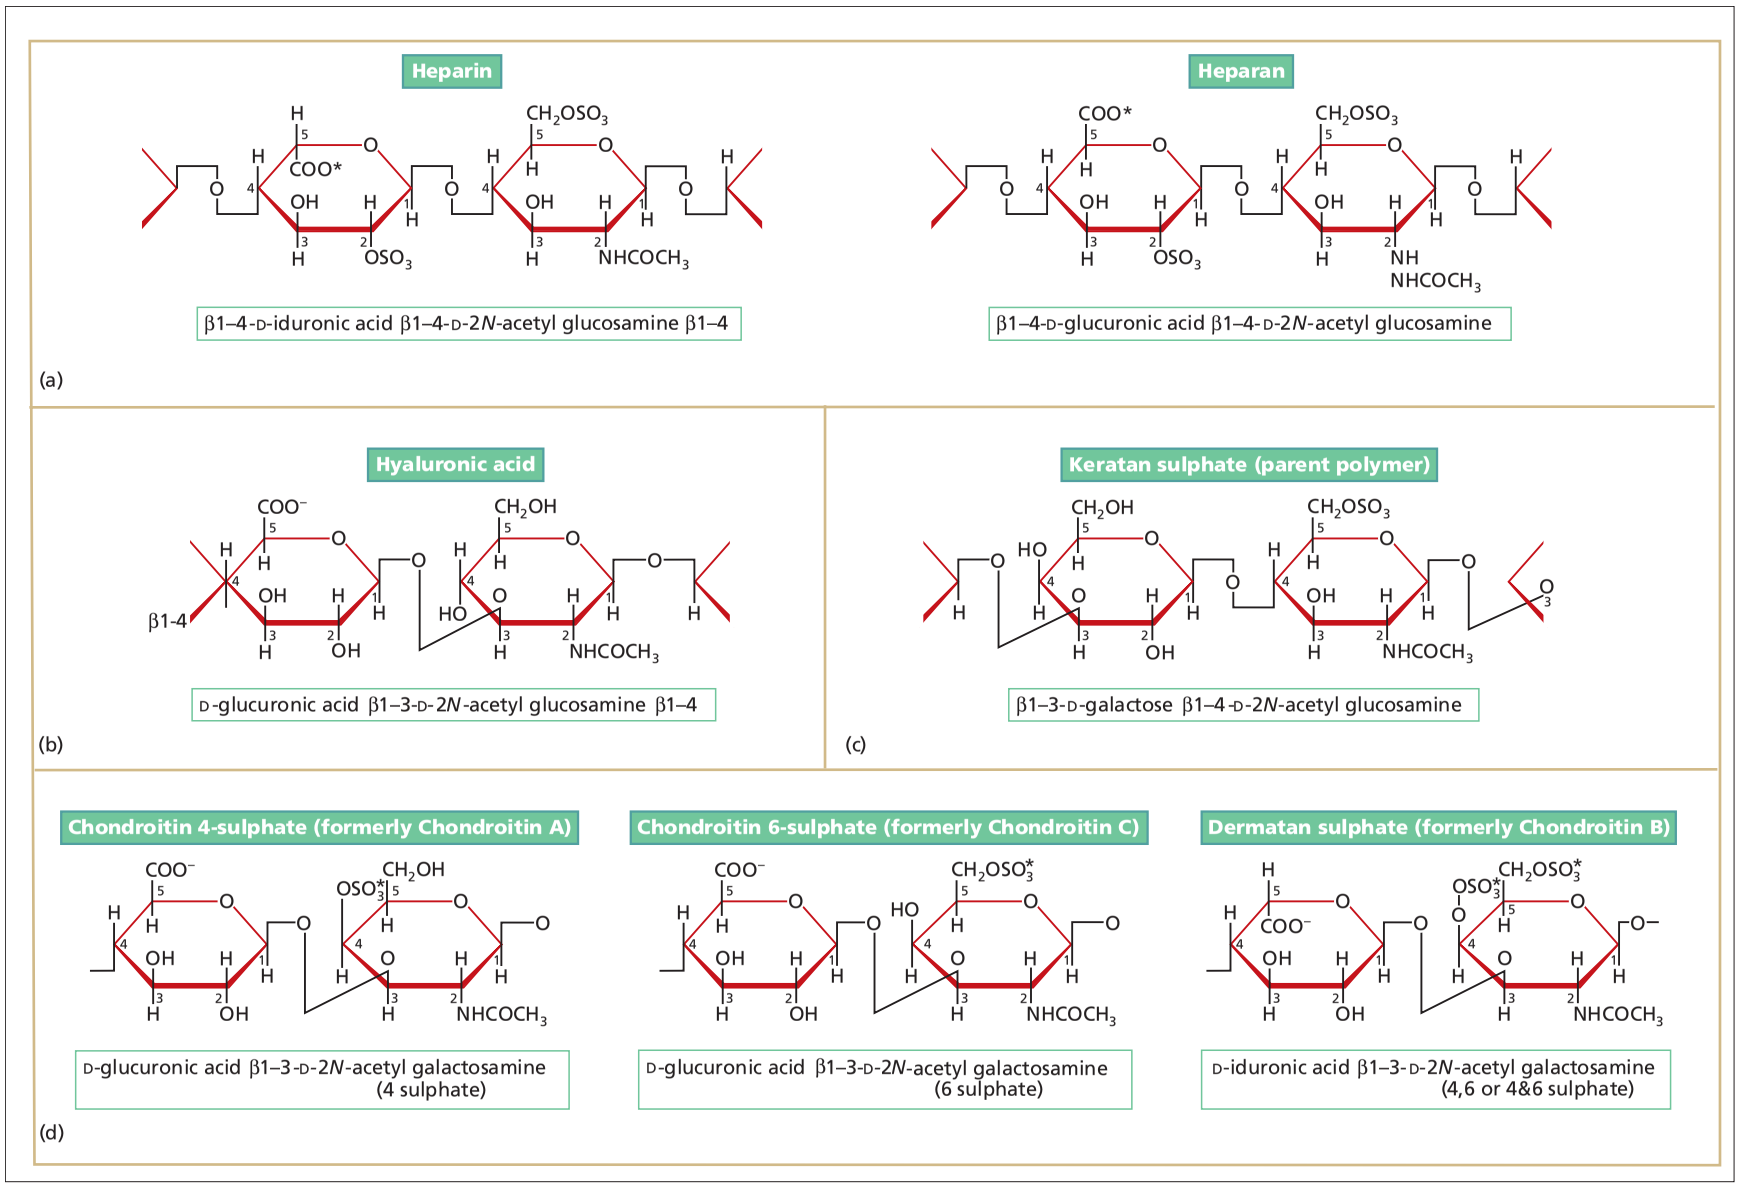

Fig. 3.33 Diagrammatical representation of the glycosaminoglycans (GAGs) which comprise the carbohydrate polymer side-chains of proteoglycan (PG) molecules. These include the arrangements of (a) heparin, (b) hyaluronic acid, (c) keratan and (d) the various chondroitin sulphates; variants include *O*-sulphation at the 6 position of both glucosamine and galactose.

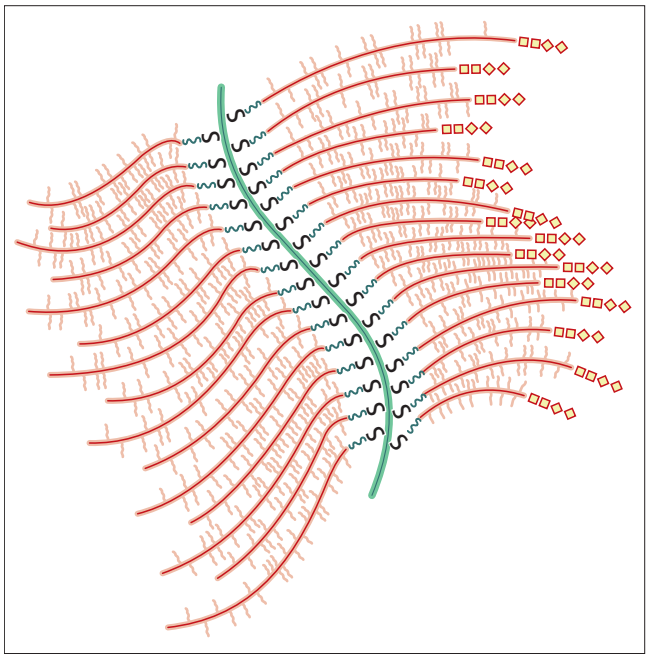

Fig. 3.34 Representation of a typical proteoglycan (PG). The central core (green) is hyaluronate and the link proteins (LPs) are represented by S shapes, joining the protein side-chains and carbohydrate polymers. (Adapted from Stryer [1].)

Fig. 3.35 Diagram of the core protein aggrecan from cartilage, joined by link proteins (LPs) to hyaluronate, with keratan sulphate (KS: blue) and chondroitin sulphate (CS: purple) side-chains: aa, amino acids. (Adapted from Heinegard and Oldberg [2].)

consequently producing compound aggregates with molecular weights of thousands of millions (10^9).

Most PGs are connected to their protein cores by *O*-glycosidic bonds of two galactoses joined to a xylose and serine. The xylosyl transferase reaction occurs in the endoplasmic reticulum and the Golgi, while the galactose and disaccharide links form only in the Golgi. Sulphation occurs just before secretion. Epimerization is also enzymatic and sequence related. Thus, different epimerase enzymes act upon dermatan (D-iduronic acid β1–3-*N*-acetyl galactosamine β1–4)$_n$ than upon heparin/heparan (D-iduronic acid β1–4-D-*N*-acetyl glucosamine α1–4)$_n$.

Classification of PGs [2,7–10]

Latterly, the traditional classification of PGs according to their disaccharide polymers has changed to concentrate upon the nature of their protein cores. This arrangement has both strengths and weaknesses. For example, there is confusion when the same core has different attachments of sugar polymers.

Degradation occurs via GAG receptors and requires endocytosis prior to lysosomal digestion.

Proteoglycan function

The functions of PGs are varied and sometimes unexpected.
1 Very probably, certain carbohydrate or protein sequences have very specific and distinctive functions.

(a) Protein-mediated properties include modulation of fibrillogenesis (decorin, biglycan and fibromodulin)

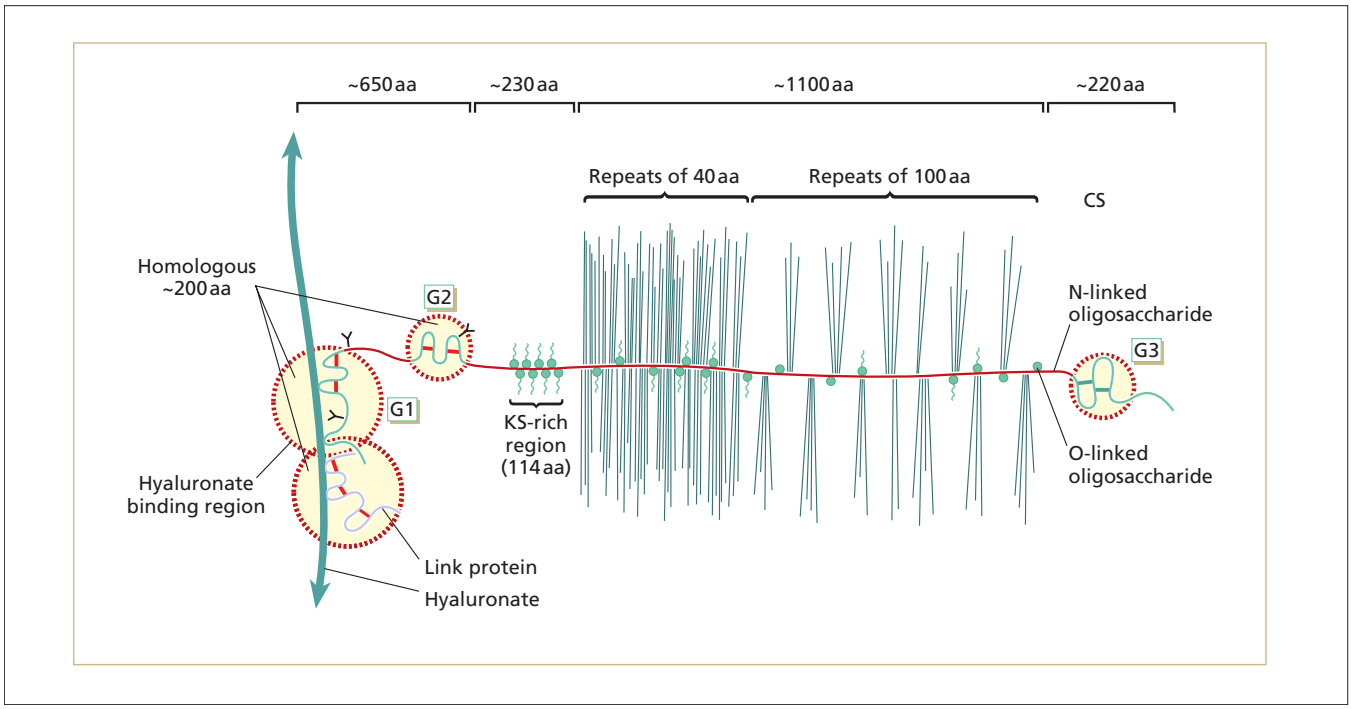

Table 3.4 Glycosaminoglycans.

Name	Parent polymer	Comments
Heparin/heparan sulphate	(D-glucuronic acid β1–4-D-2*N*-acetyl glucosamine α1–4)$_n$	Heparin and heparan differ in extent of sulphation. Heparinase and heparatinase act differently
Chondroitin/dermatan sulphate	(D-glucuronic acid β1–3-D-2*N*-acetyl galactosamine β1–4)$_n$	*Chondroitinase* *ABC* *AC* Cleave: Chondroitin + + Dermatan + –
Keratan sulphate	(D-galactose β1–4-D-2*N*-acetyl glucosamine β1–3)$_n$	
Hyaluronic acid	(D-glucuronic acid β1–3-D-2*N*-acetyl glucosamine β1–4)$_n$	

[8–11], TGF-β binding and hyluronate binding (versican, aggrecan and CD44) [2,12–14].

(b) Contrastingly, sulphated GAGs such as heparan bind basic amino-acid sequences of general formula BBXB or BBXXB; second, binding may be charge dependent as, for example, to other matrix molecules, cell adhesion or growth factors.

(c) An example of disaccharide-dependent binding, is heparin/heparan to antithrombin III [14].

(d) Similarly, highly sulphated PGs bind fibronectin. This is strongest in heparin and progressively weaker with heparan, dermatan or chondroitin.

(e) Carbohydrate length or molecular weight also influence binding. Similarly, some core proteins are stronger interactors than others. Good examples are the hyaluronic acid binding domains and lectin binding domains at different ends of aggrecan core protein. Versican has similar sequences and binding properties. Decorin binds to fibronectin and collagen.

2 Other functions include:

(a) *Cell adhesion*. Cell-surface PG modulates cell adhesion. For example, syndecan has heparan and chondroitin sulphate side-chains, which can bind both collagen and fibronectin. Such PG binding complements and enhances amino acid–RGD binding. Soluble PGs inhibit cell adhesion to collagen or fibronectin, either by blocking the PG attachment site or by steric hindrance of integrin receptors. Core proteins can also mediate cell adhesion [13]. An example is lymphocyte homing receptor, which is homologous to hyaluronic acid and also has sequence homology to the C terminus of versican, possessing similar lectin binding, EGF and complementary regulator sequences (see below).

(b) *Cell proliferation*. Heparin and dextran both inhibit cell proliferation, as does heparan sulphate purified from endothelial cells of hepatocytes. Basic and acidic FGFs bind to heparin/heparan. Binding probably regulates TGF-α or TGF-β release.

(d) *Protease and antiprotease function*. Antithrombin III tightly binds heparin/heparan sulphate. Those proteases that are regulated by antithrombin III, such as thrombin, factors IXa and XIa, are brought into close apposition by heparin/heparan. Their presence accelerates the action of antithrombin as much as 2000-fold. For this reason heparin is a very potent anticoagulant.

(e) *Polypeptide growth factors*. Some PGs are catalytic.

(f) *Cell adhesion*. Neural cell adhesion molecule (NCAM) interacts with cell-surface heparan.

(g) *Lipoprotein uptake*. Hepatocyte heparan sulphate binds lipoproteins via apoE and apoB, thereby immobilizing lipoprotein lipase and hepatic triglyceride lipase to the cell surface.

Classification and gene sequence of extracellular PGs

At least 25 genes specify a range of PG proteins with variable numbers of GAG side-chains. The nomenclature of the latter was described earlier. The first gene was cloned by Krusius and Ruosolahti [13]. They identified the cDNA sequence of a small chondroitin E/dermatan sulphate (D-glucuronic/iduronic acid β1–3-2*N*-acetyl galactosamine) PG (PG40), produced by fibroblasts. The cDNA contained GAG attachment sequences, such as serine–glycine or glycine–serine dipeptides. At the time, the core protein sequence was novel [14,15]. The PG also bound type I collagen and inhibited both collagen and fibronectin-mediated cell attachment. There were also three *N*-glycosylation sites and 12 amino-acid motifs, within which the serine–glycine sequences were implanted. Since then, the field has very rapidly advanced [2,8,11]. PGs may be separated by size, sequence motif, domain distribution, disaccharide attachments and tissue distribution. In practice, PGs form two distinctive subsets: (i) small leucine-rich PGs (SLRPs) and (ii) traditional large molecular PGs, such as versican and aggrecan, with very numerous and densely packed disaccharide polymer side-chains.

Link protein

This glycoprotein is analogous to the G1/G2 regions of aggrecan. It attaches aggrecan to hyaluronic acid core protein (Figs 3.34 & 3.35). Homologous loops in LP and the G1/G2 domains of aggrecan resemble the G3 domain of versican. The biological function of LP is to stabilize

Table 3.5 Proteoglycan (PG) group I. Small leucine-rich proteins (SLRPs).

PG	Protein (kDa)	Glycosaminoglycan (GAGs) disaccharide	Gene location	Tissue distribution
Decorin	36	CS/DS	12q21–23	Bones/tissue
Biglycan	38	CS/DS	Xq28	Cell surface
Fibromodulin	42	KS	1q32	Collagen matrix
Lumican	38	KS	12q21–22	Cornea Gastrointestinal tract Cartilage Muscle
Epiglycan	36	CS/DS		Epiphyseal cartilage

CS, chondroitin sulphate; DS, dermatan sulphate; KS, keratan sulphate.

Table 3.6 Proteoglycan (PG) group II (modular group).

PG	Protein (kDa)	Glycosaminoglycans (GAGs)	Gene location	Tissue
Versican	260–370	CS/DS 10–30	5q13	Blood vessel Brain Skin, cartilage
Aggrecan	220	CS (100)	15q26	Cartilage Brain Blood vessel
Perlecan	400–470	HS/CS	1p36	Bone marrow Cartilage
Agrin	210	HS (3–6)	1q32	Cell membranes Neuromuscular Kidney
Neurecan	136	CS 3–7		Brain
Brevican	100	CS 1–3		Brain
Testican	44	HS/CS	21	Seminal vesicle Testis

CS; chondroitin sulphate; DS, dermatan sulphate; HS, heparan sulphate.

aggregation of aggrecan and hyaluronic acid. Three variants, LP-1, -2 and -3, are variably glycosylated, and the mammalian LPs have 339 amino acids and five disulphide bonds in three loops [2,9,12].

Nomenclature

Instead of the traditional classification by disaccharide polymers, an arbritary protein-core nomenclature has emerged, including small molecules, such as decorin/biglycan and lumican, in group I and larger molecules, such as versican, aggrecan or perlecan, in the modular group (Tables 3.5 & 3.6). This has both order and logic, in comparison to the old carbohydrate method.

Accumulation of PG in human diseases

The mucopolysaccharidoses are a varied group of inherited lysosomal diseases, in which the intracellular accumulation and urinary secretion of PGs is increased from a variety of enzyme deficiencies. Thus PGs such as dermatan, keratan, heparan and chondroitin sulphates accumulate, according to the particular enzyme deficiencies. These include α-L-iduronate (Hurler's and Scheie's syndromes, mucopolysaccharidosis (MPS) types IH and IS), iduronate sulphatase (Hunter's syndrome, MPS type II), heparan *N*-sulphatase (Sanfilippo's syndrome, MPS type III), *N*-acetyl galactosamine-6-sulphatase (Morquio's syndrome, MPS type IV), Maroteaux–Lamy syndrome (aryl sulphatase B, MPS type VI), and β-glucuronidase (Sly's syndrome, MPS type VII) [16]. Most mucopolysaccharidoses are absent at birth but appear during the first 2 years of childhood. The accumulation of PGs produces hepatosplenomegaly, cardiac infiltration, corneal clouding, skin thickening and coarsening and, except for Scheie's, Morquio's and Maroteaux–Lamy syndromes, severe intellectual involvement. In addition, the accumulation of GAGs produces joint contractures, shortened long bones, scoliosis, broadened ribs and spinal deformities. Modern treatment options include bone marrow transplantation, enzyme replacement and substrate restriction, all of which vary in efficacy and indications. For example, enzyme replacement is ineffective in those individuals with CNS accumulation, as they do not cross the blood–brain barrier.

Chromosomal clustering of PG and ECM genes

Particular chromosomal localizations, such as 12q21–q23 (decorin and lumican), 5q13.2 (versican) and 15q21 (aggrecan), are close to other ECM gene loci, such as *COL2A1* (12q13–q14), fibrillin 1 (15q15) and fibrillin 2 (5q15). Elastin microfibrillar components such as *MFPG-1* and -2 also cluster nearby. Similar clusters of other ECM genes suggests functional roles, such as coordinated transcription and regulation of organ or tissue-specific proteins. For example, *COL8A2*, *COL11A1* and agrin cluster at 1p32.

Small leucine-rich PGs [8,9,11,16] (Table 3.5)

SLRPs are a homologous group of PGs sharing N- and C-terminal cysteines with (between six and 12) leucine-rich (LR) repeats. Differences include the presence or absence of tyrosine sulphate (fibromodulin and lumican) and the presence or absence of chondroitin or keratan sulphate side-chains (highest in lumican and fibromodulin and lowest in epiphycan). Despite the overall similarity in domain organization, other shared features include:

1 N termini with chondroitin sulphate/dermatan sulphate attachments (decorin, epiphycan, biglycan);
2 tyrosine sulphate-rich sequences (fibromodulin and lumican) (such differences have implications for matrix and tissue–specific interactions);
3 the N- and C-terminal cysteines are regularly spaced in 20 and 35 amino acid clusters, respectively.

Such LR repeats are shared both with other small PGs and with more members of the LR superfamily. Examples of the latter are RNA splicing and processing enzymes, DNA repair enzymes, embryonic axon synapse and photoreceptor proteins. Others are hormone receptor signal transduction proteins. Whilst a few are membrane bound, most are not. The numbers of LR domains vary from four to 30. Biglycan, decorin, fibromodulin, lumican and PG LR domains have between eight and 12 repeats.

The three-dimensional structure of ribonuclease inhibitor is very well understood and has both A and B repeats (28 and 29 residues, respectively). In contrast, most PGs have 24 repeats [16].

The non-globular and β-sheet structural patterns probably mediate protein–protein interactions.

The ECM binding functions of SLRPs regulate collagen fibrillogenesis and bone modelling through TGF-β1 and -2.

Certain *Drosophila* LR proteins, such as *toll*, *slit*, *connectin* and *chaoptrin*, which are tissue and development (embryo) specific, have very similar properties. Many of the LR repeats of these proteins share the typical N- and C-terminal cysteines but differ slightly from conventional PGs by virtue of slightly different amino-acid motifs (50 rather than 30 amino acids N terminal, but 20 amino acids C terminal) [8,9,16].

Table 3.7 Regulation of decorin and biglycan genes.

	TGF-β	Dexamethasone	Retinoic acid (on chondrocytes)	TGF-α
Decorin	↓	↓	↑	↓
Biglycan	↑	↑	↓	

TGF, transforming growth factor.

Sequence homology

There is evolutionary tree homology between the three groups. For example, the decorin and biglycan genes both have eight exons, of which numbers 3–6 code for the LR repeats. For fibromodulin there is a larger fused exon with this function.

Other features [8,11]

Gene evolution. Even though the LR repeats are 24 amino-acid proteins, it is unclear whether the decorin and biglycan genes arose from ancestral 72-bp DNA sequences. The organization of the existing exon/intron boundaries excludes exon shuffling or gene duplication of the PG genes, even though this mechanism is possible for other LR repeats.

Functions. Decorin regulates collagen fibril diameter by a negative control mechanism. It also probably orchestrates organogenesis and shape, while biglycan is cell-surface distributed.

Promoter functions. The decorin and biglycan promotors are subtly different. While the former has distinctive proximal CAAT, TATA and TNF-α domains, with distal AP1, AP5 and TGF-β elements, biglycan lacks these sequences and has only housekeeping regulatory elements. In keeping with this possibility, it is situated in a CpG island. Very probably, biglycan is switched on permanently, while decorin is a more specialized ECM product and is produced intermittently. The two genes are therefore differentially regulated as shown in Table 3.7.

Other properties. These include the following:

1 decorin specifically inhibits cell proliferation;
2 it is up-regulated in resting cells;
3 SV40 transformation suppresses decorin expression;
4 other transformed cells similarly show suppressed decorin expression;
5 it suppresses the malignant phenotype of colonic cancer cells.

Modular PGs

In contrast to the SLRP group, the modular PGs are larger and more complex. They form two distinct distantly

related subsets; i.e. (i) the hyalolectins, which strongly bind hyaluronan (D-glucuronic acid β1–3-D-2*N*-acetyl glucosamine β1–4), and (ii) those that do not.

Hyalolectins [1,2,9,12,14,15]

Versican and aggrecan are two typical examples. Both the protein and DNA sequences and their joint homologies have been fully clarified. They have very similar N-terminal hyaluronate-binding regions, while their GAG-containing central domains, although analogous, have two separate components in versican, but only one in aggrecan. Both molecules have C-terminal selectin-like sequences, with analagous exon organization. Thus, subtle differences in length allow variable binding functions; at the N terminus they attach to PG, at the C terminus they bind cellular elements, and centrally they have classical disaccharide polymer-binding capabilities. Other similar family members such as neurocan proteoglycan M (PGM) and brevican have adhesive and regulatory functions, while aggrecan and versican function in blood vessel, bone, cartilage, etc. The GAG α and β domains of versican bind to *O*- and *N*-linked carbohydrates, while tissue-specific alternate splicing of various exons fulfils subtly varying functions. The selectin-like C terminus contains dual EGF domains with and without calcium-binding capabilities, as well as C-lectin and complement regulatory protein (CRP) repeats (see below) [14,15].

The single GAG-binding protein of aggrecan has more densely distributed serine–glycine/glycine–serine dipeptides. Other modular PGs such as neurocan and brevican are abbreviated homologues of versican and aggrecan, while the non-modular PGs such as perlecan, agrin and testican have incorporated various other motifs such as SEA (shared with *s*perm protein, *e*nterotoxin and *a*grin), LDL receptor, SPARC (secreted protein acidic and rich in cysteine) and laminin domains III and IV.

Genomic structure and organization of versican and aggrecan

The versican gene (Fig. 3.36) maps to chromosome 5q12–14 and has 15 exons, which span 90 kb of genomic DNA. There is also an alternatively spliced exon of 3 kb, similar to that in chick PGM. The GAG α and β domains are separately coded by exons 7 and 8, respectively. Similarly, exons 3–6 code for the N-terminal hyaluronic acid-binding region, with exons 1 and 2 coding for the promotor region. The EGF repeats are coded by exons 9 and 10, the lectin-binding sites by exons 11–13 and the CRP and untranslated regions by exons 14 and 15 [12–15].

The pattern is highly conserved in other similar PGs. For example, the hyaluronan-binding site is homologous in human and rat aggrecan, rat LP, chick-liver PG and human CD44. Similarly, the selectin domains of versican, aggrecan and human P- and E-selectins also have very strong organizational similarities. The main analogies are illustrated in Fig. 3.37.

The hyaluronan-binding region also codes for an immunoglobulin loop, with homologies to the immunoglobulin superfamily. This contrasts with perlecan, in which numerous immunoglobulin loops are coded by two complete but separate exons, with an intervening phase 0 intron.

Evolution of the hyaluronan-coding domain requires duplication of exons 4, 5 or 6. Parallel, divergent evolution is required to explain the similarity of the hyaluronan-binding regions of human CD44 and tumour suppressor gene (TSG) proteins. Human versican is very similar to chick PGM; both alternatively splice exons coding for the two GAG domains (α and β). Whilst aggrecan is homologous to versican, its denser disaccharide polymers have slightly different serine–glycine and glycine–serine motifs. The versican PG domain is coded by very large, 3.0–5.3-kb, exons, with an equivalent aggrecan sequence of 3.9 kb. The selectin, EGF, lectin-binding and CRP motifs (exons 9–14 of versican) have analogous sequences, but slightly different exon numbers in E-selectin, L-selectin, P-selectin and granulocyte membrane protein.

Both aggrecan and versican have distinct calcium-binding and protein-interacting EGF domains, coded by similarly sized exons differing slightly from those of P- and E-selectin and coagulation factor IX.

The C-type lectin motif (encoded by exons 11–15) is identically arranged in versican and aggrecan. Homologous sequences occur in Kupffer-cell lectin, chicken hepatic lectin, and E- and P-selectin, all of which are calcium binding.

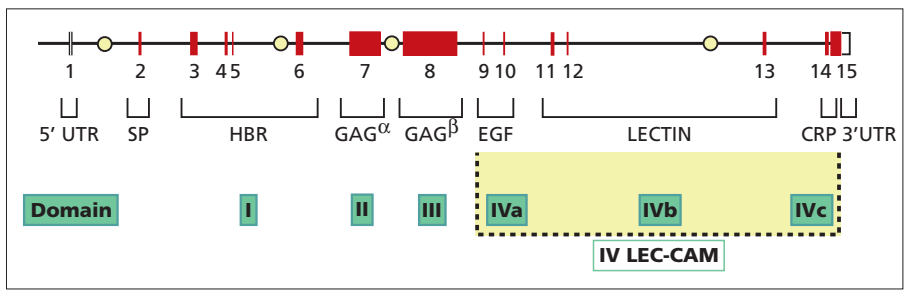

Fig. 3.36 Intron/exon organization of the human versican gene. CRP, complement regulatory protein; EGF, epidermal growth factor; GAG, glycosaminoglycan; HBR, hyaluronan-binding region; SP, promotor region; UTR, untranslated region. (After Dours-Zimmermann and Zimmermann [14].)

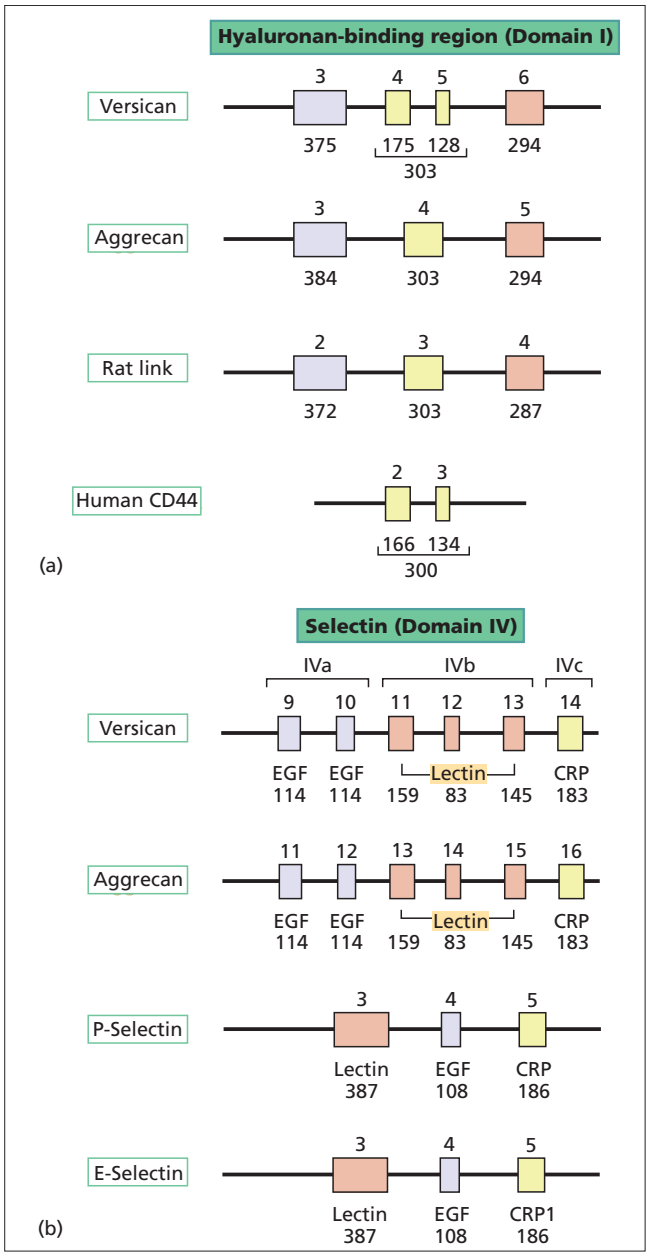

Fig. 3.37 Homology between genes for versican and other related compounds in terms of exon size and organization, at hyaluronan binding (a) and selectin (b) regions. CRP, complement regulatory protein; EGF, epidermal growth factor. (After Dours-Zimmermann and Zimmermann [14].)

Complement regulatory protein

CRP is coded by a single 183-bp exon. Other similar proteins include C4b, factor H and decay-accelerating factor, which have short consensus 60-amino-acid repeats (SCRs), coded by 45–47-bp exon clusters, as in versican and aggrecan. The CRPs interact with C3b or C4b to regulate C3 and C5 convertase in the complement cascade.

Non-hyaluronan-binding PGs [8,11]

These include perlecan, agrin and testican, which, although distinct from the hyaluronan-binding group, also differ substantially from each other. Interestingly, they possess a mixture of protein motifs shared with adhesive glycoproteins such as fibronectin and other ECM components, such as fibrillin, laminin and collagen type VII, etc. Their diversity indicates both functional heterogeneity and the remarkable capacity of nature to shuffle and distribute similar protein domains widely and create combinations with other domains, so producing proteins with differing functions, both within and across animal and plant species alike.

Of this PG subset, perlecan is the most diverse [10,11]. In addition to N-terminal GAG disaccharide polymers, other distinctive sequences include SEA, which is an 80-amino-acid protein regulating carbohydrate binding. Very probably, it is an important recognition signal for Golgi processing of secreted or membrane-bound proteins. The SEA region is adjacent to four LDL-receptor domains, which are followed by laminin III and IV sequences. Next, in marked contrast to hyaluronan-binding PGs such as versican, come 21 consecutive immunoglobulin folds. These have similarities to neural adhesion protein. The four consecutive EGF repeats closely resemble the C-terminal ends of laminin A chains.

The human perlecan gene is located on chromosome 1p36 and has 94 exons occupying 120 kb of genomic sequence. The unusual LDL, laminin and immunoglobulin sequences have close homologies to more specialized members of each respective family. Like aggrecan, the perlecan promotor has housekeeping sequences, quite unlike tissue-specific genes such as the interstitial collagens or versican, both of which have distinctive CAAT and TATA boxes [8,10,11].

Agrin has some motifs similar to domain V of perlecan, thereby sharing homology with laminin G. It also has GAG-rich sequences and a SEA module. The GAG disaccharide polymer is heparan sulphate (D-glucuronic/iduronic β1–4 D-*N*-acetyl glucosamine α1–4)$_n$. Other similar heparan sulphate PGs occur in bovine renal tubules. Additional motifs include follistatin and laminin domain III sequences, resembling laminin β and γ chains.

Genes

Perlecan has 94 exons, spanning 120 kb of genomic DNA, and there is remarkable conservation of incorporated sequences such as LDL with other more conventional members of that family [8,11].

The agrin gene lies on chromosome 1 at 1p32 and its nine follistatin repeats have very probably originated from gene duplications and unequal crossovers. In contrast, the laminin G and EGF sequences of perlecan and agrin are only distantly related [8,10,11].

Functions and properties of agrin

These include the following.

1 It anchors heparan sulphate within basement membranes.

2 It is virtually ubiquitous in basement membranes.

3 The protein core is adhesive for endothelial cells.

4 The protein is constitutive in K562 (bone-marrow-derived) tumour cells.

5 It interacts with other intracellular components, such as nidogen and laminin.

6 There is self-association via the C terminus with laminin G domains and EGF repeats.

7 Other analogues, such as laminin α chains, and *Drosophila* proteins, such as *crumbs*, *fat* and *slit*, regulate larval (embryonic) differentiation, polarization and neural patterning.

8 The binding of growth factors via heparan sulphate side-chains, which mop up and release similar factors such as cytokines and other metabolic regulators.

9 The binding of bFGF and mediators of mitogenesis and angiogenesis.

10 Agrin induces acetyl choline receptors which:

(a) aggregate myotubes;

(b) orchestrate synaptic cleft basement membranes;

(c) the follistatin repeats sequester factors such as PDGF and TGF-β;

(d) the receptor aggregates mediators for laminin G-like clusters and EGF domains.

Membrane-bound PGs

Such PGs interact through their heparan sulphate side-chains, with insoluble or soluble receptors during embryogenesis, malignant tumours and scar formation in wound repair. They include the syndecans and glypicans, which, although not sharing common homologous proteins, utilize similar heparan sulphate side-chain combinations, for signalling purposes.

Syndecans

These are transmembrane PGs with four separate family members (syndecans 1–4), distributed, respectively, in epithelia and plasma cells (syndecan 1), endothelial cells and fibroblasts (syndecan 2), neural crest cells and derivatives (syndecan 3), and universally (syndecan 4). The core proteins share N-terminal heparan sulphate chains at serine-glycine repeats, a trypsin-sensitive site close to the plasma membrane, and highly homologous transmembrane domains to the other three subclasses. Syndecans 1 and 3 contain chondroitin sulphate side-chains as well as heparan sulphate chains, whilst numbers of the latter vary according to their tissue distribution. Amongst their demonstable functions are included the binding of mammary-duct epithelia to fibronectin, thrombospondin and type I collagen, and the interaction of syndecan 4 with actin microfilaments in keratinocyte migration in wound repair. Nearly all adherent cells, especially epithelia, express syndecans close to their cell surfaces. Cleavage of the heparan sulphate containing sequences is mediated extracellularly by the TIMP (*t*issue *i*nhibitor of *m*etallo-*p*roteinase) family of metalloproteinase inhibitors. These cleave the syndecans in their ectodomains, N terminal to their membrane-bound sequences. The shedding of such ecto-domains is regulated in cultured fibroblasts or keratinocytes, but also occurs in embryogenesis, where they then change from acting as membrane-bound receptors to widely diffusable soluble receptors. Competition of these two functions would clearly have paracrine, and sometimes autocrine, roles.

Glypicans

These are also membrane-bound PGs attached to cell surfaces by glycosylphosphatidylinositol (GPI) linkages. Vertebrate glypican core proteins are homologous with at least five subtypes. The family participates in embryogenesis and cell division, and has patterning implications in developing embryos. All of them are cysteine-rich having, like the fibrillar collagens, both N- and C-terminal signal sequences. The C termini contain GAG attachment consensus sequences similar to other PGs.

Glypican 1 is widely dispersed in tissues, such as fetal lung, fetal heart, striated muscle and vascular endothelium, and the basolateral surfaces of certain epithelia. In contrast, glypican 2 is mainly confined to the CNS, where it is enriched in axonal tracts, brain and spinal cord. Glypicans 3 and 4 are enriched in fetal lung, kidney and liver but down-regulated later, whilst glypican 4 is richly expressed in kidney tubular epithelial cells and neuroepithelial cells. The gene for glypican 1 is at 2q35–37, close to the *COL3A1* gene, whilst that for glypican 5 is at 13q32. Glypicans 3 and 4 are X-linked at Xq26. Both monoclonal and polyclonal antibodies are available against glypicans 1, 2 and 3.

In summary, PGs share functions such as growth regulation, tissue differentiation and neuronal outgrowth. Such multidivergent properties promote embryogenesis, tissue regeneration and tumour metastasis or activity. Diseases caused by mutations in some of these functions are also very likely [17,18].

Histology of the ground substance

The PGs of the ground substance are analogous to the mucins. Histologists had developed empirical staining methods for the latter long before their chemical structure was elucidated.

Methods of fixation, staining and processing have been reviewed [1–3]. Many traditional fixatives remove or denature ground substance, and formalin fixation, freeze drying or use of frozen sectioned fresh tissue are therefore recommended. There are three main types of stain: metachromatic stains, colloidal iron and Alcian blue. In addition, the periodic acid–Schiff (PAS) technique stains certain sugar residues but leaves GAGs unstained. Normal human skin ground substance reacts positively with the first three methods but is PAS negative [4].

Metachromasia means the anomalous staining of the test tissue in a colour different from that of the test dye. This resembles indicator-dye changes with varying pH. Anionic groups such as sulphate, carboxyl and, probably, phosphoric acid esters exhibit this phenomenon with toluidine blue O and azure A, the stains most frequently used.

Colloidal iron staining depends on the attraction of dialysed iron hydroxide to the sulphate groups of GAGs, or the uronic acid of hyaluronic acid, and its subsequent colouration to Prussian blue with acidified ferrocyanide [5].

Alcian blue [6] is an empirical method which supplements colloidal iron or metachromatic stains. It stains substances that are removable by hyaluronidase.

The PAS method [4] involves the oxidation of sections in 0.5% periodic acid, followed by treatment with Schiff's reagent, when compounds containing –CH(OH). CH(OH)– or CH(OH)CO– groups (the hydroxyl groups may be replaced by amino or alkylamine groups) give a purplish red colour. In theory, various sugar derivatives such as glycogen, GAGs, glycoproteins, glycolipids and glycolipoproteins should be detectable. In practice, pure hyaluronic acid and condroitin sulphate are unstained. Other alternatives include the action of dyes, such as cupromeronic blue, which detect PGs linked to collagen fibres.

Collagen

Collagen refers both to certain fibrous elements of connective tissue, and also to a diverse family of genes coding for specific fibrous proteins. Of Greek origin, the term is synonymous with glue and also gelatine (the denatured form of collagen obtained from animal tissues by boiling and rendering). Collagen fibres are soft and flexible but also strong and inelastic. Their birefringence under polarizing light implies longitudinal stacking [1]. Light microscopy shows unbranched 12–15-μm fibres. Transmission electron micrographs show regularly cross-striated fibrils with a 60–70-nm periodicity [1–4].

Collagen was originally considered a single protein but in 1970 collagen type II was identified; purified from cartilage, it clearly differed from collagen type I [5,6]. Next, collagen type III was purified from skin and blood vessels [7], leading on to the identification of many other collagen types, which now comprise 22 or more proteins, coded by up to 30 genes [8,9], many of which have been cloned and syntenically located in the mouse. The characteristic regularly cross-banded fibrils were identified very early in the history of collagen biology. In particular, they are formed by collagen types I–III, but also characterize collagen types V and XI, the five members comprising the fibrous collagens.

These proteins typically form perfect triple helical α chains, which spontaneously self-assemble into irregularly overlapping staggered fibrils [10]. The geometry of the helically intertwined trimers is such that glycine is internalized on each α-helix, with the accompanying X and Y residues lying externally on the triple helix (Gly-X-Y) [11]. At the N and C termini there are non-helical globular extensions that vary in size between individual fibrous collagens, but in type I collagen are, respectively, 17 (N) and 26 (C) residues long. This contrasts with the 1000 or so residues that form the α-helix. The non-collagenous extensions (propeptides) are cleaved by specific enzymes, leaving behind the triple helix. The specific sequences cleaved by the various N and C propeptidases are known for collagen types I–III.

Since the mid-1970s, numerous other collagen types with distinctive variations have been identified [6,7,12,13]. Not all are typical fibrillar collagens, and are subclassified by α-helical organization and fibril size into traditional (fibrillar) and atypical (non-fibrillar) groups.

Classification of collagens

Historically, collagen proteins and genes have been named in the order of their discovery. Thus, collagen type I, which is the most abundant, was originally detected in bones, tendon and skin. Later, a second similar collagen with distinctive sequence variations was discovered in cartilage [1]. Shortly afterwards, a third variant (collagen type III) was purified from skin (and shown to be abundant and very important for the normal mechanical integrity of arteries, veins and capillaries) [8]. Paradoxically, collagen type I, which is the original model for all other collagen variants, is a heterogeneous molecule containing separate α1(I) and α2(I) chains. The preferred arrangement of collagen type I is a heterotrimer $\alpha1(I)_2$, α2(I). Cartilage collagen $\alpha1(II)_3$ and type III collagen $\alpha1(III)_3$ exist only as homotrimers. Collagen types I and III also co-assemble into compound fibrils in skin, tendons and arteries. Both sorts of fibril contain minority collagens, such as collagen type V (assembling with collagen types I and III) and collagen types IX and XI (which co-assemble with collagen type II). Some of these, such as collagen type IX, form the so-called FACIT (*fi*bril *a*ssociated *c*ollagens with *i*nterrupted *t*riple helices) collagens (see below) [7,8,12,13]. The latter specifically bind to the gap zones of fibrillar collagen types I–III, V and XI and somehow regulate fibre size.

When collagen type IV was first discovered, its numerous triple helical discontinuities were so different from fibrillar collagens that it was considered not to be a collagen at all (in comparison to collagen types I–III). We now know that such interruptions are common in other collagens, such as types VI–X and XII, all of which have distinctive tissue-specific functions, and consequently self-assemble into markedly different crystalloid structures from the typical fibril-forming fibrillar proteins.

Gene structure

Recombinant DNA technology has revolutionized our understanding of collagen genes and proteins. Collagen genes for types I–III and V were consecutively cloned, whilst separate genes coding for α1(I) and α2(I) chains of type I collagen were cloned for the chick before humans [12,14]. The standard nomenclature (*COL1A1* gene for pro-α1(I) protein and *COL1A2* for pro-α2(I)) was applied to all subsequent collagen genes. The genomic organization of *COL1A1* and *COL1A2* is that of an archetypal collagen gene, encapsulating the domain and cassette organization of other fibrillar collagen genes [14]. The mainly globular N- and C-terminal propeptide sequences differ substantially from the central triple helix. This is a repeating polymer of $(Gly\text{-}X\text{-}Y)_n$ (where $n = 333$). Blocks (cassettes) of Gly-X-Y coding exon sequences are all 9 bp multiples, especially of 45, 54, 63, 108 and 162 bp, which strongly implies repeated duplications and deletions of a basic ancestral 9 bp motif [8,12,13]. Alternatively, a 54-bp ancestral gene duplicated to 108 and 162 bp by exon fusion (or intron loss), whilst 45- and 99-bp sequences evolved by asymmetrical recombination.

COL1A1 and COL1A2 N- and C-propeptides are coded by six and four exons, respectively, with the central helix coded by 42 exons [14]. The central helix contains 10% proline or hydroxyproline and 4% lysine or hydroxylysine in the X and Y positions of Gly-X-Y. Continuity of the Gly-X-Y cassettes directly dictates the ordered pattern of helical winding, which starts at the C terminus and then propagates towards the N terminus. Disturbed winding is common in osteogenesis imperfecta (OI) (collagen type I helix), certain chondrodysplasias (collagen type II helix) and vascular Ehlers–Danlos syndrome (EDS type IV) (collagen type III helix). Glycine substitutions are very common. Those nearest the C terminus are both chemically and structurally disruptive, because of their severe interferance with helical winding [13]. Here the best analogy is with a well built, as opposed to a badly constructed, brick wall. Defective badly formed triple helices fail to assemble into a strong structure. Mutant and misshapen bricks make walls that crumble too easily after minor mechanical stress.

The N and C termini of collagen type I also have unique properties, showing varied pathological effects when mutated. Exons 49–52 code for the 3′ C termini of collagen types I–III, which vary between 243 and 247 amino acids. Apart from a short helical (Gly-X-Y) telopeptide sequence, the remainder is globular and is highly conserved in COL1A1, 1A2, 2A1 and 3A1 [8,14]. Whilst exons 49 and 50 may vary, the sizes of exons 51 and 52 are highly conserved between collagen types I–III. Crucially, a

C-propeptide proline both initiates chain assembly and co-association prior to helical winding. Stabilizing disulphide bonds are strategically placed at critical intervals, with very similar lengths (246 and 247 aa) of the pro-α1(I) and pro-α2(I) sequences. Alignment and association of the three C termini is catalysed by a specific enzyme (protein disulphide isomerase, PDI), without which subsequent triple-helical winding could not occur.

In contrast, fibrillar collagen N propeptides gene sequences diverge widely between, and are most complex in, COL2A1 and 5A1/5A2. There are also distinctive differences between the N propeptides of COL1A1 and 1A2. The former codes for an additional 66 amino acids next to the short 48 amino-acid triple helix, while this globular region is omitted in COL1A2. Mutational analysis has provided insights into N propeptide influences upon molecular alignment and subsequent fibril formation. Two classes of mutation cause subtle phenotypical EDS variations. Those with structural mutation of the N propeptide (pNα1 or pNα2) delete the normal enzyme cleavage sites, so that cross-linked lysines fail to align, whilst in other cases in which the enzyme itself is deficient, the cleavage sequence remains. Thus, structural mutants retain abnormally shortened but uncleavable pNα1 or pNα2 extensions (see below), and the enzyme defect retains these extensions on the three chains of the triple helix. Consequently, the abnormally long helices disrupt normal molecular packing of adjacent collagen molecules. The structural errors cause EDS types VIIA and B (in which there are angulated collagen fibrils, and ligamentous and skin fragility), while the enzyme defect causes EDS type VIIC with hieroglyphic fibrils and dermatosparaxis, due to more widespread molecular distortions.

Other similarities at the 5′ and 3′ ends of the genes include regulatory up-stream sequences, such as CCAAT, 80–100 bp 5′ of the *COL1A1* and *1A2* coding sequences. There are also several other important sequences, such as SphI and ApI, which mediate tissue-specific expression and regulation. The *COL1A1*, *1A2* and *3A1* genes also contain enhancer sequences in the first intron (between residues +418 and 1524 of *COL1A2* and +820 and 1602 of *COL1A1*). Very probably, there are other important control elements (analogous to similar β-globin sequences) such as an enhancer at the 3′ end, and a distant locus control region of many kilobases at the 5′ end. The latter remote-controls tissue-specific expression, and may eventually facilitate future gene therapy [12,13].

Structural organization of collagen

The three individual polypeptide left-handed α-helices in the triple helix [10] are each staggered by one amino acid relative to one another. They form a right-handed triple helix with interchain hydrogen bonds between adjacent carbonyl (C–O) and amide (NH) groups.

Fig. 3.38 Transmission electron micrograph of shadowed replica of unfixed, rapidly frozen and surface-sublimated rat-tail tendon showing stepped banding of collagen fibres. × 40 500.

Positive and negative staining

Such type I collagen fibres possess a characteristic banding pattern in transmission electron micrographs [1,3]. Banding patterns differ slightly, depending on whether they are unidirectionally shadowed with gold or palladium (Fig. 3.38), positively stained with phosphotungstic acid (PTA) or uranyl acetate (Fig. 3.39) at acidic pH, or negatively stained with PTA at neutral pH (Fig. 3.40) [1–3]. The D-periodic banding and gap and overlap zones in the negatively stained materials closely correlate with the amino-acid sequence. D-banding originates from the mutual hydrophobic interactions of parallel triple helices (Fig. 3.41). Individual molecules are stacked in parallel, nose to tail (N to C terminally). Gaps separate individual molecules, with overlaps between adjacent triple helices, which are mutually staggered by individual fractions of D. The combined D periods consistently overlap, but also form gaps which together contain 234 amino acids over a distance of 67 nm. Rows of parallel triple helices are axially separated by 0.286 nm [4].

Each triple helix is longitudinally separated from its nearest linear neighbour by 67 nm (234 amino acids). Similarly, every helical α chain is longitudinally staggered from its two companions by one amino acid. Positive staining at acidic pH reflects the axial distribution of charged amino-acid residues in the triple helix. From the C to N terminus these are labelled a1-IV, b1-II, c1-III and d, respectively. The charge distribution from the known gene sequence correlates closely with the positive patterns. PTA or tungstate preferentially stain the positively

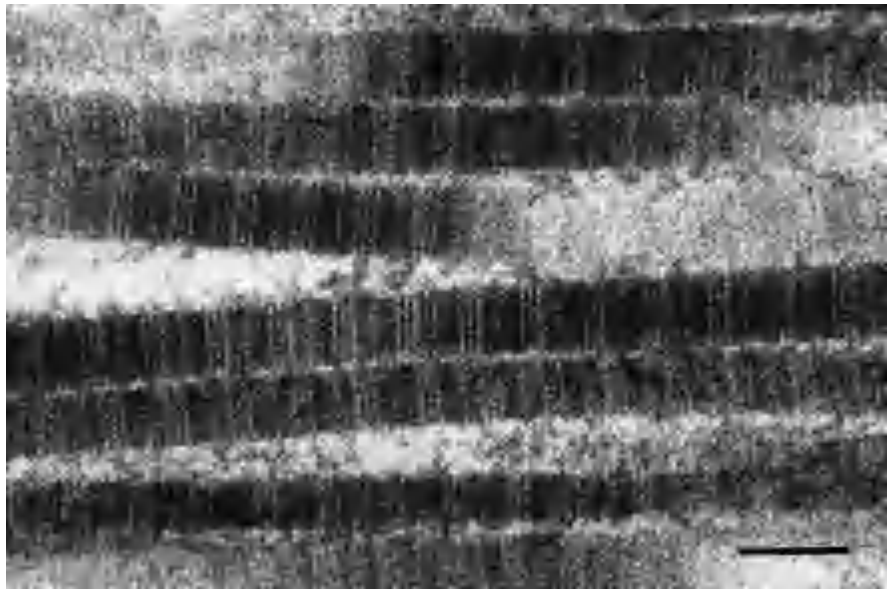

Fig. 3.39 Collagen fibrils in human reticular dermis showing characteristic banding pattern after standard processing and staining (uranyl acetate and lead citrate) for transmission electron microscopy. Scale bar = 0.1 µm.

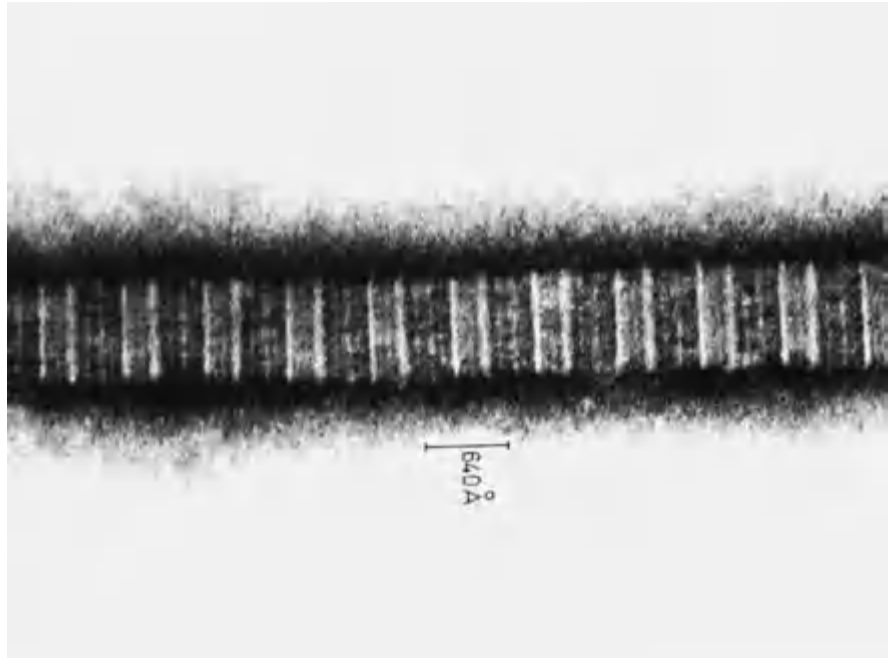

Fig. 3.40 Single fibril of rat-tail collagen, negatively stained with sodium phosphotungstate. One complete period of length 64 nm (640 Å) comprises a light D zone and a dark F zone with a number of interbands. (Courtesy of G.A. Meek.)

charged lysine and hydroxylysine residues. Uranyl salts bind both positive and negative side-chains, depending upon concentration and pH [3]. Negative staining distinguishes dark gap zones and light overlap zones. Computerized bulk distribution corresponds to both positive and negative patterns. Different fixatives will produce varied negative- and positive-staining patterns. Thus, glutaraldehyde particularly modifies negative staining by interfering with charge distribution. It binds lysine, hydroxylysine and histidine, and can also affect positive staining by stain exclusion. Formaldehyde modifies such positively staining. It ignores the positive charges of lysine and hydroxylysine but instead sticks to arginines or histidines. Diimido ester non-selectively stains all of these amino acids.

Segment long-spacing crystallography

The characteristic 60–70 nm cross-striated pattern of native collagen was discovered in 1942 [2]. At neutral pH, a different arrangement, so-called fibrous long-spacing (FLS) collagen, occurs. This has a periodicity of 180–300 nm. At acidic pH, in the presence of adenosine triphosphate (ATP), segment long-spacing (SLS) crystallites precipitate. They vary between 250 and 280 nm in length and stain positively with PTA. SLS fibrils are best examined

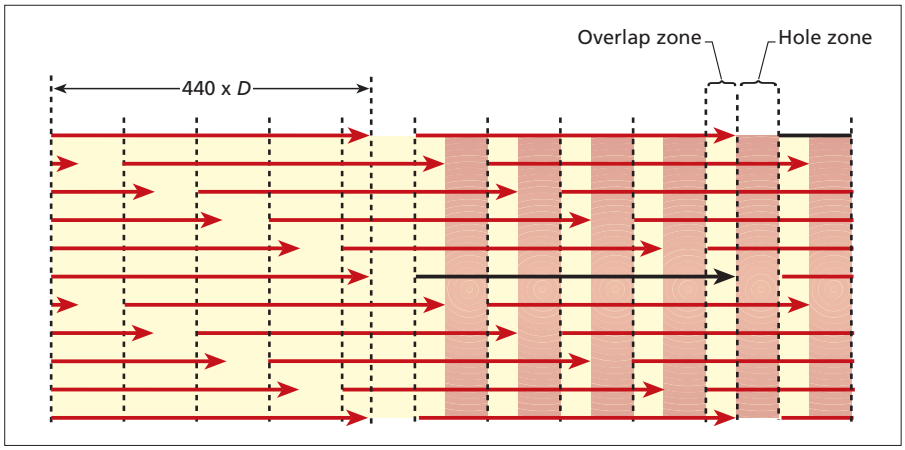

Fig. 3.41 Quarter-staggered packing of individual collagen triple helices. The latter pack nose to tail with respect to one another and are staggered, such as to create gap and overlap zones, visualized as cross-banded dark or light zones, when stained for electron microscopy. Smaller molecules such as FACIT (*fi*bril-*a*ssociated *c*ollagens with *i*nterrupted *t*riple helices) collagens, proteoglycan (PG) or calcium fit into these zones in different interstitial collagens.

after dialysis with ATP, and can be studied in fibroblast culture medium, cell layer or tissue collagens [15]. SLS crystallites have been important in deducing the native staggered axial organization of various interstitial collagens. The distinctive banding patterns of individual collagen products can identify fibrillar collagen types without the need for amino-acid analysis. Positive or negative staining with PTA and uranyl acetate, respectively, stain positive or negative side-chains. Such staining of the various lysine, arginine, glutamate and aspartate residues corresponds to the cross-striation of quarter-staggered collagen type I (α1(I), α2(I)) banding patterns. The charge distribution of each collagen type is almost congruent, although subtly different. Similarly, the fibrillar collagen types I–III and V have an overall similarity of organization (as regards the cross-striation pattern), yet are distinguishable from one another. SLS patterns have allowed the identification of the collagenase cleavage site near the N terminus, and the clear identification of the N- and C-terminal propeptide extensions. Subsequently, Kobayashi *et al*. [16–18] have shown that negative PTA staining of SLS collagen corresponds to the distribution of large hydrophobic amino acids, and positive staining with the polar ionic interactions of up to 58 transverse bands. Molecular mass studies of unstained SLS highlight bands 11, 19 and 37 in collagen type I and bands 15, 17, 19 and 37 in collagen type III. Such type I and III SLS aggregates can reliably be identified in cell cultures [16–18]. Unravelling of the N-terminal portion of the collagen type I triple helix occurred in SLS crystallites produced by a patient with lethal OI caused by a premature hiccup in triple helical winding. The defect was accurately located to lightband numbers 22–34, corresponding to amino-acid residues 460–710 of the triple helix. Such changes can be detected in less than 1 μg of unlabelled collagen protein, an amount easily obtained from fibroblast cultures. Similar SLS aggregates are detected in the cell-layer collagens. Dextran precipitation will artificially promote complete procollagen processing and assembly, providing an opportunity for *in vitro* processing studies [19,20]. As the SLS fibrils of collagens types I–III [16] are clearly distinguished, the fibrillogenesis and lateral interactions of types II and III collagen mutants in diseases such as chondrodysplasia or vascular aneurysms can also be systematically studied in the test tube.

Rotary shadowing electron microscopy

Individual collagen triple helices can also be assessed by electron microscopy. Low-angle rotary shadowing with platinum or tungsten (Fig. 3.38), detects collagen types I and III molecules [21,22]. Rotary shadowing demonstrated a 30–60° kink, lying 70 nm from the C-terminal propeptide of an α1(I) triple helix, of an OI with a glycine–cysteine substitution at residue 748 [23]. Five to 15 per cent of secreted molecules were kinked, and 20–30% of the cell layer collagens were similarly defective. This observation correlated well with the disordered protein chemistry: cysteine–disulphide linked α1(I) chains, disordered thermal stability and defective processing of procollagen to collagen. Unexpectedly, the N-terminal propeptide was excised inefficiently, implying that certain primary helical abnormalities at one position somehow disrupt other parts of the molecule some distance away from the primary mutation [24]. Such kinks are rare in other similar helical substitutions [25–29], which nevertheless sometimes affect collagen processing [30]. Rotary shadowing is therefore useful in visualizing individual mutant collagen molecules. Faulty collagen triple helices could not form normal fibrils by lateral association. Correlation of mutational position, protein stability and molecular architecture with histological and clinical abnormalities may eventually explain disparities between observed clinical phenotype and disturbed protein chemistry.

Rather interestingly, mutational gradients of glycine substitutions are clearest in COL1A1 mutations. The closer to the C terminus, or the larger the substituted amino acid, the more severe the clinical phenotype. Con-

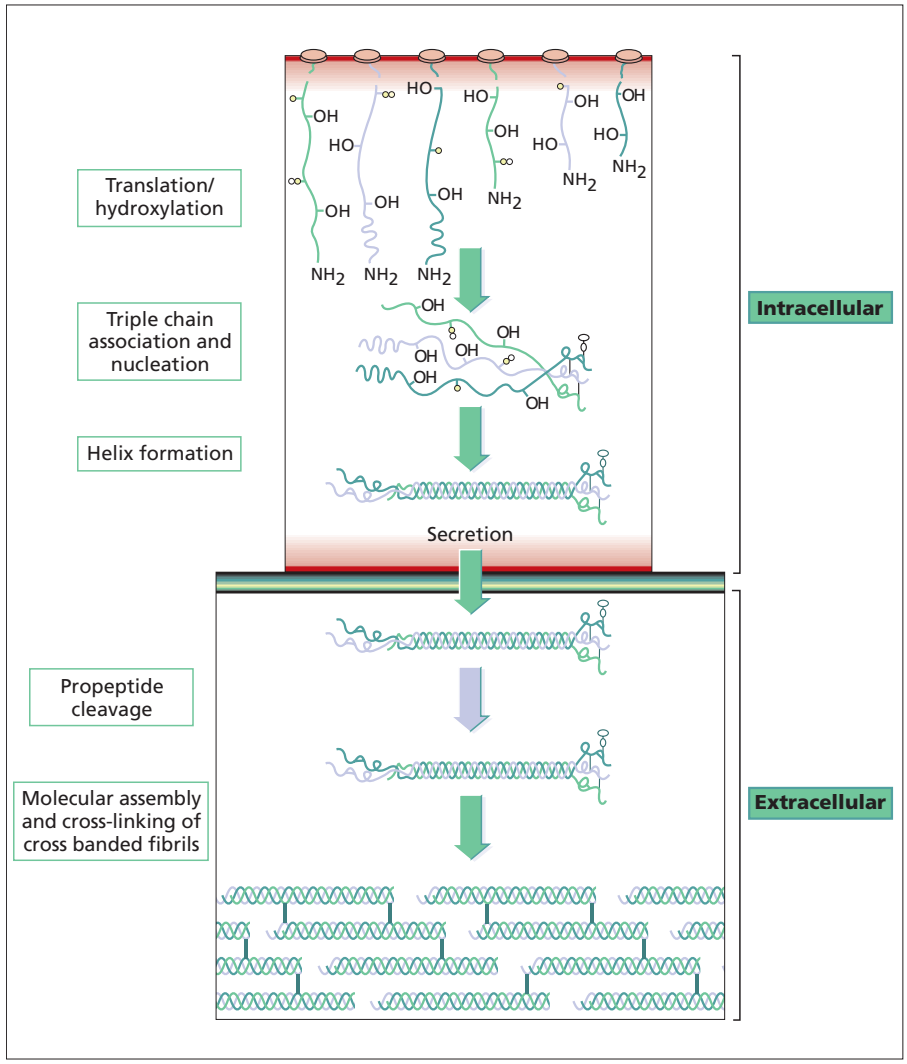

Fig. 3.42 Steps in the production of mature collagen fibrils, from translation at genomic level to the final assembly of cross-banded fibrils in the extracellular matrix (ECM).

trastingly, N-terminal mutations are the mildest. Whilst this general rule closely reflects the clinical phenotypes in OI (COL1A1 and COL1A2), as well as EDS type IV (COL3A1), it correlates very poorly in COL2A1 mutations (such as Kniest, spondyloepiphyseal dysplasia [SED], hypochondroplasia, etc.), and not at all in COL7A1 heterozygous substitutions, in which some glycine mutants are clinically completely normal.

Fibre organization and growth

Fibrils of fibrillar collagen, such as types I–III, spontaneously self-assemble in the ECM (Fig. 3.42), following secretion of procollagen, and the proteolytic removal of the N- and C-terminal propeptides. Triple-helix formation follows the spontaneous apposition of three individual C-terminal propeptides, followed by the ordered helical winding from the C to N terminus of three associated collagen α chains [24]. Until quite recently, the mechanism of the ordered production of quarter-staggered fibres was not well understood. We now know that procollagen aggregation is surface- and not concentration-dependent. Triple-helical fibril formation is now measured *in vitro* after collagen propeptide removal by purified chick N- and C-terminal propeptidases [25–29]. The association kinetics of fibril formation produced by diseased or normal fibroblast cultures can then be compared in a simple test tube assay.

Enzymatically treated (processed) fibrils are centrifuged out of suspension, so allowing the calculation of the concentration and velocity kinetics of fibril formation [25–27]. The morphology of the fibres can be simultaneously monitored either by simple dark-ground illumination or by electron microscopy with positive and negative staining. The distribution of mass within the fibre may be measured by scanning transmission electron microscopy (STEM) [31,32]. The latter has the advantage of using unfixed and unstained samples, which make it artefact-free. The transverse mass distribution is calculated along the growing fibre length [31] and STEM studies of growing

fibril tips show that the mass per unit length increases for 100 D periods close to the growing tip (calculated at 17 molecules per D period). The increase of mass is maximal at the tip and is inversely proportional to the diameter [31]. Interestingly, fibrils formed by removal of the N or C propeptides are short and unipolar, whereas longer bipolar N to N or C to C fibrils occur *in vivo*.

Alternatively, those inherited diseases with faulty removal of the N or C termini can be studied. Uncleaved N-terminal propeptides migrate more slowly by gel electrophoresis than normal α1(I) or α2 chains, and *in vivo* form angulated cutaneous or ligamentous fibrils [31–36].

Consequently, fibril misassembly in various collagen mutations is much better understood. The glycine–cysteine substitution at position 748 referred to earlier [23], which showed kinked fibres by rotary shadowing, produces abnormal collagen fibrils when examined *in vivo* by these methods [29]. When a series of such helical glycine substitutions were examined, including glycine–cysteine 718, glycine–aspartic acid 97 and 883 and glycine–arginine 550 [30], miscleavage of the distant N propeptide occurred, even when the mutated fragment was first removed by vertebrate collagenase. The kinetics of fibril formation were independent of velocity but not of concentration, implying a mysterious conformational disturbance of the N propeptide induced by the distant helical disturbance. Further work has clearly demonstrated bending-back upon itself of the uncleavable and persistent N propeptide in EDS type VIIB [35]. The uncleaved portion of the faulty molecule anonymously fills the gap region of quarter-staggered collagen fibrils, as measured by STEM, even though collagen-positive staining is normal. Probably, a gap-specific binding protein is excluded in EDS type VII, which sometimes produces the specific clinical features such as skin fragility, extreme joint laxity and angulated fibres in transverse section. In contrast, a very close mutation at amino acid 19 of the collagen triple helix, which is coded by exon 7, causes premature osteoporosis with spinal collapse, but no cutaneous fragility. Such distinctive clinical differences must ultimately be explicable in terms of fibril growth, morphology and interactions. The collagen type III propeptide is cleaved by a different enzyme from that which removes the COL1A1, COL1A2 and COL2A1 N termini [37]. Purification of this enzyme would therefore be essential for similar kinetic studies of collagen type III fibril patterns. Collagen type III mutations are just as molecularly diverse as type I errors, but in contrast are consistently life-threatening. They also consistently alter collagen fibril diameter [38,39].

Fibril kinetics

Cleavage with purified N or C propeptidases form hybrid pNα2(I)pCIII, α1(I) and α2(I) collagens. The kinetics of procollagen C (helix + C terminus: pC) type I cleavage, the incorporation of pC collagen type I into fibrils (in the pellet fraction) in the presence of procollagen N (helix + N terminus: pN) III, and the simultaneous incorporation of procollagen III and pC collagen type I in the presence of the C-propeptide, can then be objectively tested. By itself pNIII cannot form fibrils, but pNIII together with collagen type I co-assembles to make smaller fibrils than normal. Furthermore, pNIII deposits on to the surface of type I collagen fibril, and in so doing probably inhibits its rapid polymerization (therefore increasing the lag period and the rate of fibril propagation). Very probably, pNIII coats the type I surface, leaving the growing tips free. This implies that smaller fibres will normally occur in the presence of type III collagen, and in its absence type I collagen fibril diameters vary from large to small, which agrees well with the author's and other workers' empirical observations [36–39]. The increased lag time implies an action early in fibrillogenesis to hinder propagation or fibril growth [37]. It is also consistent with the author's observations of disturbed transverse collagen diameters in various inherited type III collagen mutations. Ordered fibril production may also be impaired if specific molecular interactions with substances such as the various minority collagens are impaired, with consequent misregulation of fibril diameter. Such molecules include the FACITs and collagen types V, XII and XIV (with collagen types I and III). Very probably, other ECM molecules such as PGs, calcium and certain adhesive molecules can also insert into the gap region. More detailed studies of mass distribution with STEM, similar to those of Kadler and colleagues on the packing of the persistent pNα chains of EDS type VII [35], which can measure the mass of gap and other regions, should in future allow the morphological identification of highly specific collagen-binding molecules. Obvious candidates are PGs such as decorin [40,41]. Calcium also specifically binds to the gap region of type I collagen ($\alpha I(I)_2\alpha_2$) but not $\alpha 1(I)_3$ [42]. Possibly, a complex variety of interactive substances bind to the particular fibril domains, raising the possibility of detecting and purifying specific binding proteins. Such studies should clarify the mechanisms of diseases such as OI, osteoporosis and EDS types IV and VII, in which collagen fibril morphology and tissue strength and stability are severely impaired. Disordered binding would be expected in those misassembled fibrils caused by defects in collagen or other connective tissue substrates. Calcium binding to the gap zone should be abnormal in certain abnormalities of bone collagen such as osteoporosis or OI.

Morphological studies

Regularly repeated collagen cross-striations have been clearly described by Chapman *et al*. [2,3] and Kadler *et al*. [29]. There is a succession of positively and negatively

stained bands (labelled a to e) running from the N to C terminus, in which the gap bands d and e alternate with the overlap b bands and intermediate a and c bands. Certain PGs, such as chondroitin, bind to e and d bands in the gaps, whereas keratan sulphate 80 associates independently with bands a and c as judged by keratinase/chondroitinase ABC and AC or hyaluronidase-treated samples [40]. Decorin specifically binds to the e band. The PGs possess variably sized core proteins linked to different glycan combinations. Thus, heparins contain 1–4 glucuronic acid or L-iduronic acid linked to glucosamine. Chondroitin (dermatan) glycans have *N*-acetyl galactosamine-linked 1,4 or 1,3 to D-glucuronic or L-iduronic acid. Similarly, the keratans link *N*-acetyl glucosamine and D-galactose in 1,3 or 1,4 patterns. Rotary shadowing shows a variety of attached core proteins, ranging from tadpole-like ball and sticks to very complex networks. Scott [40,41,43] has carefully studied the interactions of various collagens with PGs by mixing cold collagen solutions at physiological pH and ionic strength with purified PG solutions. This allows affinity association or mixing with either spontaneous or reconstituted fibrils. Kadler's *in vitro* fibrillogenesis methodology [25–27,29,44] could also profitably be explored in this context. Thus, solutions of intact fibril forming collagens at physiological pH and ionic strength will interact with solutions of different GAGs in particular PGs. Collagen can be constituted in a number of ways, such as using cyanogen bromide/sepharin–agarose, cross-linked collagen, reconstituted fibrils, soluble collagen residues or solid phase assays [40]. The various interactions may be monitored by light scattering, turbidometry or electrical birefringence [43,44]. GAGs will electrostatically interact with type I collagen, thereby accelerating fibrillogenesis. Chondroitin and dermatan both inhibit fibrillogenesis but are also incorporated into collagen fibrils. X-ray diffraction or magnetic resonance imaging (MRI) is used to monitor such interactions. Staining with certain anionic substances such as cupromeronic dye or cuproline blue is also useful. Observed patterns include the following.

1 Cupromeronic blue and cuproline blue staining of fibrils, when counterstained with tungstate, clearly demonstrates PGs bound to typical collagen type II fibrils. The distribution of PGs is orthogonal (i.e. lying at right angles to the long axis of collagen fibrils) but D-periodically spaced. Staining is often most marked at the d band, or sometimes the e band in the gap zone. Other PGs will span the gap between adjacent D-spaced filaments, but stain as parallel complexes. Orthogonal PG is usually dermatan sulphate, while the interfibrillar PGs are probably chondroitin sulphate. In annulus fibrosus, chondroitin sulphate forms complete loops at the d1 to e bands. In bone, gap-associated PG is replaced by Ca^{2+}. Interactions of axially bound PGs extend to 1D lengths (thereby encircling one quarter of a collagen molecule). PGs probably participate in the regulation of collagen fibril growth. Other important considerations include, firstly, that collagen/GAG interactions are electrostatic and can be abolished by an increase in salt concentration and, second, that fibrillogenesis is accelerated by dermatan, heparin or PG.

2 Chondroitin and dermatan interact strongly with collagen type I, both electrostatically and as protein–protein associations. The organization of these complex associations has been clarified by MRI rotary shadowing, molecular diagnosis and electron histochemistry [40,41].

Three-dimensional structure of collagen

Techniques such as optical and X-ray diffraction are used to mathematically deduce three-dimensional structural order. In general, X-ray crystallography is used for the computation of the detailed three-dimensional organization of large, complex molecules (such as collagen), while MRI is more suitable for the analysis of smaller molecules up to 20 kDa in size [45]. The primary structure, gene and protein sequence of the interstitial collagen types I–III and V are very well understood. Similarly, their normal two-dimensional structure both *in vivo* (tissue sections) and *in vitro* (fibroblast cultures) has been extensively studied for normal tissues. As mentioned above, positive and negative staining of individual fibres or SLS aggregates by transmission or rotary shadowing electron microscopy have been the standard techniques. Fibril growth can be measured under controlled conditions as described by Kadler *et al*. [25–27,29]. Diffraction methodology (such as X-ray and optical diffraction) applied to suitable collagen preparations, such as tissue sections, collagen fibrils or collagen crystals, allows computation of three-dimensional structure, from which tertiary structure and possible interactions with other connective tissue elements can be further deduced by high-resolution atomic mapping. For X-ray diffraction, monochromatic beams are usually produced from rotary anode generators. If high resolution is essential, higher energy polychromatic beams may be obtained from synchroton rings. Narrow parallel X-rays are directed into specially grown protein crystals, and the consequent diffracted radiation is either collected conventionally on an X-ray film or digitized and stored electronically. Interactions between the beam and electrons from each atom of the sample produce a generalized scattering of X-rays in all directions. In the presence of orderly crystalline geometry of atoms and electrons, the beam produces a characteristic interference pattern, which is directly related and dependent upon three-dimensional crystalline structure. Recently, a 1.9-Å map of collagen type I has been published. Detailed amino acid sequence is essential for the interpretation of such constructs since certain chemical groups such as ONH_2 and CH_3 are indistinguishable at resolutions between 1.7 and 3.0 Å. At this

resolution, amino-acid pairs such as valine and threonine, aspartate and asparagine, and glutamate and glycine look very similar. Similarly, distinguishing between histidine and phenylalanine is also difficult.

X-ray grade crystal growth. Crystallography requires good-quality protein crystals. These must be several tenths of a millimetre in each dimension and also be sufficiently well ordered to produce good quality X-ray diffraction spots. Methods of preparation include hanging drops, sitting drops, dialysis, seeding, batch free, capillary-diffusion and temperature gradient methodologies [46]. All gradually supersaturate the macromolecule of interest, in protein solutions that are well hydrated and at near physiological temperatures and pH. Essentially, highly concentrated protein solutions are crystallized by disruption of hydration shells and reduction of electrostatic shielding [46,47]. Usually a precipitant is required in addition to the protein. Supersaturation and subsequent crystallization follow either gradually increasing precipitant concentrations or saturation with precipitant and varying the temperature or pH. Categories of precipitants include salts (such as ammonium sulphate) and organic solvents (such as ethanol or polyethylene glycol). Hanging-drop methodologies can be used with very small quantities of protein but they produce only very small crystals. The seeding and batch methods require small crystals initially and lots of protein subsequently. Having achieved crystallization (provided the protein under test is well purified), its diffraction patterns can be systematically collected. With small unit sizes (less than 5 nm) diffractometers are suitable, whereas 5–20-nm cells will require an area detector. Higher resolution of more complex structures requires the high flux of a synchroton X-ray source. For diffractometer collection, various options include precession of crystal and film, rotation of the crystal with a stationary film and the Lane method utilizing polychromatic X-rays. Counting methods include diffractometer (crystal and detector both moving) and area detectors with computerized counting. Computer graphics, more powerful X-ray beams and microcomputation have revolutionized the speed, interpretation and analysis of crystallographic data, usually supplemented by the complementary technique of MRI.

Magnetic resonance imaging. The spin of certain ^{7}H, ^{3}C, ^{15}N and ^{31}P atoms have intrinsic magnetic moment, which can be probed by MRI. When such molecules are placed in a strong magnetic field they are excitable at radio frequencies, with the production of one- and two-dimensional spectra. Overtly joined atoms can be identified by correlation spectroscopy (COSY), and atoms that are adjacent in three-dimensional space, even when sited in different parts of the same molecule, are detectable. By 'sequential assignment' any given amino acid has a characteristic set of 'cross-peaks' with a diagnostic fingerprint for any given COSY pattern. In contrast to X-ray crystallography, which provides direct three-dimensional information, MRI produces specific coordinate spatial mapping from which a three-dimensional model can be computed. The two techniques are complementary: MRI being especially useful for studies of dynamic processes such as protein folding, whereas X-ray scanning deduces the fixed structure of the protein in its crystalline state [45].

X-ray diffraction of collagen. Ramachandran and Kartha [48] first described various intrinsic properties of vertebrate collagen fibres, and proposed a right-handed superhelix of three left-handed helical polypeptide chains. They noted a hexagonal unit cell with A = 12–16 Å, C = 9.5 Å (three residues per turn with an invariant glycine in position 1 and with proline often in the third Y position). Rich and Crick [10] modified this model slightly, placing proline as a frequent second position residue but agreeing with a three-chained coil, and postulating a single set of hydrogen bonds. More recent details have been described [4,49–51]. Thus, the collagen helix is very close to 300 nm long and 1.25 nm wide. Recent data show a separation between the tripeptides of 0.289 nm with an azimuthal distance of 8.6 nm (30 amino acids) and P, the pitch of the supercoil being 108°. The essentials of two-dimensional structure as detected by transmission electron microscopy of positively and negatively stained fibres has already been reviewed above, but the three-dimensional structure is still almost unexplored in diseased situations. Electron micrographs of transversely sectioned fibrils show some order of fibre packing, but there is no obvious regularity of structure within the individual fibril. X-ray diffraction, on the other hand, strongly suggests a three-dimensional crystallinity [4]. This varies, depending partly on whether the tissue is wet or dry, and is characterized by strong equatorial Bragg reflections. Such data provide crucial information about lateral associations and disorder and this, together with the two-dimensional details described above, have clearly defined the three-dimensional structure. Essentially, the collagen molecules in any given 68-nm section include four molecules 68 nm long and one of 35 nm. The unit cell is probably quasi-hexagonal without a microfibrillar structure [51]. The molecules are tilted 5° in the lattice at a specific plane forming a molecular crystal. Alternative models have included tetragonal packing with two, five or eight microfibrils. The two-dimensional Hodge–Petruska model postulates equal numbers of the five molecular segments in each (theoretical) 68-nm fibrillar section, with the unit cell being one molecule of five segments.

Most probably, the interpretation of five molecular segments dispersed around the surface of a crystal to form a microfibril pentameter is correct. Other possibilities include the small microfibril or square lattice models of

Fraser. Miller [4] concluded the following: (i) The quasi-hexagonal unit cell is correct and the three-dimensional cell is a triclinic of known dimensions and unit volume containing one collagen molecule. (ii) The molecules are inclined parallel to a specific plane in the lattice with less crumpled triple helices occupying 0.46 D. (iii) The equatorial intensity indicates quasi-hexagonal packing. (iv) The azimuthal inclination of the triple helices have slight irregularities of crystalline structure and correspond to the overlap region. The gap region is less ordered and there are several minor irregularities in the structure, including precise arrangement of D segments within the unit cell, the absolute quasi-hexagonal relationship of the molecules and the precise axial registration and order of the α1(I) and α2(I) chains in the triple helix. Crystallinity therefore implies rather specific molecular interactions.

Covalent cross-links also influence the X-ray diffraction data and link nearest neighbour amino acids between residues 9 and 946 or 103 and 1047. The latter is consistent with the known cross-linkage of cyanogen bromide peptide α1(I) CB3, 5 [52]. This would very probably stabilize the fibril packing, with disturbance produced by molecular abnormalities of these regions.

X-ray diffraction of various collagens and their disorders. Comparatively little work has been done upon the crystal structure of normal connective tissue such as skin, cartilage and arteries. A great deal of detailed information is available upon the three-dimensional organization of type I collagen [4,49–51]. Preliminary data are also available on normal collagen types I–III, and the organization of tissues such as rat-tail tendon, bone and cartilage. Some information has been published on hyperglycaemia-induced cross-linking and ageing, and on the animal disease dermatosparaxis.

Optical diffraction. Standard high-resolution transmission electron microscope pictures have a depth of focus of several thousand angstroms, thereby superimposing numerous three-dimensional images in two dimensions for each tissue slice. Negatively or positively stained electron micrographs are therefore suitable for three-dimensional analysis by optical diffraction [53]. The approximate images are analysed mathematically using classical X-ray diffraction algorithms. Essential steps include selection of good structural images, sampling of optical density by microdensitometry at regular intervals, computation of the Fourier amplitudes and phases, and synthesis of the three-dimensional map. It is a major advantage that phase can be readily calculated from the density of the electron micrograph images, using Fraunhoffer diffraction holography, which is analogous to heavy atom X-ray crystallography. The electron-microscopical two-dimensional image is a projection of the three-dimensional density distribution of all levels lying perpendicular to the beam. By collecting enough projections, a detailed three-dimensional image can be produced. Rotational and screw symmetry reduces the number of images produced, with a rough resolution of 30 Å in a 250-Å field. Unlike X-ray diffraction, in which phase is lost in making the two-dimensional image on a screen or X-ray plate, in optical diffraction the focusing of the electron beam preserves this information. The mathematics and rationale of the methodology has been clearly described [54]. A more modern surveying optical diffractometer suited for this type of approach has also been reported [55], and has generated detailed optical diffraction data and lattice spacings of negatively stained fibrinogen. Optical diffraction has been applied to the elucidation of the three-dimensional structure of *Salmonella typhimurium* flagellar filament [56].

This type of methodology is applicable to the three-dimensional structural analysis of the two-dimensional transversely sectioned electron micrographs of the various inherited collagen disorders. Good examples would be OI and EDS types VIIA and B (*COL1A1* and *1A2*), certain chondrodysplasias (*COL2A1*), vascular EDS (*COL3A1*), and EDS type III (*COL5A1* and probably *5A2*). Similarly, *COL7A1* mutations produce considerable fibrillar disorder, because the fibrils are not quarter-staggered but instead are laterally packed to form naturally occurring SLS fibres.

Other collagens

Non-fibrillar collagens (20+ genes) are both more diverse and numerous than the classical fibrillar types I–III, V and XI (10 genes). Most have globular interruptions to the Gly-X-Y central helix [57]. Such non-collagenous sequences allow molecule shapes other than rod-like, thereby diversifying intramolecular and intermolecular interactions with themselves or other ECM proteins, as basement-membrane proteins and collagen types IV or VII (see below). Others function in eyes, cartilage or blood vessels, whilst other collagenous components act as membrane-bound anchors or even scavenger proteins. Some are particularly important in skin or other tissues such as blood vessels or ligaments, while others resemble similar proteins that interact with certain cartilage matrix components. Collagen types IV and VII differ from the fibrillar and other non-fibrillar collagens by virtue of their large size and extended triple helices. Each of the collagen type IV proteins, which form very complex structural networks, has more than 30 globular interruptions to the Gly-X-Y helix.

Collagens that are neither fibrillar nor basement-membrane related include: (i) those with regular interruptions to the helix (collagen types IX–XII, XV and XVI); and (ii) those without, in which the helix is continuous (collagen types VI, VIII and X).

Basement-membrane collagen (types IV and VII)

Collagen type IV. Although amorphous and not fibrillar, the collagenous nature of basement membrane was first recognized more than 50 years ago by Pirie [58]. He observed both a typical collagenous X-ray diffraction pattern and the hydroxyproline and hydroxylysine ratios of collagenous proteins [57]. Purified collagen α chains from pepsinized lens and glomerular basement membranes differ in size and peptide composition from typical fibrillar collagens. They are also very diverse, containing at least five non-allelic α chains in varied tissues such as skin, lens capsule, glomerular or tubular renal basement membranes, lung, muscle and developing embryos. Even though non-fibrillar, and therefore unable to form SLS fibrils (as do collagen types I–III, V, VII and XI), individual collagen type IV molecules, when rotary shadowed, have long globular extensions at the NC-1 ends. The rat Engelbroth–Holm–Swann (EHS) tumour produces copious basement membrane, from which its chicken-wire (lattice) organization was first deduced [59]. This links individual 7S collagenous N-terminal sequences as overlapping tetramers, formed by four adjacent parallel collagen triple helices in which the 7s elements are parallel, while the triple helices form one arm of four adjacent quadrilaterals [60]. The NC-1 domains attach by multiple disulphide bonds with dimers formed both at the N and the C termini.

Basement membrane collagens α1 type IV and α2 type IV were the first to be characterized. Each is coded by adjacent genes, which are located on chromosome 13q33–q34. They are separated by only 400 kb, and are transcribed in opposite directions from their 5′ promoters, which lie head to head [61]. Thus, COL4A1 and COL4A2 have bidirectional promoters, which are coordinately transcribed from opposite strands, although separated by less than 42 bp in humans (but 130 bp in mice). Subsequently, four additional α chains have been identified (α3–α6 type IV collagen). All of them now have been cloned. Defects of α3–α5 chains of type IV collagen produce variants of Alport's syndrome, a disorder characterized by glomerular basement membrane thickening fragmentation or leakiness, together with deafness from faulty cochlear–epithelial hair-cell degeneration. In all cases, basement membranes at these loci are defective and abnormally permeable, but the clinical phenotypes range from chronic renal failure (with or without deafness) to isolated benign haematuria. The genes coding for α3–α5(IV) collagens, *COL4A3*, *4A4* and *4A5*, are located, respectively, on chromosomes 2q35–37 (α3 and α4) and Xq21–23 [62].

Collagen type VII. Although collagen type VII does form cross-banded fibrils, it is not a fibrillar collagen (such as types I–III, V and XI) by virtue of its larger size, very specific anatomical location and non-quarter-staggered parallel fibril organization. It was first isolated from pepsinized amnion as a contaminant of a collagen type V preparation [63]. The original experiments identified a disulphide-bonded collagen rich in glycine and hydroxyproline, which after reduction formed two α chains longer than either typical interstitial type IV or basement-membrane α chains. It also assembled into novel SLS fibrils [63]. The type VII molecule is 1.5 times longer than normal fibrillar collagen α chains. Unlike the latter, the triple-helical molecules do not form quarter-staggered fibrils, but instead naturally stack laterally, as SLS fibres with a highly ordered and characteristic cross-banded structure. The long central Gly-X-Y helix of 467 nm has only one globular interruption. There is a small globular region (NC-2) at the C terminus, and a large trident-shaped region (NC-1) at the N terminus. Pairs of molecules pack in opposite orientation, overlapping at the NC-2 ends by 60 nm, where they are stabilized by disulphide cross-links. Laterally stacked SLS fibrils have the N termini inserted into, and interacting with, the lamina lucida on the epidermal surface of the basement membrane of the dermis. They also attach to anchoring plaques at the dermal end of the individual collagen type VII (anchoring) fibrils [64].

Chromosomal location and gene structure. The *COL7A1* gene was originally isolated from a human keratinocyte cDNA expression library [65]. The gene sequence showed that, although the NC-2 coding domain is relatively large, it is processed into a smaller mature format. The chromosomal location at 3p21 coincides with autosomal dominant and recessive epidermolysis bullosa dystrophica (EBD), diseases in which anchoring fibril fragility and depletion produce blistering, scarring and separation of stratified squamous epithelium from the dermis. The genomic organization is the most complex of any collagen, with 118 exons distributed over 38 kb. Suitable intronic primers generate 65 amplimers that can be tested for exon mutations [66]. In general, mild autosomal dominant forms of EBD are caused by glycine substitutions or exon skips, while severe recessive EBD is caused by double combinations of stop codon mutations, exon skips and glycine substitutions [67,68]. The NC-2 domain contains 161 amino acids with eight cysteines and a potential Kunitz proteinase site. The cysteines stabilize the antiparallel tail-to-tail association of adjacent (overlapping) antiparallel collagen type VII dimers.

The genomic organization of *COL7A1* has some analogies to the fibrillar collagens. Thus, the collagenous coding region has a cassette format, whereby individual exons begin with a complete glycine codon and end with a Y triplet sequence, and are often multiples of 54 or

45 bp. Furthermore, anchoring fibrils are cross-banded when positively or negatively stained and examined by transmission electron microscopy. Other non-fibrillar collagen exon sizes, in contrast, are rarely 45 or 54 bp derivatives and are usually specified by split codons [66]. The *COL7A1* NC-1 domain also has nine fibronectin III repeats, two domains with similarities to CMP, a von Willebrand factor sequence and an RGD sequence, and must therefore have strong adhesive interactions with various other matrix components. As was predicted from Bentz's original protein data, the collagen helix has a single 39-amino-acid interruption, which is pepsin sensitive. The deduced protein size from the gene sequence is 134 kDa, slightly smaller than the 145 kDa predicted from protein electrophoresis. The difference is probably caused by *N*-glycosylation. In addition to the central 39-amino-acid Gly-X-Y interruption, there are also a further 18 smaller discontinuities. Helical cysteine pairs in the NC-2 domain stabilize the antiparallel assembly. The entire gene has 31132 bp (31.1 kb) with 118 coding exons, with the 5′ signal peptide and peptide cleavage site coded by exon 1. Exons 2–5 contain the cartilage matrix analogue, while exons 6–23 code for the nine consecutive fibronectin III repeats. Exons 24–26 code for the von Willebrand factor regimen and a proline-rich region is encoded by exons 27 and 28. The collagen triple helix is coded by 84 exons, while exon 112 contains the junction between the triple helix and the globular NC-2 domain, which is coded by exons 113–118. The longest globular interruption to the helix spans three exons and 39 amino acids. There are also many helical exons that are multiples of 9 bp.

Non-fibrillar, non-basement-membrane collagens

These are neither classical fibrillar collagens nor are they localized to basement membranes. They include:

1 the FACIT collagens;
2 the short-chain collagens;
3 other filamentous collagens.

***F**ibril-**a**ssociated **c**ollagens with **i**nterrupted **t**riple helices collagens.* Collagen types IX and XII are the prototypes, but other FACITs include types XIV, XVI and XIX. Very recently two more FACITs, type XX, which resembles types XII and XIV, and type XXIII, which occurs in cornea, have been described. Collagen type IX, which was originally copurified from cartilage extracts by differential salt precipitation [69,70], co-assembles and co-associates with fibrillar cartilage collagen (collagen type II), while collagen type XII occurs in tendons, ligaments, perichondrium and periosteum, and is only 60% as long as collagen types II or XI. Rotary shadowing showed a hinged triple helix with intervening globular non-collagenous sequences, which bound to the outside of assembled quarter-staggered collagen type II fibrils.

Three separate collagen genes (*9A1*, *9A2* and *9A3*) code for three distinct, but homologous, type IX proteins. All have analogous NC-1, NC-2 and NC-3 domains interrupting the triple-helical Gly-X-Y collagenous sequences [70]. The NC-3 domain of collagen type IX α2 chains covalently links to chondroitin sulphate/dermatan sulphate PG. The size of the N-terminal NC-4 domain varies widely between the three type IX α chains, while collagen α1 type IX has the largest NC-1 and NC-2 domains.

Collagen type XII has a very similar overall exon–intron structure, though collagen type IX trimers has a much longer NC-3 domain [71]. Rotary shadowing experiments prove that the COL-1 and COL-2 domains of type IX α1 collagen orientate parallel to the fibrillar cross-bands of type II collagen. Contrastingly, the COL-3 domain of α1(IX) collagen projects outwards at an angle. Very probably, collagen type IX subtly regulates interactions between adjacent collagen type II fibres. There are also two alternatively spliced forms of COL9A1. The longer, which includes exons 1–7, occurs only in cartilage. The shorter form deletes exons 1–6 and 7–8, and instead joins a novel variant exon to exon 8. This shorter version of collagen αI(IX) is corneal, while the more abundant longer form is cartilaginous. No doubt, the variable length dictates which particular tissue-specific constituents interact with such collagenous variants, whilst also conferring those subtle structural properties needed for widely differing functions at particular anatomical sites. Perhaps other FACITs play similar roles in specialized tissues such as skin, or blood vessels.

Other FACITs (collagen types XII, XIII, XIV, XVI and XIX). Collagen types XII, XIV and XVI, which are also FACITs, are homologous to collagen type IX [69–72]. Collagen type XIII is less obviously homologous, but has organizational similarities. Collagen type XII cDNA was first identified in chick tendon fibroblasts; its genomic sequence and exon/intron organization closely resembled collagen type IX but lacked an NC-4 domain and instead had a large NC-3 domain. The COL-I helices of types IX and XII are also homologous, whilst the N-terminal globular region of XII is homologous to the NC-4 region of IX. Antibodies locate collagen type XII protein, to tendon, perichondrium and periosteum, implying that just as type IX collagen decorates collagen type II, type XII collagen co-associates with collagen type I.

As skin, bone and cornea completely lack collagen type XII, there must be other homologous FACIT proteins fulfilling similar functions in those tissues. Thus, collagen type XIV is 60% homologous to collagen type XII, and both the cDNA and genomic organization are very similar. Similarly, collagen type XVI is also a FACIT collagen

[72]. Its genomic organization resembles collagen types IX, XII and XIV but is also much more complex, having 10 collagenous and 11 non-collagenous interruptions. It has far more cysteines than any other FACIT, and most of the collagenous regions are imperfect triple helices. Unlike the other FACITs, the non-collagenous regions are small except for the N-terminal one, which has 312 amino acids. The first collagenous domain has substantial homology to various other FACIT molecules. It has 106 amino acids, compared with the 115 and 103 for collagen types IX and XII. The second collagenous domain, COL-2, is 27% identical to the NC-4 of collagen type IX and 17% identical to the NC-3 sequence of collagen type XII. The gene, which is located at 1p31, also resembles the cuticle collagen of the worm, *Caenorhabditis elegans*. Such sequence and structural homology implies specific but subtle interactions with certain other tissue-specific ECM components.

Collagen type XIX. This is also a FACIT collagen, having an 832-amino-acid triple helix distributed in five collagenous domains, interrupted by 20–42 residue non-collagenous sequences [73]. Two of the five COL sequences are analogous to those of collagen type XVI and, like collagen types IX, XII, XIV and XVI, the distribution of the C-terminal cysteines and certain sequences of some non-collagenous domains are also homologous. The C-terminal cysteines span the C-terminal end of the triple helix and the globular non-collagenous C terminus.

There are seven cysteines within the 186-amino-acid N-terminus NC-6 region and two more in the NC-4 sequence. The five collagenous domains have 144, 224, 108, 168 and 70 residues, respectively.

The five collagenous domains of collagen type XIX contrast with two 300-amino-acid residues in collagen types XII and XV and three large collagenous domains in collagen types IX α1–3. Type XV1 collagen has 10 interruptions ranging from 14 to 421 amino acids.

Current evidence suggests that the C termini of collagen types IX, XII and XIV form cysteine-mediated covalent links: in XII and XIV, homotrimers, and in IX α1–3, heterotrimers. The gene, which has a cDNA of 5.6 kb, may be even bigger than the 140 kb *COL13A1* gene [8].

Collagen type XIII [74]. This collagen, which lies on chromosome 10q22, occurs in most connective tissues. It has an unusual N-terminal transmembrane-spanning domain, but lacks a signal peptide sequence. This strongly implies that it is membrane bound rather than secreted. Collagen type XVII, which is basement-membrane associated, is also membrane bound.

Collagen type XVI. This is yet another FACIT [72] with an open reading frame of 1603 amino acids. There are 10 collagenous domains ranging from 14 to 422 amino acids. Except for the 312-amino-acid NC-11 domain, all of the other non-collagenous interruptions are small, varying from 11 to 39 amino acids.

The amino-acid sequence is analogous to collagen types IX, XII and XIV [69,71]. Nearly all the non-collagenous domains have two cysteines separated by two amino acids. The COL-1 domain is exceptional, as the cysteines are four amino acids apart, while the most N terminal is the first amino acid of the triple helix.

The large NC-11 domain has several unexpected homologies with other FACITs, being 27% identical to the NC-4 of α1(IX) and 18% identical to the NC-3 of α1(XII). It is also 20% homologous to the N propeptide of the fibrillar α1(XI) collagen. The gene lies at 1p34.

Collagen types XV and XVIII [75–77]. These two collagens are very similarly organized but differently distributed. The former is largely expressed in kidney, pancreas and adrenal gland, while the latter mostly occurs in lung and liver.

Type XV has significantly more serine–glycine and *N*-glycosylation sequences at the N terminus, and also has a tandem repeat analogous to PG core protein. In this respect it resembles other collagen/PG hybrids, such as types IX, XII and XIV. Collagen type XVIII has no core protein homology and fewer serine–glycine and *N*-glycosylation sequences. Nevertheless, the remaining organization is very similar, with nine collagenous zones in type XV compared with 10 in collagen type XVIII. The first six (from the C terminus) are very similar to size.

In other ways, the frequent non-collagenous interruptions also resemble collagen types XVI and XVII, of which only the former is a FACIT, while the latter is membrane bound. The N-terminal homologies to collagen types V, XI and IX are unexpected. Collagen types XV and XVIII may form a small subgroup of their own [77]. Thus collagen type XVIII has 10 triple-helical regions separated by globular domains and the latter have serine-glycine attachment sequences for PG core-proteins. The gene maps to chromosome 21q22.3 and the C-terminal portion contains endostatin, which is a potent inhibitor of tumour-induced angiogenesis. Apparently, endostatin (collagen type XVIII C terminus) binds to capillary endothelium, with the help of the heparan sulphate chains of glypicans 1 and 4 [78]. Autosomal recessive mutations of *COL18A1* cause Knobloch's syndrome, a disorder similar to the Stickler's syndrome which is characterized by high myopia, vitreoretinal degeneration, macular degeneration and occipital encephalocoele. Mutations uniformly caused low plasma endostatin levels, but collagen type XV is thought to substitute for such deficiencies [79].

Short-chain collagens. These form two subsets: (i) the filamentous microfibrillar collagens (types VI α1–3); and (ii) the true short-chain collagens (types VIII and X).

Filamentous or microfibrillar collagens (collagen type VI). Collagen type VI is rather unusual as it assembles into microfibrils and therefore organizationally resembles fibrillin, lysyl oxidase and certain other microfibrillar proteins, such as MAGP, rather than other conventional collagens. Nevertheless, even though resistant to bacterial collagenase, it has numerous interrupted Gly-X-Y sequences and is therefore truly collagenous. It is cysteine rich, and was originally purified both from human aortic intima and placenta. By rotary shadowing it is 'short chain', forming 105-nm rods with N- and C-terminal globular domains, and has three α chains (two of 140 kDa and one larger one of 250 kDa). The triple helix is a highly disulphide-linked heterotrimer, forming dimers and tetramers, which pack end to end to form 100-nm beaded microfibrils. Sometimes, it appears as so-called mackerel fibres, with a rippled wave-like (seabed) pattern. The latter are also known as Luse bodies, or fusiform or zebra collagen [80]. The triple helix contains 335/336 amino acids and has separate 200-bp von Willebrand domains in both the C and N termini of the α1 and α2 chains. The α3 chain, which is longer, contains nine von Willebrand repeats [81,82]. Autosomal dominant *COL6* mutations cause a mild muscular dystrophy with joint contractures (Bethlem myopathy), whilst double heterozygotes or homozygotes have a more severe congenital muscular dystrophy, otherwise called Ullrich congenital muscular dystrophy. Whilst the milder, autosomal dominant, Bethlem's myopathy form links to the *COL6A1/6A2* locus at chromosome 21q22.3, and the *COL6A3* locus at 2q37, the Ullrich form only has *COL6A2* mutations. As sometimes happens in dystrophic epidermolysis bullosa, Ullrich heterozygotes are clinically normal, in contrast to Bethlem myopathy mutants who are heterozygous affected. As in other collagenopathies, Gly-X-Y substitutions, exon skips and second position errors have been documented (OMIM 158810 and 254090) [83,84]. Deposition of collagen type VI also occurs in the skin of patients with juvenile hyalinosis, although the gene for this disorder is on chromosome 4.

True (non-microfibrillar) short-chain collagens (collagen types VIII and X). These short collagens do not form microfibrils but have a very specific anatomical distribution. Collagen type VIII was originally isolated from aortic and corneal endothelial cells but is not confined to these tissues. Biochemical studies suggest separate α1 and α2 type VIII chains forming hetero- or homotrimers of 60 kDa in a 2 : 1 ratio, similar to type I collagen [85]. A similar 59-kDa homologous homotrimer (collagen type X) can be purified from hypertrophic cartilage, and the two genes are similar enough as to suggest a common evolutionary origin. Both collagen types VIII and X form 130-nm triple helices and have similarly sized globular N- and C-terminal ends.

The *COL8A1* gene has four exons, one of which contains the entire triple helical and C-terminal coding regions and maps to 3q12–13.1. Similarly the *COL8A2* gene also contains the triple helix and C terminus in a single exon and maps to 1p32.3–34.3 [85]. Whilst both proteins occur in vascular endothelium and corneal endothelium (Descemet's membrane), as well as keratinocytes and mesenchymal and the meninges, mutations of *COL8A2* cause certain corneal dystrophies, such as Fuchs endothelial corneal dystrophy and posterior polymorphous corneal dystrophy, both of which require corneal transplantation [86]. So far, there have been no *COL8A1* mutations identified, although given the 2 : 1 protein ratios, they should certainly be clinically very similar and hetero-allelic.

The organization of *COL10A1* resembles *COL8A1* with a small 5′ exon coding for the NC-2 domain and a much larger 3′ exon encoding both the triple helix and the NC-1 domain [87,88]. Collagen type X triple helices assemble into novel polytetrahedral structures, which resemble geodesic domes.

C-terminal mutations of collagen type X cause Schmid-type metaphyseal chondrodysplasia (metaphyseal dysostosis) [89]. The clinical phenotype is consistent with the known tissue distribution of collagen type X and includes short stature, coxa vara and bow legs, but normal facies, hands and feet [89].

Collagen type XVII. Another basement-membrane protein is bullous pemphigoid antigen 2 (BPAG2), a hemidesmosomal protein, which was first identified as an autoantigen in patients with either bullous pemphigoid or herpes gestationis. Unexpectedly, the gene contains a novel collagenous coding region and is therefore distinct from bullous pemphigoid antigen 1 (BPAG1), which is a non-collagenous 230 kDa protein [90,91]. BPAG2 is also homologous to so-called chick corneal collagen. The gene encodes 13 distinct collagenous regions, of which five are 15 amino acids in length, two are multiples of 15 and three others have 12, 18 and 42 amino acids, respectively. All of these could theoretically have evolved by triplet losses or gains, or from crossing over from an ancestral gene coding for 15 amino acids, i.e. 45 bp. The gene also codes for a membrane-spanning sequence with an extracellular collagenous portion, while the N terminus is intracellular. Antibodies to the latter detect human bovine and frog epitopes, while certain *N*-glycosylation sites are conserved between mouse and human genes. Unexpectedly, the N-terminal heptad repeat is the focus for triple helical chain association, which in other collagens occurs from the C-terminal ends. The human cDNA is 4.6 kb and codes for a membrane-bound protein of 1433 amino acids.

Compound heterozygous mutations in *COL17A1* are seen in generalized atrophic benign epidermolysis bullosa, a form of junctional epidermolysis bullosa where blistering occurs at the level of the lamina lucida [92] (Chapter 41).

Table 3.8 Collagenous non-extracellular matrix (ECM) proteins.

Protein	Molecular weight	Function	Structure
Bovine conglutinin	40×10^3	Lectin like. Binds zymosan	Monomer has a central helical stem with a large head; packs as a four-armed unit
Mannose-binding protein	29×10^3 monomer 58×10^3 dimer	Mannose binding (water soluble)	N-terminal collagenous domain is disulphide linked 140 amino-acid terminal carbohydrate binding site 20 repeats of 53–59 amino acids in the collagenous domain Analogous to C1q in terms of the interrupted helix
C1q	Similar to mannose-binding protein	IgG binding	Similar to mannose-binding protein except longer collagenous repeats of 25–27 consecutive Gly-X-Y C terminus binds Fc IgG repeats. Forms a bunch of roses pattern 78 amino acids and collagenous sequence, i.e. 26 triplets with central discontinuity
Macrophage scavenger protein	348 amino acids, 28.3 kDa	Binds low-density lipoprotein receptor	Membrane C terminus, α-helical core and collagenous sequence Collagen helix has 24 Gly-X-Y Y triplets Polar C terminus
Asymmetric acetyl cholinesterase protein		Binds to PG	Long collagenous tail
Pulmonary surfactant apoprotein	28–36 kDa	Binds phospholipids and surfactant. Important for normal lung function	24 Gly-X-Y repeats N-terminal cysteine 5 cysteines in the C terminus Interrupted central triple Gly-X-Y helix homologous to alveolar proteinosis protein

Basement-membrane-associated proteins (collagen types IV and VII and XVII). These collagens either are component basement-membrane proteins or are closely anatomically associated. They include collagen types IV, VII and XVII.

Other collagen-like molecules that are not ECM proteins [93–99]. As with various other proteins such as the immunoglobulin superfamily, nature often uses certain conserved protein motifs for a variety of unrelated functions in differing contexts. Shuffling, mixing and matching is the norm in protein biology and collagenous sequences are no exception. Thus, other triple-helical collagen proteins include C1q, asymmetrical acetylcholinesterase, surfactant apoprotein, conglutinin, mannose-binding protein and the macrophage scavenger receptor, which are good examples of this principle. Even though ECM collagens are defined by their capacity to form supramolecular aggregates, and to be part of ECM, this definition is not consistent at the protein/gene sequence level. These other triple-helical collagenous non-ECM analogues are, in some respects, more collagenous than the short-chain or basement-membrane ECM proteins described above, at least in the sense of infrequent or absent Gly-X-Y interruptions. Nor can they be separated on their membrane-binding properties, as only one non-collagenous and one collagenous membrane-bound sequence exists. Thus, macrophage scavenger protein types I and II and collagen type XVII possess membrane-spanning regions. These differences are probably examples of divergent rather than convergent evolution. Outlines of this diverse group of collagenous molecules are summarized in Table 3.8.

Metabolism of collagen

Collagenases [1–7]

Collagen is relatively inert metabolically, and usually once laid down it persists for long periods [8]. However, certain tissues and some pathological states exhibit rapid turnover. Half of the collagenous content of the postpartum uterus is resorbed in 24 h [9] and high resorption also occurs from granuloma tissue [10]. In the skin of rodents, a fluctuation during the moult cycle is superimposed on the gradual increase with body growth; the concentration appears to fall sharply prior to and during the early phase of activity of the hair follicles [11]. The possible mechanisms of resorption are not the same for the different collagen types and are subject to specific tissue regulation [4].

Native fibrillar or soluble collagen resists non-specific proteolytic degradation, and is specifically degraded by collagenase at physiological pH, temperature and salt concentrations. The first enzymes that degrade triple-helical collagen at neutral pH were isolated from *Clostridium histolyticum* [12–15].

The first vertebrate collagenases were initially purified from tadpole tails. When explants of metamorphosing bullfrog tadpole tails were cultured upon reconstituted type I native fibrous collagen substrate, they spontaneously digested this substrate [16–18]. It was also possible to show that epidermis and not dermis produced the tadpole collagenase enzyme [16,18].

Later, by similar techniques, human skin cells were shown to produce collagenase [16,19]. Collagenase activity resides in the papillary dermis but not the lower dermis [19,20]. Furthermore, although collagenase is produced by the proliferating epidermis in wound healing, it is not produced in normal epidermis [21]. Collagenase is also produced by neutrophil granulocytes [22,23], activated macrophages [24] and by cultured skin fibroblasts [25].

Table 3.9 The classification of matrix metalloproteinase (MMP) subfamilies, their substrates, molecular weights and chromosomal locations.

Proteinase	Common name	Main substrate	Mol. wt. (kDa)	Chromosomal location
MMP-1	Collagenase-1 (also called fibroblast, interstitial and tissue collagenase)	Collagen	57, 52, 42	11q22.3
MMP-2	72 kDa gelatinase (also called type IV collagenase and gelatinase A)	Cartilage collagen	72	16q13
MMP-3	Procollagenase, stromelysin 1, transin 1, SL1, PTR1	Collagens I, II, III, IX, X	59, 57	11q22.3
MMP-7	Matrilysin, matrin, PUMP-1, -protease		28, 19	11q22.3
MMP-8	Collagenase-2 (neutrophil collagenase)		75, 58	11q22.3
MMP-9	92 kDa gelatinase Gelatinase B		92, 79, 76	20q11.2
MMP-10	SL-2; stromelysin 2	Fibronectin, laminin, nidogen	57, 47, 45	11q22.3
MMP-11	SL-3; stromelysin 3; ST3	Similar to SL1		22q11.2
MMP-12	Macrophage metalloelastase	Elastin	22	11q22.3
MMP-13	Collagenase 3	Collagen	60, 48	11q22.3
MMP-18	Xenopus collagenase 4			
MMP-20	RASL-1	Amelogenin		11q22.3
MMP-23	CA-MMP			
MMP-26	Matrilysin 2 (endometase)	50% identical to MMP-3 and -12	28, 19	11p15
MMP-28	Epilysin			
MT1-MMP	MMP-14 (membrane type 14)	Broad spectrum, including fibrin, fibronectin, tenascin, aggrecan	63, 60	14q11–12
MT2-MMP	MMP-15 (membrane type 15)		72	16q12.2
MT3-MMP	MMP-16 (membrane type 16)		64	8q2
MT4-MMP	MMP-17 (membrane type 17)	Proteolyses MMP-2 enriched in brain tumours	70	12q24.3
MT5-MMP	MMP-24			20q11
MT6-MMP	MMP-25 (leukolysin)	Catalytic domain is 60% identical to MMP-17, resembles MMP-3 and cleaves collagen IV	63	16p13.3

Since then, a very large family of vertebrate collagenases and their relatives has been purified, cloned and sequenced, and presently, in 2003, comprise nearly 20 family members of the so-called matrix metalloproteinase families (*MMPs*) and at least three tissue inhibitors of metalloproteinase (*TIMPs*) (Table 3.9 & Fig. 3.43) [26–28]. The various subtypes cleave not only collagens but also PGs and other ECM constituents, and are members of a larger superfamily of so-called *matrixins*, a diverse group with almost 30 family members active in ECM regulation, as well as in general processes such as inflammation, scarring and wound repair. Other recently discovered metalloproteinases, such as the ADAM-TS family (Fig. 3.44) [29], participate in disorders, such as non-allergic late-onset asthma, with chronic obstructive airways bronchoconstriction, caused by submucosal bronchiolar fibrosis and ECM proliferation. All of them are zinc (Zn^{2+}) binding endopeptidases that degrade certain ECM components, which have a crucial role in all remodelling processes, such as ovulation, pregnancy, embryogenesis, ageing, apoptosis, inflammation and angiogenesis. Yet other MMPs promote tumour metastasis, or affect bone resorption in periodontitis and osteoporosis, hasten the enlargement of arterial aneurysms, or promote fibrotic processes such as hepatic cirrhosis, pulmonary fibrosis, pulmonary emphysema, arthritis, left venticular hypertrophy, nephritis, scleroderma, keloids and post-burns scarring. The original nomenclature and classification was proposed by Nagase *et al*. [28]. Updated information of the entire family group is very easily obtained from OMIM (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=OMIM), which lists all the MMPs by subtype and McKusick number (see below). Functionally, it is convenient to subclassify MMPs into those which cleave collagens and those which digest other substances [26,27]. They form distictive subgroups: *collagenases* (primarily, native-collagen-cleaving), *gelatinases* (denatured-collagen cleaving), *stromelysins*, *matrilysins* and *membrane-bound* MMPs. All share common structural motifs, such as an N-terminal signal propeptide domain (which contains a PRCGVPD inhibitory sequence), a catalytic domain (which in the gelatinases contain three head-to-tail repeats homologous to fibronectin gelatin-binding sequences) followed by a flexible hinge region, with a C-terminal haemopexin discoid region (which in the membrane-bound MMPs has additional transmembrane and intracytoplasmic residues, although matrilysin has no haemopexin domain) (Fig. 3.43). Generally MMPs are secreted as inert zymogens,

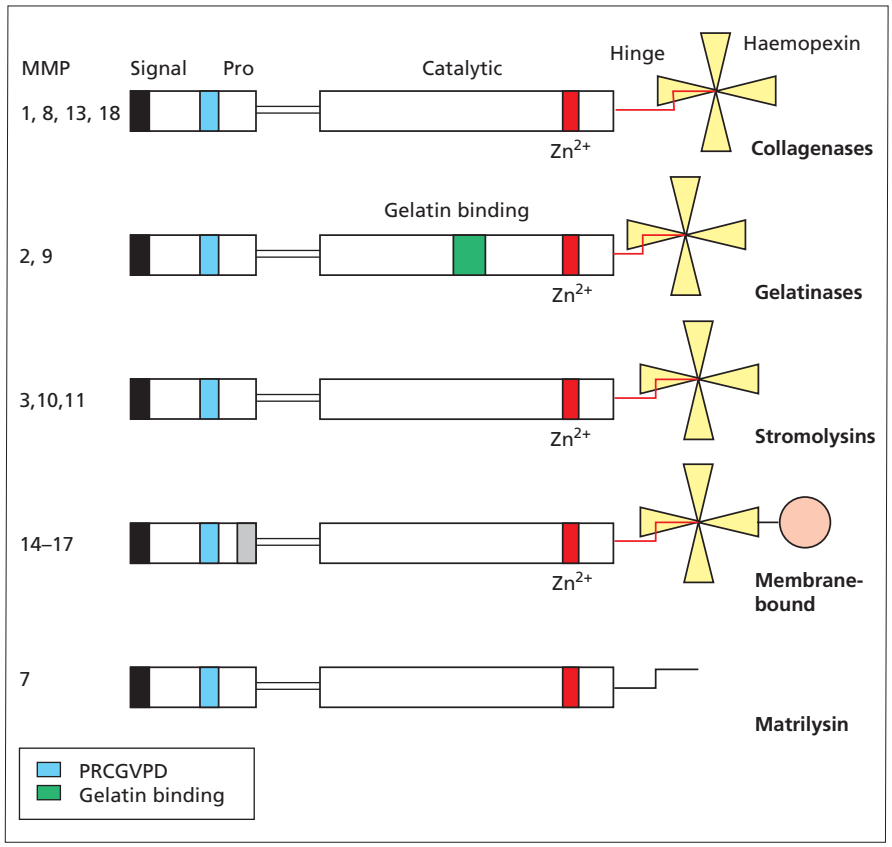

Fig. 3.43 Diagram of the various matrix metalloproteinase (MMP) subclasses. The various signal, propeptide, active catalytic hinge and haemopexin regions are illustrated. MMP-7 is notable for the absence of the haemopexin region, whilst MMPs 14–17 possess membrane-binding sequences N terminal to the haemopexin domain.

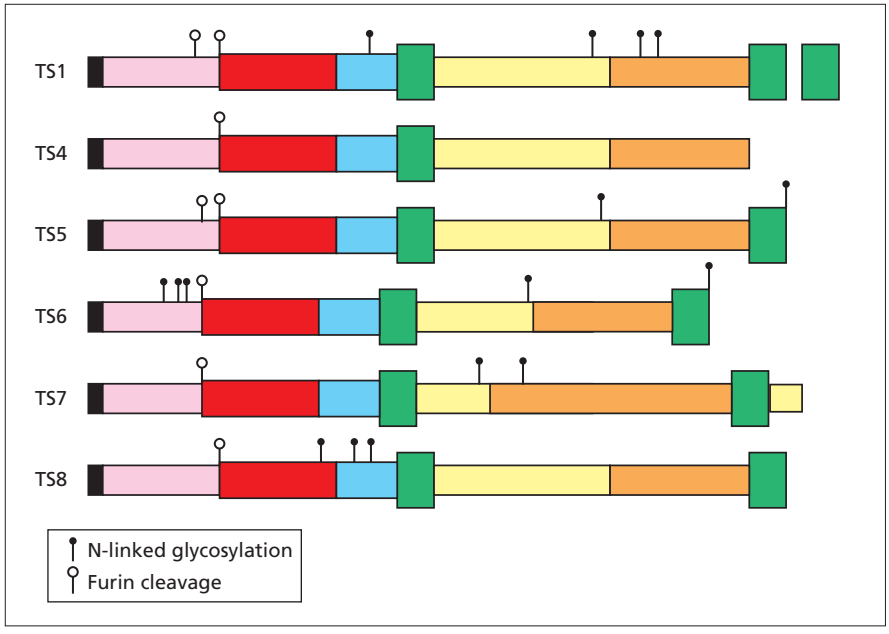

Fig. 3.44 Diagram of various ADAMS-TS families. The catalytic domains analagous to those of the matrix metalloproteinase (MMP) family are shown in red, whilst other important sequences include the thrombospondin type 1 repeat sequences (green), disintegrin-like domains (blue) and cysteine-rich domains (yellow). The signal peptides are shown in black, whilst the propeptides are coloured pink and the spacer domains orange.

which are activated by the piecemeal removal of the propeptide, initiated by disruption of the cysteine–Zn^{2+} switch.

Matrix metalloproteinase nomenclature includes types 1–3, 7–13, 16, 20, 23, 26, 28 and membrane-bound types MT-MMP 1–6. There are no MMP types 4–6, 14, 15, 17–19, 21, 22, 24, 25 or 27.

No less than eight MMPs (types 1, 3, 7, 8, 10, 12, 13 and 20) cluster on chromosome 11q22.3, whilst the others are distributed at 8q13-21, 12q14, 14q11-12, 16q12.2, 20q12-13 and 22q11.2. The intron-exon structure is generally similar, but the two gelatinases contain three extra exons coding for the gelatin-binding repeats. Generally

the catalytic domain is contained in the 3′ end of exon 2 and exons 3 and 4, with the inactive pro-domains coded by the 3′ end of exon 1 and the majority of exon 2. Protein sizes range from 19/28 kDa in the active/inactive forms of matrilysin to 66/72 kDa in the equivalent forms of 72 kDa gelatinase A (MMP-2) and 86/92 kDa in its gelatinase B (MMP-9) relative.

Group 1: native collagen-cleaving MMPs (types 1 [collagenase 1], 8 [collagenase 2] and 13 [collagenase 3])

These cleave native triple-helical fibrillar collagen types I–III. This splits specifically at a glycine–isoleucine–leucine sequence into three-quarter N-terminal and quarter C-terminal fragments, providing a useful mapping strategy in OI, certain chondrodysplasias and EDS type IV. This initial cleavage allows subsequent helical denaturation, followed by generalized digestion by other MMPs. MMP-1 also digests collagen types VII, VIII and X, as well as aggrecan, gelatin and MMP-2 and -9. MMP-3 has similar collagen targets, but also digests elastin, fibronectin, laminin, MMP-7, -8 and -13, as well as aggrecan and gelatin. MMP-8 is very similar to MMP-3, except that it digests no other MMPs, whilst MMP-13 digests fibrillar collagen types I–III, as well as IV, aggrecan and gelatin. Catalytic functions vary between the C- and N-terminal ends (where the proline-rich hinge and haemopexin sequences induce triple-helical cleavage). The conserved histidine residues 50 amino acids from the C terminus, which attach Zn^{2+} at the binding domain, impose substrate specificity, etc. Such relationships of the collagenases can be deduced by grafting this domain into a non-collagen digesting MMP, such as stromelysin or MMP-3 [26,27].

Group 2: gelatinases A and B, denatured-collagen cleaving MMP (types 2 and 9)

These MMPs possess fibronectin type II repeats, which mediate the binding and degradation of denatured collagens and also form enzyme–inhibitor complexes with the inhibitors TIMP-1–3. MMP-2 is smaller than MMP-9 by 20 kDa, but both enzymes are very similarly organized to the collagenases, except for the three extra exons that code for the fibronectin II sequences. The collagen binding sequences are quite distinct from the group 1 MMPs, where they reside at the C termini. Gelatinase A also binds to αv/β3 integrin, whilst gelatinase B binds CD44 at the cell surface. Both also jointly bind TIMP-2 and MT1-MMP as a trimeric complex at the cell surface. Both the self-processing of gelatinase A and the catalytic activation of gelatinase B, by collagenase 1, MMP-3 (stromelysin 1), MMP-7 (matrilysin 1) and trypsin occur *in vivo*, although other enzymes artefactually do so *in vitro*.

Group 3: stromelysins types 1, 2 and 3 (MMP types 3, 10 and 11)

These MMPs have typical propeptide, catalytic and haemopexin domains. The three stromelysins are all *matrixins*, which are a larger group of zincin metalloproteinases and all are activated by cysteine switching of the pro-sequence at the N termini. Thus both stromelysin 1 and 2 have 57 kDa unglycosylated (80%) and 59 kDa glycosylated-aspargine precursors, which are processed to 46–48 kDa and truncated C-terminal 28 kDa subsets. Both also have distinctive insertions of nine amino acids into the hinge regions, which join the catalytic and haemopexin regions. Enzyme activity is promoted by a conserved N-terminal phenylalanine reside. Substrates for the larger 46–48 kDa form include native collagen types III, IV, X and XI, denatured-collagen types I and III–V, and also telopeptides of collagen types I and II. The smaller 28 kDa variants degrade fibronectin, aggrecan and MMP-7, -8 and -13. Other substrates include most serpins, such as α2 macroglobulin, but not α1 antitrypsin, entactin, SPARC and E-cadherin. Stromelysin 3 (MMP-11) is only weakly proteolytic and, in contrast to types 1 and 2 which are extracellularly activated, is intracellularly triggered, in the Golgi. It has diverged substantially from stromelysins 1 and 2, which are almost 80% sequence identical and nearly 90% sequence similar to each other, showing instead only half the identity (40%) and less than 60% similarity. It participates in the metastasis of breast maligancies but is not found in benign breast fibroadenomas. It cleaves gelatin, fibrillar collagens, aggrecan, fibronectin and laminin.

Group 4: matrilysin types 1 and 2 (MMP types 7 and 26)

Like the stromelysins, matrilysin 1 (or PUMP) is a *matrixin* and an ECM-digesting metalloproteinase. It is distinguished from groups 1–3 by lacking both a hinge region and the C-terminal haemopexin domain, and is therefore only 28 kDa (zymogen) and 19 kDa in the active form. It is also confined to glandular epithelium and macrophages, but it was first purified from involuting mammalian uterus. Despite its smallness, it has a wide range of substrates, such as collagen types I, III and V, fibronectin and certain PGs, many of which overlap with those of stromelysin 1. It also occurs in maligant tumour cells, rather than stromal matrix, as is the case with certain other MMPs, such as the stromelysins. Rather surprisingly, it has also been implicated in the macrophage-mediated inflammation and degradation of atheromatous plaques, but might well play a role in macrophage-mediated processes such as pulmonary fibrosis, wound repair or inflammation. Matrilysin 2 (MMP-26) is of similar size and structure, and occurs in placenta, uterus and uterine endometrial tumours. It degrades collagen type IV, gelatin and fibronectin.

Group 5: membrane-type metalloproteinases types 14, 15, 16, 17, 24 and 25 (MT1–6 MMPs)

These are unique amongst the MMP family by being membrane-bound. They are also intracellulary activated (like stromelysin 3) by a propeptide furin convertase, for which they have recognition sequences. They may also be extracellularly activated. MT4-MMP and MT6-MMP do not possess transmembrane sequences but instead are chemically membrane-linked, by a glycosyl–phosphatidyl–sugar bond. The C-termini of all MT molecules possess short intracytoplasmic tails at the C termini. Some of the enzymes form tertiary complexes of MT-MMP, TIMP-2 and proMMP-2 at the cell surface, enabling tumour cells to penetrate vascular and other basement membranes during metastasis. Whilst MT6-MMP is confined to leukocytes, the others are produced by many other cell lineages and tissues, such as liver, heart, skeletal muscle (MT1-MMP), brain, placenta, lung and heart (MT3-MMP), brain, ovary, testis and colon (MT4-MMP). They range from 57 to 72 kDa as zymogens, and from 53 to 62 kDa as activated enzymes. They also exhibit a range of targets, including denatured collagen types I–III, aggrecan, elastin, fibronectin, gelatin and MMP-2 and -13.

Group 6: miscellaneous MMP proteins

This group consists of all other MMPs not already discussed in groups 1–5. These include human macrophage metalloelastase (MMP-12), xenopus collagenase (MMP-18), RASL 1–1 (MMP-19), enamelysin (MMP-20), CA-MMP (MMP-23) and epilysin (MMP-28).

Active macrophage MMP is only 22 kDa, although the inactivated zymogen at 54 kDa is more conventionally sized. In addition to elastin, it also cleaves fibronectin, gelatin and laminin, fibrinogen and α1 antitrypsin. It also promotes macrophage migration into ECM and participates in anerurysm formation and emphysema. Enamelysin also participates in tooth formation, and enamel production in particular.

Summary of MMP's role in disease

Matrix metalloproteinases clearly have a variety of modulating functions in numerous roles of human development. These include *embryogenesis and development* where matrix remodelling is very important, *acute wound healing*, where MMP-1, -3 and -10 are expressed by keratinocytes, *cancer and metastasis*, where MMP-7 promotes tumour invasion in lung, bladder pancreatic and colonic tumours, whilst tumour angiogenesis is promoted by MMP-1, -2, -9 and MT1-MMP. Cutaneous cancers such as basal cell (BCC) and squamous cell (SCC) cancers show increases of MMP-1, -2, -9 and -11 (BCC) or MMP-1 and 10 (SCC). Similarly, some melanomas show increased MMP-2 and decreased TIMP-2. Bullous pemphigoid eosinophils have increased MMP-9, which is also increased in granulomatous disorders such as sarcoidosis and granulomatous necrobiosis. Photodamage by sun exposure increases MMP-1, -3, -7, -9 and -12, whereas in contact hypersensitivity, MMP-2 and -3 are necessary for activation and MMP-9 for resolution of the reaction.

Other non-MMP metalloproteinases

The so-called ADAM-TS family is a very diverse group of metalloproteinases, which contain a disintegrin, a metalloproteinase and thrombospondin. Their properties have only recently been discovered but all possess at least one, and as many as three, thrombospondin type 1 repeats, together with N-terminal metalloproteinase domains adjoining disintegrin sequences, a thrombospondin repeat, followed by a cysteine-rich and then a so-called space sequence. To date, five different family members have been identified, including TS1, TS4 and TS5–TS8 subtypes. As with other MMPs, functions in repair, remodelling and regeneration, arthritis, inflammation and carcinogenesis are likely.

Collagenase and other MMP inhibitors

This is a family of metalloproteinase tissue inhibitors which specifically reversibly inhibit MMPs. Rather like insulin, and perhaps fibrillin, they form very specific intrachain disulphide bonds, which in their case produces a six-loop structure (from 12 completely conserved cysteines) but two-domain secondary structure. Equally importantly, reduction of the disulphide bridges abolishes MMP inhibition. To date, four TIMPs have been cloned and sequenced, of which TIMP-1 diverges considerably from the other three, which are most similar to one another [30,31]. The role of TIMP inhibition of MMP is mediated predominantly through the three N-terminal cysteines, whilst the remaining inhibition is mediated through the interaction between the C termini of the MMP molecule, with the three C-terminal cysteines of the given TIMP. The N terminus is contained within the large loop 1. Matrix metalloproteinase inhibition is mediated through both the N- and C-terminal loops; the latter occupies the MMP active cleft. Other important properties include extracellular secretion, binding to either inactive or active MMPs, and also their tissue specificity.

TIMP-1 and -2 react with the gelatinases (MMP-2 and MMP-9), whilst TIMP-3 is more widespread, occurring in developing embryos, placental tissues, cartilage, muscle and epithelia [31], as well as Bruch's membrane of the retina. The *TIMP-1–3* genes are, respectively, located at Xp11.23–3, 17q25 and 22q12.1–13.2.

TIMP-3 mutations have been described in Sorsby's fundus dystrophy [32], in which a central maculopathy is

caused by lipid accumulation in Bruch's membrane, which is thickened and degenerate. This change should be contrasted with PXE, in which there is elastic degeneration of Bruch's membrane, also with a progressive and debilitating macular degeneration. The Sorsby mutations of TIMP-3 are significant in mutating certain C-terminal cysteines, consequently inhibiting TIMP-3 activity.

Measuring collagen degradation or synthesis

Formerly, extracellular collagen degradation was estimated from urinary hydroxyproline/proline ratios [6]. Although most hydroxyproline derives from the degradation of incorporated fibrillar collagen, an unknown fraction arises from the degradation of newly synthesized but unincorporated amino acid. Urinary hydroxyproline should now be abandoned as a marker of collagen breakdown. Rather, urinary collagen cross-linked peptides provide an accurate estimate of degradation, both of skin, arteries and bone [33,34]. In brief, aldol condensations between adjacent lysines and or hydroxylysines produce a variety of cross-linked peptides, such as allysine/hydroxyallysine between adjacent collagen α chains, so stabilizing the various fibrillar components. Specific lysine–hydroxylsines are cross-linked within the non-helical telopeptide sequences (N terminal) of the collagen triple helix. Reducible cross-links decrease with age, producing instead mainly hydroxylysine aldehydes and trivalent 3-hydroxy pyridinium. In practice, pyrodinoline derivatives such as hydroxylysyl pyrodinoline (HP) or lysyl pyrodinoline (LP) can be directly estimated from urine samples. For example, in EDS type VIA (lysyl hydroxylase deficiency) there is a decreased HP : LP ratio in urinary breakdown products. Hydroxylysyl pyrodinoline derivatives are especially typical of bone, cartilage and dentine, chromatographic quantification of which provides a reasonable estimate of bone breakdown.

Similarly, based upon detailed knowledge of procollagen conversion into collagen, by the removal of the N- and C-terminal propeptides, there are now reliable methods that estimate collagen synthesis in bone, skin, liver and cartilage [34]. Their terminology is as follows:

1 the N- and C-terminal propeptides of type I procollagen are, respectively, named PIN and PIC propeptides;

2 the N- and C-terminal propeptides of type III procollagen are, respectively, named PIIIN and PIIIC propeptides;

3 the equivalent N- and C-terminal propeptides of types II, V and XI collagen would be, respectively, PIIN, PIIC, PVN, PVC, PXIN and PXIC propeptides, although none of these are routinely used in clinical practice.

In brief, the propeptides are stable in serum samples and can also be estimated by a variety of commercial and privately available fluorimetric, HP/LC, or immunoassays. Because of their N-terminal cysteines, PIIIN propeptides are more stable than their PIN equivalents. All of them are cleared by the hepatic reticuloendothelial system and can alter either physiologically or pathologically. A good example of physiological alteration is in puberty, in which the adolescent growth spurt increases the normal PI to PIII ratios from 1 : 1 to nearer 3 : 1, most probably from the disparate increase produced by adolescent bone growth. A very well-known dermatological example is the use of PIIIN levels, rather than liver biopsy, as an idex of hepatic fibrosis induced by methotrexate, in the long-term treatment of chronic psoriasis.

Theoretically, disorders such as OI and EDS types VIIA, B, C and IV, in all of which there are either quantitative deficiencies of either type I collagen (OI) or type III collagen (EDS type IV), or a failure to remove the N-terminal propeptides (EDS types VIIA, B and C), may be usefully screened by these means. Their use in osteoporosis also remains to be explored, as does their role in keloid scarring, scleroderma, pulmonary fibrosis, Paget's disease of bone, myeloma, hyperparathyroidism and degenerative joint disease.

Changes with ageing [1]

Collagen changes both qualitatively and quantitatively throughout life. The qualitative changes are reflected in decreasing solubility and an alteration in various physical properties [2,3]. For example, in strips of dermis, the temperature at which rapid shrinkage begins and tension develops in isometric contraction both rise with age [4]. Collagen becomes more stable with age.

As observations on animals have been made mainly during their growth phase and those on humans mainly during adulthood and senescence, there has been some confusion about how the concentration of collagen changes. As might be expected, because the skin increases in area and thickness as an animal grows, the collagen content of a complete skin and the amount of collagen per unit area are correlated with body weight [5]. In addition, there is ample evidence, for example from rats, rabbits and cattle, that the actual concentration of total collagen per unit weight of skin increases from birth to adulthood, when it remains stationary. It seems likely that in humans, also, the concentration of insoluble collagen in the skin increases from infant to adult [6]. From early adulthood onwards, however, there appears to be a gradual decrease in the absolute amount of collagen per unit area of skin, and this correlates with the clinical appearance of the skin during ageing. It occurs more rapidly in women than in men [7].

Fibroblasts [1–3]

Fibroblasts are the most numerous of the cells found in loose connective tissue. The term *fibroblast* should, historically, designate a cell at an early stage of differentiation and *fibrocyte* one that is fully differentiated [4], but in practice many researchers use fibroblast for an actively secreting cell and fibrocyte for an inactive one [2]. Fibroblasts are developed from the mesenchyme, which also gives rise to chondroblasts and osteoblasts. It has been suggested that they may also originate from other mesenchymal elements, such as the vascular endothelium or by transformation of macrophages, and it is possible that differentiated fibroblasts can themselves transform into osteoblasts. Electron microscopy reveals that the fibroblast of developing (as distinct from mature) connective tissue has an abundant cytoplasm, with a well-developed endoplasmic reticulum and prominent ribosomes attached to the membrane surfaces (Fig. 3.45). The Golgi membranes are clearly seen. Such features are characteristic of cells that are engaged in active synthesis and secretion. In studies of the fate of tritiated proline by autoradiography [5], it has been shown that material is first synthesized in the cisternae of the endoplasmic reticulum, and subsequently transferred to the Golgi region, after which it passes out of the fibroblast. Although, historically, the issue has been debated, it now seems generally accepted that fibroblasts are responsible for the manufacture of all the dermal connective tissue elements or their precursors.

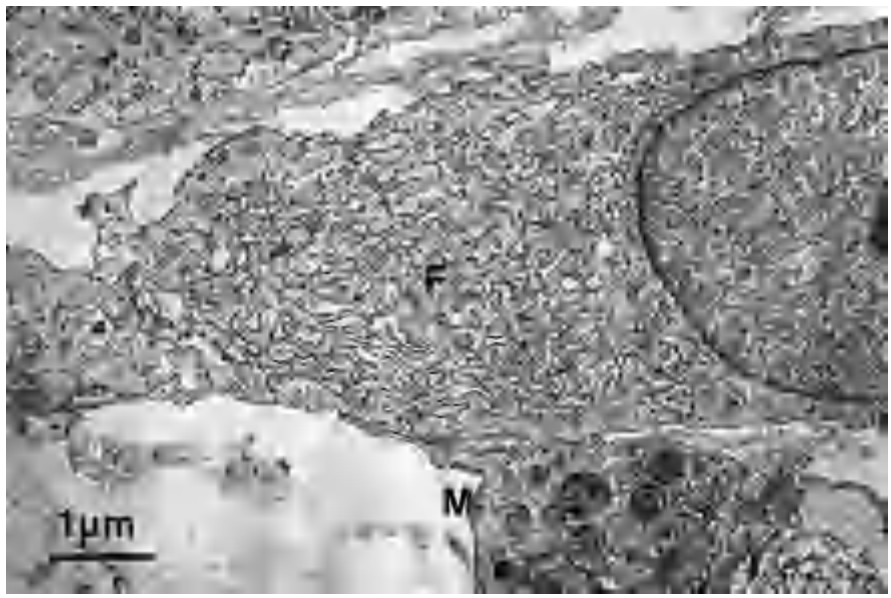

Fig. 3.45 Electron micrograph of an activated dermal fibroblast (F) in a healing wound. Note the prominent rough endoplasmic reticulum in the cytoplasm of this cell. There is an adjacent macrophage (M) with characteristic phagolysosomes, some of which contain ingested melanosomes.

Most researchers have been in agreement with Gersh and Catchpole [6] that fibroblasts are the source of the ground substance, notwithstanding the view of Asboe-Hansen [7] that the mast cell was implicated, on the grounds that it was the only connective tissue cell shown to contain acid mucopolysaccharide. There is evidence, however, from autoradiographic studies that ^{35}S is incorporated into sulphated mucopolysaccharides in the Golgi complex of fibroblasts, and that such substances are secreted [1,3]. The sulphated mucopolysaccharide produced by mast cells, however, is stored within the cell and is mainly heparin.

Human fibroblasts can be shown to produce collagen *in vitro* and there is no doubt that they are the source of the precursor of collagen [8,9]. While the source of elastin is less obvious, it has been clear that elastic tissue never occurs except in the presence of collagen, and in electron micrographs is seen always in the vicinity of fibroblasts [10]. It is now established that tropoelastin, containing a leader sequence of about 25 residues, which is ultimately lost, is synthesized on the rough endoplasmic reticulum in a similar fashion to collagen [11]. The existence of specific elastoblasts has been proposed but never demonstrated [10].

These considerations leave open the question of whether all fibroblasts are identical. Differences between papillary and reticular fibroblasts have been proposed [12], and fibroblasts from human gingiva have been shown to consist of two subpopulations differing in their response to prostaglandin E_2 [13].

Variants from scar tissue have been described. Knapp *et al*. [14] found two types from normal skin and mature scars, one small and spindle shaped (S cell) and one larger, flatter and amoeboid in appearance (A cell). In fibroblast populations derived from keloids, A cells were predominant, and keloid outgrowths often produced a third type, designated the K cell. Other researchers [15] were unable to detect differences in appearance or size distribution between fibroblasts cultured from normal skin and from keloids, although there were differences in response to hydrocortisone [16]. It has been suggested that keloid fibroblasts lack the normal ability to respond to the stresses imposed by wounding, and thus produce badly aligned collagen fibrils [17].

Langerhans' cells [1] (see also Chapter 10)

Dendritic cells of a form similar to melanocytes, but free from pigment and dopa negative, were first described by Langerhans, who demonstrated their existence in human epidermis by staining with gold chloride [2]. Dendritic cells that are dopa negative but ATPase positive have been found in human epidermis, pilary canals and the ORS of hair follicles [3], as well as in the epidermis of rhesus monkeys [4], guinea pigs [5] and hairless mice [6]. They have also, in the guinea pig, been demonstrated in the oesophageal mucosa and transitional epithelium of the urinary tract [7,8]. Whether all such cells are Langerhans' cells has been questioned, since ATPase activity may not be specific but shared by melanocytes. Thus on ultrastructural evidence, human epidermis appears to have three types of dendritic cells, namely melanocytes, Langerhans' cells and non-specific cells [9] and, similarly, it has been shown that such non-specific dendritic cells are widely distributed throughout the oral epithelium of the rhesus monkey, whereas Langerhans' cells are confined to keratinized epithelia such as the tongue [10]. The pattern of Langerhans' cell migration in skin has been recorded using transmission and scanning electron microscopy [11]; the regulation of migration has also been assessed [12].

Under the electron microscope, Langerhans' cells (Fig. 3.46) share with melanocytes a lobulated nucleus, a relatively clear cytoplasm and well-developed endoplasmic reticulum, Golgi complex and lysosomes. They differ in lacking melanosomes or premelanosomes, and in possessing a characteristic granule which is rod- or racquet-shaped [13–18]. These 'Birbeck' granules have been shown to represent subdomains of the endosomal recycling compartment and form at sites where the protein Langerin accumulates [19].

Using ultrastructural evidence of the presence of the characteristic granules, Langerhans' cells have been identified in the ORS of the human hair and the secretory duct of the sebaceous gland [20] and in the epithelium of the crypts of the human tonsil [21]. The discovery of similar granules in cells in the dermis in histiocytosis X resulted in the renaming of this condition as Langerhans' cell histiocytosis [22–24] (Chapter 52). Langerhans' cells are of mesenchymal origin and originate from bone marrow, as proved by the demonstration that, after destruction of the haemo- and leukopoietic systems of mice by X-rays, injection of bone marrow from F_1 hybrids could re-establish a population of Langerhans' cells [25].

The role of the Langerhans' cell in cutaneous immune reactions as a specialized antigen-presenting cell is considered in Chapter 10.

Mast cells [1–4]

Mast cells were first described by Ehrlich in 1877 [5] who distinguished them from other connective tissue cells by their ability to stain metachromatically with basic aniline dyes. Mast cells are larger than eosinophils and basophils. They occur in most tissues, but are particularly numerous in skin, bronchus, nasal mucosa and gut.

Mast cells are heterogeneous and fall into two main types—connective tissue and mucosal—which can be differentiated by their morphology, tissue distribution, histochemical characteristics and responses to degranulating agents [6–8]. Solubility of the granules in formaldehyde and content of neutral proteinase, namely tryptase and chymase (chymotryptic proteinase) will vary according to the type of cell [6,7]. For example, human foreskin mast cells contain both proteinases, whereas mast cells in intestinal mucosa and lung contain mainly tryptase [1,6,7].

Human lung mast cells vary in size, numbers of IgE receptors, histamine content and capacity to generate prostaglandin D_2 [7]. Two types of human nasal mast cells may be differentiated histochemically, which resemble either rodent connective tissue or mucosal types of mast cells [9].

There is increasing evidence in support of a haematopoietic stem cell origin for murine mast cells [10], and it appears that human peripheral blood mononuclear phagocytes can give rise to mast cells or mast cell-like cells *in vitro* [11–14]. Human tissue mast cells, including those in skin, have been found to express panhaematopoietic markers, but not antigens typical of either myeloid or lymphoid cells [15]. Further support for mast cell being the progeny of haematopoietic stem cells have been determined from xenotransplantation studies. Specifically, haematopoietic stem cells can proliferate and differentiate into mature mast cells in mouse skin 3 months after

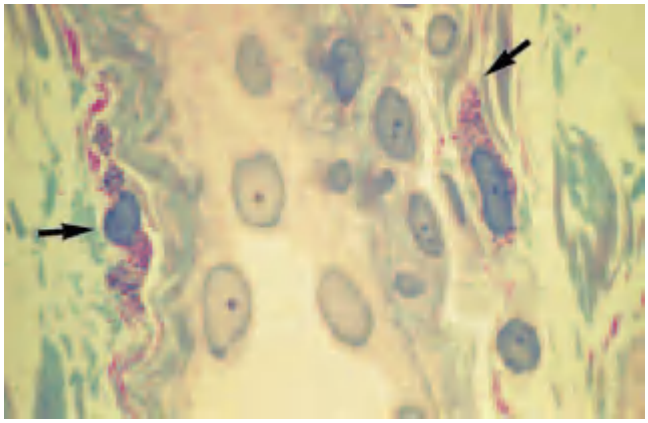

Fig. 3.47 Photomicrograph of semi-thin Epon section showing two spindle-shaped mast cells (arrowed) close to a dermal blood vessel. Methylene blue and basic fuchsin. × 400.

transplantation of human cord blood $CD34^+$ cells [16]. Cytokines such as stem cell factor and IL-6 also promote mast cell proliferation [16].

Mast cells are distributed close to blood vessels, nerves and appendages, and are most numerous in the subpapillary dermis, in the region of the superficial dermal vascular plexus [12,17]. There are about 7000 mast cells per cubic millimetre in normal skin [18]. One study has shown little age-related or regional variation in numbers of mast cells [18], whereas another found considerable differences, with four times as many cells in the facial or genital skin compared with that of the leg or back [19].

Mast cells are present in greatly increased numbers in urticaria pigmentosa, and are also numerous in diverse inflammatory disorders, wound healing and a variety of tumours including neurofibroma and BCC.

Dermal mast cells are ovoid or spindle-shaped, mononuclear or occasionally binuclear, and only rarely show signs of mitosis in normal skin [4]. Their major distinguishing feature is the presence of numerous, round cytoplasmic granules, which stain orthochromatically with alcian blue and safranin or metachromatically with toluidine blue or Giemsa. The cells have an affinity for avidin which has proved useful in examining cells by fluorescence [14] or by staining with an avidin–biotin–peroxidase complex [20,21]. Mast cells are also particularly well demonstrated in 1-µm-thick sections of plastic-embedded tissue stained with Giemsa or with basic fuchsin and methylene blue [12,22] (Fig. 3.47). Carnoy's fixative has been found to be superior to formal-saline for the fixation of human, dermal mast cells [23]. Bouin's fixative and lead subacetate solution are also recommended [4].

At the fine structural level (Fig. 3.48), mast cells are found to possess IFs containing vimentin, in addition to microtubules, Golgi apparatus, mitochondria and lipid bodies [12]. The plasma membrane extends outward to form numerous processes appearing like microvilli in ultrathin sections (Fig. 3.48), but which have been shown by scanning electron microscopy to be fine ridges or folds [24]. The cytoplasmic granules are about 0.6 µm in diameter and surrounded by a perigranular membrane. The ultrastructure of human mast cell granules (Figs 3.48 & 3.49) is highly distinctive and probably species specific. The main component is the lamellae, which are arranged in whorls or scrolls (Fig. 3.49a) and exhibit a banding or cross-striation of approximately 6-nm periodicity. A highly ordered 'paracrystalline' lattice may also occur (Fig. 3.49b). Other granules appear to have largely amorphous or particulate contents. The appearance of mast cell

(a) (b)

Fig. 3.49 High-magnification views of dermal mast cell granules. (a) Typical scroll-like configuration of lamellae, some of which show a cross-banding of regular periodicity. (b) The substructure of this granule is a highly organized lattice. Note the scroll (arrow) in adjacent granule, which is largely excluded from this view.

granules may vary in the same cell or among cells in the same tissues. By contrast, mast cell granules in rats and other species may have a uniformly amorphous composition (Fig. 3.50).

Mast cell granules with a predominantly lattice-type of substructure have been shown, by the use of immunoelectron microscopy, to contain both tryptase and chymase; whereas those with a scroll-like configuration stain only for tryptase [25]. On this basis, it has been suggested that tryptase-containing (mucosal) *T mast cells* and those containing both tryptase and chymotryptase (connective tissue), *TC mast cells*, can be distinguished by their ultrastructure [25].

During the release of mast cell-derived mediators such as histamine, mast cells undergo sequential alterations involving both granules and perigranular membranes [26]. It is not certain whether human dermal mast cells *in vivo* exhibit the same sequence of changes identified in the mouse peritoneal mast cell model, which has been studied extensively *in vitro* [26], but striking intracellular

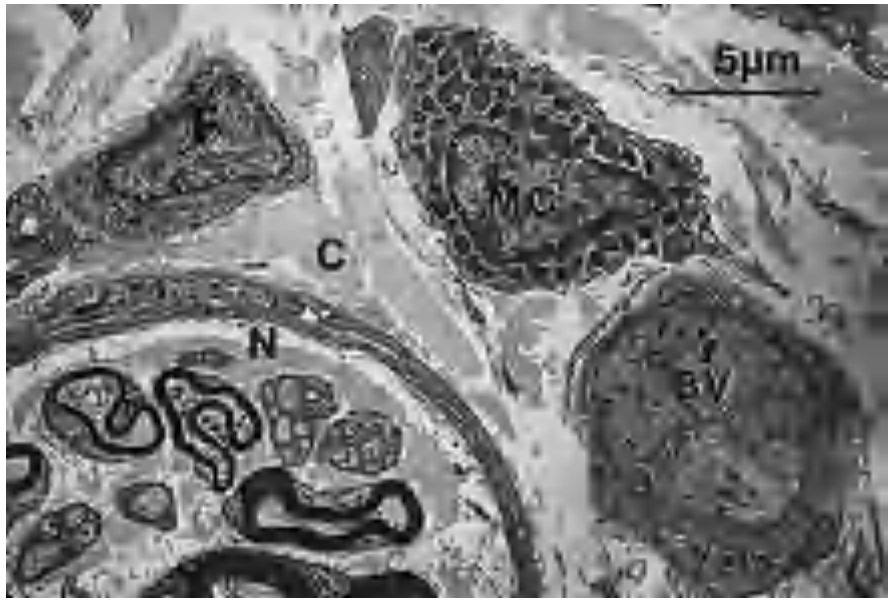

Fig. 3.50 Electron micrograph of a rodent dermal mast cell (MC) close to blood vessel (BV), nerve (N) and fibroblast (F). Note the homogeneous, non-lamellar substructure of mast cell granules. C, collagen.

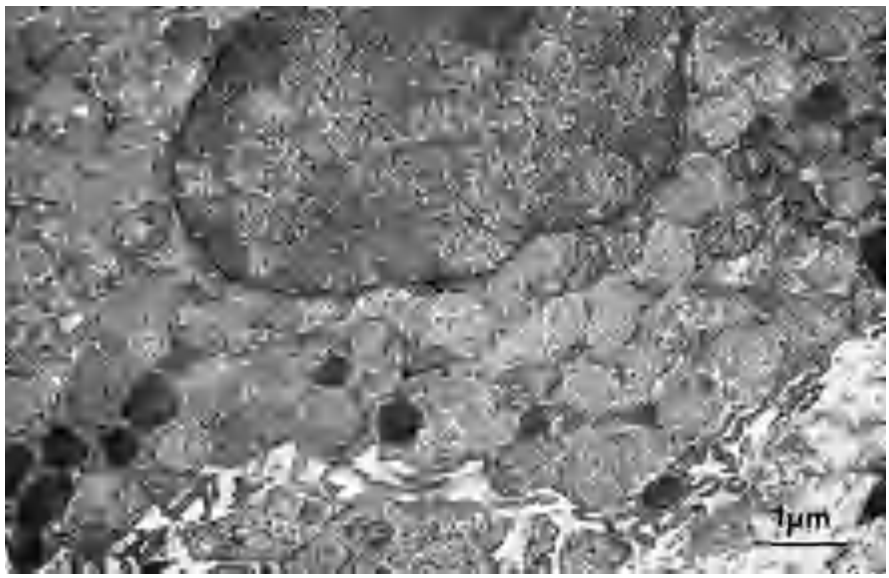

Fig. 3.51 Human dermal mast cell undergoing degranulation. Note that most granules are swollen and have lost their characteristic substructure and density. Note also that granule changes have occurred within the confines of the cell—and very few granules have been discharged into the extracellular space.

modifications can be seen, including swelling and loss in density of granules, and disruption of perigranular membranes and spaces (Fig. 3.51).

Basophils [1,2]

Human basophils are small, round cells with multilobed nuclei. Like mast cells, they contain prominent cytoplasmic granules, which stain metachromatically with basic aniline dyes [2]. At the ultrastructural level (Fig. 3.52), mature granules usually contain dense particles; however, multiple membrane arrays may also occur [3]. A smaller granule type with a homogeneous content has been reported [3]. Rarely, basophils contain Charcot–Leyden crystals, within either the granules or the cytoplasm [3].

Nerves and sense organs

The skin may be innervated with around 1 million afferent nerve fibres [1–7]. Most terminate in the face and extremities; relatively few supply the back. The cutaneous nerves contain axons with cell bodies in the dorsal root ganglia. Their diameters range from 0.2 to 20.0 µm. The main nerve trunks entering the subdermal fatty tissue each divide into smaller bundles. Groups of myelinated fibres fan out in a horizontal plane to form a branching network from which fibres ascend, usually accompanying blood vessels, to form a web of interlacing nerves in the superficial dermis. Throughout their course the axons are enveloped in Schwann cells (Fig. 3.53) and as they run peripherally an increasing number lack myelin sheaths. Most end in the dermis; some penetrate the basement membrane, but do not travel far into the epidermis.

Sensory endings are of two main kinds: corpuscular, which embrace non-nervous elements; and 'free', which do not [2,3,5–9]. Corpuscular endings can, in turn, be subdivided into encapsulated receptors, of which a range occurs in the dermis, and non-encapsulated, exemplified by Merkel's 'touch spot', which is epidermal.

The most striking of the encapsulated receptors [9] is the *Pacinian corpuscle* [9–14]. It is an ovoid structure about 1 mm in length, which is lamellated in cross-section like an onion (Fig. 3.54), and is innervated by a myelinated sensory axon, which loses its sheath as it traverses the core. The *Golgi–Mazzoni* corpuscle found in the subcutaneous tissue of the human finger is similarly laminate but of much simpler organization. Another classical receptor is the *Krause end bulb*, an encapsulated swelling on myelinated fibres situated in the superficial layers of the dermis (Fig. 3.55). *Meissner corpuscles* [3,6,9,15] are characteristic of the papillary ridges of glabrous skin in primates. They have a thick, lamellated capsule, 20–40 µm in diameter and up to 150 µm long.

Of somewhat different structure are the terminals first described by *Ruffini* [16] in human digits, in which several expanded endings branch from a single, myelinated afferent fibre. The endings are directly related to collagen fibrils [3,17].

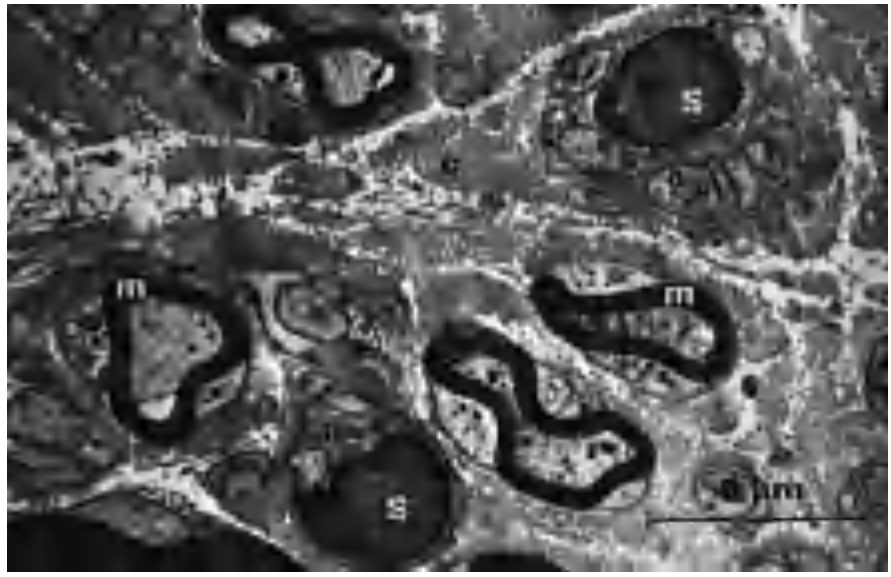

Fig. 3.53 Transverse section of sural nerve of adult human female, showing myelinated fibres (m) and two Schwann cells (S), each associated with a group of unmyelinated axons (a), all set in a bed of endoneural collagen (c). (Courtesy of Professor A.S. Breathnach, St John's Institute of Dermatology, London, UK.)

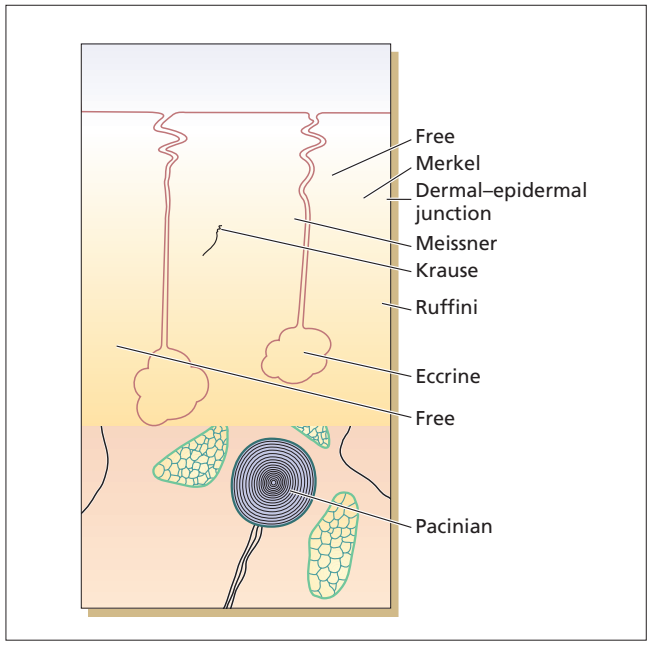

Fig. 3.54 Diagrammatic section showing nerve endings in glabrous skin of fingertip. (From Miller *et al*. [12].)

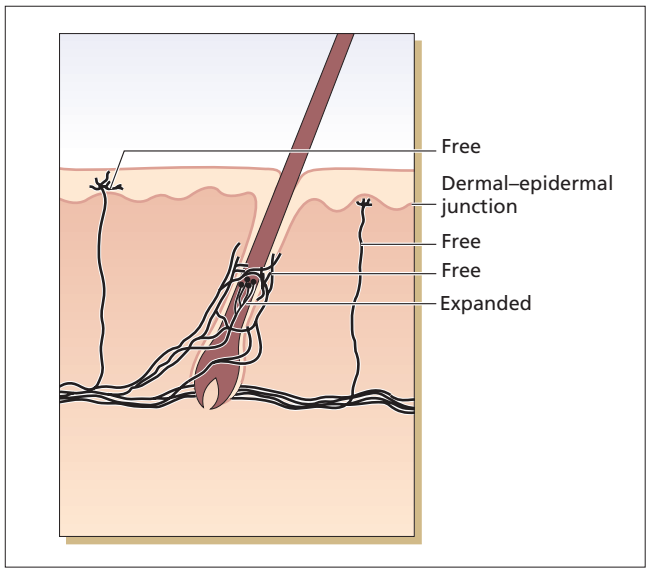

Fig. 3.55 Diagrammatic section showing nerve endings in hairy skin of the human extremities. Free nerve endings are seen in the shallow dermal papillae or between the epidermal cells. The hair follicle is innervated by free endings of the circular fibres and expanded tips of the palisade fibres. (From Miller *et al*. [12].)

'Free nerve-endings', which appear to be derived from non-myelinated fibres, occur in the superficial dermis and in the overlying epidermis [9,12,18,19]. Those in the dermis are arranged in a tuft-like manner and have thus been designated *penicillate nerve endings* [18].

Hair follicles have nerve terminals of varying degrees of complexity (Fig. 3.56). The fine nerve filaments run parallel to, and encircle, the hair follicles, forming a palisade. Each group of axons is surrounded by Schwann cells, and the side away from the glassy membrane appears to be free, lacking any specialized contacts with collagenous fibres [12,21,22]. Sinus hairs, for example the vibrissae of cats and rats, have a much more complex nerve supply, with corpuscular as well as non-corpuscular receptor elements [20,23].

Merkel cells

Merkel [1] first gave the name *tastzellen* to certain cells that he found near the base of the rete-peg in the snout skin of the mole. As there were intraepidermal neurites with expanded tips (Merkel discs) adjacent to them, he believed them to be transducers of physical stimuli. Merkel cells [2] have been described in the snout of the oppossum [3], in the fetal sheep [4], in the cat [5] and in human [6–10].

In the hairy skin of the cat [5,11], each touch spot, which is a dome-shaped elevation of the epidermis 0.1–0.4 mm in diameter, is underlaid by a battery of Merkel cells borne on branches of a myelinated axon. Each Merkel cell (Fig. 3.57) has a lobulated nucleus and characteristic granules in the cytoplasm. It is distally embedded in the basal layer of epidermal cells, with which it has desmosomal connections. A nerve plate underlies it [12]. Similar ultrastructural features are seen in Merkel cells of human skin [6–10,13,14], where the spherical granules appear to be membrane limited with a dense central core (Fig. 3.57). Cold receptors identified in the cat's nose [5] appear to be an epithelial cell–neurite complex, analogous to but less distinctive than the Merkel cell system.

There are two hypotheses about the embryonic source of Merkel cells [15]. One postulates that they are derived from the neural crest and migrate into the epidermis along the peripheral nerves [16]. The other assumes that they arise *in situ* and are derived from epithelial cells. Observations on fetal skin in the rat [17] and human [18], on human fetal skin transplanted onto nude mice [14] and on autografts of skin derived from cultured keratinocytes [19] all suggest that Merkel cells originate in the epidermis. These findings would also indicate that the dermal Merkel cells in fetal skin migrate down from the epidermis instead of moving in the opposite direction [20].

Fig. 3.57 Merkel cell in human epidermis. The dermis (d) with collagen fibres is seen in the lower part of the picture. b, basement membrane; de, desmosomes making connections with adjacent basal keratinocyte; g, spherical granules (see inset); n, nucleus of Merkel cell; t, tonofilaments. (Courtesy of Professor A.S. Breathnach, St John's Institute of Dermatology, London, UK.)

Merkel cells contain IFs composed of low-molecular-weight keratin [20,21] rather than neurofilament protein [22], and form desmosomes with surrounding keratinocytes [23].

Human Merkel cells express immunoreactivity for various neuropeptides including *Met*-enkephalin [24] and vasoactive intestinal polypeptide [25], in addition to neurone-specific enolase [26] and synaptophysin-like [27] and pancreastatin-like [28] material. They also contain chromogranin A [29].

Blood vessels [1–3]

The arteries entering the skin form a deep plexus—the 'fascial' network. From this region vessels rise to the border between the subcutaneous adipose tissue and the corium, and these form a 'cutaneous' network. This gives branches to the various cutaneous appendages, and provides ascending arterioles to supply a subpapillary plexus, which itself forms capillary loops in the papillary layer between the ridges of the dermal–epidermal frontier. From these capillaries the blood is drained by venules which descend to intermediate plexuses [1,2,4–7]. The vasculature is more elaborate than would be necessary solely for nutrition of the skin and temperature control is an important function. It is believed that the amount of blood flowing through the superficial layers of the dermis can be controlled by arteriovenous anastomoses, which act as shunts to short circuit the flow. However, although anastomoses occur in some acral sites, such as the fingertips [3], they have not been found to be regular components of the microvasculature elsewhere [6]. Recently it has been shown that peripheral nerves provide a template that determines the organotypic pattern of blood vessel branching and arterial differentiation: this process is controlled by local secretion of vascular endothelial growth factor (VEGF) [7].

The dermal microvasculature can be divided into a series of adjoining arterial and venous segments. Attempts have been made to delineate these segments using measurements of their diameter [6,8] (Fig. 3.58), but owing to the considerable overlap among these measurements and variations caused by differences in methods of fixation [6], other criteria, such as the nature of endothelium (including size and shape of the cells), and of the periendothelial investment, such as the appearance of the basement membrane, are also necessary to make these distinctions.

The innermost component of the microvessels, in common with other blood vessels, is the endothelium, consisting of adjoining endothelial cells that surround the lumen. Arterioles, except the smallest terminal arterioles, are characterized by a subendothelial layer of elastic tissue. Venules, on the other hand, generally do not have elastic tissue in their walls (Fig. 3.59).

The endothelium of capillaries and of the smallest arterioles and venules is surrounded by pericytes, which appear to share certain characteristics with both endothelial and smooth muscle cells. Capillaries contain a single, discontinuous layer of pericytes, whereas venules may include more than one pericyte layer in their periendothelial investment. Smooth muscle cells are found chiefly in the walls of ascending arterioles, but also within the arterioles of the superficial and deep plexuses and in collecting venules. Smooth muscle cells and pericytes are surrounded by basement membrane, which also encompasses the outer (abluminal) surface of endothelial cells. *Veil cells* are long thin cells, with an attenuated cytoplasm, that more closely resemble fibroblasts than pericytes. They do not have a basement-membrane investment and are situated outside the vessel wall.

At the ultrastructural level (Fig. 3.60), endothelial cells possess many of the common cytoplasmic organelles including Golgi apparatus, rough and smooth endoplasmic reticulum, mitochondria and lysosomes. Micropinocytotic vesicles and pits, of the coated and smooth types, are also evident. Intermediate filaments containing vimentin are present and have been reported to be more abundant on the venous than the arterial side [6]. Dense bodies associated with actin-like filaments of 5–6 nm diameter are found in the endothelial cells of the larger arterioles [5,6], and may have a role in endothelial contraction, a putative function that remains highly contentious.

Weibel–Palade bodies (Figs 3.61 & 3.62) are endothelium-specific inclusions [9,10] that occur more frequently on the

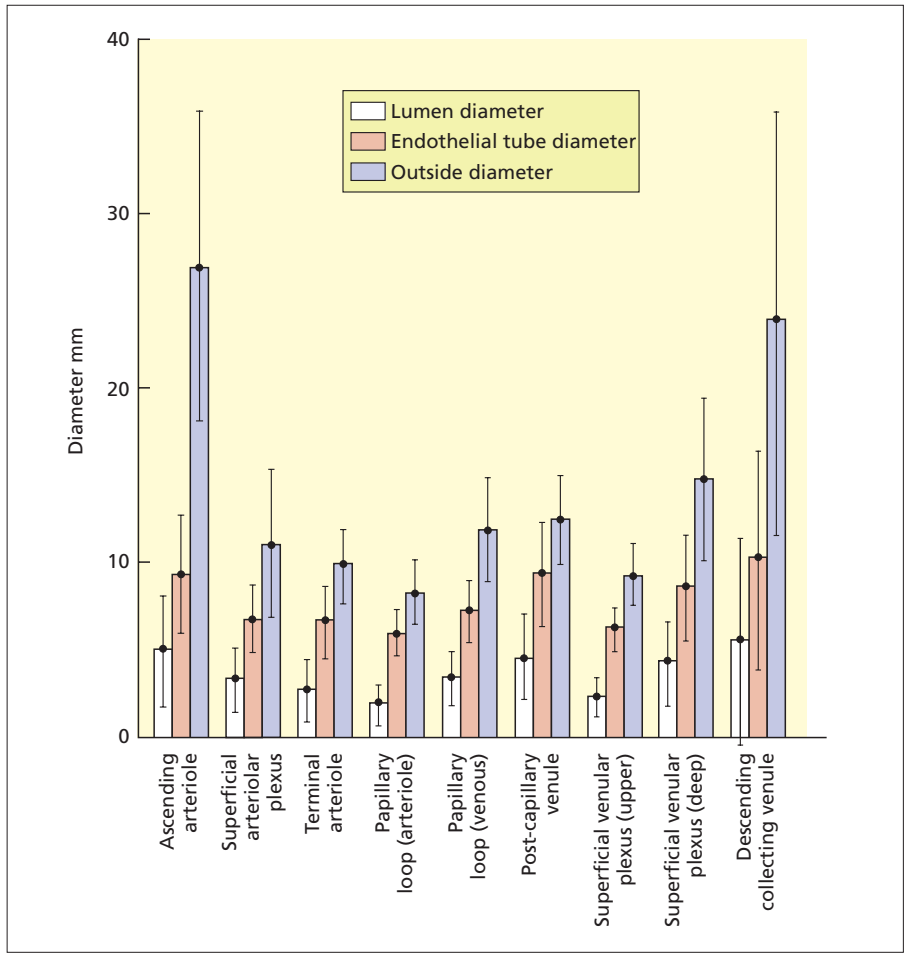

Fig. 3.58 Diagram showing diameters of nine different segments of the dermal vasculature. Bars represent the standard deviation. Note the considerable overlap between adjacent vascular segments. (From Higgins and Eady [6].)

Fig. 3.59 Photomicrograph of 1-μm Epon section of microvessels in reticular dermis. Arterioles (A) can be distinguished from venules (V) by the presence of an elastic lamina, which stains red. Surrounding mast cells can be distinguished by their prominent red/blue cytoplasmic granules. Basic fuchsin and methylene blue. × 400.

venous side of the microvasculature [6]. They are not found in dermal lymphatics but have been reported in larger lymph vessels [11]. Weibel–Palade bodies contain factor VIII-related antigen, von Willebrand factor [10] and GMP-140, a protein that was first described in platelet α-granules [12].

Closed fenestrae (or fenestrations), which allow rapid passage of water and solutes between the circulation and extravascular space, have been observed in capillaries, mainly in the vicinity of epidermal appendages [13] but also in papillary dermis, facing the epithelium [6,14].

A major feature distinguishing arterial from venous microvessels is the ultrastructural appearance of the basement membrane. Venules and venous capillaries have a multilaminated basement membrane, whereas arterioles possess a more homogeneous matrix, lacking the multiple, distinct, electron-dense strands [6,7] (Figs 3.59, 3.60 & 3.62). Vascular basement membrane contains laminin, type IV collagen, fibronectin and heparan sulphate PG [15]. It does not contain BP230 or BP180, type VII collagen or laminin 5, each of which is a component of epidermal basement membrane.

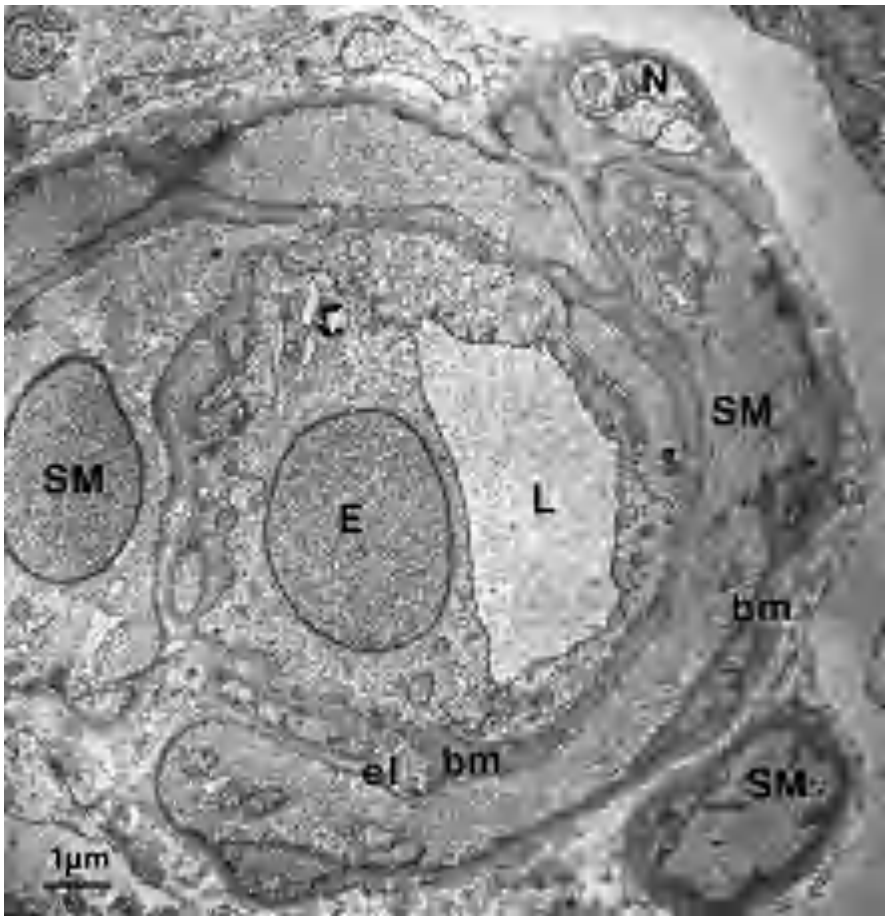

Fig. 3.60 Electron micrograph of a cross-section through a small arteriole. Note the relatively smooth surface of endothelial cells (E) around lumen (L) and the investment of smooth muscle (SM) with associated nerve (N); There is a small amount of elastic tissue (el) among the endothelial basement membrane (bm) which, unlike venular basement membrane, has a uniform density.

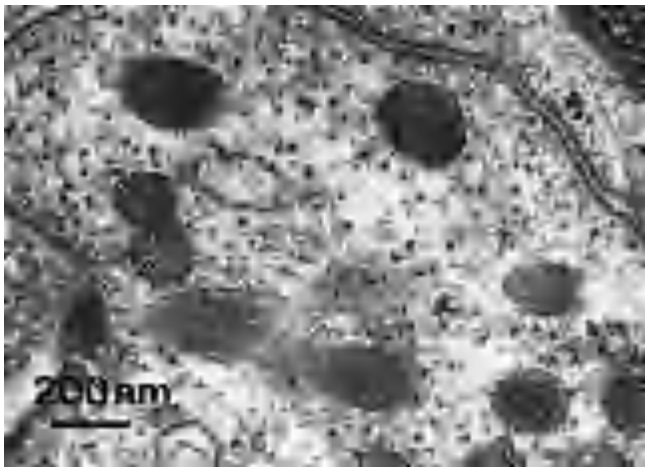

Fig. 3.61 High-magnification view of Weibel–Palade bodies illustrating tubular profiles in cross-section.

A number of endothelium-specific antigens have recently been recognized, and may have a special value in studies on pathology [16,17]. Endothelial cells are the major source of angiotensin-converting enzyme [18] as well as various cytokines and adhesion molecules [16].

The microvasculature is a rich source of enzymes [19] that may be involved in intracellular processes such as endocytosis and vesicular transport. Acid phosphatase has been localized to lysosome-like structures in the endothelium [19], and alkaline phosphatase reactivity has been used extensively to map the distribution and arborization of the dermal vascular network [20] (Fig. 3.63).

Lymphatic system

The lymphatic system (Chapter 51) serves to transport particulate and liquid materials, such as leaked protein, from the extravascular compartment of the dermis. The interconnecting lymphatic spaces arise from terminal bulbs in the papillary layer and ultimately form the system, which drains into the lymph nodes. The vessels have a broad lumen surrounded by a single endothelial layer (Fig. 3.64), which is discontinuous in the terminal components, and rests on an often discontinuous basal lamina [1,2].

Regional variation

The regional diversity of the skin has been graphically described by Kligman [1], who contrasted the tropical rain forests of the axillae with the oily tundras of the face and the comparative deserts of the trunk. Even within each such broad and grossly different zones there are often highly significant structural or functional variations. With modern investigative techniques, we are becoming increasingly aware that no area of skin is identical in all respects with any other, except the corresponding area on the other side of the body. These regional variations are of great practical importance, for they necessarily influence the microclimate on the skin surface, and hence the bacterial flora, and they play a large part in determining the distribution of dermatoses, whether of internal or external origin.

The failure to appreciate the extent and significance of regional variation has been responsible for many false generalizations. Bacteriological, histological or biochemical findings obtained in one region have been assumed to be applicable to the skin as a whole. Histopathological reports based on knowledge of the normal in one region only have frequently been misleading.

A detailed account of the known regional variations would fill a substantial textbook. Here we can consider only certain selected aspects.

1 The thickness of the epidermis. There is marked regional variation in the thickness of the epidermis, in its microanatomy and in its function. The thick epidermis with a compact, thick, horny layer on the palms, soles and other friction surfaces, contrasts with the thin epidermis of the flexures. The thickness of the horny layer influences the resistance of the skin to physical and chemical trauma.

2 The distribution of appendages [2]. The density of hair follicles (Chapter 63) varies greatly and, although the number of follicles remains unchanged until middle life, the changing balance between vellus and terminal hair throughout life frequently alters the surface microclimate of each area.

The distribution of sebaceous glands (Chapter 43), actively functioning in the newborn and from the approach of puberty onwards, modifies the composition of the surface lipid film. The distribution of eccrine and apocrine glands is described in Chapter 45.

3 The distribution of melanocytes (Chapter 38).

4 Variation in the structure of the dermal–epidermal junction [3,4]. The sculpturing of the undersurface of the epidermis shows many totally distinct patterns in different regions of the body. The pattern is modified by the number and type of epidermal appendages, but is determined largely by the mechanical stresses to which each region is subjected.

5 The structure of the dermis. The dermis varies in thickness and in structure according to the functional requirements of each region. The arrangement and size of the elastic fibres have been investigated [5]. Large elastic fibres are especially numerous in the perineal region and around the anus: there are virtually none in the scrotum.

6 Blood supply [6]. Variations in the cutaneous blood supply are considered in Chapter 50. Microangiographic studies [7] have shown strikingly different patterns in regions of distensible skin such as the eyelids in comparison with more rigid areas such as the fingertips.

7 Histamine content [8]. The histamine content of the skin is highest in the region of the eyelids and upper lip and lowest on the chest and abdomen.

8 Percutaneous absorption [9]. Regional differences in percutaneous absorption have not been thoroughly studied. The thickness of the horny layer and its structure are only two of many factors determining the efficacy of the barrier function. The size and distribution of hair follicles obviously influences the capacity for transfollicular absorption.

Chapter 4

Functions of the Skin

C.B. Archer

Introduction

The skin is arguably the largest immunologically active organ in the body, and its relative accessibility for basic scientific research has allowed much progress in our understanding of its multiplicity of functions. The most obvious functions of the skin are to provide a protective physical barrier between the body and the environment, preventing the inward and outward passage of water and electrolytes, reducing penetration by destructive chemicals, arresting the penetration of microorganisms, and absorbing radiation from the sun. The skin is important in the regulation of body temperature and is designed, to an extent, to respond to mechanical forces; the epidermis has a degree of mechanical strength to withstand damage and the ability to repair itself if damaged, and the dermis provides elasticity in response to mechanical insults.

The immunological functions of the skin depend both on cells in the epidermis and on dermal cellular constituents. Antimicrobial peptides (AMPs) are a diverse group of proteins that are involved as a first line of immune defence by many living things, including plants, insects, bacteria and vertebrates [1,2]. In human skin, AMPs provide a chemical barrier to potentially pathogenic microorganisms. The skin also contains sensory and autonomic nerves and several types of sensory receptors, which detect the incoming stimuli of touch, vibration, pressure, change in temperature (warmth and cold), pain (including heat pain) and itch. As in other animals, human skin has a role in sociosexual communication.

The aim of this chapter is to consider the functions of the skin in relation to its structure. It is important to understand physiological functions of the skin, so that one can plan a logical approach to the management of skin diseases. For example, if a patient has extensive areas of denuded skin, as seen following severe burns or in toxic epidermal necrolysis, the skin is unable to play its usual part in the maintenance of fluid balance and temperature regulation, a clinical situation referred to as 'skin failure' [3]. In addition, a knowledge of the skin as a barrier is important from the point of view of the delivery of topical treatments for skin diseases, and ceramide-dominant barrier-repair lipids have been reported to improve atopic dermatitis [4]. The contribution of bioengineering to present knowledge is also discussed.

It is beyond the scope of this chapter to provide a detailed account of skin biochemistry, and some biochemical functions of the skin are discussed in chapters referring to specific skin diseases. For example, androgen biochemistry is discussed in relation to disorders of the sebaceous glands in Chapter 43, altered cyclic nucleotide metabolism in atopic dermatitis [5] in Chapter 18, and phosphoinositide cell-regulatory abnormalities in psoriasis [6] in Chapter 35. Under the influence of sunlight, the skin is the site of vitamin D synthesis. In addition to its effects on calcium and bone metabolism, vitamin D_3 has antiproliferative and immunomodulatory effects, both of which are likely to be relevant to the treatment of psoriasis with vitamin D analogues (see Chapter 35).

Nails and hair are discussed elsewhere (see Chapters 62 and 63, respectively). Briefly, the scalp hair has a role in heat regulation and in display. Nails are mainly protective, aid in performing delicate tasks and are of cosmetic importance, a more noticeable feature when the nails are either absent or disfigured.

Barrier functions

The epidermis and stratum corneum as a physical barrier

The skin acts as a two-way barrier to prevent the inward or outward passage of water and electrolytes. The physical barrier is largely situated in the epidermis, isolated epidermis being as impermeable as whole skin, whereas once the epidermis is removed the residual dermis is almost completely permeable. The epidermal barrier is localized to the stratum corneum.

On routine histology, the stratum corneum shows a basket-weave structure, and early investigators therefore believed it to be porous, and considered the barrier must lie below it [1]. In 1953, Blank [2] found that the water permeability of excised full-thickness skin remained unchanged by successive stripping with adhesive tape until the lowest part of the stratum corneum was removed, and proposed that the barrier lay within a thin layer of the innermost region. Subsequently, these observations were considered to be consistent with the belief that there is a uniformly good diffusion barrier throughout all or most of the horny layer [3–5].

The barrier depends on both the cornified material of the keratinocytes and the intercellular material, particularly lipids, regional differences in permeability being related to lipid content and not to thickness of the stratum corneum. A two-compartment model of the stratum corneum as a barrier is currently accepted, in which protein-rich cells, the corneocytes, are embedded within a continuous lipid-rich matrix.

Within the keratinocytes are synthesized both the fibrous proteins of keratin and a histidine-rich protein known as keratohyalin or filaggrin [6,7]. Around each corneocyte is an envelope, formed by cross-linking of the precursors involucrin and keratohyalin, which forms an insoluble exoskeleton and acts as a rigid scaffold for the internal keratin filaments [8,9]. There is evidence that lipids are chemically bound to its surface [10].

The intercellular cement is the product of ovoid organelles, 0.2–0.3 μm in diameter, known as membrane-coating granules, Odland bodies or lamellar bodies [11]. They become identifiable in cells of the spinous layer, and migrate to the cell periphery and fuse with the plasma membrane in the granular layer. They then discharge their contents into the intercellular spaces, which expand to form 10–40% of the total volume of the tissue.

The lamellar bodies originally contain neutral sugars linked to lipids and proteins, hydrolytic enzymes and free sterols, but the composition of the secretion changes greatly as they migrate outwards. Phospholipids, present in the stratum basale, diminish in the stratum spinosum, and virtually disappear at the level of the stratum corneum. However, neutral lipids and sphingolipids, in particular ceramides, are increased in the stratum corneum [12–17]. Cholesterol sulphate increases from the spinous to the granular layer, but is decreased in the stratum corneum.

In parallel with these biochemical events, changes can be observed in the ultrastructure of the intercellular material (Fig. 4.1) [18]. Within the granules, bilayers become arranged to form discs, which represent flattened unilamellar liposomes. The formation of such flattened liposomes has been demonstrated *in vitro* by exposing a mixture of ceramides, cholesterol, palmitic acid and cholesterol sulphate to a hypertonic medium [19,20]. After extrusion into the intercellular space, the discs become arranged parallel to the cell membranes and then fuse to form uninterrupted sheets [21].

In consequence of their origin by fusion of flattened vesicles, the intercellular lamellae of the stratum corneum consist of two lipid bilayers in close apposition [22]. The stratum compactum has been considered to form the principal diffusion barrier. It has also been proposed that in the stratum dysjunctum, the vesicular bodies maintain the patency of the intercellular space, and thus facilitate the absorption of applied substances by a form of shunt mechanism, as well as functioning as a reservoir. Vickers [23] first showed that the horny layer can retain topically applied corticosteroids, and such reservoir effects were later confirmed for hydrocortisone [24] and established for hexachlorophene [25].

In atopic dermatitis, the xerosis and permeability barrier abnormality might have a role in driving disease activity [26]. Both involved and clinically uninvolved skin in atopic dermatitis have impaired barrier function [27], which correlates with a reduction in the stratum corneum ceramide fraction [28]. Emollients do not usually correct the underlying stratum corneum lipid abnormality, but preliminary studies have shown that ceramide-dominant barrier-repair lipids improve atopic dermatitis in children [29].

Percutaneous absorption

The skin is considered to be a composite membrane, with three anatomically distinct layers [1]: the stratum corneum (10 μm), the viable epidermis (100 μm) and the uppermost papillary layer of the dermis (100–200 μm) each having a different diffusion constant. Even healthy adult human skin allows some permeation of almost every substance, and rates of penetration of different materials may differ by 10 000-fold.

Percutaneous absorption has been studied both *in vivo* and *in vitro*. The penetration *in vivo* of topically applied substances can be assessed by physiological or pharmacological means, or analysed by chemical or histological techniques. Thus, vasoconstriction has been utilized for corticosteroids, vasodilatation for nicotinates, wealing for histamine, sweating for pilocarpine and anaesthesia for local anaesthetics. The application of compounds labelled with radioisotopes and their location through time in layers of stratum corneum, successively stripped by adhesive tape, has been particularly useful. Body fluids, such as blood and urine, can similarly be analysed for substances that have traversed the skin.

In vitro methods usually utilize sheets of whole epidermis or stratum corneum rather than whole skin. Epidermal sheets can be prepared from skin removed surgically, or obtained from cadavers within 48 h of death. The epidermis can be separated by mild heat [2], ammonia vapour [3] or even distilled water. For removal of the Malpighian layer, digestion in 0.2% trypsin [2] or in dispase, a bacterial neutral protease, has been used [4]. The prepared skin material is mounted as a membrane in a diffusion cell between an upper compartment containing a substance, the penetration of which is under study, and a lower compartment containing a buffer solution, which is replenished as samples are removed for analysis at known time intervals, to determine the content of the test substance.

The properties of the skin barrier have a purely physicochemical basis, and do not depend upon the energy-requiring activities of living cells. They are essentially the same *in vitro* as *in vivo*, are unaffected by reversal of the membrane and are maintained long after the skin is removed from the body [5]. Penetrants in weak solutions (although not those at very high concentrations) obey Fick's first law of diffusion, which states that the rate of flow, or flux, is the product of the average concentration of the molecules and their average velocity. In simple terms, the permeability of the barrier for any given penetrant can be completely characterized by the ratio of the flux to the concentration applied, which is known as the permeability constant, and is expressed in length per unit time. The principles of skin permeability and percutaneous absorption have been reviewed in detail elsewhere [1,6–8].

Permeability constants of human and animal skins have been published for a large number of different molecules [6,8]. They vary considerably between species. For example, human skin, which is slightly permeable to water, is relatively impermeable to sodium, potassium and other ions in aqueous solution. In contrast, penetration of various ions through many animal skins is comparatively rapid. Most covalent substances in aqueous solution, such as glucose, urea and the macromolecular human serum albumin, have very low permeability constants in both human and rabbit skin. Others, such as certain aliphatic alcohols, have high constants. Solutes in organic liquids generally show a permeability similar to the solvents themselves. The presence of a solvent is not necessary, for solids dried on the skin continue to penetrate long after a volatile vehicle has evaporated [9]. Thus, for example, application to the scalp of corticosteroids in alcohol may be an effective therapy. In addition, vapours and permanent gases can penetrate skin [10].

The efficiency of the barrier differs between body sites. The scrotum is particularly permeable [11] and the face, forehead and dorsa of the hands may be more permeable to water than the trunk, arms and legs. The palms are particularly impermeable to nearly all molecules except water.

The barrier is affected by many other factors, such as age, environmental conditions and physical trauma, and permeability can be enhanced by various agents, permitting increased access of topically applied drugs.

By virtue of the stratum corneum being adapted to prevent excessive water loss from the body, there is an excellent barrier to the influx of polar molecules, such as water itself. However, many potentially destructive chemicals are non-polar, and the barrier function of the skin slows down penetration of such compounds rather than impeding penetration completely.

Microorganisms: antimicrobial peptides (AMPs) as a chemical barrier

An intact stratum corneum prevents invasion of the skin by normal skin flora or pathogenic microorganisms. However, both minor injury to the skin, as well as skin diseases, can provide portals of entry to microorganisms, particularly streptococci or staphylococci. The same organisms give rise to different patterns of infection depending, in part, on the nature of the injury. Cellulitis, a dermal and subcutaneous process, may follow a minor abrasion to the skin or tinea pedis affecting the toe webs. Larger abrasions of the skin, as one sees with the lesions of atopic dermatitis (atopic eczema), tend to be associated with superficial infections, such as the crusted lesions of impetigo. In addition, the appendages of the skin can provide a route for infection by some organisms, such as *Staphylococcus aureus* (as seen in folliculitis or a boil) or fungal infections. Colonization with microorganisms occurs more readily in moist areas (flexural sites), and the dryness of the skin surface and continuous shedding of corneal cells help prevent sustained growth of pathogenic organisms.

Sebaceous lipids have been reported to possess antibacterial properties [1], and glycophospholipids and free fatty acids of the stratum corneum have bacteriostatic effects [2], selective for pathogenic microorganisms.

AMPs are a diverse group of peptides that are present on epithelial surfaces such as the epidermis and its appendages as a first line of immune defence by many living things [3,4]. AMPs directly kill a broad spectrum of microbes, including Gram-positive and Gram-negative bacteria, fungi and certain viruses. In addition, these peptides interact with the host itself, targeting events that complement their role as naturally occurring antibiotics.

AMPs can be divided into several categories on the basis of their structures, and most of them include a cationic charge and the ability to interact with bacterial membranes through hydrophobic amino acids. Two major families of AMPs have been characterized in mammals: defensins and cathelicidins.

Defensins are a broadly dispersed family of gene-encoded antibiotics that are subdivided predominantly into the α-defensins and the β-defensins, according to the alignment of the disulphide bridges and their molecular structure [5]. Human neutrophils express a number of distinct defensins, six α-defensins having been identified [6]. Four of these are known as α-defensins 1, 2, 3 and 4 (also referred to as human neutrophil peptides (HNPs) 1–4). The other two α-defensins, known as human defensins 5 and 6 (HD-5 and HD-6), are abundantly expressed in Paneth's cells of the small intestinal crypts and in epithelial cells of the female urogenital tract [3].

In humans, four types of β-defensins have been identified, referred to as human β-defensins (HBDs) 1–4, but it seems that many β-defensins have yet to be discovered [7]. β-defensins have a broad spectrum of antimicrobial activity and act indirectly, being chemotactic for immature dendritic and memory T cells [8], promoting histamine release and prostaglandin D_2 production in mast cells [9,10], and acting as an adjuvant in enhancing antibody production [11]. Human neutrophil α-defensins (HNPs 1–3) also increase the expression of tumour necrosis factor-α (TNF-α) and interleukin-1 (IL-1) in human monocytes that have been activated by bacteria (*Staphylococcus aureus*) [12].

Cathelicidins have been found only in mammals, being limited to a single gene in humans. The human cathelicidin LL-37/hCAP18 was cloned from cDNA isolated from human bone marrow as FALL-39 [13]. The mature AMP is referred to as LL-37 because it begins with two leucine residues and is 37 amino acids long. The term hCAP18 was independently used, because the peptide is a cationic AMP whose mass before proteolytic processing is approximately 18 kDa [14]. The bactericidal activity of human cathelicidin peptide requires proteolytic activation from its precursor by enzymes including neutrophil elastase and proteinase [15]. LL-37 has a broad spectrum of antimicrobial activity and is a chemoattractant for various inflammatory cell types [16,17]. As with the defensins, LL-37 has the potential to participate in the innate immune response both by killing bacteria and by recruiting a cellular immune response.

HBD-2 is present in psoriatic scale [18] and HBD-2 and HBD-3 are increased in keratinocytes from patients with psoriasis [19]. Dermcidin and LL-37 have been found constitutively in sweat gland secretions [20] and HBD-1 and HBD-2 have been demonstrated in ductal epithelia of sweat glands and in normal hair follicles [21]. Other proteins with antibacterial activity in the skin include adrenomedullin [22], cystatin [23] and secretory protease inhibitor [24]. Impaired production of AMPs has been observed in the epidermis in atopic dermatitis, and Th2 cytokines inhibit the expression of HBD-2, one of the AMPs deficient in atopic skin [25].

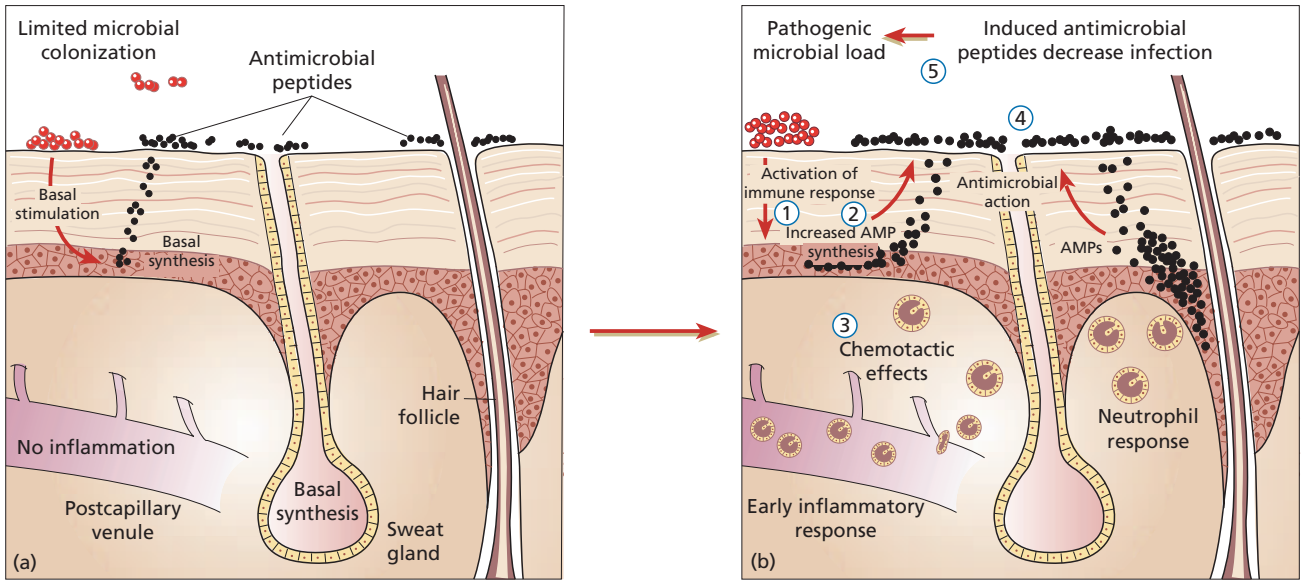

Fig. 4.2 Antimicrobial peptide (AMP) defence. (a) In normal skin, small amounts of AMPs are produced by the epidermis and are concentrated around hair follicles and in sweat. (b) After injury or infection, keratinocytes increase synthesis of AMPs and further AMPs are produced by neutrophils that are recruited as part of the acute inflammatory response. (Modified from Gallo *et al*. [3].)

In normal skin, potential sites of entry of bacteria such as hair follicles and sweat glands produce small amounts of AMPs that provide a chemical barrier to infection where a physical barrier is absent or limited. After injury, the skin responds rapidly with increased production of AMPs from the epidermis and recruited neutrophils (Fig. 4.2) [3].

Ultraviolet radiation

The sun's radiation is made up of infrared, visible and ultraviolet (UV) light (see Chapter 24), and it is the UV rays that affect the skin. The shorter wavelength UVB rays penetrate the epidermis and are the cause of sunburn and, in the long term, contribute to premature ageing of the skin and the pathogenesis of skin cancer. UVA rays penetrate the skin more deeply and are considered to have an important role in chronic sun damage, particularly skin ageing but also skin cancer development.

The skin has two barriers to UV radiation: a melanin barrier in the epidermis; and a protein barrier, concentrated in the stratum corneum. Both function by absorbing radiation, thereby minimizing absorption by DNA and other cellular constituents. Melanin is synthesized by melanocytes in the basal layer of the epidermis and transferred to surrounding keratinocytes in melanosomes. The partially protective mechanism of delayed tanning [1] is associated with an increase in the number of functional melanocytes, an increase in the number of melanosomes synthesized, and an increased rate of transfer of melanosomes to the keratinocytes. In the long term, there is thickening of the epidermis in response to chronic sun exposure.

Absorption of radiation by epidermal lipids may contribute to protection from UV radiation, in a similar way to that suggested for some low-molecular-weight degradation products of epidermal proteins, including urocanic acid [2]. The role of UV-induced cytokines in the regulation of melanin production is not yet clear [3,4].

Temperature regulation

The advantage of maintaining a constant body temperature is that the metabolic processes are not directly dependent on changes in the environmental temperature. However, at extremes of ambient temperature, heat may need to be lost or retained. The skin provides a sensory input to thermoregulation and functions to allow heat loss or conservation.

The thermoreceptor cells of the skin are distributed irregularly over the skin, there being warm- and cold-sensitive thermoreceptors. Information on changes in their stimulation in response to changes in temperature is sent to the hypothalamus, leading to either inhibition of sweating or stimulation of shivering [1]. However, the skin thermoreceptors have a relatively minor role in modifying core temperature, and skin temperature has a greater role in mediating behaviour, for example by turning on the heating or putting on extra clothing. At high temperatures, heat pain via nociceptors is perceived rather than warmth.

From an effector point of view, the skin has a major role in thermoregulation of the human body [2]. Heat can be lost through the skin surface by radiation, convection, conduction and evaporation. Of importance in these mechanisms is the rich blood supply of the dermis, which is much greater than that needed for nutrition. The cutaneous circulation is described elsewhere (see Chapters 3 and 50). The essential point about its function, however, is that a system of arteriovenous shunts, which are plentiful in the feet, hands, lips, nose and ears, enables the blood flow to an extensive and more superficial venous plexus to be considerably varied.

In high environmental temperatures, the process of evaporation is considerably enhanced by eccrine sweating.

Skin failure

Skin failure has been defined by Irvine [1] as 'a loss of normal temperature control with inability to maintain the core temperature, failure to prevent percutaneous loss of fluid, electrolytes and protein with resulting imbalance and failure of the mechanical barrier to penetration of foreign materials'. The term was initially used to bring to the attention of non-dermatologists the need for specialist care in this dermatological emergency. Apart from in thermal burns, skin failure can occur as a consequence of a number of dermatological diseases, including Stevens–Johnson syndrome, toxic epidermal necrolysis, pustular psoriasis and erythroderma of various causes. Depending on the extent of the disease, pemphigus vulgaris, graft-versus-host disease and epidermolysis bullosa are other potential examples.

Used in this specific sense, skin failure is an interesting concept that has not gained common usage. The term is sometimes used in a more general sense to reflect disability in dermatology [2].

Hence, Ryan [2] has included a wide range of skin diseases as examples of 'skin failure', such as hand dermatitis, the development of sunburn and skin cancer in the albino African, and failure of display because of disfigurement. He has emphasized the need for dermatologists and allied health professionals to use a language that can be understood by everyone, particularly patients, when referring to the consequences of skin disease [3].

Both authors [1,2] have drawn attention to the fact that skin failure represents severe loss of function as occurs in other organ systems, for example heart failure, liver failure, renal failure and respiratory failure.

Mechanical functions

Although the epidermis and subcutaneous fat each have a role in the protective function of the skin, the mechanical properties of the skin related to hard blows with blunt objects depend mainly on the dermis. Skin is elastic to a degree and can, for a few seconds at a time, be stretched reversibly by 10–50%. Skin pulls easily at first. The initial response appears to involve a reorientation of collagen fibres towards the load axis and a decrease in their convolution [1]. The tonus of skin is probably maintained by the elastic fibres, and it seems likely that these fibres provide the small forces that restore the extensibility of slack skin.

Once the initial slack has been taken up, the skin becomes much more difficult to extend. It gradually stretches if it is maintained taut for a long time, as, for example, when using tissue-expanding techniques in skin surgery. This further extension under continued stress is referred to as 'viscous extension', 'viscous slip' or 'creep', and is irreversible. This slip depends on the collagen fibrils. It is unlikely that slipping occurs within the fibril itself; either the individual fibrils slip relative to each other, or whole fibrils do so within the related ground substance. The most probable hypothesis to explain the relative lack of slip is that slip is interfibrillar, that the collagen fibrils are very long and that the interfibrillar substance is highly viscous. It appears that dermatan sulphate is more closely connected to the collagen than hyaluronic acid, and it is probable that this material is the one responsible for restraining the viscous slip.

From these considerations it is clear that disorders in which the skin is hyperelastic, such as Ehlers–Danlos syndrome (see Chapters 3 and 46), must involve a breakdown of the collagen mechanism. The striae seen in adolescence, pregnancy and in situations of excessive systemic corticosteroids, whether administered or as part of Cushing's syndrome, are thought to involve a breakdown of the fibril overlap, so that there is no viscous force to limit further slip.

A further property of skin is that it can be compressed. If a small object is pressed into the skin, a depression is formed that remains after the object is removed; thus, skin becomes moulded round the object exerting the force, and the pressure on any one point is reduced. This compression is primarily because of a flow of ground substance through the dermis between the collagen fibres.

The epidermis itself is relatively strong and holds together under the pressure from blister fluids. On the other hand, the dermal–epidermal junction in human skin is relatively weak. The superficial collagen in the papillary layer appears to be particularly easy to weaken, and many blistering agents appear to act at this level.

By virtue of its protein and lipid constituents, the stratum corneum is a relatively strong elastic tissue. The network of structural proteins allows exogenous forces to spread throughout the tissue. The elasticity of the stratum corneum is also influenced by the degree of hydration of the corneal cell proteins, which in turn depends on the water content of the tissue and by the humidity of the surrounding environment [2]. Stratum corneum proteins, lipids [3,4] and low-molecular-weight by-products of keratohyalin breakdown, referred to as natural moisturizing factors [5], bind and retain water in the stratum corneum, thus maintaining its elasticity.

Immunological functions

The immunological functions of the skin have been the subject of intense research in recent years, and it is clear that the skin has an important role in immunological host defence, particularly involving those cells residing in (keratinocytes, Langerhans' cells) or passing through (T lymphocytes) the epidermis (see Chapters 9 and 10). The role of AMPs as a first line of defence against microorganisms has been discussed above (see p. 4.5).

Antigens are from either the external environment (exogenous antigens) or are newly formed in the cell itself

(endogenous antigens). T lymphocytes are able to recognize antigen only when it has been presented by specialized cells, termed antigen-presenting cells (APCs) or accessory cells [1–3]. The T cell recognizes the antigen in association with products of the major histocompatibility complex (MHC) gene region of the APC. In helper T cell (Th cell) activation, the antigen moiety is usually presented in the context of MHC class II molecules, whereas most cytotoxic T cells recognize the antigen in association with MHC class I molecules.

Any cell expressing the respective MHC gene product can act as an APC [4] and the predominant APC populations in the MHC class II-dependent antigen-presenting pathway are mononuclear phagocytes [3,4], Langerhans' cells [5–7], B cells [8] and lymphoid dendritic cells [9]. T-cell activation is preceded by interaction of surface molecules, including T-cell antigen receptor (TCR) occupancy by the antigen–MHC complex.

In human skin, most T cells are found in the dermis, usually grouped around postcapillary venules and the appendages. Intraepidermal T cells account for less than 10% of T cells in human skin. Langerhans' cells involved in antigen presentation in damaged epidermis undergo phenotypic and functional changes prior to leaving the epidermis, entering the dermal lymphatics and migrating to the paracortical areas of the draining lymph nodes. At this stage, they present the antigen–MHC complex on their surface to the TCR on either $CD4^+/CD8^-$ or $CD4^-/CD8^+$ naïve resting T cells, and elicit an antigen-specific T-cell response. The T-cell blasts thus generated then seem to preferentially return to the skin sites bearing the antigen.

It will be seen from this brief outline that epidermal cells are intimately involved in the afferent and effector limbs of the immune response. The broader principles of immunology, the mechanisms of immune responses and the implications for clinical dermatology are fully explored in Chapters 9 and 10. As discussed elsewhere, immunological dysfunction probably has a pathogenetic role in a wide range of skin diseases, including the immunobullous disorders, allergic contact dermatitis, atopic dermatitis, psoriasis and cutaneous T-cell lymphoma (mycosis fungoides).

Sensory and autonomic functions

The skin is innervated by a dense three-dimensional network of highly specialized afferent sensory and efferent autonomic nerve branches. The sensory nervous system detects the sensations of touch, vibration, pressure, change in temperature (warmth and cold), pain (including heat pain) and itch [1,2]. The autonomic nervous system is innervated by postganglionic cholinergic parasympathetic nerves and adrenergic and cholinergic sympathetic nerves. The autonomic system has an important role in maintaining cutaneous homeostasis by regulating vasomotor functions, pilomotor activity and eccrine sweat gland secretion, and is discussed further in Chapter 60.

The sensory nerves are either myelinated A fibres or unmyelinated C fibres, the latter containing sensory and autonomic fibres. The rate of transmission of a nerve impulse is proportional to the diameter of the nerve, and the various types of A fibres are thicker (1–20 μm) than the slow-conducting unmyelinated C fibres (0.2–1.5 μm). The myelinated human cutaneous nerves have been divided into Aβ and Aδ types on the basis of their conduction velocities, corresponding to 35–75 m/s and 5–20 m/s, respectively [2]. In the upper dermis, small myelinated nerves lose their nerve sheaths, and together with the unmyelinated nerves end in either free nerve endings or as specialized sensory receptors, such as Meissner's corpuscles or Merkel's receptors [2].

Much of the research into the sensory functions of the skin was carried out from the 1950s to the 1970s but, since the discovery of neuropeptides with implications for potential pharmacological modulation, there has been renewed interest in this field. Electrophysiological studies showed the existence of functionally specific afferent units [3]. Two major categories of afferent unit have been clearly established: mechanoreceptors and thermoreceptors [4,5]. A third group of pain receptors (nociceptors) respond only to high-threshold stimulation, including mechanical, thermal (heat pain) or chemical stimulation. Within each of these categories some of the afferent units determined functionally can be clearly identified with morphologically distinct structures.

Touch is mediated by mechanoreceptors in the skin, there being two main functional groups [5] according to the way they respond to constant or persistent stimuli. *Slowly adapting* mechanoreceptors respond continuously to a persistent stimulus, whereas *rapidly adapting* mechanoreceptors respond at the onset and frequently at the end

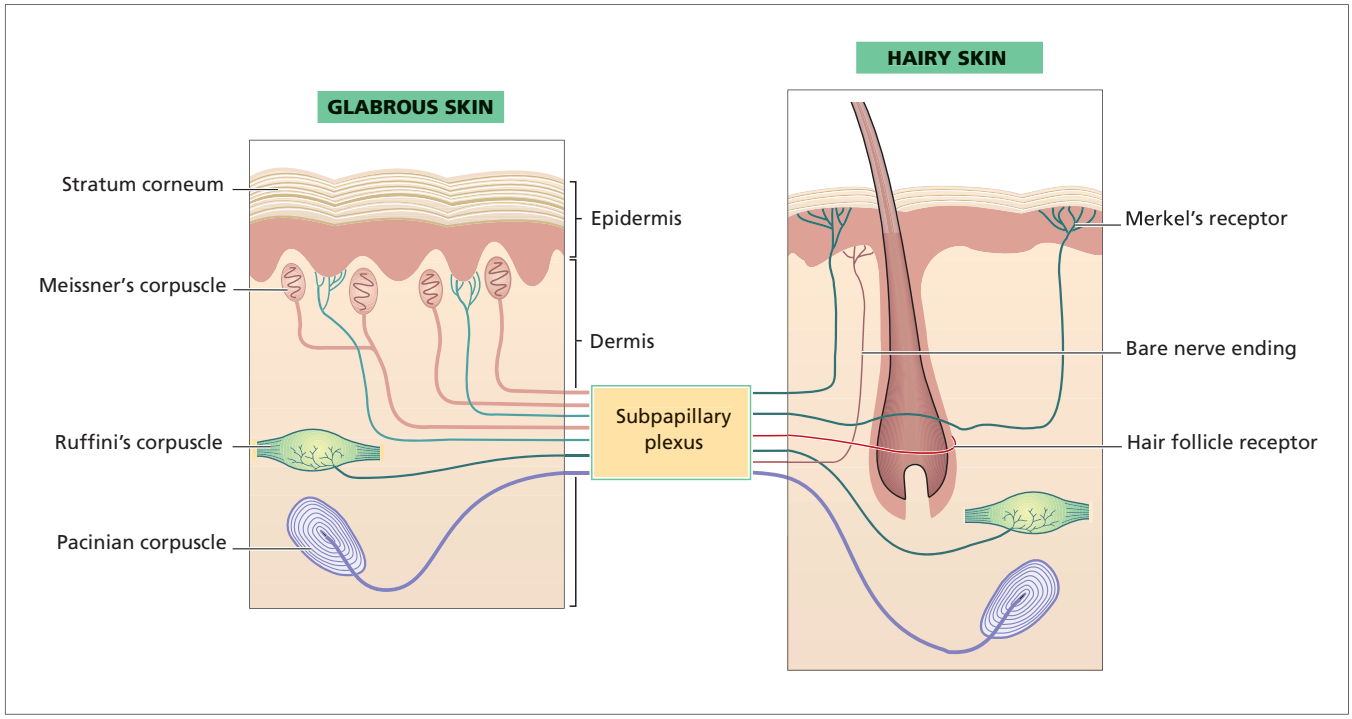

Fig. 4.3 Diagram to show the location of sensory receptors in hairless (glabrous) and hairy skin. The receptors of glabrous skin are Meissner's corpuscles and Merkel's receptors in the dermal papillae, and bare nerve endings. The receptors of hairy skin are hair-follicle receptors, Merkel's receptors, and bare nerve endings. Pacinian corpuscles and Ruffini's corpuscles are situated in the subcutaneous fat and deeper dermis in both glabrous and hairy skin.

of the stimulus, but not throughout the duration of the stimulus.

Glabrous and hairy skins have different types of mechanoreceptor (Fig. 4.3). The predominant mechanoreceptor in hairy skin is the hair-follicle receptor. Glabrous skin (e.g. the hairless skin of the palmar surface of the hands) has two main types of superficial mechanoreceptor: a rapidly adapting receptor, the Meissner's corpuscle; and a slowly adapting receptor, the Merkel's receptor.

Subcutaneous tissue and the deeper dermis beneath both hairy and glabrous skin contain two types of mechanoreceptors: the Pacinian corpuscle, a rapidly adapting receptor; and Ruffini's corpuscle, a slowly adapting receptor. In contrast to the small receptive-field size of Meissner's corpuscles and Merkel's receptors in the upper dermis, the receptive fields of Pacinian and Ruffini's corpuscles are large. When Pacinian corpuscles are tested with uniform or constant-velocity displacement, no impulses result, but sinusoidal displacement (vibration) generates a regular stream of impulses.

The sensations of warmth and cold are mediated by thermal receptors. Two distinct kinds of thermoreceptor [3,6] have been identified in tongue, hairy and glabrous skin of a number of mammals, including humans. Such fibres show a steady discharge dependent on temperature, but no response to non-painful intensities of mechanical stimulation. Temperature sensitivity is punctate, each afferent fibre being connected with a few receptive spots with a diameter in hairy skin of less than 1 mm.

Cold and warmth spots correspond to discrete zones of innervation by cold and warmth receptors. Cold receptors show a frequency rise on sudden cooling, the frequency of firing being proportional to the rate and degree at which the temperature is lowered. Cutaneous cold receptors are activated from approximately 1–20°C below the normal skin temperature of 34°C. Warmth receptors show a steady discharge at constant temperatures in the range 32–45°C, an acceleration of the discharge on warming the skin, small receptive fields and a high sensitivity to temperature change. At temperatures greater than approximately 45°C, heat pain via nociceptors is perceived rather than warmth.

Pain is mediated by *nociceptors*, receptors that respond selectively to stimuli that can damage tissue. Three types of nociceptor can be distinguished. Mechanical nociceptors are activated by strong mechanical stimulation, such as sharp objects. Pricking of the skin gives rise to two kinds of sensation. The initially felt 'pricking' or 'fast' pain is punctate, superficial and local, and this is followed by a more diffuse 'burning' or 'slow' pain [5]. Thermal nociceptors respond to heat or cold. In humans, heat nociceptors respond when the temperature of their receptive field exceeds 45°C, the heat pain threshold. Cold nociceptors respond to cold noxious stimuli. In addition, there are

polymodal nociceptors that respond to several different kinds of noxious stimuli, including mechanical, heat and chemical [5].

Itching [7–10] is closely related to pain and is discussed in detail in Chapter 16.

In addition to classical neurotransmitters such as noradrenaline (norepinephrine) and acetyl choline, peripheral nerves contain neuropeptides. Neuropeptides are released from nerve terminals following depolarization, and have a role in regulating synaptic transmission. A number of neuropeptides have been demonstrated in human skin, including substance P, vasoactive intestinal peptide (VIP), somatostatin, calcitonin gene-related peptide (CGRP), neuropeptide Y and bombesin [11–13]. In addition to acting as neurotransmitters, neuropeptides have a role in the mediation of inflammation in the skin, and are discussed more fully in Chapters 9 and 60.

Bioengineering and the skin

In recent years, there has been much emphasis on the importance of objective measurement in dermatology and, driven in part by the cosmetics industry, there have been a number of advances in bioengineering technology. Relatively non-invasive bioengineering techniques can be used to assess the functions of the skin either in the resting state or in test conditions (e.g. the use of transepidermal water loss [TEWL] measurement in irritancy testing), or to quantify the response of clinical disorders to treatment (e.g. the use of ultrasound to assess therapeutic responses in chronic dermatoses). Selected aspects of bioengineering and the skin are discussed here. The importance of validation of and comparison between the plethora of similar techniques has been emphasized [1].

TEWL measurement is used to assess the barrier function of the stratum corneum, usually to predict irritancy of substances or to contribute to the assessment of clinical disorders. Various methods have been used, but an open-chamber gradient-estimation method in the form of the *evaporimeter* is preferred, because it allows continuous measurement in ambient air, with little alteration of the microclimate overlying the skin surface [2].

In the past, TEWL was taken to indicate the water vapour passing through the stratum corneum by passive diffusion [3], but currently TEWL refers to the total amount of water loss through the skin, which includes sweating [2]. Many irritants, such as detergents and solvents, damage the skin by impairing the barrier function of the stratum corneum, and TEWL measurement has been reported to be more sensitive in assessing such irritancy effects than visual scoring [4,5], laser Doppler flowmetry, colorimetry and skin thickness by ultrasound A scan [5]. A higher TEWL has been demonstrated in lesional skin of various types of dermatitis [6,7], in psoriatic plaques [8] and in non-lesional skin of patients with atopic dermatitis [9,10].

Cutaneous gaseous exchange, a term preferable to cutaneous respiration, is the absorption of oxygen and the elimination of carbon dioxide through the skin surface [11]. In clinical medicine, transcutaneous oxygen tension (tcPo_2) measurement is used to quantify the adequacy of skin circulation, and to estimate the severity of leg ulceration, because tcPo_2 reflects the degree of oxygen supply by tissue perfusion.

The mechanical properties have been assessed by a number of techniques, designed either to induce a skin deformation and record the resisting force, or to place a load on the skin and measure the resulting deformation. The assessment of vertical forces to the skin is often avoided because this, in part, measures the contribution of the subcutaneous fat, which varies considerably between different subjects and different sites of the body in the same subject [12]. Non-invasive methods include twistometry [12], suction techniques [13], indentometry [14] and ballistometry [15].

TEWL decreases during the ageing process, becoming obvious after the fifth decade [16]. The decrease in TEWL with age is considered to be partly caused by an increased size of corneocytes and increased thickness of the stratum corneum, related to an elevated accumulation of corneocytes resulting from impaired desquamation [17]. Stratum corneum hydration is also decreased in elderly subjects [18,19], the 'dryness' of the skin in the elderly differing from pathologically dry skin, in which there is impaired barrier function.

Sociosexual communication

The skin, by virtue of its visual appeal, smell and feel, has an important role in social and sexual communication in humans, as it does in other animals. Cosmetics and clothes are used to enhance the appearance and sometimes (but not always) sexual attraction. There are many interesting parallels between humans and other animals, particularly primates, in terms of both visual communication and body odour. The reader is referred to Ebling's fascinating account for further information [1].

Chapter 5

Diagnosis of Skin Disease

N.H. Cox & I.H. Coulson

Fundamentals of diagnosis

As for any other organ system, diagnosis of skin disease involves a history, examination and sometimes additional tests. The visibility of skin allows an instant diagnosis in some cases, using a variety of visual clues such as body site distribution, colour, scaling and arrangement of lesions. Such apparently effortless pattern recognition is actually quite complex when the individual components are analysed separately [1]. Individuals who examine the skin less frequently often also fail to appreciate the additional value of palpation in determining induration, quality of scaling and temperature changes. This chapter briefly introduces aspects of the history, examination and other diagnostic manoeuvres.

Disease definition

Most skin diseases do not have a cause which is both identified and unique to that disorder. Conversely, many known causes of skin disease may play a part in several different types of disorder (for example, ultraviolet light may cause or contribute to skin cancers, skin ageing and various patterns of photosensitivity). Current definitions of most skin diseases therefore rely on the presence of a constellation of clinical, histopathological and sometimes immunopathological or genetic features. Even common and important diseases such as psoriasis have no strict and unique diagnostic criteria. The diagnostic stringency required for day-to-day clinical management may differ from that required in epidemiological and therapeutic research, in which it is clearly important to be sure that all studies are actually describing the same entity [1]. In some disorders which remain difficult to classify, such as parapsoriasis [2], numerous names may have been applied over the years and it may be difficult to know exactly what was meant in a previous publication. This problem applies even in atopic eczema, generally considered a fairly straightforward diagnosis, and has significant implications for epidemiological research. Similarly, treatments and prognosis may vary between different types of cutaneous T-cell lymphoma (CTCL), but it is impossible to be certain about the types of CTCL that have been assessed in some studies.

Scientific advances are resolving some of these diagnostic and terminology issues, but many disease definitions in dermatology are still based on a constellation of clinically determined morphological cutaneous features. Some of these have distinct anatomical correlates (e.g. myxoid cyst), a specific external cause (e.g. scabies), or have a known genetic or biochemical defect (e.g. many genodermatoses). Many will have characteristic histological features, although—particularly in the case of inflammatory dermatoses—there are often areas of overlap between disease entities.

In other cases, there may be a number of different cutaneous features or multiorgan involvement which are associated together as a syndrome, such as systemic lupus erythematosus (SLE) or Behçet's disease. A syndrome is

usually defined by the simultaneous presence of a fixed combination of disease indicants, but these may not all be present in an individual case and may not require to be present concurrently; additionally, 'overlap' syndromes can occur where features of two or more related syndromes are present in the same patient. In such instances, making a diagnosis may rely on fulfilling a certain number of criteria—for example, the American Rheumatism Association (ARA) criteria for diagnosis of SLE [3]. This can be further refined by having major and minor criteria in order to achieve a given sensitivity and specificity. In some instances, such as the diagnostic criteria for Behçet's disease, a single diagnostic criterion must be fulfilled (recurrent oral aphthae) together with a given number of minor criteria [4]. In other instances, the number of criteria in each category which need to be fulfilled may vary—for example, in the diagnostic criteria for streptococcal toxic shock, the number of minor criteria that need to be fulfilled depends on the strength of the major criteria which are achieved [5]. All such diagnostic criteria may need to be updated to take into account new diagnostic techniques. However, it should be noted that many such criteria have been derived for confirmation of diagnosis for epidemiological or research reasons, rather than being a prerequisite for clinical diagnosis and management of individual patients.

The history

It is often possible to make a diagnosis of the type of eruption or lesion by inspection alone, but additional clinical examination techniques are often helpful, such as palpation and rubbing or scratching the skin. However, clinical morphology alone does not usually determine the aetiology of a skin disorder, and a carefully directed history is usually important for both diagnosis and optimal management. The amount of history required, and the sequence of history-taking and examination, may vary depending on the condition and referral information already provided to the dermatologist. Several audit studies and therapeutic guidelines have suggested minimum data sets for the medical history and morphological findings in skin diseases [1,2].

The presenting complaint

Symptoms. Itch is the prime dermatological symptom, but may be variously described by different patients; there are individual differences in threshold and perception. Intense itch is typical in scabies, atopic dermatitis and lichen planus, whereas psoriasis and pityriasis versicolor usually cause less severe itch for the same degree of body surface involvement.

Other symptoms include sharp pain (e.g. chondrodermatitis of the ear), burning (e.g. chilblains) or tenderness (e.g. erythema nodosum). The site may influence symptoms; for example, urticaria causes itch, but the same pathology affecting the palms often causes pain (because the oedema is deeper and the firmer tissues of the palm cannot distend easily). Both the quality and intensity of symptoms should therefore be recorded.

Symptoms usually parallel overt development of an eruption, but discordance can be diagnostically useful—for example, localized itch preceding herpetic vesicles, or fever and malaise preceding erythema and swelling in cellulitis of the leg or erysipelas.

Duration, evolution, periodicity and previous episodes. The overall duration of a rash or localized lesion is usually apparent to the patient, although there are exceptions; basal cell carcinoma, for example, is often noticed only when it ulcerates, and the patient will therefore underestimate the duration of the lesion. Whether the onset of a rash was sudden or gradual may be diagnostically useful. The overall duration is also of diagnostic help for localized lesions. For example, a presumed keratoacanthoma that is still enlarging after a few months is probably a squamous cell carcinoma; lesions which turn black overnight do so due to intralesional bleeding, not as a result of becoming a melanoma.

More precise details may require carefully phrased questions. In urticaria, the diagnostic feature is that individual lesions change from day to day (usually over a few hours), but the overall duration of the process may be years. Asking the patient about the duration of the eruption needs to distinguish between these two aspects. Similarly, if lesions are not present, then diagnosis may depend on the patient's description, but there are pitfalls; weals are often described as 'blisters', a term which should not be taken at face value, and distinguishing between eruptions triggered by heat or sunlight often causes confusion. It is helpful to ask the patient whether

any particular factors (e.g. dietary items, cosmetics, work chemicals, sunlight) appear to provoke (or alleviate) the condition.

Some dermatoses have a characteristic evolutionary sequence (e.g. pityriasis rosea, in which a solitary larger 'herald patch' precedes the widespread eruption by a few days, or 'pre-pemphigoid' eczematous lesions). Other disorders may demonstrate periodicity; for example, occupational contact dermatitis may improve at weekends or holiday periods, and photosensitivity and airborne contact allergy to plants may be seasonal.

Previous episodes of a similar type are likely to be relevant, but other skin problems may be important even if they do not appear to be the same process. For example, patients with type IV hypersensitivity to fragrance materials might at different times have eyelid rash due to cosmetics, axillary rash due to deodorants, widespread eczema due to soaps or clothing detergents or diffuse facial rash due to airborne perfume agents. In such cases the body site distribution may be confusing, but the sequence of sites affected should be determined, especially the site of initial involvement in the case of rashes.

Previous episodes are also potentially relevant for localized lesions (e.g. patients with two or three previous basal cell carcinomas have a high risk of another, so the level of suspicion may be greater in those with a positive previous history of these lesions).

Previous therapy. Previous treatment and response should be documented to guide future therapy, and to exclude the possibility of the diagnosis being obscured (for example, tinea incognito due to use of topical corticosteroids).

General history

Medical history, medications and dietary history. General medical conditions may have cutaneous features, and should be noted especially in patients with rashes or generalized skin symptoms. Recent illnesses, even if apparently resolved, deserve special attention, as conditions such as urticaria, vasculitis, guttate psoriasis and erythema multiforme can be triggered by viral or bacterial infections in the weeks preceding the onset of the rash. Any recent or current systemic medication should be noted, including regular or intermittent self-medication or that received from relatives or friends, both as a possible cause of drug eruptions and to avoid interactions with treatment prescribed for the skin complaint. Medicament and other allergies may be important, as are drugs which might interact with anaesthetics or cause surgical bleeding.

Dietary history may be important in some individuals, especially those with intermittent urticaria or anaphylaxis. However, diet is often erroneously blamed for skin eruptions.

Family history. This may be important if a genodermatosis is suspected, in disorders with more complex inheritance (e.g. atopic dermatitis, psoriasis), and in some non-inherited disorders in which family contact is important (e.g. scabies, chickenpox).

Occupation and leisure activities. An occupational history may be of importance, both current and previous, particularly in individuals with eczema; a detailed account of processes and chemicals may be required, together with additional testing (Chapters 19, 20 and 21). Hands are the most commonly affected site in occupational dermatitis, and it is useful to record details of hand protection (e.g. gloves, barrier creams) as well as the agents to which the patient is exposed. Hobbies less commonly cause problems, but may involve exposure to a variety of common allergens. Outdoor work or hobbies may also involve exposure to sun, cold or to plant allergens.

Ethnicity and cultural aspects (Chapter 69). Several disorders have a predilection to occur in specific racial groups—for example, the high frequency of sarcoidosis in black patients [1], or prurigo pigmentosa in the Japanese [2]. The morphology of common diseases may be altered by racial pigmentation, and normal pigmentary variations may be apparent. The severity of diseases may appear to be different between races or cultural groups; atopic eczema has been noted to be more frequent in children born in England of Asian or Caribbean origin [3,4]. Cultural differences may be diagnostically important, such as use of hair pomades and skin depigmenting agents, or may influence acceptance and understanding.

Geographical factors. Foreign travel, especially if recent, is a potentially important cause of dermatological disease. The place(s) visited may lead to specific likely diagnoses, and documentation should include any brief stopping-off countries. A long visit increases the risk of significant exposure to environmental agents, but dust-borne spores and insect vectors may be carried in aircraft and potentially alter the natural history of a disorder by allowing exposure outside the anticipated geographical distribution.

Social and psychological factors. The living conditions, economic status and standard of nutrition of the patient may be relevant both as a guide to diagnosis and to ensure compliance with the treatment advised. Specific examples of important social factors include the strong association between cigarette smoking and palmoplantar pustulosis, and the multiple influences of excessive alcohol intake on the severity and therapeutic options in psoriasis. A sexual history is also required in some instances. The effects of skin problems on lifestyle, relationships, costs to the patient and costs to the community from work days lost are important, and it is helpful to know the patient's main

concerns. This applies particularly to chronic skin eruptions, but many patients with discrete lesions primarily want reassurance that they are not malignant. It is unlikely that many skin eruptions are due to 'nerves', but psychological factors can clearly be of importance in aggravating or perpetuating symptoms, and may be the primary abnormality in some instances (Chapter 61).

Examination of the skin

Most patients referred to the dermatologist have objective changes in the appearance or consistency of the skin. Even those who describe itch without rash often have dry skin or other features that can be elicited, such as dermographism. Most lesions and eruptions can either be diagnosed fully, or at least assigned to a diagnostic category, by clinical examination; indeed, clinical diagnosis is more precise than laboratory tests in many disorders. The ability to elicit and interpret cutaneous physical signs is therefore of fundamental importance in dermatological training.

The patient should always be examined in a good light, preferably daylight, and with magnification of lesions if necessary. Ideally, the entire skin should be examined in every patient, and particularly if the diagnosis is in doubt, as this may reveal lesions that are more easily identifiable and have not been modified by secondary changes. Adolescents and elderly people will often deny the existence of lesions other than those presented for examination, the former because they are unwilling to undress and the latter because they have not seen them.

In the examination of the skin, it is helpful to consider the morphology of individual lesions, their overall pattern and spatial relationship to each other, and their body site distribution. Each of these aspects is discussed more fully below. Specific attention to hair, nails and the mucous membranes is required. Careful description and use of nomenclature aids monitoring of changes during follow-up, and any discussion with colleagues.

Touching the skin is important in most instances, and is discussed in more detail below. Gloves should be worn for examination of the mouth, genital/perineal region, or in the case of infective or infected dermatoses.

Additional simple aids to clinical examination include use of Wood's light, diascopy, dermoscopy, iodine-starch testing to identify sweat duct orifices and hair microscopy.

Individual lesions—nomenclature

The commoner descriptive terms applied to cutaneous lesions are listed below. These definitions are broadly in agreement with those recommended by the Nomenclature Committee of the International League of Dermatological Societies [1]. However, it is important to note that some of these definitions have been challenged subsequently [2–5]. A particular problem that many authors have glossed over is the dynamic aspects of skin disease. For example, some papules (less than 0.5 or 1 cm, depending on the source of the definition) are destined to grow larger and become nodules, whereas others (such as syringomas) rarely do so. Additionally, some eruptions may have essentially similar lesions but whose size may include both papules and nodules. Recording of actual size of lesions, or the range of sizes, is often a more useful clinical record [6].

Glossary

alopecia—absence of hair from a normally hairy area.
aphtha—a small ulcer of the mucosa.
atrophy—a loss of tissue from one or more of the epidermis, dermis or subcutaneous tissues. There may be fine wrinkling and increased translucency if the process is superficial.
burrow—a small tunnel in the skin that houses a parasite, such as the scabies acarus.
callus—a localized hyperplasia of the stratum corneum.
cellulitis—an inflammation of cellular tissue, particularly purulent inflammation of the deep dermis and subcutaneous tissue.
comedo (pl. comedones)—a plug of keratin and sebum in a dilated pilosebaceous orifice.
crusts (scabs)—crusts consist of dried serum and other exudates.

cyst—any closed cavity or sac (normal or abnormal) with an epithelial, endothelial or membranous lining and containing fluid or semisolid material.

ecchymosis (bruise)—a macular area of haemorrhage more than 2 mm in diameter.

en cocarde (or 'cockade')—a rosette pattern of concentric rings, usually applied to naevi.

erosion—a loss of epidermis, which heals without scarring. It commonly follows a blister.

erythema—redness of the skin produced by vascular congestion or increased perfusion.

excoriation—loss of skin substance, specifically produced by scratching.

exfoliation—the splitting off of the epidermal keratin in scales or sheets.

fibrosis—the formation of excessive fibrous tissue.

fissure—any linear gap or slit in the skin surface.

fistula—an abnormal passage from a deep structure, such as a hollow viscus, to the skin surface or between two structures. It is often lined with squamous epithelium.

gangrene—death of tissue, usually due to loss of blood supply.

guttate lesions—small round or oval lesions distributed as a 'shower' of droplets. Usually applied to a form of psoriasis.

haematoma—a localized tumour-like collection of blood.

keratoderma—a horny thickening of the skin.

lichenification—thickening of the epidermis (and to some extent also of the dermis) in response to prolonged rubbing.

macule—a circumscribed alteration in the colour of the skin. Authorities vary on the issue of scaling causing texture change within the definition.

maculopapular—rash consisting of both macules and papules.

milium—a tiny white cyst containing lamellated keratin.

nodule—a solid mass in the skin, which can be observed as an elevation or can be palpated. It is more than 0.5 cm in diameter. It may involve epidermis and dermis, dermis and subcutis, or subcutis alone. It may consist of fluid, other extracellular material (e.g. amyloid), inflammatory or neoplastic cells.

papilloma—a nipple-like mass projecting from the surface of the skin.

papule—a circumscribed palpable elevation, less than 0.5 cm in diameter. By careful examination it is often possible to determine whether the thickening involves predominantly the epidermis or the dermis and what type of pathological process is concerned. The only distinction between a papule and a nodule is the size, and this is artificial; some lesions characteristically occur at the smaller size of a papule, whereas others typically enlarge from a papule to become a nodule. Recording a finite size is more useful.

petechia (pl. petechiae)—a punctate haemorrhagic spot, approximately 1–2 mm in diameter.

plaque—an elevated area of skin, usually defined as 2 cm or more in diameter. It may be formed by the extension or coalescence of either papules or nodules as in psoriasis and granuloma annulare, respectively. Small plaque is sometimes used for such lesions 0.5–2 cm in diameter.

poikiloderma—the association of cutaneous pigmentation, atrophy and telangiectasia.

pustule—a visible accumulation of free pus. It may occur within a pilosebaceous follicle or a sweat duct or, less often, on glabrous skin. Most commonly due to infections, but some eruptions typically cause sterile pustules.

pyoderma—any purulent skin disease.

scale—a flat plate or flake of stratum corneum. A *collarette* scale is a fine, peripherally attached and centrally detached scale at the edge of an inflammatory lesion. *Furfuraceous or pityriasiform* scales are fine and loose. *Ichthyotic* scales are large and polygonal. Scaling may accompany or follow many inflammatory disorders. Silvery scales are characteristic of processes involving parakeratosis, especially psoriasis. The silvery colour is due to reflection of light at the many air–keratin interfaces and can be altered by wetting the skin.

scar—replacement by fibrous tissue of another tissue that has been destroyed by injury or disease. An *atrophic* scar is thin and wrinkled. A *hypertrophic* scar is elevated, with excessive growth of fibrous tissue. A *cribriform* scar is perforated with multiple small pits.

sclerosis—diffuse or circumscribed induration of the subcutaneous tissues. It may also involve the dermis, when the overlying epidermis may be atrophic. It is characteristically seen in scleroderma, but may occur as a sequel to or in association with many different processes.

sinus—a cavity or track with a blind ending.

target lesions—these are less than 3 cm in diameter and have three or more zones, usually a central area of dusky erythema or purpura, a middle paler zone of oedema, and an outer ring of erythema with a well-defined edge.

tumour—literally a swelling. The term is used to imply enlargement of the tissues by normal or pathological material, or cells that form a mass. It may be inflammatory or non-inflammatory, benign or malignant. The term should be used with care, as many patients believe it implies a malignancy with a poor prognosis.

ulcer (of skin)—a loss of dermis and epidermis, often with loss of the underlying tissues.

vegetation—a growth of pathological tissue consisting of multiple, closely set, papillary masses.

vesicles and bullae—visible accumulations of fluid within or beneath the epidermis. Vesicles are small (less than 0.5 cm in diameter) and often grouped. Bullae, which may be of any size over 0.5 cm, should be subdivided as

multilocular (due to coalesced vesicles, typically in eczema) or unilocular.

weal—a transient area of dermal or dermal and hypodermal oedema, white, compressible and usually evanescent. It is the characteristic lesion of urticaria. It is often surrounded by a red, axon-mediated flare.

Shape of lesions, linear and annular lesions

The shape of each lesion and the pattern in which neighbouring lesions are arranged in relation to each other is often of great significance and may provide an easily recognizable clue to a rapid visual diagnosis. The main shapes, with examples, are listed in Table 5.1. The mechanism or anatomical factor dictating the shape can sometimes be inferred, as in the case of many linear lesions (Table 5.2, Fig. 5.1) or the vascular patterning leading to livedo; in other instances, such as many annular lesions (Table 5.3, Fig. 5.2) and reticulate lesions (Fig. 5.3), this is less clear.

A specific cause of a linear lesion is the Koebner or isomorphic phenomenon [1]. This term is applied when localized non-specific trauma locally provokes lesions of a dermatosis which is usually spontaneously present elsewhere, and usually in a relatively 'active' or eruptive phase. It is particularly characteristic of psoriasis (Fig. 5.4, Chapter 35) and lichen planus, but occurs in several other dermatoses (Table 5.2). Less common dermatoses in which this may occur include erythema multiforme [2], Sweet's disease and scleromyxoedema [3]. The trauma may be mild, and is usually a scratch or similar, although light or heat may do the same. Occasionally, one disease may be responsible for the localization of another, such as granuloma annulare developing at sites of herpes zoster, or psoriasis developing at sites of contact dermatitis; this has been termed the isotopic response [4]. Development of lesions of pyoderma gangrenosum or Behçet's disease at sites of injection of serum or saline (or even just pinprick or venepuncture) is known as pathergy.

Some annular shapes result from centrifugal extension of an infection from the point of inoculation (e.g. tinea corporis with dermatophyte fungi or erythema chronicum migrans in *Borrelia burgdorferi* infection). In others, a spreading neoplastic or inflammatory process leaves central scarring or ulceration, e.g. superficial basal cell carcinoma and discoid lupus erythematosus. In eruptions in which an allergic process is probably involved, the annular configuration is attributed to the refractory state of the central area. In some conditions, annular shapes can be related to the vascular network (see livedo, Chapter 48). Some involve an iatrogenic component, e.g. warts recurring at the margin of a blistered cryotherapy site. However, in many diseases, such as lichen planus, sarcoidosis or psoriasis, there is no satisfactory explanation for the occurrence of annular lesions. In clinical evaluation of annular lesions, it is particularly helpful to consider surface features such as scaling as an aid to identifying epidermal involvement and thus narrowing the differential diagnosis.

Table 5.1 Main shapes of skin lesions. (Adapted from G.M. White and N.H. Cox, *Diseases of the Skin*, London: Mosby, 2000: 5.)

Shape	Description	Examples
Discoid (nummular)	A filled circle	Discoid eczema, psoriasis
Petaloid	Discoid lesions which have merged together	Seborrhoeic dermatitis on the trunk
Arcuate	Incomplete circles	Urticaria
Annular	Open circles with different central skin compared with the rim	Tinea corporis, granuloma annulare
Polycyclic	Circles which have merged together	Psoriasis
Livedo	Chicken-wire criss-cross pattern	Erythema ab igne, polyarteritis nodosa, other types of vasculitis
Reticulate	Fine lace-like pattern	Oral lichen planus
Target	Multiple concentric rings	Erythema multiforme
Stellate	Star-shaped	Lesions of meningococcal septicaemia
Digitate	Finger-shaped	Chronic superficial dermatosis
Linear	Straight line	Koebner reaction to a scratch in lichen planus or psoriasis (see also Table 5.2)
Serpiginous	Snake-like	Cutaneous larva migrans
Whorled	Swirling pattern	Epidermal naevi, late-stage incontinentia pigmenti

Table 5.2 Anatomical and causative factors in linear lesions. (From C.M. Lawrence and N.H. Cox, *Physical Signs in Dermatology*, 2nd edn, London: Mosby, 2002: 21.)

Determinant of pattern	Examples
Blood vessels	Thrombophlebitis, Mondor's disease (linear thrombophlebitis on the trunk)
	Eczema related to varicose veins
	Temporal arteritis
Lymphatics	Lymphangitis
	Sporotrichosis, fish tank granulomas
Dermatome	Herpes zoster, zosteriform naevus, zosteriform Darier's disease, zosteriform metastases
Nerve trunks	Leprosy (thickened cutaneous nerves)
Developmental, Blaschko lines	Pigmentary demarcation line, linea nigra
	Epidermal naevi, incontinentia pigmenti, hypomelanosis of Ito
	Linear psoriasis, linear lichen planus, lichen striatus
Skin stretching	Striae due to growth spurt (on lower back)
Infestation	Scabies, larva migrans (both usually serpiginous)
External factors	
Plants	Phytophotodermatitis
Allergens	Elastoplast, nail varnish (neck), necklace, waistbands, etc.
Chemical	Caustics, e.g. phenol
Thermal	Burns
Physical	*Trauma to previously normal skin*
	Keloid scar, bruising, dermatitis artefacta, amniotic constriction bands
	Trauma to skin with a pre-existing dermatosis
	Purpura (cryoglobulinaemia, amyloid, vasculitis)
	Blisters (epidermolysis bullosa, porphyrias)
	Koebner phenomenon
	Psoriasis, lichen planus, lichen nitidus, vitiligo, lichen sclerosus, pityriasis rubra pilaris
	Inoculation
	Warts, molluscum contagiosum
	Other mechanism
	Scar sarcoid
Other determinants	Linear scleroderma (limb, central forehead)
	Senear–Caro ridge (on hands in psoriasis)
	Dermatomyositis (dorsum of fingers)
	Flagellate pigmentation due to cytotoxic drugs (e.g. bleomycin)

Pattern of lesions

The arrangement of individual lesions may create a characteristic pattern, such as the grouping of vesicles in herpes simplex—this pattern is so striking that it is applied to other lesions which do not share the same aetiology (herpetiform mouth ulcers).

Useful terminology to describe patterns includes:

Agminate—clustered; used to describe lesions such as acne agminata, where granulomatous lesions cluster around the lids, or agminate naevi, an unusual clustering of melanocytic naevi.

Grouped—characteristic of some infections (herpetic vesicles, molluscum contagiosum, plane warts), flea bites, lichen planus, leiomyomata, lymphangioma circumscriptum (Fig. 5.5).

Satellite—a cluster of lesions around a larger central lesion. May occur due to local lymphatic spread of neoplasm such as melanoma; may occur in chronic bullous disease of childhood/linear IgA disease.

Confluent—lesions merging together, locally or widespread, e.g. pityriasis versicolor.

Scattered, disseminated and exanthematous—for example, many drug eruptions, viral exanthemata.

Spared—patterns of sparing may also be diagnostically important, e.g. islands of sparing occur within the otherwise often confluent orange-red erythema of pityriasis rubra pilaris, sparing within skin folds in papuloerythroderma of Ofuji, or areas shielded by clothing or a wristwatch may be overtly spared in photosensitivity (Fig. 5.6)

Symmetrical—often endogenous (e.g. psoriasis) and *asymmetrical*, often of exogenous cause (e.g. tinea).

Distribution of lesions

The overall distribution of lesions in many common dermatoses may be so characteristic that it is of great assistance in clinical diagnosis, even though the mechanism in most instances is not understood. Even some demarcations that presumably have an anatomical basis are not fully understood, e.g. Wallace's line on the foot or the equivalent on the hand (Fig. 5.7). Important factors in determining the distribution of dermatoses include the following:

Fig. 5.1 Linear lesions. (a) Growth striae. (b) Lichen striatus. (c) Dermographism. (d) Linear epidermal naevus. (e) Linear excoriations in dermatitis artefacta.

Anatomical factors

—blood supply, e.g. venous eczema
—skin appendages, e.g. acne, hidradenitis
—type of skin, e.g. eruptions may be localized to the glabrous skin of palms and soles
—neural, e.g. herpes zoster
—developmental, e.g. disorders which follow lines of Blaschko (Chapter 12)
—regional variation in the skin surface microenvironment, e.g. erythrasma is usually localized to flexures
—others, e.g. polychondritis is restricted to sites where there is cartilage, affecting ears, nose, joints (and trachea)

External factors

—solar exposure, e.g. photosensitivity disorders
—chemical exposure, e.g. contact dermatitis
—infective, e.g. orf

Colour of skin and of lesions

Normal skin colour is due to melanin, phaeomelanin, haemoglobin, oxyhaemoglobin and carotenoids (Chapter 39). The colour of the skin is greatly modified by the scatter of light, which is responsible, for example, for the whiteness of scale and the blueness of any melanin deep in the dermis, although colour contrast with surrounding skin also alters perception of the colour of skin and subcutaneous structures [1]. The range of colours that may be seen in individual skin lesions is enormous (Table 5.4). Although many red, scaly rashes tend to resemble each

Table 5.3 Examples of annular lesions.

Infections	'Ringworm' dermatophyte infections
	Impetigo
	Erythema chronicum migrans
	Syphilis (secondary, tertiary)
	Leprosy
	Lupus vulgaris
Inflammatory	Psoriasis
	Seborrhoeic dermatitis
	Subacute cutaneous lupus erythematosus
	Lichen planus
	Sarcoidosis
	Granuloma annulare
	Erythema multiforme
	Urticaria
	Serum sickness
	Linear IgA disease/chronic bullous dermatosis of childhood
	Subcorneal pustular dermatosis
	Erythema annulare centrifugum
	Jessner's lymphocytic infiltrate
	Erythema marginatum rheumaticum
Vascular	Purpura annularis telangiectoides
Neoplastic	Superficial basal cell carcinoma
	Mycosis fungoides
Keratinization disorders	Porokeratosis

other, many dermatoses have their own distinctive colour which aids recognition—for example, the orange and yellow-orange palms of pityriasis rubra pilaris and carotenaemia, respectively. Some colours can be logically explained—for example, the purple of lichen planus is due to the redness of inflammation combined with the blue-brown of melanin within the dermis.

Examination of pigmented skin requires a degree of practice, as the physical signs may be modified. Erythema is seen as a dark area, macular or diffuse. Dermal oedema lightens the skin and weals appear pale. Papules may be pale or dark according to the degree of oedema or the presence of acanthosis or hyperkeratosis, which mask pigment. Purpura may be difficult to detect, but may appear jet-black in lighter-pigmented skin. Post-inflammatory depigmentation and hyperpigmentation are exaggerated compared to paler skin—for example, after herpes zoster, syphilis, leprosy, lichen simplex and many other conditions. Normal pigmentary variation between body sites is also more apparent in darker skin, and may cause confusion (for example, dark crease lines on the relatively pale palms); pigmentary demarcation lines may also be visible (Futcher's and Voigt's lines) [2].

Palpation of the skin

Palpation of rashes or localized lesions imparts additional information about texture, consistency, thickness, tenderness and temperature. Gentle scratching or rubbing alters visibility of scaling and may elicit dermographism. The main 'touch' modalities in examining the skin are:

Simple palpation—to determine texture, etc., as above.

Blunt pressure—for example, to detect oedema, assess capillary refill, identify the dermal defect that occurs in anetoderma.

Linear or shearing pressure—to elicit dermographism, or Nikolsky's sign in pemphigus (Chapter 41).

Squeezing or pinching—to determine localization and consistency of lesions. For example, a pinch of skin can be lifted up over a subcutaneous nodule, whereas squeezing a tethered intradermal process such as a dermatofibroma produces dimpling.

Stretching—may produce blanching of vascular lesions, and helps in visualizing lesions such as 'submarine' comedones, the elastomas of Buschke–Ollendorf syndrome and the glassy edge of a superficial basal cell carcinoma.

Rubbing—may cause release of chemicals; e.g. rubbing a mastocytoma causes urtication and a flare due to histamine release (Darier's sign), rubbing a neuroblastoma causes surrounding pallor due to catecholamine release.

Scratching and picking—scratching scale in psoriasis makes the scale appear more silver in colour by introducing air–keratin interfaces; more vigorous scratching or picking off the scale produces small bleeding points (Auspitz's sign). Neither of these is specific to psoriasis. Removal of crusts overlying nodules may demonstrate the extent of the lesion, and additional diagnostic features, more accurately.

Additional simple clinical examination

Wetting the skin with water or mineral oil (which lasts longer) fills air spaces in scale and allows underlying features to become more visible. In some instances, this just enhances underlying redness—for example, in psoriasis. In other instances, diagnostic features may become apparent to the naked eye (such as Wickham's striae in lichen planus) or with the aid of additional magnification (e.g. use of a dermatoscope to examine pigmented lesions). Soaking of the skin may make the lesions of pitted keratolysis more apparent.

Application of heat or cold may identify specific physical urticarias. Whole-body warming may confirm cholinergic urticaria. Even whole-body cooling has been used, to identify dysarthria as being due to Raynaud's phenomenon of the tongue.

Pinprick sensation may be lost in leprosy.

Paring the skin allows distinction between a wart and a

corn, or may confirm the presence of old blood in *talon noir* or a haematoma.

Smell may be useful—for example, in suspecting anaerobic wound infection, or rarities such as trimethylaminuria.

Simple microscopy may be diagnostic for hair shaft abnormalities and for distinguishing between hair casts and head lice egg cases (nits), and is used to detect cutaneous fungal disease.

Additional clinical investigations

Diascopy

Pressing a glass slide or (more safely) a stiff, clear, colourless piece of plastic onto the skin compresses blood out of small vessels, to allow evaluation of other colours. Diascopy is of particular value in detecting granulomatous nodules, which have a translucent brownish colour known as 'apple jelly' nodules (e.g. in lupus vulgaris). In naevus anaemicus, a localized area of vasoconstriction, other pigments are unaltered—diascopy of adjacent skin therefore reveals an identical colour to that of the 'depigmented' area. By contrast, diascopy of skin adjacent to

vitiligo, in which there is loss of melanin, demonstrates that the vitiligo remains paler. Application of medium pressure to a spider naevus can compress radiating arterioles and allow visualization of pulsatile flow in the feeding vessel.

Wood's light

This is a source of ultraviolet light from which virtually all visible rays have been excluded by a Wood's (nickel oxide) filter. Applications of Wood's light are listed in Table 5.5 [1,2].

Variations in epidermal pigmentation are more apparent under Wood's lamp than under visible light, whereas variations in dermal pigment are less apparent [3]. Thus,

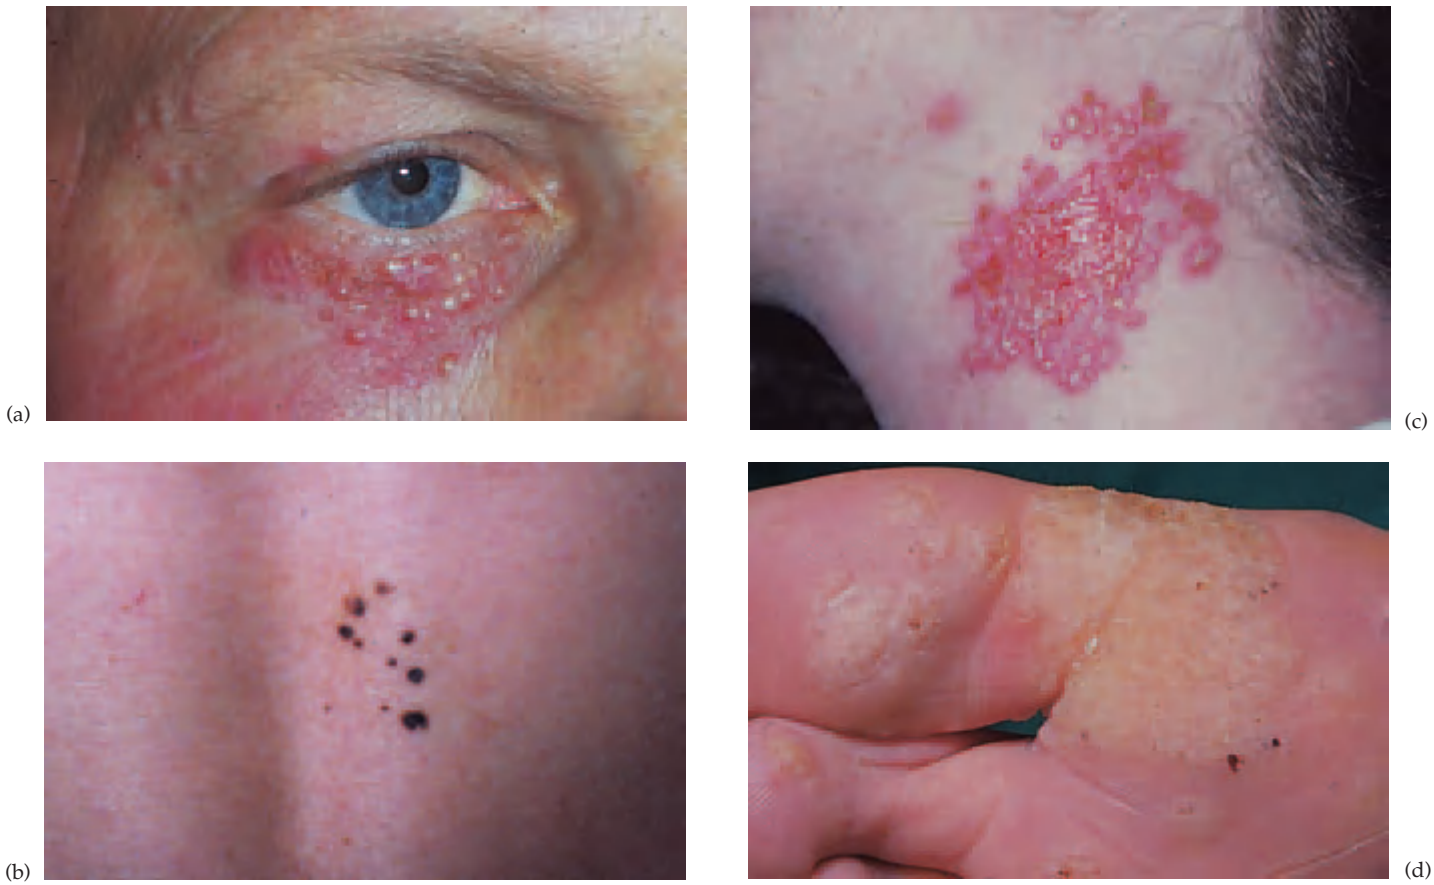

Fig. 5.5 Grouped lesions. (a) Agminate acne. (b) Grouped pigmented areas in a speckled lentiginous naevus. (c) Grouped vesicles in herpes simplex. (d) Grouped lesions within a mosaic plantar wart.

for example, it can be used to distinguish vitiligo from naevus anaemicus. Vitiligo is due to loss of epidermal melanin, and the depigmented areas are greatly exaggerated under Wood's light—naevus anaemicus is due to localized dermal vasoconstriction with normal overlying epidermal pigmentation, and the pallor completely disappears under Wood's light. The ash-leaf macules of tuberous sclerosis are much more prominent under Wood's lamp [3].

Many organisms produce chemicals that fluoresce under Wood's light [4,5] including *Propionibacterium acnes* [6], and *Corynebacterium minutissimum*, the bacterium responsible for erythrasma (Fig. 5.8), and conversion of aminolaevulinic acid to protoporphyrin occurs in several tumours and other skin lesions, leading to the technique of photodynamic diagnosis [7]. Fluorescein can be added to topical agents in studies of their use—for example, to detect areas that are missed during sunscreen application [8]. Wood's light can also be used to view *ex vivo* specimens, such as blood or urine in porphyrias [9], or even

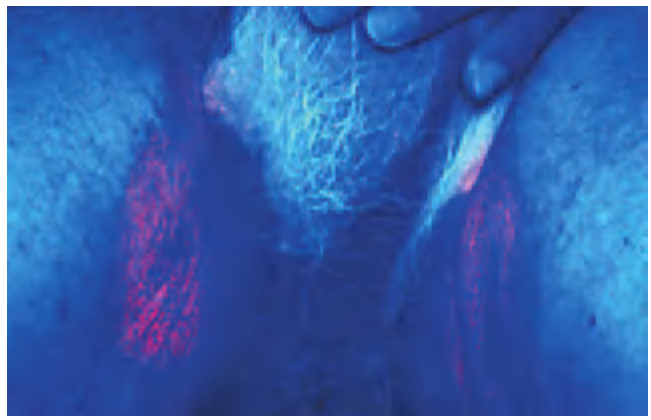

Fig. 5.8 Coral pink fluorescence of groin erythrasma.

inanimate objects, such as clothing from patients with chromhidrosis [10].

There are pitfalls of using Wood's light:

- It is useful to diagnose tinea capitis acquired from cats or dogs, but most fungi do not fluoresce, so a negative test does not exclude the diagnosis.
- There is some reflection of light from any scaly dermatosis, which may be confused with the relatively subtle colour change of pityriasis versicolor.
- Optical brighteners in detergents fluoresce strongly—white shirts and coats may be a considerable distraction.
- Erythrasma fluoresces pink due to porphyrins—it is a reasonably frequent finding that the expected

Table 5.4 Colours of skin lesions. (Adapted from C.M. Lawrence and N.H. Cox, *Physical Signs in Dermatology*, 2nd edn, London: Mosby, 2002: 21.)

Colour	Examples
Black	Melanin, e.g. some naevi, melanoma
	Exogenous pigments, e.g. tattoos, pencil/ink
	Exogenous chemicals, e.g. silver nitrate, gold salts
	Deeply situated blood or melanin, e.g. angiomas, blue naevus
Blue-grey	Inflammatory diseases, e.g. orf
	Drug-induced pigmentation, e.g. phenothiazines, minocycline
Dark brown	Melanin near the skin surface, e.g. most melanocytic naevi
	Exogenous pigments, e.g. dithranol (anthralin) staining
Pale brown	Melanin near the skin surface, e.g. lentigo, freckles
Muddy brown	Melanin in the superficial dermis, e.g. post-inflammatory pigmentation
Purple	Vascular lesions, e.g. angiomas
	Other disorders where telangiectasia is a prominent feature, e.g. lupus pernio (chronic sarcoidosis), dermatomyositis
Dusky blue	Reduced amounts of oxygenated haemoglobin, e.g. poor arterial supply, central causes of cyanosis, methaemoglobinaemia
Violaceous and lilac	Lichen planus, edge of plaques of morphoea,connective tissue disorders, e.g. dermatomyositis
Pink-red	Many exanthemata and common disorders, such as psoriasis
Red-brown	Inflammatory dermatoses, e.g. seborrhoeic eczema, secondary syphilis
	Haemosiderin, e.g. pigmented purpuric dermatoses
Scarlet-red	Lesions with a strong arterial supply, e.g. pyogenic granuloma, spider naevus
	Altered haemoglobin, e.g. carbon monoxide poisoning
Orange	Haemosiderin, e.g. lichen aureus
	Inflammatory disorders, e.g. pityriasis rubra pilaris
Yellow-white/yellow-pink	Xanthomatous disorders
Yellow-orange	Carotenaemia (ingested carotene, myxoedema)
Yellow-green	Jaundice
Green	Exogenous pigment, e.g. copper salts
White-ivory	Lichen sclerosus et atrophicus, morphoea
White (or pale pink, depending on vascularity)	Vitiligo, naevus anaemicus, arterial insufficiency, chemical depigmentation

Table 5.5 Uses of Wood's light.

Fungal infection	Tinea capitis—green fluorescence associated with *Microspora* species and favus (see also Chapter 31) Pityriasis versicolor—yellow
Bacterial infections	Erythrasma, acne—coral pink (porphyrins) *Pseudomonas pyocyanea*—yellowish green (pyocyanin)
Infestations	Scabies—fluorescein solution fills the burrows and can be viewed with Wood's light
Porphyrias (see also Chapter 57)	Urine, faeces and occasionally blister fluid fluoresce in porphyria cutanea tarda; teeth in erythropoietic porphyria; blood in protoporphyria
Pigmentary disorders	Vitiligo is accentuated (see text), dermal pigment becomes less apparent Detection of ash leaf macules in tuberous sclerosus
Drugs and chemicals	Detection in tissues, e.g. staining of teeth or sebum from tetracyclines and of the nails from mepacrine Detection of fluorescent contact or photosensitizers on the skin, or in cosmetics and industrial agents, e.g. ballpoint-pen ink, eosin, furocoumarins, halogenated salicylanilides, pitch ingredients Fluorescein can be added to topical medications to investigate sites of application or of manipulation (e.g. in the investigation of dermatitis artefacta)
Tumours	Red fluorescence can occur in some malignant tumours and other lesions of the skin, especially squamous cell carcinomas. Conversion of aminolaevulinic acid to protoporphyrin IX occurs within tumours as the first step in photodynamic therapy and can be detected with Wood's light
Miscellaneous	Lipofuscins in sweat from patients with chromhidrosis can be identified by Wood's light examination of stained clothing. Research use of fluorescent 'markers' for the investigation of cutaneous penetration and epidermal turnover. Detection of mineral oil on the skin in the assessment of barrier creams

fluorescence is negative if the affected skin has been washed prior to a clinic appointment.

Clinical microscopy and dermoscopy

Microscopy is an important laboratory technique, discussed briefly later. However, microscopy in a clinical setting also has several uses.

Dermoscopy

This technique, also known as dermatoscopy or epiluminescence microscopy, is an extension of the use of simple magnification. Dermoscopes have built-in illumination, and are applied to the skin surface with a film of oil on the lesion to enhance visibility of subcorneal structures. The technique is mainly used in the diagnosis of doubtful pigmented lesions (Chapter 38). The images may be viewed directly, photographed or recorded digitally for subsequent or sequential analysis. A structured system of analysing the colours and appearances of the structural elements (pigment network, globules and dots, horn cysts and pseudofollicular openings and the vascular patterns visualized) may increase the accuracy of diagnosing malignant melanoma [1]. Scoring systems such as the ABCD dermatoscopy score (assessing *a*symmetry, *b*order *c*olour and *d*ermatoscopic structures) [2] and a 'seven-point check list' [3] have been devised. Computerized image analysis is being developed to aid in distinguishing benign melanocytic lesions from melanoma [4]. Dermoscopes can also be useful in the identification of scabies burrows and mites, and in distinguishing haemangiomas, angiokeratomas, pigmented basal cell carcinomas and seborrhoeic keratoses from melanocytic lesions.

Identification of scabies mites

Scabies mites can be extracted from the end of a burrow using a needle, with microscopy to confirm the diagnosis. The technique can be useful to convince sceptical sufferers of their infestation. Alternatively, application of mineral oil [1] or 5% potassium hydroxide to an affected interdigital space, followed by light scalpel scraping, reveals the acarus or its eggs. The faecal pellets (scybala) of the mite are also diagnostic, but are dissolved by potassium hydroxide; they remain intact in oil. Burrows can also be removed by a very superficial shave technique, and can be made more apparent by application to the skin of either black ink, or fluorescein with Wood's light visualization. Dermatoscopy (see above) can also be used—the mite appears as a dark triangle shape—or higher-resolution microscopy with a standard light microscope [2]. Outwith the scope of this section, scabies can also be identified using polymerase chain reaction (PCR) to detect mite antigens [3].

Other simple microscopy procedures

Simple light microscopy is helpful in evaluating hair shaft abnormalities (this, and more complex electron microscopy, are discussed in Chapter 63).

Microscopy of skin scrapings for fungi is discussed in Chapter 31. Scraping the base of a herpetic vesicle with simple Giemsa staining may reveal giant cells (Tzanck smear); molluscum contagiosum can be identified in a similar fashion. Examination of skin pustule smears after fixation and haematoxylin and eosin staining may be useful in the rapid diagnosis confirmation of infantile eosinophilic folliculitis and incontinentia pigmenti; in both conditions, the pustules are filled with eosinophils.

Skin surface biopsies using tape-stripping or adhesive microscope slides pressed onto the skin allows observation of cells of the stratum corneum and of bacteria, fungi such as *Pityrosporon* species, and *Demodex* mites [1–3]. Plastic polymer (Silflo) skin surface impressions may be useful for the study of eccrine gland pore size and numbers.

Fine-needle aspiration of lymph nodes (FNA)

Aspiration of lymph node tissue using a 25- or 27-gauge needle allows cytological assessment of lymph nodes and is useful in the staging of metastatic malignant melanoma and squamous cell carcinoma of the skin, as well as the assessment of lymph nodes in suspected lymphoma. In patients with palpable lymph nodes and melanoma, the technique has been shown to have high specificity and sensitivity [1]. Combining the technique with flow cytometry can help in the differentiation of lymphoma from reactive and dermatopathic lymphadenopathy [2].

Commonly used laboratory tests

Numerous special investigations are used to refine a dermatological diagnosis, or for disease or therapy monitoring. Many of these are discussed specifically in relevant chapters—for example, testing for photosensitivity (Chapter 24) or for contact allergy (Chapter 20). The commonest tests which involve additional laboratory processing of samples are as follows:

- Blood tests for haematology or biochemistry. These are used in numerous situations, both diagnostically and for assessing the impact of a skin disease or for monitoring systemic therapy. Many infective disorders or acute inflammatory conditions are associated with neutrophilia or with abnormal results of inflammatory markers such as erythrocyte sedimentation rate or C-reactive protein; eosinophilia is also a feature of several dermatological conditions (Table 5.6).
- Blood tests for immunological studies. For example, in the diagnosis of connective tissue diseases (Chapter 56), IgE and radioallergosorbent test (RAST) in atopic and allergic diseases (Chapters 10 and 18).
- Histology of skin biopsy (Chapter 7). This may include special staining methods, direct immunofluorescence studies and immunocytochemistry. 'Rush' frozen sections may be necessary—for example, during micrographic surgery or in the urgent diagnosis of some blistering conditions [1].
- Other immunological and microscopy studies for bullous diseases, e.g. immunoblotting (Chapter 41), electron microscopy (Chapters 13 and 40).

Table 5.6 Some 'dermatological' causes of eosinophilia (more than 0.44×10^9/L eosinophils).

Atopic disorders, especially asthma and eczema
Parasitic infestations
Worms (intestinal or systemic)
Scabies
Allergy to food or drugs
Tryptophan myalgia syndrome
Collagen vascular disease (especially polyarteritis nodosa and variants), dermatomyositis and eosinophilic fasciitis
Malignancy, especially Hodgkin's disease and eosinophilic leukaemia
Bullous disorders
Dermatitis herpetiformis
Pemphigus
Pemphigoid
Erythema neonatorum
Hypereosinophilic syndrome

- Bacteriology and mycology samples (Chapters 25–31). May include samples for microscopy and culture, serological tests, PCR tests (e.g. for mycobacteria).
- Cytological examination. Usually in the context of FNA from lymph nodes, discussed above.

Radiological and imaging examinations

These have an important role in dermatology, but less than in many other specialties, because the skin can so readily be seen and felt. Ultrasound [1,2], magnetic resonance imaging [3–5] and even positron emission tomography [6,7], when available, are all used in clinical practice, but more often at present as research tools. They are used, for example, for the accurate assessment of the thickness of lesions in scleroderma, the extent of infection in severe forms of cellulitis or in the assessment of tumours. They also come into their own in the management of diseases like neurofibromatosis, where there may be central nervous system involvement, or in the assessment of muscle change in dermatomyositis. Lymphoscintigraphy may be a useful functional assessment of the lymphatic system of the swollen lower limb (Chapter 51). Doppler assessment of the peripheral lower limb arteries is an essential bedside technique prior to the use of high-compression bandaging in the management of venous leg ulcers (see Chapter 50).

Skin testing

Substances may be introduced into the skin by a variety of techniques to study pharmacological and immunological [1] reactions under controlled conditions. Such tests are extremely valuable, but details of the type of test and the time at which it is read must correspond to the pathological process under consideration. Interpretation of the relevance of tests, either positive or negative, must always be correlated with the clinical picture. All too often, evidence adduced from tests is either meaningless or misleading.

Absorption of many substances through the intact skin is poor and variable, but direct application to the surface of the skin is used for patch testing. The epidermal barrier may be overcome either by removing it or by introducing the material directly into the dermis. The following techniques for skin testing are most commonly used.

Techniques for skin testing

Epicutaneous tests—patch tests. Patch tests are usually used to detect contact allergy of the delayed hypersensitivity type. They are usually read at 48–72 h and again up to 1 week, but can also be read at 15–30 min to detect contact urticaria. At times, patch testing may usefully be combined with scratch testing. Details of these techniques are discussed in Chapters 19–21.

Intradermal injection

The injection is made into the superficial layer of the dermis through a fine-bore (26- or 27-gauge) needle with its bevel pointing upwards. The quantity that may conveniently be injected varies from 0.01 to 0.1 mL. Precise measurement of smaller quantities is difficult and requires syringes with especially well-fitting plungers and a micrometer screw gauge. For routine clinical purposes, an approximation is sufficient—either 0.05 mL or the amount that just causes a visible weal (0.01–0.02 mL).

The optimal time for reading the reaction naturally varies with the pharmacological agent or the type of immunological reaction. Most such tests are read at either

Fig. 5.9 A positive prick test reaction to latex allergen.

15–20 min or at 48 h, but it may be important to read the tests at other times, for example at 4–12 h or after 4 days. The response to be observed at 15 min—for example, after an injection of histamine or after immediate-weal allergy tests—is a weal with a surrounding flare (Fig. 5.9). The weal is a more accurate measure than the flare. When the test is read at 48 h—for example, in the tuberculin reaction—the sizes of the indurated papule and of the erythematous reaction should be observed.

The site of the test is of some importance [2,3]. In general, the whole skin surface is capable of responding to skin tests, but there are regional variations. The back and the flexor aspects of the forearms are most conveniently used. The skin on the ulnar aspect of the forearm is more sensitive than the radial, and the proximal more sensitive than the distal. These differences are not of sufficient magnitude to affect routine testing, but must be taken into account by using symmetrical areas for controls in any accurate quantitative testing.

A test solution must always be compared with a control solution injected in a comparable site at the same time. A positive test may be taken as one that is significantly different from the control. Assessment of what is significant is difficult, and varies with the enthusiasm of the tester. If a difference of less than 5 mm is accepted, reproducible results may not be obtained on retesting [4].

The measurement of a weal is usually made by diameter, although more sophisticated methods such as volume measurements and Doppler flow have been used [5]. If the weal is not circular, an approximation may be made by averaging maximum/minimum diameters, or more accurately the area may be calculated by the formula $D_1 \times D_2 \times \pi/4$, where D_1 and D_2 are the maximum and minimum diameters [6]. For irregular weals, a tracing may be made on squared paper. Pseudopodia should be noted, but for measurement of diameter they are ignored. Attempts to assess the volume of a weal are less satisfactory for routine use.

The size of the weal is not directly proportional to the dose of the active agent, but varies also with the total volume of fluid injected. An approximation of a linear relationship may best be achieved, often only over a narrow range, by plotting the response against the log dose. For accurate quantitative observations, weal diameters below 4 mm or above 15 mm cannot be relied upon.

Antihistamines may greatly inhibit the immediate weal tests. In the case of very long-acting agents, this effect may last as long as 3 weeks. They have no appreciable effect on delayed hypersensitivity patch tests. Moderate to large doses of corticosteroids, in contrast, may somewhat inhibit patch tests, although smaller doses—for example, prednisone 10 mg daily—are not necessarily a contraindication to testing. Steroids do not greatly inhibit the immediate weal tests. When a patient feels faint, any immediate weal test may be completely inhibited.

Prick test

This is a modification of the intradermal injection. A small quantity of the test solution is placed on the skin and a prick is made through it with a sharp needle. This should be superficial and not sufficient to draw blood. The quantity has been estimated as 3×10^{-6} mL [3]. The size of the weal and flare are measured after 15 min (Fig. 5.9). This test gives reproducible results and is convenient for much routine allergy testing. Because of the discrepancy in quantities injected, the testing solutions are made up at different strengths for prick testing and intradermal testing. The intradermal injection of prick-test solutions may be dangerous.

Scratch test

The scratch test resembles the prick test. A linear scratch about 1 cm long, but not sufficient to draw blood, is made through the epidermis. This test gives less reproducible results than the prick test.

Modified prick test

Here, a drop of the test solution is placed on the skin. A needle is then inserted very superficially and almost horizontally into the skin and lifted to raise a tiny tent of epidermis. This test is slightly more sensitive than the ordinary prick test, but gives no more reproducible results.

Skin-window technique [7,8]

The surface of the skin over an area a few millimetres square is scratched off with a scalpel, the test solution applied and the area covered with a coverslip. This is removed at various intervals—for example, 3 h, 6 h, 12 h, 24 h and 48 h—and immediately replaced by another

coverslip. The cells on the coverslip are stained with ordinary haematological stains. The cellular response at varying time intervals can be assessed.

Immediate weal tests

These tests are used for detecting IgE antibodies. The passive transfer test may be used to detect circulating IgE, but is not recommended because of the risk of serum hepatitis or human immunodeficiency virus (HIV). These antibodies play a role in hay fever, asthma, atopic dermatitis and anaphylactic reactions. They occur especially, but not exclusively, in patients with a personal or family background of atopy. Positive skin tests to a wide variety of antigens are extremely frequent in these patients and must always be correlated with the history. They are principally used in the assessment of hay fever and asthma and have a limited place in the management of atopic dermatitis (Chapter 18). They are disappointing in the diagnosis of urticaria. False-positive and false-negative reactions are common.

Severe systemic reactions and, very rarely, fatalities may occur after correct use of standard testing solutions, and epinephrine (adrenaline) and hydrocortisone injections should always be at hand when skin tests are performed [1,2].

Alternative methods of detecting and measuring circulating antibodies are the RAST and the enzyme-linked immunosorbent assay (ELISA). RAST correlates well with skin testing [3,4]. It is particularly useful in (i) testing very young children; and (ii) with allergens associated with risk on prick testing (e.g. drugs).

The autologous serum test is a technique used in the investigation of chronic idiopathic urticaria whereby the patient's own serum is injected intradermally. It is regarded as being positive if at 30 min there is a weal 1.5 mm larger than at the saline control injection site. Positive reactions are indicative of functional autoantibodies against the high-affinity IgE receptor FcεRI, or against IgE [5] (Chapter 47).

Delayed (4–8 h) tests

The clinical interpretation of tests that are positive at 4–8 h can be difficult. Sometimes, these represent an Arthus reaction, but ideally this should be confirmed histologically. Other such tests represent a delayed variant of the immediate weal (15-min) test.

Intradermal tests for the detection of delayed sensitivity to bacterial, fungal and viral antigens

The tuberculin test. A positive result to the standard strength (10 tuberculin units, TU) is an indication of previous mycobacterial infection, but not necessarily by *Mycobacterium tuberculosis* (especially if the reaction is weak or doubtful). Reactions to 1 TU (1/100 dilution of purified protein derivative (PPD)) are, however, significant. In sarcoidosis, reactions may be wholly negative, or only positive to 100 TU. The minimum size of a positive reaction is taken as 5 mm. An intermediate (24-h) reaction sometimes occurs.

Comparable doses of PPD may vary according to their source. Misleading negative reactions may occur in anergic patients. Tuberculin tests are discussed further in Chapter 28.

The Heaf test. Used in mass testing and in children. It is roughly equivalent to, or perhaps slightly more sensitive than, a dilution of 1 : 100 old tuberculin [6].

Candida antigen is used in a similar manner to the tuberculin test. Depressed reactivity occurs in sarcoidosis and other immunosuppressed conditions. Negative reactions in normal subjects are, however, not uncommon and depend on age and locality.

Trichophytin detects past infection by *Trichophyton* species. Its value is limited.

The lepromin test. This is discussed in Chapter 29.

Histoplasmin, coccidioidin and similar antigenic tests are of most value in areas where these diseases are not endemic. The *Frei test* and *cat scratch fever antigen* are of some value in the UK, where the relevant diseases are comparatively rare. A positive reaction is then significant. Conversely, *Brucella antigen* and *toxoplasmin* are of limited use in dermatological practice.

Delayed-type bacterial antigen tests [7–9]. These are not widely used, partly because their specificity and interpretation are difficult to assess. They consist of standard preparations of bacterial extracts, each probably containing a mixture of antigenic components, which may produce an immediate, or delayed 48-h reaction or an

even later reaction. The normal 48-h response is a papule showing, histologically, a tuberculin-type reaction of lymphocytic type. Occasionally, however, especially in cases of vasculitis, an acute leukocytoclastic reaction occurs within 6–8 h [8] and is fully established at 24–48 h. Sometimes, the reaction is severe enough to produce a sterile abscess. It is tempting to believe that these reactions may be of some significance in conditions such as erythema multiforme, erythema nodosum (streptococcal), allergic vasculitis and, perhaps, pustular psoriasis. However, the antigens at present in use are relatively impure and the reactions may be non-specific. Further careful immunological studies are required.

Long-delayed (6-week) intradermal reactions. These comprise the *Kveim test* and the *Mitsuda test*. They are read at 6 weeks, but biopsy is essential with the Kveim test. Kveim test antigen is no longer available in the UK.

Oral provocation tests

The administration of a drug, food or chemical by mouth may sometimes be called for to confirm the diagnosis of an eruption or to establish its exact cause. Such tests are used in the following situations.

1 To determine the cause of a drug eruption or to isolate one from a number of drugs or ingredients of a compound drug. It is applicable only when the drug given and the dose chosen are unlikely to provoke a severe reaction in the patient. It may be a valuable method of proving the cause of a fixed drug eruption but should rarely, if ever, be used if the reaction has been of a generalized or acute nature. The subject is discussed in more detail in Chapter 73.

2 In the course of the investigation of food allergens [1–3]. The reintroduction of specific foods, one at a time, is an established part of exclusion, elimination and challenge diets. It is important that the role of the suspect food is subsequently confirmed by reintroducing it in a disguised form to avoid identification by the patient.

The procedure is applicable to patients with atopic eczema (Chapter 18), chronic or recurrent urticaria (Chapter 47) and possibly to some other dermatological conditions that have an allergic basis. However, it must be carried out with care and is only valuable if the tests are properly controlled and the patient is cooperative and well motivated.

3 In establishing the role of additives in chronic urticaria or angio-oedema (Chapter 47). Tartrazine, benzoates and antioxidants have been especially implicated [4–6]. Although oral provocation with increasing test doses of these substances is theoretically simple, the same reservations apply, and the administration of the diets and the 'blind' challenge require time, patience and motivation. Audit has shown that these tests appear to benefit the patient at low cost, but their scientific validity remains uncertain [7].

The role of oral nickel and chromate in the behaviour of endogenous hand eczema has been studied [8,9]. Some authors have produced flares of vesicular hand eczema after oral administration of nickel, but others have been unable to reproduce these results when interspersing test doses with placebo capsules.

Oral provocation with balsam of Peru was used in a series of 221 patients [10]. Flares of an existing dermatitis occurred in 45 patients, only 17 of whom had shown positive patch-test reactions to this substance. Subsequent dietary restriction of flavourings was said to clear or 'markedly improve' the dermatitis in half the patients.

Sublingual food tests are unreliable [11].

Telemedicine

Considerable clinical experience is needed in order to make correct dermatological diagnoses, and since trained dermatologists are in relatively short supply even in many developed countries, telemedicine—remote consultation via an electronic link—may become an attractive option. It is particularly useful in remote or rural areas where there are no specialists.

Dermatologists have for many years conducted long-range consultations by telephone or by mailing histology slides or clinical photographs, but the unique feature of telemedicine is the two-way electronic network that now allows immediate interactive communication between the patient, the primary care physician and the specialist (so-called real-time teleconsultation). Different parts of the patient can be viewed at various magnifications, and the specialist can ask supplementary questions and advise on the most suitable biopsy sites if necessary. A less satisfactory, but time-efficient, approach is the 'store and forward' system, whereby history details and images taken remotely are reviewed later by a distant specialist. This does not allow simultaneous supplementary history and directed image choice, which may hamper appropriate management.

Several trials have shown that telemedicine can be effective, with high levels of satisfaction reported by patients, GPs and hospital specialists [1–3], although a recent study involving telemedicine in several specialties showed that the visual images were not adequate for the dermatologist [3]. A personal encounter between specialist and patient may offer additional advantages, such as enhanced information about the patient's personality, with more patient participation in decisions and a placebo effect, which can lead to greater compliance [4].

Further technical developments will lead to better visual definition, which will be particularly helpful to dermatologists, and telemedicine clearly has considerable potential for dermatological diagnosis [5,6].

Chapter 6

Epidemiology of Skin Disease

H.C. Williams

What is epidemiology and why is it relevant to dermatology?

> *Epidemiology is the simplest and most direct method of studying the causes of diseases in humans and many contributions have been made by studies that have demanded nothing more than an ability to count, to think logically and to have an imaginative idea.*
>
> (Sir Richard Doll, 1987 [1])

Many dermatologists still think of epidemiology in terms of describing the prevalence and the age, sex and geographical characteristics of a particular skin disease. Whilst it is true that epidemiology is often used in this fashion to describe the *burden* of disease in human populations, as Sir Richard Doll points out above, epidemiology offers one of the most powerful and direct methods of evaluating the *causes* of skin diseases in human populations. One definition of epidemiology is therefore 'the study of the distribution and causes of diseases in human populations'. In addition to describing the burden and causes of skin diseases in populations, *clinical epidemiology* is concerned with describing the natural history and prognosis of diseases and evaluating interventions which seek to prevent or treat diseases [2]. The term *dermato-epidemiology* refers to the study of the epidemiology of dermatological disorders [3]. Because epidemiological studies are often concerned with making observations about highly complex natural experiments, methods for minimizing bias or adjusting for confounding factors (see glossary) have had to be developed. These new methods, along with the high scientific rigour necessary for designing and interpreting epidemiological studies, are aspects from which all dermatological research can benefit. Epidemiology is therefore relevant to dermatology for the five reasons shown in Table 6.1.

Although epidemiology is often perceived as a novel addition to dermatology, the first epidemiological discoveries in dermatology can be traced back to 1746, when James Lind [4] concluded that scurvy in sailors was related to dietary factors. He then showed, by means of a controlled study, that the disease readily responded to the addition of fresh oranges and lemons in the sailors' diet. In 1914, Joseph Goldberger [5] observed that 8% of 418 patients admitted to the Georgia State Sanatorium developed pellagra, compared with none of the 293 Sanatorium employees. He suggested that pellagra was due to an absence of 'essential vitamins', today recognized as nicotinic acid, and proceeded to test his suggestion in a community trial. Thus, dermato-epidemiology is not such a new subject, and with over 2000 skin disease reaction patterns described, the scope of the topic is vast. This chapter will therefore not deal with the epidemiology

Table 6.1 The relevance of epidemiology to dermatology.

To quantify the burden of skin disease in the community
To identify the causes or risk factors for skin diseases
To describe the natural history, prognosis and disease associations of skin diseases
To evaluate the effectiveness of dermatological health services
To provide a methodological framework for designing and interpreting clinical dermatological research

of specific skin diseases—which will be described where possible under the relevant disease sections—but it will attempt to illustrate the relevance of modern epidemiology to dermatology by using specific examples from dermatology. A glossary of commonly used epidemiological terms and further reading sources are to be found at the end of this chapter.

Thinking in terms of populations rather than individuals

The community diagnosis

One of the first hurdles to overcome when considering the epidemiology of a skin disease is to think in terms of *populations* rather than *individuals*. Many physicians find this conceptual jump quite difficult, as they are used to dealing with *individual* patients on a daily basis, whereas epidemiological studies refer to *groups* of individuals. Just as molecules, genes and individuals exhibit various aggregate characteristics, entire groups or populations exhibit their own unique characteristics and problems that enable a *community diagnosis* to be achieved [1].

Interesting patterns can occur when one explores the potential implications of treating an entire community (the public health approach) rather than sick individuals who present themselves to doctors (the high-risk approach). Rose [2], for example, showed that a 10-mm lowering of blood pressure distribution as a whole (e.g. from reducing salt intake) would correspond to about a 30% reduction in the total attributable mortality, simply because of the shape of the change conferred on the distribution curve in relation to specific 'disease' cut-off points.

During the scabies epidemics which occurred on the islands near Panama in the 1980s [3], it was found that even the best topical treatments when administered properly had no sustainable impact on the overall prevalence of scabies (which was very high in this population and associated with considerable morbidity from secondary pyoderma). When a *population* approach was adopted, i.e. treating all individuals with a programme of continuing surveillance, the prevalence of scabies fell dramatically to less than 2%, as shown in Table 6.2, and was sustained at that level until the US invasion of Panama interrupted these efforts. Thus, just as individuals become 'diseased', entire populations can become sick [2]. In these situations, a treatment policy based on a population diagnosis is usually beneficial, cost-effective and appropriate [4].

Skin diseases as 'entities' in the population

The concept of considering the health of entire populations also applies to the classification of skin diseases. Typically, dermatologists are preoccupied with deviants at the extreme end of the normal distribution curve who are selected because of disease severity and/or chronicity. Such individuals usually have well-defined physical signs which prompt those studying them to declare them as discrete 'entities' [5,6]. Such distinctions often become blurred when community surveys are undertaken. In a community survey of atopic eczema, for instance [7], it was noticed that indeterminate or borderline cases who had limited areas of dry skin or a single patch of eczematous inflammation were quite common. In these circumstances, perhaps the more relevant question is not 'Has the person got atopic eczema?' but 'How much atopic eczema does the person have?'

The concept of a distribution of disease severity at a population level may also be helpful in evaluating different treatment policies. For example, it has been estimated that a small change in the treatment threshold

Table 6.2 Prevalence of scabies among 756 Kuna Indians on the island of Ticantiki, Panama [3].

Date	Community treatment status	Prevalence of scabies (%)
July 1986	Conventional treatment	33.0
October 1986	Community control and surveillance instituted	0.7
July 1987	Breakdown due to supply problem	3.6
December 1988	Programme running again	1.5
March 1990	US invasion of Panama	12.0

of isotretinoin from severe to moderate cases of acne could result in a 15-fold increase in prescriptions in absolute terms, simply because moderate cases outnumber severe cases by so much [8].

Making comparisons and drawing inferences

Epidemiological reasoning usually progresses in an ordered fashion, starting with a hypothesis that has been suggested by a good clinical observation (e.g. palmoplantar psoriasis seems to be commoner in smokers) or descriptive studies of populations. This hypothesis is then tested in an epidemiological study which gathers and analyses data in a systematic fashion in relation to an appropriate comparison group to see if a statistical association exists. *Analytical epidemiology* is therefore concerned with making comparisons. These comparisons rely upon the uneven distribution of disease within and between populations to shed light on possible causes of ill health. Thus, previous case–control studies [9] showed that smoking was far more common in patients with lung cancer—a finding which led to more sophisticated studies to establish disease causality [10]. If everyone had smoked, it is possible that smoking would not have been identified as a cause of lung cancer.

In the simplest form of epidemiological study, a count is made of the number of cases with a particular skin *disease* (the numerator) within a catchment population (the denominator). The probability or frequency of disease occurrence may then be compared in two or more populations—for example, one exposed to a putative causative agent compared with another which is not. Inferences are then drawn based on the magnitude of the differences of disease frequency between the populations in light of possible *alternative explanations* such as chance, bias and confounding (see glossary). If such associations are genuine, further evidence is usually needed to determine whether they are causal in nature [11]. The whole process brings us one step nearer to the dermato-epidemiologist's ultimate goal—that of preventing skin disease, providing such causes are amenable to individual/public health manipulation. Prevention of skin disease is clearly more desirable than treating diseased individuals (Fig. 6.1).

When referring to an epidemiological study, it is important to make a distinction between the study population chosen for a particular study (e.g. those attending a hospital outpatient clinic) and the target population about whom one wishes to make inferences, as shown in Fig. 6.2.

The prevention paradox

Interventions that confer large population health gains may not confer much benefit to individuals. Thus, in the example of scabies in Panama above [3], although the population's health as a whole benefited greatly, many apparently healthy individuals may have not appreciated being treated for scabies, as it was not known who would have developed scabies in the absence of the prevention programme. Similarly, it is difficult to say which child will benefit from being immunized for tuberculosis in a BCG immunization programme, because events have not yet occurred. This conflict between large gains in the health

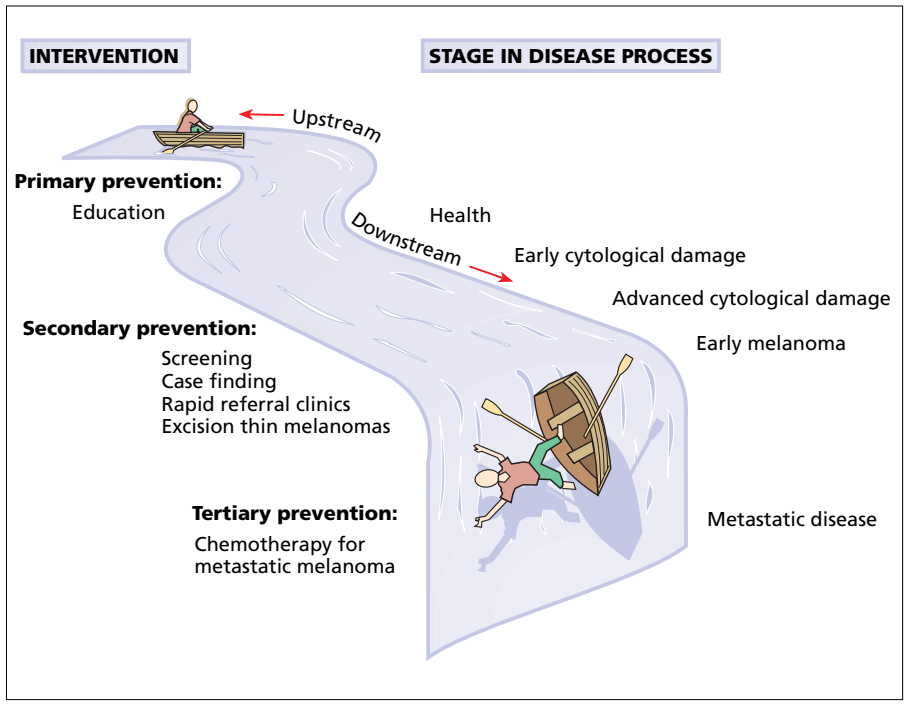

Fig. 6.1 Disease prevention in a serious condition such as melanoma is much more sensible than treating sick individuals with expensive drugs at the end of a long chain of irreversible pathological events.

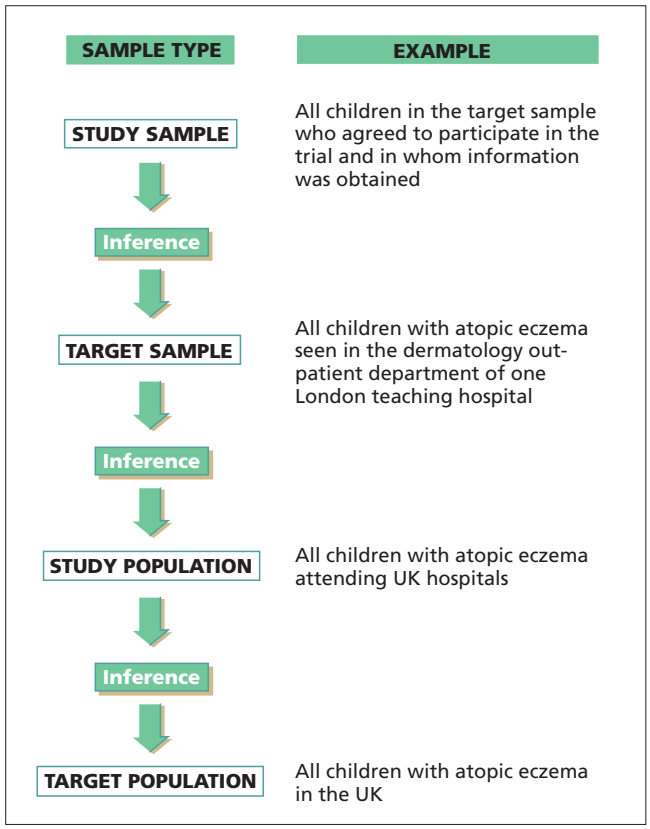

Fig. 6.2 Generalizing the results of a clinical trial of a new treatment for atopic eczema from a study of children attending one hospital department to all children with atopic eczema in the UK requires several jumps of inference.

of entire populations vs. small gains in individuals has been termed the 'prevention paradox' [4]. In the field of contact dermatitis, for example, eradication of a rare but potent contact sensitizer may have a great impact on affected individuals but little impact on the overall total burden of contact dermatitis in the general population. On the other hand, reduction in the amount of contact with formaldehyde, a less potent but far more common sensitizer in the general population, will result in a much larger reduction in the burden of contact dermatitis in that population, simply because far more people are exposed to formaldehyde [12]. As Table 6.3 illustrates, a little bit of harm affecting a lot of people can therefore add up to more than a lot of harm affecting a few people, in *population terms*. The first step when considering the epidemiology of skin disease is therefore to think about *populations* rather than *individuals*.

How much of a public health problem is skin disease?

The need for a clear disease definition in epidemiological studies

A glance at the dermatological journals makes it clear that the subject matter of most current research is defined—wholly or in part—by diagnostic criteria. But if these criteria are not explicitly stated, are prone to vary from one patient to the next in unpredictable ways, and vary systematically from place to place and time to time, the usefulness of such research is gravely impaired. Although phrases such as 'diagnosed by dermatologists' or 'diagnosed independently by two experienced physicians' and 'all with typical symptoms' may be adequate for dealing with individual patients, they are hopelessly inadequate when describing *groups* of individuals in epidemiological studies [1]. For instance, it has been shown that even experienced physicians are perfectly capable of disagreeing

	Eradication of exposure in:	
	The population	The individual
Rare—Exposure with high relative risk	Small benefit	Large benefit
Common—Exposure with low relative risk	Large benefit	Small benefit

Table 6.3 The prevention paradox: a little bit of harm affecting a lot of people can add up to more than a lot of harm affecting a few people. From Williams [12] with kind permission from Karger, Basle.

Table 6.4 The attributes of a good disease definition for use in epidemiological studies. From Williams [45], with permission.

Validity: it measures what it purports to measure by including cases and excluding non-cases
Repeatability: good replication of the definition between and within observers
Acceptability: to the study population in order to ensure high response rates
Coherence: with prevailing clinical concepts
Easy to administer by field workers
Reflects some degree of morbidity
Comprehensiveness: applicable to a range of ages, ethnic groups and disease severities
Comparability: they should contain elements which allow some comparison with previous studies

with each other over the classical signs of atopic dermatitis [2], and when two agree, a third is capable of disagreeing. What is regarded as 'typical' in London may be nothing of the sort in Lourdes, Lima, Lhasa or Lusaka.

Diagnostic criteria that work well in hospital studies may perform poorly in community studies because of the effect of low disease prevalence on positive predictive value (see glossary) and an increase in borderline cases. The properties of good diagnostic criteria for use in epidemiological studies are summarized in Table 6.4.

Not only is it important to use diagnostic criteria of known validity and repeatability in epidemiological studies, but it is sometimes important to qualify cases identified by such criteria by some measure of disease severity. For example, prevalence surveys of acne in the absence of severity measures are not very helpful in quantifying the disease problem, since physiological acne (non-inflammatory lesions) affects over 90% of adolescents [3]. Again, severity grading systems used in a hospital setting (which are usually non-linear and tend to favour severe and currently active disease) may not be so helpful in separating disease severity in milder community cases, where intermittent disease may be more common.

Impairment, disability and handicap caused by skin disease

Consideration of the three concepts of impairment, disability and handicap may be helpful in separating those effects which result from disordered function from those which are conferred on individuals by society. Impairment refers to the organic lesion produced by a disease, for example a broken limb; disability is the dysfunction which results from that impairment, for example not being able to walk; and handicap is the disadvantage that society confers upon the individual as a result of that impairment, for example unemployment. Handicap in skin disease may not be as explicit as that associated with a broken limb, but the psychological consequences of skin disease,

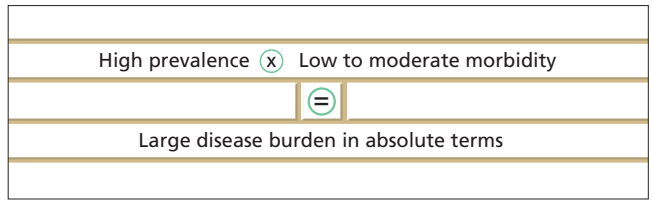

Fig. 6.3 Skin disease is a major public health problem: in public health terms, a little bit of misery affecting a lot of people can add up to more than serious illnesses which affect only a few people.

which include 'failure of display' [4,5], may be just as important. It has been shown that relatively minor skin complaints often cause more anguish to people than other more serious medical problems [4]. Also, because skin disease is so common, a little bit of morbidity affecting a lot of people can add up to far more than a lot of morbidity affecting only a few people. It is this product of high prevalence times moderate morbidity that makes skin disease very important from the public health point of view (Fig. 6.3). Small changes in health policy can have large financial implications, simply because they affect so many people.

One population-based cross-sectional study conducted in the USA on a random sample of 20 479 people examined by dermatologists in 1971–74 [6] has pointed to the magnitude of disability and handicap from skin diseases: skin conditions were reported to limit activity in 10.5 per 1000 of the population aged 1–74 years, or 9% of those persons with such skin conditions. About 10% of those persons with skin complaints considered the condition to be a handicap to their employment or housework, and 1% considered themselves severely handicapped. About one-third of those persons with skin conditions indicated that the condition(s) were a handicap in their social relations. The dermatological examiners rated more than two-thirds of those persons with skin complaints as disfigured to some extent from the condition, and about one-fifth of those were rated moderately or severely disfigured. More than half of those persons with skin complaints reported some overall discomfort from the condition such as itching or burning. An estimated 62.8 per 1000 US civilians (or 56% of those with skin complaints) indicated that the conditions were recurrent, with 49% active in the preceding 7–12 months.

The 1989 UK General Household Survey estimated that 16 per 1000 persons were affected by a long-standing skin disorder sufficiently severe to limit their activities [7]. Another survey of disability amongst 14 000 adults conducted in the mid-1980s found that 1% of complaints causing disability in private households and 2% in communal establishments were due to skin disease [8]. A recent survey of self-reported skin problems in 8000 adults in Uppland, Sweden, found that 20.5% reported skin problems [9]. Those reporting skin problems scored

lower on all eight dimensions of the SF-36, a generic quality-of-life instrument.

Quantification of such disability in monetary terms has not been evaluated. In addition to disability and handicap, some chronic skin diseases such as atopic eczema also incur considerable additional direct costs to families, such as that needed to purchase moisturizers, special soaps, extra laundry expenses, cotton clothing and bedding. The Lothian atopic dermatitis study estimated that the mean cost to the patient was £25.90 per 2 months, while the mean cost to the Health Service was £16.20 in 1994 [10]. Another study has estimated the direct cost of care for patients with psoriasis and psoriatic arthritis in the United States [11].

Routine data which describe the burden of dermatological disease

Generally speaking, routinely published medical statistics on skin disorders are scanty and, when available, are of limited use to the dermatologist in describing the burden of skin disease in the community. Special surveys are usually required to determine the prevalence and morbidity of skin diseases in general or specific skin diseases.

Some routinely published data on skin disease morbidity have limited uses.

1 *Mortality*. Overall mortality is relatively low for skin diseases, accounting for at least 2578 deaths in 1992 in the UK [12] (or 0.46% of deaths from all causes and all ages). Melanoma alone accounted for a total of 1142 deaths in England and Wales in 1992, with 48% of deaths occurring in economically active adults [12]. Mortality statistics of melanoma and non-melanoma skin cancer may be useful in discerning trends over time which may be related to the biology or treatment of these diseases.

2 *Morbidity*. Most routinely published morbidity data refer to those who seek medical help in the primary-care setting. With the exception of a few conditions, such as cellulitis, where incidence and demand are closely related, the extent to which routine morbidity data reflect the burden of dermatological need in the community is unclear. Despite these limitations, routine statistics such as the UK morbidity surveys from general practice [13] are useful in that they provide an estimate of the magnitude and demographic determinants of those who seek medical care.

3 *Skin cancer registration data* (i.e. cases presenting to physicians for the first time who are also reported) are of variable completeness and accuracy [14], but they have contributed some knowledge to understanding secular trends in reported cancer incidence and variations by sex, age and latitude. Special skin cancer registers such as the Scottish Melanoma Group Database [15] and the German Central Malignant Melanoma Registry [16] are examples of more complete databases with stringent controls on data quality.

4 *Other special registers* maintained by groups of enthusiastic individuals exist and may be useful for certain types of epidemiological studies, for example the UK Epi-Derm surveillance system for monitoring occupationally acquired skin diseases, the US National Epidermolysis Bullosa Registry [17], the German *Dokumentationszentrum schwerer Hautreaktionen* for severe cutaneous drug reactions [18] and national registers of sexually transmitted diseases. Other sources of data, such as in-patient and outpatient statistics and prescription data, tell us something about those who present themselves to tertiary medical care. Record-linkage studies may provide useful insights into the determinants of in-patient vs. outpatient care [19].

Special prevalence studies of skin disease in general

Self-reported skin disease

In 1986, the Proprietary Association of Great Britain commissioned a detailed nationwide survey of 1217 adults and the parents of 342 children to determine how British people manage minor ailments and some chronic recurring illnesses [20]. Skin complaints were the commonest ailment reported in the previous 2 weeks, comprising 25% of 6009 adult 'ailments' and 36% of 806 child 'ailments'. In addition to estimating the age- and sex-specific incidence of skin complaints over a 2-week period, the study provides a useful estimate of the proportion of skin complaints that are not considered by the public to be sufficiently severe to seek medical care, and the potential service implication should that threshold change. For example, of the 291 people complaining of acne/spots/greasy skin, 47% took no action, 34% used or bought an over-the-counter preparation, and 12% used medicines prescribed by a doctor, the remaining 7% using home remedies.

Similar proportions of self-reported 'skin disease in the last 2 weeks' have been recorded in two earlier studies [21,22]. A survey of 20 000 randomly chosen residents aged 20–65 years in Gothenburg, Sweden, found that 27% of females and 25% of males reported symptoms of skin disease in the previous 12 months [23]. Another survey of 8000 people aged 20–84 years in Sweden found that 20.5% reported a skin disease and/or use of topical dermatological drugs, with a higher frequency in women (23.3%) than men (17.3%) [9].

Examined skin disease

The Lambeth Study

Only one study in the UK has ever estimated the prevalence of skin diseases in the general population according to some form of physical examination. This study, conducted by Rea *et al*. in 1975 [24], was based on a question-

Table 6.5 Prevalence of examined skin disease expressed as rates per 1000 in a survey of 2180 adults in Lambeth [22]. Prevalence rates have been rounded to the nearest whole number, and 95% confidence intervals for the main findings are shown in parentheses.

	Both sexes		Male		Female	
Skin condition	All grades	Moderate and severe	All grades	Moderate and severe	All grades	Moderate and severe
Tumours and vascular lesions	205	14	142	1	264	27
Eczema	90	61	100	80	81	43
Acne	86	35	109	35	64	35
Scaly dermatoses	85	29	118	39	53	19
Scalp and hair disorders	82	14	79	8	95	18.9
Prurigo and allied conditions	82	39	61	17	95	60
Erythematous and other dermatoses	75	21	31	21	117	22
Infective and parasitic conditions	46	7	48	11	44	3
Warts	34	2	36	—	33	3
Nail disorders	33	19	24	13	42	25
Psoriasis	16	6	24	4	8	8
Mouth and tongue disorders	9	1	15	—	3	1
Chronic ulcer	2	—	4	—	—	—
Any skin condition	555 (496–614)	225 (178–272)	479 (400–559)	213 (147–280)	607 (520–693)	236 (170–302)

naire on skin symptoms which was sent to a stratified sample of 2180 adults in Lambeth, London. All positive respondents and one-fifth of those responding negatively were then interviewed and examined at home by a team of seven doctors and 11 nurses trained in the recognition of common skin disorders. Only exposed skin (face, scalp, neck, forearms, hands, knees and lower legs) was examined, and the overall response rate was 90.5%. Because of difficulties in agreeing on objective criteria for skin disease severity, skin disease was classified into trivial (not justifying medical attention), moderate (justifying medical attention) and severe (needing early medical attention because of severe symptoms or risk of progression), based upon the judgement of the examiner. The key findings of this study were as follows.

1 The overall proportion of the population found to have any form of skin disease was 55% (95% confidence intervals 49.6–61.3%).

2 The overall proportion considered to have skin disease worthy of medical care (i.e. moderate or severe) was 22.5% (95% confidence intervals 17.8–27.2%).

As shown in Table 6.5, the group containing tumours and naevi had the highest overall prevalence (20.5%), but 90% were considered as trivial by the examiners. In the eczema group, on the other hand, with an overall prevalence of 9%, more than two-thirds were graded as moderate/severe, so that the highest prevalence of conditions justifying medical care fell into this group (6.1%). Clear age trends emerged for specific disease groupings, for example acne and warts in younger age groups, although age, sex and social class trends were not found when all forms of skin disease were considered together, since several conditions had trends in opposite directions.

HANES-1

Another detailed cross-sectional study of skin diseases was conducted within the first US Health and Nutrition Examination Survey (HANES-1) [6]. This study, conducted on a representative population sample of 20 749 persons aged 1–74 years from 65 primary sampling units throughout the USA during 1971–74, included a detailed structured skin examination by 101 dermatologists. Clinical findings were backed up by laboratory investigations such as mycology culture and skin biopsy where possible. Key points emerging from this study were as follows.

1 Nearly one-third (312 per 1000 population) had one or more significant skin conditions which were considered by the dermatologist to be worthy of evaluation by a physician at least once.

2 The prevalence of significant skin pathology increased rapidly with age from 142 per 1000 children aged 1–5 years to 362 per 1000 youths aged 12–17 years and to 365 per 1000 young adults aged 18–24 years, due primarily to the increase in acne at puberty.

3 After a slight decline at age 25–34 years, the prevalence of skin pathology again increased steadily, reflecting the increase in chronic diseases such as psoriasis, vitiligo, malignant and benign tumours, actinic and seborrhoeic keratoses.

4 In this study, significant skin pathology was slightly commoner in males.

5 An additional 12.5% of the population was deemed to have a skin condition that was clinically inactive at the time of examination.

Both of these studies therefore suggest that significant skin disease is extremely common. Even though dermatology is characterized by an enormous range of

Table 6.6 Overall prevalence of skin disease in population based studies conducted throughout the world.

Country	Author	Date of survey	Sample size	Study population	Definitions	Overall prevalence of skin disease	Five commonest diagnoses	Comment
UK	Rea [24]	1975	2180	Stratified sample of adults	Examination by team of seven dermatologists and 11 nurses	23%*	Eczema Acne Scaly dermatoses Prurigo Erythematous and other disorders	Only 21% had sought medical advice
USA	Johnson [6]	1971–4	28 043	65 primary sampling units throughout the USA, population aged 1–74 years	Examination by 101 dermatologists	31%†	Diseases of sebaceous glands Fungal diseases Malignant and benign tumours Atopic dermatitis Other eczemas	Detailed survey of usage of health care
Sweden	Larsson [34]	1976	8298	School pupils 12–16 years old in AC county, North Sweden	Examination by dermatologists	Not stated	Acne Verrucae Atopic dermatitis Striae Pigmented lesions	Many children had more than one diagnosis
Faroe Islands	Lomholt [35]	1948	10 984	Survey of seven islands between Norway and Iceland	Examination by dermatologists	5%‡	Eczema Seborrhoeic dermatitis Neurodermatitis Acne Leg ulcer	Part of detailed psoriasis survey
Mexico	Estrada-Castañón [36]	1990	50 000	41 representative communities in Guerrero state (all ages)	Examination by team of dermatologists and nurses	50% of all households included someone with a skin problem	Pityriasis alba Scabies Pyoderma Acne Melasma	60% of skin conditions could be classified into 10 diagnoses
Brazil	Bechelli [37]	1981	9995	School children of 6–16 years in four urban and three rural communities in north-west Brazil	Examination by four dermatologists	26%	Pediculosis capitis Pityriasis versicolor Pyoderma Pityriasis alba Dermatophytosis	Tropical region with 85% relative humidity
Brazil	Romiti [38]	1976	9414	School children aged 5–15 years in Santos municipality	Examination by dermatologist	37%	Infestations Superficial mycoses Viral infections Eczemas Acne	Different disease spectra seen at local dermatology service

Tanzania	Henderson [39]	1991	958	Complete survey of two administrative units at Mvumi village	Examination by dermatologist	49%§	Pyoderma Scabies Pediculosis capitis Dermatophytosis Leg sores	Dry, central plateau
Tanzania	Gibbs [40]	1994	1114	254 randomly selected households from two villages	Examination by dermatologist	27%	Prurigo Scabies Viral warts Pyoderma Papular urticaria	Infectious dermatoses increased in the young. Overcrowding linked with increased skin disease prevalence
Mali	Mahé [41]	1994	1817	Random sample of 30 clusters of children aged less than 13	Examination by dermatologist	34%	Pyoderma Tinea capitis Pediculosis capitis Scabies Mollusca	Pyoderma and scabies significant health problem
Ethiopia	Figueroa [42]	1994	3979	House to house survey in three rural communities	Examination by dermatologist	14%	Ectoparasites Onchodermatitis Dermatophytosis Pyoderma	Only those who considered themselves to have a skin problem were examined
Pakistan	Porter [43]	1980	444	All children aged less than 5 years in three villages in Punjab	Examination by research assistants trained by a dermatologist	36%	Pyoderma (54% of skin disease) Atopic eczema Scabies Warts Other eczemas	Marked variation in prevalence of pyoderma between villages, possibly due to differences in malathion control of insect population

‡ Only those who presented themselves spontaneously with a skin disease.
§ Some of those examined might have more than one diagnosis.

disease-reaction patterns, prevalence surveys suggest that the bulk of the skin disease problem is made up of less than 10 disease groups [25]. The prevalence of skin disease documented in these two large population studies [6,24] also suggests that most individuals with skin disease do not seek medical help. Knowledge of this submerged section of the dermatological iceberg is important, as small changes in the population's perception of the need for medical help can have large effects on the delivery of health care.

Caution should be applied to prevalence studies with low response rates, as it cannot be assumed that respondents share the same characteristics as non-respondents. Indeed, a survey of non-respondents to a prevalence survey for skin disease in Australia found that people who did not respond to the initial survey were more likely to have skin cancers than respondents [26]. This important finding emphasizes the need to sample non-respondents in general prevalence surveys of skin diseases.

Surveys limited to children

A large comprehensive survey of examined skin disease in 2491 schoolchildren was conducted in the state of Victoria, Australia, with specific reports published pertaining to warts, atopic dermatitis, acne and tinea pedis [27–30]. Another survey of 1006 primary and secondary schoolchildren in Hong Kong found that 31.3% had one or more skin disorders, 70% of whom did not seek medical attention [31]. A study of 2788 children from eight randomly selected schools in Amman, Jordan, found a similar prevalence of 19.23% [32], and a study which involved a dermatologist examining 1114 children aged 6–12 years in Bucharest, Romania, found a point prevalence of one or more skin diseases of 22.8% [33].

Collectively, these surveys suggest that, like adults, around one-fifth to one-quarter of schoolchildren in urban centres have one or more skin diseases. Skin examination surveys conducted at one point in time (point prevalence surveys) are likely to underestimate the true burden of skin disease in children, since they will miss many children with infectious skin diseases of short duration, such as impetigo.

The burden of skin disease in developing countries

Table 6.6 summarizes studies of skin disease prevalence that have been conducted in developing countries compared with data from some developed countries [6,24, 34–43]. Making comparisons between countries is difficult, as survey methods have differed in terms of population ages, method of sample selection, and classification of diseases. The distinction between any form of skin disease and that which would benefit from medical care is particularly prone to vary according to the views of the dermatologist examiner and the availability of local services. Use of traditional healers is common in developing countries, especially amongst older community members [44]. Some general points can be made regarding the prevalence surveys in these countries: (i) skin diseases are very common; (ii) infections and infestations predominate; (iii) skin diseases are most common among the younger age groups; and (iv) most are easily treated. Making such generalizations is always hazardous, as even within 'developing' countries, urban pockets may occur with a disease spectrum very similar to developed countries.

What determines the frequency of skin disease in populations?

Risk factors, association and causation

In the first instance, epidemiological studies seek to establish *risk factors* for diseases, i.e. factors which are associated with an increased frequency of disease. When *associations* between skin diseases and risk factors are discovered (e.g. by demonstrating an increased risk of palmoplantar psoriasis in smokers [1]), it should be understood that such *associations* do not necessarily imply *causation*. The association between smoking and psoriasis may simply be a *chance* finding (around one in 20 studies with a P value of less than 0.05 in favour of rejecting the null hypothesis of no association will be wrong due to chance alone), or it could be due to *confounding* (i.e. a third factor such as alcohol, which is independently associated with both smoking and psoriasis [2]). The association could be due to a *bias*—for example, people with psoriasis in hospital may be more likely to recall antecedent events or seek reasons for explaining their illness in comparison with healthy controls [3]. Further analyses or new studies are usually needed to establish whether risk factors are *causative*—for example, by evaluating the strength of the association, biological gradient, relationship in time, the consistency between different studies, biological plausibility, coherence of evidence with external sources, experimental evidence, and specificity of findings as suggested by the Bradford-Hill criteria of causality [4].

The causes of some skin diseases are already established—for example, the herpes simplex virus causes cold sores—but for most dermatological conditions, the causes are unknown. Nevertheless, epidemiological research has already established many *risk factors* for skin diseases which maybe help to serve as pointers to specific causes. Direct manipulation of these risk factors may help in preventing or reducing disease even before the specific cause is found. For example, in the London cholera epidemics of the 1850s, John Snow [5] postulated that the disease was spread by some 'morbid matter' in the water supply and proceeded to intervene by removing the pump handle in Broad Street. This resulted in a dramatic fall in incident cholera cases. All of this occurred some 20 years before germ theory had become established in Europe. Snow's work illustrates one of the beauties of epidemiological research, i.e. that knowledge of pathophysiology is not a prerequisite for determining aetiology.

Even when a causative agent is discovered, for example *Vibrio cholerae*, exposure to this agent does not necessarily imply disease. Of those exposed to cholera during an outbreak, some will die from the disease, some will be very ill, some will be slightly unwell, some will be apparently healthy (but still carry the organism) and some will not be affected at all. The absence of disease in some individuals following exposure is probably due to a whole range of factors such as chance, infecting dose, genetic heterogeneity, and other constitutional and environmental factors which interact together to produce the final clinical picture. This phenomenon of apparent health in the presence of an established harmful exposure has been exploited by individuals in order to avoid modifying their behaviour. One often hears statements such as 'my grandfather smoked 40 cigarettes a day all his life and he did not get lung cancer'. In order to explain such phenomena, we return to the epidemiological concept of *groups* of people

or *populations* and *probability* of disease [6]. On average, groups of people who smoke cigarettes are 10 times more likely to develop lung cancer when compared with those who do not smoke.

It is also important to separate risk factors associated with disease *incidence*, i.e. number of new cases in a given population occurring over a defined period, from those which determine disease *chronicity*, i.e. the determinants of how long a particular disease will last once an individual has it, as the risk factors for each of these aspects may be different. Many dermato-epidemiology surveys have measured the *prevalence* of skin disease when examining risk factors [7], but because prevalence is a function of incidence times chronicity, it is often difficult to say whether these risk factors are important in people developing a disease for the first time, or whether they maintain the disease once established.

Risk factors for skin disease may operate at many different levels. Some may predispose to disease (e.g. a mother with atopic eczema genetically predisposes her child to atopic eczema), some may precipitate disease (e.g. exposure to high levels of house-dust mite may precipitate atopic eczema for the first time), and some may be important in perpetuating that disease (e.g. failure to use prescribed treatments may worsen the course of atopic eczema).

Some of the commonest risk factors for skin disease are discussed below.

Genetics

In addition to a few rare diseases such as epidermolysis bullosa, where specific chromosomal mutations have been closely correlated with different disease phenotypes, several genes may be important in many of the major inflammatory skin diseases. Some genes may be responsible for disease predisposition and some may be responsible for disease severity.

The early environment

There is evidence to suggest that the experience of the fetus *in utero* (e.g. in terms of nutrition) is critical in 'programming' adult diseases such as hypertension and diabetes [8], and *in utero* programming may well operate for many skin diseases such as atopic eczema [9].

The later environment

Age and sex are often included in the descriptive epidemiology of many skin diseases and may point to further risk factors. The marked female preponderance of lichen sclerosus, for example, suggests that hormonal factors may be important in this disease.

Ethnic group may account for some variations in disease rates. Thus, it has been shown that atopic eczema is twice as common in black Caribbean children in comparison with similar white children [10] and, conversely, that mortality from most cancers is less common in black ethnic groups in the UK [11]. Ethnic group, which refers to a way of life encompassing a whole range of dietary and cultural factors, must be distinguished from racial factors [12], which are often more difficult to define because of the considerable mixing of modern populations. Care also has to be taken in lumping many distinct ethnic groups together —for example, combining the diverse cultures of black Africans and black Caribbeans into 'blacks' may be totally inappropriate, both in terms of respecting the identity of the separate cultures and because such lumping together may obscure important epidemiological associations [13]. The term 'race' should not be used in epidemiological studies, as it has no scientific meaning [14]. Migration itself may be an important factor in determining skin diseases; for example, individuals who migrated from China (where atopic eczema is not very common) developed much higher rates of disease (similar to the rates in the local population) after migration to Hawaii [15]. Migrants may not be totally representative of their indigenous peoples, but they may nevertheless show the effect of the environment in determining the frequency of skin disease.

Secular factors may reflect changes in the natural history of skin disease or transient environmental exposures. Thus, the epidemic of melanoma skin cancer has been attributed by some to increased exposure to sunlight over the last 40 years [16]. There is reasonable evidence to suggest that the prevalence of atopic eczema has increased two- to threefold over the last 30 years, but the reasons for this change are less clear [17].

Socio-economic factors may also be crucial in accounting for the distribution of skin disease. In many poorer countries where overcrowding and poor sanitation may occur, infectious or ectoparasitic skin diseases such as secondarily infected scabies or pediculosis are commoner [18,19]. In wealthier countries where such infectious dermatoses are less common, new 'diseases' such as concern regarding the cosmetic appearance of sun-damaged skin or thread veins may preoccupy the population in their quest for a perfect skin. Some skin diseases, such as atopic eczema, also demonstrate a genuine positive social class trend, i.e. higher prevalences in more wealthy groups [7]. Some of this increase in reported eczema may have been due to differences in reporting between socio-economic groups, but other genuine environmental factors such as hygiene, carpets, central heating, family size, or differences in treatment also probably play a part.

Geography and climate are important considerations in describing the frequency of skin disease. Thus, consideration of the marked latitude gradient of melanoma in white-skinned peoples has supported the concept that

exposure to sunlight is an important risk factor for this disease [20]. Paul [21] has drawn attention to the concepts of *macroclimate*, which in the ordinary geographical sense refers to temperature, rainfall and humidity, and *microclimate*, which refers to the immediate domestic and occupational environment a given individual finds himself or herself in. These are discussed further by Marshall [22] and Canizares [23]. The combination of temperature, rainfall and humidity may be crucial to sustain certain infectious disease vectors such as the *Simulium* fly in onchocerciasis, and may for example account for seasonal fluctuations in pyoderma secondary to scabies during the wet season in Lilongwe in Malawi [24].

Occupational factors are occasionally a very important factor for skin disease. Thus, exposure to irritants and contact sensitizers in light and heavy industry accounts for a very large burden of hand dermatitis and lost revenue for both individuals and the state. Certain occupations, for example mining, where workers are constantly exposed to damp conditions, may predispose to fungal infections. Some diseases may occasionally occur in outbreaks from work-related substances, for example chloracne due to dioxins, vinyl chloride disease, and hydroquinone-induced leukomelanoderma. The reader is referred to standard texts of occupational dermatoses and Chapter 21 for further reading [25,26].

Infective agents may directly cause or be suspected to cause many skin diseases. Thus, for a long time, it was suspected that fifth disease was caused by an infectious agent, but it was not until 1983 that human parvovirus B19 was identified as the causative organism [27]. Similarly, there is reasonable circumstantial evidence to suggest that diseases like pityriasis rosea are caused by infectious agents, even though no specific agents have yet been consistently isolated [28].

Dietary factors may be crucial in some skin diseases. As the examples of Lund and Goldberger in the opening section showed, vitamin deficiency states may directly cause skin diseases. Other deficiency diseases with skin manifestations, such as acrodermatitis enteropathica, are completely reversible with administration of the appropriate agent, in this case zinc. Some diseases, such as phenylketonuria and dermatitis herpetiformis, may be transformed by restricting substances which affected individuals cannot handle—for example, phenylalanine and gluten, respectively. Some skin diseases, such as atopic eczema and acute urticaria, may be modified by avoidance of dietary allergens in a proportion of cases. Leisure activities such as gardening or habits such as smoking cigarettes and drinking alcohol may be important risk factors for many skin diseases such as contact dermatitis, psoriasis and porphyria cutanea tarda. Medicines, although intended to alleviate human disease, are a very common cause of cutaneous eruptions, some of which (e.g. toxic epidermal necrolysis) can be fatal.

Describing the natural history and associations of specific skin diseases

Questions commonly asked by patients with a skin disease are 'How long will it last?' and 'Will it come back again?' Special studies are required to answer these questions, which ideally involve following, over many years, individuals with typical and well-defined disease in terms of morphology and severity [1]. Such prospective studies

are rare in dermatology. Another approach is to identify cases with a specific skin disease from old hospital records and then to trace them in order to find out what has happened to them since they were seen [2]. Studies on the natural history of disease are often difficult to interpret because of incomplete follow-up, the intermittent nature of many skin diseases (leading to the need to distinguish between 'real' and 'apparent' clearance rates) [3] and because the treatment of many diseases has improved with time. Guidelines regarding the attributes of what makes a good follow-up study are summarized elsewhere [4].

Disease associations of specific skin diseases may also give insight into possible causative factors. Thus, the high incidence of laryngeal carcinoma in psoriasis patients might be evidence for the possible role of cigarette smoking in psoriasis [5]. Establishing disease co-occurrence, for example atopic eczema and psoriasis, may also shed light on shared or opposed immunopathological mechanisms [6,7]. Great care has to be exercised in interpreting disease associations generated from hospital sources because, in the absence of an appropriate denominator, many types of bias may occur [8,9].

Health-services research in dermatology

Broadly defined, dermatological health-services research is concerned with studying how we deliver dermatological health care with the ultimate aim of benefiting patients. Dermatological health services research thus covers a wide variety of service aspects, such as determinants of referrals to hospital departments, evaluation of cost-effectiveness of alternative treatment strategies, quantifying the dermatological needs of the community, evaluating the role of dermatological nurses and exploring economic aspects of screening and other prevention strategies. These diverse studies require a range of quantitative and qualitative research methods, such as focus groups, comparative studies, randomized controlled trials and economic analyses. Research establishes which treatments/services should be used, whereas audit seeks to establish whether health-care providers perform these services to a required standard [1]. As in any other branch of epidemiology, health-services research requires meticulous attention to be given to aspects of study design, which have to be addressed at the design stage. Other pitfalls are discussed further by Chren [2].

Needs assessments in dermatology

In evaluating dermatological health services, certain steps need to be followed [3].

1 Establish the size and nature of the dermatological need based on epidemiological data.
2 Summarize currently available services for that problem.
3 Appraise the evidence for effectiveness of those services.
4 Propose models of care which best fit the epidemiological data and evidence of effectiveness of care within current resources.
5 Propose outcome measures and targets which can be monitored after implementation.

Such an assessment has been attempted for UK dermatological health services by the author [4].

Services available for people with skin diseases

People with skin problems obtain help from various sources, including self-help, advice from pharmacists, advice and treatment from the primary-care team and specialist services. Little research has been conducted to clarify the relative health gain and appropriateness of the various health-care settings for different subgroups of skin disease. The estimated number of people using current dermatology health services in the UK at various entry points, for a population of 100 000 over a 1-year period, is summarized in Table 6.7 [5–10].

Self-help

Although self-help/medication is not traditionally regarded as a health service, the range and availability of over-the-counter skin products is an important element in the equation of balancing need, supply and demand. Around 30% of those with a skin complaint decide to self-medicate, and this proportion is similar for trivial and for moderate to severe disease [6]. Many effective skin treatments are available over the counter in the UK, such as 1% hydrocortisone for mild eczema, topical aciclovir cream for cold sores, topical benzoyl peroxide for acne, and numerous antifungal preparations and wart removers. Pharmacists occupy a key role in advising the public on the use of these products, but whether this advice

Table 6.7 A guide to the number of persons per 100 000 per year using dermatology services. From Williams [4] with permission.

Number with a skin complaint	25 000 (at least 25% of total population) [5]
Number who will self-treat	7500 (30% of those with skin complaint) [6]
Number who will seek advice from GP	14 550* (15% of total population or 19% of all GP consultations) [7]
Number referred to dermatologist	1162 (8% of those attending their GP for skin problems, or 1.2% of the total population) [8]
Number admitted to hospital	24–31 (2–3% of all new dermatology referrals) [9]
Number of deaths due to skin disease	5† (0.4% of all new dermatology referrals) [10]

* Excludes skin neoplasms, viral warts, herpes simplex and scabies.
† Includes people dying from cellulitis, chronic ulcer of the skin and severe drug reactions who might not have been admitted under a dermatologist's care.

is beneficial or whether it simply delays appropriate medical consultation has not been studied adequately in the UK [11]. Self-help groups are often a useful source of advice to those with chronic skin diseases [12].

Primary care

The majority of those with a skin complaint who seek medical help are treated by their general practitioner (GP). In the UK, around 6–8% of all GP diagnoses involve the skin [13,14]. The most recent GP morbidity statistics [7] suggest that 1455 people per 10 000 person-years at risk (approximately 15% per year) consult their GP because of a skin condition in the UK (excluding benign and malignant skin neoplasms and some skin infections). In the US, it has been estimated that around 36.5% of patients attending their GP over a 2-year period had a skin complaint [15].

The range of skin disorders seen in general practice is similar to that in the general population, with relatively few subcategories accounting for the majority of consultations [13,16]. As one would anticipate, proportionally more incident diseases such as skin infections (e.g. impetigo, herpes simplex and viral exanthems) are seen in general practice than in secondary care [7,16].

Secondary care

Although dermatology covers around 2000 disease-reaction patterns, over 70% of specialist activity is concerned with less than 10 main disease categories as shown in Table 6.8 [4]. Age-specific attendance rates are more common in female patients and also increase with increasing age. Around 12% of referrals were considered inappropriate by dermatologists in one UK study [17]. Another UK study showed that even a relatively junior physician with 3 months' dermatology training considered that 26% of 490 consecutive referrals were probably unnecessary [18], and that 75% of these unnecessary referrals belonged to just six disease categories (warts, eczema, naevi, basal cell carcinoma, acne, psoriasis and seborrhoeic warts). There is considerable variation in referral rates to specialist care

Table 6.8 The nine categories of skin disease which account for over 70% of dermatological diagnoses in primary and secondary care. From Williams [4].

Skin cancer (including melanoma)
Acne
Atopic eczema
Psoriasis
Viral warts
Other infective skin conditions
Benign tumours and vascular lesions
Leg ulceration
Contact dermatitis and other eczemas

within the UK and there is some evidence to suggest that much of the regional variation in referral rates may be governed by established patterns of care and the number of available consultants, rather than by any objective dermatological need [4]. Roland and Morris [19] showed no relationship between referral rates for dermatology services and medical need as suggested by standardized mortality ratios or mean number of prescriptions issued by GPs (standardized regression coefficient of 0.1). It should be emphasized, though, that mortality ratios are not a suitable surrogate measure for dermatological need. A strong relationship between dermatology referral rates and the number of dermatology consultants/100 000 population was present, however, in their study (standardized regression coefficient of 0.82, $P < 0.001$).

The relationship between need, supply and demand for dermatological care

Unlike commerce, which aims to balance supply with demand, caring for sick human beings requires consideration of a third factor—that of medical need. Medical need may be defined as the ability to benefit from medical care, demand as that which people ask for, and supply as what the service does or could provide [3,4]. Not all dermatological need is demanded (e.g. a person may be unaware that he or she has an early melanoma), not all that is demanded is needed (e.g. cosmetic removal of all moles), although all that is supplied is usually needed or

demanded. The division between what constitutes reasonable need (e.g. somebody worried that a mole may be cancerous) and demand (e.g. somebody requesting removal of an 'ugly' mole) is especially blurred in dermatology. Defining 'need' in dermatology is therefore quite difficult, and is a process which requires participation of society so that appropriate policies can be set in the light of finite resources.

Two population surveys conducted in the 1970s have produced useful data on the relationship between the need, supply and demand for dermatological care. In a study of 2180 adults in Lambeth who were examined for skin disease [6], it was shown that for those with moderate/severe skin disease, only 24% had made use of any medical service in the previous 6 months. A further 30% had used self-medication. Medical usage was still considerable for those with trivial skin disease, with 10% using medical services and 33% self-medicating.

In the US HANES-1 study [20], there was a considerable mismatch between what the dermatologists considered to represent medical need and what the population were concerned about. Only one-third (31%) of persons with significant skin pathology diagnosed by the dermatologists expressed concern about these specific skin conditions, whereas nearly 18% of those who complained about their skin conditions were not considered to have serious conditions by the dermatologists.

Thus, both of these population studies suggest that, at any one time, around one-quarter to one-third of the population have a skin problem which could benefit from medical care, yet around 80% do not seek medical help. As Savin points out [21], with increased public and professional awareness of effective treatment, this submerged sector of the population is likely to surface and place heavy demands on the current system.

The relationship between need, supply and demand for dermatology services in developing countries may be very different from those in developed countries. Many surveys have shown a high prevalence of need, mainly due to infectious dermatoses [22,23]. There is marked maldistribution of care for people with skin diseases throughout the world, with meagre to absent dermatological services in many countries [24]. Leprosy, onchocerciasis and leishmaniasis are probably the commonest skin diseases worldwide, but the epidemiological research afforded to these diseases is usually scanty. Groups such as the International Foundation for Dermatology work to remedy such inequalities, with the ultimate aim of a healthy skin for all [24]. Getting the right people to the right services is a major challenge. In the state of Guerrero in Mexico, for instance, skin complaints represent the second commonest reason for referral to rural clinics, resulting in a detrimental effect on other important activities such as immunization programmes and antenatal care [25]. In addition to such opportunity costs, this study also showed how much family income is wasted on ineffective treatments for skin infections and scabies.

Systematic reviews and evidence-based dermatology

Reviewing the effectiveness of services in the light of an epidemiologically based needs assessment helps health service planners to distinguish those interventions which confer maximum health gain (e.g. establishment of community leg-ulcer clinics) from those where services are ill-deployed (e.g. specialists involved in the routine treatment of viral warts) [4]. Using published evidence to help us make everyday clinical decisions on disease treatment is something that most physicians aspire to, yet with over 200 journals in dermatology alone [26], keeping abreast of important therapeutic developments in dermatology is difficult. Even enthusiastic teachers place their median reading time at about 2 h per week [27]. Most physicians therefore rely on reviews of the primary research in order to help them make therapeutic decisions in their daily practice. Unfortunately, the quality of such reviews is often suspect, because reviewers have not conducted their review in a systematic fashion with regard to the scientific principles of considering bias and sampling error [28]. Expert therapy reviews published in the top medical journals have been shown to miss important studies and to be far more biased in their conclusions when compared with systematic reviews [29]. Lessons from general medicine have suggested that deficiencies in reviews have meant that advice on some highly effective forms of care have been delayed for many years and other forms of care have continued to be used long after research has shown them to be ineffective or even harmful [30].

Over 20 years ago, the late Professor Archie Cochrane drew attention to our great collective ignorance on the effects of health care and explained how evidence from randomized controlled trials could help the use of resources more rationally, and proceeded to criticize the medical profession for not producing a critical summary by specialty of all relevant trials which is periodically updated [31]. The worldwide Cochrane Collaboration—groups of individuals dedicated to preparing and maintaining systematic reviews of health care—has evolved in response to this challenge [32]. Unlike traditional reviews, systematic reviews employ a structured methodology, which includes: (i) defining the primary objective of the review; (ii) defining the outcome measures; (iii) the systematic retrieval of all (published and unpublished) relevant material; (iv) abstracting the quantitative information; (v) summarizing the evidence; and (vi) interpreting the results. In addition to the benefits of reducing bias by inclusion of unpublished data and by giving more weight to high-quality studies according to predefined criteria, the increased statistical power afforded by the

quantitative pooling of many small studies (meta-analysis) can often provide a clear answer to many small studies which appear at first to be 'conflicting' in their recommendations [33].

Summarizing the effectiveness of various dermatological interventions (be these aimed at preventing new disease, treating established disease or preventing disability) is a time-consuming process. Like any scientific methods, techniques such as meta-analysis have their limitations [34,35]. Several systematic reviews of dermatological intervention have already been conducted, although the poor quality of dermatology trials in terms of unclear entry criteria [36], diversity of outcome measures [37] and inadequate details [38] have served as an obstacle for some reviews. The quality of reporting clinical trials in dermatological journals was poor when reviewed by Bigby *et al*. in 1985 [39]. This situation had changed little in the 1990s [40], although the adoption of the CONSORT guidelines for better clinical trial reporting by several of the top dermatology journals should help to improve the situation [41–43]. An international Cochrane Skin Group formed in 1997 in response to the challenge of providing an up-to-date summary of dermatological health-care interventions [44]. The editorial base of the Cochrane Skin Group coordinates a worldwide voluntary effort in preparing, maintaining and disseminating systematic reviews of health-care interventions in relation to skin diseases and maintains its own specialized register of dermatological clinical trials. Further information about the Cochrane Skin Group is available on the website indicated at the end of this chapter.

Conclusions

This chapter has demonstrated the fundamental importance that the discipline of epidemiology plays in understanding skin diseases in context, from the clinic to the population. Not only is epidemiology concerned with issues such as describing the incidence, prevalence and human and financial cost of skin disease, but it is also one of the most direct ways of finding out the causes of skin diseases. Finding out causes is important because it may lead to prevention of skin disease on a massive scale. For example, it has been found through a number of epidemiological studies that atopic eczema is less common in large, less economically advantaged families [1,2]. This observation gave rise to the hygiene hypothesis which postulated that increased exposure to microbes and infections in early life might protect against atopy [1,3]. The hygiene hypothesis led to a full-scale randomized controlled trial of lactobacilli cultures given to pregnant mothers and infants, a study which suggested that around 50% of atopic eczema could be prevented by such a measure in infants [4]. Even though this particular study had some potential flaws [5], it nevertheless demonstrates the power of prevention.

I have also shown how application of epidemiological principles has become a backbone to understanding and applying the principles of evidence-based medicine and health services research in relation to dermatology. Although traditional epidemiology may be superseded by genetic epidemiology and other new hybrids as biomedical knowledge develops, there will always be a need for a thorough understanding of the principles of assessing risk and the roles that chance, bias and confounding may play in any study. Similarly, the principles of critically appraising published literature using a framework derived from epidemiology are as basic to dermatological clinical practice as diagnosing skin rashes [6].

Glossary of epidemiological terms

Measures of disease frequency

Prevalence. The proportion of people with a disease at any one time. *Point* prevalence refers to prevalence at one point in time. *Period* prevalence refers to proportion with a disease (existing and new cases) over a longer period, for example 1 year.

Incidence. The rate of new cases developing over a specified time period, for example the incidence of melanoma in the USA in men in 1983–87 was 6.9 per 100 000 per year [1].

Measures of disease associations

Relative risk. This is the *ratio* of the risk of disease occurring in those exposed to the agent under investigation divided by the risk of those not exposed. It is a measure of the strength of the risk factor.

Attributable risk. This is the *difference* between the incidence rate in those exposed to a factor and the incidence rate in those unexposed. It is a measure of the absolute effect of the exposure.

Risk factor. A factor which increases the risk of disease. This could be a specific exposure, for example asbestos giving rise to mesothelioma, or an attribute such as gender or social class which is indirectly associated with an increased frequency of disease.

Odds ratio. An approximation of relative risk used in case–control studies. It is the ratio of the odds of exposure in cases to the odds of exposure in controls.

Interpreting results

Sampling error. This refers to the variation in values that a given sample could be expected to show by chance alone.

P-value. When referring to the association of a disease with a particular exposure, a *P*-value of < 0.05 means that a value as extreme as that obtained by the study would be expected to be observed by chance in less than one in 20 such studies (or $< 5\%$ of the time). It is convention at this level of significance to reject the null hypothesis of no difference between the compared groups.

*Confidence interval*s. This refers to the range of plausible values for a main study finding. It is based on the size of the sample and the size of the difference between compared groups. For example, the 95% bounds of a relative risk of 2.0 for smoking in a sample of psoriasis sufferers was 1.5–2.5. If the association is a genuine one, this means that the reader can be 95% confident that the true population relative risk resides between the values of 1.5 and 2.5.

Bias. Bias is a systematic error resulting in an incorrect conclusion about the association between an exposure and an outcome. Over 30 types of bias have been described [2], but they fall into two main groups: (i) *selection*, i.e. the two groups to be compared are not comparable in terms of factors in addition to the exposure of interest; and (ii) *information*, i.e. collection of information about the disease and exposure in a fashion that could bias response—for example, those evaluating a new drug were aware of the treatment allocation when assessing patients' response to treatment.

Confounding. This is where the association between an exposure and disease is mixed up with a third factor which is independently associated with both the exposure and the disease, for example the protective effect of prolonged breastfeeding (the exposure) on the development of atopic eczema (the disease) may be due to confounding by parental atopy. The risk of atopic eczema is increased in children born to atopic parents, and atopic parents are more likely to practise prolonged breastfeeding in their infants because they may be more aware of a possible protective effect of breastfeeding.

Association and causation. Association between an exposure and disease does not necessarily imply causation. Other factors such as chance, bias and confounding may explain that association.

Validity and repeatability

Internal validity, for example of a diagnostic test, refers to the extent to which the test measures what it is meant to measure. This is normally measured in terms of sensitivity (proportion of true cases correctly identified) and specificity (proportion of non-cases correctly identified).

External validity refers to the extent to which findings from one particular study (the study population) can be generalized to the target population—for example, to what extent are the favourable results of a clinical trial to test a new oral agent for children with severe atopic eczema attending hospital applicable to children with milder eczema in the community?

Predictive value. When comparing the performance of a test or diagnostic criterion to a gold standard (e.g. clinical diagnosis of melanoma against histological diagnosis), the positive predictive value refers to the probability that someone is a genuine case given a positive test result. Negative predictive value refers to the probability that a person does not have that disease given a negative test result. In addition to sensitivity and specificity, predictive value is dependent on the overall prevalence of the disease being studied [3].

Repeatability. This refers to the extent to which two observations agree with each other. This may be between two observers (interobserver agreement) or between replicate measurements in one observer (within-observer agreement). Repeatability is measured by chance-corrected agreement measures such as the κ statistic [4] or differences between two observers plotted against corresponding means of observations and *not* correlation coefficients [5].

Types of epidemiological study

Observational or descriptive studies. These are studies where the frequency of a disorder is described in terms of its association with various background attributes such as age, sex and ethnicity.

Analytical studies. These set out to test specific hypotheses on the relationship between a potential exposure and disease. These may be *cross-sectional*—for example 'Is atopic eczema more common in black Caribbean children in London compared with white children?'; *case–control*—for example 'Is a history of preceding infection more common in people with pityriasis rosea than in controls?'; or *cohort*—for example 'Are people who are exposed to diesel fumes more likely to develop asthma than those who are not?'

Intervention studies. These are studies in which groups of individuals are allocated to an experimental treatment prospectively. Clinical trials are the commonest examples. Occasionally such trials are conducted at a community level—for example, vaccine trials.

Screening. This refers to the examination of healthy people who would not otherwise have sought medical help for the presence or absence of disease. Principles for evaluating the usefulness of screening are described elsewhere [6].

Checklist for reading 'epidemiological studies' in dermatology

1 Is there a clear objective(s)?

2 Is the study design appropriate and efficient for the question posed?

3 Have cases (numerators) been clearly defined?

4 Is there a population denominator?
5 Have the main hypotheses and outcome measures been stated a priori?
6 Is there a rationale for the study's sample size?
7 Have potential confounders been considered and measured?
8 Has the study attempted to minimize selection and information biases?
9 Have the data been analysed appropriately?
10 Are the main results clearly presented with confidence intervals?
11 Have subgroups or *post hoc* findings been treated appropriately?
12 Have the authors discussed alternative explanations such as chance, bias and confounding?
13 Are the study's conclusions supported by the main results?
14 Who sponsored the study? Could sponsorship have affected the choice of data and the way they were presented?

Chapter 7

Histopathology of the Skin: General Principles

R. Cerio & E. Calonje

Introduction

As well as clinical examination, microscopic examination of skin tissue is probably the single most important diagnostic ancillary technique used by dermatologists in the management of patients with skin disorders. The correlation of clinical appearances with the dermatopathological findings is not only of direct benefit to individual patients, but has also led to the recognition of many new skin disorders and increased our understanding of the mechanisms of skin disease. The science and art of dermatopathology had its beginnings in early 19th-century Europe with the writings of pioneers like Simon, von Baerensprung, Unna and Gans. It is interesting that these individuals were dermatologists, and this tradition of dermatologists writing about histopathological aspects of skin disease was carried on by researchers such as F. Pinkus, A. Civatte, J. Darier, H. Montgomery, H. Pinkus, W. Lever, and more recently R.K. Winkelmann, E. Wilson-Jones and A.B. Ackermann. In the last century, major contributions to the discipline were made by British dermatopathologists [1,2]. During the last 20 years, the definition of numerous new disease entities and great advances in histopathological and related techniques have led to a wealth of publications on the histopathology of skin disease. Many major reference texts—largely written by dermatologists, but also by individuals trained as pathologists—are now available [3–9].

Close cooperation between the clinician and the diagnostic dermatopathologist is not only desirable, but also essential. The spectrum of skin disease, including rare genetic disorders, infectious diseases, neoplasms and a wide range of inflammatory disorders, is huge, and although in many conditions the histological features are pathognomonic of a particular skin disorder, in others the changes may be characteristic but not specific for one disease. Only by close liaison between the disciplines of clinical dermatology and histopathology can the usefulness and limitations of skin biopsy examination be appreciated. The clinician who reviews the histology of his or her own biopsies appreciates the problems of interpretation of an inadequate biopsy, a biopsy from an inappropriate or unrepresentative lesion, and the effects of artefact caused by undue trauma at the time of biopsy. The pathologist in turn can learn, for instance, that epidermal spongiosis and mild dermal inflammatory changes can represent chronic superficial dermatitis as well as the much commoner subacute eczema. He or she will learn with experience that features once signed out as 'non-specific dermatitis' are in fact specific for certain disorders.

Dermatopathology as a medical specialty is a rapidly expanding discipline, as witnessed by the plethora of recent publications, the development of many national societies for dermatopathology and the many international meetings currently taking place [1]. In several countries, including the UK, examinations such as the Diploma of the Royal College of Pathologists have been set up to assess proficiency in dermatopathology, and this practice is likely to spread. It is hoped that increasing numbers of clinicians and pathologists will become interested and expert in the discipline of histopathology of the skin and discover it to be both exciting and fun.

Table 7.1 Indications for skin biopsy.

Excision of epidermal or dermal neoplasm, whether benign or malignant. Clear margins are required
An incisional biopsy for confirmation of diagnosis of a lesion too big for removal, which will be treated by alternative methods, e.g. more complex surgery, radiotherapy or cryotherapy. Most useful for basal cell carcinoma or *in situ* squamous cell carcinoma (Bowen's disease); avoid in melanocytic lesions, particularly malignant melanoma
An incisional biopsy of a hard-to-categorize skin eruption. Most will be inflammatory; sometimes cutaneous T-cell lymphoma is suspected and two or three biopsies may be necessary
Fresh-tissue incisional skin biopsies for immunopathological study, especially immunofluorescence, in suspected autoimmune dermatoses, e.g. blistering disorders (perilesional skin) or lupus erythematosus (lesional skin)
Simultaneous processing of contiguous incisional biopsies for pathology and for culture of fresh, unfixed tissue when infection is suspected. The tissue can be cultured for various organisms including mycobacteria, deep fungi or examined for protozoa or filarial worms

Biopsy of the skin

A thorough understanding of both the indications for skin biopsy and the various biopsy techniques and their limitations is essential if the histopathologist is to provide the maximum useful information from study of biopsy sections. In addition to light-microscopic examination of paraffin-embedded tissue, material obtained from skin biopsy may be used for a variety of investigative procedures. These include ultrastructural examination, immunofluorescence studies and immunohistochemistry, microbiological studies, tissue culture and molecular biological methods such as *in situ* hybridization and polymerase chain reaction, mainly for immunoglobulin and T-cell-receptor gene rearrangement studies. These various investigative techniques often require specific specimens and transport conditions. The individual undertaking skin biopsy should have a clear idea, before carrying out the procedure, of the studies that are to be performed on the specimen obtained. It should be borne in mind that division of the specimen into many small portions for various techniques such as culture, direct immunofluorescence studies and light microscopy may lead to specimens too small, too unrepresentative or too traumatized to provide useful results.

Of the various indications for skin biopsy (Table 7.1), diagnostic skin biopsy is frequently used to confirm a clinical diagnosis or to aid in the establishment of a diagnosis where a clinical diagnosis is not apparent. Excision biopsy in the treatment of skin lesions, particularly malignant neoplasms and other lesions removed for cosmetic reasons, is often performed. In some situations, even when a clinical diagnosis is not in doubt, a biopsy reassures the patient that the clinician is taking an interest in his or her condition.

The type of biopsy, the selection of the site to be biopsied and the type of lesion to be biopsied where there is a widespread eruption are of utmost importance. Ideally, the lesion biopsied should be an early and untreated lesion and representative of the skin disorder as a whole. If lesions are present at all stages of evolution, such as may be seen in pityriasis lichenoides, it may be appropriate to biopsy more than one lesion. Multiple biopsies are also often helpful in conditions such as early cutaneous T-cell lymphoma, where definite histopathological diagnosis is often difficult. Normal skin should be included with a diagnostic biopsy wherever possible, and the inclusion of perilesional skin is essential when submitting biopsies for direct immunofluorescence studies. In certain conditions such as connective tissue naevi, the changes may be very subtle and comparison with normal neighbouring skin may be very helpful. It is equally important to ensure that the biopsy is deep enough. It is frustrating for the pathologist and clinician alike to receive a specimen with a request form suggesting a diagnosis of panniculitis where sections from the biopsy show only a portion of epidermis and superficial dermis. If lesions are widespread and there is a choice of biopsy sites, it is sensible to avoid areas liable to heal badly, such as areas over bony prominences and the lower limbs, and to avoid cosmetically important areas. Secondary changes in some areas of the body, such as changes of venous stasis in biopsies from the lower legs of older people, may be confusing to the inexperienced diagnostic dermatopathologist, and such sites are also best avoided.

Prior to skin biopsy, written informed consent is normally obtained from the patient, and in all but the smallest biopsies, local anaesthetic—usually 1% or 2% lidocaine (lignocaine) with or without epinephrine (adrenaline)—is injected around the biopsy site. Superficial blebs resulting from injecting local anaesthetic into the skin itself should be avoided. Injection of too much local anaesthetic into one area of the skin can cause a prominent distortion artefact in sections that are prepared from biopsy tissue. The effect of epinephrine on dermal blood vessels and mast cells has probably been overemphasized in the past. However, when biopsying conditions such as urticaria pigmentosa, it may be prudent either to avoid the biopsy site itself and inject the anaesthetic in a circle around it or to use an anaesthetic not containing epinephrine. Epinephrine and other vasoconstrictors should not be used in biopsies taken from the fingers or toes, as occasional intense vasospasm can result in tissue necrosis. Recently, topical anaesthetic gels have been developed as an alternative to injections for removal of superficial skin lesions. These topical anaesthetics are particularly helpful with biopsies performed in children. There are circumstances when skin biopsy is best avoided unless absolutely essential (Table 7.2).

Table 7.2 Relative contraindications to skin biopsy.

Infants	Although local anaesthetic creams/gels make this easier
Upper trunk	In order to avoid keloid formation
Lower legs in elderly patients	Poor healing may occur
Cardiac patients	Valvular disease means there is a potential risk of subacute bacterial endocarditis
	Aspirin/anticoagulants can produce extensive bleeding
Melanoma (incisional) biopsy	Primary excision is preferable to allow proper evaluation and an accurate diagnosis

Table 7.3 Skin biopsy techniques.

Excision	For removal of a single lesion. An elliptical or fusiform-shaped area of skin is removed
Incision biopsy ('wedge')	Similar to excision, but narrower; to include fat in suspected panniculitis. Some normal perilesional skin is included for comparison
Punch biopsy (3–6 mm)	Useful if tissue available is limited, but accurate sampling is essential. A rapid procedure sometimes useful in children
Curettage	For hyperkeratotic lesions, e.g. seborrhoeic keratoses, viral warts, basal cell carcinomas. Usually accompanied by cautery
Shave biopsy	For facial protuberant lesions, e.g. benign intradermal naevi
Snip	For skin tags. Skin snips also for onchocerciasis

Techniques of skin biopsy (Table 7.3) [10,11]

Elliptical surgical biopsy

This is one of the most commonly used diagnostic skin biopsy techniques. Equipment required includes scalpel, fine-toothed forceps, needle holder, scissors and eyeless needle with suture (Fig. 7.1). The use of a skin hook greatly facilitates manipulation of the biopsy specimen and avoids undue trauma. A reasonable size for an elliptical biopsy is about 5 mm, but smaller specimens may be adequate where indicated for cosmetic reasons. Small lesions may be totally excised, but a biopsy of a larger lesion should be at right angles through the margin to include adjacent normal skin. The long axis of the wound should, where possible, follow the natural crease lines of the skin. A full discussion of surgical techniques and suture materials is beyond the scope of this chapter, but there are several excellent reviews [10–12] and aspects of cosmetic dermatological surgery are discussed in Chapter 78.

Fig. 7.1 Instruments for skin biopsy, including scalpel, scissors, needle holder and skin hooks.

Punch biopsy

The biopsy punch is a metal cylinder of variable diameter with a sharp cutting edge at one end, usually attached to a plastic handle (Fig. 7.2). The punch is pushed into the skin with a downward twisting movement, and then removed. The tissue specimen is lifted and separated from the underlying tissue, and removed from the biopsy punch.

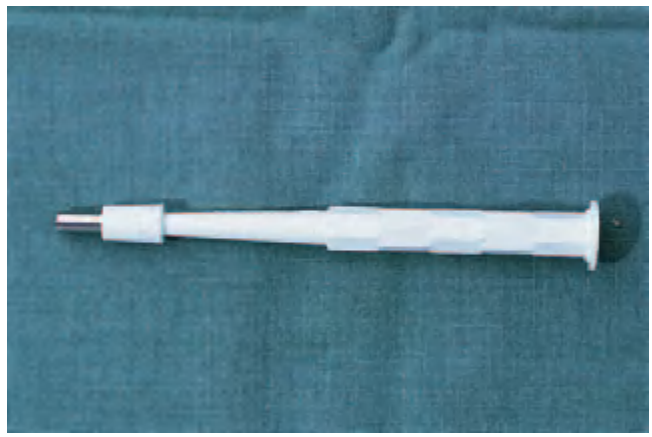

Fig. 7.2 Disposable punch for cutaneous biopsy.

The wound may be left to heal without suturing, the base of the wound being cauterized by electrocautery or some other haemostatic agent. Many operators, however, prefer to insert one or two sutures to secure haemostasis.

Punch biopsies are convenient and quick to use, but it is preferable to use at least a 3-mm punch to obtain a satisfactory specimen. Biopsy punches blunt easily, and therefore disposable punches are recommended. Another problem with small punch biopsies is that the specimen is often difficult to orientate, and most pathologists greatly prefer elliptical excision biopsies for diagnostic interpretation. In general, a punch biopsy should not be used for the diagnosis of cutaneous tumours, and this is particularly true for melanocytic lesions. Nevertheless, punch biopsies do have a place in busy outpatient departments and office practices, particularly for diagnosis and management of small cutaneous lesions.

Curettage [10,13]

The technique of curettage with a sharp-edged Volkmann's spoon or disposable curette followed by cautery is often used for the treatment of small benign and malignant skin lesions, such as viral warts, solar and seborrhoeic keratoses, and basal cell carcinomas. The resulting specimen is often badly fragmented, and it is often impossible to comment on adequacy of removal. A combination of curettage and shave excision has been proposed to overcome this problem [14]. Curettage alone is more useful as a therapeutic procedure than as a technique for providing ideal specimens for histopathological diagnosis. It must be emphasized that all specimens should be submitted for histopathological examination. Haemostasis may be achieved by electrocautery, alginate dressings or using aluminium chloride hexahydrate solution on a cotton bud rolled over the wound.

Shave biopsy

Certain superficial benign papular or nodular lesions may be treated by shaving off the lesion flush with the surface of the surrounding skin. Many sorts of superficial skin lesion may be treated in this way, in particular melanocytic naevi. Although often a useful cosmetic result may be obtained, this technique has several drawbacks. The whole lesion is rarely removed, and recurrence of the lesion is sometimes a problem. In the case of melanocytic naevi, it is known that lesions that recur following partial excision may often demonstrate atypical histopathological features, sometimes leading to an erroneous diagnosis of a malignant lesion [15]. As with the techniques of curettage and punch biopsy, the wounds resulting from the procedure of shave biopsy normally require some form of cauterization or use of aluminium chloride hexahydrate to achieve haemostasis.

Other biopsy techniques

Various other ways of obtaining portions of skin tissue for diagnostic purposes have been described, including needle biopsy, similar to that used for tissue diagnosis of liver disease and lymph-node pathology (see section on cytodiagnosis). The results from such a technique are generally unsatisfactory for skin lesions, and in no way compare with those achieved using more conventional surgical procedures. One technique that has been described particularly in relation to establishing the diagnosis of basal cell carcinoma—for example, prior to considering treatment with radiotherapy—involves use of a dental broach [16]. This instrument is inserted into the suspected tumour and is drawn out; a smear is made from the cells adhering to the shaft of the instrument. The smear is then dried, stained and examined microscopically. Cells of basal cell carcinoma may be identified in the smear, but in the authors' opinion false-negative results are frequent. Various techniques have been described for the study of the detailed anatomy of the skin surface, including the examination of adhesive tape peeled from the skin and the use of various polymerizing adhesives such as cyanoacrylate, which form a replica of the microanatomy of the skin surface [17]. Although in some clinicians' hands these provide useful information in the study of keratinizing disorders such as the ichthyoses, and in disorders of the hair follicle [18], the amount of information they provide is limited. Techniques for slit-skin smears for leprosy and skin snips for onchocerchiasis are discussed in Chapters 29 and 32, respectively.

Information to be provided with the specimen

For the clinician to obtain the optimum help from the pathologist, it is essential that full clinical details be provided. A fully completed histopathology request form should include the following details for each specimen. The patient should be identified by name, sex, age and usually a hospital reference number, or some other identification record number. It is useful to know the patient's racial group, as prominent epidermal basal layer melanin pigmentation may be pathological in some situations, and represents normal skin for other individuals. A brief clinical history of the duration of the skin condition should be provided, together with details of any treatment including topical and systemic therapy. The site of each biopsy taken should be clearly identified on the request form, and accompanied by specimens in separate, individually labelled containers. Unfortunately, it is not uncommon to receive several biopsies from what are thought to be trivial lesions from the same patient in one container. Sometimes it turns out that one of these lesions is histologically malignant and the others are benign, and in these circumstances it may be impossible to determine the site of the malignant tumour.

Details of previous biopsies, and where possible the histopathology report reference numbers, should always be included on a request form, and finally a suggested clinical diagnosis or list of differential diagnoses is helpful. Where possible, abbreviations should be avoided. It may be that many pathologists will recognize the letters PLC as standing for pityriasis lichenoides chronica, but perhaps there would be fewer who would immediately recognize the letters TMEP as representing a form of urticaria pigmentosa.

Finally, but most importantly, the dermatologist or surgeon sending the biopsy material to the pathologist should give some clear indication on the request form from whom the biopsy is being sent, or to whom the report should be forwarded. If some of the simple advice above were more often heeded by clinicians performing biopsies, it would make the life of a dermatopathologist very much easier.

Care of the specimen

Care is required throughout the biopsy procedure, to avoid trauma to the specimen with forceps or any of the other instruments used during biopsy. The use of skin hooks in manipulating the specimen during biopsy is helpful in this respect [19] and, in order to avoid trauma artefact, division of small specimens into multiple smaller portions of tissue for different diagnostic purposes should be avoided. If a specimen is needed for four separate studies—such as paraffin embedding, direct immunofluorescence studies, electron microscopy and microbiological culture—it is often better to take two separate specimens and divide each of these into two portions than to attempt to divide one specimen into quarters. Biopsies taken for ultrastructural studies should be small (of the order of 1–2-mm cubes) to allow for adequate fixation. Once the biopsy specimen has been taken, it should be placed epidermal side uppermost on a small portion of filter paper, to prevent curling, and transferred promptly to the appropriate transport medium.

For routine diagnostic microscopy of paraffin-embedded material, 10% neutral buffered formalin is still the most widely used fixative and is satisfactory for most purposes [20]. Many other fixatives [20,21] and transport media such as Michel's [22] (Table 7.4) are available, and these are indicated for either the study of specific diseases or tissue components, or for the application of specific diagnostic techniques such as immunofluorescence [23]. The use of Michel's medium allows the preservation of antigens for immunofluorescence studies for up to 6 months [24]. By using Michel's medium, specimens may be sent safely without the need for immediate freezing. This medium is also useful for fixation of samples used in immunoelectron microscopy studies [25] and also seems to preserve the antigens relevant for investigation of genetic blistering skin diseases [26]. Table 7.5 gives some details of the more important fixatives and transport media.

Table 7.4 Michel's transport medium for fresh cutaneous tissue.

Ammonium sulphate	55 g in 100 mL buffer
Buffer	1 mol/L potassium citrate (pH 7), 2.5 mL 0.1 mol/L magnesium sulphate, 5 mL 0.1 mol/L ethyl maleimide, 5 mL Distilled water, 87.5 mL Mix 1 : 2 with 1 mol/L potassium hydroxide to pH 7.0

Table 7.5 Fixatives and transport media for skin biopsy specimens. (Details of most methods are given in Bancroft and Stevens [20].)

Investigative technique	Fixative/transport medium	Comments
Most routine diagnostic studies on paraffin-processed material	10% neutral buffered formalin solution (pH 7)	Most useful fixative for general use
	10% aqueous formalin (unbuffered)	H&E staining generally better than with buffered preparation Formalin pigment a nuisance
	Carnoy's solution (pH 2.8)	Good preservation of nuclear chromatin Haemolyses red blood cells. Use small specimens
Where rapid fixation required	Place specimen in the oven in alcohol	Microwave fixation
When good preservation of mucopolysaccharides is required	Formal saline solution (pH 3.8)	Nuclei badly distorted. Not satisfactory for routine purposes
Demonstration of leprosy bacilli	FMA fixative or Zenker's fluid	Good results for acid-fast bacilli with Wade–Fite stain Mercury deposits must be removed
Transmission electron microscopy and some electron immunocytochemistry	Karnofsky's solution or 2.5% buffered glutaraldehyde solution. Post fixation with osmium tetroxide	Small specimens required, normally no more than 1-mm cube
Immunofluorescence and immunoenzyme techniques	Various. Periodate lysine paraformaldehyde fixation and cold processing useful for some endothelial cell markers	Various fixatives suitable depending on technique and antigen/substance to be identified. Frozen tissue may be required
Transport of specimens for immunofluorescence studies	Michel's medium	Specimen must be thoroughly washed in phosphate-buffered saline before immersion in Michel's medium
Microbiological studies, studies on fat tissue and some immunohistological investigations	Fresh or frozen tissue	Specimens for microbiological examination should be placed in sterile containers and transported to the laboratory as soon as possible

Laboratory methods

Specimen preparation

Frozen sections are not used routinely in dermatopathology, except for Mohs' micrographic surgery (described in Chapter 78) and immunofluorescence. Most antibodies used in diagnostic dermatopathology work adequately in samples fixed in formalin, and except in the context of research, frozen sections are therefore not used on a regular basis for immunohistochemical studies. Frozen sections are used for the diagnosis of autoimmune blistering disorders and also for the diagnosis of blistering genetic skin diseases. Although it has been advocated that autoimmune blistering disorders may be diagnosed with immunohistochemistry performed on samples fixed in formalin, the results are often of inferior quality and interpretation is difficult, leading to false-negative and false-positive results.

Careful identification and preparation of tissue specimens prior to processing is most important. The first requirement is that the biopsy specimen be placed immediately into a fixative solution. Various routine fixatives are employed; most contain 10% formalin. Because a stock solution of formalin consists of 40% formaldehyde, 10% formalin is really 4% formaldehyde. A minimum of 12 h fixation is recommended for most specimens, but small specimens may only need 6 h, and larger specimens a longer period of fixation, to produce optimal results. After fixation, the biopsy tissue is removed from its container, double-checking that the specimen corresponds with details given on the request form, and the pathologist produces a macroscopic description together with details of 'the cut up'.

Special care should be taken where multiple fragments of tissue are present, for example, in specimens obtained by curettage. It may be necessary to pass the contents of the biopsy container through a filter paper to ensure that all relevant portions of tissue are processed and examined. After orientating the specimen, a description should be made of the size and shape of the specimen, and a note made of whether subcutaneous or other tissue is included. A careful description of surface changes is then made, with particular reference to changes of colour and surface texture, such as erosion or ulceration. Any obvious clinical lesion present on the gross specimen should be described. In some surgical specimens, an identification label, such as a skin suture, is left in place in the biopsy specimen by the surgeon, to enable precise orientation of the specimen. This is particularly important when dealing with neoplastic lesions, where clearance of tumour in the margins of the biopsy specimen needs to be assessed.

Prior to sectioning of a gross specimen, especially excised tumours, it is good practice to paint the margins of the biopsy specimen with coloured dyes that are resistant

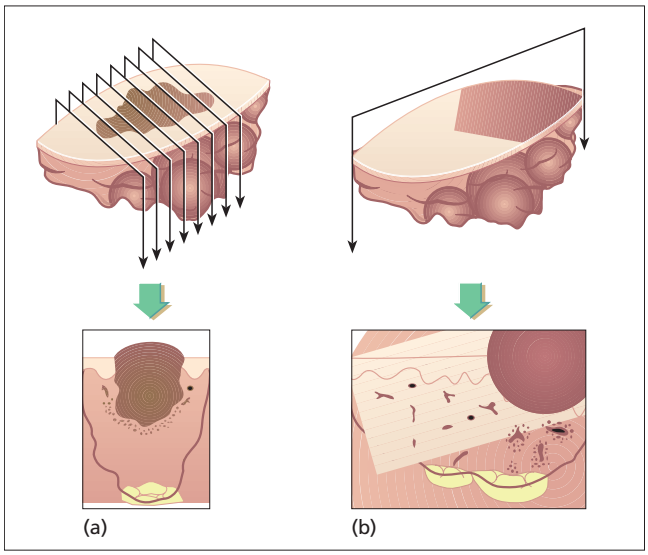

Fig. 7.3 Blocking of elliptical skin biopsy specimens. (a) Neoplastic lesions. Multiple transverse blocks through the whole lesion allow for histopathological examination of the tumour at all levels, and assessment of the narrowest excision margins. (b) Incisional biopsy of inflammatory lesion. Longitudinal blocking is recommended. This allows optimal visualization of the affected and adjacent normal skin.

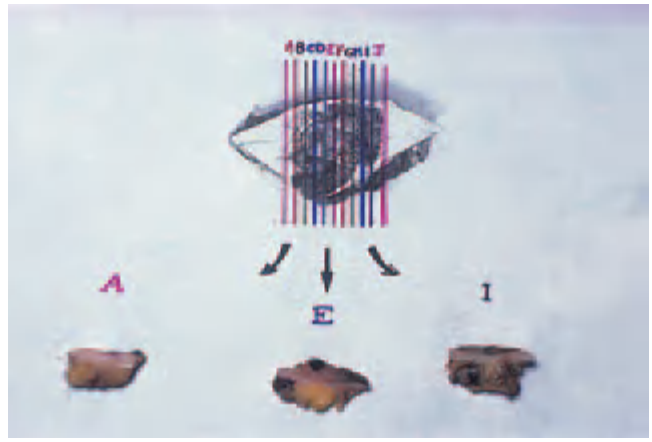
(a)



(b)

Fig. 7.4 Photocopy procedure for recording the preparation of blocks. (a) The appearance of a macroscopic specimen of malignant melanoma. (b) Transverse blocks are taken from the specimen, and their exact position is recorded on a photocopy made from the surface of the gross specimen.

to tissue processing. Various commercial preparations are available, and one or several colours may be used. If the dye is visible on the final tissue section examined by the pathologist, this implies that no tissue has been lost in processing, and that the edge of the section corresponds to the genuine margin of the biopsy. After painting of the biopsy margins, the gross specimen is then sectioned prior to the preparation of histological blocks. There are various techniques for cutting up a standard elliptical skin biopsy. The ideal method depends to some extent on the nature of the suspected diagnosis. A specimen from an excision biopsy of a benign or malignant skin tumour is better handled by taking transverse blocks through the specimen, so that the narrowest excision margins may be examined. For malignant lesions, particularly for suspected malignant melanoma, ideally transverse blocks should be taken at 2-mm intervals throughout the whole length of the lesion (Fig. 7.3a) [1]. An elliptical biopsy, taken, for instance, from the margin of a patch of inflammatory alopecia on the scalp, is best sectioned longitudinally, so that both normal and abnormal skin can be visualized (Fig. 7.3b). With larger specimens, examination of a selection of transverse blocks made from various portions of the tumour may be adequate for diagnostic purposes. Any biopsy tissue not processed should be labelled, and returned to the fixative in the container and stored. Laboratories have different policies regarding the retention of fixed tissue specimens. Ideally, all specimens should be retained, but limitations of space often mean that most routine specimens can be discarded after a period of a few weeks after the histopathological report has been approved and signed.

In addition to a written description of the gross specimen, and how it has been prepared for blocking, a rough diagram of the specimen is very useful, particularly with larger specimens. This enables clear identification of the portion of the specimen from which various blocks have been taken. An alternative approach for larger specimens, especially when dealing with neoplastic lesions, is to wrap the specimen in clear cling-wrap film and take a photocopy of the surface. This produces an image the same size as the gross specimen, and details of the blocks taken can be recorded directly on the photocopy image (Fig. 7.4).

Very small specimens may be blocked in their entirety after trimming. Other blocking techniques may be used for specific purposes. An example is the blocking of transverse sections of cylindrical punch biopsies of scalp

disorders [2,3]. This technique is particularly useful in the assessment of various forms of inflammatory alopecia, and facilitates the quantitative morphometric analysis of pilosebaceous follicles and the hair itself. The technique also provides a useful method of studying the morphological details of the normal transverse anatomy of follicular structure, including the various phases of the normal hair cycle. Ideally, when investigating a condition presenting with alopecia, two biopsies should be provided: one for vertical sectioning and one for horizontal sectioning. If immunofluorescence studies are required, the specimen for vertical sectioning can be divided into two portions.

Table 7.6 Potential dermatopathological artefacts.

Poor orientation confusing true epidermal and papillary dermis appearance
Formaldehyde fixation vacuolation of epidermis
Scratch marks across tissue due to nick in microtome knife
Tissue carry-over from microtome knife
Foreign bodies, e.g. formaldehyde pigments, suture, *Alternaria*, spores, starch
Polarization of cell nuclear material by electric current in curetted specimens
Clumped mitoses in podophyllin-treated warts
Pyknotic prickle cells from methotrexate- or hydroxyurea-treated patients

Routine tissue processing

Although the skin biopsy specimen may be examined with various techniques, at least a portion of most skin biopsies is routinely processed for light microscopic evaluation of sections from paraffin-embedded tissue. In most modern histopathology departments, the tissue processing is carried out by the use of automated machines. Although it is maintained that superior results may be possible by manual means, this often involves the changing of processing fluids at inconvenient times, and is a time-consuming and labour-intensive procedure. Two main types of automated tissue-processing machine are in use: the traditional carousel type and the enclosed pumped fluid type. Both types of machine have the facility for multiple separate stages in processing. Whether tissue processing is carried out by machine or by hand, after completion of fixation the same basic steps of dehydration, clearing and embedding are involved. The process of dehydration removes aqueous fixative and any tissue water. Clearing refers to the use of a substance such as xylene, which is totally miscible with both the dehydrating agent that precedes it, and the embedding agent that follows it.

For embedding, paraffin wax at 56°C remains by far the most popular material; it is cheap, large numbers of tissue blocks may be processed in comparatively short times, and later sectioning and staining are straightforward. The use of vacuum impregnation in modern and automated tissue-processing machines considerably reduces the overall processing time. At the end of the embedding procedure, paraffin blocks are cut and stained and are then ready for microscopic examination. The dermatopathologist should be aware of relatively common potential artefacts that can cause confusion and misinterpretation (Table 7.6). When urgent preparation of tissue specimens is required, various processing steps can be shortened. The use of very thin portions of tissue, increasing the temperature of the fixative, microwave-fixation techniques [4–6] and shortening the time used for clearing, can all facilitate rapid processing. Alternatively, cryostat sections can be examined. The tetrahydrofurin (dioxane) method for embedding specimens, which also allows for very quick processing and produces sections of a high technical quality, is nowadays rarely used because of concern over toxicity of reagents.

Routine staining techniques, including histochemistry (Table 7.7)

By far the most widely used stain for section from skin biopsies used in histopathology laboratories is haematoxylin and eosin (H&E). This staining technique gives good definition of many cellular and tissue structures in the skin, and is sufficient for the diagnosis of most skin diseases. This stain, however, does not clearly demonstrate certain tissue components, such as elastic fibres, and does not allow differentiation between melanin, haemosiderin and other skin pigments. Special stains are required for these purposes, and also for confirming the nature of abnormal dermal deposits, such as calcium, mucin and amyloid. Another important indication for special staining techniques is the demonstration of microorganisms. Full details of the techniques and applications of special stains used in diagnostic dermatopathology are given in standard reference texts [7–9]. Examples of commonly used staining techniques that are useful in the diagnosis of specific conditions are given below.

The periodic acid–Schiff (PAS) stain demonstrates the presence of carbohydrates, particularly some polysaccharides such as glycogen, and mucoproteins containing neutral mucopolysaccharides. These substances are stained reddish purple by the PAS reaction. Because the cell walls of fungi and yeasts contain neutral polysaccharides, they also stain positively with the PAS reaction. The technique is also useful in demonstrating blood-vessel walls, basement membrane (Fig. 7.5), fibrin deposition and the presence of glycogen deposits, for instance in certain sweat gland tumours, such as clear cell hidradenoma, trichilemmoma and some epithelial lesions of uncertain histogenesis, such as the clear cell acanthoma of Degos. The identification of glycogen can be further confirmed by removal by enzyme digestion with diastase in 1% aqueous

Table 7.7 Some tinctorial stains used in dermatology.

Special stains	Tissue constituent	Appearance
Periodic acid–Schiff (PAS)	Glycogen	Magenta red (diastase sensitive)
	Mucopolysaccharides	Red (fungal wall red)
Van Gieson	Collagen	Red
	Muscle, nerve	Yellow
Congo red	Amyloid	Red with green birefringence
Acid orcein–Giemsa	Elastic fibre	Dark brown
	Collagen	Pink
	Melanin	Black
	Haemosiderin	Green/yellow
	Amyloid	Light blue
	Mast cell granules	Purple
Masson's trichrome	Collagen	Green
	Muscle + fibrin	Red
Aldehyde fuchsin	Elastic fibre	Purple
Gomori's	Reticulin	Black
Alcian blue (pH 4.5, 0.5)	Acid mucopolysaccharides	Blue
Toluidine blue	Acid mucopolysaccharides	Metachromatic purple including mast cells
Perls' Prussian blue	Iron (haemosiderin)	Blue
Masson's Fontana	Melanin	Black
Von Kossa	Calcium salts	Brown/black
Grocott's	Fungus wall	Black
Methenamine silver	Bacteria	
	Gram+	Blue/violet
	Gram–	Red/pink
Ziehl–Neelsen/Wade–Fite	Acid-fast bacilli	Red

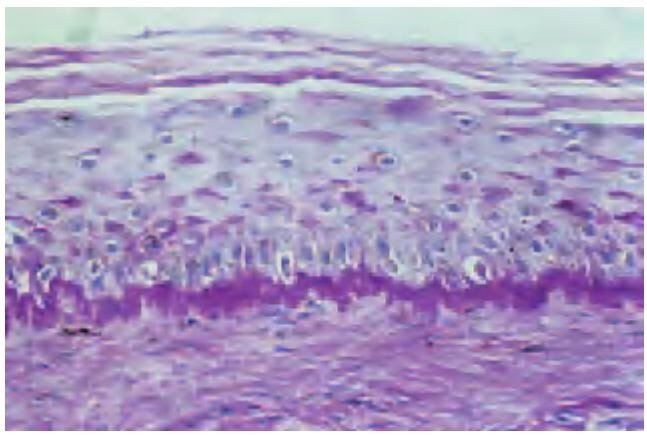


Fig. 7.5 Periodic acid–Schiff (PAS) stain, showing thickening of the basement membrane zone in cutaneous lupus erythematosus.

solution at 37°C for 30 min. Positive staining after the use of diastase indicates the presence of neutral mucopolysaccharides.

The Alcian blue reaction produces a blue coloration in the presence of acid mucopolysaccharides. In addition to demonstrating the presence of mucin in cutaneous mucinoses, the technique is also of value in some cases of extramammary Paget's disease, and occasionally in the demonstration of goblet cells in metastatic carcinoma of the gut. There are small amounts of acid mucopolysaccharide present in the ground substance of normal dermis, and the Alcian blue reaction is very pH-dependent. Care should therefore be exercised in the interpretation of a positive result.

Acid orcein and Giemsa stain was popularized by Pinkus and Mehregan, who recommend its use as a second routine stain [10]. It is a valuable technique which, demonstrates, in addition to structures normally visible with H&E stain, the presence of mast cells, eosinophils, metachromatic substances and elastic fibres. The routine use of the orcein–Giemsa stain often avoids recutting of blocks for other special stains. Orcein itself is a constituent in other staining methods, particularly those used to demonstrate elastic fibres.

Special staining techniques are often essential to differentiate between epidermal and dermal deposits of melanin, haemosiderin and other substances. Masson's ammoniacal silver nitrate technique produces a densely black reaction product with melanin. Melanin deposits appear greenish black with the acid orcein–Giemsa stain referred to above. Iron, which in the context of skin biopsy material normally means haemosiderin pigment, is demonstrated by Perls' Prussian blue reaction, which yields a deep-blue reaction product in the presence of ferric and ferrous iron.

Trichrome stains can demonstrate various elements of connective tissue. Common examples are the van Gieson stain, in which collagen appears red and muscle and

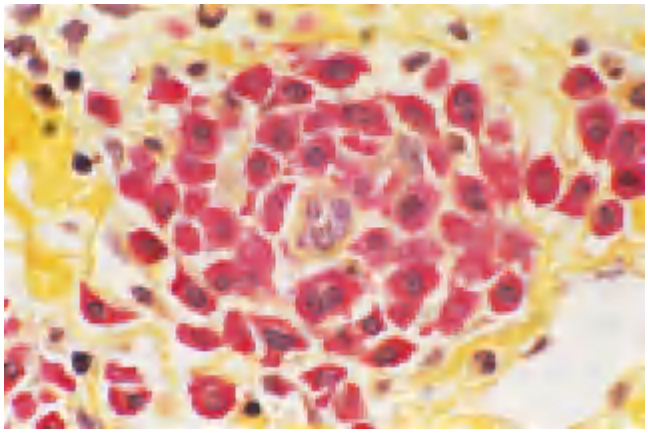

Fig. 7.6 The chloroacetate esterase stain. Mast cells appear red with this technique.

nerves yellow, and Masson's trichrome stain, in which collagen is green and muscle red.

Reticulin fibres are demonstrated by Gomori's silver impregnation technique. This technique is particularly useful in the study of certain cutaneous tumours, including vascular tumours and malignant melanoma. The application of this method to melanocytic lesions may reveal foci of expansile growth undetectable in normal H&E-stained preparations.

Certain types of cell present within the skin may be difficult to recognize on conventional H&E-stained material. Mast cells are best demonstrated either by the use of a metachromatic staining technique, such as toluidine blue, or with one of the few enzyme histochemical methods that may be carried out on paraffin-embedded tissue, such as the chloroacetate esterase reaction. The use of this technique applied to formalin-fixed paraffin sections was described by Leder [11], and mast cells and myeloid white cells are easily identified by their bright pinkish red staining (Fig. 7.6). Other histiocytic and dendritic cells that are difficult to visualize on routinely stained material are best visualized with immunohistochemical methods.

Cutaneous deposits of various naturally occurring and foreign substances often require special staining techniques for their demonstration. The von Kossa method produces a black coloration in the presence of calcium salts, and amyloid deposits may be demonstrated using crystal violet or Congo red. With this latter technique, amyloid deposits stain pinkish red, and under polariscopic examination there is a green birefringence. Another technique useful for the demonstration of amyloid deposits is the thioflavine T method, yielding green fluorescence on examination with a fluorescence microscope. Unfortunately, several of the staining techniques recommended for the demonstration of amyloid are technically unreliable, and none is absolutely specific for amyloidosis. Some cotton dyes other than Congo red, such as pagoda red, have been claimed to be as sensitive as Congo red while being more specific [12]. It is recommended that more than one special stain be used if amyloid is suspected. Occasionally, even with the use of several special stains, amyloid cannot be demonstrated and electron microscopy is necessary for this purpose.

A wide range of techniques is employed for the demonstration of microorganisms in the skin. Reference has already been made to the usefulness of the PAS stain in the demonstration of yeasts and fungi. The silver staining technique of Grocott is also very helpful in the identification of fungal hyphae and yeast bodies. These structures stain black on a pale-green background. Other silver techniques, including the Warthin–Starry technique, are useful in demonstrating spirochaetes, *Bartonella henselae* (the organism that causes bacillary angiomatosis) and *Borrelia* in tissue sections. *Bartonella* may also be demonstrated by the use of a Giemsa stain. The traditional Gram stain demonstrates coccal and bacillary organisms in the skin. Several techniques are available for the demonstration of acid-fast bacilli. The Ziehl–Neelsen method is widely used for the demonstration of mycobacteria, particularly *Mycobacterium tuberculosis.* It is based on the capacity of the lipid-rich cell wall of mycobacteria to take up strong phenol-dye solutions. This dye is retained after differentiation in acid or alcohol. Mycobacteria stain magenta and the background is blue. Auramine–rhodamine is also a sensitive method for demonstrating mycobacteria in tissue sections. Its main drawback is that it requires the use of a fluorescence microscope for interpretation [13]. The Ziehl–Neelsen method should not be used for demonstration of leprosy bacilli. The use of this technique often leads to a false-negative result. The reason for this is that the leprosy bacilli are less acid- and alcohol-fast. The Wade–Fite stain, or a modification of this technique, is more appropriate for identification of leprosy bacilli because it uses minimal treatment with alcohol and acid.

Even with the above techniques, demonstration of small numbers of microorganisms in the skin may be very difficult, and may require the examination of very many sections. Using one of the newer antibody-labelling techniques, with immunofluorescence or immunohistochemical methodology may save some time. Recently, *in situ* hybridization and polymerase chain reaction (PCR) techniques have also been applied to routine skin specimens to confirm the presence of various microorganisms, especially viruses, leishmania and mycobacterial DNA in suspected infected skin [14–22]. PCR is a very valuable tool for confirming the diagnosis in these infections, but very stringent conditions are required to avoid false-positive results. This method is particularly useful in cases with suspicious histology in which special stains and cultures have been negative. It is important to highlight that mycobacterial DNA has been found in cutaneous lesions of nodular vasculitis and papulonecrotic tuberculid [19,23].

While this confirms the relationship between these two entities and tuberculosis, it does not necessarily mean that the finding may be interpreted as evidence of tuberculous infection in the affected sites.

Immunopathology

There are some situations where even after careful biopsy of an appropriate lesion, expert tissue processing and sectioning, and the use of several special staining techniques, a specific histological diagnosis is still not possible. The use of immunological methods permits the identification of antigens, antibodies and various other cell and tissue components, and has greatly facilitated our ability to achieve a specific diagnosis. Hybridoma monoclonal antibody technology paved the way for the development of numerous antibodies to cell and tissue structures. Further refinement and experimentation with immunohistological techniques has brought this powerful new diagnostic tool within the reach of most histopathology laboratories, particularly with increasing commercial availability of diagnostic cell markers that label routine paraffin sections (Table 7.8).

Immunofluorescence methods

Immunofluorescence is a technique for detecting the presence and position of antigens, antibodies, other cell secretions and cell components in cells or tissue sections. The principle of the technique is that certain fluorochrome dyes exposed to ultraviolet (UV) light emit fluorescent radiation, the colour of which depends upon the particular fluorochrome. When these dyes are conjugated to proteins that are subsequently added to tissue sections, or injected into an animal, the position of the proteins can be traced microscopically by the fluorescence they emit under illumination with UV light with suitable filters.

Two fluorochromes are generally available. Fluorescein is most commonly used. It is best conjugated to protein in the form of fluorescein isothiocyanate, which emits an apple green fluorescence. The second dye is rhodamine RB200, which is conjugated to protein as rhodamine isothiocyanate or sulphonyl chloride; it emits an orange fluorescence.

Preparation of tissues

Tissues to be examined are usually snap frozen in liquid nitrogen, cut in a cryostat at about –20°C, dried and stained without fixation. Sections can be fixed, before staining, in cold acetone or methanol, provided that these agents do not alter the antigenicity of, or dissolve, the substances to be detected [1]. This provision also applies to the technique of cold formaldehyde [2] or alcohol fixation of tissues, and embedding in paraffin for cutting on a microtome at room temperature. The use of acetone, ethanol and methanol enhances tissue preservation, but sometimes increases non-specific staining.

Some antigens can be detected in routine paraffin tissues [3]; others are masked after fixation in formalin, para-formaldehyde or glutaraldehyde and paraffin embedding. Such antigens can be 'retrieved' or revealed, and detection improved, by heat in strictly controlled conditions [4–8]. Heat treatment is by pressure cooker or by microwave. Before treatment, paraffin-embedded sections must be baked overnight at 55°C on charged or silane-coated slides to ensure adherence and then

dewaxed. The heat retrieval solution is citrate buffer, 10 mmol/L sodium citrate made pH 6.0 by HCl. When heated in a pressure cooker, the slides in open metal racks, well spaced, are placed in hot buffer in the pressure cooker and as quickly as possible heated to 15 lb pressure for 1 min only. Then the pressure cooker is plunged into a sink of cold water. In the more often used microwave method, the slides are placed in Coplin jars containing the same buffer; the jars are placed in an open dish. The dish may contain water but this is not essential. The tissues are heated for variable periods; 15 min is usually adequate. Antigens in skin should not require more than 10 min. After the first and every 5 min after, the fluid in the Coplin jar is replenished with water to replace that lost by evaporation. Unfortunately, the dermis is susceptible to disintegration if heating is excessive, though eccrine and sebaceous glands and larger blood vessels remain. The treated sections are stained by standard methods of immunofluorescence or by immunoenzyme techniques.

Some antigens require protease treatment instead of heat; this is usually indicated on the leaflets accompanying vials of commercial antibodies.

Labelling procedures

Tissue sections must be wetted and treated with protein to block or reduce non-specific binding for at least 30 min. The diluent is phosphate-buffered saline (PBS) +0.1% Triton X100 and protein which may be 0.5% chick albumin, or 0.5–2.0% bovine serum albumin or, rarely, 2–5% of the serum of the same species as the primary antibody. The diluent for the antibody is PBS with 0.1% Triton X100 and 0.5% chick or bovine albumin.

The two principal labelling techniques (Fig. 7.7) are direct staining (Fig. 7.7a), in which sections are incubated with fluorochrome-labelled antibody to detect substances (i.e. the corresponding antigen) in tissues, and indirect staining (Fig. 7.7b), in which unconjugated antibody is incubated with the section, and any bound antibody is detected by the subsequent addition of fluorochrome-conjugated antiglobulin sera. These simple techniques may be modified for more sophisticated investigations by using double staining (Fig. 7.7c) on the same section, one with a fluorescein-labelled antibody, the other labelled with rhodamine or some other fluorochrome-conjugated antibody. Thus, it is possible to detect antigen and antibody in an immune complex (Fig. 7.7c) or a secreting cell and its secretions. Usually, the two-labelled antibodies are derived from different species.

Direct labelling. Direct staining is used to detect substances, including antibody immunoglobulins in tissues (e.g. *in vivo* bound immunoreactants as in pemphigus and pemphigoid), by the addition of fluorochrome-conjugated antibodies (Fig. 7.7a) with subsequent washing to remove

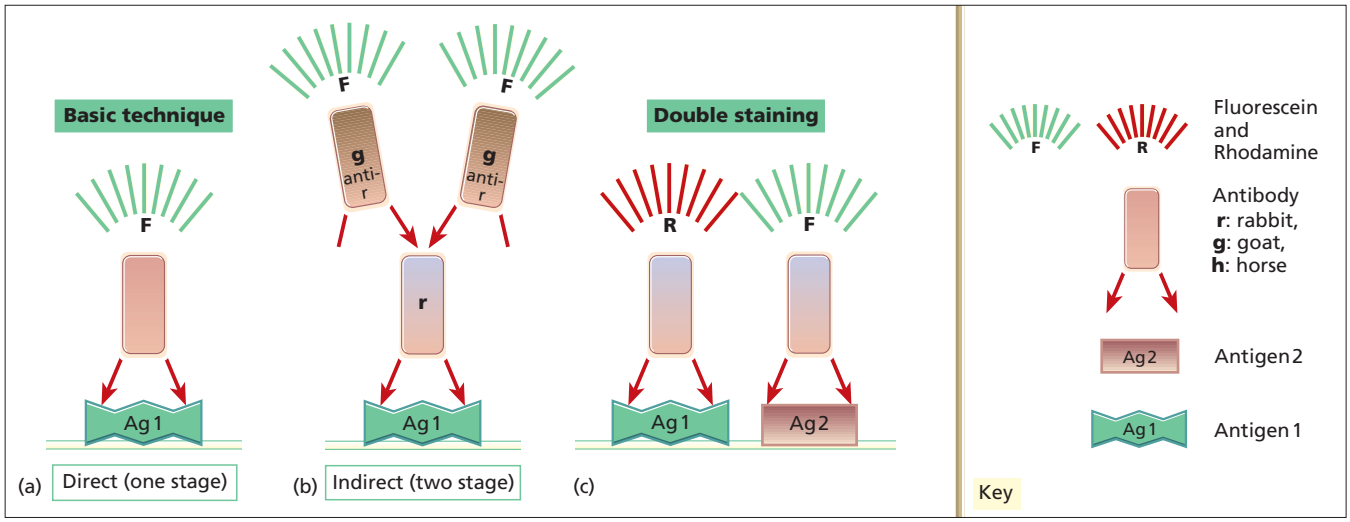

Fig. 7.7 Diagrammatic representation of immunofluorescence techniques.

from the preparation all the conjugated antibody except that fixed to the particular substance. The details of the method are as follows.

1 For critical examination to detect small amounts of antigen, sections treated with the conjugated antibody are maintained in humid conditions overnight at 4°C. For more routine procedures, antibody treatment is for 2–4 h at room temperature in a humid container. The containers must be light-proof.

2 Wash tissue in PBS pH 7 with three changes for a total of 20 min.

3 Mount in commercial antifade mountant fluids.

Indirect labelling. The unconjugated antibody, or primary antibody, is incubated with the specimen to bind to the test antigen; the uncombined surplus is removed by washing, and the preparation stained by a fluorochrome-conjugated antiglobulin serum, i.e. this is the secondary antibody which binds to the primary antibody (Fig. 7.7b). The details of the indirect staining method are as follows.

1 Incubate the tissue with the antibody to the test antigen. This is the primary antibody. Overnight treatment is preferable.

2 Wash in PBS with three changes for at least 20 min.

3 In a light-proof humid container, incubate the sections for 30–45 min at room temperature with the conjugated antiglobulin antibody; this is the secondary antibody, to bind to and label the primary antibody.

4 Wash in PBS for 20 min (three changes) with the least exposure to light.

5 Mount.

Indirect staining with conjugated antiglobulin sera is more sensitive than direct staining with conjugated antibodies, because more conjugated antiglobulin molecules are fixed to antibody in the second stage than are antibody molecules fixed to antigen in the first stage. The method has, however, the disadvantage that it increases the likelihood of non-specific staining.

Results are dependent upon the quality of the antibodies. Monoclonal antibodies, which bind to a small sequence of antigen determinants (epitopes), may have weak affinity and be eluted during washing. False-negative results also occur when the particular epitopes are not exposed; thus monoclonal antibodies to different epitopes of the same antigen vary in their ability to detect the antigen.

Technical limitations

All that glows is not specific fluorescence. The two major sources of error are autofluorescence and non-specific binding.

Control tests. In routine use, the specificity of the conjugated antisera and optimal washing dilution is established and blocking tests are not required, except perhaps in sites of severe inflammation. For critical or experimental studies, blocking tests may be required to prove antibody specificity. Before addition of the conjugated antibody, sections may be treated with normal serum of the same species, or unconjugated specific antibody of the same subclass but against an irrelevant antigen, or unconjugated specific antibody, although this is usually expensive. If the selected pretreatment does not block the binding of the subsequent addition of the test-conjugated antibody, the staining is considered to be antigen-specific. Labelled antisera should be centrifuged before use, to remove any particulate matter, and the glass slides, sections and washing solutions should be free of dust, which readily adsorbs conjugates.

Autofluorescence. Tissues exposed to UV light emit their own fluorescence. In skin, this is not quenched by fixation, and is best controlled by appropriate filters.

Antigen non-specific staining. Non-specific staining refers to fluorescent staining of a section by a labelled antibody, not resulting from a specific antigen–antibody reaction. The causes of non-specific staining and the methods available for removing it are described in detail by Nairn [9].

Appropriate blocking before antibody treatment is essential (see above). The use of optimal dilutions of labelled antibody avoids excess fluorochrome application to the tissue, thus reducing potential non-specific staining. Neutrophils, eosinophils and histiocytes are particularly prone to absorb globulins non-specifically, which accounts for much of the apparently specific fluorescence of inflammatory lesions.

The antigen non-specific binding of fluorescein conjugates by eosinophils can be inhibited by prior treatment of the sections with diaminobenzidine in hydrogen peroxide [10,11].

Another source of confusion is the presence of 'natural' antibodies in the labelled antiserum that combine with sites other than those containing the antigen under examination. This does not apply to monoclonal antibodies and rarely to commercial polyclonal antibody, but they may be present in laboratory-prepared polyclonal antibodies. Natural antibodies are removable by absorbing the antisera with tissue powder from the same species as the tissue under test. Aggregated IgG in the conjugate will also bind non-specifically. Aggregation will occur in conjugates frozen and thawed repeatedly; therefore, conjugates should be stored as small samples and discarded after use. It is advisable to centrifuge the antibody before use.

A peculiarity of immunofluorescence tests on skin is the affinity of the stratum granulosum for antibody–fluorescein conjugates. The nature of this antigen non-specific binding has not been ascertained. Tests on the basic protein or filaggrin peculiar to stratum granulosum cells have not shown this to be the binding substance. However, careful preparation of the conjugates provides reagents with little or no affinity for the stratum granulosum.

Counterstaining. Identification of the particular cells or structures binding labelled antibody may be difficult if there is poor contrast with the background, if there is much autofluorescence and if the specific fluorescent binding is weak. Procedures to identify sites of specific binding are combined phase contrast and immunofluorescence, counterstaining for all the background tissue, or selective stains for nuclei. Counterstains have been used successfully but no one technique is applicable to all preparations. The emission from the counterstain may swamp the specific immunofluorescence if the preparation is thick or the charge affinity is strong, as may occur following the addition of Evans blue or brilliant cresyl violet [9] or of unconjugated rhodamine isothiocyanate to provide contrast to the green specific immunofluorescence. Instead of staining all the structures in a tissue, another counterstain procedure is to use dyes that selectively bind to nuclei to identify cells, for example propidium iodide [12,13], ethidium bromide [14] or *p*-phenylenediamine [15], the latter having the additional advantage of reducing fading of the immunofluorescence.

Photobleaching. Fading or photobleaching is a technical limitation of immunofluorescence. Prolonged or repeated examination reduces the intensity of emission, which also decays if preparations are exposed to sunlight. This fading can be reduced by the addition of *p*-phenylenediamine to the buffered glycerol mounting fluid [16]. This dye was subsequently found to be a useful nuclear counterstain.

Immunoenzyme methods [1,2]

The immunoenzyme (immunoperoxidase) methods have several advantages over immunofluorescence:
1 Standard microscopes and illumination are used.
2 The preparations are permanent, and the reaction products do not usually fade on repeated examination.
3 Counterstains enable cells containing antigen to be identified with more certainty than using immunofluorescence with dark-ground illumination.
4 Examination is less tiring for the microscopist.
5 The preparations may be examined by electron microscopy.

Technical limitations

Inflammatory lesions may contain endogenous peroxidase activity, and such sections have to be pretreated to remove it [3–5]. Furthermore, it is possible for the antigen to be modified by the pretreatment, with the result that it is more difficult to detect. This mainly applies to examination of lesions. Normal tissues, e.g. those used as a substrate to detect antibodies in a patient's serum, rarely require pretreatment. The problem with endogenous peroxidase is analogous to the disadvantage of autofluorescence in the immunofluorescence preparations.

There is less contrast with immunoperoxidase methods than in slides treated by the immunofluorescence technique, and fine stippling or cytoskeletal structures seen by immunofluorescence are not quite so easily detected by immunoperoxidase. Although immunofluorescence may be more discriminating in detecting small amounts of antigen in cryostat-cut sections, the immunoperoxidase methods, used on paraffin-embedded tissues [6] for antigens that are stable during preparation, provide more definite resolution of the tissue and sites of antigen.

Immunoperoxidase methods have another advantage in being the preferred method to re-examine tissues stored in paraffin blocks after routine histology, provided that the antigens are stable in the fixative and dehydrating agents.

Recent improvements in immunoenzyme techniques have resulted in their application to many investigations. The reagent antibody is conjugated with an enzyme, usually horseradish peroxidase, and the antibody conjugate combines with the antigen in the test preparation. The site of binding is detected by adding a substrate for the enzyme: the degradation of many molecules of substrate leaves a deposit confined to the site of binding. Sites of peroxidase activity appear as dark-brown granular deposits that are seen distinctly in contrast to suitable counterstains, for example methyl green or Mayer's haemalum.

Although the application described is the detection of antigen in tissue sections and cell suspensions or monolayers, the principle of the method is the same as that of the enzyme-linked immunosorbent assay (ELISA).

Chemical conjugation of peroxidase to antibody

Antiglobulins conjugated with peroxidase, and peroxidase–antiperoxidase (PAP) complexes, described below, are available commercially. There are occasions, however, when it is desirable to prepare the conjugated reagents. Peroxidase may be conjugated to antibody by glutaraldehyde [7] or by periodate oxidation.

Use of conjugates

The horseradish peroxidase, conjugated to antibody or to globulin, may be applied to sections to detect antigen by procedures similar to those used for immunofluorescence. There are, however, modifications that increase the sensitivity of the method so that it is equal to, or possibly more sensitive than, indirect immunofluorescence [8–10].

The diagrammatic representation of the procedures seen in Fig. 7.8 shows the different forms of conjugate. Antibody against the antigen to be detected may be conjugated directly with the enzyme (Fig. 7.8a). This is not a very discriminating procedure. The indirect or two-stage procedure, whereby the unlabelled antibody bound to the antigen is detected by antiglobulin conjugated to enzyme (Fig. 7.8b), increases sensitivity by increasing the number of conjugated antibodies binding to the site, and is more versatile, because one conjugated antiglobulin can detect any antibody of that species.

Two other procedures increase the sensitivity of the technique. The antibody bound to the antigen is treated with unconjugated antiglobulin, which in turn is treated with normal globulin of the same species as the first antibody (Fig. 7.8c), for example, a sequence of rabbit antibody, goat antirabbit globulin and then rabbit normal globulin conjugated with peroxidase.

In the second modification, instead of using globulin conjugated chemically with enzyme in the third stage, a PAP complex is added (Fig. 7.8d) [8,10], for example, rabbit antibody to peroxidase, which gives a more discrete, intense reaction product than chemically prepared conjugates of normal globulin–peroxidase, possibly because chemical treatment tends to alter the antigenic determinants of the normal globulin, and to polymerize the peroxidase.

If the antibody applied to the section is human, it is not possible to use a human antiperoxidase antibody in the PAP complex in the third stage. Instead, a baboon antiperoxidase, which is antigenically similar to human IgG, is a satisfactory alternative [11].

The enzyme most frequently used is horseradish peroxidase, which forms a dark-brown product from its substrate. Alkaline phosphatase may also be used, and the

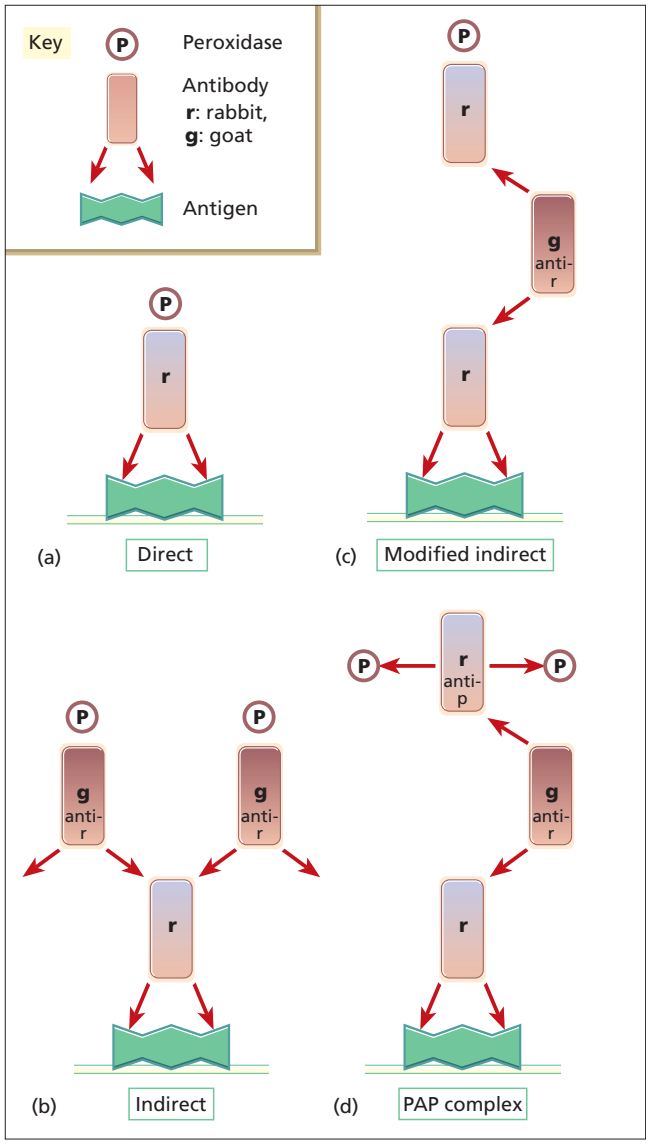

Fig. 7.8 Diagrammatic representation of immunoperoxidase techniques.

reaction product with its substrate is blue. The two enzymes may be used with appropriate antibodies on the same tissue or cells to detect different antigens, and the relationship of one antigen to another (i.e. double staining).

Examination of fixed frozen sections

There are three stages in the procedure:
1 The preparation of the tissue sections.
2 Treatment of the sections with the peroxidase-labelled antibody.
3 Chemical reaction to detect the peroxidase in the tissue.

Preparation and fixation of sections. Sections may be prepared from routine cryostat-cut samples or paraffin-embedded material, and may be treated for antigen-retrieval as described above. Some improvement in cryostat-prepared sections may be achieved by short-term fixation in dilute formalin, as follows.
1 Fix thin slices (2 mm thickness) with 1% formaldehyde in 0.1 mol/L phosphate buffer pH 7.2–7.4 for 30 min.
2 Wash in three changes of 15% sucrose in 0.1 mol/L phosphate buffer pH 7.2–7.4 for 18–24 h at 4°C.
3 Snap freeze in isopentane at the temperature of liquid nitrogen.
4 Cut sections 4–6 µm in a cryostat. Mount on slides, and dry under a fan at room temperature.

Treatment of the sections with antibody. Control for antibody specificity is as described for immunofluorescence. Sections may be treated by the methods described above (Fig. 7.8). The indirect method is probably the most suitable for general use, applying unlabelled antibody, followed by labelled antiglobulin.
1 Moisten section in PBS.
2 Treat with suitable dilution of specific antibody in PBS in a moist chamber at room temperature for 30 min–2 h.
3 Rinse well in PBS: then in two washes of PBS, each for 5 min with gentle agitation. (As the tissues are fixed they are less likely to be washed off the slides than unfixed tissues in the immunofluorescence technique.)
4 Treat with peroxidase-conjugated antiglobulin specific for the antibody applied in step 2. Use at optimum dilution in PBS for 30 min.
5 Rinse well: wash in PBS for 15 min.

Detection of the peroxidase reaction product by staining. The substrate is a carcinogen and should be handled in small quantities with appropriate precautions. It is made up as follows:
- 3′,3′–diaminobenzidine tetra-HCl (DAB), 25 mg
- 0.05 mol/L pH 7.6 Tris–HCl buffer, 50 mL
- 3% hydrogen peroxide (H_2O_2), 0.15 mL

Dissolve the DAB in the buffer and add the H_2O_2 immediately before staining.
1 Slides treated with conjugated antibody or antiglobulin and washed are incubated with the substrate solution for 5–15 min (the longer period is not always an advantage).
2 Wash in tap water for 5 min. (If required, the reaction products may be intensified by 2% osmium tetroxide for 1 h, and the slides then washed.)
3 If required, the slides may be counterstained with methyl green, or Mayer's haemalum.
4 Treat for about 1 min each with 70%, 90% and twice with 100% industrial spirit, followed by two treatments with xylol.
5 Mount with DPX or Permamount.

Controls

It is necessary to confirm that the reaction observed reflects antibody-conjugated peroxidase and not endogenous peroxidase, and that the antibody binding is specific for antigen.

One section should be stained with DAB only; another section with DAB–methanol–H_2O_2, to confirm the absence of endogenous peroxidase.

Paraffin sections

If the antigens to be detected are stable in the fixatives and dehydrating agents, the immunoperoxidase methods may be applied to sections from paraffin-embedded tissue. The best results are obtained when the tissue is prepared for this particular purpose [6,8,12], but tissues prepared routinely for histology may also be examined by this method. The paraffin is removed from the sections with xylol and alcohols; sections are subsequently treated as for frozen sections.

The identity of the cells and tissues containing the antigen is much more easily determined by this method than by cryostat-cut sections, or by immunofluorescence. Immunoglobulins and hormones may be readily detected, but some antigens, such as those of bacteria in vasculitic lesions, tend to be extracted during processing.

Conjugates involving avidin–biotin coupling of antibody and enzyme

Instead of chemical covalent binding of antibody to enzyme to prepare conjugates, the two reagents may be linked non-covalently by the very strong affinity between biotin (a vitamin widely distributed in mammalian tissues) and avidin (a glycoprotein of egg white). Biotin is coupled to the reagent antibody through formation of an intermediate biotin derivative, and the avidin is coupled to the selected enzyme by glutaraldehyde [13]. Each biotin molecule has one combining site for avidin, and avidin has four sites for biotin, although not all of these would combine in a test system. Guesdon *et al*. [13] described two procedures.

1 The antibody–biotin conjugate is incubated with and combines with antigen in the test section or cell. This is followed by addition of peroxidase conjugated with avidin. The avidin binds the peroxidase to any biotin, and subsequent treatment with the substrate for the enzyme reveals the antigen sites (Fig. 7.9a).

2 The antibody–biotin conjugate is used as above to bind to any antigen. Avidin is then added, which becomes strongly linked to the biotin. Then biotin-labelled enzyme is added and the avidin bridges the biotin molecules. As the avidin has a potential four valencies for biotin, there is an enhancement or amplification of the enzyme binding, and therefore greater discrimination of the sites of antigen (Fig. 7.9b).

A further modification has been reported, the avidin–biotin–peroxidase complex (ABC) method (Fig. 7.9c), similar to the PAP method already described. A prepared ABC follows the use of biotin-labelled antiglobulin (to detect unlabelled reagent antibody, or tissue-bound antibody in the tissue). The complex binds through the avidin bridge to biotin on the antiglobulin; the method results in greater intensity of staining [14].

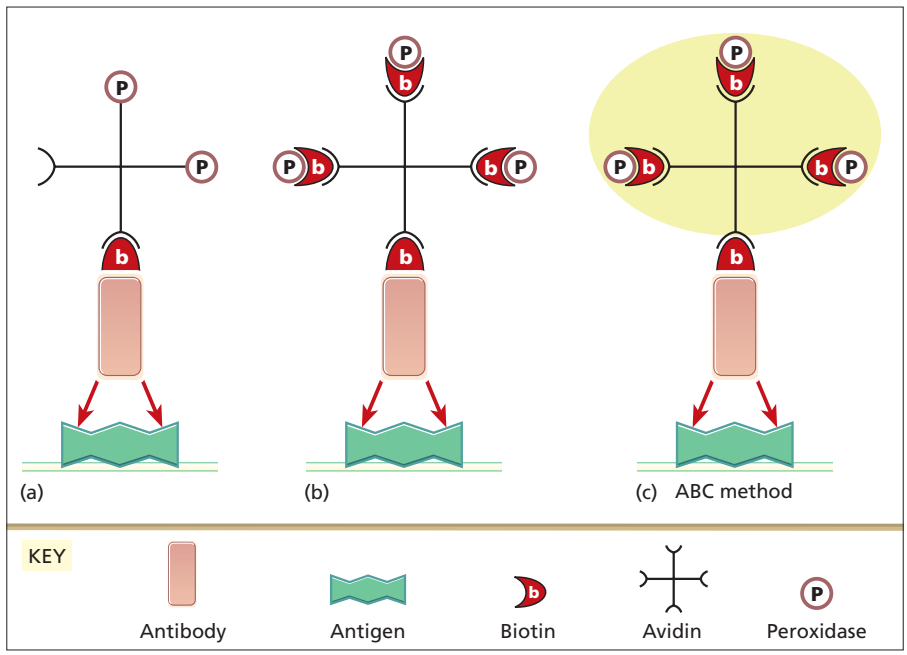

Fig. 7.9 Avidin–biotin staining methods. (a) Antibody coupled with biotin binds with the antigen in tissue. Avidin coupled with peroxidase binds to the biotin on the antibody. Treatment with enzyme substrate reveals the bound peroxidase, and therefore site of antigen. (b) Antibody coupled with biotin binds with the antigen in tissue. Avidin will bind the biotin–antibody complex. Biotin coupled with peroxidase will then bind to the free avidin-combining sites. Finally, treatment with enzyme substrate reveals the bound peroxidase. (c) Complexes (shown within yellow circle) are formed of biotin, coupled with peroxidase, incubated with moderate excess of avidin (ensuring some free avidin combining sites). Antibody coupled with biotin binds to antigen in tissue. The complexes are added to the tissue and the free avidin sites bind to the biotin on the antibody. Finally, treatment with enzyme substrate reveals the bound peroxidase.

As in the other immunodetection techniques, it is necessary to ensure that there is no autologous tissue background activity that will cause confusion when interpreting results. In the biotin–avidin methods, it is necessary to eliminate the possibility of endogenous peroxidase activity as in any peroxidase method. It is also necessary to inactivate endogenous biotin present in tissues that would bind the avidin-labelled reagents. However, overcoming any endogenous activity is a complex multistep activity [15] and is not necessary if the appropriate controls (e.g. tissue treated with the avidin conjugates) show no binding.

Applications of immunopathology techniques [1,2]

The immunopathological methods described above have revolutionized diagnostic histopathology, and have helped us to recognize, classify and understand the pathogenesis of a wide variety of cutaneous disorders. Although there are many antigens of diagnostic value that are not stable following formalin fixation and paraffin-embedding of tissue, there is still a wide range of antigens that are stable. Refinements to processing techniques, such as the periodate lysine paraformaldehyde technique [3] have increased the range of antibodies and labels that may be used for diagnostic purposes [1,4,5]. A few of the more important areas of diagnostic dermatopathology that highlight the usefulness of immunopathological techniques are described below (Table 7.9). Immunopathological techniques for the diagnosis of connective tissue diseases and autoimmune blistering diseases mainly rely on the use of immunofluorescence methods. Although some have suggested that immunoperoxidase methods are equally reliable in this setting, formalin fixation results in poor preservation of the antigens of interest and false-negative results are frequent. In the last decade, immunofluorescence studies have been increasingly used with success in the diagnosis of genetic blistering diseases particularly, epidermolysis bullosa (see Chapter 40). Samples are fixed in Michel's medium and frozen sections are processed in the same way as samples submitted for the diagnosis of autoimmune blistering disorders.

Table 7.9 Direct immunofluorescence findings in autoimmune blistering disease.

Disease	Pattern and nature of immunoreactants
Pemphigus	Epidermal cell-surface deposits of IgG and C3
Bullous pemphigoid	Linear, homogeneous deposits of IgG (epidermal side on salt-split skin) and C3 at the dermal–epidermal junction
Linear IgA dermatosis	Linear homogeneous deposits of IgA at the dermal–epidermal junction
Herpes gestationis	Linear homogeneous deposits of C3 at the dermal–epidermal junction
Epidermolysis bullosa acquisita	Linear homogeneous deposits of IgG (dermal side on salt-split skin) and C3 at the dermal–epidermal junction
Cicatricial pemphigoid	Linear homogeneous deposits of IgG and C3 at the dermal–epidermal junction
Dermatitis herpetiformis	Focal granular deposits of IgA at the papillary tips
Bullous eruption of lupus erythematosus	Linear homogeneous, or non-homogeneous, deposits of multiple immunoglobulins, C3 and fibrin at the dermal–epidermal junction

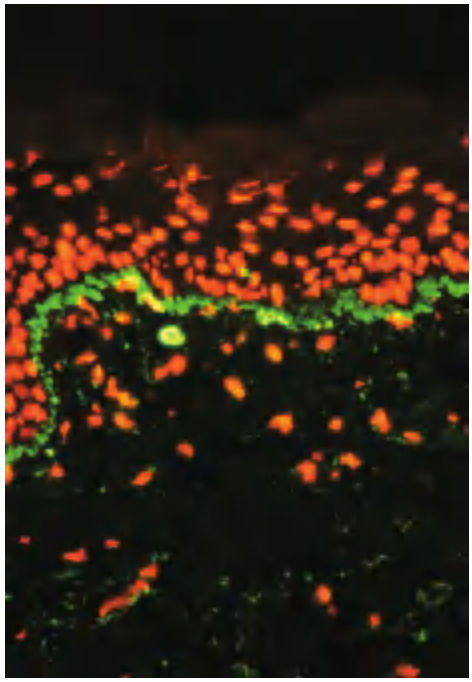

Fig. 7.10 Direct immunofluorescence of lupus erythematosus, showing speckled basement membrane zone deposition of IgM (green); ethidium bromide counterstain (orange). (Courtesy of Mr B.S. Bhogal, St John's Institute of Dermatology, London, UK.)

Lupus erythematosus

The deposition of immunoglobulins and complement at the dermal–epidermal junction is of diagnostic value in patients with lupus erythematosus (Fig. 7.10) and is known as the lupus band test. The presence of immunoglobulins, particularly those other than IgM, at the dermal–epidermal junction in normal non-sun-exposed skin correlates to some extent with the presence of systemic lupus erythematosus and renal involvement. Sequential biopsies may demonstrate the disappearance of a positive lupus band during periods of disease inactivity, and may aid the clinician in the management of the disease. However, this approach is hardly ever used, as it implies repeated invasive procedures and disease activity may be monitored in a simpler way with blood tests. A positive lupus band is usually seen in involved skin in cutaneous lupus erythematosus, but false-positive results may be seen in sun-exposed skin from patients who do not have lupus. Immunofluorescence studies, in conjunction with other serological investigations, have led to the recognition of various important subsets of lupus erythematosus. Examples of this include the high incidence of anti-Ro/SSA and anti-La/SSB antibodies in the sera of patients with subacute lupus erythematosus and neonatal systemic lupus erythematosus [6].

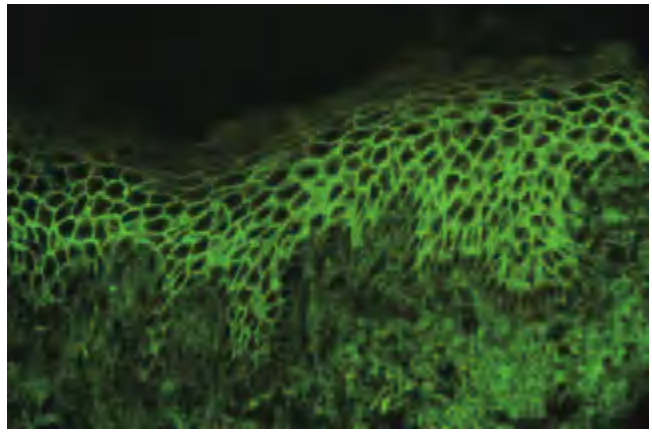

Fig. 7.11 Direct immunofluorescence of pemphigus, showing deposition of intercellular IgG in the epidermis. (Courtesy of Mr B.S. Bhogal, St John's Institute of Dermatology, London, UK.)

Bullous disorders (see also Chapter 41)

The histological diagnosis of the various cutaneous autoimmune blistering diseases should always be confirmed with immunofluorescence studies. Although in many non-autoimmune blistering diseases a diagnosis can be made on the basis of light microscopic features in biopsies from formalin-fixed tissue, in immunological diseases a specific diagnosis is often not possible. In these circumstances, immunofluorescence studies are essential. Other techniques including immunoelectron microscopy and immunoblotting are extremely helpful. The classification and understanding of the pathogenesis of numerous bullous disorders has been greatly facilitated by advances with these techniques. Ideally, tissue for immunopathological examination and serum for indirect immunofluorescence studies should always be taken at the time of a skin biopsy in a patient with an acquired blistering disorder. The biopsy submitted for immunofluorescence should be from perilesional or clinically normal skin. If lesional skin is submitted for immunofluorescence studies, a false-negative result is often obtained. The results of direct immunofluorescence studies on skin biopsies vary considerably depending on the disease being investigated, and the site of the biopsy. Intercellular epidermal deposition of IgG is present in almost all cases of pemphigus (Fig. 7.11). Complement is also frequently present, and IgA and/or IgM may be seen in a smaller percentage of cases. The additional presence of basement-membrane-zone IgG, or the C3 component of complement, points to a diagnosis of pemphigus erythematosus. Linear basement-membrane-zone IgG and complement deposition, and less commonly IgA or IgM, is associated with bullous pemphigoid (Fig. 7.12). Identical results are usually obtained in epidermolysis bullosa

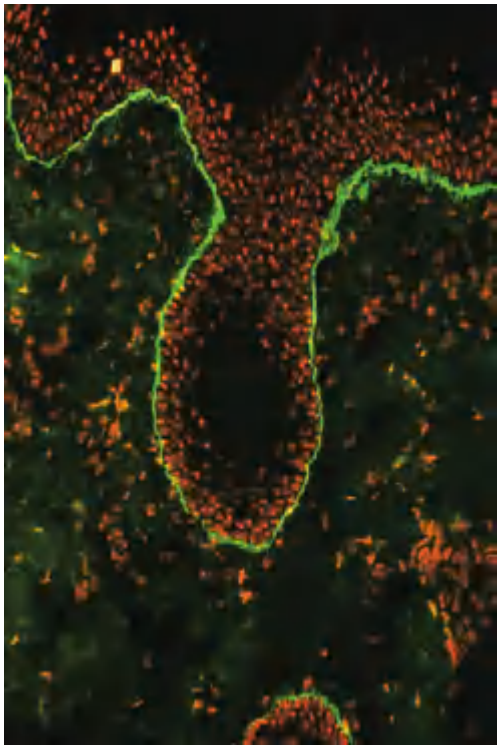

Fig. 7.12 Direct immunofluorescence of bullous pemphigoid, showing linear basement membrane zone deposition of IgG (green); ethidium bromide counterstain (orange). (Courtesy of Mr B.S. Bhogal, St John's Institute of Dermatology, London, UK.)

acquisita. The differential diagnosis is greatly aided by the use of the split-skin technique. In this technique, the exposure of the specimen to 1 mol/L NaCl induces a subepidermal blister. In epidermolysis bullosa acquisita, the immunoreactants line the floor of the blister and in bullous pemphigoid, the immunoreactants line the roof of the blister. With the indirect immunofluorescence technique using patient serum, the detection of linear basement-membrane-zone immunoglobulin antibodies is much more common in the classical form of bullous pemphigoid than in the cicatricial form of the condition, where positive results are obtained in approximately only 10% of cases. The diagnosis of other blistering diseases such as herpes gestationis (pemphigoid gestationis) and dermatitis herpetiformis is also greatly facilitated by immunopathological studies. In addition to direct immunofluorescence examination of skin biopsy material, and indirect immunofluorescence studies carried out on patient serum, the split-skin technique is valuable in the study of most of the subepidermal blistering disorders, enabling localization of the antibody-binding sites to be visualized [7]. Data obtained from such research has shed considerable light on the pathogenesis of many blistering diseases. Since the advent of immunopathological techniques, several new blistering diseases have been categorized. These include linear IgA bullous dermatosis, which is probably identical to some forms of chronic bullous disease of childhood, and epidermolysis bullosa acquisita, where linear basement-membrane-zone immunoglobulin is almost always demonstrable, and circulating antibasement membrane immunoglobulin antibodies may be found in approximately one-quarter of cases investigated. Immunoblotting and related techniques enable specific antigens to be categorized more precisely [8,9] and such techniques are likely to lead to the delineation of new bullous dermatoses in the future.

Cutaneous neoplasms [1,5,10–12]

One of the most useful applications of immunopathology is in helping to determine the line of differentiation of poorly differentiated benign and malignant neoplasms that may arise from the various cellular components within skin and related tissues. The development within the last few years of increasing numbers of antibodies and other labels that can be utilized on formalin-fixed paraffin-embedded material has increased the usefulness of this application. All the antibodies discussed below work well in formalin fixed paraffin-embedded material.

Keratins and other epithelial markers

Cytokeratins represent a group of intermediate filaments known as tonofilaments of variable molecular weight that may be demonstrated in keratinizing and non-keratinizing epithelia [13,14]. They represent the main structural component of the cytoskeleton of epithelial cells. About 30 different keratins have been demonstrated in humans by the use of double-diffusion gel electrophoresis. Their molecular weight ranges from 40 to 68 kDa. Keratins are divided according to molecular weight and their charge properties into acidic (type I) and neutral-basic (type II) [13,14]. They associate as pairs of one acidic and one basic keratin polypeptide molecule with each epithelial cell containing at least one keratin pair. The antibodies against keratins most commonly used in dermatopathology include AE1/AE3, MNF116 and CAM 5.2. They are all cocktails containing several monoclonal antibodies of different molecular weight. CAM 5.2 is a low-molecular-weight keratin antibody, which labels most epithelia, with the exception of stratified squamous epithelia [15]. CAM 5.2 is usually negative in squamous cell carcinoma. It should therefore not be used in the diagnosis of poorly differentiated squamous cell carcinoma, as a negative result is the norm. Positive staining however, may be seen in sebaceous carcinoma, and this is an aid in the distinction between this tumour and squamous cell carcinoma. The main use of CAM 5.2 in dermatopathology is in the diagnosis of Merkel cell carcinoma (primary cutaneous neuroendocrine carcinoma), as tumour cells in this lesion

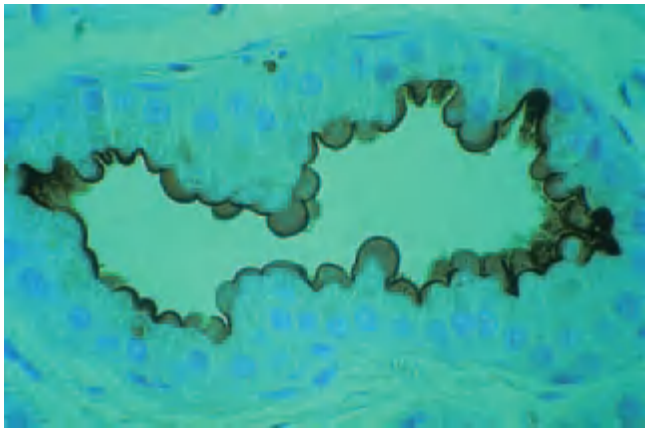

Fig. 7.13 Positive epithelial membrane antigen (EMA) staining of the luminal surface of an apocrine gland. (Courtesy of Dr R. Russell Jones, St John's Institute of Dermatology, London, UK.)

display a typical perinuclear dot-like positivity for this antibody. More recently, a new cytokeratin antibody, cytokeratin 20 (CK-20), has been developed which is very useful in the diagnosis of Merkel cell carcinoma [16,17]. The staining pattern is identical to that of CAM 5.2, and a positive result strongly suggests a primary cutaneous origin rather than a metastatic neuroendocrine carcinoma originating in another organ. Only Merkel cell carcinoma and salivary gland small cell carcinoma tend to be positive for this marker, while neuroendocrine tumours from other organs are consistently negative.

Cytokeratin 7 (CK-7) is a very useful antibody for confirmation of the diagnosis of mammary and extramammary Paget's disease [18]. Tumour cells in the latter stain consistently for this antibody while the surrounding epidermis is negative.

It is important to remember that keratin expression is commonly seen in various sarcomas including epithelioid sarcoma, synovial sarcoma, epithelioid angiosarcoma, and more rarely in other tumours such as leiomyosarcoma and rhabdomyosarcoma.

Epithelial membrane antigens (EMA) [19] are derived from human milk fat globulin membrane, and consist of high-molecular-weight glycoproteins. Antibodies to EMA and related labels react with a range of normal and neoplastic epithelia, and positivity may be found in squamous and ductal epithelia as well as eccrine, apocrine and sebaceous glands (Fig. 7.13). EMA tends to be at least focally positive in squamous cell carcinoma, sebaceous carcinoma and a wide variety of adnexal carcinomas. It is also positive in plasma cells, in epithelioid sarcoma, synovial sarcoma, epithelioid angiosarcoma and in systemic $CD30^+$ large-cell anaplastic lymphoma [20].

Carcinoembryonic antigen is a protein that is normally found in the goblet cells of the small and large intestine. It is found in many adnexal carcinomas particularly tumours displaying ductal differentiation [21]. It is also expressed in many glandular carcinomas arising in other organs. Its main use in dermatopathology is to highlight ductal differentiation in adnexal tumours.

Neuroendocrine markers

Besides CK-20, whose use in the diagnosis of Merkel cell carcinoma has been described before, markers of neuroendocrine differentiation include neurone-specific enolase, chromogranin and synaptophysin.

Neurone-specific enolase is an enzyme described in the brain but also found in neuroendocrine cells [22]. Its use in diagnostic pathology is very limited because of the lack of specificity.

Chromogranin A is part of a family of calcium-binding proteins present in the secretory granules of neuroendocrine cells. This protein is very specific for neuroendocrine differentiation [11].

Synaptophysin is a transmembrane glycoprotein with a molecular weight of 38 kDa and is a specific marker of neuroendocrine differentiation [23].

Melanocytic markers

Over the years, a wide array of markers for melanocytes have been described including S-100, HMB45, Melan-A, tyrosinase and MIFT-1 (microphthalmia transcription factor-1).

It is important to emphasize that no marker allows distinction between benign and malignant melanocytes and that the sensitivity and specificity of different markers is variable. S-100 protein is very sensitive but much less specific than other markers including HMB45, Melan-A and MIFT-1. Melanocytic markers are particularly useful as part of a panel in the differential diagnosis of poorly differentiated malignant tumours. Desmoplastic melanomas are usually positive for S-100 but negative for melanocytic markers such as Melan-A, HMB45 and MIFT-1.

S-100 protein is an acidic protein, originally derived from ox brain, and named because of its solubility in 100% ammonium sulphate. It is a sensitive marker of melanocytes [24–26]. Antibodies to S-100 protein, however, also react with Schwann cells, glial cells, adipocytes, chondrocytes, Langerhans' cells and cells of the eccrine sweat coil, and therefore tumours and hamartomas derived from these cells. S-100 also stains the cells in Rosai–Dorfman disease. S-100 protein is particularly useful in the study of suspected malignant melanoma, as the great majority of, but by no means all, melanomas are positive for this marker [27] (Fig. 7.14). In this context, the technique is particularly valuable in the differentiation of melanoma from other spindle cell neoplasms, and in identifying

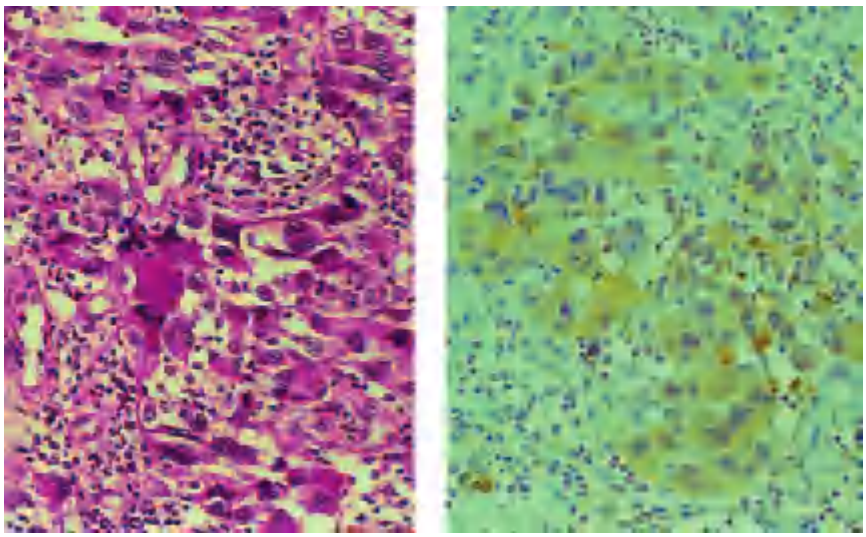

Fig. 7.14 Confirmation of melanocytic origin of large atypical cells in skin biopsy: (left) H&E stain; (right) positive labelling of tumour cells with S-100 antibody.

small deposits of melanoma that may be present in deep dermal tissues, as in determination of accurate Breslow thickness and/or intravascular spread, or the evaluation of spread to sentinel lymph nodes. S-100 is less reliable when used to delineate the epidermal component of a melanocytic lesion. The reason for this is that it also stains Langerhans' cells. More specific markers of melanocytes like Melan-A should be used for this purpose. S-100 is also often focally positive in a number of soft-tissue tumours and should therefore be used as part of a panel of markers in the diagnosis of poorly differentiated tumours.

HMB-45 (gp100) [28–30] recognizes a 10-kDa antigen localized in premelanosomal vesicles. The antibody was developed from an extract of a lymph-node metastasis of melanoma. This antibody does not stain normal adult melanocytes or intradermal naevi. It is a very specific antibody, which is usually negative in desmoplastic melanoma. Around 90% of primary and metastatic melanomas are positive for this marker.

Melan-A (MART-1) [31,32] is a recently described melanocyte marker that recognizes an antigen present in melanoma cells and recognized by $CD8^+$ cytotoxic T lymphocytes. It is a fairly specific marker of melanocytes. Melan-A stains naevi and melanomas, but it tends to be negative in desmoplastic melanoma, spindle cell melanoma and neurotized naevi.

MIFT-1 is the latest addition to the armamentarium of melanocytic markers [33]. This is a nuclear protein involved in the development of melanocytes and in the regulation of melanin synthesis. It stains naevi and melanoma but is usually negative in desmoplastic melanomas. Although it was initially regarded as fairly specific, it has been found to be expressed in macrophages, fibroblasts, lymphocytes, Schwann cells and even smooth muscle cells [34]. Its utility as part of a panel for the diagnosis of difficult tumours is likely to be limited.

Mesenchymal markers

There are many markers of mesenchymal differentiation that are useful in the differential diagnosis of neoplasms particularly those that are poorly differentiated. As with many of the other antibodies discussed so far, the specificity and sensitivity of each of these markers is very variable. What this means is that they should always be used as part of a wider panel of markers. Commonly used markers include vimentin, desmin, smooth muscle actin, muscle-specific actin, S-100, CD34, CD31 and factor VIII-related antigen [11].

Vimentin has a molecular weight of 57 kDa and it is found in all mesenchymal cells and their tumours. It has a very low specificity and can be found in melanomas, lymphomas and even carcinomas. Its value is therefore very limited [35].

S-100 has already been described above. It is a very useful marker for neurofibroma and Schwannoma. While the latter tumour tends to be uniformly positive for S-100, the percentage of tumour cells positive for this marker varies in neurofibroma.

Desmin is a polypeptide with a molecular weight of 53 kDa, and is characteristic of smooth, skeletal and cardiac muscle [36]. In skeletal muscle desmin filaments are found in association with the Z-discs of the sarcomeres and the sarcolemmal attachment plaques. In smooth muscle cells, desmin filaments interconnect the fusiform dense bodies with the plasmalemmal dense bodies. Desmin is very specific for muscular differentiation and it is a useful marker only occasionally reported in other tumours such schwannoma and epithelioid sarcoma [11,37,38].

Actin represents a family of intermediate filaments present in the cytoskeleton of eukaryotic cells. They are contractile proteins involved in the control of motility of muscle cells and non-muscle cells. Actin proteins are

classified according to their amino acid sequences, and six major isoforms have been described. Of the monoclonal antibodies used in diagnostic pathology the most useful ones are HHF35 (muscle-specific actin) and 1A4 (alpha-smooth-muscle actin) [39–41]. The former reacts with skeletal and smooth muscle and the latter only reacts with smooth muscle. Both types of antibody stain myofibroblasts, pericytes and myoepithelial cells [40].

CD34 is a glycosylated transmembrane protein with a molecular weight of 110 kDa. It is normally present on haematopoietic progenitor cells and vascular endothelial cells [42,43]. This marker however, is fairly non-specific and it is expressed in a wide number of soft-tissue tumours including dermofibrosarcoma protuberans (DFSP), neurofibroma and spindle cell lipoma. Its main use in dermatopathology is as an endothelial cell marker and in the differential diagnosis between DFSP and fibrous histiocytoma and its variants, particularly cellular fibrous histiocytoma. CD34 tends to be diffusely positive in the former and negative in the latter [44,45].

One large group of soft-tissue tumours where useful markers are badly needed is the group of fibrohistiocytic tumours. So-called markers of histiocytic cells including alpha-1-antitrypsin and alpha-1-antichymotripsin are very non-specific and have no role in the diagnosis of these tumours. Besides, it appears clear that the so-called fibrohistiocytic tumours usually do not show true histiocytic differentiation. Another interesting polyclonal antibody produced against the blood coagulation transglutaminase, factor XIIIa, seems to be a cell marker for a particular subpopulation of dermal dendritic mononuclear macrophage cells termed dermal dendrocytes [46–48]. A number of positive cells may be identified in very many different types of soft-tissue tumours. However, combined with other markers, FXIIIa is useful in the differential diagnosis between benign fibrous histiocytoma and DFSP. The former is normally rich in factor XIIIa positive cells particularly at the periphery, in contrast to DFSP which is negative [44].

A wide range of endothelial markers now available can identify various vascular tumours. The most useful of these markers are CD31, CD34 and FVIII-related antigen.

CD31 refers to a glycoprotein that belongs to the immunoglobulin supergene family and has a molecular weight of 130 kDa. It is also known as platelet-endothelial cell adhesion molecule type I (PECAM-1) and it stains endothelial cells and some haematopoietic cells. CD31 is the most sensitive marker of endothelial cells [49–51]. However, interpretation should be cautious as CD31 also stains macrophages [52].

Antibodies to factor VIII-related antigen label normal and neoplastic endothelium in routine paraffin sections [53]. This marker, however, may be negative in lymphatic capillaries, and because of the presence of factor VIII-related antigen in plasma and tissue exudates, false-positive labelling may be encountered. None of these endothelial cell markers allows distinction between lymphatic and vascular endothelium. In recent years, a number of antibodies have been described with claims as to their specificity for lymphatic endothelium. These antibodies include vascular endothelial growth factor receptor-3 (VEGFR-3), podoplanin and LYVE-1 (lymphatic vessel endothelial hyaluronan receptor) [54–56]. The first two antibodies have not proven to be specific for lymphatic differentiation in vascular tumours and the final verdict is still awaited on the third.

Metastatic cutaneous tumours

It is important to remember that all tumours that are present in the skin are not necessarily of cutaneous origin. Reference has already been made to several epithelial markers, many of which may be useful in diagnosing metastatic adenocarcinoma. Immunohistochemistry, however, does not usually allow determination of the site of the primary tumour except in a few instances. The latter include prostate-specific antigen in prostatic carcinoma and thyroglobulin in thyroid carcinoma. A recently described marker, thyroid transcription factor-1 (TTF-1), is a 38-kDa nuclear protein expressed in epithelial cells of lung and thyroid. TTF-1 is therefore useful in the diagnosis of cutaneous metastatic tumours [57]. Markers for oestrogen and progesterone receptors are not useful in the diagnosis of metastatic breast carcinoma, because adnexal carcinomas may also be positive for these markers.

Histiocytic markers

CD68 (KP1) is the main marker used to demonstrate histiocytic differentiation in paraffin-embedded material [58,59]. It is an antibody raised against a 110-kDa glycoprotein present in pulmonary macrophages. This antibody stains normal histiocytes, granulocyte precursors, tumour cells in myelomonocytic neoplasms and true histiocytic lymphomas. KP1, however, is not specific for histiocytic differentiation, and expression may be seen in many tumours, including carcinoma, melanoma, granular cell tumours and a variety of sarcomas [60–62].

Lymphoid markers

One of the most difficult areas in diagnostic dermatopathology is the interpretation of heavy lymphoid infiltrates in cutaneous biopsies. The wide range of conditions that may produce a histological picture simulating lymphoma ranges from insect bites, through syphilis, to reactive lymphoid hyperplasia where an aetiological factor cannot be demonstrated. Furthermore, recognition of the number of different varieties of malignant lymphoproliferative disorders that may be encountered in the skin continues to

increase. Very many different markers for lymphocytes and their subsets are now available, and are particularly useful when used as a battery. It should be remembered that histological and antibody-labelling patterns of cutaneous lymphomas do not necessarily mirror their nodal counterparts, and that very few markers are absolutely specific for cells of one lineage. Furthermore, it has to be realized that in the course of a disease process, many lymphoid cell types may lose their antigenic determinants and label in an anomalous fashion. This is particularly common in some forms of advanced cutaneous lymphoma. Nevertheless, with careful interpretation and the use of antibody panels, considerable information can be derived from the use of newer monoclonal antibodies [5].

The rationalization of nomenclature in relation to human leukocyte antigens, the CD (or cluster of differentiation) nomenclature has been a great advance, enabling useful comparison of numerous different monoclonal antibodies developed in different laboratories, and facilitating their classification [5,63]. As in other areas of immunopathology, a further bonus for the diagnostic dermatopathologist is the possibility nowadays of using many of these leukocyte antigen markers in paraffin-processed tissue [64,65]. A full discussion of the applications of immunopathology to the recognition of subsets of lymphocytes in skin biopsies is beyond the scope of this chapter. Useful antibodies available for use on routinely processed material include CD45 (leukocyte common antigen), pan-B-cell markers such as CD20 (L26) and CD79a, and pan-T-cell markers such as CD3, CD2, CD5 and CD7 [66,67]. Determination of the subset of T cells in paraffin-embedded skin biopsies is also possible, as there are commercially available antibodies to CD4 (helper T cells) and CD8 (cytotoxic T cells) T cells [5,68,69]. Immunohistochemistry is also very useful in the determination of clonality, particularly in B-cell infiltrates. Antibodies against kappa and lambda light chains can be used in paraffin-embedded material to demonstrate clonality [5,70,71]. Monotypic Ig light chain expression is very suggestive of a B-cell lymphoma.

Other markers of interest include determinants closely associated with T-cell activation, such as the CD30 antigen. An example of an antibody to the CD30 epitope is Ber-H2, which identifies activated T cells, B cells and Reed–Sternberg cells. In cutaneous biopsies, it is commonly present in examples of lymphomatoid papulosis type A [72] (Fig. 7.15), and lymphomas that are best categorized within the group of large cell anaplastic CD30 positive lymphomas [73,74].

Anaplastic lymphoma kinase (ALK) is a marker of the protein that results from translocation 2;5 between the ALK and nucleophosmin. Its usefulness resides in the fact that this protein is expressed in systemic large cell anaplastic lymphoma, but it is usually not expressed in primary cutaneous large cell anaplastic CD30 positive lymphomas [75,76].

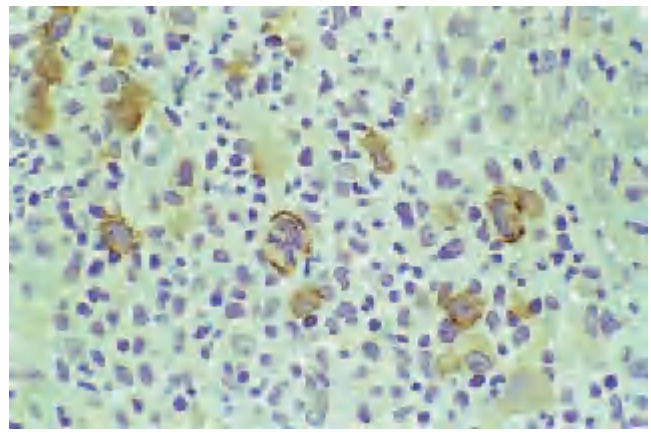

Fig. 7.15 Positive staining of atypical cells in a case of lymphomatoid papulosis with the CD30 marker, Ber-H2. This reaction may be carried out on sections from paraffin-embedded tissue.

CD56 (neural cell adhesion molecule) is expressed in the central and peripheral nervous system, and it is also a marker of natural killer (NK) cells. Its main use in dermatopathology is in the diagnosis of cutaneous NK/T-cell lymphoma [77,78]. Some subcutaneous panniculitis-like T-cell lymphomas may also express this marker [79].

TIA-1, granzyme and perforin are cytotoxic proteins present in the cytoplasmic granules of NK and cytotoxic T cells. Expression of these proteins can be demonstrated in paraffin-embedded material and this is useful in the diagnosis of NK or cytotoxic lymphomas [80,81].

Markers of B follicle-centre cells such as CD10 and bcl-6, although not entirely specific, are useful in demonstrating the presence of these cells in the skin. Positive staining does not indicate that the cells are neoplastic but that they are of follicle-centre origin [5,82–84]. Reactive cutaneous germinal centres are positive for these markers. On the other hand, an infiltrate with follicle-centre cells which are positive for bcl-2 is very suggestive of a follicle-centre cell lymphoma, and usually indicates the presence of a 14;18 chromosomal translocation [5,85]. Many primary cutaneous follicle-centre cell lymphomas, however, do not stain for this marker and the t(14;18) chromosomal translocation is often absent [86]. It is worth remembering that normal reactive T lymphocytes are usually bcl-2 positive and these tend to be prominent in B-cell infiltrates. Normal mantle B cells are also bcl-2 positive.

The field of immunopathology in general, and with relation to the study of lymphoid proliferations in particular, continues to grow apace. In addition to the techniques discussed above, it is likely that within the next few years further information of use to the diagnostic pathologist will be gained from studies of cytokines, adhesion

molecules and similar substances. The correlation of immunophenotypic studies with immunogenotyping using the latest molecular biological techniques is likely to contribute further to our understanding of cutaneous and systemic lymphomas.

Other special laboratory techniques

Cytodiagnosis and Tzanck smears [1,2] (Fig. 7.16)

Cytodiagnosis in dermatopathology should not be regarded as a substitute for formal biopsy. The technique has been used as an aid to rapid diagnosis of numerous skin conditions, including epithelial tumours, Paget's disease, malignant melanoma, cutaneous lymphomas and skin metastases. In most of these conditions, a diagnostic

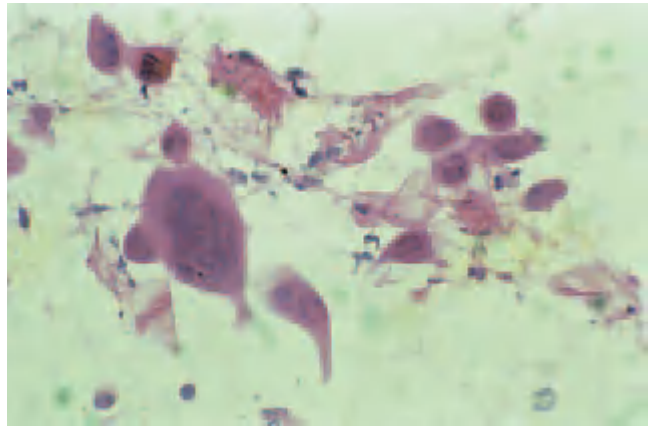

Fig. 7.16 An H&E-stained smear from a lesion of herpes simplex, showing multinucleate giant cells and degenerative nuclear changes.

surgical biopsy rather than fine needle biopsy, is always preferable. Examination of cytological specimens from skin lesions is of most value in bullous disorders, vesicular virus eruptions and basal cell epithelioma.

In blistering disorders, a small, early, uninfected lesion should ideally be selected. The roof of the blister is removed with scissors, and the base of the blister gently scraped with a blunt scalpel so as not to produce bleeding. The material obtained is spread thinly on a glass slide. This is called a Tzanck smear. However, herpes simplex infections cannot be differentiated from herpes zoster using such a simple technique. For cytodiagnosis of suspected basal cell epitheliomas, any surface crust should be removed from ulcerated tumours, and non-ulcerated tumours should be incised with a sharp, pointed scalpel. The incision should be superficial enough to avoid undue bleeding. A sample of tumour is then obtained with either a blunt scalpel or a small curette, and the tissue obtained is pressed between two glass slides. Smears from blisters and basal cell epitheliomas should be fixed immediately for 2 min in absolute alcohol, and stained with H&E. Following rinsing and drying, the smears are cover slipped for microscopic examination.

Microscopic appearances

Bullous disorders. Cytodiagnosis is of most value in pemphigus in its various forms, and in Hailey–Hailey disease, because of the presence of numerous acantholytic keratinocytes. In pemphigus vulgaris, pemphigus vegetans and Hailey–Hailey disease, the cells obtained in the skin smear are usually rounded, and more or less uniform in size, with a relatively large nuclear cytoplasmic ratio. There may be a perinuclear pale halo, with the peripheral part of the cell staining more darkly. In the more superficial forms of pemphigus, including pemphigus foliaceus and Senear–Usher pemphigus, the keratinocytes tend to be more cuboidal in shape, with a small nucleus and more prominent cytoplasm. The cells may contain keratohyalin granules and show evidence of keratinization. Occasional giant cells may be seen, but are quite unlike virus giant cells, which show ballooning degeneration. In addition to the acantholytic disorders mentioned above, occasional acantholytic cells may be obtained in Darier's disease, where dyskeratosis may also be present, and in bullous impetigo. In this latter condition, normally in addition to acantholytic cells there are numerous neutrophil polymorphs and bacteria. The usefulness of cytodiagnosis in subepidermal bullous eruptions is limited, the smear in most instances containing only inflammatory cells. Eosinophils are commonly found in bullous pemphigoid, but may also occur in dermatitis herpetiformis.

Viral disorders. The cytology of herpes simplex, herpes zoster and varicella is often diagnostic because of the presence of characteristic multinucleated giant cells. Keratinocytes of varying size are seen, and as the cell enlarges the nucleus shows some blurring of chromatin pattern and loss of staining. Some of the cells may show condensation of chromatin of the nuclear membrane. The multinucleate giant cells often contain eight or more nuclei, and these nuclei show great variation in size and shape (Fig. 7.16).

Eosinophilic inclusion bodies are very occasionally identified in the herpes virus group of disorders, but commonly examination of many smears may fail to reveal any evidence of this change. Typical ballooning degeneration and giant cell formation as described above does not normally occur in vaccinia or cowpox, but occasionally somewhat enlarged acantholytic cells may be found, and sometimes eosinophilic intracytoplasmic inclusion bodies may be detected. In molluscum contagiosum, characteristic molluscum bodies are easily identified. These are large, rounded, eosinophilic bodies, and may be identified without H&E stain in a potassium hydroxide preparation.

Basal cell carcinoma. In smears obtained from basal cell carcinoma, clumps of closely set oval or round deeply basophilic cells are found. The cytoplasm is usually very scanty and in some cases may not be detectable. The nuclei are finely granular with poorly defined nucleoli, and the cells in the smear are very regular in size and shape. In the presence of significant cytological atypia, an alternative diagnosis, such as squamous cell carcinoma or Bowen's disease, should be considered.

Electron microscopy

Electron-microscopic examination of cutaneous tissues is performed much less than light microscopy and is nowadays rarely used in diagnostic dermatopathology. Electron microscopy has been replaced by antigen mapping by immunohistochemistry in the diagnosis of many genetic disorders, particularly those in the epidermolysis bullosa group. This technique and its applications are described in Chapter 40. Transmission and scanning electron microscopy have greatly increased our understanding not only of the microanatomy of normal skin, but also of many disease processes. The use of newer embedding materials, has enabled ultrastructural examination to be carried out on single blocks of tissue prepared primarily for light microscopy. With care, even routinely fixed and paraffin-embedded material may produce electron micrographs that provide useful diagnostic information. In recent years, the combination of electron microscopy

with immunopathological techniques, autoradiography and cytochemical methods, has greatly enhanced our knowledge of tissue and cell pathophysiology. The contribution of ultrastructural studies to our understanding of normal microanatomy of skin structures and their variants has been referred to in Chapter 3. Below are listed some of the cutaneous disorders where electron microscopy may be of diagnostic help.

Bullous disorders

The classification and subdivision of bullous disorders has been dramatically advanced by electron microscopy and immunoelectron microscopy. With the electron microscope, it is much easier to separate the varieties of epidermolysis bullosa. In epidermolysis bullosa simplex, the plane of cleavage is within the basal cells. Additionally, tonofilament clumping may be seen. Junctional epidermolysis bullosa has various clinical forms, and, although with the electron microscope there is separation in the lamina lucida zone, junctional epidermolysis bullosa is probably a heterogenous group of disorders. In some forms of this condition, hemidesmosomes are reduced in number, and this may represent a primary defect. In other forms of junctional epidermolysis bullosa, however, hemidesmosomes may be apparently normal. In dystrophic epidermolysis bullosa, again, various abnormalities are observed, but in this case the split is below the lamina densa. Immunoelectron microscopic techniques provide further information in epidermolysis bullosa, and also in some of the other idiopathic blistering disorders. In cicatricial pemphigoid, for instance, immunoreactants may be identified at a lower level in the lamina lucida than in classical bullous pemphigoid. In linear IgA disease, immunoreactants may be found either in the lamina lucida or below it. Sublamina densa deposits of immunoreactants are also seen in epidermolysis bullosa acquisita.

Pigmentary disorders

The quantitative and qualitative evaluation of melanocytes and melanosomes at ultrastructural level can be of great value in the examination of disorders of hyper- and hypopigmentation. In albinism, normal numbers of melano-cytes are present, although melanosomes are immature. In vitiligo, a biopsy from affected skin shows either a complete absence or greatly diminished population of melanocytes. In early stages of vitiligo, some vacuolar degeneration of epidermal melanocytes may be identified.

Cellular identification

In addition to the demonstration of melanocytes, various other cells, both in inflammatory and neoplastic disorders, can be identified clearly with the aid of the electron microscope. The shape of the convoluted nucleus in the peripheral blood from patients with Sézary syndrome is diagnostic. Annulate lamellae, large, dense granules and decapitation secretion are all found ultrastructurally in apocrine secretory cells. Other cellular substructures that may be of diagnostic value are the identification of desmosomes in various epithelia, myofilaments in tumours of muscular origin, the Birbeck granule characteristic of Langerhans' cells, and the Weibel–Palade body found in the endothelial cells of blood vessels.

Identification of dermal deposits

Ultrastructural examination of various forms of amyloidosis shows characteristic deposits of straight, non-branching, non-anastomosing filaments of approximately 6–7 nm in diameter. The apparent increased electron density at their periphery produces a superficial appearance of hollow cylinders. Colloid milia of both the adult and juvenile type may on occasions be confused with amyloid deposition at the light-microscopic level. Ultrastructurally, however, the fibres of colloid milia are of a different thickness to those seen in amyloidosis, and are wavy rather than straight. Other conditions where amorphous hyaline deposits may be seen with the light microscope, such as forms of porphyria and lipoid proteinosis, also have characteristic electron-microscopic appearances.

Viral diseases

Many of the conventional techniques for confirmation of a diagnosis of virus infection, such as virus isolation and culture and the various serological tests, are slow, and the patient has often recovered by the time the diagnosis is established with certainty. Conventional histology either from biopsy or from the scraping of the base of blisters, for instance in herpes simplex or zoster infections, can be useful in experienced hands, but there is quite a high rate of false-negative results. Molecular biological techniques are more specific, especially for identification of human papillomavirus (HPV) infection, but are not widely available. Direct visualization of virus particles with the electron microscope, using a negative staining technique, can give a positive result within half an hour of a lesion being sampled. This technique has become invaluable for confirmation of diagnosis in disorders caused by many of the main families of viruses, particularly lesions such as herpes simplex and zoster, and hand, foot and mouth disease.

Immunogenotyping

In most inflammatory disorders, the lymphocyte population in skin tissue is normally polyclonal, containing progeny of many different parent lymphocytes. In con-

trast, most lymphomas are monoclonal, with cells being derived from the same parent cell. With the development of DNA probes to detect rearrangements of genes encoding for immunoglobulin and T-cell receptor molecules, it has become possible to assess clonality of T- and B-cell populations by immunogenotyping [1–4]. Refinements in technique mean that significant results can now be obtained from relatively small portions of tissue. The PCR technique is now widely used for the study of clonality in cutaneous lymphoid infiltrates. This subject is discussed in detail in Chapter 54.

Artefacts (Table 7.6)

The microscopic appearance of the end product produced by processing a tissue specimen is in many ways an artificial representation of what is going on in a complex organ at one point in time. The procedures of biopsy fixation and tissue processing produce significant alterations in size, shape and structure of tissue constituents. We tend to think of fat cells as large, round, empty cells with peripheral nuclei, because this is how we are used to visualizing them microscopically. Cysts that normally contain lipid-rich substances, such as those of steatocystoma multiplex, appear relatively empty when sections from paraffin-embedded material are viewed. The clear halo often seen around melanocytes in the lower layers of the epidermis is at least in part an artefactual change. Some routinely observed tissue artefacts are useful for diagnostic purposes. The so-called separation artefact, where dermal connective tissue separates away from islands of basal cell carcinoma, aids us, for instance, in differentiating a basal cell carcinoma from a trichoepithelioma. In addition to these everyday artefacts, there are a wide range of other changes that may be induced accidentally or by poor processing technique. These changes may in some instances mislead the diagnostic pathologist.

Artefacts due to poor biopsy technique

Undue squeezing of the specimen with forceps can produce a marked artefact, causing the connective tissue to become amorphous and basophilic. Considerable distortion of cellular infiltrates is also seen. Toothed forceps

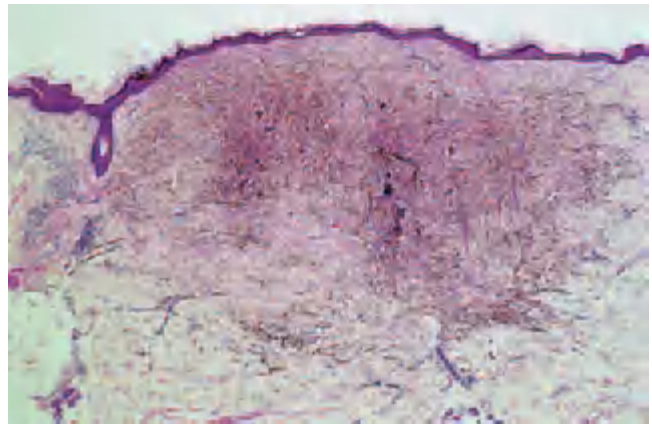

Fig. 7.17 Extensive dermal pigmentation as a result of the application of Monsel's solution.

can produce a hole within the tissue specimen, which, although rarely causing diagnostic confusion, is aesthetically unpleasing. When a small tissue specimen is cut up into even smaller pieces, the pressure produced by the knife at the edge of the smaller biopsy portions may lead to connective tissue and cell distortion. It is far better to carry out several small separate biopsies, perhaps with a punch, from the same area than to try and divide a single specimen after it has been removed from the patient. Various techniques of cautery used to secure haemostasis following either a shave biopsy or curettage can lead to unusual histological appearances. Diathermy produces a bizarre alteration of cellular and nuclear morphology, as well as producing a stringy eosinophilic and homogenized appearance to connective tissue. The haemostatic agent, Monsel's solution (20% aqueous ferric subsulphate), can occasionally produce extensive ferrugination of fibrin, dermal collagen and even striated muscle in skin biopsies [1]. The iron pigment deposition can be very confusing and simulate melanin (Fig. 7.17). Particular problems are encountered where this technique is used following shave biopsy of melanocytic naevi. The deposition of this pigment could lead to an erroneous diagnosis of a malignant melanoma [2]. Artefacts may occasionally be induced by local anaesthetic. The epinephrine contained in some local anaesthetics may result in some degranulation of mast cells, and have minor effects on dermal blood vessels, but these are not normally important problems. A large quantity of local anaesthetic, particularly when injected directly into a lesion or superficially in the dermis, can cause appearances simulating marked tissue oedema, or in the case of a cellular naevus, disruption of the normal architecture of the tumour.

Artefacts related to fixation media

It has already been stressed that adequate fixation of skin-biopsy tissue specimens is needed for optimum

histological interpretation. Specimens that have been fixed for insufficient time show poor definition of cell structure and connective tissue. Cells may appear swollen, and staining of such poorly fixed specimens often produces a rather smudged appearance. Similar results may be seen when the specimen has not been placed in the correct fixative, but rather in some inappropriate solution such as normal saline. Formalin pigment may be precipitated out into the tissues in some skin biopsies, particularly where the biopsies have been fixed in a formalin-containing fixative with an acid pH. Formalin pigment artefact is particularly common in biopsies from tissue containing large amounts of haemorrhage, or tissues heavily congested with blood. Even in neutral buffered formal saline, a long fixation may increase the tendency to formalin pigment production. There are some fixatives, such as Zenker's fluid and Heidenhain's Susa, that contain mercuric chloride. Tissues fixed in these media may develop a granular brownish black deposit. This deposit can be removed normally by treatment in Lugol's iodine followed by sodium thiosulphate.

Artefacts due to blocking and sectioning

One of the most commonly encountered problems is with the orientation of the specimen. Oblique blocking can give a very misleading picture—for example, suggesting that there is pseudoepitheliomatous hyperplasia of the epidermis or psoriasis, when one is in fact dealing with normal skin. Correct and accurate vertical sectioning and blocking is particularly important where measurements are to be made, such as in the assessment of Breslow thickness and Clark's level of malignant melanoma. Occasionally, fragments of a biopsy adhere to the microtome blade and 'knife carry' may occur, with the result that, for instance, a fragment of basal cell carcinoma may be seen just above the epidermis in a section from a histiocytoma. Normally this artefact is easy to spot, but occasionally it can give rise to confusion. Partial blunting of the microtome knife causes uneven thickness of the histological section. This can give a false impression, both of the density of cellular infiltrates and of the qualities of the connective tissue. Irregularities in the microtome knife edge can cause an unaesthetic artefact known as shatter marks. In the presence of very hard or dense foreign material in the tissues, such as calcium, the foreign material may be drawn through the tissue, forming a tear in the resulting sections.

Artefacts due to staining techniques

It should be remembered that the various staining solutions have a very short shelf-life once made up, and that staining solutions that are old produce a very unsatisfactory end-result. It is also quite common for staining solutions to be contaminated with various foreign materials, such as plant hairs [3] or microorganisms, which may appear to be present within the tissue biopsied, when viewed in the finished mounted preparation.

The approach to microscopic examination of tissue sections

Some understanding of the basic principles of microscopy and careful microscope maintenance are essential for optimal visualization of tissue sections, and ultimately therefore for achieving a correct histopathological diagnosis. Knowledge of the techniques and applications of fluorescence microscopy, interference microscopy and polarized light microscopy is also recommended [1].

Preparing for microscopy

Before using the microscope, some attention should be given to various practical points. Are all the optical surfaces clean? Greasy fingerprints and dust may seriously impair the quality of the image, and before using the microscope all lens surfaces should be cleaned. This may be done with an optical lens tissue. Petroleum spirit is recommended by some manufacturers. Cleaning of objectives with a concave shape can be difficult. A recommended method is to use a small, freshly broken-up piece of expanded polystyrene. It is important that there is no trace of xylene or other organic solvent on an objective treated in this way, or there is a risk of a film of dissolved plastic being left behind.

The microscope light source should be centred, and on most modern microscopes this is easily achieved by a pair of centring screws acting against a spring, or by loosening a screw column and orientating the lamp holder.

The condenser is then adjusted. The aperture diaphragm in the base of the microscope should be closed, and the condenser height adjusted, until the image of the field diaphragm is in focus. The diaphragm should then be centred with adjusting screws. After centring, the field diaphragm should be opened until it just disappears from view. The aperture (substage iris diaphragm) is then adjusted. With experience, this can be done while viewing the image on the slide. Alternatively, an eyepiece can be removed, and while looking down the eyepiece tube the diaphragm is opened until it occupies approximately one-third of the field of view. In this position, the numerical

aperture of the condenser is approximately that of the objective in use, and optimum resolution is achieved.

The slide to be examined should then be viewed with the naked eye. Is the specimen a section of solid tissue, or uniformly spread across the slide, like a tissue or cell smear? The size and shape of sections on the slide should be noted, and it may be possible with naked eye examination to identify several tissues. It is important to note the number of sections mounted on one slide, and whether these are likely to represent sections from the same block, or different blocks mounted together. Finally, before putting the slide on the microscope stage, the name or identification number carried by the slide should be correlated with the details on the clinical request form. When inserting the slide into the microscope, make sure that it is the right way up, otherwise it may be impossible to focus the image with higher power objectives.

Microscopic interpretation

Examination of sections

The normal and recommended procedure is to start with lower power examination of the sections and gradually move up to higher power, detailed examination. Low-power scanning examination with a × 2.5 or × 4 objective provides a wealth of information. Identification of tissues is made, orientation of the specimen is possible, and the main site of any pathological changes is often identified. The basic nature of the pathological changes may also be recognized—for example, whether the main pathology represents a neoplastic or inflammatory process. Low-power scanning of all the material on the slide makes it clear whether all sections are from the same block, or whether they represent different portions of tissue. Low-power examination of biopsy material is the first step in the problem-solving exercise, and is the key to good diagnostic dermatopathology. During low-power examination, the site of biopsy and whether this correlates with the clinical information should be evaluated, and secondly, some attempt at pattern diagnosis should be made.

Site of biopsy and normal histological variation

Without a working knowledge of the differences in skin microanatomy in the different regions of the body, it is very easy to come to a wrong diagnostic conclusion. For instance, the prominent sebaceous glands seen on facial skin, particularly the nose, may lead to a diagnosis of sebaceous hyperplasia, and the normally thick stratum corneum present on the palms and soles may be interpreted as hyperkeratosis. The following notes describe some of the more typical features seen in skin biopsies from specific sites.

Skin from the palms and soles. In biopsies from these sites, there is a fairly thick Malpighian layer with a thickened basket-weave stratum corneum, and a very prominent epidermal rete ridge pattern. Occasionally, specialized nerve endings (Meissner's corpuscles) may be seen in the dermal papillae. Eccrine sweat glands are fairly numerous, but no pilosebaceous follicles are identified. Vater–Pacini corpuscles are characteristically found in the subcutis. They are large specialized nerve endings and have an ovoid or round shape with a typical onion ring appearance.

Skin from the areola of the nipple and the scrotum. In these sites, papillomatosis is a common finding, and in the upper dermis there are often numerous small fascicles and fibres of smooth muscle. In biopsies from the areola and nipple, occasional lactiferous ducts may be identified.

Mucous membranes. Histology of mucosal surfaces often shows fairly thick epithelium lacking well-defined keratinization. Focal mild parakeratosis is often seen. The rete ridge pattern normally associated with glabrous skin is not marked, and the cells of the Malpighian layer are large, pale and typically vacuolated.

Axillary skin. In skin from the axillae, papillomatosis of the skin surface is often marked. Abundant hair follicles are present, as are numerous apocrine glands, which are seen in addition to eccrine glands commonly present in other sites.

Scalp skin. Biopsies from the scalp are normally readily identified by the presence of numerous large hairs with the hair bulbs frequently in the subcutaneous fat.

Facial skin. Facial skin is characterized by the presence of smaller hair follicles than in the scalp and, particularly in the central facial area, large numbers of mature sebaceous glands. The epidermis is very thin and melanocytes are numerous. The rete ridge pattern at the epidermo-dermal junction is often very poorly developed, which makes a distinction between papillary and reticular dermis often difficult to assess. *Demodex* organisms may be seen in the ostia of hair follicles and deeper within the sebaceous glands. Muscle may be identified relatively close to the epidermis in certain areas of the face, such as round the eyes or mouth.

Truncal skin. Skin from the trunk shows no very specific histological hallmarks. However, it is normally quite thick, with the distance between the epidermis and the subcutaneous fat being much greater than in biopsies from other sites. Eccrine sweat glands are normally identified at the junction between the dermis and the subcutaneous fat, and may, in skin from the trunk, appear within the reticular dermis itself. The skin from the back

contains a very thick dermis with thick collagen bundles in which the ground substance is minimal. This normal pattern is often confused with evidence of a sclerosing dermal process such as morphoea.

Low-power histological pattern diagnosis

Having attempted to recognize the site of the biopsy, and having correlated this with the clinical information, the next task is to interpret any abnormal findings and attempt to come to some diagnostic conclusions. Sometimes, the site of the abnormality in the section is immediately obvious on scanning magnification. This then leads one to examine the appropriate area in more detail. When there is no obvious pathology in the section, a useful approach is to examine each identifiable cutaneous structure in turn. For instance, starting outwards with the stratum corneum and working inwards. Is it increased or decreased in thickness? Is parakeratosis present? Is the pattern of keratinization normal producing a basket-weave pattern, or is the stratum corneum compacted? Examination of the epidermis may reveal atrophy or acanthosis, spongiosis or cell atypicality, and may also reveal colonization of the epidermis by inflammatory or other abnormal cells. Various forms of epidermal degeneration may be noted. Some variants of these are described below. A vesicle or bulla may be present within the epidermis or below it.

Moving on to the dermis, is the arrangement of connective tissue fibres in the papillary and reticular dermis normal, or are the collagen fibres thickened and hyalinized? Is there an increase in interstitial oedema fluid, or is there evidence of increased amounts of mucin separating the collagen bundles? Is the elastic pattern normal? Careful examination of all adnexal structures should be made, and then, finally, any dermal infiltrate should be assessed. The density of the infiltrate, the pattern of the infiltrate (diffuse and interstitial and/or focal and localized) and the composition of the infiltrate are important. The position of the infiltrate in the dermis, whether it is predominantly deep or predominantly involves the epidermis, is also worth noting, as is the relationship of the infiltrate to adnexal structures and blood vessels. The blood vessels themselves should also be examined carefully for evidence, for example, of any vasculitic change or dilatation, increased tortuosity or thickening. A search should be made for any abnormal deposits or pigments such as amyloid, calcium or tattoo pigment. When one has some experience in assessing the different structures in a skin biopsy, one soon learns to recognize certain patterns of neoplastic change and inflammation. Ackerman has described a method of pattern diagnosis appropriate for the study of inflammatory diseases [2]. He suggests recognition of nine major patterns of inflammatory change in the skin, ranging from superficial perivascular dermatitis to panniculitis. Having classified the appearances in the section according to one of these patterns, closer examination enables one to come to a more precise diagnosis. Other authors have described similar schemes of microscopy [3]. The system of pattern analysis can be recommended to those new to dermatopathology. More experienced pathologists have almost always developed their own pattern analysis system.

High-power microscopical examination

By the time one has examined a histological section with a $\times 2.5$ objective, a $\times 4$ to $\times 8$ objective depending on personal preference, and a $\times 10$ objective, one should have some idea in most cases of a differential diagnosis. High-power examination with $\times 25$, $\times 40$ or $\times 50$ and sometimes with a $\times 100$ oil-immersion lens, provides an opportunity to confirm one's initial impressions.

Under high-power examination, one examines carefully cells and other structures in the skin in various specific ways. When dealing with neoplastic disorders, the cytology of individual tumour cells, with particular reference to nuclear detail and the variation in size and shape between cells of the same population should be studied. The number of mitotic figures and the number of abnormal mitoses are noted. The pattern of relationship of tumour cells to each other is also an important feature. Loss of polarity of keratinocytes in squamous epithelium is a characteristic feature associated with premalignant epithelial dysplasias, such as Bowen's disease and actinic keratoses, although it can of course also occur in invasive epithelial tumours. The relationship of tumour cells to neurovascular bundles is also important, and the pattern of neoplastic cells in relation to dermal connective tissue should also be evaluated. The so-called Indian-filing pattern of tumour cells lining up one behind another, sandwiched between collagen bundles, is in some contexts suggestive of malignant disease.

In inflammatory conditions under high-power examination, there is an opportunity to try and categorize the different types of cells in the infiltrate. It is important to look over the whole section, as in some areas the infiltrate may be composed of one cell type and in other areas another cell type may predominate. Some infiltrates are composed of almost pure populations of, for example, lymphocytes, and are described as monomorphic, whereas other infiltrates are composed of plasma cells, histiocytes, lymphocytes and eosinophils, and are described as polymorphic. It is only with experience that one becomes confident in recognizing the cytology of cutaneous infiltrates, and one must remember that in some biopsy material, cells may be seen that are impossible to classify by conventional criteria. The following notes describe the more typical appearances of commonly seen inflammatory and related cells, and describe some of the situations where they may be encountered.

Lymphocytes

Lymphocytes originate in the bone marrow and mature through a series of stages both in the bone marrow and the thymus gland, before being released into the peripheral blood and body tissues. The family of lymphocytes is a very heterogeneous one, with many subtypes of lymphocytes. T lymphocytes and B lymphocytes are indistinguishable by normal light microscopy, although on scanning electron microscopy *in vitro* B lymphocytes appear to have rather rougher surfaces than T lymphocytes, and show villous projections. On light-microscopic examination of sections stained with H&E, lymphocytes are roughly 7–12 μm in diameter, and possess small, round, deeply basophilic nuclei, surrounded by a thin rim of cytoplasm, which is usually very difficult to visualize. Numerous immunohistochemical methods are available that readily distinguish T and B lymphocytes, and most of these methods can be carried out using paraffin-embedded sections. In the majority of inflammatory conditions affecting the skin where a significant dermal infiltrate is seen, T cells outnumber B cells. Mature T and B cells are, of course, not the only lymphoid cells that may be found in the skin. In addition to plasma cells (see below), various follicular centre cells and T and B immunoblasts may be seen under certain conditions.

Plasma cells

Plasma cells are responsible for immunoglobulin production. They are a variety of B lymphocyte, approximately 10 μm in diameter, that have a distinct appearance in H&E-stained sections. They have abundant basophilic cytoplasm with a round, eccentrically placed nucleus. The nuclear chromatin is scattered in coarse clumps at the periphery of the nucleus giving it a 'clock face' appearance. Closely adjacent to the nucleus there is a zone of pallor in the cytoplasm, sometimes called the perinuclear hof. This area corresponds to the site where the Golgi apparatus is located. Older plasma cells often contain homogenous eosinophilic globules of varying size within their cytoplasm, known as Russell bodies. Plasma cells are seen in many situations in the skin, particularly in inflammatory conditions affecting hairy areas, near mucous membranes and in the late stages of some granulomas.

Neutrophils

Neutrophils are the most numerous of the circulating white blood cells, comprising in normal individuals 50–70% of the blood leukocytes. They have a multilobed nucleus (3–4), with the lobes connected by narrow bridges of nucleoplasm. The slightly basophilic cytoplasm contains many smallish granules, many of which ultrastructurally correspond to membrane-bound lysosomes. Neutrophils function primarily as phagocytes, and are directed by chemotactic factors, including the complement cascade to noxious materials present in tissue. Such foreign materials include bacteria, fungi and tissues that have been injured. Collections of neutrophils may be seen in the skin in various infectious conditions, such as impetigo and staphylococcal folliculitis, in various inflammatory disorders of unknown cause, such as pyoderma gangrenosum and Sweet's syndrome, and in various vasculitic disorders, including leukocytoclastic vasculitis, granuloma faciale and erythema elevatum diutinum.

Eosinophils

Eosinophils, like neutrophils, originate in the bone marrow, but are rather larger than neutrophils, being 12–17 μm across. The nucleus of the eosinophil is usually bilobed, and the cytoplasm is filled with eosinophilic granules that are larger than the granules found in neutrophil leukocytes. Eosinophils are highly phagocytic, capable of ingesting various bacteria, fungi, immune complexes and inert particles and, like neutrophils, eosinophils contain hydrolytic and proteolytic enzymes contained in membrane-bound granules. Eosinophils are seen in skin biopsies in certain infections, in reactions to insect bites and other foreign bodies, in some drug reactions, and in bullous eruptions such as bullous pemphigoid, and some forms of pemphigus. They are of major importance in the condition known as eosinophilic cellulitis, and may also occur in association with proliferations of cells of the lymphoid series in certain cutaneous T-cell lymphomas.

Histiocytes/monocytes/tissue macrophages

The term histiocyte is used by different authors to mean different things, and is an unsatisfactory term. Monocytes circulating in the blood may be attracted into the skin for the purposes of phagocytosis. They are then called histiocytes or tissue macrophages. However, many other mesenchymal cells and cells of the granulocyte series are also capable of phagocytosis. The appearances of a histiocyte vary considerably. Many of the cells are fairly large with a lightly staining, sometimes vesicular, elongated nucleus. The cytoplasm is usually pale and cell margins may be indistinct. The cells may be dendritic, spindle-shaped or epithelioid, taking on the latter form particularly in epithelioid cell granulomas. The size of histiocytes is also very variable, ranging from 15 to 25 μm. Compared with some of the cells described above, they are less easy to identify, particularly for the novice, in skin biopsies, and immunohistological methods are often necessary to demonstrate histiocyte subsets. Several factor XIIIa-positive, dendritic phagocytes (dermal dendrocytes) are

seen in close proximity to the superficial microvascular plexus. These cells, together with other immune cells, mast cells and endothelial cells, probably collaborate to coordinate antigen presentation, induction of cellular inflammation, wound healing and haemostasis in this microenvironment. Various histiocytes are found in a wide range of inflammatory and neoplastic disorders, but are particularly important in the production of granulomatous inflammation, both in conditions such as granuloma annulare, and in response to cutaneous infection such as mycobacteria.

Giant cells

Many types of giant cell may be recognized in skin tissues. The three best known are the Langhans' giant cell, the foreign-body giant cell and the Touton giant cell. All these giant cells are derived from tissue macrophages, and forms intermediate between the different characteristic types are sometimes seen. The size of these cells varies greatly, but is usually of the order of between 40 and 120 μm. Langhans' giant cells show a characteristic horseshoe distribution of the nuclei arranged at the cell periphery. They are most characteristically seen in sarcoidosis and tuberculosis. Foreign-body giant cells contain a haphazard arrangement of nuclei scattered throughout the cell cytoplasm, and may also contain foreign material. Although typically seen in foreign-body granulomas, they are common in other forms of granulomatous inflammation, and in situations where there is disruption of pilosebaceous follicular structures with keratin release into the dermal connective tissue. Touton giant cells have a central ring of nuclei enclosing a layer of ground-glass cytoplasm, with a peripheral zone of clearer cytoplasm. They are typically seen in some xanthomas and juvenile xanthogranuloma.

It should be noted that many other forms of giant cell are seen, such as the fairly typical giant cell with scattered nuclei, prominent nucleoli and PAS-positive cytoplasm in multicentric reticulohistiocytosis. Not all giant cells are derived from cells of the macrophage series. Multinucleate cells derived from infected keratinocytes may be seen in various virus infections such as herpes and poxvirus infections, and multinucleate cells derived from melanocytes are quite typical of epithelioid and spindle cell (Spitz) naevi (Fig. 7.18).

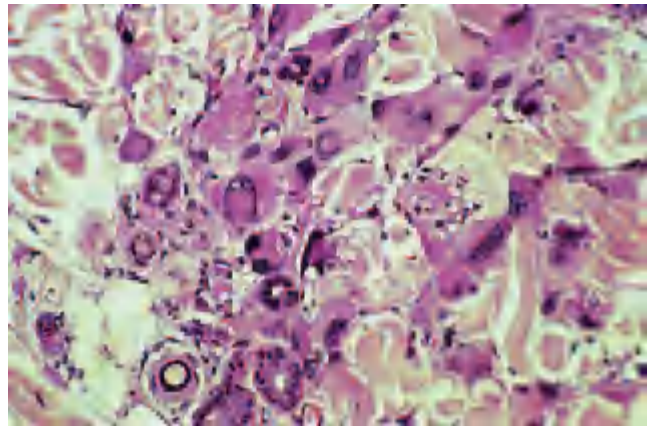

Fig. 7.18 Bizarre multinucleated giant cells from a Spitz naevus.

Mast cells

Mast cells, unlike the white blood cells and some histiocytes, all of which probably originate from the bone marrow, are likely to arise from undifferentiated mesenchymal cells. In normal skin, they are present around small blood vessels in the dermis. They are approximately 9–16 μm in diameter, and they possess a central round to ovoid dark-staining nucleus. The cytoplasm contains small granules that stain metachromatically with such stains as toluidine blue. The granules contain vasoactive substances such as heparin, histamine, and eosinophilic and neutrophilic chemotactic factors of anaphylaxis. Mast cell activation may be triggered by neuropeptides derived from unmyelinated axons that surround perivascular mast cells. This in turn triggers adhesive events between leukocytes and endothelial cells, resulting in angiocentric inflammation.

Although in normal skin the cells tend to have a dendritic morphology, in various pathological conditions, including some forms of urticaria pigmentosa, the cells are larger and polygonal with a central, rounded nucleus. In addition to being found in increased numbers in the mastocytoses, they are also commonly seen in various benign and malignant nerve tumours, and in association with some melanocytic naevi.

Fibroblasts

Fibroblasts are often difficult to identify on routine light microscopy. Their nuclei tend to be oval or spindle-shaped, and with moderately basophilic staining. They are usually found between collagen bundles, and may be prominent in conditions where there is an increase in the production of dermal connective tissue or ground substance, such as morphoea and scleromyxoedema. They may also contribute to the histogenesis of the wide range of so-called fibrocytic tumours that may occur in the skin.

Myofibroblasts

These cells are mainly defined by their electron microscopic appearances and display features intermediate between those of fibroblasts and smooth muscle cells. They are mainly seen in reactive reparative processes

and in neoplasms. Histologically, they have indistinct cytoplasmic margin, pink pale cytoplasm and vesicular nuclei with a single inconspicuous nucleolus.

Smooth muscle cells

Smooth muscle cells occur normally in the skin in the arrector pili muscles, in the tunica dartos of the external genitalia, in the areola of the nipple and in the walls of blood vessels. They are easy to identify by recognizing the normal structures in which they occur and also by their cytomorphology that consists of abundant bright eosinophilic cytoplasm and vesicular nuclei with a single inconspicuous nucleolus.

Rhabdomyocyte (striated muscle cell)

Skeletal muscle occurs in the skin of the neck and of the face. The constituent cells are arranged in bundles and have characteristic cross striations and abundant bright pink cytoplasm.

Schwann cells

Schwann cells are the main constituent cells of nerves. They envelop the neuroaxons and are characterized by a slender hyperchromatic thin nucleus and inconspicuous cytoplasm.

Endothelial cells

A single layer of endothelial cells lines all types of vascular channels in the skin. These cells usually appear flat with inconspicuous cytoplasm and small histiocyte-like vesicular nuclei. However, in most pathological processes, they become more prominent and may appear somewhat hyperchromatic. This, coupled with an increase in mitotic activity, may lead to confusion with malignant cells, particularly in cross-sections, where the normal architecture of the vascular channel is often not apparent.

Pericytes

Pericytes occur as a single layer of indistinct cells around small dermal blood vessels. They are recognized by their location and by positive staining for actin.

Miscellaneous

In addition to closely examining cytology under the high-power objective, the opportunity should also be taken to look carefully for organisms, foreign bodies or deposits of foreign material such as amyloid. Special staining techniques will often be needed to confirm suspicions, and with these stains bacterial, fungal and protozoal organisms may be identified as well as various forms of parasite. The presence of viral organisms can also be inferred by the presence of characteristic cytopathic changes, such as occur for instance with herpesvirus infections and infections with cytomegalovirus. Close examination of nerves and blood vessels should be carried out, particularly in relation to the presence of any organisms or tumour deposits. After examining adnexal structures and the subcutaneous tissues, it is useful to return to low-power examination and attempt to be certain one has not missed any pathology. It is not uncommon to discover more than one abnormality in a tissue section. Patients who develop solar keratoses may also have seborrhoeic warts, naevi and basal cell epitheliomas. Biopsies from patients with acquired immune deficiency syndrome (AIDS) often have multiple pathologies, and one may, for example, see a biopsy of perianal tissue in which there is evidence of cytomegalovirus infection in the endothelial cells, HPV infection of the overlying epithelium and the presence of Kaposi's sarcoma.

The importance of carefully assessing both the low-power pattern of changes in a skin section, as well as a more detailed examination of the cytology of the pathological changes, cannot be too strongly emphasized.

How to produce a histopathology skin report

After carefully carrying out the recommended procedure for low scanning power and high-power examination of a skin biopsy slide, the pathologist will either need more information, or will be in a position to provide a microscopic histopathological report to supplement the report on the gross pathological appearance of the biopsy specimen before processing. If there is very little obvious abnormality, it may be appropriate to cut deeper levels from the tissue block, or even consider blocking any remaining wet tissue that is in storage. If the specimen has been blocked obliquely or, for instance, the epidermis is missing, reblocking will be necessary. Serial sections may be required to determine pathological features that are only focal, such as changes affecting pilosebaceous follicles in a biopsy from the scalp. Special stains may be required for the evaluation of abnormal dermal deposits, to detect the presence of organisms, or to elucidate the nature of various pigments in the biopsy material. Immunohistochemical studies may also be requested in, for example, cases of cutaneous lymphoma or malignant spindle cell tumours. If there is going to be undue delay in these various extra investigations, a preliminary report should always be issued.

Although reporting of histopathology is to some extent a subjective art, and every pathologist will have his or her own idea of what is an appropriate report, a description of the objective histological changes, and either a suggested diagnosis or a differential diagnosis, are always desirable.

In a description of the pathology, it is important never to describe features that are not present, even though they may be consistent with the correct diagnosis. The differential diagnosis suggested by the pathologist should fully take into account the clinical information supplied by the clinician. If the clinician suggests on the request form chronic superficial scaly dermatitis, it would be churlish to sign out the report as subacute eczema without further qualification. In addition to a description of the objective pathological changes and a diagnostic suggestion, it is quite legitimate to add a further comment in certain situations. If the clinician suggests a tumour has been excised, then a comment on the adequacy of excision is obviously useful. Conversely, if the clinician states that this is a diagnostic/incisional or superficial biopsy, it is irritating for the clinician to receive a report stating that tumour extends to one margin of excision.

In some situations where the various histopathological parameters need to be recorded repeatedly in biopsies from specific skin disorders, for example malignant melanoma, specially designed forms facilitate both the recording of information and subsequent computer analysis.

There is some degree of disagreement as to whether it is the role of the histopathologist under any circumstances to make recommendations for treatment, and no general rule can be given on this. If one knows one's clinical colleagues well, it is quite appropriate under certain circumstances to recommend a modest re-excision of the biopsy site, for instance in early superficial spreading melanoma. Some pathologists prefer to make such comments in a separate covering note. With some rarer conditions, particularly if they have serious implications for the patient, a telephone call to the clinician, or again a covering note, may be a reasonable approach. An offer from the pathologist to discuss any interesting case in more detail is often a good idea, and is usually taken up. It is always in the best interests of the patient for there to be a close working relationship between the histopathologist and the clinician.

Finally, it is most important always to appreciate one's own limits of ability. One should never be afraid of asking for a second opinion from a colleague. It has been said that sections from skin biopsies fall into three groups. Firstly, there are those sections where the histological appearances are easy for anyone to interpret and diagnose. Secondly, sections from biopsies, for instance of a very poorly differentiated spindle cell tumour, where one does not know what the diagnosis is, but knows that it is likely that no one else will either. Thirdly, sections where one does not know how to interpret the histological appearances oneself, but does know it is likely that someone else will! Once one is able to divide histological material into one of these three groups, one is already on the way to becoming an accomplished diagnostic dermatopathologist.

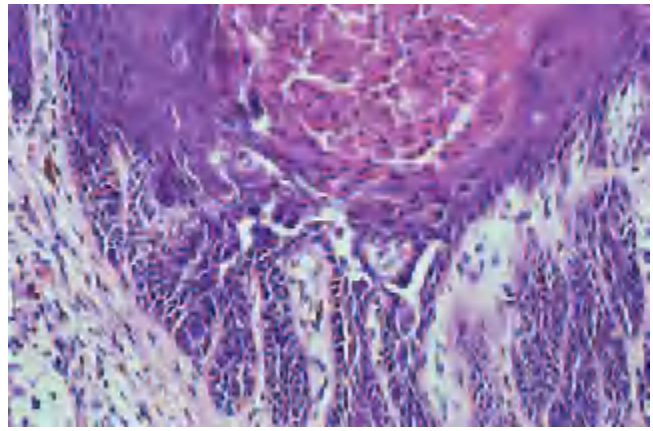

Fig. 7.19 A biopsy from a case of Darier's disease, showing the histological features of parakeratosis, dyskeratosis, acantholysis and formation of villi.

Commonly used descriptive terms in dermatopathology, and their diagnostic significance

Acantholysis

Acantholysis is the term used to describe loss of cohesion between keratinocytes, due to breakdown of intercellular bridges. It results in the formation of intraepidermal clefts, vesicles and bullae. It appears to be the primary pathological change in a group of diseases including pemphigus and its variants, Darier's disease, transient and persistent acantholytic dermatosis and warty dyskeratoma. The site of acantholysis in these disorders is important. In pemphigus foliaceus and pemphigus erythematosus, acantholysis is usually confined to the upper portion of the epidermis, whereas in pemphigus vulgaris the split is formed at a lower level in the epidermis. In benign familial pemphigus (Hailey–Hailey disease), although acantholysis is often focal or incomplete, where it does occur it tends to affect the full thickness of the epidermis.

Acantholysis may also be seen secondary to some other pathological change, where there is alteration or damage to epidermal cells. It may occur, for example, in bullous impetigo, viral disorders, solar keratoses and some forms of squamous cell carcinoma. When acantholysis occurs in these disorders, the term secondary acantholysis is often used to distinguish the process from primary acantholysis, which occurs in pemphigus and related diseases (Fig. 7.19).

Acanthosis

This term is used to describe an increase in number of cells in the Malpighian or prickle cell layer of the epidermis (from the Greek for prickle or thorn). Sometimes, a distinction is made between increased thickness of the epidermis due to enlarged keratinocytes (pseudoacanthosis)

and true acanthosis due to increased numbers of keratinocytes. In practice, acanthosis is commonly used to cover both senses. Increased thickness of the epidermis may result from increased length of rete ridges, as in a psoriasiform tissue reaction, or may effect the whole epidermis, such as in lichenification. Acanthosis is commonly accompanied by other histological changes such as hypergranulosis, hyperkeratosis and papillomatosis.

When reactive epidermal proliferation is marked, the process may simulate an epithelial carcinoma, and in this situation is referred to as pseudoepitheliomatous hyperplasia. Acanthosis may be seen in a wide variety of inflammatory and neoplastic disorders. Some of the common situations where this feature may be seen include the following:

1 Naevoid conditions and localized benign epidermal tumours—for example, keratodermas, epidermal naevi and seborrhoeic keratosis.

2 Virally induced papillomas—for example, viral wart, molluscum contagiosum.

3 Secondary to inflammatory conditions affecting the epidermis, particularly where chronic—for example, persistent friction, lichenification, prurigo and chronic eczema, psoriasis and lichen planus.

4 Secondary to conditions associated with loss of keratinocyte adhesion—for example, the pemphigus group of disorders and Darier's disease.

5 Secondary to conditions associated with the presence of foreign cells within the epidermis, such as malignant melanoma, Paget's disease, mycosis fungoides and Langerhans' cell histiocytosis.

6 Acanthosis is commonly seen overlying a variety of abnormalities in the dermis:

(a) dermal tumours such as fibrous histiocytoma and granular cell tumour;

(b) certain forms of cutaneous infection such as lupus vulgaris and blastomycosis;

(c) overlying dermal deposits of substances such as amyloid, abnormal elastic tissue or in association with foreign bodies; and

(d) in association with chronic oedema, such as chronic lymphoedema of the lower limb and myxoedema.

Anaplasia

This is a term used to describe variations in nuclear size, dense and clumped heterochromatin, and nuclear contour angulation typical of malignant cells, as in metastatic melanoma.

Apoptosis [4]

This is a morphologically distinct type of cell degeneration and death, usually applied to keratinocytes that become homogenous and eosinophilic and are extruded into the underlying upper dermis. These eosinophilic bodies (known as Civatte or colloid bodies), and the process of apoptosis, occur characteristically in lichenoid tissue reactions. A similar process may be observed in many other processes, for example, following UV light exposure, in graft-versus-host disease and in cutaneous lupus erythematosus.

Basal lamina (Chapter 3)

This structure, also known as the basement membrane, is a submicroscopic structure approximately 40 nm in thickness, which extends along the undersurface of the epidermal basal cells. It is not visible with light microscopy. The term basement-membrane zone is sometimes applied to the area that may be visualized with the PAS-staining technique (see Fig. 7.5). This area not only includes the basal lamina itself, but also the lamina lucida and anchoring fibrils.

Bullae

Bullae represent fluid-containing cavities occurring within or below the epidermis. Small bullae are known as vesicles. Determination of the site of bulla formation is most important in histological assessment of skin biopsies. Intraepidermal bullae may arise as the result of spongiosis, as in acute eczema, from reticular and ballooning degeneration seen in association with viral disorders, or from acantholysis or epidermal cell necrosis. Subepidermal blisters usually result either from a defect in the basement membrane region, such as occurs in some forms of epidermolysis bullosa and porphyria, from a disruption of the basement membrane from intense liquefaction degeneration or necrosis of the basal cell layer, such as may occur in bullous lichen planus or bullous lupus erythematosus, or as a result of dermal inflammatory processes involving the upper dermal connective tissue and basement-membrane region. In some conditions, such as erythema multiforme, both subepidermal and intraepidermal factors seem to be involved in bulla formation.

Colloid body

This term, usually regarded as synonymous with Civatte body, describes the homogeneous eosinophilic rounded body resulting from degeneration and death of keratinocytes, particularly in the lower layers of the epidermis. This structure is found in various lichenoid tissue reactions and is involved in the process of apoptosis.

Crust

This term is used to describe collections of inflammatory cells, red blood cells, plasma and fibrin in the superficial

portion of the epidermis. A crust may also contain micro-organisms, and often replaces a partial or total loss of the epidermis itself.

Curlicue pattern

This descriptive term refers to the twisting and curving of dermal fibrohistiocytic cells around collagen bundles, often at the margins of a dermal tumour. The pattern is mainly observed in fibrous histiocytomas. The pattern described by this term is the same as that referred to by the term storiform.

Degenerations

Dermal

Colloid degeneration. Colloid degeneration refers to the deposition of extracellular homogeneous gelatinous material of variable composition. It is typically seen in colloid milium, but may also be found in certain epithelial tumours.

Elastotic degeneration. This describes the degenerative changes that develop with increasing age, particularly in the upper part of the dermis in sun-exposed skin. Early changes include an increase in the number and size of connective tissue fibres staining with elastic stains. In advanced stages of the condition, there are masses of disorganized elastotic fibres occurring, particularly in the upper third of the dermis, and appearing to replace the normal collagen. This elastotic degeneration is normally separated from the epidermis by a narrow band of normal-staining connective tissue. In sections stained with H&E, the elastotic material is basophilic.

Fibrinoid degeneration. This term describes the deposition in tissue of eosinophilic, granular or fibrillary material resembling fibrin. The composition of the eosinophilic amorphous material may vary in different situations, but fibrinogen, plasma proteins, immunoglobulins and dermal ground substance may be components of the material. It is most typically seen in forms of necrotizing vasculitis, and is also found in disorders such as lupus erythematosus and the collagen diseases.

Hyaline degeneration. This term refers to the presence of homogeneous eosinophilic degenerative material in dermal connective tissue, or in relation to blood vessels. The material has a glassy and refractile appearance. Hyaline degeneration occurs in forms of porphyria, lipoid proteinosis and sometimes in lichenoid tissue reactions. Epithelial structures may also show a similar type of change, for instance the tumour cells of cylindroma frequently undergo hyaline change.

Myxoid degeneration. This indicates the deposition or replacement of dermal connective tissue by amorphous, stringy, basophilic material. This pattern of degeneration is seen in localized myxoedema, papular mucinosis, scleredema and dermatomyositis, as well as being seen in various neural, epithelial and adnexal neoplasms.

Epidermal

Ballooning degeneration. This form of degeneration of keratinocytes is associated with marked swelling and pallor of individual cells, with loss of intercellular bridges. A blister forms as a result of the consequent acantholysis. Ballooning degeneration along with reticular degeneration is characteristic of virus disorders affecting epithelia, such as herpesvirus infections.

Hydropic degeneration. This is also known as liquefaction degeneration, and refers to a vacuolar change that affects the basal cell layer of the epidermis. Small droplets and vacuoles develop within and in between basal cells. The process is commonly associated with pigmentary incontinence, and when marked may lead to subepidermal blister formation. It occurs typically in the whole range of lichenoid tissue reactions, including lupus erythematosus, lichen planus, dermatomyositis, poikiloderma atrophicans vasculare and lichen sclerosus (Fig. 7.20).

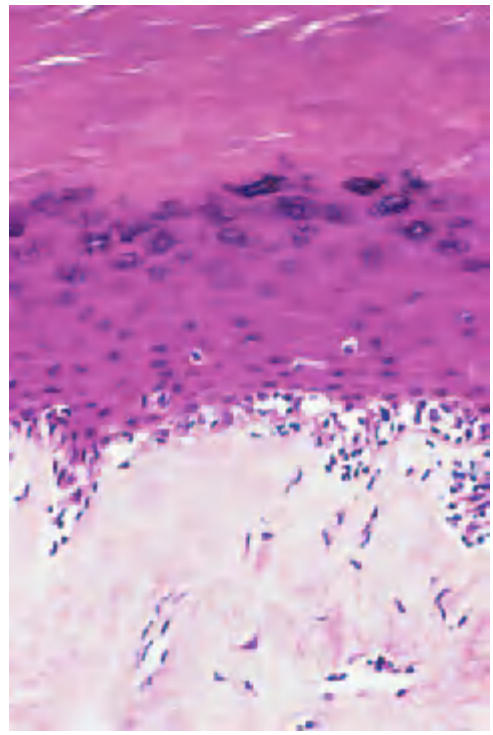

Fig. 7.20 Prominent liquefaction degeneration from a case of lichen sclerosus.

Reticular degeneration. This indicates the development of large, multiple, intraepidermal vesicles, where there remains a ragged network of epidermal cell remnants. As mentioned above, reticular degeneration often occurs in association with ballooning degeneration in acute virus infections of the herpesvirus and poxvirus groups. This pattern of epidermal degeneration may also sometimes be seen in the acute bullous reaction of contact dermatitis.

Desmoplasia

This term describes a pattern of fibrosis or sclerosis of dermal connective tissue, usually in association with an epithelial or melanocytic proliferative lesion. Examples of the use of this term are in desmoplastic trichoepithelioma and desmoplastic malignant melanoma.

Dyskeratosis

This term relates to some abnormality in the process of epidermal cell keratinization. The changes usually consist of nuclear pyknosis and bright pink condensation of the cytoplasm of keratinocytes. The process occurs in two main contexts. Firstly, in malignant and premalignant epithelial lesions, such as squamous cell carcinoma, Bowen's disease and solar keratosis. Secondly, in various forms of acantholytic disorder such as Darier's disease. In this latter condition, specific types of dyskeratotic cell include corps ronds and grains (see Fig. 7.19).

Dysplasia

This term is a confusing one, especially when used to describe atypical melanocytic naevi, because if communication with the clinician is inadequate, it may be interpreted to mean different things. Its use normally reflects some abnormality in cell maturation, cytomorphology or the relationship between cells in epithelial structures. It has the connotation of possible progression to neoplastic disease.

Exocytosis

This term describes the migration of inflammatory cells from the blood vessels of the dermis into the overlying epidermis. The process may be associated with spongiosis, as in eczema, or occur in the absence of spongiosis, such as may be seen in mycosis fungoides. In the later setting, the word epidermotropism is usually preferred.

Granuloma

A granuloma describes circumscribed foci of inflammation containing monocytes, macrophages, lymphocytes and epithelioid cells. Multinucleated giant cells of foreign body, Langhans or Touton type may also be observed. Varying degrees of epidermal hyperplasia, capillary proliferation and dermal fibrosis are common accompanying changes. Granulomatous inflammation occurs in a wide variety of infectious and non-infectious conditions. Many different types of organism ranging from viruses through bacteria to fungi can produce a tissue granuloma. The presence of granulomas in a skin biopsy may indicate a systemic disease, such as sarcoidosis, or a localized dermatosis of unknown cause, such as granuloma annulare or acne agminata. The precise histological appearance of a dermal granuloma depends not only on the underlying cause, but on the period over which the disease has been active, and the immune status of the host.

Grenz zone

This comes from the German word for border, and in dermatopathology is applied to a narrow zone of normal dermis between the epidermis and pathological changes in the underlying dermis.

Hypergranulosis

This refers to an increase in thickness of the granular layer of the epidermis, and is commonly accompanied by hyperkeratosis and acanthosis. It is often seen in chronic lichenification and lichen planus and related disorders.

Hyperkeratosis

Hyperkeratosis refers to increased thickness of the stratum corneum, and may be associated with acanthosis of the Malpighian layer. Hyperkeratosis may occur in various disorders of keratinization, such as the keratodermas and some ichthyotic disorders, and relative hyperkeratosis is quite common in chronic discoid lupus erythematosus. In certain conditions, such as in Flegel's disease, in addition to increased thickness of the stratum corneum there is a change from the normal basket-weave pattern to a compact arrangement of the stratum corneum cells. When assessing the thickness of the stratum corneum, it is important to correlate the histological appearances with the site of the biopsy. The stratum corneum is normally thick on the palms and soles, and very thin, or even absent, around the eyelids and near mucous membrane junctions.

Epidermolytic hyperkeratosis

This particular change, also sometimes referred to as granular degeneration, is a peculiar and characteristic change seen in a number of skin disorders. There is an increase in the thickness of the granular layer, where keratinocytes appear to contain an increased number of

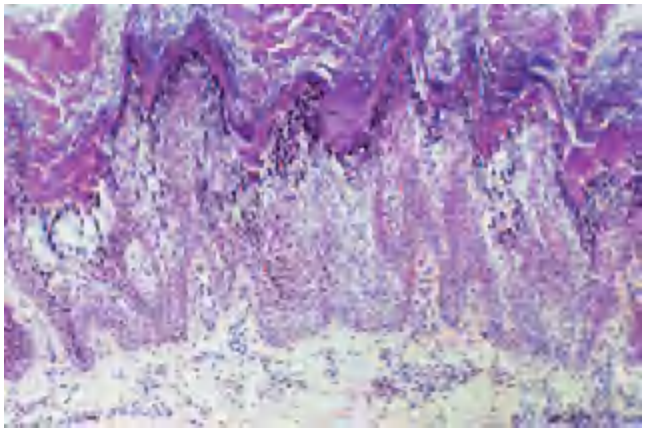

Fig. 7.21 Epidermolytic hyperkeratosis seen in a biopsy from a patient with congenital bullous ichthyosiform erythroderma.

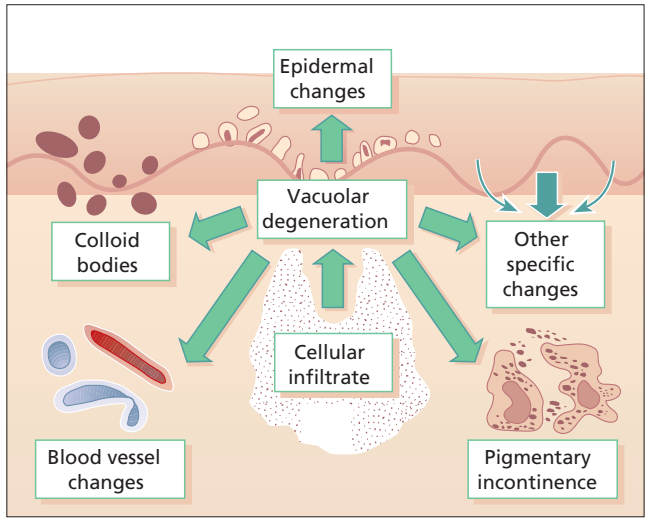

Fig. 7.22 The lichenoid tissue reaction. Various histopathological consequences follow damage to the dermal–epidermal junction. These histopathological changes are seen in a wide variety of lichenoid reactions, ranging from lichen planus to lupus erythematosus, poikiloderma atrophicans vasculare, lichen sclerosus and lichenoid drug eruptions.

keratohyalin granules. Perinuclear vacuolization occurs in this area, and the cell boundaries may be indistinct. The vacuolization may be marked, in some cases appearing to lead to intraepidermal vesicle formation. Although this change is best known as the characteristic histopathological feature of bullous ichthyosiform erythroderma (Fig. 7.21), it also occurs in many other inherited and acquired conditions, including a form of palmoplantar keratoderma, so-called epidermolytic acanthoma, and some forms of linear epidermal naevus. It is also occasionally seen as an incidental finding, either in normal skin or in association with a lesion, such as a naevus, a viral wart or a seborrhoeic keratosis.

Follicular hyperkeratosis

This describes varying degrees of hyperkeratosis and plugging of the ostia of hair follicles, and this change may be associated with the rupture of the follicular wall. It occurs in many conditions including pityriasis rubra pilaris, lupus erythematosus, lichen planopilaris and lichen sclerosus.

Kamino bodies

This term describes the eosinophilic globules seen in the epidermis or in the region of the dermal–epidermal junction in spindle- and epithelioid cell (Spitz) naevi.

Karyorrhexis

This refers to the fragmentation of cell nuclei, and the process may be seen in various forms of neutrophilic dermatoses and cutaneous pyoderma. It is commonly seen in necrotizing vasculitic processes. The term leukocytoclasis specifically refers to the fragmentation of nuclei of neutrophil polymorphonuclear leukocytes. However, the term is sometimes used to refer to fragmentation of other inflammatory cells such as lymphocytes.

Lichenoid tissue reaction

This is a pattern of changes occurring both in the epidermis and especially the dermis, seen in a wide variety of conditions, ranging from lichen planus itself to lupus erythematosus, lichen sclerosus and the poikilodermas. Lichenoid changes may also be seen in some examples of cutaneous drug eruptions. In the upper dermis, there is a band-like infiltrate consisting predominantly of mononuclear cells. This is closely related to the dermal–epidermal junction, which itself may have a saw-toothed pattern. Liquefaction degeneration of the basal cell layer is seen, and colloid body formation may be present. There is often an increase in thickness of the overlying epidermis, affecting both the Malpighian layer and the stratum corneum (Fig. 7.22).

Metaplasia

This term is used to indicate an alteration of one type of tissue into another, such as the formation of bone in certain epithelial tumours, for example pilomatricoma.

Necrobiosis

Necrobiosis is an unsatisfactory term derived from words for life and death. It is applied to certain granulomatous disorders where the dermal connective tissue becomes

homogenized and loses its normal staining characteristics, resulting in mucinous, fibrinoid or sclerotic alteration. The outlines of the normal architecture are usually still present, and the amount of inflammation varies. Changes of necrobiosis are normally surrounded by a palisading histiocytic granuloma. The condition is seen in association with granuloma annulare, necrobiosis lipoidica, rheumatoid nodule and acne agminata.

Necrosis

This term describes the death of cells or tissue.

Necrolysis

This is used to describe the separation of tissue constituents as a consequence on cell death. Epidermal changes of necrolysis are seen in various inflammatory reactions such as erythema multiforme, toxic epidermal necrolysis and necrolytic migratory erythema seen in association with the glucagonoma syndrome.

Papilloma

This term indicates a tumour or tumour-like proliferation exhibiting both papillomatosis and hyperkeratosis. Acanthosis is also present. Examples of skin papillomas include viral warts, seborrhoeic keratoses and some epidermal naevi.

Papillomatosis

This change is characterized by elongation upwards of the dermal papillae, giving an accentuated and sometimes irregular, undulating configuration to the dermal–epidermal junction. The feature is commonly seen in psoriasis, and a wide variety of other inflammatory and neoplastic cutaneous disorders.

Parakeratosis

Parakeratosis can be defined as the retention of keratinocyte nuclei within the horny cell layer. It represents a disturbance of keratinization, and is normally associated with an absence or reduction in thickness of the granular cell layer. The histological feature of parakeratosis is commonly seen in many different forms of inflammatory dermatosis, and is closely associated either with increased epidermal cell turnover or with inflammatory changes in the epidermis itself. It is commonly seen in psoriasis and subacute eczematous reactions, and in conditions such as pityriasis lichenoides where the change reflects an earlier disturbance in the underlying epidermis. In chronic inflammatory conditions where epidermal turnover is unaffected, such as in lichenoid reactions, parakeratosis is rarely seen. Dysplastic epithelial changes, such as those occurring in actinic keratoses and Bowen's disease, are normally accompanied by parakeratosis.

Pigmentary incontinence

This refers to the loss of melanin from cells of the basal layer of the epidermis, and the accumulation of melanin, both free and within dendritic macrophages, in the underlying dermis. It is associated with damage to keratinocytes of the lower epidermis, and is commonly seen in lichenoid tissue reactions. Small amounts of melanin may be seen in the upper dermis in normal pigmented skin.

Pleomorphism

This describes variability in the appearance of cells, and in particular the nuclei of cells of the same type. Although it may be seen in malignant and premalignant conditions, marked pleomorphism may also be seen in benign lesions such as Spitz naevi.

Polymorphism

Conventionally this is used to describe a variation in types of cells in a cutaneous lesion. This term is not the same as pleomorphism.

Pustules and abscesses

These terms are used to describe cavities within the epidermis or dermis formed by collections of neutrophil or eosinophil polymorphonuclear cells. Occasionally, the term is used to describe collections of other leukocytes, as in the term Pautrier microabscesses (see below). Cutaneous pustules may be sterile, or associated with an infectious microorganism. Certain specific types of microabscess and pustule are of diagnostic value in dermatopathology.

Kogoj's spongiform pustule. This describes the multilocular micropustules that form in the superficial portions of the epidermis in pustular psoriasis. They form in a similar manner to Munro microabscesses but the process is more extensive.

Munro microabscesses. These lesions are small collections of neutrophil polymorphs usually found within the stratum corneum. They are normally seen in lesions of chronic established psoriasis, and the other histological features of the psoriatic reaction, such as irregular epidermal thickening and parakeratosis, are normally present.

Papillary tip microabscesses. These are small focal collections of neutrophil polymorphs or occasionally eosinophils, in

the tips of dermal papillae. Although they are characteristic of dermatitis herpetiformis, they may occur in other bullous eruptions such as epidermolysis bullosa acquisita and the bullous form of lupus erythematosus.

Pautrier microabscesses. These small, intraepidermal collections of lymphoid cells in the absence of marked spongiosis are characteristic of mycosis fungoides. The cells within the epidermis may show some degree of nuclear hyperchromatism or atypia. Single cell colonization of the epidermis is more commonly seen than true Pautrier microabscess formation in many cases of early mycosis fungoides.

Subcorneal pustules. Large, subcorneal collections of neutrophil polymorphs usually represent either impetigo or subcorneal pustular dermatosis. Sometimes, the distinction of either of these two conditions from pustular psoriasis may be difficult.

Pyknosis

This term is used to refer to hyperchromatism and shrinkage of the cell nucleus. It is normally associated with cell death, and may be seen in a wide variety of conditions, including epithelial dysplasias, drug reactions and reactions to UV light.

Saw-toothing

This refers to an alteration in the pattern of the dermal–epidermal junction where dermal papillae are expanded and the tips of the rete pegs are pointed. The resulting pattern bears a superficial resemblance to the teeth of a saw and the change is seen in lichen planus and other lichenoid reactions.

Spongiosis

Spongiosis is also known as intercellular oedema, and describes the widening of intercellular spaces between keratinocytes due to fluid accumulation. Spongiosis is the characteristic histopathological change seen in acute and subacute eczematous reactions, but is also seen in a wide variety of other conditions; when spongiosis is marked it leads to intraepidermal vesiculation. Spongiosis of follicular epithelium may be associated with increased mucin deposition in the histopathological reaction pattern known as follicular mucinosis.

Storiform patterning

This is a pattern of proliferation commonly seen in various dermal and soft-tissue tumours, where strands of spindle-shaped tumour cells or even collagen bundles are arranged so as to resemble the pattern seen in woven cloth. The term is also sometimes applied to the presence of strands of spindle-shaped tumour cells or connective tissue cells that appear to extend radially from a central hub, similar to the spokes of a wheel. Cartwheel patterning is probably a better term to describe this particular appearance. Storiform and cartwheel patterning, although commonly referred to in DFSP, are by no means specifically diagnostic (Fig. 7.23).

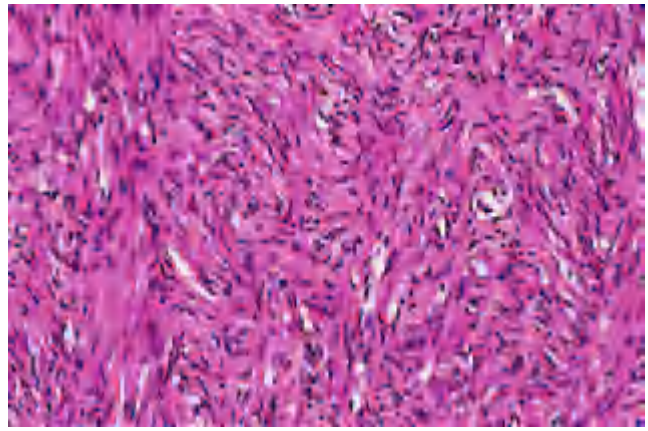

Fig. 7.23 A storiform or woven appearance to the proliferating tumour cells of dermatofibrosarcoma protuberans.

Theque

This term is derived from French and Greek words for a box (*thèque*, θηκη) and is conventionally used in dermatopathology to describe small aggregates or nests of cells, particularly the collections of naevus cells at, and in the region of, the dermal–epidermal junction.

Villi

This term refers to elongated dermal papillae covered usually with a single layer of epidermal cells, and which form the base of a blister cavity that has resulted from the process of suprabasal acantholysis. Villi are seen in the various forms of pemphigus and Darier's disease (see Fig. 7.19), warty dyskeratoma, and transient and persistent acantholytic dermatosis.

Special problems that may be encountered in skin biopsies

Histological sections that reveal little or no abnormality

It is not uncommon for the diagnostic dermatopathologist to come across histological sections where at first sight the appearances resemble normal skin. It may be that the pathological changes have been missed. This can be the

fault of the clinician who has perhaps taken too superficial a biopsy from a lesion of suspected panniculitis, or it can be the fault of the pathologist who has inappropriately blocked the biopsy specimen, or taken too few sections from the material. The importance of studying numerous serial sections in this situation cannot be overemphasized. There are a number of conditions, however, where subtle pathological abnormalities are present, but where a high index of suspicion is needed to make a correct diagnosis. The following list includes some of the more important of these.

Epidermal lesions

Fungal infections. In the presence of patchy epidermal spongiosis and focal overlying parakeratosis, it is always important to exclude the presence of a fungal infection with a PAS stain. Occasionally, a few neutrophil polymorphs may be seen in the upper Malpighian layer of stratum corneum, and this may provide a clue to the correct diagnosis. Pityriasis versicolor may be present in the absence of spongiosis, and is frequently missed.

Ichthyotic disorders. The dominant form of ichthyosis vulgaris is usually characterized by some degree of compact hyperkeratosis, and an absent or attenuated granular layer. If the hyperkeratosis is not significant, the diagnosis may be overlooked. When assessing the stratum corneum, it is always important to look at not only the thickness, but also the quality of the corneocytes. An alteration from the normal basket-weave pattern to a compact cornified layer usually indicates some pathological abnormality.

Porokeratosis. The epidermal changes, usually of atrophy, in the various forms of porokeratosis are often not striking, and the diagnostic cornoid lamella may not be seen on the first sections cut from the block. In diagnostic biopsies, the cornoid lamella may not be present. All forms of porokeratosis may be misdiagnosed, but the disseminated actinic form of the disorder is the most commonly overlooked.

Actinic keratoses. Some flat actinic keratoses may show very little evidence of keratinocyte atypia, and unless a reasonable amount of normal skin is included the biopsy material may be signed out as non-diagnostic.

Pigmentary disorders

Various disorders of epidermal pigmentation may be difficult to diagnose with certainty, particularly if one is not certain of the skin colour of the patient from whom the biopsy has been taken. The loss of pigment in established vitiligo is normally associated with absence or reduction in number of melanocytes. However, in café-au-lait spots and ephelides, melanocytes are normal in number. A melanin stain may reveal a difference between lesional and adjacent skin. In postinflammatory hypo- or hyperpigmentation, the number of melanocytes remains normal with increase or decrease in melanin in basal cells. Often, melanophages are seen in the papillary dermis particularly in post-inflammatory hyperpigmentation.

Dermal deposits

The small amounts of amyloid seen in macular amyloidosis are often difficult to visualize with H&E stain. Special stains are indicated, but the presence of slightly expanded dermal papillae, together with a hint of lichenoid tissue reaction, may alert the pathologist to this possibility. A further useful clue is the presence of scattered apoptotic keratinocytes. The presence of iron pigment in small quantities in the dermis is easily missed, either in common conditions, such as bruising, or in rare situations, such as idiopathic haemochromatosis. A Perls' stain usually highlights iron deposits that have not been detected in slides stained with H&E. The deposits of silver in argyria are often best seen around the basement-membrane zone of dermal sweat ducts.

Connective tissue diseases

Scleroderma, particularly in the late stages, often shows little histopathological abnormality. The coarsening and hyalinization of collagen bundles, with a reduction in the space between them, is often not prominent particularly in the superficial form of morphoea. In the early stages of the condition, there is normally some increase in cellularity around dermal blood vessels. It is always important to try and assess normal skin if there is some present in the biopsy. Similar problems may be encountered with various forms of connective tissue naevi, and abnormalities of elastic tissue such as anetoderma. In atrophoderma, the elastic pattern is more or less normal, but there is a reduction in total thickness of the dermis, which may be difficult to evaluate. A solution to this problem is to obtain an ellipse of skin in which half of the specimen represents clinically normal skin. To indicate the clinically normal skin, the clinician marks the specimen with a stitch.

Dermal infiltrates

Urticaria. In biopsies from urticarial lesions, there may be very little more than slight dermal oedema, which is often difficult to evaluate on processed tissue, together with a slight increase in inflammatory cells around upper dermal blood vessels. It should be remembered that, in normal skin, a few mononuclear cells, fibroblasts and other cells are present in the dermis. A clue to the diagnosis of urticaria is the presence of at least a few eosinophils.

Blue naevus and related disorders. The dendritic melanocytes seen in the dermal melanocytoses, particularly Mongolian spot, are often difficult to recognize without the use of special stains such as the S-100 immunohistochemical marker. The main problem resides in the distinction between melanophages and melanocytes, as most dermal melanocytoses excluding blue naevus contain only few scattered dermal pigmented melanocytes. The use of the immunohistochemical marker for melanocytes such as S-100 is useful, but the product obtained in the detection of the final peroxidase product is usually brown and this is very similar to melanin. This problem can be overcome by bleaching the slide before immunohistochemistry, or by changing the diaminobenzidine for amino-ethyl carbazole, which results in a red product.

Granuloma annulare. In the majority of cases this diagnosis is straightforward, with evidence of a dermal palisading granuloma with necrobiosis. However, in the disseminated form of the condition the changes are often very slight, and may be represented by just a few mononuclear cells dissecting bundles of collagen.

Mast cell disorders. The adult form of urticaria pigmentosa, and particularly its variant telangiectasia macularis eruptiva perstans, frequently shows only a relatively slight increase in numbers of mast cells within the dermis. In these forms of urticaria pigmentosa, the mast cells tend to be rather dendritic or short spindle-shaped. Their granules may not be obvious, and they may resemble normal connective tissue cells, such as fibroblasts. In mastocytoma and some juvenile forms of mastocytosis, the mast cells are larger, rounded cells with central nuclei and are easier to recognize.

Scalp disorders

Unless an adequate biopsy is available for examination, many disorders of the scalp may be difficult to evaluate. Conditions such as telogen effluvium and long-standing alopecia areata show very little sign of inflammation, and diagnosis may have to be made purely on the number of pilosebaceous structures, and the relative number of follicles in different phases of the hair cycle. The study of horizontally sectioned biopsies is the ideal method to study hair follicles with regards to their cycle, pathological alterations and numbers (see Chapter 63).

Conclusion

As mentioned at the start of this chapter, histopathological examination of a skin biopsy taken from an appropriate lesion is a great help in assisting the clinician to come to a correct diagnosis, and therefore to come to a decision regarding management of the patient. Light microscopic examination of sections from skin-biopsy tissue fixed in formalin and embedded in paraffin is likely to remain the single most useful diagnostic technique for the foreseeable future. The wide range of tissue and cytological changes that may be encountered within normal skin and inflammatory and neoplastic conditions mean that considerable experience is required for the dermatopathologist to contribute helpfully to patient management. Many excellent texts are now available on the histopathology of the skin, but there can be no substitute for personal study on a day-to-day basis of as much material as possible under the supervision of an experienced guide. Feedback and communication between clinician and pathologist is essential, and has been perhaps one of the most important factors in the advances in dermatopathology in the last decade. The light microscopist already has a very wide range of additional techniques available to assist in diagnosis and to study the anatomy and physiology of normal and diseased tissues, some of which are outlined above. The numerous new areas of investigation that have developed over the last few years, including molecular biological techniques, such as PCR, *in situ* hybridization and studies on biological response modifiers, cytokines and adhesion molecules, will no doubt continue to further major advances in our understanding of skin in health and disease.

Chapter 8

Molecular Biology

J.L. Rees

Introduction

There is no single all-embracing definition of molecular biology. However, it is possible, certainly with hindsight, to plot and recognize the growth of a unique blend of biochemistry, genetics and cell biology—the subject we now call molecular biology—which is having a revolutionary impact on all areas of biology, not least clinical medicine. The Nobel Laureate James Watson and colleagues, writing in a preface to one of the standard texts of molecular biology, commented that whereas only 25 years ago it was possible for one individual to know all the important topics in molecular biology, this was no longer the case [1]. This explosion of knowledge is not just due to a revolution in our conceptual understanding, but owes as much to an astonishing expansion in our technical facility to characterize and manipulate nucleic acids. The emphasis on nucleic acid rather than, for example, protein or other macromolecules is important. The caricature of a molecular biologist as somebody who believes that proteins are just an intermediary by which one nucleic acid creates another nucleic acid (whereas, in contrast, biochemists believe that nucleic acids are intermediates that allow proteins to generate yet more proteins), like all good caricatures, only serves to highlight the difference in relative success between gene-based and protein-based strategies: nucleic acid-based approaches have, over the last 10 years, provided a remarkably tractable way in which to solve many medical problems. This may change: development of 'proteomics'—defined as the systematic study of proteins in biological systems, with parallels with genomics—is thought by some to be poised to play a major role in drug discovery. Several features of the organization and structure of nucleic acids go some way to explaining the power of this gene-centred approach to biology. Genetic information is conveyed in a *linear* sequence of only four bases; genes are *colinear* with proteins; and genes themselves are arranged in chromosomes in a fixed *linear* sequence, without which cloning of genes on the basis of position (so-called positional cloning or reverse genetics) would be impossible. What is still extraordinary, and was once not obvious, was how much biologically meaningful information could be revealed by merely understanding the linear base sequence of a particular gene [2].

The development of molecular biology as a discipline has not been a gradual step-by-step process but, by contrast, has faltered at several stages [3,4]. Intellectual landmarks include Avery's work with *Pneumococcus*, demonstrating that nucleic acids (rather than protein) carry genetic information; Watson and Crick's Nobel Prize-winning description of the structure of DNA; and subsequent work by Crick, together with Sidney Brenner and others in the late 1950s and early 1960s, describing how information encoded by DNA was realized in protein structure [1–8]. In the early 1960s, however, there was a hiatus lasting until perhaps the mid 1970s. Both Brenner and Crick have described how in one sense they felt the major intellectual problems—how genes encode macromolecular information and how this is converted into protein—had been solved: consequently they both went to work in new areas, Crick in neuroscience, and Brenner on a host of other biological problems including developmental biology [6,9] for which he was subsequently awarded a Nobel Prize in 2002. At this stage, many of the ground-breaking discoveries, whilst having a general applicability, were experimentally limited to simple organisms such as bacteriophages or bacteria. There were not the experimental tools to allow human genome analysis, and consequently genetic approaches to disease were still beyond reach. In the 1970s, a number of fundamental

advances in an area that would later become known as biotechnology changed this situation [3,4]. The identification and experimental manipulation of plasmids and the identification of restriction, and other DNA-modifying, enzymes heralded a new era in our ability to study the human genome and start utilizing genetic approaches to human disease. In particular, combinations of techniques, together with considerable insight, led to the ability to study those rare but important differences between individuals' protein-coding DNA, which are the cause of most inherited disease. Perhaps counter-intuitively, the detection of variation in non-coding DNA (so-called 'junk DNA') was also to have a great influence; virtually all present-day mapping of disease-causing genes relies on such variation. In addition, an ever-enlarging armamentarium of techniques allowed the increased experimental manipulation of DNA, including the reintroduction of DNA initially into cells, firstly in culture, and later into animals, leading to the development of transgenic technology. This new biology now permeates all areas of clinical medicine, and dermatology is no exception: there has been astonishing progress in identifying the genes for a host of skin disorders. As well as providing and hinting at explanations for the underlying pathophysiology of these diseases, these advances promise an increase in the speed of development of new therapeutic approaches, either those based on genes themselves such as gene therapy, or by allowing a quickening of the pace of drug discovery. Whereas it has been possible for many to continue to feign ignorance of this new biology, those who do so are increasingly consigned to understanding an ever-diminishing fraction of the scientific and clinical literature, and of its limitations.

It is not possible within this chapter to give a comprehensive or even fair treatment of the whole of molecular biology as it applies to dermatology. For those interested, there are some unusually readable (and exciting) books on molecular biology to which the reader is directed [1,4,5,7,8]. Nor can the chapter be viewed merely as a catalogue of genetic disorders of the skin: review of the Online Mendelian Inheritance in Man (OMIM) database suggests that up to one-third of the listed disorders may involve the skin. However, what I will try to do is (i) briefly review the structure of nucleic acids; (ii) explain how the structure of DNA allows the development of a number of techniques, which in turn permits further analysis of the relation between genes and organisms; and (iii) give examples of how molecular biological approaches have been informative for the study of skin disease, including a section on cancer genetics. Finally, a brief treatment is given of the use of molecular biological techniques in diagnosis and therapy.

Basic molecular biology of the cell

Structure of nucleic acids [1–3]

DNA is an antiparallel double helix in which the backbones of the helix are made from sugar and phosphate groups; these are linked by one of four bases (cytosine, guanine, thymine and adenine) that form hydrogen bonds with a complementary base on the opposing backbone (Fig. 8.1). The primary genetic information is coded by the pattern of these bases. Importantly, and central to the

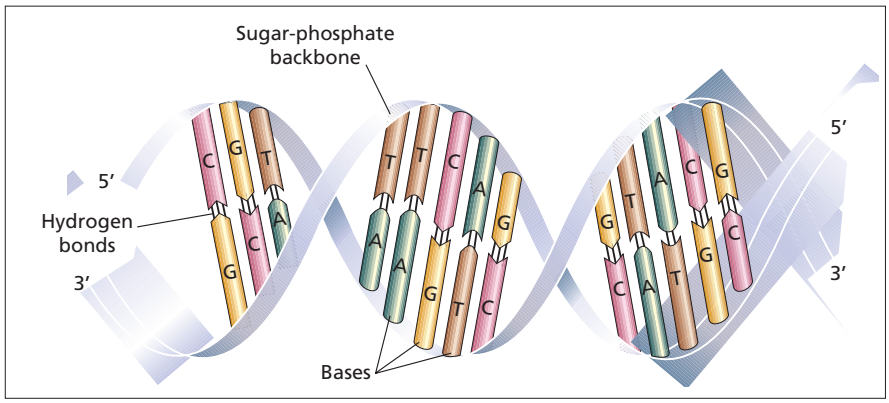

Fig. 8.1 Schematic of the DNA double helix. The backbone of the helix is made up of sugar and phosphate moieties that run in opposite directions (5′→3′ and 3′→5′). The strands are linked by the bases, which pair via hydrogen bonds in a particular fashion, cytosine with guanine, and adenine with thymine. Because of the specific nature of the base pairing, if the hydrogen bonds are broken, each strand can act as a template for the other, such as occurs at transcription of DNA into RNA or when DNA is replicated. It is also evident that because each strand of DNA is complementary to the other, then one strand can be used as a probe for the other.

Watson and Crick model, cytosine always binds with guanine, and adenine with thymine. Because these base pairings are held together by hydrogen bonds only, one can imagine how, if the bonds are broken (such as by treatment with heat), each strand of DNA could act as a template for the opposing strand. Each cell in the human body contains 3 billion bases of DNA arranged on 23 chromosomes. Unless the DNA were organized and packaged in particular ways, the length of DNA in each cell would be 2 m; that from a human body would stretch further than to the moon and back! Surprisingly, perhaps 90% of the DNA on the 23 chromosomes does not appear to code for protein, and is therefore often referred to as 'junk DNA'. Much of this DNA is made up of repeated sequences of DNA, the function of which is unclear. It has, however, been experimentally fortuitous, in that this 'junk DNA' is a rich source of genetic variation between individuals, and forms the basis for genetic mapping of disease traits. Thus for any one chromosome, the genes residing on that chromosome will be diluted by a much larger volume of DNA that does not appear to code for protein. Finding genes is therefore sometimes like searching for a needle in a haystack, even when the area of a chromosome harbouring a gene for a particular disorder has been closely localized by mapping of the disorder in affected kindreds. Not only are genes arranged on chromosomes in an intermittent way, but while genes and proteins are colinear, the DNA that directly codes for particular groups of amino acids is in itself discontinuous on the chromosome, being arranged into introns and exons (Fig. 8.2). With certain important exceptions (which are not central to this description), DNA in every cell in the body is identical in terms of its primary structure. The keratinocyte's DNA is the same as that in a red-cell precursor or a neurone. This immediately raises the problem of how a keratinocyte knows how to make keratins, a red-cell precursor globins and a neurone synapses. How do the different types of cells produce different proteins if they carry identical DNA? DNA is transcribed into RNA, which is then translated into protein. If one were to examine the RNAs produced in these different cell types, one would detect differences. A major area of interest in molecular biology has therefore been in understanding the control of such differences in *gene expression*. This control occurs at two main levels: first, transcription—whether particular RNAs are copied from a particular gene; and second, translation—whether proteins are then made from any particular RNA molecule. Whether a particular gene is transcribed into RNA is determined by the interaction between a variety of proteins in the cell, and by extracellular signals mediated through a number of pathways that interact with RNA polymerases (enzymes that copy DNA into RNA) via the promoter region of the gene. The promoter, located (usually entirely) 5′ to the coding region of the gene ('upstream'), functions akin to an on/off and

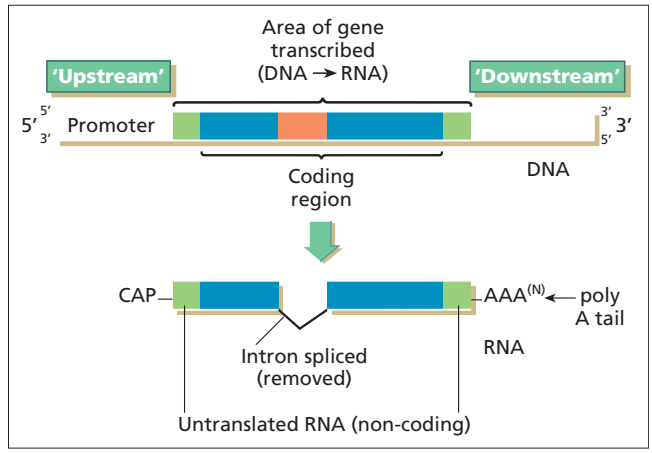

Fig. 8.2 Schematic of a gene and transcription to, and processing of, RNA. The gene comprises the transcribed region, which largely consists of the coding region (including the introns, which will be spliced out and do not code for protein) and the upstream and downstream regions. The promoter region is upstream, although sequences important in determining the level of gene expression in response to a variety of stimuli can be located upstream or downstream. DNA is transcribed into RNA by a DNA-dependent polymerase and the resulting RNA strand processed by removal (splicing) of introns, addition of a string of adenines at the 3′ end (polyA tail) and 'capping' of the 5′ end. Some of the RNA that is transcribed and not spliced out (the untranslated 5′ and 3′ sequences) does not code for protein, but appears to be important for RNA stability and translation into protein. The number of introns is extremely variable: some genes have no introns, whereas others have hundreds of introns, with the length of the introns greatly exceeding the length of the region that directly codes for protein.

volume control on a record player, controlling whether, and how much, gene transcription takes place in response to instructions received from a myriad of pathways. As mentioned above, the gene itself is likely to be discontinuous, such that the RNA produced may contain what are called introns (areas that do not code for protein), which are cut or spliced out once the RNA is made (see Fig. 8.2). The spliced version of the RNA then proceeds to the ribosome (in the cytoplasm) where protein synthesis occurs. Other changes to the RNA also occur, including the addition of a string of adenines (the so-called polyA tail, which appears to be important for the stability of the RNA) and a process termed capping at the 5′ end of the RNA (see Fig. 8.2). The structure of a protein from the same gene may therefore differ in different cells, depending on the splicing and any other changes to the RNA. Throughout this transfer of information, however, it is the linear sequence of bases within and around the gene that appears important in determining the structure of the protein. Within the coding region of the gene, each group of three adjacent bases ('triplet') specifies a particular amino acid. Outside the coding region, although the DNA may not code for protein directly, the pattern of bases, particularly that before the start of a transcription site in

the promoter of the gene, is also important in determining the level of transcription (in response to a variety of stimuli). Primary sequence is therefore more than just a shorthand for the three-dimensional structure of the resulting protein.

Molecular techniques

Extraction of nucleic acid is straightforward. Take a few millilitres of venous blood, or a small skin biopsy, treat with a proteinase overnight, separate the nucleic acid from protein using phenol or chloroform, and then precipitate the several hundred micrograms of DNA with cold alcohol. The resulting DNA can be easily spooled on the bottom of a glass rod or pelleted in a microcentrifuge, and appears as a slightly yellow, sticky substance that can subsequently be dissolved in water and assayed on the basis of its absorption of UV radiation. This isolated DNA is made up of the 3 billion bases of genomic DNA from each cell, multiplied by the 100 million or so cells from which the DNA has been made. However, at this level of analysis, the DNA from different individuals would look much the same. Mere examination with the eye does not provide any insight into the primary base sequence. The technical revolution in the last quarter century allows such analysis. While whole volumes are devoted to describing the techniques of molecular biology, the principles involved are usually straightforward, and it is often possible intuitively to appreciate how and why they work, and to see how they take advantage of the basic structure of DNA.

Restriction enzymes are naturally occurring enzymes that cleave DNA in a sequence-specific manner. They have been identified in a variety of bacteria, where their principal function seems to be to defend bacteria against particular forms of bacteriophage infection (the principle being that particular sequences might occur in an invading organism but not in the host, and that enzymes specific for these sequences would be able to defend the host from invasion). If the DNA isolated from blood or skin, which consists of pieces upwards of 50 kilobases (kb) in length, is suspended in buffer and incubated with a restriction enzyme, the DNA is cleaved into much smaller fragments. The exact size of the fragments depends on the particular restriction enzyme chosen: some might be expected to cut the DNA every few hundred base pairs, whereas others whose target sequence is not so common might only cut once every million base pairs or so. It is therefore possible to characterize the DNA in terms of its primary sequence structure based on the pattern of fragments obtained following restriction enzyme digests. Furthermore, differences between DNA from different individuals (which are particularly common in the non-coding region of DNA) may show up as differences in the size of the fragments following digestion with particular

Fig. 8.3 DNA labelled with ethidium bromide and run through an agarose gel and examined under a UV radiation source. Ethidium bromide intercalates into DNA and fluoresces in response to short-wave UV radiation. The first two tracks show a sample of genomic DNA before and after digestion with a restriction enzyme (note the smearing present in track 2). Track 3 shows the human melanocortin 1 receptor (melanocyte-stimulating hormone receptor) amplified using the polymerase chain reaction (PCR). Tracks 4 and 5 show the PCR, shown in track 3, from two individuals digested with a restriction enzyme that reveals a polymorphism due to a mutation at codon 84 of the melanocortin receptor gene.

restriction enzymes (Fig. 8.3). An important feature of many restriction enzymes is that although their action depends on the presence of a particular sequence of bases, DNA is cleaved in such a way that, with another enzyme known as DNA ligase and a source of energy, it can be stuck together again—'cut and paste' in word-processing terminology. This 'cut-and-paste' facility allows small pieces of DNA (say a couple of kilobases long) that have been cut with the enzyme to be inserted into a vector such as a plasmid. The subject of vectors may appear confusing but, for present purposes, molecular biologists have identified and created a whole range of experimental vehicles that allow the propagation of DNA; very much the workhorses underlying the phrase 'cloning of DNA'. A commonly used vector is a plasmid. Plasmids are naturally occurring, extrachromosomal, circular pieces of DNA found in bacteria. Their medical importance has

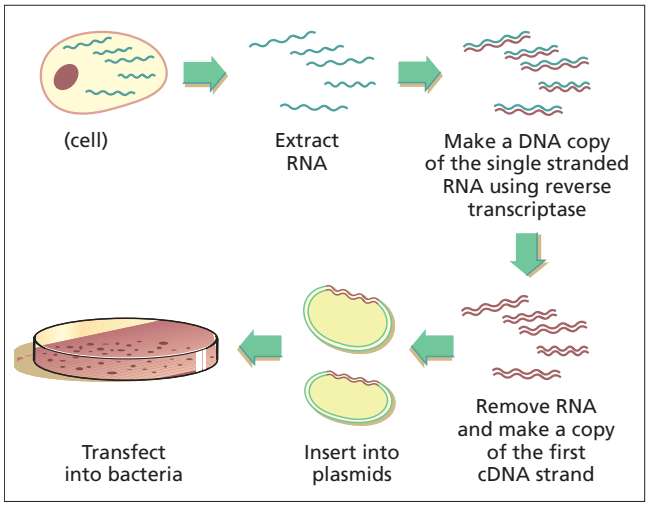

Fig. 8.4 Making a complementary DNA (cDNA) library. RNA (single stranded) is extracted and a cDNA copy of the RNA made using reverse transcriptase. The RNA is then removed, and the first strand of cDNA acts as a template for the second strand of DNA. The short fragments of double-stranded DNA (inserts) are then 'pasted' into plasmids, transfected into a suitable bacterial host, cultured and plated out on agarose. Each bacterial colony will contain a clone of bacteria that contains only one insert. The number of colonies expressing the same insert should reflect the frequency of the RNA species in the cells the library has been made from. Libraries can also be made from genomic DNA, in which case no cDNA synthesis is necessary, but because the desired fragments to be cloned are larger, a variety of other vectors (rather than plasmids) are used.

been that they may carry antibiotic-resistance genes and transmit these from one bacterium to another. Experimental manipulation makes it possible to 'cut and paste' a piece (an 'insert') of DNA into a plasmid, *transfect* the plasmid back into a bacterium, and wherever the bacterium divides, the plasmid and insert will also be copied. Because bacteria can grow in an exponential fashion, this technique allows large amounts of the insert to be produced (cloned).

Additionally, it is possible to restrict (in other words, digest with a restriction enzyme) the DNA isolated from a cell, and 'paste' many of the resulting small pieces of DNA into plasmids (or other suitable vectors), such that each vector will contain only one insert of DNA and that the majority of plasmids would be expected to contain a unique insert. These plasmids can then be transfected back into bacteria, and the resulting collection of bacteria containing many different plasmids comprises a *DNA library*—a representation of a cell's DNA, now in a form that can be cloned, promulgated and used experimentally. An analogous technique can be used for making a complementary DNA (cDNA) library, i.e. a library that represents the RNA species expressed by a particular cell, in which each 'book' corresponds to a particular RNA molecule (Fig. 8.4). Unlike DNA, RNAs are not ordered in the cell in linear arrays like genes on chromosomes, but rather the RNA from a particular cell consists of hundreds of thousands of individual RNA molecules, each of which can be translated into a particular protein. Unlike DNA, RNAs are expected to differ dramatically between different cell types: keratinocytes will produce a large number of RNAs coding for keratins, whereas these would not be seen in a red-cell precursor, which by contrast will be rich in globin RNAs, and vice versa. Because RNA is difficult to manipulate experimentally, the RNA species can be converted using reverse transcriptase into a cDNA—very much the reverse of normal transcription, which converts DNA into RNA—and the resulting DNA inserted into a plasmid, such that the population of plasmids now represents the RNA species in any one cell. The resulting library is known as a cDNA library, 'c' because it is complementary to the RNAs in the original cell.

Southern and Northern blotting

If the DNA extracted from a eukaryotic cell is cut with a particular restriction enzyme, the resulting fragments might be expected to differ between different individuals, the organization of the fragments therefore providing information about any DNA sequence differences. In order to display the DNA, it is possible to order the resulting fragments of DNA by passing them through an agarose gel within an electric field. The charged DNA molecules will migrate through the gel depending on their mass, with the smallest fragments travelling furthest. In terms of strength, the gels used in such gel electrophoresis are not dissimilar to a jelly prepared for a children's party, and they therefore need to be handled with care. However, once the nucleic acid has migrated through the gel, it can be conveniently transferred to a nitrocellulose (or better still a nylon) membrane, in a process called Southern transfer (Fig. 8.5). The DNA is then fixed (cross-linked) to the membrane (which, while looking like a piece of paper, has similar tensile properties to a plastic carrier bag) using UV radiation. Importantly, although the nucleic acid is now covalently bound to the membrane, it is still free to take part in hydrogen-bond reactions. This transfer of DNA from an agarose gel to a membrane is known as Southern blotting, after its inventor Ed Southern; Northern blotting (a pun on Southern!) refers to the transfer of RNA and Western blotting to the transfer of proteins. Because RNAs exist as individual molecules rather than as long arrays on chromosomes like DNA, RNA extracted from cells is fractionated immediately, and does not have to be first digested with restriction enzymes. Following Southern blotting, the DNA attached to the membrane will not be visible to the naked eye, although it is possible to see the DNA when it is size fractionated through an agarose gel by virtue of the fact that dyes such as ethidium bromide intercalate in DNA and fluoresce under UV radiation (see Fig. 8.3). If such a

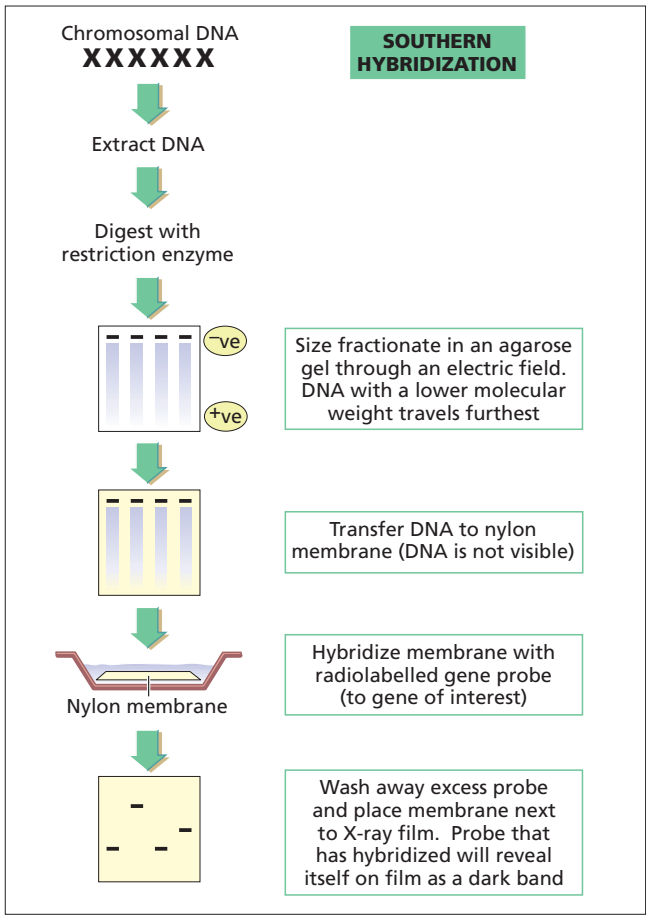

Fig. 8.5 Southern hybridization. Genomic DNA extracted from cells can be cut with a suitable restriction enzyme and then size-fractionated through an agarose gel within an electric field. The DNA in the gel can then be transferred (or blotted) to a nylon (or nitrocellulose) membrane, which is then hybridized with a radiolabelled probe complementary to the target sequence. Following hybridization, the membrane is washed to remove excess probe and sequences that have bound non-specifically. The membrane is then placed next to radiation-sensitive film overnight. Wherever the radiolabelled probe has bound to a complementary sequence, a band will be visible on the film. In this example, DNA from four individuals was run on the gel and hybridized. The differences in the position of the black bands on the autoradiograph reflect that the size of the DNA fragment containing the gene of interest differs between individuals. The most likely explanation for this polymorphism is that the restriction enzyme has cut the DNA differently because of variations in the DNA between the individuals close to, but probably not within, the gene of interest (see text). A similar procedure can be carried out to examine RNA expression and is called Northern (as compared with Southern) blotting. Because RNA molecules exist individually rather than as large chromosomes (as for DNA), no restriction digestion is necessary; the details of the transfer of RNA to a nylon membrane also differ from that needed for DNA. When the membrane is placed next to film, the intensity of the resulting band will reflect the amount of that RNA species in the target cell of interest. More than one band may be seen in a single track, reflecting differences in how the RNA is spliced (there may be more than one splice variant in a particular cell).

gel or membrane is examined, a long smear comprising millions of molecules of DNA will be evident; for most purposes it will be necessary to characterize the DNA further, so that individual genes or stretches of DNA can be examined (see Fig. 8.3). This is usually accomplished by using a radiolabelled gene probe that is complementary to the target of interest, which will bind to the target nucleic acid located somewhere within the smear (and which will comprise only a tiny fraction of the total DNA, for instance one gene out of 100 000).

Imagine that an individual is suspected of harbouring an abnormal keratin gene. As long as the gene of interest has been previously cloned, then it is possible to 'cut and paste' the gene into a plasmid, transfect it into bacteria to amplify the plasmid overnight, and then separate the plasmid DNA from other bacterial DNA, by virtue of the fact that plasmid DNA is smaller than chromosomal DNA. In order to label the gene probe, the plasmid DNA is mixed with the various bases, one of which has been tagged with radioisotope, and a DNA polymerase. Because one of the bases in the mix is radiolabelled, any copied DNA produced will be radioactive. The nylon membrane that contains a smear of eukaryotic DNA can now be mixed (*hybridized*) with the radiolabelled gene probe, which will bind to any complementary sequence it encounters; the keratin probe would therefore be expected to bind to any sequence complementary to it. Following hybridization, the membrane can be washed with salt solutions, to clear any non-specific binding, and placed next to radiation-sensitive film, which when developed should show a band reflecting the binding of the probe to the target sequence on the membrane. If this procedure is carried out in many different individuals, depending on the restriction enzyme used there is a good chance that variations will be seen between these individuals, reflecting sequence differences either in, or close to, the keratin gene. These differences are known as restriction fragment length polymorphisms (RFLPs), which have, until the advent of polymerase chain reaction (PCR) methodology, formed the basis of the mapping of disease-causing genes. Using this assay, a keratin gene that harbours a deletion may also show up as a smaller-than-expected fragment. Alternatively, one might wish to determine the level of expression of a particular RNA species in a diseased skin sample (i.e. how many RNA molecules per cell were present). There are analogous techniques based on Northern blotting, which can be used to study the expression of a particular RNA species. RNAs from various tissues can be size fractionated on an agarose gel, transferred to a nylon membrane, and then probed with the labelled plasmid for a particular keratin gene. Of course, whether any signal is seen will depend on whether that particular cell type expresses keratin RNA. One would not expect to see a positive keratin signal in RNA from red blood cell precursors or fibroblasts.

Furthermore, the intensity of the signal would give some indication of the abundance of any particular transcript. For instance, if cells had been differentially isolated from skin, one might expect that the RNAs for keratins 5 and 14 might be strongly expressed in basal cells in comparison with suprabasal cells, and vice versa for keratins 1 and 10.

The study of gene expression has been revolutionized in the last few years by the development of two new techniques. The first, reverse transcriptase PCR (RT-PCR) makes use of PCR preceded by conversion of RNA to a cDNA copy. The second is the use of microarray technology to study the expression of a large number of RNA species simultaneously. Both these techniques are discussed below.

Polymerase chain reaction

Mention has already been made of the use of DNA or RNA polymerases, enzymes that allow copies of a nucleic acid to be made. For example, a DNA-dependent DNA polymerase will make complementary DNA copies of a DNA molecule, whereas reverse transcriptase is an RNA-dependent DNA polymerase and will therefore make DNA copies of RNA. As well as an energy source and the necessary nucleotide bases, most polymerases require a primer or short sequence of DNA complementary to the strand to be copied, from which to start the synthesis of the complementary copy. The most celebrated use of DNA polymerases is PCR (Fig. 8.6), application of which has revolutionized much of molecular biology and more recently clinical diagnostics. The principle underlying PCR is that if primary sequence information is available for a primer area (usually 15–25 bases long) outside the target area of interest, then once a copy of both strands is made using a DNA polymerase and the resulting daughter strands reanneal, heating the DNA to near 100°C causes the daughter strands to separate again and in turn act as templates for further rounds of replication. The technical breakthrough has been the identification of thermally stable DNA polymerases that are not destroyed by the high temperature needed to separate the complementary strands. Intuitively, one can see that this replication is logarithmic, and therefore PCR allows the amplification of DNA many millionfold. In practice, there are some constraints: amplifying short sequences of 400–500 bases is straightforward but the limit is reached at around 10–15 kb; the extreme sensitivity of the technique can also be a disadvantage, as laboratory contamination can be a major hazard, a drawback which should not be forgotten when PCR is used to diagnose infectious agents in clinical biopsies.

Analogous caveats must apply to the use of RT-PCR. In this technique, RNA is extracted from tissue or cells, converted to its corresponding cDNA and then this cDNA subject to PCR. The technique is extremely sensitive and has been of great use in the study of gene expression patterns in skin pathophysiology. Its utility in skin disease has partly been because of the difficulty of extracting high-quality RNA in suitable amounts for Northern blotting from intact skin (as compared with cell culture). The disadvantages of RT-PCR are that, in the past, reproducibility has been problematic and, because it is so sensitive, RNA species of little biological purpose might be amplified. However, recent developments based on Taqman technology allow a greater quantitative estimation of RNA species, and the technique is now in widespread use.

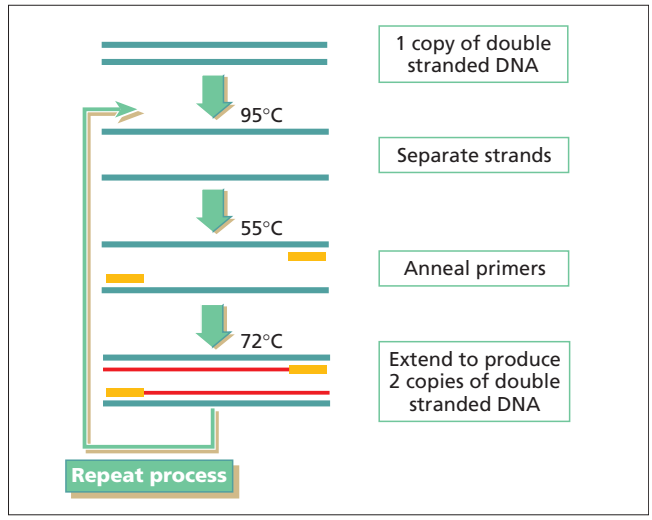

Fig. 8.6 Polymerase chain reaction (PCR). A double-stranded molecule of DNA is denatured into two complementary strands using heat (95°C). Primers are short stretches of DNA, usually 18–25 base pairs in length, complementary to sequences on the separated strands of DNA. For the primers to anneal, the temperature needs to be approximately 55°C, and the presence of a primer is essential for the polymerase (in the presence of the necessary bases and energy) to make complementary copies of each strand of DNA ('extension'). The two double-stranded molecules that are produced can then act as templates for further rounds of replication; hence the term 'chain reaction'. The technical breakthrough that has made PCR so successful was the discovery of polymerases that are so heat stable that they are not destroyed during the denaturation (strand separation) step (such polymerases were found in bacteria that inhabit hot springs).

DNA sequencing

DNA-dependent polymerases also play a central role in the commonest method of sequencing DNA. As long as there is a cloned source of DNA, either from the gene being cloned in a plasmid or from PCR, it is now possible to determine the primary base sequence. Traditionally, this makes use of a DNA polymerase and the four nucleotide bases, only one of which is radioactively labelled. As well as bona fide bases, particular nucleotides ('terminators') are added to the mix; these cause the DNA

Fig. 8.7 An example of a DNA sequence obtained using the dideoxy method of sequencing for which Sanger was awarded a second Nobel prize. References to a full description of the technique are given in the text. Essentially, copies of the template are made using a DNA polymerase only. The presence of dideoxynucleotides (instead of deoxynucleotides as in normal DNA) in the reaction causes the template copies to terminate prematurely. Four such copying reactions are carried out, one for each dideoxy base, such that the reaction terminates where the base was being added. When the products of all four reactions are run out on one gel, then reading across the bands reflects the order of premature termination products, which in turn reflects the primary sequence of the DNA strand being copied. (Courtesy of M. Birch-Machin, Department of Dermatology, University of Newcastle, Newcastle, UK.)

polymerase to fall off the template, resulting in complementary strands that have terminated prematurely. These aborted transcripts will therefore reveal themselves as shorter fragments when the products of the reactions are run on a polyacrylamide gel, resulting in a ladder of lines that will reflect the primary sequence. If separate terminator bases are used in each of the four reactions, one for cytosine, one for guanine, one for thymine and one for adenine, and the resulting four reactions are run out side by side on a gel, then the resulting pattern of radiolabelled prematurely terminated bands will correspond to the primary sequence (Fig. 8.7).

For large-scale sequencing, such as was necessary to sequence the human and mouse genomes, new technology had to be developed. In particular automation coupled with new fluorescent dye labelling allowed previously unheard of rates of DNA sequencing (Fig. 8.8). Radioisotope sequencing is increasingly of historical interest only.

Application of molecular techniques

The utility of the techniques described above has in the recent past been extended in two particular directions. Firstly, it has been possible to marry the approaches of classical genetics and molecular biology to such a degree that mapping of human diseases characterized by a Mendelian pattern of inheritance has now become commonplace; often, the only limiting factor to the identification of disease-causing genes is a paucity of suitable kindreds. Secondly, it has become possible to manipulate genes experimentally such that they can be transfected into either living cells in culture or, more recently, living organisms (transgenic animals).

The principle of mapping of genetic disorders is straightforward and easily grasped: when chromosomes recombine (at meiosis), genes or chromosomal regions that are close together are less likely to be separated than those on opposite ends of the chromosomes [3]. To map human disorders, it is first necessary to construct a genetic map of a chromosome, so that the putative diseased gene can be positioned in relation to other loci on the chromosome. This in turn requires polymorphic loci ordered along each chromosome. Early attempts at linkage of human disorders related particular traits to known protein polymorphisms. This approach was limited because protein polymorphisms are few, and often difficult to detect. By contrast, as mentioned in an earlier section, the majority of human DNA actually comprises DNA that does not code for any particular protein. This so-called 'junk DNA' appears to be under little evolutionary selective pressure, and has therefore provided an excellent vehicle for the delineation and characterization of polymorphic sequences throughout the genome. In particular, recent mapping attempts have made use of hundreds of

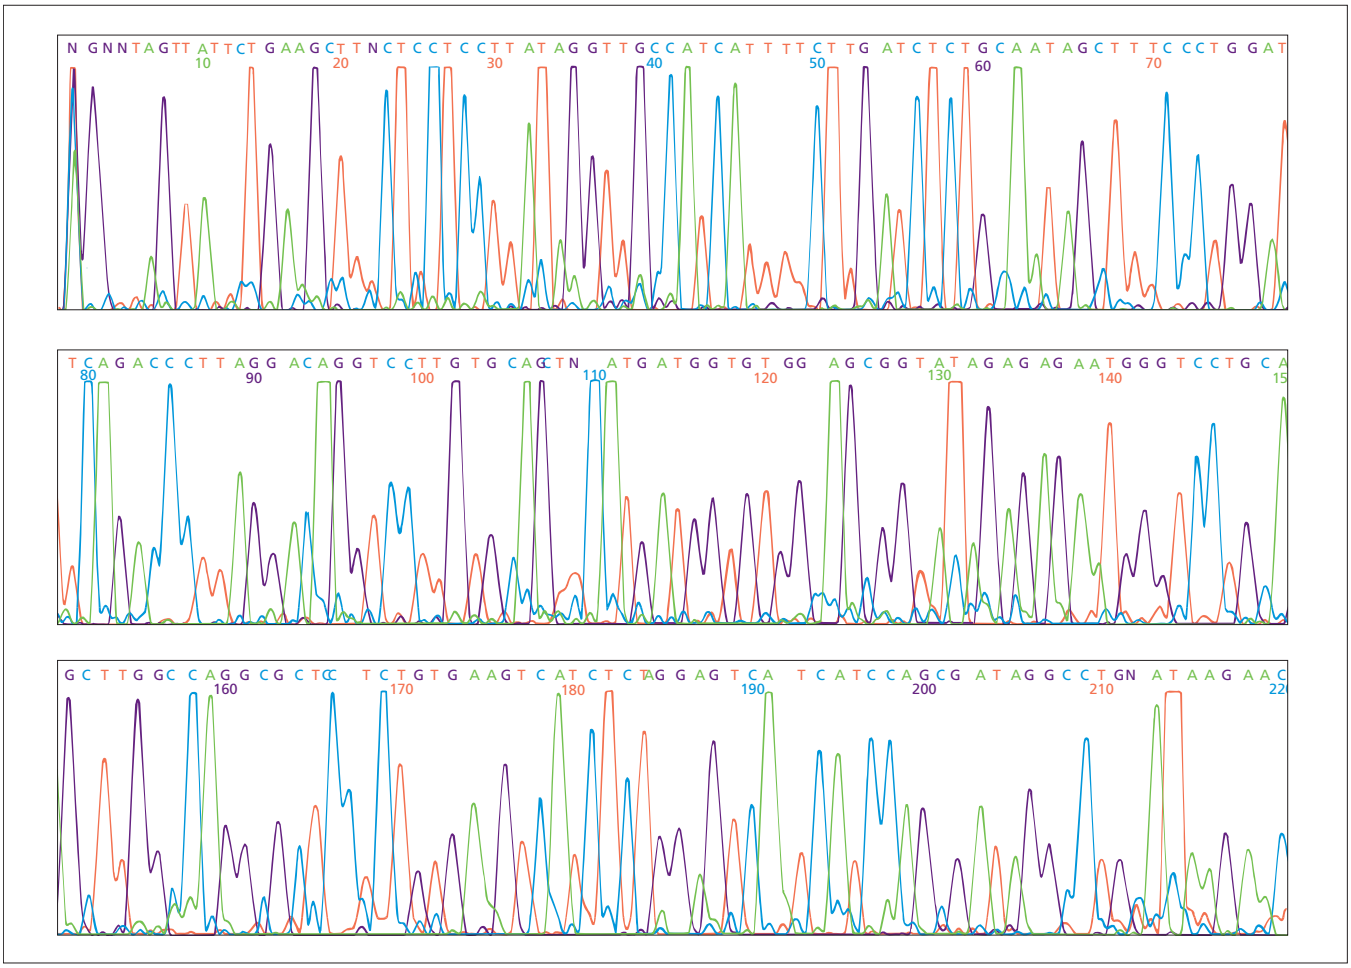

Fig. 8.8 An example of an automated sequence output using fluorescent primers. In this method, each base or primer pair is labelled with a fluorescent dye, the sequencing reaction carried out as described in Fig. 8.7, and the products run in one lane of a gel. A laser beam directed at one point of the gel causes the dyes to fluoresce as the DNA fragments move past, and because the maximum fluorescence occurs at a different wavelength for each of the four dyes, the sequence can be read by computer. (Courtesy of M. Birch-Machin, Department of Dermatology, University of Newcastle, Newcastle, UK.)

thousands of copies of so-called microsatellite DNA dispersed throughout the genome, i.e. at hundreds of loci on each chromosome [4]. These microsatellite loci are each made up of hundreds or even thousands of repeats of a particular core sequence such as $(CA)^n$. The number of repeats is highly variable (polymorphic), such that for many of these loci the chances of an individual's maternal and paternal allele having the same number of repeats is small. Importantly, the DNA outside the repeated sequence is *constant* in all individuals, thereby allowing the design of primer sequences for a PCR reaction. If an individual is polymorphic at one of these loci, PCR analysis using the unique sequence as primer will result in two bands of different length, which can be separated on a polyacrylamide gel: one band originates from the maternal and the other from the paternal chromosome. Analysis using hundreds of such markers up and down each autosome is straightforward and has now been semi-automated. It is now therefore possible with even modest-sized kindreds to track the course of a disease in relation to these markers. If a particular allele at a polymorphic locus always co-segregates with the disease in a kindred, it is likely that the disease is close to that marker (Fig. 8.9).

The second direction in which techniques have advanced relates to the ability to take a cloned gene and process it *in vitro* in order to develop functional assays of its function. Although one may associate a particular change in DNA sequence with a particular disease state, at some stage one wants to be able to prove functionally how the mutation leads to disease. The ability to clone DNA in vectors such as plasmids allows the possibility of transferring these plasmids containing the target gene into human cells in the laboratory. If the plasmids are engineered with appropriate regulatory sequences (promoter and related upstream sequences) that will be recognized by eukaryotic cells, the cells may proceed to transcribe genes from

(c) A A A A A A A A A A A A A A A A A A A A A A A A A

Fig. 8.9 Mapping a gene's position using PCR analysis of microsatellite alleles. In this example, a pedigree (a) with pachyonychia congenita was examined with two polymorphic microsatellite markers (b, c) close to the keratin cluster on chromosome 12. The number of persons in the pedigree identify the origin of the DNA samples analysed in the corresponding lane numbers in (b) and (c). Affected individuals in (a) are identified as filled circles or squares, and in (b) and (c) are marked 'A'. For the two markers used, D17S800 (b) and KRT10 (c), most individuals show alleles of different sizes. Arrows mark the position of the allele for each marker segregating with the disease A. Individuals with the disease can be seen always to have an allele of a particular size, suggesting that the disease-causing gene might be close to this marker. Subsequently it was shown that a keratin mutation caused the disease in this kindred (see text). (From Munro *et al*. [20].)

the plasmid in a temporary fashion (*transient transfection*) or, if particular selective markers are encoded by the plasmid, the plasmids may stably integrate into the host nuclear DNA (*stable transfection*). Use of such experimental systems allows examination of the effects of any cloned gene on a cell's phenotype, although experiments can also be performed with different plasmids harbouring different genes, which can then be transfected into the same cells in order to allow an understanding of the various signalling pathways involved in transcriptional regulation of particular genes. In recent years, techniques have moved beyond the ability just to insert DNA into cells in culture to allow the production of transgenic animals, which either carry an additional copy of the gene or, by taking advantage of the presence of endogenous recombinases, allow a particular gene to be deleted. Readers are directed elsewhere for details of these techniques [3]. For instance, imagine one wanted to examine the effects of a particular mutant form of a human keratin gene that had been associated with a particular skin disease. The mutated human gene, once identified, can be cloned and inserted into a plasmid with the appropriate upstream regulatory sequence (promoter), which means that the gene will only be expressed in a particular target situation. Obviously, for this particular experiment one would only wish to express the mutant gene in a physiologically appropriate manner and so ideally its own promoter should be used. Of course it is not necessary to wait for a spontaneous mutant in a human population from which to make a transgenic mouse. One can always mutate a normal human gene and then insert this into a mouse to see what happens. In fact, it was this approach that first suggested that mutations of *K14* or *K5* cause epidermolysis bullosa: transgenic mice in which a mutated *K14* gene was expressed in the basal layer of skin showed a phenotype corresponding to that of epidermolysis bullosa [5].

An added twist to these sort of experiments is that it is possible, by using the appropriate regulatory regions that determine where a gene is expressed, to express a gene in an unphysiological context. This can be experimentally revealing. For instance, β1 integrin is normally expressed in the basal layer of skin, but when transgenic mice are produced in which β1 integrin is expressed suprabasally by expressing the gene under the involucrin promoter, a phenotype resembling psoriasis is seen [6]. Because of the specificity of expression patterns of the various keratin genes, their promoters have been frequently used to regulate the expression of a variety of other genes within skin, including various cytokine genes or oncogenes [7–9]. An alternative transgenic experimental design is that of homologous recombination, in which endogenous recombinases allow wild-type sequence and a mutated vector sequence to be interchanged in embryonal stem cells. These cells can then be used to create chimeric mice, which later can be bred so that they are null for the relevant gene (i.e. they do not have any functional gene on either chromosome) [3]. One difficulty with this approach is that because some gene products serve multiple functions at different stages of development, a null mutation could be embryonically lethal but, given the survival of the embryo, not lethal in the adult. Obviously a knock-out for this gene product would not survive to adulthood and therefore no adult phenotype would be seen. To circumvent this, the technique of CRE-LOX recombination allows a focal knock-out of the gene product (i.e. not in the whole animal) such that frequently the mutation is not embryonically lethal and that some animals will survive into adulthood where a phenotype may be seen in at least part of the animal. Despite the expense and time required, these approaches are extremely powerful, and can go a long way to resolving what the function of a certain gene is at the physiological or whole-animal level or how mutations of a gene contribute to a particular phenotype. This notwithstanding, perhaps the most striking observation in 'knock-out' animals made using homologous recombination is how often such animals are grossly normal. This has inevitably prompted re-examination of the amount of redundancy, and the biological significance of this redundancy, in various biological pathways.

Strategies for identification of disease-causing genes

Human genetics has sparked a revolution in medical science on the basis of the seemingly improbable notion that one can systematically discover the genes causing inherited diseases without any prior biological clue as to how they function (Lander & Schork [1]).

The spectacular advances in the application of molecular biology to the genetics of human disease have largely been confined to disorders characterized by a simple Mendelian inheritance pattern (such as autosomal dominant or autosomal recessive). Examples include the discovery that mutations in keratin genes can cause a range of skin diseases [2,3] and the identification of *patched* as the tumour-suppressor gene underlying Gorlin's syndrome and sporadic basal cell carcinoma [4–6]. By contrast, for the common dermatoses such as eczema or psoriasis, which show a more complex pattern of inheritance, relatively little progress has been made [7–10]. The reasons for this are obvious: in an autosomal-dominant disorder a single abnormality (in context) is both necessary and sufficient, whereas for polygenic disorders a whole host of genes may interact in a complex way with each other and with the environment. There are two approaches for identifying the causative gene for a disorder that shows a Mendelian pattern of inheritance: positional cloning (originally called reverse genetics) and candidate gene approaches. In many instances, the successful identification of a disease-causing gene relies on a combination of these approaches, and such examples are discussed below.

In the candidate gene approach, a starting point is the suspicion that a particular gene may be implicated in a particular disorder. The candidate gene is then examined for the presence of mutations in an affected kindred. The obvious limitation of this approach is that it only works if understanding of the pathophysiology of a disorder is sufficient to allow a candidate to be identified and if the relevant gene has been cloned. For instance, once the tyrosinase and tyrosinase-related genes were identified, they were obvious candidates to examine for mutation in individuals with albinism or other pigmentary disorders [11]. Mutation detection can be undertaken using a number of strategies, including, of course, DNA sequencing. Often, however, particularly when large genes are examined or a large number of individuals need to be studied, screening techniques are used that, while not providing full sequence information, can detect many, if not all, changes in comparison with the known sequence (e.g. single-stranded conformational polymorphism or heteroduplex scanning) [12]. The disadvantage of the candidate gene approach is that, for many skin disorders, our knowledge of the underlying pathophysiology is so limited that we are unable to identify suitable candidates. Nonetheless, as the technical facility of genetics increases, and knowledge accumulates, this is less of a problem than it once was. For instance, in the previous edition of this book, two examples of this difficulty were quoted: Rothmund–Thomson syndrome and incontinentia pigmenti. Since this previous edition, a combination of research strategies, including testing of likely candidates, has identified genes for these clinical syndromes. Nevertheless, at present the use of mapping and limited positional cloning and scanning of available sequence information remain a useful way of limiting the number of candidates to be examined.

When little is known about the underlying pathophysiology of the disorder, the only viable strategy is that based on positional cloning. This requires a suitable kindred, preferably showing a Mendelian inheritance of the trait, and the use of polymorphic microsatellite markers. Genetic mapping compares the inheritance pattern of the trait with the inheritance pattern of a chromosome region, allowing one to find out *where* a gene is without knowing *what* it is. It is worth remembering, as Lander emphasizes, that in many ways this is the ultimate black box approach [1]. One does not need to know anything about the clinical disorder except being able to diagnose it correctly (a key point, worthy of emphasis); knowledge of the mechanism by which the disease occurs is at least formally superfluous. Although mapping of traits was possible in simple model systems from the beginning of the 20th century, it was only in the 1970s that it was realized that the widespread differences in human DNA (principally the non-coding regions) could form the basis for mapping of human disease [1,13]. Ideally, large kindreds are needed, but if these are not available then it may be possible to analyse several different kindreds, assuming that the same gene causes the disorder in the respective kindreds. This assumption is not always warranted; for instance, mutations of *K5* and *K14* located on different chromosomes both cause epidermolysis bullosa. When numerous loci are examined for linkage to a particular trait, statistical tests are required to determine whether the association between a particular trait and a particular chromosomal position could have occurred by chance. This is conventionally quoted as the log of the odds ratio (lod score), and as a rule of thumb a lod score of at least 3 and preferably higher is required [13]. (A lod score of 3 approaches a similar level of significance as that seen with a conventional statistical test with a value of $P = 0.05$.)

A major brake on the process of gene identification using reverse genetics and subsequent positional cloning had been the difficulty of moving from chromosomal position to the identification of the putative gene underlying the disorder. The Human Genome Project has changed this process considerably. Whereas mapping based on the study of families may pinpoint the disease-causing gene to a couple of million bases, prior to human sequence being available identification of the underlying gene was far from straightforward. For the majority of chromosomal positions this situation has been dramatically improved, because the availability of sequence data allows automated programmes based on bio-informatic algorithms to make predictions about which sequences may code for genes (and which are non-coding), thereby facilitating mutational analysis of candidate genes.

Although candidate gene approaches and positional cloning have been described as alternative approaches, in practice they are often combined, and dermatology has already provided some pertinent examples of such experimental synergism, notably the identification of mutations in keratin genes as the cause of a range of cutaneous disorders. Keratin genes were among the first human genes identified, largely because their expressed RNA represents such a major proportion of the RNA species of a keratinocyte; early cDNA libraries from keratinocytes would consist predominantly of keratin cDNA clones. Similarly, globin was one of the earliest genes identified because it formed such a large part of the RNA species of a red-cell precursor. Despite the high levels of keratin expression in keratinocytes, the raising of antibodies, and numerous studies trying to relate keratin gene expression to disease states, the exact function of keratins remained uncertain. One can imagine two experimental approaches: (i) what disease would result from a mutated keratin ('gene looking for a disease'); and (ii) knowing that keratins are highly expressed in skin, would positional cloning of various skin diseases centre on the known clusters of keratin genes located on chromosomes 12 and 17 ('diseases looking for a gene') [14]? As it turned out, for keratins and epidermolysis bullosa the answer to both these questions was the same, and arrived at within weeks of each other. Mice that had been born harbouring an experimentally mutated keratin showed a phenotype strikingly similar to that seen in epidermolysis bullosa simplex [15]. Almost simultaneously, positional cloning in kindreds mapped the cause of the same disorder literally on top of *K14*, a coincidence too good to ignore [16]. Because *K14* combines with *K5*, it was predicted and subsequently shown that the same phenotype could be produced from mutations in *K5* (even though *K5* and *K14* are located on different chromosomes). Because many keratin genes are clustered on chromosomes 12 and 17, it took little effort to examine whether other inherited blistering disorders might involve other keratin genes. Analysis of kindreds with bullous ichthyosiform erythroderma showed that this disorder also mapped to the keratin cluster and subsequently was found to be due to mutations of *K1* or *K10* [17]. It has been possible to extend this 'phenotypic walking' (by analogy with chromosome walking) even further. Given that bullous ichthyosiform erythroderma is the result of *K1* or *K10* mutations, it was no surprise when ichthyosis of Siemens, a condition with many similarities to bullous ichthyosiform erythroderma, was found to be due to mutations of *K2e* (expression of *K2e* is similar to that of *K1* or *K10*, but more superficial, in keeping with the histological features) [18]. Similarly, some of the cases of palmoplantar keratoderma, where the pattern of blistering is restricted to sites of maximal expression of *K9*, were shown to be secondary to *K9* mutations [19]. However, this process can be taken even further. Patients with pachyonychia congenita show similar involvement of the palms, and a collection of other phenotypic features suggestive of defects in *K17*. Candidate-directed mapping in several kindreds showed linkage to the keratin clusters [20], and pachyonychia congenita has subsequently been shown to arise (depending on the clinical subtype) from mutations of *K17*, *K16* or *K6* [21,22]. Patients with pachyonychia may also show changes in the mouth akin to those of white-sponge naevus and, on the basis of this overlap, mutations of *K4* or *K13* were recently found to underlie white-sponge naevus syndrome [23,24]. Similarly, some patients with pachyonychia have cysts like those seen in steatocystoma multiplex, which in turn can also be caused by mutations of *K17* [25]. Abnormal hair is also a feature of pachyonychia congenita and suggested to some that monilethrix might be secondary to a keratin mutation: candidate mapping studies show that some kindreds of monilethrix do indeed map to a major keratin cluster [26], and the exact keratin gene concerned has recently been identified as that encoding for the hair cortex keratin hHb6 [27]. One could hazard a guess that the keratosis pilaris seen in monilethrix might mean that keratin mutations underlie some independent cases of keratosis pilaris. And so the process continues. The speed at which researchers have uncovered the genes responsible for so many cutaneous disorders attests to the power of the combination of mapping and candidate approaches. There are other examples that one could quote, including the identification of *PAX* mutations as a cause of some cases of Waardenburg's syndrome that relied on the combinations of candidate genes from the mouse and took advantage of the fact that many areas of human chromosomes show syngeny with the mouse (the location of genes on certain chromosomal regions is the same or similar in the mouse and human) [28,29]. Conversely, just as localization of a gene to a particular area followed by examination for possible candidates in this area can speed up the identification of disease-causing genes, it is possible using mapping approaches to quickly exclude some genes as the cause of a disease. For instance, it was always possible that keratin mutations could underlie Darier's disease, yet mapping studies quickly allowed these candidates, like some cell adhesion molecules, to be excluded from consideration [30,31].

Until recently, in the absence of a candidate gene, one of the bottlenecks in the identification of disease-causing genes was the difficulty moving from chromosomal position, which might encompass up to 10 million bases, to identification of the disease-causing gene. This is very much like searching for a needle in a haystack, as the majority of this DNA will be non-coding. These problems, however, have diminished considerably in recent years. This is partly due to a number of collaborative ventures that have made life easier for the experimental gene hunter. First, the number of informative polymorphic markers

spaced at appropriate intervals along the chromosome has increased considerably. Second, there have been concerted attempts to sequence expressed DNA sequences from a variety of tissues and map those expressed sequence tags (EST) to chromosome position [13]. Finally, sequencing of the genome and integration of the sequence with polymorphic markers will allow researchers to move quickly from candidate region to testing for causative mutations in candidate genes in that chromosomal region.

Complex traits

The term 'complex trait' describes any pattern of inheritance of a phenotype that does not fit a classic Mendelian pattern [1]. Examples in dermatology include atopic eczema and psoriasis. In an absolute sense, the distinction between complex and simple traits is artificial, as even a disorder with an apparently straightforward pattern of inheritance, such as epidermolysis bullosa simplex or Darier's disease, may show variations of clinical phenotype between affected individuals that are the result of other modifying genes or differences in environmental exposure. Nevertheless, the distinction is worthwhile.

Most common skin diseases do not follow a straightforward Mendelian pattern of inheritance. Whereas positional cloning of Mendelian traits has had considerable success, genetic analysis of complex traits is still in its infancy [1]. In some instances, there have been reports of genes that have been thought to underlie particular complex disorders, for instance the major psychiatric conditions, but further work has failed to replicate earlier results. One can see that if a disorder is due to mutations at a number of different loci (i.e. it is polygenic), the influence of any one particular loci will tend to be modest, and conventional linkage analysis may be of limited utility. There are, however, alternative strategies that are being pursued for eczema, psoriasis and other disorders [1,2]. For instance, allele-sharing methods tend to be more robust than linkage analysis, because no underlying model of inheritance is assumed. In allele-sharing methods, one tries formally to demonstrate that the inheritance pattern of a chromosomal region is *not* consistent with random Mendelian segregation (by showing that affected relatives inherit identical copies of the region more often than one would expect by chance). Examples of allele-sharing methods include affected sibling-pair analysis, where the frequency of sharing of particular regions is only compared in siblings affected with the disease (avoiding the problems of incomplete penetrance). Of course, for complex disorders the problem of moving from highlighted chromosomal region to the actual gene is considerably

more difficult than in highly penetrant disorders. This is because co-segregation of a marker and the disease may not be absolute; rather, one has to work with statistical confidence intervals. This raises the question of the number of individuals that need to be examined, because of the absence of the all-or-nothing principle of a gene that is both necessary and sufficient for a particular disease. In this situation, a variety of other strategies including linkage disequilibrium mapping may be needed. Alternative strategies include association studies, which are in effect case–control studies based on the presence of a particular allele in affected and unaffected individuals, for example the association of human leukocyte antigen (HLA)-Cw6 with psoriasis [3]. A recent example of this approach has been the report of an association between particular alleles of the melanocortin 1 receptor and red hair and skin type I [4]. Pedigree analysis suggests that the inheritance of skin colour or hair colour does not follow a classic Mendelian pattern, and therefore pursuing a linkage analysis approach may be difficult. However, if a candidate gene exists, as was the case in this instance, then it is possible to measure the frequency of particular alleles in those with a particular hair colour or skin type. Obviously, the weakness of association studies compared with positional approaches is that for an association study to be performed a clear candidate has to be known. With regards to the association between melanocortin 1 receptor gene variants and red hair, a considerable body of evidence in the mouse and other species suggested that this receptor was a strong candidate for a pigment-determining gene in the human [5,6]. However, there are also significant methodological hazards as for all case–control studies. For instance, any association between melanocortin 1 receptor variants and skin type or hair colour might be confounded by the fact that both the cases and controls may be drawn from different populations. For instance, because those with Celtic ancestry are more likely to have skin type I, any differences between skin type I and skin type IV individuals might reflect other confounding differences between Celtic populations and non-Celtic Anglo-Saxon populations.

How successful, or clinically relevant, the identification of genes that underpin complex disorders such as eczema or psoriasis will be is a topic of debate. The fundamental issue is that of penetrance, i.e. the relation between a particular allele and phenotype. On the one hand, there are those who believe that complex diseases require scaled-up versions of the techniques that have been very successful in the study of Mendelian disorders. This approach admits that the penetrance is lower, but argues that this can be compensated for by larger sample sizes and the range of techniques based around association studies or sibling-pair studies. On the other hand, there are those who argue that many commentators have exaggerated the genetic component to these disorders, at the expense of the environmental precipitants, and more importantly have used inappropriate models to attempt to partition nature and nurture [7]. There also remains a confusion between the use of odds ratios or relative risks and the predictive value of a test. Alleles that carry a moderately increased relative risk (say of three to five) may be interesting mechanistically but will have limited, if any, use as a predictor of clinical state. Interested readers are directed to the articles listed below [8–10].

Cancer genetics

Molecular biological approaches to understanding the mechanisms underlying cancer, particularly the relation between genotype and phenotype, have been particularly fruitful [1,2]. Interest in the molecular biology of cancer not only reflects the importance of the disease to human health overall but also the intrinsic interest in many of the physiological processes that are deranged in the cancer cell, including cell-cycle control, cell proliferation and differentiation, and the control of cell death. Molecular biological approaches have led to a new conceptual understanding of the genetic contribution to cancer, which can be summarized as follows. First, cancer is a genetic disease in which the accumulation of multiple genetic abnormalities, coupled with the selection of cells for a more and more malignant phenotype, leads to, and correlates with, the clinical behaviour of the tumour. Second, the underlying defective pathophysiological mechanisms in a wide range of human cancers are similar, and increasingly can be seen to relate to a few key cellular pathways, many of which appear to influence whether a cell cycles or not. Third, the same genes are often involved in sporadic tumours as in inherited tumours; for instance, the same gene *patched* is important in Gorlin's syndrome and in sporadic basal cell carcinomas (in the former one

germ-line allele is mutated and the other inactivated somatically, whereas in the latter both alleles are inactivated somatically) [3–5].

Genetic abnormalities in cancer cells can be classified into two types: oncogenes and tumour-suppressor genes [6,7]. Oncogenes are cellular genes that, when mutated, push the cell towards the adoption of a malignant phenotype. In genetic terms they are dominant, and therefore only one mutated copy per cell is enough to observe a different phenotype. Oncogenes were originally identified in animal models in which host genes had been hijacked by viruses and mutated. When these viruses infected animal cells, they contributed towards the adoption of a malignant phenotype. Although the heuristic value of this experimental paradigm has been considerable, and within animal models of cancer viruses are not infrequently implicated, in humans the association between viruses and cancer is weaker, and where it exists, it may not be because viruses harbour oncogenes. Early functional assays for oncogenes relied on extraction of DNA from a tumour, and then transfection of this DNA into cells that had been manipulated experimentally such that they were on the verge of neoplasia. If an oncogene were present, clones of these cultured cells would progress and adopt a malignant phenotype, which could be assayed on the basis of phenotypic characteristics (such as colony formation in soft agar). This sort of assay system is cumbersome, and many more oncogenes in human cancers have been identified either on the basis of homology to known oncogenes in other animal systems or by candidate approaches based on their physiological role. Mutations in oncogenes are rarely involved in inherited cancer syndromes, and appear uncommon in both melanoma and non-melanoma skin cancer. An exception has been the recent report of mutation of a cyclin-dependent kinase in two kindreds with familial melanoma [8]. This finding is of great interest, as it is complementary to the defect seen in the tumour-suppressor gene *p16*, itself a commoner cause of familial melanoma. Cyclin-dependent kinases are important in allowing progression through the cell cycle; *p16* normally acts as a physiological inhibitor of cyclin-dependent kinase, and thus mutations of *p16* remove a brake on cell-cycle control. In families with melanoma harbouring a mutated cyclin-dependent kinase, the kinase is unable to bind *p16*, the net result being functionally equivalent to an absence of *p16*; the difference is that whereas *p16* is recessive, mutation of cyclin-dependent kinase is dominant. Oncogenic mutations of the *ras* family of genes, genes coding for proteins that play a key and wide-ranging role in many signalling pathways, have also been described in both sporadic melanoma and non-melanoma skin cancers [9]. By contrast, abnormalities in the other class of tumour-related genes, namely tumour-suppressor genes, appear far more common in most epithelial malignancies [2,7], including skin cancer [10], and have also been implicated in inherited cancer syndromes involving melanoma and basal cell carcinoma [9,10]. A tumour-suppressor gene is a gene that, when functioning normally, acts so as to protect against the development of the malignant phenotype—the product of the gene possesses *tumour-suppressing* activity. As with oncogenes, many of these genes appear to be involved in interactions with regulatory proteins controlling the cell cycle. Unlike oncogenes, tumour-suppressor genes are (at the level of the cell) recessive, in that homozygous mutation is required for them to lose their normal physiological role. Of particular importance has been the discovery that the same tumour-suppressor genes are frequently implicated in sporadic and familial tumours; mutations of *patched* are the cause of Gorlin's syndrome and sporadic basal cell carcinoma [5].

One aspect of tumour-suppressor genes that is not self-evident is that although these genes are recessive at the level of the cell, when examined in a kindred the trait appears dominant. Based on observations of the epidemiology of retinoblastoma, Knudson [11] proposed a model in which a critical step in the development of tumorigenesis required the inactivation of both maternal and paternal alleles of a particular gene. Importantly, he showed that in an individual inheriting one faulty gene, a second 'hit' leading to loss of the remaining allele (in any particular gene) was far more likely to occur than in an individual who had inherited two wild-type genes. Implicit in this hypothesis was that the same genes were involved in familial and sporadic cancer [11]. This model is illustrated in Fig. 8.10. In Gorlin's syndrome, for instance, those with a family history inherit one abnormality in every cell in the body. If a second hit or mutation occurs (hence the name 'two-hit hypothesis') and if other genetic events are also present, then a tumour may result. In an individual who does not inherit one abnormal copy, a tumour may still result, but in this case both maternal and paternal alleles would have to be somatically inactivated, an event far less likely to occur. This explains why tumours are more common in those who inherit one faulty allele through the germ line. It is of interest to dermatologists that the origin of this idea was first proposed over 50 years ago in order to explain certain aspects of experimental skin carcinogenesis in the mouse [12].

There are a number of mechanisms by which a tumour-suppressor gene can be inactivated: the gene may be mutated; viral proteins may interact with the tumour-suppressor gene product, targeting it for degradation (as happens with some human papillomaviruses); or, quite commonly, the area of the chromosome harbouring the gene may be lost [13,14]. This loss of genetic material can be easily detected using polymorphic PCR microsatellite markers identical to those used in positional cloning, so that instead of two bands—one representing the maternal chromosome and the other the paternal chromosome—

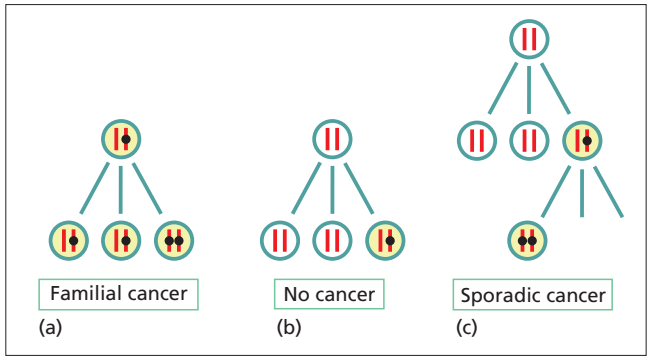

Fig. 8.10 Knudson two-hit hypothesis. Based on the epidemiology of retinoblastoma, Knudson hypothesized that the same genes were involved in familial cancer as in sporadic cancer and that they were recessive at the cellular level—two hits were required to observe a phenotype. Gorlin's syndrome appears to fall into this tumour-suppressor paradigm. A member of a Gorlin's kindred inherits one abnormal germ-line allele (*patched*) in every cell (a). Because tumour-suppressor genes are recessive at the cellular level, the phenotype of all the somatic cells is normal until the remaining wild-type allele is mutated. Once both alleles are inactivated, a rate-limiting step for cancer development has been passed. By comparison, in an individual with no cancer predisposition (b), both germ-line alleles are normal; if an occasional cell undergoes inactivation of one allele, no phenotype will be seen. For a tumour to develop without an inherited predisposition (c), both alleles would have to be inactivated somatically, an event orders of magnitude less likely to occur. This model explains why the frequency of basal cell cancer (in this example) is so much higher in a Gorlin's kindred than in ordinary individuals. Note that despite the gene being recessive at the cellular level, the trait is inherited as a dominant.

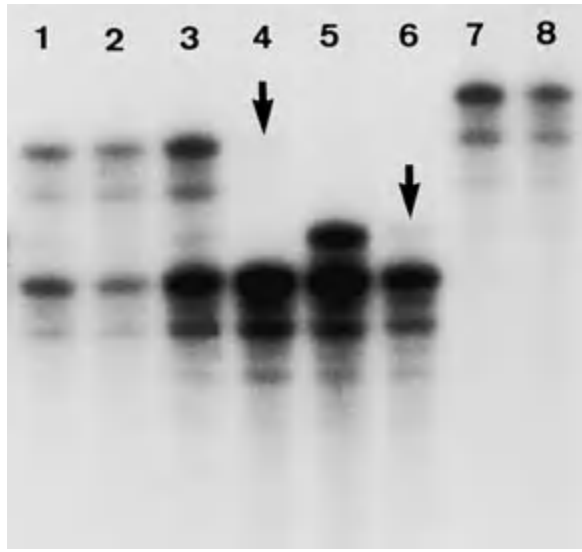

Fig. 8.11 An example of loss of heterozygosity in skin cancer. Polymorphic microsatellite markers have been used to compare tumour and normal skin in order to determine whether chromosomal areas have been deleted. In normal tissue two bands, one maternal and one paternal, are seen. By contrast, in two of the tumours one allele has been deleted (marked ↓; compare tracks 3 and 4, and 5 and 6). The remaining allele is likely to be inactivated by point mutation or by alternative mechanisms.

being visible in the tumour, loss of one allele will be evident as loss of one band (Fig. 8.11). Rarely both alleles will be lost, although it is more common for both alleles to be inactivated by different mechanisms. This loss of genetic material, which is referred to as loss of heterozygosity, is one of the major methods by which tumour-suppressor genes may be identified. There are therefore at least two approaches to the identification of new tumour-suppressor genes. First, one can study an affected kindred and, using conventional positional cloning with polymorphic markers, look for alleles that segregate with the tumour cases. Alternatively, one can study sporadic tumours (tumours occurring in individuals without any family history) and examine DNA for areas of loss of heterozygosity. These approaches of course can be combined, as was the case for the identification of the gene *patched*. Early loss of heterozygosity studies suggested that a candidate gene for basal cell carcinoma resided on chromosome 9q, and subsequent linkage studies in kindreds with Gorlin's syndrome supported these observations. By using positional cloning methodology together with the study of patients harbouring deletions, the underlying gene was cloned (reviewed in [10]). The advantage of loss of heterozygosity studies is that it is not necessary to know the target gene, whereas to detect mutation one obviously needs to know the gene that one wishes to sequence or screen for mutation. On the other hand, loss of heterozygosity is quite common in many epithelial tumours, and it is by no means proven that every area of loss corresponds to a relevant tumour-suppressor gene. Another caveat is that it is still not clear why in certain circumstances the gene is inactivated by mutations, whereas in others inactivation is due to loss of chromosomal material. For instance, in some melanoma kindreds *p16* mutation is common [15], whereas in sporadic melanomas *p16* point mutation is rare (although loss of heterozygosity of the relevant area of chromosome arm 9p is common) [13,16]. It seems possible that for melanoma, as for some other extracutaneous tumours, inactivation of *p16* may occur by changes in methylation status of the gene rather than through any of the mechanisms discussed above. Finally, notwithstanding Knudson's hypothesis, the effects of germ-line inactivation may be very different from those occurring somatically, and the parallel between familial and sporadic tumours may break down.

Besides oncogenes and tumour-suppressor genes, a third category of gene is of relevance to human skin cancer. There are well-known associations between sebaceous carcinoma and a variety of systemic malignancies, particularly colorectal cancer (Muir–Torre/Lynch syndrome) [17]. Work over the last several years has shown that a particular group of genes involved in DNA repair (but

distinct from those genes involved in xeroderma pigmentosum) are important in these disorders [18]. Studies mapping particular forms of non-polyposis coli hereditary colorectal cancer have shown that the microsatellite sequences seem to be frequently abnormal in length, with additional bands being seen following PCR. Positional cloning and candidate gene approaches have shown that a number of human homologues of mismatch repair genes in *Escherichia coli* are at fault in these kindreds, resulting in a decreased ability to repair a particular type of base change. Although these changes in the microsatellite sequences, which originally signalled, and provided insight into, the basis of this disorder, are unlikely to be functionally significant, such failures to repair normal genes, particularly those that have oncogenic potential [19], are thought to contribute to the development of the malignant phenotype.

The rate of identification of cancer-causing genes has intensified. Sequencing of the human genome has also allowed newer approaches. For instance, mutations of the gene *BRAF* have recently been found in over half the malignant melanomas examined. The protein product of this gene is part of the Ras signalling pathway involved in cellular signalling. Identification of this gene followed the new approach based heavily on use of sequence data. Rather than sequencing the whole genome from the tumours, the key signalling pathways were prioritized, and sequencing of all the known genes in these pathways undertaken and compared with germ-line sequence [20].

In broad terms, there seems to be an important correlation between the frequency of genetic abnormality and the clinical behaviour of the tumour [2]. For instance, based on the sorts of analysis described above, it is easy to distinguish between benign tumours such as seborrhoeic keratoses and squamous cell carcinomas, or alternatively between squamous cell carcinomas, keratoacanthomas and basal cell carcinomas [21,22]. However, there are exceptions to this rule that are of interest. For instance, actinic keratoses, despite their relatively banal clinical course, frequently show a greater degree of genetic instability than that seen in squamous cell carcinoma [23]. The explanation for this is not clear at present.

Putting it all together and future trends

Perhaps one of the most astonishing aspects of the growth in technical prowess of molecular biology has been the way in which, from initial 'boot-strapping' methodology, there has been a rollercoaster of more powerful experimental techniques, allowing increasingly precise and ambitious questions to be answered. For instance, when a gene for a particular disorder has been identified using positional cloning methodology, it is frequently possible to obtain a good idea of the function of that gene, based on either sequence similarity to genes previously identified or knowledge about similar genes in model organisms such as *Drosophila*, mouse or yeast. For instance, *patched*, the gene underlying the naevoid basal cell carcinoma syndrome, once identified, was shown to have a homologue in *Drosophila*, while work in this 'model organism' had already provided important insights into the protein's cellular localization and participation in various signalling pathways [1,2]. As an increasing number of genes and

proteins are characterized and stored in online sequence databases, the power of this process increases. Identification of new genes that do not bear some sequence similarity to known genes is going to become uncommon at some stage. In one sense, the converse of this approach is the way in which sequence similarity may be used to identify new genes. For instance, a whole new family of steroid/thyroid/retinoid hormone receptors have been cloned following screening of cDNA libraries using the oestrogen receptor as a molecular probe [3,4]. The basis of this assay is that complementary pairing between different strands of DNA, if the conditions of hydrogen bonding are relaxed and 'tolerant', can be used to identify not just identical sequences but sequences with varying degrees of similarity. Complementary DNA libraries can therefore be screened with one particular receptor as a probe in order to find 'relatives' of that receptor. PCR analysis allows a different and complementary approach to this procedure: with limited knowledge of the important functional domains of a molecule, degenerate PCR primers can be made that will then amplify homologous sequences from cDNA. This technique has been widely used to identify further members of the transmembrane seven-pass G-protein-coupled family of receptors such as the melanocortin receptor family [5]. The availability of sequencing data from the Human Genome Project has now allowed analogous prediction based on what is described as *in silico* experimentation: human sequence can be screened using a variety of bio-informatic techniques in which expressed sequences can be predicted and similarities to known gene products scored and putative functions suggested.

The ability to transfect genes into cells under experimental conditions has also led to the development of a myriad of experimental techniques [6,7]. For instance, a cDNA of interest may be transfected into cultured cells simply to obtain large amounts of the resulting protein for further analysis. Alternatively, the function of the protein can be studied by examination of changes in behaviour of the cultured cells. Mutated genes, either spontaneously occurring or constructed in the laboratory (usually using PCR-based techniques), can also be transfected, and the influence of these mutations used to map out important domains of the protein's function. A similar assay can be used to study the upstream regulatory regions that are important in controlling a gene's expression. Key regulatory sequences upstream of a gene's start site can be placed in a plasmid vector and transfected into cells. The gene's product itself can be assayed, or more often the gene of interest can actually be replaced with a gene called a 'reporter' that lends itself to experimental analysis. For instance, if one is interested in studying the regions upstream of a gene that are important in determining its expression (i.e. the regions of the promoter that mediate binding to a variety of other cellular proteins and signalling pathways), then one can clone this particular region of the genomic DNA, attach it to a reporter gene that codes for a fluorescent material such as luciferase, and transfect this into cells. The cells can then be treated with a variety of agents to discover whether they are able to induce, or alter, transcription of the reporter gene acting through the promoter sequence under experiment. Such approaches can also be carried out not just in transfected cells but also in transgenic mice, where the natural promoter region of the gene or one that has been experimentally manipulated might be attached to a reporter, a transgenic line created, and the resulting expression pattern studied in mouse embryos. Usually, this system makes use of the expression of β-galactosidase, resulting in (with appropriate development) a blue colour throughout the areas of the embryo where the promoter region is active.

Once a gene is identified, either through positional cloning techniques or from screening based on homology as described above, a number of techniques facilitate studies of the gene's expression and function. Northern blotting relies on complementary base pairing between the strand of the cDNA or RNA used as a probe and the endogenous RNA that one wishes to detect. An application with widespread use in dermatology, and related to Northern blotting but carried out on tissue sections, is *in situ* hybridization. Instead of the hybridization taking place on membranes, tissue sections are prepared and exposed to a cDNA or RNA probe, which is tagged with either a radioisotope or a colour label (as used in immunocytochemistry), and the experimental conditions manipulated such that where there is base pairing between the probe and the target, RNA signal is detected. If radioactive detection systems are used, the probe is labelled with an isotope such as ^{35}S, and the β particles emitted can be detected by dipping the slide (following hybridization) into a radiographic emulsion and waiting for development of the latent image. The end result is that where the probe has sought out and bound to target RNA, silver grains will be seen in the emulsion overlying the cell. Alternative detection systems have also become increasingly popular, particularly those based on the development of colour substrates that allow a more precise cellular localization and also avoid the hazards of working with radioisotopes. In many ways, these colour-detection systems are similar to those familiar from immunocytochemistry, only in this instance the cDNA or RNA probe is actually labelled with a molecule that subsequently binds to antibodies, which are usually in turn attached to other detection reagents. Using this approach, it is therefore possible to study RNA expression using fluorescence or other systems such as biotin and streptavidin, or digoxigenin [7,8] (Fig. 8.12). One particular strength of *in situ* hybridization is that it provides anatomical information about the control of gene expression at the level of

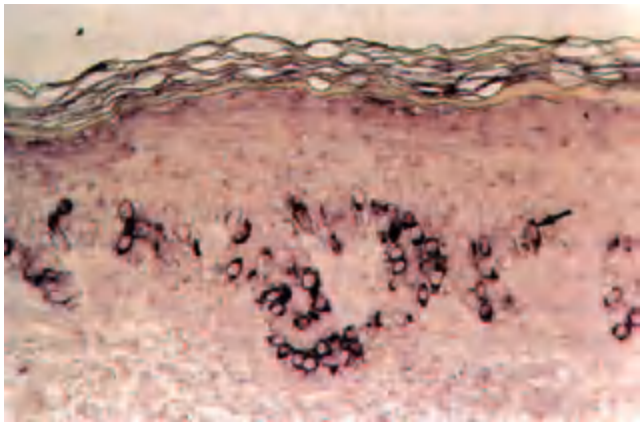

Fig. 8.12 Examples of *in situ* hybridization using a probe that detects histone mRNA, which is expressed during the S phase of the cell cycle. The probe has been labelled with digoxigenin, which affords excellent resolution. The dark stain visible within the lower compartment of the epidermis corresponds to RNA detected within the cytoplasm of the keratinocytes. (Reprinted with permission from Fisher *et al*. [8].)

RNA; in some instances, the gene can be transcribed into RNA but, perhaps surprisingly, little protein may be made. By contrast, immunohistochemistry detects protein expression, and therefore the two techniques can be considered complementary. Molecular biological techniques have also altered antibody technology and consequently the way in which the distribution of cellular proteins can be studied using immunochemistry. For instance, target antigens necessary for the development of polyclonal or monoclonal antibodies can now be made by transfecting the cDNA coding for the desired protein antigen and purifying the resulting overexpressed product [7]. Alternatively, once the cDNA structure is known, short stretches of oligonucleotides can be synthesized and used to immunize mice. Humanized antibodies, which are less immunogenic, can now be made and because they do not attract an immune response themselves may be of therapeutic use. Techniques such as *phage display* bypass the need for immunization of mice or hybridoma technology [7]. Identifying the molecular targets of naturally occurring antibodies is also more straightforward. A collection of cDNAs such as those present in a cDNA library can be cloned into, and expressed on the surface of, bacteriophages. The phage expressing the appropriate antigen can be selected using the antibodies (of unknown specificity) and the phage expressing the particular cDNA purified, allowing identification of the cDNA sequence coding for the antigen to which the antibody has bound [7].

As the pace of mapping and discovery of disease-related genes increases, researchers are increasingly looking to the next stage ahead—what has been referred to as the 'post-genome era'. There are several reasons for this, apart from the continual obsession with technical facility that has characterized the development of molecular biology. First, the rate of mapping of disorders with a defined pattern of Mendelian inheritance is now moving at such a pace that virtually all that limits further progress is the identification of suitable kindreds. Many of the required experimental procedures are already partially automated. It seems likely that the majority of these disorders will therefore be mapped within the next few years. There is also optimism (expressed by some but not all) that even those disorders that show a more complex pattern of inheritance, such as eczema or psoriasis, will also fall to currently available technologies. The identification of the relevant genes should quickly follow identification of the target chromosomal areas, due to rapid progress in sequencing of the human genome and the now industry-led process by which random cDNAs from a variety of cell types are being sequenced and mapped.

However, perhaps the most pressing force driving change is the desire to narrow the gap between the identification of disease-causing genes and the development of therapeutic agents. It is worth remembering that, maybe with the single exception of gene therapy (discussed below), there is no obvious formal scientific procedure that connects the identification of the gene underlying a disorder with the development of a useful and safe pharmacological agent. Of course, one of the great strengths of positional cloning is its ability to identify the gene underlying a particular disorder, based solely on the gene's chromosomal position rather than on any prior knowledge of its physiological or pathophysiological role; this undoubted strength is of little help as far as therapy is concerned. In some instances, however, cloning of the gene does have immediate clinical implications: identification of the genes underlying the inherited bullous disorders means that prenatal diagnosis has become a reality; and identification of the gene underlying the naevoid basal carcinoma syndrome allows identification of those individuals in a kindred at risk prior to the development of the clinical phenotype. For carriers of highly penetrant genes, modification of lifestyle may be appropriate, as for carriers of *p16* mutations who are at high risk of melanoma.

There are other ways in which gene identification improves clinical practice. For instance, it is likely that the apparently heterogeneous group of non-blistering ichthyosiform erythrodermas, some of which are due to transglutaminase mutations [9] and some of which appear not to be, will be classifiable on a more rational basis, once analysis of the separate genes allows a gold standard for measuring genotype against phenotype. This is not to imply that there are no polygenic or environmental influences on the phenotype, such that identical genotypes cannot give rise to different phenotypes or conversely that the same phenotype, as is seen with epidermolysis bullosa, can be due to mutations in different genes.

Although the emphasis in this chapter has been on eukaryotic genetics, rapid progress in prokaryotic genetics also directly impinges on clinical practice. Using PCR-based assays, both in theory and in practice, only one copy of the gene or a single microorganism is required to allow precise identification based on the specificity of amplification of genomic material of the putative infectious agent. PCR-based diagnosis of infectious disease is therefore particularly helpful when the causative microorganisms are relatively inaccessible and present in low numbers, and can implicate viral infection even in the absence of visible viral particles or the ability to culture the virus. For instance, using molecular techniques a novel DNA sequence, related to that of various herpesviruses, was identified in Kaposi's sarcomas from human immunodeficiency virus (HIV)-positive individuals [10]. Subsequent work has implicated a causal role for this virus in Kaposi's sarcomas from both HIV-positive and HIV-negative individuals [11,12]. DNA from mycobacteria or viruses such as human papillomavirus can also be readily detected using PCR techniques. An added bonus is that these techniques can be applied not just to fresh material but also to paraffin-embedded histopathological material that has been routinely collected, and studies can therefore be carried out retrospectively. The extreme power of PCR to amplify starting material many millionfold can also be a weakness, as contamination from other samples or the operator is a significant hazard. Finally, cloning of human genes allows the production in prokaryotes of recombinant pharmaceuticals, such as interferons, and vaccines by genetic engineering.

Future strategies

Future work relating to the development of new therapeutic strategies lies in two directions: first, the detailed characterization of differences in gene expression; and second, gene-based therapies. In what is becoming known as the 'post-genome era' there are the beginnings of attempts to develop generic and automated approaches to the identification and description of gene expression in different cell types. Just as it has been possible for a number of years to use gel electrophoresis to represent (to a limited degree) the pattern of protein expression in a particular cell type, molecular strategies based on RNA can be used to represent in a global way the activity of a particular cell. One approach has been to use a technique called differential display, which relies on random (or at least almost random) PCR primers being applied to cDNA, with the result that with different combinations of primers thousands upon thousands of bands can be represented on the gel, each of which relates to a particular RNA species [1]. This technique can be used to attempt to identify differences in gene expression between cells from different tissues, or following treatment of a particular cell type with an experimental agent. Bands that are differentially expressed can then be cut out, cloned and the gene studied.

Two overlapping, but complementary, techniques have been developed and are revolutionizing the study of gene expression in biomedicine. The first is known as serial analysis of gene expression (SAGE) [2]. SAGE attempts to describe quantitatively the total production of RNA from a particular group of cells. This technique relies on the specificity of restriction enzymes, and the location of these restriction sites within different cDNA species, to allow one to concatenate small parts of RNA into larger arrays that can then be sequenced. By analogy with computing technology, these 'digtags' (digital tags) can then be counted and estimates made of the proportion of a particular RNA species compared with the total amount of RNA produced by a cell.

An alternative technique, based on advances in the 1990s at Stanford University, has been the development of microarray technology. This technique involves plating at high density a large number of cDNAs on glass slides. Subsequently, target RNA can be fluorescently labelled and hybridized to the glass slides and the signal read as fluorescent intensity. Because there is more than one fluorescent label, the relative intensity of RNA from different tissues or cells that have undergone an experimental intervention can be hybridized at the same time and the readout quoted as the ratio of expression in one sample to that in another (based on the ratio of fluorescence for each probe). This allows the characterization of gene expression from cells in culture or from tissue. For instance, a recent example of this approach has allowed

the gene expression pattern for a large number of genes to be studied in patients with melanoma. With appropriate statistical techniques, the pattern of expression of hundreds of genes has allowed prediction of prognosis beyond that obtained from other conventional histopathological or cell biological variables [3]. As with other recently described techniques aiming to characterize the RNAs produced by a particular cell type, the emphasis is on a generic approach that can be applied to different cells and tissues in different situations, and that facilitates the move from gene back through biochemistry to pharmacology.

Thinking specifically of therapy, there are clear alternative, and perhaps complementary, strategies being pursued. For instance, the development of new small-molecule pharmacological agents is now heavily dependent on molecular biological techniques. In fact, many of the systematic attempts at cloning RNAs from different cell types are being carried out by pharmaceutical companies. The identification of genes, the ability to study gene expression and the ability to produce large amounts of the protein experimentally all facilitate functional studies of protein activity, identification of key domains and characterization of protein structure by crystallography. The identification of the myriad of receptor isoforms for many receptors offers new targets for small-molecule design. The ability to model disease processes in animals also aids pharmacological intervention. For instance, transgenic mice in which the β1 integrin receptor has been placed under the control of the involucrin promoter (resulting in aberrant expression of β1 integrin) have recently been proposed as an animal model of psoriasis [4]. The production of knock-out mice that are null for a particular retinoic acid receptor means that it is possible to study the physiological role of these receptors and their ligands, and also to infer how pharmacological agents with known efficacy are actually working [5]. The approach that not surprisingly has attracted the most attention, and for some raised the greatest hopes, has been the development of therapies directly involving nucleic acids. Defective genes are either replaced or supplemented with a correctly functioning gene, or the products of particular genes antagonized by the introduction of antisense DNA or RNA. Some of these approaches are discussed below.

Gene therapy

Gene therapy describes a range of technologies that have in common the treatment of disease based on the introduction of genes or nucleic acids (including oligonucleotides). Despite the considerable media attention, success has been limited and most work has concentrated on the development of the technology and toxicity assessment [6–8]. Most observers believe that the only unequivocal success for gene therapy has been in the treatment of X-linked severe combined immunodeficiency. However, two children who have been treated with retroviral vectors for this disorder have gone on to develop leukaemia. It seems likely that there is a causal relationship between the therapy and the development of the leukaemia and this finding has caused concern and a slowing down of clinical trials of similar approaches. Nevertheless, the field is young and there are a host of experimental strategies being applied. Some think that cutaneous disorders will lend themselves to gene therapy because of the skin's accessibility and the ability to culture keratinocytes and fibroblasts, treat them *ex vivo* and then reimplant the cells after genetic modification [9,10]. The majority of gene therapy trials so far have been concerned with cancer and many of these have involved gene therapy for melanoma [6]. The exact scientific rationale underlying some of the studies is not always obvious; indeed, where an experimental effect has been seen, it is not always clear why.

Genetic material may be passed to the cell of interest either *in vivo* or *in vitro*. With *in vitro* gene therapy, cells from the individual are cultured, and genetic modification is carried out *in vitro* before returning the cells to the patient. With *in vivo* gene therapy, the manipulation occurs *in vivo*. There are a number of different experimental strategies under consideration. First, it is necessary to dispense the genes or genetic material in an appropriate vector or transfer material. Although naked injection of DNA has been used in experimental animals, and perhaps surprisingly appears to result in low-level transient gene expression, more promising is the use of retroviruses or adenoviruses as targeting vectors. Alternatively, naked genes may be applied within liposomes, which are then taken up by target cells. This latter approach might seem to have considerable potential as far as skin disease is concerned [11]. An alternative strategy is to use antisense oligonucleotides (antisense because they are complementary to the normal sense), which would be expected to bind to the normal-sense RNA for a particular gene and consequently interfere with translation. Despite the theory, and even with appropriate controls, in some experimental systems the effects of such antisense therapy are not always as intended. Antisense genes can also be inserted into vectors such that when they are transcribed (into RNA), they are complementary to the normal wild-type RNA product and therefore might be expected to reduce protein expression. It is even possible to design genes that code for intracellular antibodies, which within the cell could be expected to inactivate particular target proteins.

There have been a number of different approaches suggested for gene therapy of cancer, many of which have been tried on melanoma because of the highly antigenic nature of many human melanomas [7,10]. For instance, it may be possible to insert genes into cancer cells that render the cells sensitive to a particular drug. Alternatively, gene therapy may be aimed not so much at the primary

tumour cell but so as to enhance the ability of the normal immune cells to attack cancer calls. For instance, in melanoma, early gene therapy protocols took a population of lymphocytes called tumour-infiltrating lymphocytes (literally lymphocytes that tend to home-in on tumours), transfected them with tumour necrosis factor-α (TNF-α) and then reinfused them into the patient [12]. The idea was that the tumour-infiltrating lymphocytes would act as a carrier for TNF-α, which when localized to the tumour would lead to tumour regression. Alternative strategies have included adding other cytokine genes to skin fibroblasts and then injecting these fibroblasts with autologous tumour cells into the individual, with the hope that the cytokines produced by these fibroblasts assist the immune system in attacking the tumour cells. Perhaps one of the strangest results that has been described is that in many situations there is what is called a 'bystander effect', i.e. even though not all the tumour cells can be targeted with any particular gene, the death of many of the tumour cells is not a direct effect of the introduction of the gene but merely because many of the cells in the vicinity are cells that have been successfully transfected. This phenomenon offers hope because it is most unlikely that all the tumour cells are going to be successfully targeted with the necessary gene product.

Gene therapy for inherited cutaneous disorders where the primary genetic defect has been identified is attractive to many, and a number of groups are beginning to perform such studies. It is possible to imagine that different sorts of disorders, depending on the particular molecular pathology, may be more or less amenable to therapy. For instance, where there is an enzyme deficiency and the disorder is recessive, even the production of a small amount of enzyme by the insertion of genetic material may be of benefit. For example, such a study on an individual with adenosine deaminase deficiency has been reported, in which T lymphocytes were treated with a retroviral vector containing the deficient gene and then transferred back into the patient [8]. The results are promising, although because the patient received other treatments, the results cannot be considered unequivocal. It might be considered that cutaneous disorders such as steroid sulphatase deficiency or disorders secondary to mutations in transglutaminase (lamellar ichthyosis [13]) might be amenable to similar approaches. Nevertheless, there are a number of technical and conceptual problems which remain. There are concerns about the safety of the vectors being used. Although retroviruses can be altered such that they are incapable of replication in the host, there is always the outside possibility of recombination between the therapeutic form and wild-type retroviruses, such that they may recreate their ability to infect other cells. Adenoviruses may appear less hazardous than retroviruses and are currently being used in a variety of gene-therapy protocols. A disadvantage, however, is that they tend to provoke an immune response, which may limit their clinical effectiveness in the long term. Considerable problems remain in ensuring that the introduced genes continue to be expressed over a long period of time and that insertion does not occur in host genes of importance. Other challenges remain. If one is wishing to treat by gene therapy an inherited autosomal disorder where the mutation causes a loss of function (the mutated protein does not work), the patients will in effect be heterozygous and already produce 50% of the normal protein. Attempts to raise this to the necessary physiological level may be difficult. Alternatively, if a mutation causes a gain of function (the mutant protein takes on a new function not present in the wild-type protein or works so as to inactivate the normal wild-type protein, such as occurs in some of the inherited keratin disorders), simply adding normal protein by gene therapy may not be sufficient.

A final consideration with gene therapy is how generic the techniques can be made. This assumes importance because although studies on cancer using gene therapy have been well funded, to take gene therapy approaches through to the clinic, industrial-scale funding is probably necessary. For many rare dermatological disorders, as for development of new drug-based strategies, it is not clear that the size of the market will justify the necessary investment. A second limitation on application, particularly with respect to dermatological therapy, may be concern about safety. The majority of studies so far have been carried out on cancer patients, reflecting the widespread acceptance of dangerous therapies in disorders that are themselves life-threatening. Obviously, since the vast majority of cutaneous diseases are not life-threatening, one imagines that these sorts of approaches will in the short term be restricted to disorders that are potentially fatal, such as melanoma or some of the inherited blistering disorders.

Conclusion

Molecular biology and the application of molecular biological techniques to the study of disease have come an astonishingly long way in a short period of time. Disease-causing genes continue to be identified at a significant pace. Molecular biological technology has opened up the study at increased speed of whole areas of medicine, because of both DNA-based diagnostics and an increased facility to carry out classical biochemistry and pharmacology. If nothing else, genomics has set an example that other branches of modern medicine are keen to follow. For instance, proteomics refers to the systematic attempt to characterize and annotate proteome, where proteome is defined as the protein content of a particular unit of biological enquiry such as a cell [1]. It remains possible that nucleic acid-based technologies such as gene therapy may also play an important role in therapy. Nevertheless, there are perhaps cogent reasons for some of the exuberant optimism being bridled with a little caution. Many liken the explosion of knowledge about disease-causing genes to the birth of the science of human anatomy, exemplified by Vesalius' *De Humani Corporis Fabrica*; it was, however, at least another 300 years following publication of Vesalius' masterpiece that visiting a doctor increased one's chances of surviving from any serious disorder. There still remains an enormous gap between the 'anatomy of the cutaneous genome' [2], understanding the pathophysiology of cutaneous disease and the ability to produce successful remedies with the necessary efficacy and low toxicity required for everyday clinical practice. On the other hand, there are some obvious advantages in studying the skin, in that its accessibility lends itself to topical and usually less hazardous therapy. Nevertheless, a look back over the last 30 or 40 years of dermatology suggests that many of the major breakthroughs in therapy have not proceeded from a linear understanding of the cause of a disease but have been arrived at through trial and error, careful clinical observation of agents introduced for therapy of other diseases and intuition [3]. In part, of course, this reflects the reality of the economics of pharmacological development in terms of the market share held by skin diseases. One of the interesting areas to observe over the next few years will be whether molecular-based strategies will alter this state of affairs.

Chapter 9

Inflammation

M. Steinhoff, C.E.M. Griffiths, M.K. Church & T.A. Luger

Introduction [1–3]

Inflammation can be defined as a complex body defence response to noxious or dangerous stimuli. Classically, inflammation is associated with the host defence against infectious agents. However, a variety of other exogenous and endogenous stimuli (e.g. ultraviolet light) may induce an acute inflammatory response. Inflammation also constitutes the body's response to injury. Physical stimuli such as heat, cold or mechanical irritation may affect skin homoeostasis and activate the release of inflammatory mediators such as eicosanoids, cytokines, chemokines and neuropeptides.

The inflammatory response comprises various cellular and molecular mechanisms that enable reconstitution of body integrity, and is characterized by successive phases. The initial phase, in which resident cells of the damaged tissue release immediate inflammatory mediators, is clinically silent. In the second phase, a vascular reaction characterized by vasodilatation and increased permeability can be observed. This is in turn followed by a cellular phase, in which inflammatory cells infiltrate the injured microenvironment. As will become clear, the pathogenesis of many skin diseases involves dysregulation of the inflammatory response.

Inflammatory cells, such as neutrophils, seen early in the response, release a variety of mediators, including cytokines or enzymes to remove dead cells, detritus and microbiological organisms and to neutralize toxins. Leukocytes closely interact with endothelial cells, which express adhesion molecules to allow leukocyte emigration into the inflammatory environment. Upon activation, endothelial cells stimulate a plethora of cytokines, chemotactic agents, cell adhesion molecules and selectins. In addition, other important mediators such as kinins, biogenic amines, neuropeptides, nitric oxide, haemoxygenase (HO), various oxygen compounds, growth factors, complement components, prostaglandins, leukotrienes and adenosine diphosphate (ADP) are released, which regulate the inflammatory response. Under normal circumstances, inflammatory effects are rapidly attenuated by anti-inflammatory mechanisms, to protect the body from the consequences of uncontrolled stimulation, and prolonged activation. Several types of resident cutaneous cell can generate inflammatory mediators and their receptors, resulting in termination of cellular responses to released pro-inflammatory molecules and initiation of tissue repair. As a consequence of uncontrolled conditions, an inflammatory response may become chronic, resulting in disease (e.g. in chronic eczema).

The molecular mechanisms underlying the acute and chronic phase of inflammation are different, and only partly understood. Over the last few years, however, our knowledge of the pathophysiology of inflammation and

the mediators involved has expanded substantially. This chapter highlights some of the important recent advances in skin inflammation, and discusses the impact of modern therapeutic strategies on the treatment of cutaneous inflammation. Cellular constituents of the adaptive immune system (T cells, B cells and antigen-presenting cells) are described in Chapter 10. Therefore, the main focus of this chapter is on cells and mediators of the innate immune system, and their role during inflammation.

Characteristics of inflammation

Five characteristic signs of inflammation were described by Celsus centuries ago: redness, heat, pain, swelling and loss of function. However, not all signs may be necessarily observed in all skin lesions during a given inflammatory response.

Redness (Rubor). This reflects the presence of red blood cells or haemoglobin in the skin. Increased redness may follow increased blood flow through superficial dilated vessels, resulting from stimuli leading to vasodilatation, or from obstruction in deeper vessels causing diversion or 'shunting' of blood through more superficial vessels. Redness in the skin may also result from stasis and congestion without increased flow of blood. Such partial stasis increases the chances for leukocytes to emigrate from vessels.

Heat (Calor). This is a usual consequence of increased blood flow through the skin. In acute lesions, the temperature of the skin may increase as a direct result of an elevated local metabolic rate. In chronic inflammation, neither local metabolism nor blood flow may be increased, and the skin may feel cool. Heat loss cannot be correlated exactly with redness, because areas of fast flow may be on the border of a more congested and slow-flowing system. Thus, conduction of heat to the surface of the skin may be considerable over a large deep arteriovenous fistula, while the upper dermis may show all the effects of severe stasis consequent on raised venous pressure.

Pain (Dolor). The sensations that accompany inflammation of the skin include burning, stinging, itching and tenderness, and are thus more variable than in most internal organs. Which of these sensations predominates depends in part on the site, depth, intensity and duration of the inflammatory process. Thus, in urticaria, stinging may accompany transient superficial lesions; itching is the usual sensation in papular urticaria or in wheals resulting from mediator release from mast cells such as histamine. Pain and tenderness may accompany deeper lesions of long duration, as observed in delayed pressure urticaria. Other mediators such as bradykinin and proteases may also induce pain by activating specific receptors on primary afferent neurones.

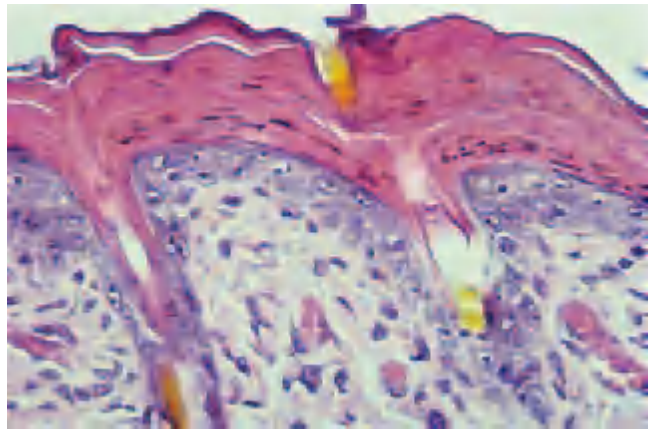

Fig. 9.1 Chemically induced mild irritation of rabbit skin resulting in stimulation, manifested as hyper- and parakeratosis, slight oedema of the epidermis, an occasional neutrophil and capillary hyperaemia. H&E.

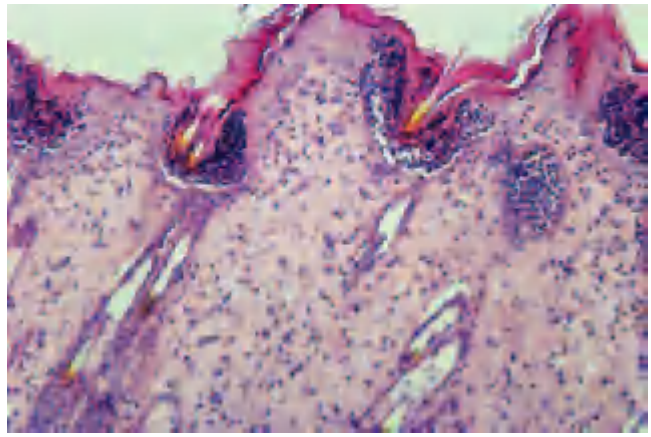

Fig. 9.2 Chemically induced mild irritation of rabbit skin. Example of focal attraction of neutrophils to site of penetration in the hair follicles. Beneath the neutrophil aggregates are small clefts resulting from leukocyte enzyme degradation, below which the follicular epithelium is regenerating. H&E.

Swelling (Tumor). Rapid swelling is caused by oedema, the increased leakage of water and mineral salts (transudate), or proteins (oedema fluid) from blood vessels. This fluid accumulates at the site of inflammation when the rate of exudation from venules and capillaries is greater than the rate of clearance by the lymphatic vessels. In most lesions, swelling is mainly brought about by oedema, or to plasma constituents (e.g. fibrin in delayed hypersensitivity reactions). In chronic inflammation, swelling is also caused by an increase of extracellular matrix components. Even a dense leukocytic infiltration usually does not contribute substantially to swelling, except in the case of abscess or granuloma formation. Neutrophils may accumulate at a site in large numbers within 4 h, but macrophages and lymphocytes, which contribute to a firmer, more persistent swelling, usually accumulate more slowly over 48–72 h (Figs 9.1–9.4). The duration of the leukocyte infiltration

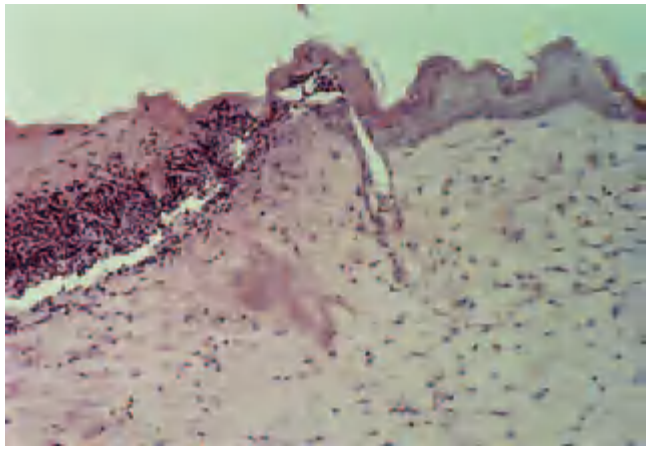

Fig. 9.3 Chemically induced irritation of mouse skin at 24 h. Necrotic epidermis on left. Neutrophil infiltration and proteases forming cleft beneath damaged tissue; the outermost neutrophils are also degenerate. Epidermal cells from outer edge of follicle begin to under-run the separating necrotic tissue. H&E.

depends upon the nature of the causative agent. Tissue hypertrophy with acanthosis, fibroblast proliferation and formation of new blood vessels may also promote more persistent swelling.

Phases of inflammation

Inflammation induced by exogenous or endogenous stimuli can either occur as an acute response or develop into a chronic condition. Normally, the acute inflammatory response is terminated by a variety of negative feedback mechanisms such as receptor antagonists for cytokines or protease inhibitors, for example. Under certain conditions, however, an imbalance in the inflammatory response can lead to persistance of pro-inflammatory stimuli resulting in a chronic condition.

The acute phase (first 6 h) of inflammation consists of a vascular reaction, including vasodilatation, plasma extravasation, oedema formation, activation of endothelial cells and release of early messengers from the injured tissue. Subsequently, the site becomes a target for inflammatory cells charged with eliminating the noxious stimulus. Vasodilatation of small vessels is caused by several mediators, such as kinins (bradykinin), amines (serotonin), prostaglandins (PGE_2) and neuropeptides (calcitonin gene-related peptide), released by platelets, mast cells and sensory nerves, for example. Subsequently, plasma extravasation leads to oedema, which supports the acute inflammatory response. Most of these effects are exerted via the up-regulation of specific receptors such as bradykinin-2 receptor or PGE_2 receptor. In contrast, peptidases released in the vicinity of the vessel wall may inhibit and thereby effectively terminate the vasodilatory response. Macrophages and neutrophils represent the first-line rapid host defence against microorganisms by phagocytosis and killing, until the adaptive immune response is initiated. Subsequently, activated immune cells release cytokines and other mediators in a more directed and effective host immune defence. Moreover, chemokines may be released by most resident cutaneous cells to facilitate recruitment of leukocytes to the site of inflammation. Infectious agents, and the local inflammatory response, activate the complement system, and production of plasma proteins, which destroy pathogenic agents. Finally, the innate immune system also contributes to the effective activation of the adaptive immune response.

The chronic phase of inflammation is characterized by a cellular phase, with recruitment of inflammatory and immunocompetent cells into the site of inflammation. Finally, resident and infiltrated cells collaborate in the phagocytosis and killing of pathogens, removal of debris including necrotic and apoptotic cells, and in the restoration of the tissue. The outcome of the inflammatory response is crucially determined by the removal of the primary pro-inflammatory stimulus. Thus, progression of an acute into a chronic state of inflammation is a result of the persistence of the stimulating agent. Exogenous factors may consist of toxins or pathogens, whereas endogenous factors might be autoantigens, for example. Microorganisms may induce chronic inflammatory states by evading routine immune surveillance, as observed in leishmaniasis or mycobacterial infection. On the other hand, chronic inflammation in pemphigus vulgaris, lupus erythematosus and other autoimmune diseases may result from defective down-regulatory mechanisms.

Innate defence mechanisms

Antimicrobial peptides

Antimicrobial peptides constitute a novel family of effector molecules with an important role in host defence, inflammation or cytotoxicity, and that may be of potential substantial benefit in the treatment of infectious and inflammatory skin diseases. In humans, peptide antibiotics of three families have been identified: defensins, cathelicidins and histatins. All antimicrobial peptides characterized share the capacity to kill and/or to inactivate bacteria, fungi and enveloped viruses *in vitro*. They apparently kill mammalian target cells and microorganisms by a mechanism involving initial electrostatic interactions with negatively charged surface molecules on target cells, followed by insertion into the cell membrane, permeabilization and formation of voltage-regulated channels. In addition to their antimicrobial and cytotoxic properties, some defensins act as opsonins, while others inhibit signal transduction pathways such as protein kinase C, competitively inhibit receptor activation (e.g. adenocorticotrophic hormone (ACTH) receptor), block steroidogenesis or act as selective chemoattractants for monocytes. Thus, in addition to their capacity to kill microbes, endogenous antibiotic peptides may also contribute to both innate host defence and adaptive immune responses.

Defensins

Defensins are antimicrobial and cytotoxic peptides that consist of 29–35 amino acids, including six invariant cysteines whose intramolecular disulphide bonds cyclize and stabilize them in a triple-stranded β-sheet configuration. They are generated by proteolytic processing from 93–95 amino acid precursor prepropeptides, and can be detected in plants, insects and various mammals [1,2]. The prosegment keeps the peptide in an inactive state; subsequent activation occurs by proteolysis. Matrilysin (MMP-7) was identifed as the enzyme responsible for generation of mature defensin in mice. In the human setting, the situation is less clear, and other enzymes such as trypsinogen-2 may be involved [3]. Interestingly, they make up to 5% of the total protein content in human neutrophils and are also produced by macrophages, keratinocytes and mucosal epithelial cells of the respiratory, digestive, urinary and reproductive systems [4–7]. In mammals, neutrophils are capable of generating and releasing all three classes of defensin. The antimicrobial spectrum of defensins includes Gram-positive as well as Gram-negative bacteria, mycobacteria, *Treponema pallidum*, many fungi and some enveloped viruses. Defensins exert non-specific cytotoxic activity against a wide range of normal and malignant targets, including cells resistant to tumour necrosis factor-α (TNF-α) and natural killer (NK) cell cytolytic factor.

α-Defensins contain three disulphide bridges, and reveal a triple-stranded β-sheet structure with a β-hairpin that contains cationic amino acids. The first human α-defensin was isolated from neutrophils [8] and, so far, six human α-defensins (HNP-1 to -6) have been identified. Human neutrophils generate four α-defensins, termed human neutrophil peptides (HNP) 1–4. They are all localized in azurophilic granules of neutrophil granulocytes, where they are the principal protein and contribute to the oxygen-independent killing of phagocytized microorganisms. In contrast, mouse neutrophil granules do not contain α-defensins. HNP-5 and -6 are primarily found in Paneth's cells of the small intestine and epithelial cells of the female urogenital tract.

*β-Defensin*s were first isolated from cow tongue in 1991, and originally named tracheal antimicrobial peptide (TAP). They contain six cysteine residues connected by three disulphide bridges, spaced differently from those in α-defensins. The genes encoding β-defensins are localized in the same chromosomal region as α-defensins. They consist of 36–42 amino acids, and possess a different disulphide alignment as compared to other defensins. Human β-defensin-1 (HBD-1) is expressed constitutively in epithelial cells of the skin, the gastrointestinal, urinary and respiratory tracts. HBD-2 was isolated from psoriatic skin [9]. HBD-1 and -2 are expressed diffusely throughout different epithelial structures and glandular cells of different tissues. HBD-3 was isolated from psoriatic keratinocytes, and has a potent antimicrobial activity against many skin-pathogenic bacteria [10].

θ-Defensins constitute a novel class of defensins that has recently been isolated from Rhesus monkey neutrophils. The peptide Rhesus θ-defensin-1 is produced by the post-translational ligation of two truncated α-defensins, and demonstrates salt-independent antimicrobial activity. So far, θ-defensins have not been detected in the skin.

Cathelicidins

Peptide antibiotics of the cathelicidin ('cathe-lin' from cathepsin L inhibitor) family contain a highly conserved signal sequence, but show substantial heterogeneity in the C-terminal domain encoding the mature peptide, which can range in size from 12 to 80 amino acid residues. The only human cathelicidin, LL-37/hCAP-18, was originally isolated from human bone marrow [1,2] but is also detectable in inflamed skin. LL-37/hCAP-18 has been found to be regulated by various inflammatory stimuli such as cytokines [11].

Histatins

Histatins are a family of histidine-rich peptides present

in human saliva [12], consisting of approximately 38–32 amino-acid residues. The five members of the histatin family are modulated by post-translational processing. Their antimicrobial activity includes especially strong antifungal effects.

Function of defensins

The expression of defensins is tightly regulated. While the expression of HBD-1 has been found to be constitutive, HBD-2 expression seems to be inducible by infectious and pro-inflammatory stimuli. In the skin *in vivo*, HBD-2 transcripts and peptide levels are found to be up-regulated during infectious diseases [11]. *In vitro*, pro-inflammatory cytokines such as the interleukins IL-1α and IL-1β, and TNF-2, but also lipspolysaccharide (LPS) and microorganisms (Gram-positive and Gram-negative bacteria, and *Candida albicans*) are able to induce hBD-2 production. In addition, the expression of LL-37/hCAP-18 is up-regulated in inflamed skin, and found to be co-localized with IL-6. Interestingly, the LL-37/hCAP-18 gene contains several potential binding sites for transcription factors (acute-phase response factor and nuclear factor for IL-6 expression [NF IL-6]) that are possibly involved in the regulation of inflammation. However, the mechanisms that induce antimicrobial peptides and corresponding signalling pathways can only be speculated upon at present.

Antimicrobial peptides, including defensins, cathelicidins and histatins, have a broad spectrum of activity against Gram-positive and Gram-negative bacteria, as well as against fungi and enveloped viruses. Antimicrobial peptides show synergistic activity with other host defence molecules such as lysozyme and lactoferrin. The microbicidal activity of defensins is based on permeabilization of anionic lipid bilayers and the subsequent release of cellular contents, and destruction of the membrane's electrode potential. A second model describes the aggregation of peptides into positively charged patches resulting in the formation of transient gaps. Additionally, defensin-related cell death has been related to interference with protein synthesis and DNA damage.

So far, the evidence that defensins contribute to innate immunity *in vivo* is largely indirect. Evidence for the host defence function of antimicrobial peptides comes from a study involving MMP7-knockout mice, which showed an increased susceptibility to infections. In addition to their antimicrobial activity, defensins and cathelicidins can bind to LPS and inactivate the biological functions of this endotoxin. Bacterial resistance to antimicrobial peptides is a rare phenomenon. Mechanisms that result in the development of resistance involve modifications of outer cell wall components, such as LPS, teichoic acids or phosphocholine, and the modulation of efflux pumps [2].

Besides their role as endogenous antibiotics, antimicrobial peptides have other functions in inflammation, wound repair and regulation of the adaptive immune system. Human neutrophil defensins have been described to be cytotoxic for various cell types, and to induce cytokine synthesis in epithelial cells, monocytes and T cells. Furthermore, they increase the binding of bacteria to epithelial cells and induce the liberation of histamine from mast cells. Finally, α-defensins are involved in the chemotaxis of monocytes and T cells, the modulation of cell proliferation and B-cell production, and the inhibition of complement activation and proteinase inhibitors [3,13,14]. The human β-defensins have recently been identified as potent ligands for the chemokine receptor CCR6, which is present on dendritic and T cells, therefore suggesting a link between innate and adaptive immunity [15].

There is strong evidence that antimicrobial peptides serve as mediators of host defence, not only by their direct antimicrobial activity but also by their function as inflammatory mediators. Defensins attract inflammatory cells such as neutrophils, B cells and macrophages, and activate epithelial cells including keratinocytes. HNP-1 enhances the phagocytosis of cultured mouse peritoneal macrophages. Human defensins are also able to degranulate mast cells, resulting in the release of histamine and tryptase with consequent recruitment of more neutrophils to the inflammatory sites. In contrast, mast cells release cathelicidin LL-37, which is involved in the killing of bacteria [16].

Neutrophil defensins stimulate IL-8 production, which also helps to recruite more neutrophils to the site of inflammation. This is in accordance with a report that *in vivo* administration of human neutrophil defensins increases the ability of mice to resist local infection by enhancing neutrophil recruitment to infected tissues. Human neutrophil defensins are also reported to bind to complement component 1q [17]. Therefore, it is possible that defensins may participate in the regulation of complement activation. Defensins induce the release of pro-inflammatory mediators such as IL-8, interferon-γ (IFN-γ), IL-6, IL-10 and leukotrine B_4 (LTB_4). On the other hand, defensins might also exhibit anti-inflammatory activities by inducing the secretion of IL-10 [18].

In the skin, defensins such as HBD-2 are up-regulated in psoriasis [9], acne [19] and folliculitis [20]. In contrast, decreased expression and release of HBD-2 and LL-37 was found in lesional skin of atopic dermatitis patients [21]. Interestingly, antimicrobial agents such as LL-37 and HBD-1 are up-regulated in the inflamed skin of newborn infants during erythema toxicum neonatorum [22]. Moreover, growth factors such as insulin-like growth factor-1 and transforming growth factor-α (TGF-α) enhance the expression of hCAP/LL-37 and HBD-3, indicating up-regulation of antimicrobial peptides during wound healing [23]. HNP-1 increases the expression of pro-α-(I)-collagen and decreases MMP-1 release, supporting a role of defensins in wound repair [24]. IL-1 seems to be an important inducer of HBD-2 synthesis in human keratinocytes [25].

Antimicrobial peptides are also involved in adaptive immune responses [2,6,13,14,26]. Defensins have also been shown to modulate the cytokine profile of T cells. For example, HNP-1 and HNP-2 are T-cell chemoattractants, and induce the recruitment of T cells to the sites of inflammation *in vivo*. Human neutrophil α-defensin enhances antigen-specific humoral immune responses, and $CD4^+$ T cells isolated from mice immunized with antigen in the presence of α-defensins displayed higher antigen-specific proliferative responses and elevated production of IFN-γ, IL-5, IL-6 and IL-10 than T cells from mice immunized with antigen alone.

Defensins also modulate dendritic cell function. Human α- and β-defensins are selectively chemotactic for human immature, but not mature dendritic cells. Although *in vivo* neutrophil defensins are stored in azurophilic granules, they can be released into the extracellular environment by neutrophil disruption or degranulation [27]. Murine BD2 has been demonstrated to directly modulate dendritic cell function and maturation [28], indicating that defensins are involved in immunosurveillance. Thus, defensins presumably present at sites of inflammation form chemotactic gradients for immature dendritic cells. Because dendritic cells are crucial for the induction of adaptive immune responses, defensins may directly contribute to antigen-specific immune responses.

Toll-like receptors

The toll-like receptors (TLRs) are key molecules involved in microbial recognition by the immune system. At present, 10 members of the TLR family have been identified in mammals. They recognize microbial structures such as bacterial LPSs, bacterial DNA and viral double-stranded DNA. There is also evidence that some probiotics that appear to be effective in allergy prevention, may function via interaction with TLRs. The number of ligands for these receptors is growing, and it appears that multiple ligands exist for each receptor. TLRs activate common signalling pathways leading to the activation of nuclear κB transcription factor (NF-κB) and the mitogen-activated protein kinases (MAPKs), which results in the production of pro-inflammatory cytokines. On the other hand, individual TLRs may induce an immune response to a given microbial agent via their specific signalling systems. Thus, TLRs are crucial components of both the innate and adaptive immune response.

TLRs are defined by the presence of a Toll/IL-1 receptor (TIR) domain in their cytosolic regions and an extracellular domain comprising leucine-rich repeats. A key ques-

Table 9.1 Potential use of toll-like receptor (TLR) agonists in various diseases.

Disease/condition	TLR involved	Therapeutic approach	Comments and expected outcome
Acne	TLR-2	Antagonist	Suppression of *P. acnes*-induced cytokine production
Atopic dermatitis	Many	Bacterial vaccine Agonists	Shifting of a Th2 into a Th1 response
Pathogen invasion	TLR-7	Agonist	Reinstatement of cytokine-induced host defence and elimination of viruses
Acute inflammation	TLR-2, -4	Antagonist	Reduction in inflammation by inhibiting TLR-2, -4 expression and HSP-70 release
Chronic inflammation	TLR-2, -4	Antagonist	Reduction in TLR-induced release of inflammatory mediators (heat shock proteins, fatty acids, hyaluronic acids)
Autoimmune disease	TLR-9	Antagonist	Blocking of production of autoantibodies and proliferation of B cells induced by immune complexes containing DNA
Sepsis	Many	Soluble TLRs Antagonists Signalling inhibitors	Ligand neutralization Mediator blockade Receptor blockade

tion concerns signal transduction and whether different responses induced by different TLRs are important for the tailoring of host defence against different microbes. In this regard, two TIR domain-containing adapter proteins, MyD88 and TIRAP/Mal, are of interest. There is evidence from MyD88-deficient mice that MyD88 is an universal adapter for a wide range of TIR domain-containing receptors tested [1], while TIRAP/Mal is implicated in signalling by the LPS sensor TLR-4 but not the bacterial cytosine-phosphate-guanine (CpG) DNA sensor TLR-9 or IL-1 [2,3]. TLRs are expressed on immunocompetent cells and thereby involved in the activation as well as differentiation of dendritic cells and T cells [4]. While undoubtedly important in downstream signalling responses and NF-κB activation, TLRs have not been shown to bind directly to ligands such as LPS or their complexes with LPS binding protein (LBP) [5]. Instead, they bind to CD14, also implicated in apoptotic cell, heat shock protein and fibrinogen clearance. TLRs have recently been found to be expressed on several cells in the skin, including keratinocytes, in addition to immunocompetent cells.

The ligands so far identified that signal through TLR are mainly exogenous, but there are reports of endogenous ligands and of intracellular rather than surface engagement, through which selected TLRs act. Imidazoquinolones such as imiquimod and resiquimod were found to bind to TLR-7 and TLR-8, respectively, and thereby activate macrophages. The resulting secretion of pro-inflammatory cytokines, predominantly IFN-γ, TNF-α and IL-12, was found to be responsible for an immunodeviation towards a T helper 1 (Th1) response required for cytotoxicity and effective antiviral and antitumoral activity. Accordingly, topical imiquimod is successfully used for the treatment of anogenital warts and several types of skin tumour. A similar Th1-inducing effect has been observed for CpG oligodeoxynucleotides (ODN), and was found to be mediated via TLR-9. The efficacy of CpG ODN in the treatment of allergic diseases or as an adjuvant immunotherapy for tumours is currently under study. The potential for using modulation TLRs for therapy of various inflammatory disorders is shown in Table 9.1.

Type 3 complement receptor

Type 3 complement receptor (CR3) is a myeloid cell phagocytic receptor for complement opsonized particles, irrespective of the host or the microbial origin, and also for direct interactions with pathogens such as *Mycobacterium tuberculosis* and yeast-derived zymosan, as well as for host ligands [6]. It is a β2 integrin also known as CD18/CD11b, which has a key role in myelomonocytic cell recruitment to sites of inflammation. The expression of CR3 by macrophages is tissue-selective, and is thus not generated by all macrophages. It is promiscuous in its range of binding of ligands, including intercellular adhesion molecule-1 (ICAM-1) on endothelial cells or platelets, indicating a role at early stages of inflammation and wound healing. Moreover, CR3 contributes to clearance of apoptotic cells. The opsonic phagocytic mechanism differs from that mediated by Fc receptors, and CR3-mediated uptake by macrophages does not trigger release of prostaglandins or reactive oxygen species.

Scavenger receptors

Scavenger receptors (SR) represent a family of structurally unrelated membrane molecules expressed by macrophages and selected endothelial cells, with a broad specificity for polyanionic ligands such as low-density lipoprotein (LDL), suggesting a role in host defence and inflammation. SR-A, for example, contributes to the resistance of the host towards Gram-positive microbial infection *in vivo*. SR-A is also involved in the phagocytic uptake of unopsonized *Neisseria meningitidis* [7]. In contrast, LPS, a previously known ligand of SR-A, is not required for the uptake of *Neisseria* by macrophages, but is responsible for the TLR-4-mediated induction of pro-inflammatory responses. This is associated with an overproduction of

TNF-α and other pro-inflammatory mediators, perhaps resulting from an imbalance between SR-A-dependent clearance of LPS and TLR-4-dependent pathways of secretory stimulation. Thus, the role of SR during inflammation and infection has many interesting features. First, they are able to function as adhesion molecules, but can also mediate endocytosis and phagocytosis of modified-host components and of exogenous ligands (LPS, lipoteichoic acid, and others). The structural basis for receptor–ligand interactions remains unclear. Additionally, the signalling pathways induced by SR-A in the infected cell are poorly defined, and the ligands utilized in many studies can bind to a wide range of SR molecules. Future studies, with the availability of knockout mice for various SR, will help to clarify their role within the innate and acquired immune system and, more generally, in homoeostasis.

Mannose receptor and other C-type lectins

The mannose receptor (MR) is expressed by macrophages, dendritic cells and some endothelial cells. It is a multilectin, which binds mannosy/fucosyl or GlcNAc-glycoconjugate ligands through its Ca^{2+}-dependent carbohydrate recognition domains (CRD) [8]. The ligands are present on several bacteria, fungi, virus-infected cells and parasites. Endogenous self-ligands for CRD include L-selectin, implicated in cell migration and a number of mannose-terminal lysosomal hydrolases [9]. Recent data also suggest novel ligands for MR in peripheral lymphoid organs. Interestingly, macrophages are capable of releasing a soluble form of MR into the plasma. Thus, MR participates in complex functions related to tissue clearance, homoeostasis, immunomodulation and host defence.

Apoptosis

Apoptosis (Greek: falling, as of leaves from a tree) is a physiological and programmed form of cell death that is characteristic for all nucleated cells. It also modulates the function of leukocytes by directly regulating various effector subtypes. The first step is the induction of endogenous endonuclease activation and proteolysis. In terms of the inflammatory process, recent knowledge indicates that inflammatory cells such as neutrophils, macrophages and dendritic cells are capable of directing the inflammatory response in both pro- or anti-inflammtory directions, depending on the signals that they receive. Thus, apoptosis may be a pro- or anti-inflammatory process, depending on the microenvironment in which this interaction occurs [1].

During the past few years, it has become evident that apoptosis is not a 'neutral' process in inflammatory terms, but is rather an active event in which apoptotic cells become phagocytosed, thereby inducing inflammatory responses. Thus, clearance of apoptotic cells can result in powerful anti-inflammatory and immunosuppressive effects [2]. For example, apoptosis of neutrophils infiltrating damaged tissue may contribute to the termination of inflammation. Accordingly, in the perturbed epidermis, particularly after ultraviolet (UV) light irradiation, apoptotic cell residues are known as Civatte or colloid bodies, or sunburn cells [3]. Recent data, however, also indicate that clearance of apoptotic cells can result in the generation of pro-inflammatory stimuli, which may ultimately lead to chronic inflammation and immune-mediated diseases [4].

During early stages of keratinocyte apoptosis, the nuclei become convoluted and chromatin aggregates on the nuclear membrane, the cell shrinks and separates from the contiguous cells (disaggregation). Fragments of nucleus and small apoptotic bodies ('apical blebbing') are released. They are composed of nuclear remnants, particles of organelles and cytoplasm within a capsule of transglutaminase cross-linked protein resembling differentiated involucrin in keratinocytes. The apoptotic cell residues (e.g. sunburn cells) or bodies may be ingested by professional phagocytes such as macrophages, dendritic cells or neutrophils [5,6].

Apoptosis differs from necrosis in that single or very small groups of cells are affected, there is nuclear pyknosis and condensation of the cytoplasm, and phagocytosis of the residual material without excitation of inflammation, and resolution of organized tissue without major structural change can occur. Nuclear pyknosis occurs in coagulative necrosis, but the change in apoptosis is caused by endonuclease splitting of the DNA, resulting in a 'ladder' pattern on separation in agarose gels, whereas necrotic cell DNA forms an amorphous smear [4]. In the skin, apoptosis is induced during hypoxia, tissue repair, allergic reactions, exposure to toxins and drugs, and after skin radiation with ions or UV light. Thus, apoptosis can be observed as a physiological defence mechansim against 'danger signals' that occur in the skin. For example, distinct subsets of hapten-specific T cells are also capable of inducing apoptosis in autologous keratinocytes, and

nickel-specific $CD8^+$ and $CD4^+$ T-cell subsets can exert a cytotoxic activity against keratinocytes. Finally, glucocorticoids and other immunosuppressants induce apoptotic pathways in several immune cells, thereby contributing to healing during inflammation, autoimmune disease and infection [7–9].

Major histocompatibility complex

The genetic loci responsible for the rejection of non-self tissues are located in a region known as the major histocompatibility complex (MHC) on chromosome 6. The MHC genes encode for highly polymorphic cell surface structures termed MHC antigens or human leukocyte antigens (HLA). Three classes of molecules (I–III) have been identified. The class I and II glycoproteins, which share a similar overall structure, are involved in antigen presentation. There are three main class I genes (HLA-A, HLA-B and HLA-C) and three main class II genes (HLA-DP, HLA-DQ and HLA-DR). The class III proteins, although encoded by genes residing in the same chromosomal region as those for the class I and II molecules, consist of components of the complement system and molecules that are involved in the processing of antigens, such as the proteasome-like genes and transporter genes [1–3].

Each class I MHC protein is expressed on the cell surface as a dimer composed of two non-covalently linked polypeptide chains (heavy or α-chain associated with a non-MHC-encoded β_2-microglobulin). The peptide-binding capacity of the class I MHC is enormous because each individual carries six different HLA-A, HLA-B and HLA-C alleles, and each allelic gene product is capable of generating a variety of different peptides [1,2].

The class II MHC is highly polymorphic, with the polymorphic residues concentrated in the α_1 and β_1 domains, which are involved in peptide binding. Multimeric receptor forms are also possible for other molecules involved in cognate recognition (e.g. class I MHC, T-cell receptor) and probably increase the avidity of interaction of juxtaposed cells [1–3].

Class I MHC molecules bind cytoplasmic proteins (e.g. viral proteins in infected cells) that are degraded into peptides by a large cytoplasmic proteolytic complex derived from at least two genes in the HLA class II region [4]. Class II MHC molecules bind peptides derived from exogenous proteins that have been internalized in antigen-presenting cells in a coated pit into the endocytic pathway, where antigen degradation generates functional peptides. The resulting peptide–protein complex is then translocated to and expressed on the antigen-presenting cell surface [5].

Under normal circumstances, self-proteins are displayed, leading to a state of tolerant inactivity. However, deleterious intracellular events lead to the display of MHC class I molecules complexed with foreign peptides, activation of $CD8^+$ T cells and the generation of cytolytic T cells. Similarly, extracellular exposure to foreign substances results in the cell-surface display of class II MHC molecules complexed with foreign peptides, leading to the activation of $CD4^+$ T cells, the induction of B cells through helper T-cell activity and immunoglobulin production.

The CD8 class I pathway is associated with internal cellular events. Because virtually all nucleated cells express class I molecules, essentially all cells can act as antigen-presenting cells for $CD8^+$ T cells, providing important protection against harmful intracellular processes such as inflammation, viral infection and neoplasia. The CD4 class II pathway is responsive to external cellular events, but the relative restriction of constitutive class II expression and antigen-presenting capacity to B cells, macrophages, dendritic cells, venular endothelial cells and probably keratinocytes limits the possibilites and consequences of activating $CD4^+$ T cells.

Dysfunction or genetic alterations of MHC alleles have been found in various skin and immune diseases. For example, MHC class I-restricted $CD8^+$ T cells play an important part in the pathophysiology of contact hypersensitivity (CHS). Class I-restricted $CD8^+$ T cells are sufficient for the induction of CHS, supporting the idea that MHC class II-restricted $CD4^+$ T cells down-regulate this inflammatory response. Moreover, $CD8^+$ T cells mediate the skin inflammation through their cytotoxic activity using either the perforin or the Fas–Fas ligand pathway. Thus, cytotoxic $CD8^+$ T cells directly contribute to delayed-type hypersensitivity reactions [6]. Inflammation-associated regulation of MHC function appears also to be crucial in microvascular endothelial cells (HDMEC). For example, cytokines such as IFN-γ or TNF-α, but not IL-1α, increase MHC class I expression on HDMEC [7].

MHC class II antigens have been implicated in the pathophysiology of lichen planus and Behçet's disease. However, histopathological analysis of the skin revealed marked hyperkeratosis of the epidermis and dramatic thickening of the granular layer, with slight infiltration

of inflammatory cells in the dermis, in transgenic mice carrying MHC class I chain-related gene B (MICB) [8]. Moreover, the absence of MHC class II permitted the development of systemic autoimmune effects in a mouse model of acute graft-versus-host disease (GvHD) [9]. In general, variation among individuals in their susceptibility to a variety of autoimmune disorders and a cluster of genes encoding inflammation-related proteins along with MHC genes seems to be crucial for the development of MHC-associated diseases [10].

Modern anti-inflammatory therapeutic strategies are effective in the treatment of MHC-associated inflammatory diseases. For example, recombinant human IL-11 therapy was associated with suppression of mucosal inflammation and concomitant improvement of epithelial resistance and neurally mediated secretion in a model of chronic HLA-B27 colitis; oral treatment of HLA-B27 rats with rhIL-11 reduced myeloperoxidase (MPO) activity in the colon and suppressed clinical signs of diarrhoea [11]. For detailed information on the role of MHC in the adaptive immune response see Chapter 10.

Cellular components of cutaneous inflammation

Epidermis

To avoid repetition, this chapter focuses on the role of components of the innate immune system during inflammation. The functions of the aquired immune system and dendritic antigen-presenting cells are described in Chapter 10.

Keratinocytes

In the past, the keratinocyte was viewed as a 'brick' in the wall surrounding the body. However, beside their role in producing cytokeratins and lipids, keratinocytes are capable of generating and releasing an armada of different inflammatory mediators. Upon stimulation during inflammation, keratinocytes actively secrete large amounts of cytokines, chemokines, peptides and growth factors, and express receptors for these mediators, as well as several co-stimulatory molecules (Table 9.2).

Keratinocytes respond to both external stimuli and endogenous trigger factors. External stimuli include bacteria, fungi, house-dust mites, viruses, antigens, mechanical stress, UV light or temperature change. Moreover, endogenous inflammatory mediators such as cytokines, neuropeptides, proteases, eicosanoids, nitric oxygen or other free radicals may directly modulate keratinocyte function. Thus, cytokines and other factors derived from keratinocytes may have an important regulatory role in many physiological and pathophysiological conditions in the skin such as inflammation, immune defence and wound healing. Keratinocytes are important regulators of cutaneous inflammation, orchestrating the communication between epidermal and dermal cells and immigrating immune cells, in order to re-establish skin homoeostasis.

The response of keratinocytes to injury may be separated into two phases. In the first phase they produce pro-inflammatory mediators that contribute to the body defence mechanism by reacting to danger signals. In the second phase, keratinocytes induce cutaneous regeneration by activating fibroblasts and proliferation of keratinocytes.

One of the central molecules for the inflammatory response is IL-1. In the skin, IL-1 is mainly synthesized in basal, but also suprabasal keratinocytes, and is released upon various injurious stimuli. IL-1 release can be induced in an autocrine or paracrine fashion by IL-1 itself, or by other cytokines such as TNF-α or IL-6 [1]. Keratinocyte-derived IL-1 can stimulate the release of granulocyte–macrophage colony-stimulating factor (GM-CSF), which serves as a crucial mediator for the activation and differentiation of Langerhans' cells. Keratinocyte-derived cytokines such as TNF-α, IL-1 or IL-6 may enter the circulation and subsequently exert systemic effects such as fever and acute-phase protein production. Keratinocytes also release various chemokines such as CCL-8, CCL-27, RANTES, GRO-α, monocyte chemotactic protein 1 (MCP-1), interferon-inducible protein 10 (IP-10), eotaxin and others, which regulate trafficking of lymphocytes, neutrophils, eosinophils, dendritic cells and mast cells.

Table 9.2 Human *keratinocyte* cytokines and pro-inflammatory mediators.

Agent	Abbreviation
Interleukins	
Interleukin-1α and β	IL-1α and β
Interleukin-3	IL-3
Interleukin-6	IL-6
Interleukin-8	IL-8
Interleukin-18	IL-18
Interferons	
Interferon-α	IFN-α
Interferon-β	IFN-β
Interferon-γ	IFN-γ
Pro-inflammatory mediators	
Tumour necrosis factor-α	TNF-α
Monocyte chemotactic protein-1 CCL27	MCP-1
Epidermal cell lymphocyte chemotactic factor	ELCF
Macrophage migration Inhibitory factor	MIF
Prostaglandin E_2*	PGE_2
Leukotriene B_4*	LTB_4
12-Hydroxyeicosatetraenoic acid	12-HETE
Epidermal proteases	Cathepsins
Serine protease	Trypsinogen
Lysozyme	—
Neuropeptides	SP, NKA
Anti-inflammatory mediators	
α-Melanocyte stimulating hormone	α-MSH
Colony-stimulating factors	
Granulocyte–macrophage colony-stimulating factor	GM-CSF
Granulocyte colony-stimulating factor	G-CSF
Macrophage colony-stimulating factor	M-CSF
Growth regulators	
Transforming growth factor-α	TGF-α
Transforming growth factor-β	TGF-β
Platelet-derived growth factor	PDGF
Basic fibroblast growth factor	bFGF
Vascular endothelial growth factor	VEGF
Endothelin-1	ET-1

* Detection in skin *in vivo*, presumably from the epidermis.

Thus, keratinocytes actively participate in the regulation of many inflammatory skin diseases including psoriasis and atopic dermatitis.

Growth factors such as epithelial growth factor (EGF) also modulate keratinocyte function during inflammation and tissue repair. Recently, an autocrine loop of keratinocyte proliferation and migration was observed during wound healing, which was found to be regulated by the receptor for EGF [2]. Increased TGF-β, basic fibroblast growth factor (bFGF) and vascular endothelial growth factor (VEGF) expression levels can be also observed in keratinocytes after injury and inflammatory stimuli, indicating that keratinocytes are autocrine and paracrine key regulators of growth factors during skin inflammation and remodelling. Resting keratinocytes constitutively synethesize TNF-α, which at low concentrations may control keratinocyte proliferation and the maturation of Langerhans' cells. During inflammation and wound repair, keratinocyte-derived TNF-α also participates in the regulation of T-cell activity and dendritic cell functions [3]. Moreover, keratinocyte-derived cytokines such as TNF-α are involved in the regulation of dermal microvascular endothelial cells, via stimulation of the production of cytokines and chemokines, and up-regulation of cell adhesion molecule expression, such as ICAM-1 or vascular cell adhesion molecule (VCAM). Other growth factors generated by keratinocytes are transforming growth factors (TGF-α, TGF-β) and colony-stimulating growth factors (G-CSF, M-CSF, GM-CSF), which exert multiple functions in the skin.

In human keratinocytes, the expression of co-stimulatory molecules such as CD80, which is an important signal for professional antigen-presenting cell and T-cell interactions, is up-regulated by allergens or irritants [4]. In

addition, various inflammatory stimuli up-regulate the expression of MHC molecules such as MHC II or CD1d on keratinocytes, suggesting a role for keratinocytes in antigen presentation [5]. Keratinocytes also provide a source of antigenic proteins to which chemical haptens can conjugate. Lymph node cells from hapten-sensitized mice were found to proliferate in the presence of a keratinocyte extract without hapten [6]. Keratinocyte-derived chemokines also have an essential role during the induction, as well as the elicitation phase of contact hypersensitivity [7].

UV radiation is an important trigger factor that modulates keratinocyte function during inflammation. UV causes DNA damage and, via the activation of the transcription factor NF-κB, induces the production of cytokines, growth factors, proteases and matrix metalloproteinases, which regulate keratinocyte function. Recently, keratinocyte- as well as mast cell-derived cytokines such as TNF-α have been demonstrated to be involved in UV-mediated cutaneous immune responses [8,9]. It was observed that UV failed to induce tolerance in mast cell-deficient mice, and that tolerance occurred if mast cells were triggered to degranulate after activation of the IgE receptor [6]. Recent findings also support a role for NF-κB target genes (IL-1, IL-6, TNF-α, VEGF) in sunburn reactions after UV [10]. Finally, UV also induces the production of suppressor factors, such as IL1-RA, IL-10, TGF-β and α-MSH, which exert an anti-inflammatory and immunosuppressive action. The secretion of these signals following UV usually occurs later, after the initiation of pro-inflammatory mediators, and may therefore reflect mechanisms for the down-regulation of inflammation and the prevention of chronic inflammation [11].

Various microbiological agents such as viruses, bacteria, fungi or house-dust mite antigens, via multiple mechanisms including proteases, proteins and glycoproteins, may also affect keratinocyte functions, ultimately resulting in an inflammatory response. For example, human papillomaviruses (HPV) are known to modulate the expression of signals in keratinocytes that regulate their proliferation, as well as the release of mediators of inflammation. HPV-16 down-regulates IFN-responsive genes and up-regulates NF-κB-responsive genes in keratinocytes, resulting in a modified immune response. Moreover, an HPV-16 protein was found to induce the secretion of chemokines such as IL-8, RANTES, macrophage inflammatory protein-1α (MIP-1α) and IFN-γ-inducible protein. IFN-inducible genes and STAT1 appear to be crucial target genes for keratinocyte-targeting viruses [12]. Thus, keratinocytes may directly alter gene expression in response to pathogens, and thereby influence host resistance to infection and inflammation. Bacterial infections of the skin are another example of the interaction of microbes with keratinocytes. Streptococci and staphylococci frequently infect the skin by using strategies to overcome keratinocyte defence mechanisms. Beside defensins, CD44 appears to have an important role as a receptor for the colonization of keratinocytes by group A streptococci. Thus, receptor-blocking strategies on keratinocytes (e.g. TLRs, CD44) may be novel tools for the treatment of cutaneous infections [13]. In summary, keratinocytes, via the release of mediators and the expression of surface molecules, subserve multiple important functions in the skin during inflammation and infection, tissue repair and autoimmunity.

Lymphocyte-mediated cytotoxicity

T lymphocytes have a pivotal role in the pathogenesis and pathophysiology of any immune-mediated and inflammatory skin diseases. Many of them, such as psoriasis, atopic dermatitis, contact dermatitis and lichen planus, are T-lymphocyte driven. The crucial role of T cells in the pathogenesis of these diseases is also supported by the finding that deletion of T cells *in vivo* leads to a significant improvement. Depending on the microenvironement, T cells are key players both as effector and regulatory cells. The role of T cells during inflammation and the immune response is extensively discussed in Chapter 10 so this chapter only deals with recent knowledge on the role of perforins in T-cell-mediated cytotoxicity.

T-cell-mediated cytotoxicity is involved at several stages of cutaneous inflammation. Cytotoxic T cells (CTL)

secrete the pore-forming glycoproteins termed perforins, which are able to integrate into the cell membrane, thereby leading to disintegration of target cells. Perforins are markedly up-regulated during infection and inflammatory skin diseases such as atopic dermatitis. Moreover, CTL recognize target cells and present the processed antigen. In contrast, NK cells exert their effects by up-regulating and releasing Fas ligand, which activates Fas on the target cell during inflammation [1]. Thus, in different ways, CTL and NK cells are critically involved in tissue protection during inflammation, infection and tumour growth.

There is evidence that $CD4^+$ T cells are also capable of generating cytolytic activity. Whether they secrete a direct cytolytic factor or exert their effects via an immunoregulatory mechanism is still unclear. However, both Fas- and perforin-dependent cytolytic pathways seem to be possible [2,3].

Natural killer cells

NK cells or large granular lymphocytes are bone marrow-derived lymphocytes that were originally characterized by their ability to lyse a variety of tumour targets and infected cells, and which share a common progenitor with T lymphocytes. They originally were referred to as null cells, because they display neither T- nor B-cell-specific characteristics. These cells typically express CD56, which is homologous to neural cell adhesion molecule, and sometimes express CD16, a low-affinity receptor for the Fc portion of IgG. CD16 is often associated with the CD3-ζ homodimer found in the T-cell receptor–CD3 complex. NK cells comprise approximately 10% of peripheral blood lymphocytes, and express neither B-cell-specific membrane immunoglobulins nor the T-cell receptor–CD3 complex. However, they may express some T-cell differentiation antigens, such as CD2 and CD8, and myelomonocyte differentiation antigens, such as CD11b, CD11c, CD14 and CD15 [1].

It is well known that NK cells are able to secrete significant amounts of cytokines (IFN-γ and TNF-α) as well as chemokines. In contrast to T- and B-cell responses to antigen, which typically require a proliferation phase, the innate NK-cell response is immediate, implying that NK cells are involved in curbing pathogens during the initial several days of infection. Indeed, there is strong evidence that NK cells contribute to the defence against intracellular bacteria and parasites and that they are crucial for controlling several types of viral infection. Moreover, their antitumour capacity is well established *in vitro* as well as *in vivo* [2–4].

As other cells, NK cells express inhibitory receptors specific for MHC class I proteins and stimulatory receptors with diverse specificities. Thus, they do not require the specialized gene rearrangement machinery that assembles T- and B-cell antigen receptor genes. Nevertheless, NK cells exhibit a clear capacity to discriminate between target cells. In the case of cellular targets, sensitivity to NK cells is correlated in many instances with decreased levels of MHC expression. NK cells are also able to reject MHC-incompatible bone marrow grafts. These observations led to the formulation of the 'missing self' hypothesis, by which NK cells may ignore potential targets expressing normal levels of autologous class I molecules and attack cells that do not. However, 'missing self-recognition' is only one of several modes of NK cell–target cell discrimination [5–9].

NK cells preferentially kill target cells that lack surface expression of MHC class I molecules. This implies the existence of triggering receptors that recognize non-MHC ligands on these target cells. Unlike T lymphocytes that recognize MHC–peptide complexes using clonally distributed T-cell receptors generated by gene rearrangement, NK cells appear to use triggering receptors that do not require this genetic process. These triggering receptors can initiate NK-cell activation and target cell lysis, provided that NK cells are not turned off by activation of MHC class I-specific inhibitory receptors. These data suggest that triggering NK receptors involved in natural cytotoxicity recognize non-MHC ligands expressed not only by abnormal but also by normal cells [10,11].

NK receptors. NK cells are regulated by opposing signals from receptors that activate and inhibit effector functions. Three distinct receptor families, Ly49, CD94/NKG2 and KIR (killer cell-inhibitory cell receptors), are involved in NK-cell recognition of polymorphic MHC class I molecules. Recent studies suggest these inhibitory NK-cell receptors are members of a larger superfamily containing immunoreceptor tyrosine-based inhibitory motif (ITIM), defined as the inhibitory receptor superfamily (IRS). Thus, NK cells are regulated by a balance of signalling via stimulatory receptors, specific for diverse ligands, and inhibitory receptors, specific for MHC class I molecules [12].

Three novel NK-specific triggering surface molecules that are involved in natural cytotoxicity have been identified (NKp46, NKp30 and NKp44). They represent the first members of a novel emerging group of receptors collectively termed natural cytotoxicity receptors (NCRs) [13]. Interestingly, there exists coordinated surface expression

of the three NCRs, their surface density varying in different individuals and also in the NK cells isolated from a given individual. While an altered expression or function of NCR or NKG2D is being explored as a possible cause of immunological disorders, dysfunction has already been associated with a severe form of immunodeficiency. Upon activation of NCRs, NK cells undergo blastogenesis, generate cytokines, enhance cytotoxicity and migrate. In contrast, inhibitory receptors prevent killing of normal cells and limit the production by NK cells of inflammatory cytokines including TNF-α, IFN-γ and GM-CSF.

Another more classic NK-cell receptor is the low-affinity receptor for IgG, CD16 (Fc RIII). The transmembrane-anchored CD16 isoform is expressed on the majority of, but not all NK cells, as well as on activated monocytes and a subset of T cells. Upon CD16-mediated activation, NK cells secrete cytokines [14], mediate antibody-dependent cellular cytotoxicity and may undergo apoptosis as a consequence of Fas ligand-induced cell death [15]. CD2 may be a co-stimulatory receptor that augments primary activation of NK cells.

MHC-specific receptors discriminate among different MHC class I alleles and are expressed in a variegated overlapping fashion, such that each NK cell expresses several inhibitory and stimulatory receptors. Together these mechanisms ensure a self-tolerant and maximally discriminating NK-cell population.

Upon stimulation, NK cells produce high levels of certain cytokines and chemokines. They have a crucial role in the defence against a number of different infectious agents and tumours. The first evidence for this function came from observations that virus-induced interferons (IFN-α and -β) are potent inducers of NK-cell-mediated cytotoxicity, and that NK cells are important contributors to innate defence against viral infections. Since that time, a wide range of other innate cytokines have been detected that mediate biological functions regulating the NK-cell responses of cytotoxicity, proliferation and IFN-γ or TNF-α production. For example, certain viral infections induce IL-12, which elicits IFN-γ production by NK cells, thereby inducing antiviral mechanisms. Thus, after microbial stimulation, NK cells have immediate effects resulting in host defence, especially with regard to viruses. In addition, chemokines such as MIP-1α are capable of stimulating migration of NK cells, probably via binding of the CCR5 chemokine receptor. Other chemokines that activate NK cells are MIP-1β, MCP-1, -2, -3 and RANTES. In addition, numerous cytokines have been found to modulate NK-cell function, including IFN-α and -β, which induce cytotoxic activity, stimulate proliferation and inhibit IL-12 production [13,16].

Unlike T or B cells, NK cells develop normally in *scid* mice or mice with disrupted rearrangement genes, indicating that gene rearrangement is not required for their differentiation or function. NK cells are instrumental in innate immune responses, in particular providing for the early production of IFN-γ and possibly other cytokines necessary to control certain bacterial, parasitic and viral infections. The factors responsible for activation of NK cells during infection have remained elusive, but likely involve soluble factors such as IFN-α and -β, cytokines (TNF-α, IL-12, IL-15) and chemokines, as well as the presence of certain membrane-bound molecules on surrounding tissues. Although positive stimuli are required to activate NK-cell migration and effector function, the process is tightly regulated by inhibitory receptors and cytokines that limit and potentially terminate the response [17–19].

Thus, NK cells serve as sentinels in the immune system, which is constantly assailed by pathogens as well as antigens, and where the achievement of a balance is crucial to permit elimination of pathogens but avoid autoimmunity. For example, the potential for self-aggression is dramatically illustrated by the phenotype of mice with disrupted *CTLA-4* genes. In these animals, CD28 stimulation via CD80 or CD86 in the absence of negative regulation by CTLA4 [20,21] leads to a T-cell lymphoproliferative disease that results in death. Receptors which possess the consensus ITIM (CD22, LAIR-1, gp49, LIR1, gp91/PIR, ILT1/2, ILT3) sequence seem to be crucial in this context [13,19–21].

Polymorphonuclear granulocytes

The polymorphonuclear granulocytes, basophils, eosinophils and neutrophils, are the mobile attack forces of the allergy army. All arise from haematopoietic precursors, undergo maturation within the bone marrow and are released into the blood as mature leukocytes. Eosinophils and basophils are thought to arise from a common mononuclear stem cell, which is stimulated to divide by the cytokines IL-3 and GM-CSF acting in concert with stromal factors. While the production of these cells is limited in normal conditions, in allergy increased levels of GM-CSF and IL-5 result in their increased production. Both eosinophils and basophils are primarily tissue cells with a very limited lifespan in the blood. For eosinophils, the lifespan in the blood is approximately 24 h and the tissue : blood ratio is about 100 : 1. In contrast, neutrophils are produced constitutively by the bone marrow in large numbers. Because of the large number produced and the relatively short lifespan (less than 24 h), more than half of the work done by the bone marrow is dedicated to the production of neutrophils. In inflammation, increased levels of inflammatory cytokines stimulate enhanced neutrophil production. IL-3, IL-6, GM-CSF and TNF-α are the cytokines that are most likely to be involved.

Basophils

Although representing less than 1% of the circulating leukocytes, basophils can be purified from the blood and have been studied extensively *in vitro*. Like mast cells, basophils stain metachromatically with aniline dyes but can be distinguished from mast cells by their bilobed nucleus.

Structurally and functionally, basophils have a lot in common with mast cells. Perhaps the most important similarity is the presence of FcεRI, the high-affinity receptor for IgE, on their surface. Basophils derived from allergic patients contain up to 500 000 IgE receptors per cell [1]. However, they can be activated by cross-linkage of only approximately 1% of this number [2], making them exquisitely sensitive to allergen stimulation. It has been suggested that IgE on basophils may be in one of two forms, IgE^+ or IgE^-; cells with the former form being activated by IL-3 and histamine-releasing factors [3,4]. Furthermore, like skin mast cells, basophils are activated by the complement fraction, C5a. Other receptors on basophils are for IL-3, IL-4 and GM-CSF, which prolong their survival, and a histamine H_2 receptor, which down-regulates their function. The ease with which basophils can be obtained from patients has led to their widespread use *in vitro* in research and diagnosis of allergic disease (e.g. to detect circulating histamine-releasing autoantibodies in chronic urticaria [5]).

Basophils contain about 1 pg/cell of histamine, which, as in mast cells, is stored in modified lysosomal granules in combination with proteoglycans, predominantly chondroitin sulphate in the case of the basophil. Basophils contain very small amounts of tryptase, but no chymase. On stimulation, basophils generate relatively large amounts of the leukotrienes (LT) LTC_4, but not LTB_4 or the prostaglandin (PG) PGD_2 [6]. Another important function of the basophil is the generation of IL-4 and IL-13, which are critical for switching the B lymphocyte to IgE production [7,8].

In allergic diseases, basophils migrate from the bone marrow, enter the circulation as mature cells and infiltrate tissues in response to inflammatory stimuli. Knowledge of their role within the tissues is largely circumstantial. One reason is that basophils infiltrating an area of active allergic disease are likely to undergo degranulation quite rapidly and therefore be difficult to detect. Another is that until recently it has been difficult to distinguish tissue basophils from mast cells. However, monoclonal antibodies to a basophil granule protein have been described recently [9,10], which should revolutionize basophil research; for example, evidence for basophil recruitment during late-phase allergic response is now unequivocal [11].

Eosinophils

The idea of an association between eosinophils and allergic disease, particularly asthma, has a long history. Until the 1980s, it was thought that eosinophils might be anti-inflammatory. However, with the realization that eosinophil granule proteins are highly toxic, this view changed to one of eosinophils being considered as pro-inflammatory cells. Indeed, many of the features of asthma and related allergic diseases were considered to be mediated by eosinophil products. However, recent studies with anti-IL-5 and IL-12, which ablated eosinophils but failed to relieve asthma [12,13], are now throwing doubt on the pivotal role ascribed to eosinophils in allergic diseases.

Coming from a common precursor, eosinophils and basophils are closely related. Eosinophils, like basophils,

are approximately 8 μm in diameter, have a bilobed nucleus and use the blood merely as a transport system to reach the tissues. The eosinophil cytoplasm contains two types of granule, the most characteristic of which is the core-containing specific granule, which contains the basic proteins. Such granules avidly take up acidic dyes (e.g. eosin), giving eosinophils their characteristic microscopic appearance. The other granule is the so-called 'primary granule', which lacks a core and is of variable size. Also present in the cytoplasm are a number of lipid bodies, thought to be a store of arachidonic acid for eicosanoid synthesis.

The eosinophil membrane is particularly rich in receptors for adhesion proteins, chemokines and cytokines. For example, the coordinated action of IL-5, CCR3 binding chemokines and the adhesion molecules P-selectin and VCAM-1, acting in concert, cause selective recruitment of eosinophils into allergic tissue [14]. Once in the tissues, GM-CSF, IL-5 and eotaxin serve to both prime eosinophils for chemotactic and degranulatory responses and adhesion and cytotoxicity, and to prolong survival. Interestingly, eosinophils produce large quantities of GM-CSF and IL-5, so ensuring their own survival [15]. Eosinophils also possess immunoglobulin receptors for IgA, IgG and IgE, and therefore have wide interactions with the immune system.

The major proteins of the eosinophil granule are major basic protein (MBP), eosinophil cationic protein (ECP), eosinophil peroxidase (EPO) and eosinophil-derived neurotoxin (EDN). To explain their presence, it must be remembered that the allergic response was originally developed as an immune defence system against helminth parasite infestation. All the above proteins are highly toxic to helminths. As they are also potentially toxic to mammalian cells, they may cause tissue damage in allergic responses. In addition, the peroxidase actions of EPO may lead to the generation of toxic oxygenated free radicals.

Eosinophils are probably the major producers of LTC_4 in allergic inflammation. Although this has profound implications for asthma, the importance in allergic responses in the skin is less clear. However, the beneficial effects of leukotriene receptor antagonists in atopic dermatitis [16] and urticaria [17] suggests an involvement.

In peripheral blood and non-inflamed tissue, eosinophils are in a resting state to prevent unwanted tissue damage from eosinophil-derived mediators. In order to become activated, eosinophils must first be primed by exposure to the cytokines IL-5, GM-CSF and IL-3, or the lipid products platelet-activating factor (PAF) and LTB_4. As the majority of these substances are also chemoattractants, the end result is large numbers of degranulating eosinophils and heavy granule protein deposits at sites of allergic inflammation. Such a strategy would be ideal if the target was the surface of a large helminth parasite. However, in allergic skin disease, the stimulus is allergen and not a parasite. Even so, large deposits of extracellular eosinophil granule proteins are found in both urticaria [18] and atopic dermatitis [19,20], with raised MBP levels being found in the circulation [21].

Neutrophils

Neutrophilic polymorphonuclear leukocytes (or neutrophils), are approximately 7 μm in diameter and are easily recognized in conventional cytological preparations by their pinkish cytoplasm and distinctive polymorphic nuclei. When neutrophils are viewed under the electron microscope, a number of heterogeneous granules are obvious. The larger of these, the so-called primary or azurophilic granules, are peroxidase-positive, whereas the smaller ones, the so-called secondary or specific granules, are peroxidase-negative. Other subcellular structures, such as Golgi apparatuses, are scarce.

Neutrophils are the most numerous of the blood leukocytes and represent the first line of defence of the immune system against infection and tissue injury. As a consequence, it is necessary for them to be able to reach an inflammatory site very rapidly. Once released from the bone marrow, the majority of neutrophils are 'stored' intravascularly by the process of margination. It has been calculated for a 70-kg male that the number of marginated neutrophils is approximately 3×10^{10} [22]. The expression of a high density of adhesion proteins on their cell surface allows large numbers of neutrophils to move rapidly from their marginated sites into inflamed tissues. Indeed, evidence of their accumulation may be seen within minutes of a tissue stimulus. Several adhesion proteins have been identified on the neutrophil, the most important being the integrin LFA-1 (CD11a/CD18), which is the ligand for ICAM-1 [23]. In order to move rapidly to an inflammatory site once in the extravascular compartment, neutrophils must also express high levels of receptors for a wide range of chemotactic agents, such as IL-8 and LTB_4 (Fig. 9.5).

Like the other granulocytes, neutrophil mediators may either be preformed and stored in granules or be synthesized *de novo* on cell activation. The preformed mediators are mainly enzymes that facilitate the primary function of the neutrophils—to phagocytose and digest bacteria and other foreign particles. Neutrophil lysosomal granules contain more than 20 enzymes, including proteinases, elastase, gelatinase, collagenase, lysozyme, cathepsin G and defensins [24]. These enzymes may act either intracellularly to digest ingested bacteria or be released into the extracellular environment during inflammation. A further enzyme, myeloperoxidase, facilitates the bactericidal respiratory burst, which is characteristic of neutrophil activation [25]. In this reaction, oxygen radicals, hydrogen peroxide (H_2O_2) and superoxide (O_2^-) generated by the peroxidase converted into the even more toxic hypochloric acid (HOCl) and hydroxyl ($OH^\bullet$) radicals.

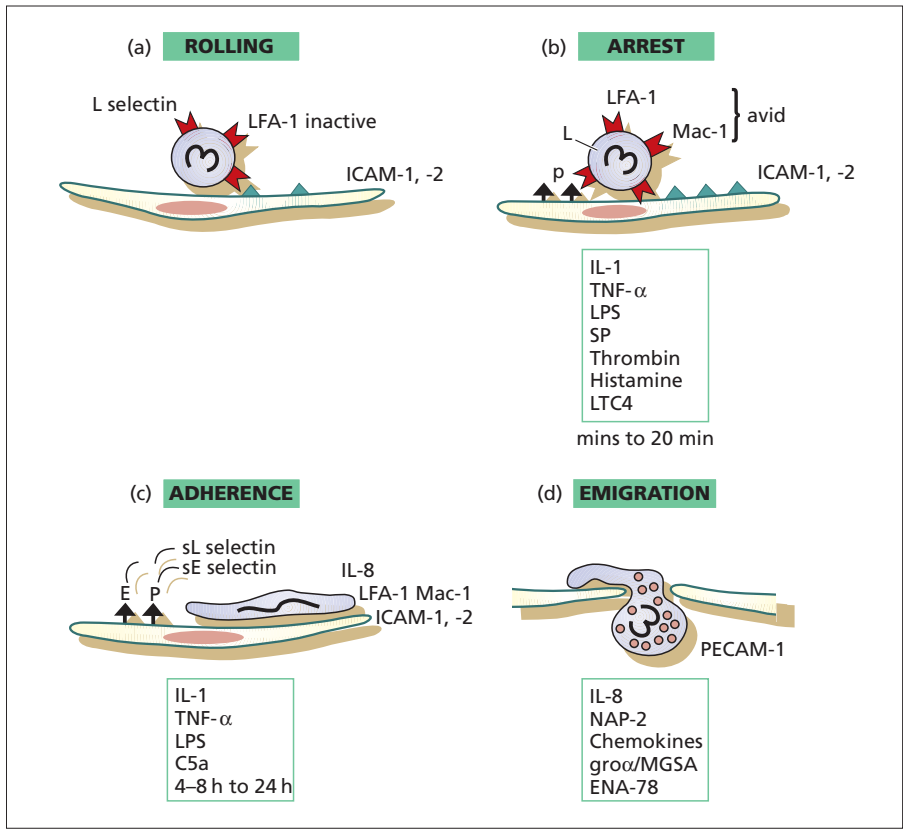

Fig. 9.5 Neutrophil emigration. (a) Rolling: cells roll over the endothelium by brief non-adherent contacts via the selectins, particularly L-selectin. The integrins are non-binding. (b) Arrest: on contact with activated endothelium, selectin binding briefly increases, integrins become avid and intercellular adhesion molecule 1 (ICAM-1) increases on the endothelial surface. (Monocytes and eosinophils also bind via α4β1 to vascular cell adhesion molecule 1 (VCAM-1).) (c) Adherence: the neutrophil flattens on the endothelium, affinity increases and motility response to chemokines is initiated. (d) Emigration: neutrophil leaves vessel through interendothelial cell junction, regulated by integrins, platelet/endothelium cell adhesion molecule 1 (PECAM-1) and chemokines.

Evidence of the capacity of neutrophils to cause tissue damage is, for example, the tissue degradation round an implanted foreign body, such as a splinter, in order to facilitate its rejection as part of the healing process. Pus is an extreme example of neutrophil activity resulting from severe degradation of tissue and of dead leukocytes. However, the potential for neutrophils to cause overt tissue damage is limited by the presence of antiproteinases, such as α_2-antiproteinase, α_2-macroglobulin and antielastins, which penetrate the tissues from plasma during inflammation. Therefore, it is unlikely that neutrophils cause overt tissue damage in the presence of normal levels of antiproteinases. However, in antiproteinase deficiency, as has been suggested is the case in emphysema, the potential for neutrophil-induced tissue damage is enhanced [24].

The primary role of the newly generated mediators appears to be directed to the recruitment of more neutrophils. In the short term, this is facilitated by the synthesis and release of large quantities of LTB_4, a potent neutrophil attractant. *In vitro*, neutrophils certainly have the capacity to synthesize the cytokines IL-1β, TNF-α and IL-8, which would serve to recruit and activate further neutrophils, and IL-6, IL-12 and GM-CSF, which stimulate haematopoiesis of neutrophil precursors. However, bearing in mind that the peak production time for cytokines is often 12–24 h after cell stimulation, the clinical significance of their production in a cell with a tissue lifespan often less than 6 h is questionable.

The potential role(s) of neutrophils in inflammatory diseases is even less clear than that of basophils and eosinophils. In many situations when the neutrophils are present microscopically, it is difficult determine whether their presence is a cause or consequence of the condition. However, there is evidence that damage to the blood vessel wall in cutaneous leukocytoclastic vasculitis is caused by enzymes from activated neutrophils [26]. It has also been suggested that neutrophil elastase is involved in the dermal–epidermal cleavage observed in bullous pemphigoid [27].

The L-selectin molecule is localized to neutrophil microvilli and is cleaved or 'shed' during neutrophil activation, possibly permitting neutrophils to migrate from the intravascular lumen into sites of inflammation. After activation, P-selectin facilitates and supports neutrophil degranulation, superoxide (O_2^{2-}) production, and polarization in response to PAF and bacterial formylated peptides, such as formyl-methionyl-leucyl-phenylalanine (fMLP) [28]. In response to chemoattractant, cross-linking of L-selectin on neutrophils primes cells for increased O_2^{2-} production and calcium influx, and stimulates adhesion. Interaction of neutrophils with endothelial cells also results in increased mRNA levels for TNF-α and IL-8.

Many chemokines, including IL-8 and other chemoattractants such as formyl peptides, complement C5a, LTB_4 and PAF, cause rapid neutrophil adhesion, thereby supporting their emigration from the vasculature [29]. In contrast, the role of various mediators and chemokines in activation of the process of rolling of neutrophils in inflamed venules is still unclear. In certain *in vitro* systems, neutrophil arrest from rolling can be attributed to a single chemoattractant. For example, human umbilical vein endothelial cells (HUVEC) treated with histamine or thrombin support P-selectin-dependent neutrophil rolling and PAF-dependent activation [30]. However, in most inflammatory models *in viv*o, PAF synthesis or receptor antagonists have little or no effect.

Inflammatory or bacterial substances in sufficient amounts may depress the activities of neutrophils, as observed in patients with extensive leg ulcers, for example. Acquired defects in neutrophil chemotaxis are also observed in diabetes mellitus, which may be corrected *in vitro* by the addition of potassium, glucose and insulin. Thus, reduced random movement and response to chemotactic substances may be induced in previously normal neutrophils by severe bacterial infection, without obvious granule changes. This is reversible, because the reduced responsiveness of neutrophils returns to normal during effective treatment. In such cases, it is necessary to differentiate diminished activity induced in mature cells from the normal, lesser activity of immature cells mobilized as a result of the infection.

Abnormalities in neutrophils can have profound effects on resistance to disease. Several defects in enzyme activity have been observed. A deficiency in the H_2O_2–myeloperoxidase–halide system impairs the bactericidal activity of leukocytes. A very good example is chronic granulomatous disease, characterized by recurrent granulomas of skin and lymph nodes, which is associated with defective ability of neutrophils to kill bacteria [31]. An impairment in nicotinamide adenine dinucleotide (NADH) oxidase results in a failure to form H_2O_2 [32], which is critical for effective bactericidal activity. Moreover, deficiency of glucose-6-phosphate dehydrogenase (G6PD) results in the inability to kill catalase-active bacteria.

Several diseases have been revealed to be associated with defects in neutrophil function. In leukocyte adhesion deficiency-I (LAD-I), patients lack CD18 and therefore all β2 integrins; their neutrophils can neither tightly adhere to endothelium nor exit from the circulation in response to infection. LAD-I patients have recurrent skin and mucosal infections, with most patients dying before the age of 10 years [33]. However, qualitative activation rather than quantitative expression of β2 integrins seems to be critical for stimulated neutrophil adhesion [34,35]. Another class of patient has defective carbohydrate fucosylation and lack of expression of Sle x ligands [36]. These 'LAD-II' patients have decreased neutrophil motility *in vitro*, neutrophilia and recurrent bacterial infections. Interestingly, classic drugs such as colchicine have been shown to decrease E-selectin density on endothelial cells and to down-modulate L-selectin expression on neutrophils [37]. Methotrexate inhibits neutrophil adhesion to connective tissues [35]. Corticosteroids lower adhesion molecule expression on both endothelium [38] and neutrophils [39]. Salicylates also inhibit neutrophil adhesion, probably by blocking activation of CD11b/CD18 [40].

Chédiak–Higashi disease is a rare autosomal recessive disease affecting neutrophils and all other lysosomal granule-containing cells in the body. The disease is secondary to mutations in *Lyst*, a gene encoding a cytoplasmic protein involved in lysosomal trafficking [41,42]. The neutrophils contain giant granules resulting from specific and azurophilic granule fusion. Patients have recurrent bacterial infections, neurological disease, partial albinism, platelet dysfunction and early death [33].

Another inherited granule disorder characterized by recurrent bacterial infection is specific granule deficiency, marked by the absence of neutrophil-specific granules and defensins. The disorder is likely secondary to the deficiency of transcription factor CCAAT/enhancer binding protein E, which has a critical role in normal myeloid cell development. Recently, a mutation in the gene encoding this protein has been characterized, and a knockout mouse for this gene has been engineered, showing impaired nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activity [43], phagocytosis, intracellular killing and migration [44].

Mast cells

Mast cells are a heterogeneous group of multifunctional tissue-dwelling cells with roles in conditions as diverse as allergy, parasite infestation, inflammation, angiogenesis and tissue remodelling. The cells were named mastzellen (Greek *mastos*, breast) in 1876 by Paul Ehrlich because he believed that the intracellular granules, which appeared purple in colour when stained with aniline blue dyes, contained phagacytosed materials or nutrients [1]. This change in colour, or metachromasia, we now know to represent the interaction of the dyes with the highly acidic heparin contained within mast cell granules. Mast cells are haematopoietic in origin, entering the circulation from the bone marrow as mononuclear cell precursors that both express mRNA for stem cell factor (SCF) and have SCF receptors (SCFR, CD117) on their cell membranes [2]. From the blood, the precursors migrate into the tissues where, under the influence of local microenvironmental factors, they undergo their final phases of differentiation and maturation into recognizable mast cells. It is pertinent at this stage to distinguish mast cells from basophils, which were originally thought to be circulating mast cells, but are actually related more closely to eosinophils, developing in the bone marrow from granulocyte precursors and entering the circulation only when fully mature [3]. Mast cells and basophils differ in their repertoire of mediators released (Table 9.3).

Mast cells are distinguished immunocytochemically by their neutral protease content, the MC_T phenotype containing only tryptase and the MC_{TC} phenotype containing both tryptase and chymase [4]. MC_T and MC_{TC} mast cells also express different receptors (Table 9.4). Initially, these respective subtypes were suggested to be the equivalents of the 'mucosal' and 'connective tissue' previously described in experimental animals. However, it is now realized that variable amounts of both mast cell subtypes are present within any given tissue, their relative abundance changing with disease (e.g. in allergy or fibrosis). MC_T

CD117 c-*kit* (KL)	+	+	(+)	Stem cell factor c-*kit* ligand

GM-CSF, granulocyte–macrophage colony-stimulating factor; IL, interleukin.

appear to be 'immune system-related' mast cells with a primary role in host defence, whereas MC_{TC} appear to be 'non-immune system-related' mast cells with functions in angiogenesis and tissue remodelling rather than immunological protection. However, it should be remembered that both phenotypes express FcRI and may therefore participate fully in IgE-dependent allergic reactions.

In addition, there appears to be a functional heterogeneity between mast cells of different tissues, which is largely unrelated to immunocytochemical heterogeneity. For example, human skin mast cells alone express CD88, the receptor for the anaphylatoxin C5a, allowing them to be activated in complement-mediated disease [5,6]. Also, skin mast cells alone respond to a variety of basic non-immunological secretagogues, including neuropeptides and drugs, such as morphine, codeine and muscle relaxants [7,8]. Interestingly, activation by these agents is incomplete, in that eicosanoid generation does not accompany degranulation [7]. The ability of human skin mast cells, but not those from other tissues, to respond to anaphylatoxins and basic non-immunological secretagogues explains the flushing reactions observed in sensitive individuals in the absence of overt rhinorrhoea or bronchoconstriction. Such responses may also be involved in physical urticarias.

The secretory granule of the human mast cell contains a crystalline complex of preformed inflammatory mediators ionically bound to a matrix of heparin proteoglycan. The mediator most readily associated with the mast cell, the simple diamine histamine, is present in the granules at approximately 100 mmol/L, equivalent to about 1–4 pg/cell. Histamine exerts many effects pertinent to the immediate phase of allergic responses, including initiation of the wheal and flare response [9]. However, these effects are normally of relatively short duration as histamine is rapidly metabolized, usually within 1–2 min, by histamine-*N*-methyltransferase (approximately 70%) and by diamine oxidase (histaminase) (approximately 30%). Interestingly, reduced diamine oxidase activity has been associated with recurrent urticaria [10].

The other 'early phase' mediators released from the skin mast cell are PGD_2 and LTC_4 [11]. While there is little evidence for a role of the former in skin inflammation, the success, particularly in individuals with a variant LTC_4 synthase allele [12], of leukotriene receptor antagonists in atopic dermatitis [13] and urticaria [14] suggests that this eicosanoid may be more important in skin disease than considered previously.

The major mast cell protease is tryptase, an approximately 130-kDa serine protease that is stored in a fully active form in the granule [15,16]. When released into the extracellular environment, the neutral pH allows tryptase to become enzymatically functional as a tetramer bound to

heparin. The properties of tryptase pertinent to the skin include cleavage of the vasodilator calcitonin gene-related peptide (CGRP); a kallikrein-like activity; cleavage of matrix components, including 75-kDa gelatinase/type IV collagen, fibronectin and type VI collagen, and activation of stromelysin, which may, in turn, cleave other matrix components; and mitogenic activity for fibroblasts. While there appear to be no endogenous inhibitors of tryptase, it is likely to have very local effects because, in the absence of heparin, the biologically active tetrameric form of tryptase rapidly dissociates into inactive monomers. In addition to acting as an enzyme in the extracellular space, tryptase and other serine proteinases have been demonstrated to activate specific receptors by proteolytic cleavage (see p. 9.42). In the skin, tryptase activates proteinase-activated receptor-2 (PAR-2), which is constitutively expressed by keratinocytes and myofibroblasts. Upon inflammatory stimuli, endothelial cells, nerves and immune cells up-regulate PAR-2 expression. Interestingly, tryptase mimics various effects of histamine via activation of PAR-2 such as oedema, plasma extravasation, recruitment of neutrophils and induction of pruritus. Thus, beside histamine, tryptase is an important mediator of inflammatory responses, suggesting a role in inflammatory skin diseases such as atopic dermatitis, urticaria and angio-oedema [17,18].

Chymase is a 30-kDa monomeric protease stored in the same secretory granules as tryptase in the MC_{TC} subset of mast cells. Chymase degrades the neuropeptide neurotensin, but not substance P or VIP, cleaves angiotensin I to angiotensin II more effectively than angiotensin-converting enzyme (ACE), and may also contribute to the splitting of the dermal–epidermal junction in bullous pemphigoid [16,19]. Two other proteinases, carboxypeptidase and cathepsin G, have been associated with the MC_{TC} subset of human mast cells. Carboxypeptidase is a unique 34.5-kDa metalloproteinase that removes the carboxyl terminal residues from a range of peptides, including angiotensin, leu^5-enkephalin, kinetensin, neuromedin N and neurotensin. Cathepsin G is a chymotryptic enzyme with a structure seemingly identical to that of neutrophil cathepsin G. When mast cells are activated, chymase, carboxypeptidase and cathepsin G are released together in a 400–500-kDa complex with proteoglycan, and are likely to act in concert with the other enzymes to degrade proteins.

With the recent discovery that polymorphisms in *SPINK5*, a gene encoding for a serine protease inhibitor, is associated with Netherton's syndrome and other allergic diseases [20], the potential role for proteases in skin disease seems to be extending.

Cytokines are responsible for the initiation and coordination of allergic inflammation. It is logical therefore that the mast cell is a source of such cytokines. Of particular note are the NF-κB-dependent cytokines, TNF-α, GM-CSF and IL-8 [21,22] and the Th2 cytokines, IL-4, IL-5 and IL-13 [23,24]. Thus, not only have mast cells the capacity to initiate immediate phase allergic and anaphylactoid reactions and tissue damage, they also have the capacity to stimulate allergic inflammation, which is characterized by the influx of basophils, eosinophils and neutrophils.

Monocytes and macrophages

The monocyte–macrophage system, formerly known as the 'reticuloendothelial system', represents a heterogeneous family of cell types that vary within different tissues. The range of functions of monocytes and macrophages is summarized in Table 9.5, and their receptor expressing and mediator repertoire is shown in Table 9.6. They all derive from identical progenitors in the bone marrow, where they mature from monoblasts to pro-monocytes. The maturation time is approximately 16 h in the rat and 19–25 h in humans. As mature cells, monocytes may remain in the blood for approximately 2–5 days. Following inflammatory stimuli, monocytes emigrate into the site of inflammation where they differentiate into macrophages or dendritic cells (antigen-presenting cells). During acute inflammation, the rate of monocyte formation may be dramatically increased. Additionally, monocytes adhere to the endothelium and subsequently migrate to the site of inflammation. This is important because resident macrophages show only a poor ability to divide [1,2].

Macrophages rapidly recognize pathogens and 'danger signals' in the connective tissue by means of cell surface receptors [3] such as CD14, mannose receptor, the SR and TLRs (see above). These receptors recognize specific ligands released by microorganisms, leading to intracellular signal transduction pathways and ultimately initiating an immune response. Macrophages also represent an important link to the adaptive immune system by generating immunomodulating cytokines such as interferons. In addition, they release IFN-γ and express MHC class II antigen HLA-DR and may thus stimulate lymphocytes.

Table 9.5 List of major functions of monocytes and macrophages, their receptors and secretory products.

Antitumour activity
Atherogenesis
Control of T and B lymphocytes
Control of dendritic cell function
Coagulation and fibrinolysis
Detoxification
Granuloma formation
Host defence
Metabolism and storage of lipids and iron
Mediation of acute and chronic inflammation
Modulation of keratinocyte function
Processing of antigens
Recruitment of leukocytes
Regulation of haemopoiesis
Release of enzymes for degradation
Scavenging of necrotic debris and effete cells
Wound healing

Respiratory burst reactive oxygen radicals

Macrophages have also been shown to utilize molecules from the complement system to interact with pathogens, and may subsequently undergo apoptosis or become degraded. Under pathophysiological conditions, macrophages may become incorporated into a granuloma or be converted into an epithelioid cell, with an increased ability to synthesize enzymes or other mediators of inflammation. Moreover, macrophages can also be incorporated into a giant cell by fusion with other macrophages. Such pathophysiological chronic inflammatory processes are observed in diseases that may affect the skin, such as tuberculosis, leprosy and sarcoidosis.

Macrophages are professional phagocytes: they recognize pathogens by specific receptors and subsequently phagocytose them. During this active energy-driven process, macrophages generate acidic phagosomes and lysosomal mediators such as oxygen radicals. Macrophage-derived proteolytic enzymes, cathepsins D and G, acid phosphatases or matrix metalloproteinases are released during inflammation. Under normal circumstances, this network of defence molecules is a very effective barrier in the maintenance of tissue homoeostasis. Under pathophysiological conditions, however, when defence mechanisms are impaired, these mediators may also have deleterious effects on the host, resulting in tissue destruction and fibrosis, as observed in various diseases such as arthritis.

Macrophage migration inhibitory factor (MIF) was originally described as a T-cell-derived lymphokine with the potential to inhibit the random migration of macrophages. However, recent reports have shown a much broader tissue distribution of production, including the skin. Recently, a MIF has been localized to many skin cells such as keratinocytes [4], fibroblasts [5] and endothelial cells. An important role for MIF has been reported in several skin diseases such as lupus erythematosus [6], contact hypersensitivity [7], atopic dermatitis [8], psoriasis [9,10], wound healing [11], systemic sclerosis [12], GvHD [13] and sepsis [14,15]. Thus, MIF may represent an important target molecule for the treatment of skin diseases in which macrophages are involved.

The production of arachidonic acid derivatives appears to be crucial for macrophage-mediated responses during inflammation. PGE_2, for example, is involved in lymphocyte activation by macrophages and also inhibits macrophages in an autocrine manner, indicating a negative-feedback system via specific prostaglandin receptors.

Macrophages are major targets for infection by human immunodeficiency virus type 1 (HIV-1). In addition to their role as productive viral reservoirs, inappropriate activation of infected and uninfected macrophages appears to contribute to pathogenesis. These responses establish a complex cytokine network, which may enhance or suppress HIV-1 replication. In addition, dysregulation of macrophage function by gp120–chemokine receptor signalling may contribute to local inflammation and injury and further recruit additional inflammatory and/or target cells [16].

Other receptors expressed by monocytes–macrophages are the proxisome proliferator-activated receptors (PPARs). These are ligand-activated transcription factors that form a subfamily of the nuclear receptor gene family. This subfamily consists of three isotypes, PPARα (NR1C1), -γ (NR1C3) and -β/δ (NRC1C2) with a heterogeneous tissue distribution. PPARs are activated by ligands, such as naturally occurring fatty acids, which are activators of all three PPAR isotypes. In order to be transcriptionally active, PPARs need to heterodimerize with the retinoid-X-receptor (RXR). PPARs have a critical role in lipid and glucose homoeostasis, but lately they have been implicated as regulators of inflammatory responses including in the skin. The first evidence of the involvement of PPARs in the control of inflammation came from PPARα knockout mice, which showed a prolonged inflammatory response. PPARα activation results in the repression of NF-κB signalling and inflammatory cytokine production in different cell types. A role for PPARγ in inflammation has also been reported in monocytes–macrophages, where ligands of this receptor inhibited the activation of macrophages and the production of inflammatory cytokines (TNF-α, IL-6 and IL-1β), although part of the anti-inflammatory effects of these ligands seems to be mediated by a mechanism not involving PPARγ. PPARs also regulate the gene expression of key proteins involved in vascular inflammation. By modulating transcription of pro-inflammatory genes such as cytokines, chemokines, endothelial cell adhesion molecules and metalloproteinases, PPARs directly affect inflammatory events. Together, these findings suggest a role of PPARs in the control of the inflammatory response with potential therapeutic applications in inflammatory diseases such as acne, atopic dermatitis and psoriasis [17–21].

A novel family of monocyte-derived receptors have been described, which seems to be important in the regulation of inflammatory responses. Triggering receptors expressed by myeloid cells (TREMs) belong to a rapidly expanding family of monocyte-derived receptors that include activating and inhibitory isoforms encoded by a gene cluster linked to the MHC. TREM1 and TREM2 activate myeloid cells by signalling through the adaptor protein DAP12. TREM1 triggers phagocyte secretion of pro-inflammatory chemokines and cytokines, amplifying the inflammation that is induced by bacteria and fungi [22].

Macrophages can remain within the tissue in a quiescent resting phase for months until stimulated through ligand binding to one or more of their numerous receptors (Fig. 9.6). They express receptors for IgG (FcγRI, FcγRII, FcγRIII) and complement components C3b and C3bi [23]. They also express receptors for C-reactive protein (CRP),

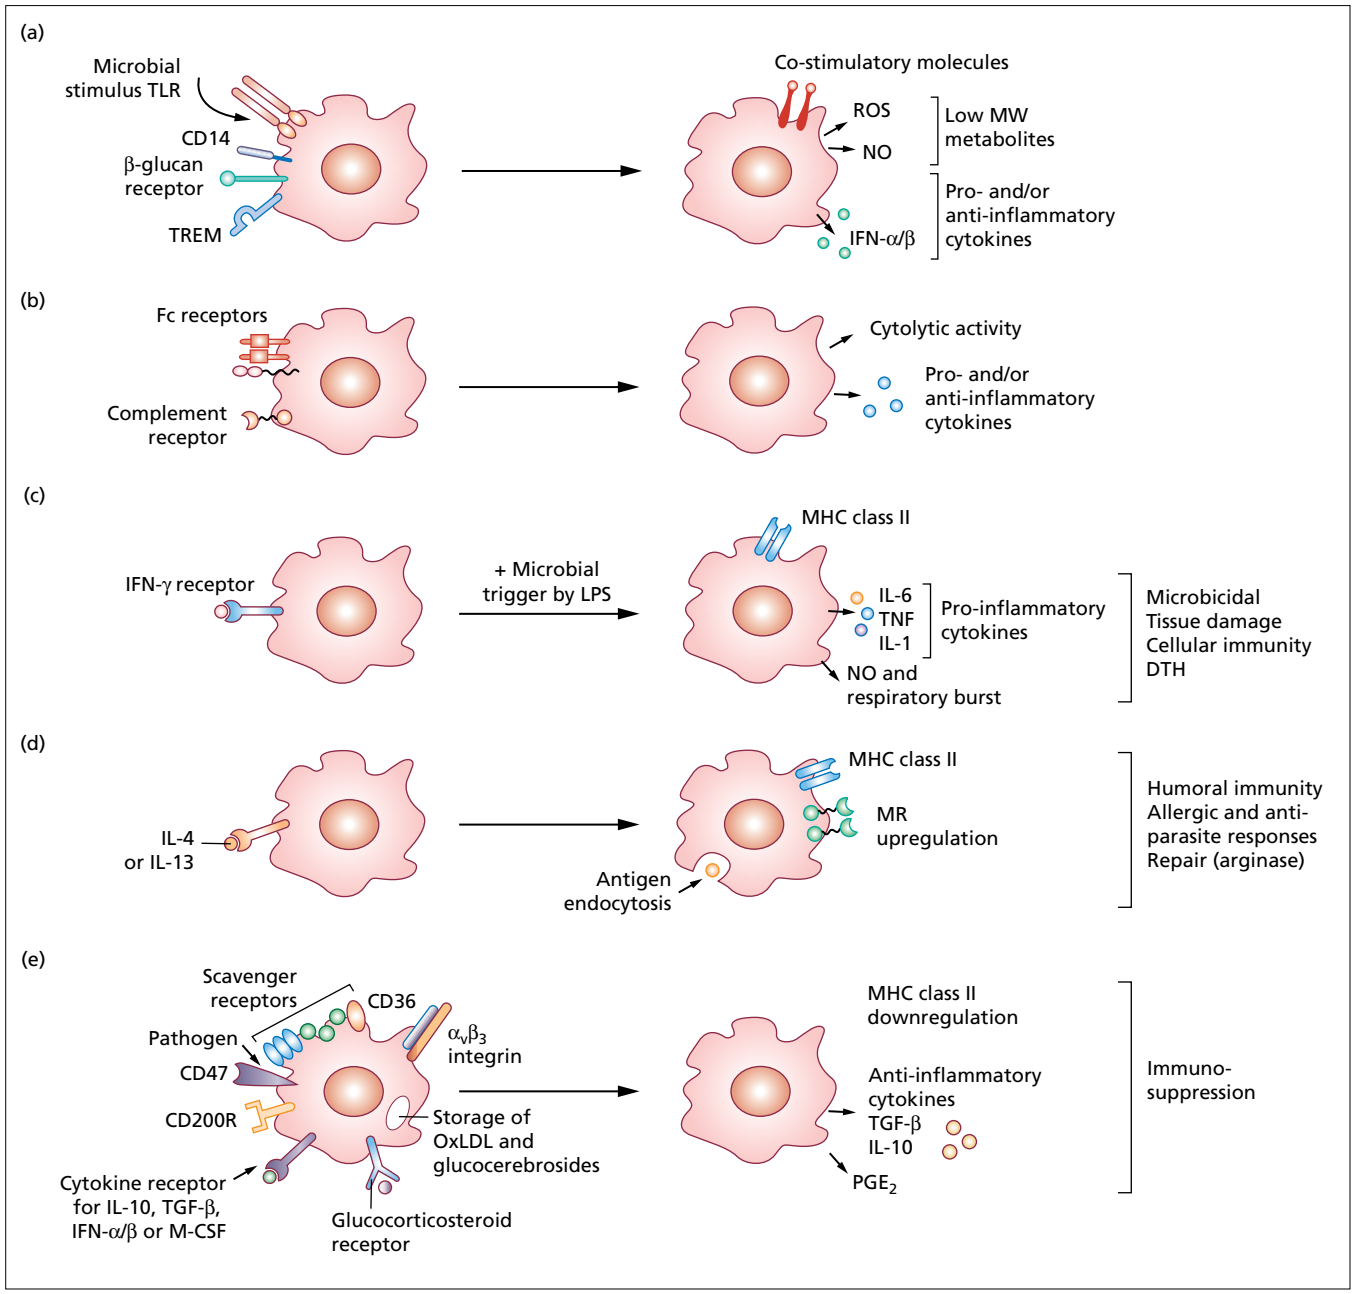

Fig. 9.6 Role of macrophages for innate and acquired immune function. (Modified from Gordon S. Alternative activation of macrophages. *Nature Rev Immunol* 2002; **3**: 26.) (a) Macrophages recognize pattern-recognition receptors such as toll-like receptors (TLRs), CD14–LPS-binding protein and others. These stimuli induce production of pro-inflammatory cytokines such as interferons, nitric oxide and reactive oxygen species. This is followed by a well-tuned anti-inflammatory response. Scavanger receptor (SR-A) and mannose receptor (MR) promote phagocytosis and endocytosis of host and of exogenous ligands. (b) Humoral activation and phagocytosis are mediated by some Fc and complement receptors, whereas other receptors down-regulate these responses. (c) Classical activation is triggered by the priming stimulus IFN-γ, followed by a microbial trigger (e.g. LPS). (d) Alternative activation is mediated by interleukin-4 and IL-13, acting through a common receptor chain (IL-4Rα). (e) Inactivation can be of innate as well as of acquired origin. Uptake of apoptotic cells or lysosomal storage of host molecules generates anti-inflammatory responses. Cellular activity is modulated by interactions of macrophages with T cells, fibroblast or extracellular matrix by activating specific receptors. Glucocorticoids and anti-inflammatory agents can suppress macrophage function. Pathogens can deactivate macrophages thereby contributing to infection. DTH, delayed-type hypersensitivity; M-CSF, macrophage colony-stimulating factor; OxLDL, oxidized low-density lipoprotein; PGE_2, prostaglandin E_2, TGF-β, transforming growth factor-β; TREM, triggering receptor expressed on myeloid cells.

which in blood monocytes induces synthesis of IL-1β and IL-1 receptor antagonist (IL-1RA).

There is evidence for a close interaction between T lymphocytes and macrophages. T-cell-derived IFN-γ both primes macrophages for an enhanced response to other cytokines and activates them to increase oxygen utilization and H_2O_2 formation. It also induces nitric oxide formation, increases phagocytic and tumoricidal activities, initiates or enhances MHC class II membrane antigen expression, and stimulates the synthesis of several cytokines and receptor expression. T-cell IL-2 stimulates macrophages, particularly if they are primed by IFN-γ. Macrophages also synthesize many cytokines such as IL-1, a potent pro-inflammatory signal.

Fibroblasts

Fibroblasts are part of the connective tissue and the source of most of the extracellular matrix elements in the dermis. Intercellular substrates are mainly composed of collagens and glycosaminoglycans (GAGs). GAGs covalently bind to proteins to form proteoglycans, which are able to bind proteins such as cytokines, chemokines or growth factors in the extracellular space. Collagens or fibronectin can modulate cell–cell interactions between fibroblasts and inflammatory cells. For instance, migrating T cells or mast cells interact with extracellular matrix proteins via β2 integrin activation.

After stimulation, fibroblasts are able to transform into several types of specialized cell such as myofibroblasts, smooth muscle cells, chondrocytes and osteocytes. It is not known if the different phenotypes arise from pluripotential stem cells, or from subtypes with restricted properties of differentiation. Some differentiated fibroblasts can revert to the original mesenchymal state, whereas others persist as mature committed cells. Therefore it is not suprising that fibroblast-derived cartilage and bone may occasionally be found in scar tissue. Under normal circumstances, fibroblasts mature into dermal fibrocytes, and after maturation their function is merely restricted to the synthesis of extracellular matrix proteins such as collagens, elastin and proteoglycans. In the skin, collagens I, III, IV, VII, fibronectin and laminins are of special interest because of their capability to regulate dermal–epidermal interactions via modulating the composition of the basal lamina.

During inflammation, the morphology and properties of fibroblasts are strictly dependent on the surrounding microenvironment. Dermal fibroblasts grown *in vitro* on different substrates (e.g. collagen or laminin) but maintained in the same medium, show differences in morphology, integrin expression and cytokine synthesis. Moreover, dermal fibroblasts cultured in contracting collagen gels form sixfold more PGE_2 than do cells cultured on plastic [1]. Fibroblasts in floating collagen gels are stellate with long cytoplasmic processes [2], and after gel contraction DNA synthesis is reduced [3] and collagenase

synthesis increases [4]. Fibroblasts in anchored (non-contracting) gels are elongated, bipolar and lie along lines of tension [5]. They synthesize DNA, proliferate [3,6] and do not exhibit an increased collagenase synthesis.

Alterations of the extracellular matrix may depend on certain cytokines. Thus, platelet-derived growth factor (PDGF) regulates expression of β1-series integrin chains α2, α3 and α5 in fibroblasts grown on fibronectin and fibrin substrates as in fresh wounds. However, in fibroblasts grown on collagen substrates, PDGF modulates integrin synthesis to resemble that of granulating tissue [7]. Differences in matrix composition alter PDGF receptor phosphorylation [8], and therefore responsiveness to PDGF, one of the most potent mediators controlling fibroblast proliferation and collagen formation. The above clinical evidence of matrix-regulated differences in fibroblast function reflects the *in vivo* situation during wound healing and scar formation, where the environment changes from freshly damaged tissues with fibrin clots in the early stages to organized extracellular matrix in the late stages. Moreover, hypertrophic scars are characterized by a stable phenotype fibroblast, which differs from normal fibroblasts and exhibits a reduced response to epidermal growth factor (EGF) and increased synthesis of collagen [9]. In systemic scleroderma, however, collagen formation is increased, as the α2 chain of the α2β1 integrin is reduced [10]. Similarly, down-regulation of collagen mRNA expression in fibroblasts of systemic scleroderma patients tended to be less than that in controls. This increased potential to form collagen was associated with a decrease in α1β1 integrin [11]. Both α1β1 and α2β1 integrins, but particularly α2β1, recognize collagen I in the dermis, and the reduced integrin expression associated with increased collagen synthesis may reflect defective signalling between fibroblasts and their collagen matrix environment.

Dermal fibroblasts synthesize prostaglandins, leukotrienes and several cytokines, and as resident cells they release pro-inflammatory mediators in an early response to skin injury and growth factors to promote subsequent healing. Fibroblast production of leukocyte activating and/or attracting agents is somewhat in contradiction to *in vivo* histological findings, which rarely reveal accumulations of leukocytes round fibroblasts. Therefore, it is possible that proteoglycan binding of some cytokines results in more diffuse leukocyte infiltration. Fibroblast proliferation is stimulated mainly by PDGF, TGF-β and FGF. Two cytokines, TGF-β and TNF-α, may either stimulate or reduce proliferation, depending upon the state of cell activation [12]. Synthesis of collagen or other connective tissue elements is induced by PDGF and TGF-β, whereas TNF-α may stimulate or repress synthesis [12]. In normal skin, there is an interdependency between fibroblast and epidermal growth and differentiation regulated by cytokines.

Several *in vitro* studies suggest that eosinophils may have a role in fibrosis, remodelling and repair processes associated with IgE-mediated hypersensitivity. Eosinophil-derived TGF-β and IL-13 is temporarily associated with myofibroblast formation and deposition of tenascin and pro-collagen I, suggesting that both inflammatory mediators may contribute to repair and remodelling events of inflammatory skin diseases by modulating fibroblast function [13]. There is also recent evidence of a role for neuropeptides in the modulation of fibroblast functions. Thus, it has been shown that expression and cellular levels of SCF are up-regulated in fibroblasts by substance P [14]. In summary, fibroblasts contribute crucially to the interaction of epidermal and dermal components to maintain skin integrity.

After skin injury, particularly wounding involving the dermis, activated fibroblasts migrate on to fibronectin and fibrin, proliferate and synthesize new collagen to form granulation tissue. Proliferation is gradually reduced as the collagen matures and the wound contracts [6,15]. The forces inducing wound contraction originate in the granulation tissue formed in the wound. The fibroblasts are transformed into myofibroblasts, with several morphological, chemical and antigenic differences to resident mature fibroblasts [16,17]. Myosin in activated cells is phosphorylated to expose actin-binding sites, to form actin–myosin contractile or stress fibres across the cell; via focal contacts and integrins on the cell membrane they exert tension on the matrix. The first formed collagen gel is compacted and modified to form strands of fibres. The fibroblasts migrate to lie along the fibres as seen in normal dermis, at which time they lose their myosin stress fibres although they continue to contribute to the overall tension of the skin.

Platelets

Platelets are derived from megakaryocytes in the bone marrow and are the major components involved in blood clotting and homoeostasis. Upon injury and inflammation, platelets regulate leukocyte aggregation and adherence to the endothelium, reflected by cell arrest and emigration into the tissue. Using video microscopy, transient platelet rolling on endothelium has recently been observed. Platelets accumulate in the vicinity of an injury, making them available for an immediate response [1]. Moreover, platelets contain a variety of potent inflammatory mediators and growth factors that contribute to normal homoeostasis of blood cells, acute inflammation, tissue repair and immune responses. Accordingly, platelets release mediators such as eicosanoids, ADP, amines, proteolytic enzymes and cationic proteins. They are also a source of serotonin (5-HT), which is released during vascular injury, resulting in enhanced deposition of immune complexes on the endothelium. Thus, the formation of platelet aggregates and the subsequent release of mediators appear to have a role in tissue damage during cutaneous small vessel vasculitis [2].

Platelets are functionally closely associated with all types of leukocytes. Activated platelets secrete chemotactic substances, facilitate the binding of leukocytes to the endothelium as well as their subsequent extravasation, and may influence the inflammatory responses of leukocytes by both stimulation and inhibition. However, platelets also contain an array of potent pro-inflammatory substances, and are therefore effector cells of inflammation. Because of the role of platelets in IgE-dependent killing and eosinophil infiltration, they are currently considered to be directly involved in allergic IgE-mediated reactions [3].

Platelets express several receptors and can be activated by plasma products, immunoglobulins, complement, extracellular matrix components, leukocytes (particularly neutrophils) and endothelial cells. Receptors for soluble agonists include ADP [4], FcγRII [5,6] and complement component C3a [7]. They also express PARs belonging to a novel subfamily of G-protein-coupled receptors with seven transmembrane domains activated by serine proteases [8,9]. PAR-1, -3 and -4 are thrombin receptors in mice (PAR-3, PAR-4) and humans (PAR-1 and PAR-4). During inflammation, PARs become activated by thrombin on platelets, leading to mediator release and regulation of endothelial cell and leukocyte function. PAR-1 is critically involved in angiogenesis and leukocyte transmigration [9].

α11bβ3 (also designated glycoprotein 11b–111a or GP11b–111a) represents an important platelet-specific integrin. Upon activation, it is recruited to the cell surface, where it is capable of binding to thrombin, collagen or laminin [10]. The platelet integrin α2β1 (GP1a–11a) binds collagen [11], α5β1 and α6β1 (GP1c–11a) bind to fibronectin, collagen and laminin, while CD36 (GPIV) binds thrombospondin and possibly collagen [12]. Complement binds to the granule membrane protein 140 (GMP-140). Upon activation, GMP-140 expression is induced on platelets and endothelium, resulting in up-regulation of E-selectin and the promotion of leukocyte adherence [13].

Some receptors may bind to several ligands, and the activating potential of distinct ligands varies. Whereas 'strong agonists' (thrombin, collagen, thromboxane A_2 [TXA_2] and PAF) elicit a direct response, 'weak agonists' (9-ADP, adrenaline [epinephrine], vasopressin and serotonin) depend upon secretion to mediate a full response. Antagonists include PGI_2, PGD_2, endothelium-derived relaxing factor (EDRF) and nitric oxide [14]. Several of these are generated as the result of platelets activating other platelets (TXA_2, ADP and serotonin).

Receptors of normal platelets are either intracellular or, if on the cell surface, do not contact their ligands in undamaged tissue. On activation, rapid exposure and realignment of receptors stimulates second-messenger G proteins, protein tyrosine kinases and phospholipases [14]. The platelets change shape to develop numerous microspicules, which leads to aggregation of platelets and binding to other cells [15]. Platelets are reported *in vitro* to release microparticles that preferentially bind, activate and aggregate neutrophils, increasing expression of the CD11b receptor [16]; *in vivo* this would increase neutrophil–endothelium binding. Platelet–neutrophil interaction promotes formation of leukotrienes and lipoxins, the precursors of which are derived from both cells. Di-HETE is formed by the interaction of platelet 12-lipoxygenase (12-LO) and neutrophil 5-LO; neutrophils release LTD_4 and LTC_4 [17,18]. Such transcellular mediator synthesis results in concentrations of pro-inflammatory lipoxins and leukotrienes at the site of vascular damage. Using 12-LO-deficient mice, a role for platelet-type 12-LO in normal transepidermal permeability barrier function in mice was shown [16]. Other platelet pro-inflammatory

mediators include TGF-α and -β, PDGF and prostaglandins; platelet aggregates in clots are the source of most prostaglandins in the blood during inflammation [19]. PDGF is both a pro-inflammatory mediator by virtue of activating neutrophils and monocytes, and a growth factor inducing tissue repair by regulating fibroblast proliferation, chemotaxis and collagen synthesis.

The expression receptors for immunoglobulins and complement on platelets may contribute to inflammation and to the removal of potential agonists. Thus, via signalling through IgG as well as IgE receptors [3,5,6], the release of pro-inflammatory mediators is enhanced, and the activation of C3a receptors induces release of serotonin and synthesis of thromboxane [6]. The IgG receptors bind IgG–antigen complexes, which are removed from the circulation when the platelet complex is subsequently ingested by phagocytes in the spleen, liver and elsewhere.

Thrombospondin 1 (TSP-1), an adhesive glycoprotein expressed by endothelial cells, fibroblasts and macrophages, has an important role in platelet adhesion, inflammation and cell–cell interaction [20,21]. TSP-1 is upregulated early during tissue injury, and is involved in angiogenesis, inflammation and vascular skin diseases by directly interacting with endothelial cells.

Mediators of inflammation

The main role of the inflammatory response is the elimination of external noxious stimuli such as irritants, allergens and pathogens, or of endogenous stimuli such as toxic or infectious agents. There is also a necessity to avoid tissue disruption and cell destruction, and to restore tissue homoeostasis. Balance between these potentially opposing requirements is achieved by generating a variety of inflammatory mediators, which may exert their effects in an autocrine, paracrine, juxtacrine or endocrine manner.

A wide variety of distinct mediators including cytokines, phase proteins, kinins, prostanoids, leukotrienes, neuromediators, oxygen, nitrogen and carbon products are involved in the orchestration of inflammation. Importantly, these mediators are not only released by leukocytes and lymphocytes, but also upon activation during injury by almost any cell residing at the site of inflammation. The final outcome depends on the nature, severity and duration of the injurious stimuli, and reflect a cascade of well-tuned interactions between several mediators released by different cell types. Furthermore, the activation and upregulation of specific receptors for each of these mediators is crucial for the outcome of any inflammatory reaction. Occasionally, some mediators can activate more than one receptor and, vice versa, some receptors can be activated by several ligands.

Acute-phase proteins

During the acute phase of inflammation, cytokines such as TNF-α, IL-1 and IL-6 rapidly stimulate the release of proteins from hepatocytes to coordinate tissue integrity. Acute-phase proteins (APPs) are defined as plasma proteins if their serum concentration increases by more than 25% after tissue destruction. They are released by the liver to opsonize pathogens, inhibit protease function and clear cell detritus. APPs such as CRP, mannan-binding lectin, complement proteins, fibrinogen, α_1-antitrypsin, α_1-antichymotrypsin, haptoglobin, serum amyloid A and acid α-glycoprotein may have several pro- or anti-inflammatory activities. Moreover, hormones (e.g. glucocorticoids) are capable of stimulating APP synthesis within hours.

CRP is an APP that can be detected in the serum during infection and tissue damage within 24–48 h. Because CRP correlates well with disease progression, it is a reliable activity marker for inflammatory or infectious processes. It binds phosphorylcholin of LPSs in the cell membrane of bacteria and fungi, activates the classical complement pathway [1], stimulates leukocyte chemokinesis and phagocytosis, and induces a spontaneous vasculitis [2]. It is proposed that one function of CRP is to mobilize cells rapidly to counteract infection, before specific antibody is formed.

Another APP that activates the complement pathway is mannan-binding lectin. Together with the pulmonary surfactant proteins, mannan-binding lectin belongs to the family of 'collectins' that contain a globular lectin-like domain which is able to bind the membrane of pathogens [3,4].

The classic complement pathway is initiated by CRP, heparin, protamine sulphate and DNA, and also by plasmin or trypsin action on C1s. The alternative pathway is initiated by bacterial and endogenous endotoxin and cell debris. Complement C5 is cleaved by leukocyte enzymes, particularly neutral proteases, neutrophil elastase and acidic protease cathepsin G [5]. Epidermal cells contain serine proteinases active at neutral pH, which appear to cleave C5, resulting in a greater neutrophilia than seen in similar tests with plasmin and trypsin [6]. C3 is activated by trypsin and neutrophil elastase. The processes of clotting, generation of kinins and fibrinolysis all activate complement. The pro-inflammatory properties of C5a, C3a and C4a on mast cells and basophils, as anaphylatoxins releasing cell mediators and, in the case of C5a, attracting and activating leukocytes, are described in Chapter 10.

Cytokines

Cytokines are structurally related polypeptides or glycoproteins that exert their effects at concentrations within the pico- or nanomolar range. Originally, they were regarded as immunocompetent cell-derived immunomodulators. However, recent knowledge demonstrates that a clear-cut differentiation between cytokines, growth factors, neurotransmitters and hormones is not possible. The predominant role of cytokines is to mediate inflammatory and immune responses. Cytokines determine the direction of immune responses and control tissue integrity during injury. Thus, the quality and quantity of cytokine production within the injured tissue determines whether the immune system is directed into a humoral or cytotoxic cell-mediated allergic response. Moreover, cytokines (along with other mediators) determine the switch of the immune system from a pro- to an anti-inflammatory state.

Over the last decades, a large body of knowledge has accumulated on the role of cytokines in cutaneous inflammation. They are ultimately involved in all phases of inflammation. While pro-inflammatory cytokines induce the body response to external or internal danger, anti-inflammatory cytokines are capable of restoring tissue homoeostasis by suppressing inflammatory processes. Various molecular biology and modern immunological techniques have been applied to cytokine research, and the genes for many of these factors have been cloned and characterized in the skin. Together, these studies clearly demonstrate that many cytokines exert pleiotropic functions. For example, IL-1 was originally described as a leukocytic pyrogen, endogenous pyrogen, B-cell-activating factor and lymphocyte-activating factor. Today it is well known that various skin cells, including keratinocytes, use IL-1 to communicate with neighbouring cells in the skin during inflammation [1]. Thus, the IL nomenclature was introduced to replace the older descriptive and often misleading names.

To understand fully the role of cytokines in skin inflammation one has to collate information from human and animal studies as well as *in vitro* and *in vivo* data. The availability of recombinant cytokines and cytokine antagonists was of tremendously benefit in the verification of the specific effects of cytokines *in vivo*. Modern techniques such as genomic and proteomic approaches have given new insights into the regulatory mechanisms underlying the actions of cytokines. Moreover, the use of cytokine and cytokine receptor gene-deficient mice have helped in our understanding of the specific role of these molecules during cutaneous inflammation. It must be appreciated that *in vivo* a cocktail of several cytokines acts simultaneously or sequentially upon the inflammatory microenvironment. Thus, the biological activities of cytokines during inflammation are the sum of well-tuned synergistic and antagonistic processes.

Cytokines use different cell biological mechanisms to modulate inflammation. Some cytokines (e.g. IL-1, IL-2 or IL-4) exert their effects by exclusively binding to cell surface receptors. Others (e.g. TGF-β or IL-6) may additionally interact with components of the extracellular matrix to modulate skin function during inflammation.

Interleukins

Interleukins are polypeptides participating in all normal and reactive cell functions. So far, 27 interleukins have been described and characterized. Some prime cells, making them responsive to other agents, and most act synergistically.

IL-1. The first cytokine detected in the skin was IL-1, originally named epidermal thymocyte-activating factor. Cytokines of the IL-1 family are key players in immunity and inflammation in virtually every organ of the body. Members of the IL-1 family discovered so far include IL-1α, IL-1β, IL-1 receptor antagonist (IL-1RA), IL-1H, IL-1F7b, IL-18 and IL-18BP. They may function as agonistic or antagonistic ligands for the members of the IL-1 receptor (IL-1R) family. IL-1 and IL-18 are structurally very closely related and both are synthesized as biologically inactive precursor molecules lacking a signal peptide. Almost all cells of the body, including keratinocytes, have been found to synthesize many of the IL-1 family members upon stimulation. In some cells, such as macrophages, fibroblasts, endothelial and dendritic cells, IL-1 may also exist in a membrane-bound form.

The currently known 10 members of the IL-1R family are defined as membrane-spanning molecules that consist of at least one immunoglobulin-like domain exterior to the cell and, except for the IL-1RII, a Toll/IL-1R (TIR) domain in the cytoplasm. Type I IL-1R (IL-1R) binds both IL-1α and IL-1β. In addition, a homologue of the IL-1R, known as IL-1R accessory protein (AcP), which has no affinity on its own for either of the IL-1 forms, is required for IL-1 signalling. The second natural IL-1 binding protein is IL-1RII, which has a high affinity for IL-1α, but a much lower affinity for IL-1β or IL-1RA.

IL-1RI is expressed on keratinocytes, fibroblasts, endothelial cells, lymphocytes and other cells. IL-1RII can be detected on B lymphocytes and neutrophils. An endogenous soluble IL-1RA type I acts as a competitive IL-1R inhibitor. There is evidence of differences in responses mediated via each receptor. Cultured keratinocytes predominantly express mRNA for IL-1β, but *in vivo* in normal epidermis IL-1α is also detectable. IL-1 is present in the stratum granulosum, and considerable amounts have been detected in psoriatic scales [1]. However, this is confined to IL-1β, which is functionally inactive, while active IL-1α is reduced [2].

IL-1 is pro-inflammatory, stimulates repair and differentiation, and is an important mediator of immune regulation. It is mitogenic for thymocytes and T cells, inducing IL-2 synthesis and receptor expression, proliferation and release of lymphokines (see Chapter 10). Furthermore, IL-1 is a growth factor for B cells, inducing proliferation and enhancing antibody formation, and it also increases NK cell activity. Macrophages and neutrophils are activated, their enzymes released and prostaglandin synthesis is induced.

It has been contended that, despite the large amounts in epidermis, IL-1 is largely inactive and contributes little to the inflammatory response. Nevertheless, injection of keratinocyte IL-1 and recombinant IL-1 (rIL-1) into mice and rabbits induces oedema, erythema and neutrophil infiltration. There is also evidence that during wound healing, human keratinocyte IL-1 stimulates synthesis of PGE_2 by subpopulations of human fibroblasts, which feeds back to stimulate keratinocyte proliferation and differentiation.

IL-1 is increased in the early phase of numerous skin diseases and induces the release of further cytokines and growth factors, and the recruitment of T lymphocytes, in the inflammatory tissue. IL-1 participates in the regulation of microvascular dermal endothelial cells by the up-regulation of cell adhesion molecules such as ICAM-1 or E-selectin. IL-1 also regulates the expression of ICAM-1 on keratinocytes, thus participating in the recruitment of lymphocytes into the epidermis, and activates IL-6 or NF-κB [2], which may be of considerable relevance in inflammatory dermatoses.

IL-1 is considered to be a key cytokine in the pathogenesis of autoimmune diseases such as pemphigus vulgaris. Increased levels of IL-1α and TNF-α have been detected in lesional skin of patients with pemphigus. Acantholysis of keratinocytes was found to be inhibited by antibodies directed against IL-1α and TNF-α. Furthermore, in IL-1-α and TNF-α receptor-deficient mice, a decreased susceptibility for pemphigus was observed.

IL-2. IL-2, or T-cell growth factor, is an essential mediator for developing an immune response (see Chapter 10). Activated T lymphocytes secrete IL-2 and express IL-2 receptors, resulting in their proliferation and clonal expansion. IL-2 is also an important mediator for the proliferation of B lymphocytes and the activation of NK cells. Furthermore, IL-2 participates in the regulation of T-cell functions in Th1-mediated skin diseases such as psoriasis and cutaneous T-cell lymphoma [3,4]. The role of IL-2 in these diseases has recently been proven by the successful therapeutic use of specific anti-IL-2 strategies.

IL-3. This belongs to the group of haematopoietic colony-stimulating factors (CSF) (see above), and also promotes growth of T-cell lines and mast cells. It is synthesized by T lymphocytes, myeloid cell lines and keratinocytes. Although IL-3 has multi-CSF activity, in the skin it may activate both mast cells, contributing to fibrosis, as seen in scleroderma, and neutrophils, to release oxygen radicals cytotoxic for microorganisms. Moreover, monocyte proliferation, adherence to endothelium and secretion of IL-8 is induced or enhanced by IL-3, as is eosinophil chemotaxis and phagocytosis.

IL-4. Originally named B-cell growth factor, IL-4 acts mainly on immunocompetent cells, and induces proliferation of activated mature T cells, and enhances T-cell cytotoxic properties, but suppresses cytokine formation by Th1 cells, thereby reducing delayed hypersensitivity responses. IL-4 stimulates MHC class II expression (see Chapter 10), and expression of the low-affinity IgE receptor (CD23) on B cells. IgE synthesis is regulated by IL-4 together with IL-13, and is inhibited by IFN-γ and TGF-β. Cytokines such as IL-2, IL-5, IL-6 and IL-9 synergize with IL-4 and IL-13 to enhance IgE production. On macrophages, however, IL-4 decreases CD23 expression. Mast cell growth is stimulated by IL-4, as is the growth of precursor haematopoietic cells, both directly and indirectly, by stimulating G-CSF and M-CSF production in monocytes. IL-4 is important for the differentiation towards a Th2 T-cell subtype. In contrast, cytokines such as IL-12, IL-18 and IL-23 inhibit the differentiation of IL-4-producing T cells. Although IL-4 is generated in high amounts by T cells, there is also evidence that IL-4 is released in the skin by keratinocytes or mast cells. The IL-4 receptor was detected on T and B cells, macrophages, dend-ritic cells, mast cells, fibroblasts and keratinocytes. IL-4 proved to be an essential mediator for the differentiation of dendritic cells [5]. Thus, IL-4 is an important regulator of IgE production and Fcε-receptor expression. *In vivo*, IL-4 has been found to mediate immunodeviation towards Th2 responses and in preliminary studies has been successfully used for the treatment of Th1-mediated skin diseases such as psoriasis.

IL-5. IL-5, a helper T-cell lymphokine (see Chapter 10), induces growth and differentiation of activated B cells, and is a key mediator for the switching of immunoglobulin class synthesis. It is the most important promoter of eosinophil formation and differentiation. Mature eosinophils are activated and their survival is prolonged in parasitic infestations. IL-5 works synergistically with IL-3 and GM-CSF on eosinophils.

IL-6. This is mainly generated by monocytes, bone marrow cells, fibroblasts, endothelial cells, some T cells, B cells and keratinocytes [6]. IL-6 is involved in the regulation of the function of T, B and NK cells, which express both of the IL-6 receptor chains. It has an essential role in the maturation of B cells to produce antibody, and also participates in inflammation by inducing formation of APP by hepatocytes. In T cells, IL-6 mediates activation, growth and differentiation. Thus, IL-6 is an 'early' pro-inflammatory cytokine, induces APP production, and the increased formation of IL-6 by fibroblasts, endothelial cells and keratinocytes stimulated by IL-1 and TNF-α may represent a significant amplifying process in inflammation [7,8]. Despite the finding of increased IL-6 serum levels in autoimmune diseases such as systemic lupus erythematosus (SLE), systemic scleroderma and pemphigus vulgaris, a specific role for IL-6 in any skin disease has not been established.

IL-7. IL-7, synthesized by monocytes and T cells, is a haematopoeitic growth factor, stimulating T- and B-cell proliferation. Moreover, immune functions such as the proliferation of cytotoxic T and NK cells, as well as the activation of monocytes and macrophages, can be triggered by IL-7.

IL-8. This is a member of the CXC subfamily of chemokines (see p. 9.40).

IL-9. This is produced by $CD4^+$ T lymphocytes and was originally described in the murine system as P40, T cell growth factor III (TCGF III) and mast cell growth enhancing activity (MEA). IL-9 is a growth factor for T-helper lymphocytes, mast cells and megakaryoblastic leukaemic cells, and stimulates the development of erythopoietic colonies as well as IL-4-induced IgE production by B lymphocytes. IL-9 transcripts have been detected in Hodgkin's lymphoma and large cell anaplastic lymphoma, suggesting a role for IL-9 in the pathogenesis of these tumours.

IL-10. This was originally described as a cytokine secreted by Th2 cells that inhibited the release of cytokines from Th1 cells [9,10]. Later it was found that IL-10 can be synthetized by Th1 as well as Th2 lymphocytes, and also by cytotoxic T cells, mast cells, B cells and monocytes, the latter being the major source of IL-10 in humans [11].

IL-10 diminishes IFN-γ and IL-2 production by Th1 cells, as well as IL-4 and IL-5 generation by Th2 cells. IL-10 inhibits release of IL-1β, IL-6, IL-8, IL-12 and TNF-α in monocytes, and IFN-γ or TNF-α in NK cells. In monocytes or dendritic cells, IL-10 also down-regulates expression and release of MHC class II molecules, CD23, ICAM-I and the accessory B7 molecule. Thus, IL-10 is an important cytokine for the regulation of antigen presentation and suppression of Th1 and Th2 cytokine production.

The anti-inflammatory effect of IL-10 is a result of the inhibition of pro-inflammatory cytokines such as IL-1, IL-2, IL-6, TNF-α and IFN-γ, and the inhibition of chemokines and chemokine receptors such as IL-8 and CXC-2 receptor. In eosinophils, IL-10 inhibits eosinophil survival and IL-4-induced IgE synthesis, indicating an important role for this cytokine in allergic responses. In contrast, IL-10 activates the proliferation of, and immunoglobulin by production B cells. Thus, IL-10 is also a survival and differentiation factor for B cells. IL-10 contributes to inhibition of cellular and allergic immune responses while stimulating humoral and cytotoxic immune mechanisms [11].

Increased expression of IL-10 occurs in patients with allergic contact dermatitis [12], and IL-10-deficient mice

show a delayed contact by hypersensitivity immune response [13]. Stimulators of keratinocyte IL-10 synthesis include contact allergens and UVB light. The effect of IL-10 is mediated via a specific IL-10 receptor expressed on numerous skin cells. IL-10 has been proposed as a therapeutic target for the treatment of inflammatory diseases such as psoriasis, atopic dermatitis and asthma, and other autoimmune diseases [14,15]. Together with IL-19, IL-20, IL-22, IL-24 and IL-26, IL-10 belongs to a subfamily of cytokines that share a similar structure and biological functions.

IL-11. This stimulates precursor or progenitor haematopoietic blast cell mitosis, and promotes similar activity by GM-CSF, IL-3 and IL-4. It also promotes helper T-cell regulation of B-cell immunoglobulin synthesis. IL-11 induces formation of APPs by the liver, stimulates fibroblast function and supports differentiation of lymphocytes, but depresses differentiation of fat cells. It appears to be involved in cytotoxic immunity and the pathophysiology of asthma.

IL-12. This cytokine is generated by monocytes, macrophages, dendritic cells, B cells, neutrophils, mast cells and keratinocytes. The active form is a heterodimer consisting of a p40 and a p35 subunit. Interestingly, homodimers and monomers of p40 serve as competitive antagonists by binding to the IL-12 receptor without activating the signal transduction cascade. IL-12 is an important activator of NK cells. It further increases IFN-γ production, modulates T-cell functions and inhibits tumour angiogenesis [16]. Other stimulators of IL-12 secretion in the skin include bacteria and UV light. A protective effect of IL-12 on UV-induced DNA damage was demonstrated recently in keratinocytes [17].

IL-13. This is a cytokine with effects similar to IL-4, that is released from T cells, mast cells and keratinocytes [18]. It affects the function of B cells and monocytes, and decreases production of pro-inflammatory cytokines in keratinocytes and endothelial cells. IL-13 also reduces chemokine-induced chemotaxis of T cells. IL-6 expression on monocytes is inhibited by both IL-4 and IL-13 (see Chapter 10).

IL-15. This is thought to be of relevance in the pathophysiology of atopic dermatitis in view of its function in modulation of IFN-γ and IgE synthesis. In human keratinocytes, IL-15 inhibits anti-Fas and methylcellulose-induced apoptosis *in vitro* [19]. Moreover, IL-15 seems to be of significance in the maturation of dendritic cells [20] and activation of NK cells. IL-15 expression can be induced by IFN-α and -β.

IL-16. This is secreted from keratinocytes and Langerhans' cells amongst others, and is an important chemokine for the recruitment of $CD4^+$ T cells, monocytes, eosinophils and Langerhans' cells into inflamed skin. Serological levels of this cytokine correlate positively with the severity of atopic dermatitis [21].

IL-17. This is expressed by numerous immunocompetent cells. In keratinocytes, IL-17 initiates the release of growth-related oncogene-α (GRO-α), GM-CSF, IL-6 and the IFN-γ-induced expression of ICAM-1. In dermal endothelial cells, IL-17 induces IL-1 secretion and up-regulation of cell adhesion molecules. IL-17 activates skin fibroblasts [22] and results in increased IL-6 secretion and collagen synthesis. A pathophysiological role for IL-17 in systemic scleroderma has been proposed [23].

IL-18. Expression of IL-18 has been described in dendritic cells, macrophages, keratinocytes, osteoblasts, microglial cells and fibroblasts. IL-18 mRNA can be stimulated by LPS, GM-CSF and Fas ligand. Keratinocytes also express the receptor for IL-18, indicating autocrine regulation by IL-18 [24]. Functional IL-18 requires activation by an IL-18-converting enzyme (ICE or caspase-1) or proteinase-3.

Together with IL-12, IL-18 is an important activator of IFN-γ stimulation. Our knowledge of the biological effects of IL-18 is rapidly increasing. IL-18 induces maturation of T and NK cells, and stimulates release of cytokines and chemokines. On NK cells, IL-18 increases Fas-mediated cytotoxicity. It also induces IgE production by B cells and synergizes with IL-2 to enhance IL-4 production. In mice, IL-18 also promotes Th2 differentiation. However, the effects of IL-18 on T cells seem to vary, depending on endogenous and exogenous factors such as the maturation state and the micromilieu. In basophils, IL-18 contributes to IL-4 and IL-13 production. Stimulation of macrophages by IL-18 induces cytokine production, such as IL-6 and IFN-γ, TNF-α and IL-1β. IL-18 induces IL-6, IL-8, ICAM-1 and expression of matrix metalloproteinases by endothelial cells.

IL-18-binding protein (IL-18BP) is a secreted protein able to bind IL-18 with high affinity, leading to inhibition of IL-18-induced IFN-γ and IL-8 production and NF-κB activation. Recently, another secreted protein, IL-1H, has been shown to have IL-18 receptor antagonist activity.

Functions in the skin regulated by IL-18 include the migration of Langerhans' cells, Th-cell regulation and wound healing [25]. IL-18 also regulates ICAM-1 expression on microvascular endothelial cells, indicating a role in leukocyte–endothelial interactions during inflammation. IL-18 may be of relevance in the pathophysiology of diseases such as atopic dermatitis [26]. Enhanced expression of IL-18 has been found in patients with lupus erythematosus and psoriasis. Finally, IL-18 seems to be an important regulator of host defence mechanisms against viruses, bacteria, fungi and protozoa.

IL-19. This is a member of the IL-10 family that is released by monocytes and macrophages upon stimulation by LPS and GM-CSF. It can also be released by B cells. IL-19 exerts its effects by stimulating the receptors of IL-20 or IL-22.

IL-20. This exhibits a distinctive homology with IL-10. It is expressed in the skin and trachea and signals via a signal transducer of transcription 3 (STAT-3) pathway. In mice, overexpression of IL-20 genes leads to neonatal lethality with marked abnormalities in the skin, especially of epidermal differentiation. Overexpression of IL-20 in transgenic mice leads to skin lesions similar to psoriasis. Two putative receptors for IL-20 have been identified on keratinocytes. Interestingly, these receptors are highly expressed in psoriasis patients, indicating a potential pathophysiological role for this novel cytokine in psoriasis.

IL-22. This (IL-10-related T-cell-derived inducible factor) is synthesized by $CD4^+$ T and mast cells amongst others, and can be stimulated by IL-9 and LPS [27]. The IL-22 receptor has also been detected in the skin. There are two soluble IL-22 receptor antagonists (IL-22RA1 and -RA2); IL-22RA2 is expressed by immune cells as well as epithelial cells in the skin. However, the exact localization and significance of IL-22 in the skin is still unclear. Although IL-22 belongs to the IL-10 family of cytokines, it mediates acute-phase responses in inflamed tissue and hepatocytes.

IL-23. This recently discovered cytokine is structurally closely related to other mediators such as IL-6, G-CSF and IL-12. Transgenic mice overexpressing IL-23 show an intensive inflammatory infiltrate of lymphocytes and macrophages in numerous organs including the skin [28].

IL-24. This is the fourth member of the anti-inflammatory IL-10 cytokine family. Murine IL-24 is generated by Th2 cells in an IL-4 inducible manner. It has also been found to be generated by differentiated melanoma cells, with anti-tumorigenic activity, and LPS-stimulated monocytes.

IL-26. IL-26, formerly known as AK155, is produced by monocytes and various T-cell types. Our knowledge of its receptor expression, signalling mechanisms, biological effects and relevance to diseases is scant.

IL-27. This novel family member of the long-chain four-helical cytokine family has recently been described [29]. It is a heterodimer protein consisting of an IL-12p40-similar protein (EBI3) and an IL-12p35-similar polypeptide (p28). As an early product of activated antigen-presenting cells, IL-27 is able to induce clonal expansion of naive $CD4^+$ T cells in mice and humans, but not of memory T cells. It acts synergistically with IL-12 on the induction of the Th1- or the NK cell-mediated production of IFN-γ. IL-27 probably binds to the orphan-receptor WSX-1/TCCR, which has a high structural homology with the IL-6–IL-12 receptor family. It is thought that IL-27 is of importance in the proliferation and activation of naive T cells. Thus, this novel cytokine may be involved in the pathophysiology of T-cell-mediated skin diseases, autoimmune diseases and defence against infectious skin diseases.

IL-28 and IL-29. Very recently, novel members of the cytokine family have been cloned in humans, and designated IL-28A, IL-28B and IL-29 [30]. They are distantly related to type I interferons and the IL-10 family because of their capacity to enhance antiviral activity in cells. In addition, IL-28 and IL-29 activate a heterodimeric class II cytokine receptor, defined as IL-28Rβ, and an orphan receptor, designated IL-28Rα. Their distribution and biological function under physiological and pathophysiological circumstances have yet to be determined.

Interferons

IFNs were originally described as factors that 'interfere' with the replication of virus replication. IFNs are an important protein family of cytokines of great significance in the defence against cancer cells and viral infections. Moreover, IFNs are key regulatory agents with many activities in normal tissue physiology, inflammation and the immune responses, enhancing or depressing the activities of other cytokines.

IFN-α and IFN-β are rapidly released after viral infections upon stimulation by double-stranded RNA. In contrast, IFN-γ is induced indirectly during the inflammatory response against pathogens, but also contributes to host defence. Very recently, a novel member of the type I interferon family has been cloned, defined as IFN-κ [1]. IFN-κ induces the release of several cytokines from monocytes and dendritic cells, and inhibits IL-12 release from monocytes. Synthesis of IFN-κ is inducible by IFN-γ in monocytes and dendritic cells, and IFN-κ can be found in these cells in lesional skin of atopic dermatitis and psoriasis.

The three IFNs, IFN-α from macrophages and B cells, IFN-β from fibroblasts and IFN-γ from activated T cells, have specific receptors and different properties that may act synergistically or in opposition. IFN-α and IFN-β exert their effects by inhibiting virus replication in host cells. Additionally, via binding to IFN receptors, both molecules not only act on infected cells, but also activate defence mechanisms in neigbouring 'healthy' cells in a paracrine manner. Activation of the receptor by IFN-α and IFN-β leads to the induction of intracellular signalling pathways involved in inflammation and host defence. For example, IFN-α and IFN-β activate STATs, P1-kinase and Mx-protein, all factors that increase the resistance of cells to viral replication [2].

IFN-γ alone induces formation of MHC class II molecule HLA-DR on membranes of monocytes and keratinocytes [3–5], while IFN-α and IFN-β induce expression of the MHC class I antigens on many cell types. This leads to optimal antigen presentation to cells of the adaptive immune system such as T cells. IFNs activate NK-cell activity, leading to the successful killing of infected cells. In contrast, INFs save non-infected cells from destruction by NK cells by up-regulating MHC class I molecules on these cells. In addition, IFN-γ up-regulates the activity of a proteinase, cathepsin S, by cultured human keratinocytes [6]. The release of VEGF is induced in keratinocytes and suppressed in fibroblasts by IFN-γ, indicating that this cytokine is involved in the regulation of angiogenesis [7].

IFN-γ augments monocyte secretion of TNF-α and TNF-β, which contribute to the antiviral and antiproliferative properties of IFNs [8], and increases the expression of IL-2R and ligand binding on human leukaemic and normal lymphocytes [9]. All three IFNs augment activity of NK lymphocytes and macrophages [10], and stimulate macrophage synthesis of arachidonic acid products [11]. IFN-α stimulates formation of IgG and IgM by B cells and, although it is not a helper T-cell factor, it enhances the response of helper factor to stimulate antibody formation [12]. Thus, IFNs directly modulate various functions within the innate as well as adaptive immune system.

In inflammatory diseases (e.g. atopic dermatitis), a positive effect of IFN-γ upon the healing of the eczema and pruritus has been documented in non-placebo-controlled single reports. Recent data in mice suggest that mast cells contribute to the regulation of IFN-γ in the inflamed skin [13].

IFN-γ may be of relevance to the pathogenesis of SLE. IFN-γ receptor knockout mice rarely develop lupus nephritis, and overexpression of IFN-γ in the epidermis leads to skin alterations similar to those in SLE. Systemic treatment of inflammatory or infectious skin diseases with IFNs is hampered by side effects such as fever, fatigue and local necrosis [14].

The pro-inflammatory effects of keratinocyte activation by IFN-γ can be inhibited by regulatory molecules defined as suppressors of cytokine signalling (SOCS). SOCS1, SOCS2 and SOCS3 proteins are up-regulated in the epidermis of psoriasis and allergic contact dermatitis but

not in atopic dermatitis patients [15]. They exert multiple anti-inflammatory effects on keratinocytes, such as down-regulation of HLA-DR, ICAM-1, IP-10 and MCP-1.

In summary, interferons not only act as antiviral agents but are also important mediators of inflammatory and immune responses within the skin.

Tumour necrosis factor

TNF, also defined as cachectin or endogenous pyrogen, is a protein of approximately 17 kDa that exists in a secreted and transmembrane form, and builds dimers or trimers after release into the environment [1]. It is secreted by monocytes and macrophages, mast cells, fibroblasts, smooth muscle cells, endothelial cells, T cells and certain NK cells. It has multiple pro- as well as anti-inflammatory activities, and is also a growth factor in normal physiological regeneration and wound healing [2,3]. Upon stimulation by exogenous factors such as bacterial LPS, staphylococcal toxin, viruses and other organisms, or by endogenous mediators such as C5a, IL-1, IL-2, GM-CSF, substance P, bradykinin and TNF itself, large amounts are released within minutes, and synthesis is rapidly increased. The rate of synthesis is controlled by IFN-γ [4], but several other cytokines may antagonize and influence further release (e.g. TGF-β, IL-6, PGE_2 or vitamin D_3). TNF-α is activated after processing at the cell membrane by a transmembrane enzyme, TNF-α converting enzyme.

TNF binds to three types of receptor, TNF-R1 (CD 120a, p55) and TNF-R2 (CD 120b, p75), which are expressed by almost all cells and bind both TNF-α and TNF-β, and TNF-R3 which is only synthesized by human hepatocytes and which binds TNF-α. Each receptor appears to mediate different cellular responses [5]. TNF receptors also belong to the superfamily of death receptors which induce apoptosis (e.g. in keratinocytes and leukocytes during cutaneous inflammation; see p. 9.8).

The soluble forms of the receptors, released from cell membranes, neutralize both forms of TNF, thereby preventing systemic effects resulting from local inflammation [6]. The soluble receptors occur in the blood and urine of normal persons, and in markedly increased amounts during various inflammatory disorders and sepsis [6–8]. TNF-binding proteins (TBPs) are also capable of regulating TNF function after release into the extracellular space.

TNF has many biological properties, shared with IL-1, with which it is closely associated, and which synergistically enhances TNF activity. It induces septic shock and fever [9], cachexia [10] and is a potent mediator of inflammation, increasing macrophage and neutrophil chemotaxis, phagocytosis, cytotoxicity and respiratory burst activity [11–16]. The protective role of TNF is supported by the observation that mice that lack the gene for TNF do not develop septic arthritis but cannot resist systemic infection [17]. Thus, an important role of TNF is to protect tissues by localizing inflammation. On the other hand, once infection becomes systemic, TNF may have deleterious effects leading to sepsis and shock [16]. Some of these effects may result from its ability to stimulate synthesis of many other cytokines and mediators, including IL-1, GM-CSF, PDGF, TGF-β, prostaglandins and leukotrienes.

TNF-α exerts numerous effects in the epidermis. Toxins and haptens as well as UV light induce the release of TNF-α from keratinocytes. TNF receptors are involved in the regulation of keratinocyte apoptosis [18]. TNF-α also induces intensive expression of ICAM-1 in keratinocytes. Via activation of NF-κB and C/EBPβ, TNF-α regulates the synthesis of cytoskeletal proteins participating in epidermal responses to inflammation or wound healing. In contrast to its many tissue-damaging properties, TNF is also a growth factor, stimulating fibroblast proliferation and synthesis, and shows synergy with EGF, by increasing the EGF receptor, PDGF and insulin [2].

In endothelial cells, TNF promotes leukocyte adherence by increasing expression of E-selectin, ICAM-1 and VCAM, probably via activation of the transcription factor NF-κB. TNF-α is also a potent activator of neutrophils, leading to the regulation of cell recruitment, chemotaxis, degranulation and release of cytokines and oxidative burst mediators.

TNF-α probably exerts a direct effect on Langerhans' cells and type IV hypersensitivity reactions. The pathophysiological relevance of TNF-α has been demonstrated in various models of infection, inflammation and autoimmune disease [19,20].

Syndromes exist that are linked to TNF-receptor type I dysfunction. For example, TNF-receptor-associated periodic syndrome (TRAPS) is a rare hereditary syndrome accompanied by prolonged attacks of periodic fever and severe localized inflammatory reactions. This disease is based on a dominantly inherited mutation within the TNF type I receptor. This defect leads to decreased levels of soluble TNF receptor, resulting in an unopposed TNF-α reaction clinically evident as a prolonged inflammatory response [21].

Cytokine suppressors and inhibitors

In addition to pro-inflammatory cytokines, certain cytokines including IL-1RA, TGF-β and members of the IL-10 family exert potent anti-inflammatory effects.

The physical state of cytokines in body fluids has rarely been determined. Detection of a cytokine by immunological techniques indicates only its presence, not its potential activity. The cytokine may be coupled to a substance that prevents binding to the specific receptor. Coupling may occur as: (i) dissociable complexes with a protective lipoprotein that releases the cytokine to react with its receptor; (ii) firmly bound complexes of cytokine and a carrier protein that interferes with receptor linkage [1,2]; or (iii) complexes of cytokine with its specific soluble receptor that blocks interaction with cell receptors [3].

Anti-inflammatory cytokines exert their effects by:

1 Regulation of cytokine secretion, and differences in the agonists stimulating secretion
2 Regulation of cytokine receptor expression
3 Receptor competition of different cytokines
4 Soluble binding factors and/or inhibitors
5 Regulation of proteases that activate the cytokine proform (converting enzymes).

IL-1RA and IL-18RA

IL-1 receptor antagonist (IL-1RA) is naturally secreted during inflammatory processes, and its production and release is modulated by many cytokines such as IL-4, IL-6, IL-13 and TGF-β. IL-1RA is important in potentially inhibiting the deleterious effects of IL-1 during the inflammatory process.

Two types of specific blocking agent for IL-1 activity have been identified. The first is a soluble receptor without a transmembrane structure that binds to free IL-1, inactivating its binding site. The second, IL-1RA, is an inactive IL-1 homologue that blocks receptor sites on cells.

IL-1α or IL-1β activity normally follows binding of the cytokine to the IL-1 type I receptor on all responding cells [4]. Other cells, B cells and neutrophils, have another IL-1R, type II receptor [5]. It has been suggested that the IL-1RII receptor can be shed from cells and bind with free

IL-1, blocking its ability to couple to cell-bound IL-R1. An alternative inhibitory molecule is an inactive homologue of IL-1, IL-1RA, which binds to cell receptors without inducing a signal. The inert homologue therefore blocks the receptor, preventing later binding of active IL-1 [6–9]. This type of antagonist is peculiar to IL-1. It is secreted mainly by monocytes and macrophages, but also by neutrophils and fibroblasts. It has been designated secreted interleukin-1 receptor antagonist (sIL-1RA).

Keratinocytes, fibroblasts and monocytes are capable of generating an intracellular form of IL-1RA. Knowledge about its function is still scant. Other cytokine receptors may occur in a soluble form; most of these have blocking and/or inhibitory activity [3].

Both the IL-1α and the IL-18 precursor require cleavage into an active mature molecule by an intracellular cysteine protease termed IL-1α converting enzyme (ICE), which is also known as capsase-1. Thus, ICE inhibitors may limit the activity of IL-1α as well as IL-18. IL-1RA is a physiological antagonist that has a similar structure to IL-1α and IL-β, and thus competes with the binding of the natural ligand to the receptor. IL-18BP is a naturally occurring antagonist that is able to bind IL-18 with high affinity and to neutralize its activity, but not that of IL-1. Recently, another IL-18 antagonist, IL-1H, was discovered, which has sequence homology with IL-1RA, and binds IL-18R but not IL-1R. IL-1F7b shares sequence homology with IL-18 and binds IL-18Rα but has no IL-18-like agonistic or antagonistic activity. IL-F7b binds to IL-18BP and subsequently may block IL-18Rα, which ultimately results in the inhibition of IL-18 activity.

A non-receptor soluble protein that may function as a protective carrier protein or inhibitory substance is α_2M [10]; it is a carrier for IL-1, IL-6 and PDGF [10,11], but inactivates IL-2 and FGF [10]. Other soluble inhibitors, mainly directed against IL-1, have been found in the medium of UV-exposed keratinocyte cultures, and in the sera of UV-exposed mice and humans. The identity of these substances, and a related epidermal cell contra-IL-1, which blocks the activity of IL-1, is still to be determined.

TGF-β

TGF-β belongs to a family of peptides involved in growth and differentiation in almost all cells. It is involved in the regulation of extracellular matrix proteins and pathophysiological processes such as fibrosis, wound healing and scar formation. Within the immune system, TGF-β down-regulates the function of T cells, B cells, monocytes and NK cells. T cells undergoing apoptosis release TGF-β, leading to immunosuppressive effects in the inflammatory micromilieu [12]. TGF-β also diminishes mast cell function by inhibiting mast cell proliferation and IgE synthesis. TGF-β reduces the synthesis of IL-1 and IL-2. TGF-β, secreted in an inactive form, can bind weakly after exposure to acid pH in wound fluid to epidermal growth factor receptor (EGFR) on keratinocytes and endothelium, and compete with the stimulating molecules EGF and TGF-β, thereby reducing keratinocyte and endothelial proliferation.

IL-10 family of cytokines

Because of their similarity to IL-10 function, interleukins IL-10, IL-19, IL-20, IL-22, IL-24 and IL-26 have been grouped together as the IL-10 family. IL-28 and IL-29 share similarities to both type I interferons and IL-10 cytokines. Their function and role during inflammation and immune response are as described above.

Chemokines

Chemokines constitute a large family of soluble chemotactic cytokines with four conserved cysteines linked by disulphide bonds. Four subfamilies, CXC, CC, CX3C and C chemokines, are distinguished according to the position of the first two cysteines. So far, more than 40 chemokines have been defined and characterized (Table 9.7). Most chemokine genes encode for proteins of approximately 90–125 amino acids. The different chemokine subfamilies are clustered on different chromosomes [1].

The main characteristic of chemokines is their potential to activate and attract leukocytes. Thus, chemokines have a pivotal role during inflammation and immunity. Interestingly, while CXC chemokines mainly attract neutrophils and lymphocytes, CC chemokines are capable of attracting monocytes, eosinophils, basophils and lymphocytes, but not neutrophils.

Table 9.7 Nomenclature for human chemokines. (From Keystone Chemokine Conference, Keystone, CO, USA, January 18–23, 1999.)

Systematic name	Human ligand	Mouse ligand	Chemokine receptor(s)
CC chemokine/receptor family			
CCL1	I-309	TCA-3, P500	CCR8
CCL2	MCP-1, MCAF	MCP-1, JE	CCR2
CCL3	MIP-1α, LD78α, LD78β, AT464.1, AT464.2, GOS19-1, GOS19-2	MIP-1α	CCR1, CCR5
CCL4	MIP-1β, AT744.1, AT744.2, Act-2, G-26, HC21, H400, LAG-1	MIP-1β	CCR5
CCL5	RANTES	RANTES	CCR1, CCR3, CCR5
CCL6	Unknown	C10, MRP-1	Unknown
CCL7	MCP-3	NC28, FIC, MARC	CCR1, CCR2, CCR3
CCL8	MCP-2, HC14	MCP-2	CCR2, CCR3
CCL9, CCL10	Unknown	MRP-2, CCF18, MIP-1γ	Unknown
CCL11	Eotaxin	Eotaxin	CCR3
CCL12	Unknown	MCP-5	CCR2
CCL13	MCP-4, NCC-1, CKβ-10	Unknown	CCR2, CCR3
CCL14	HCC-1, HCC-3, NCC-2	Unknown	CCR1
CCL15	HCC-2, MIP-1δ, NCC-3, MIP-5, LKN-1	Unknown	CCR1, CCR3
CCL16	HCC-4, NCC-4, LEC, LMC	LCC-1	CCR1
CCL17	TARC, dendrokine	TARC	CCR4
CCL18	DC-Ck1, PARC, MIP-4, AMAC-1	Unknown	Unknown
CCL19	MIP-3β, ELC, exodus-3, CKβ-11	MIP-3β	CCR7
CCL20	MIP-3α, LARC, exodus-1	MIP-3α	CCR6
CCL21	6Ckine, SLC, exodus-2, TCA-4	6Ckine	CCR7
CCL22	MDC, STCP-1, DCtacin-β	ABCD-1	CCR4
CCL23	MPIF-1, MIP-3, CKβ8, CKβ8-1	Unknown	CCR1
CCL24	Eotaxin-2, MPIF-2, CKβ-6	Unknown	CCR3
CCL25	TECK	TECK	CCR9 (GPR9-6)
CCL26	Eotaxin-3	Unknown	CCR3
CCL27	CTACK/ALP	CTACK, ALP	Unknown
CXC chemokine/receptor family			
CXCL1	GRO-1, GROα, MGSA-α	GRO (KC)	CXCR2 > CXCR1
CXCL2	GRO2, GROβ, MIP-2α, MGSA-β	GRO (KC)	CXCR2
CXCL3	GRO3, GROγ, MIP-2β	GRO (KC)	CXCR2
CXCL4	PF4	PF4var1, PF4alt	Unknown
CXCL5	ENA-78	LIX	CXCR2
CXCL6	GCP-2	CKα-3	CXCR1, CXCR2
CXCL7	NAP-2	Unknown	CXCR2
CXCL8	IL-8, MDNCF, NAP-1, NCF	Unknown	CXCR1, CXCR2
CXCL9	Mig, Humig	Mig	CXCR3
CXCL10	IP-10	crg-2, mob-1	CXCR3
CXCL11	I-TAC, H174, b-R1	Unknown	CXCR3
CXCL12	SDF-1α, SDF-1β, PBSF	SDF-1α/β	CXCR4
CXCL13	BLC, BCA-1	BLR1L, Angie	CXCR5
CXCL14	BRAK/bolekine	BRAK	Unknown
CXCL15	Unknown	Lungkine	Unknown
C chemokine/receptor family			
XCL1	Lymphotactin, SCM-1α, ATAC	Lymphotactin	XCR1
XCL2	SCM-1β		XCR1
CX3C chemokine/receptor			
CX3CL1	Fractalkine, neurotactin	Fractalkine	CX3CR1

MDC, macrophage-derived chemokine; TARC, thymus and activation-regulated chemokine.

The classic role of chemokines is to attract leukocytes to the site of inflammation. For instance, $CD34^+$ dendritic cells (DCs) secrete ligands for chemokine receptors such as CCR1, CCR5, CCR6, CXCR4 or CCR9 to enter the target tissue. After maturation in epithelial tissues such as the epidermis, DCs change their phenotype by up-regulating CCR7, for example, to traffic to lymph nodes [2].

In addition to attracting leukocytes, chemokines also modulate leukocyte–endothelial interactions. They promote transendothelial emigration by supporting the binding of cell adhesion molecules with integrins (e.g. linkage of VCAM with α4β1 integrin on monocytes, eosinophils and basophils) or the binding of L-selectin to E-selectin on neutrophils. CC chemokines may also induce the syn-

thesis and release of inflammatory mediators such as histamine from basophils [3,4] or leukotrienes.

The effects of chemokines are mediated via binding and activating heptahelical G protein-coupled receptors. Chemokine activation instantly leads to rearrangement of the cell cytoskeleton, and activation of intracellular second messengers and integrins. Chemokine activation in neutro-phils or monocytes results in the generation of inflammatory agents such as lipid mediators, NO, prostaglandins, amines, proteases and oxygen radicals [5]. RANTES and MIP-1α also release histamine from basophils [6].

Besides their specific ligand–receptor interaction, chemokines may also adhere to extracellular matrix proteins and the apical surface of endothelial cells. This appears to be crucial for the migration of leukocytes to sites of inflammation. For example, CXCL8 and CCL19 attach to the endothelial cell surface, thereby stimulating transmigration [7]. In contrast, glycosaminoglycans such as heparan sulphate are capable of inactivating chemokine effects on endothelial cells [8].

Chemokines bind and activate chemokine receptors, which comprise a large family of seven transmembrane receptors. They are expressed by numerous cell types and modulate not only inflammation, but also embryogenesis and innate as well as adaptive immune responses. Chemokine receptors have been implicated in the pathophysiology of several diseases such as HIV infection, malaria, psoriasis and wound healing [9]. Moreover, viruses such as herpesvirus and poxvirus encode for chemokine receptors, thereby entering their hosts, indicating an important role for chemokines in certain infectious diseases [10].

In the skin, a special subset of memory T cells normally bears cutaneous lymphocyte-associated antigen (CLA), with resultant selective trafficking of these cells to the skin. The CLA protein seems to be crucial for T-cell interaction with the endothelium, the extracellular matrix and other cell types in the skin. Approximately 80–90% of T cells found in lesional skin in cutaneous inflammation express CLA. In contrast, in non-cutaneous sites of inflammation CLA^+ T cells constitute only approximately 5% of lesional T cells. During contact dermatitis, specificity to skin-associated allergens such as nickel or house-dust mite allergens is restricted to CLA^+ T cells [11].

CC chemokines

RANTES. RANTES, an acronym for regulated upon activation, normal T cell expressed and secreted, attracts basophils, eosinophils, lymphocytes and monocytes. It induces granule release and leukotriene synthesis in basophils and eosinophils, and histamine release from basophils. The activity is enhanced by priming with IL-5. It is formed by macrophages, fibroblasts and T cells. RANTES is one of the more potent chemokines in inflammation and allergy, and is believed to be an important mediator of tissue eosinophilia. RANTES mRNA has been detected in skin of atopic subjects 6 h after challenge by antigen, and the secreted protein is present in atopic dermatitis skin scales [12].

Macrophage inflammatory protein 1a. This is formed by monocytes, fibroblasts, activated T and B cells, and attracts monocytes, lymphocytes, basophils and eosinophils. When bound to endothelial cells, it is reported to increase binding of $CD8^+$ T cells. In mice, it releases histamine from mast cells and basophils, but histamine release from human basophils is little above control amounts.

Macrophage inflammatory protein 1b. This is closely related to the α-form and shares many of its properties. It has been reported to increase adhesion to endothelium by $CD8^+$ T cells, or adhesion of $CD4^+$ cells, by α4β1 integrin–VCAM binding.

Monocyte chemotactic proteins. MCPs are capable of attracting T cells, DCs and NK cells. They are also potent attractants of monocytes and modulate expression of adhesion molecules. MCP-2 and MCP-3 also attract eosinophils. MCP-1 and MCP-3 attract basophils, and induce histamine release and synthesis of LTC_4. Recently, MCP-2 has been reported to be as potent as MCP-3 in activating eosinophils and basophils [13]. These proteins contribute to leukocyte infiltration of damaged tissue, possibly especially in atopic disorders. Antibodies against MCP-1 rendered animals less susceptible to delayed-type hypersensitivity, indicating a potential therapeutic strategy for the treatment of allergic reactions in the skin.

Eotaxin. Eotaxin, a potent chemokine for eosinophils [14], has more than 50% amino acid homology with the MCP mediators. It has been detected in the epithelium of nasal polyp biopsies and possibly contributes to the eosinophilia of allergic inflammation. Eotaxin attracts T cells and eosinophils to the skin in patients with atopic dermatitis. In eotaxin-deficient mice, allergen-induced attraction of eosinophils seems to be impaired; this effect, however, appears to be compensated for by other chemokines at later stages [15].

CCL27. This is a skin-associated CC chemokine member that binds the receptor CCR10 with high affinity. CCL27–CCR10 interactions are critical for skin-homing CLA-bearing memory T cells [16,17]. Recent data suggest that CCL27 directly contributes to cutaneous inflammation. For example, patients with psoriasis, atopic dermatitis and contact dermatitis express CCR10 on $CD4^+$ T cells, fibroblasts and endothelial cells. Cutaneous application of CCL27 attracts lymphocytes into the skin [18].

CXC chemokines

IL-8. The first chemokine to be defined was IL-8, which is the most potent chemokine for attracting neutrophils. IL-8 binds to and activates CXCR-1 and CXCR-2. CXCR-1 (IL-8R1) is exclusively activated by IL-8, while CXCR2 (IL-8R2) can also be activated by GRO-α, GRO-β, GRO-γ, NAP-2, ENA-78, GCP-2.

GRO-a. This product of a growth-regulated gene, which also has melanoma growth-stimulating activity (MGSA), attracts and activates neutrophils. It is formed by monocytes, fibroblasts, platelets, endothelial cells and melanoma cells. Increased amounts occur in psoriatic scales, together with IL-8 [19].

NAP-2. This is a product cleaved from a basic protein derived from platelet granules. It attracts neutrophils, induces influx of calcium ions, degranulation and the respiratory burst [20].

Interferon-inducible protein 10. IP-10 is induced by IFN in monocytes, activated T cells, fibroblasts, endothelial cells and keratinocytes. It attracts monocytes and T cells and promotes T-cell binding to endothelium; it may contribute to the cell changes of delayed hypersensitivity [21]. Neutrophil attraction is doubtful.

Epithelial neutrophil activating peptide 78. ENA-78 attracts and activates neutrophils with resultant release of their granules and mediators. It is synthesized by type II alveolar epithelial cells stimulated by IL-1, by neutrophils, monocytes, endothelial cells and vascular smooth muscle cells stimulated by IL-1 or LPA; ENA-78 mRNA has been reported in platelets. ENA-78 has been detected in lungs infiltrated by neutrophils in adult respiratory distress, and increased amounts are found in the sera of patients with rheumatoid arthritis [22].

Chemokine receptors

So far, five CXC receptor subtypes have been defined, 11 for CCR and 1 for CX3C chemokines. Most receptors can be activated by more than one chemokine, and several chemokines bind to more than one receptor [1,9].

IL-8 was the first chemokine to be demonstrated in 1987. Later, the first chemokine receptors for IL-8, defined as CXCR1 and CXCR2, were characterized. They are expressed by T cells, activated eosinophils, mast cells, basophils and dendritic cells, suggesting a role for IL-8 during acute inflammation and innate immunity. Both CXCR1 and CXCR2 can be activated by IL-2. CXCR1 appears to be the dominant receptor for chemotaxis, phospholipase D production and superoxide generation after IL-8 or NAP-2 activation. CXCR2 mediates neutrophil chemotaxis in response to low-concentration NAP-2 and GRO-α. Interestingly, human herpesvirus (HHV) and HHV8 both express functional CXCR2 receptors, although the significance of this remains unclear [23]. CXCR3 is a receptor for T-cell activation. It binds I-TAC, Mig and IP-10. Eotaxin and MCP-4 also bind CXCR3, but with lower affinity. CXCR3 is expressed mainly by Th1-type T cells and $CD45RO^+$ memory T cells. In sarcoidosis, virtually all T cells express CXCR3. CXCR4 has been detected on most haematopoietic cells such as B cells, DCs, Langerhans' cells, macrophages and T cells. Moreover, CXCR4 has also been identified as an HIV virus co-receptor, in that the glycoprotein gp120 from the HIV envelope binds to CXCR4 in the presence of CD4 [24]. However, CD4 independent association of gp120 to CXCR4 has also been shown. Thus, CXCR4 may be involved in HIV infection and HIV neurotoxicity. CXCR5 is a B-cell chemokine receptor. After T-cell activation, CXCR5 is up-regulated on memory and/or effector T cells via the chemokine BCA-1, suggesting a role in T–B cell interaction.

CCR1. This is a receptor for several chemokines such as MIP-1α, RANTES, MCP-2, MCP-3, MIP-5, MPIF-1 and HCC-1. MIP-1β and MCP-1 are also poor agonists. CCR1 is expressed by T cells, especially memory $CD45RO^+$ T cells. CCR1 knockout mice do not acquire spontaneous infections, but show increased mortality when infected with *Aspergillus fumigatus*, indicating a role for CCR1 in neutrophil-mediated diseases [25]. This receptor also appears to regulate granuloma formation and Th1–Th2 cytokine balance. Recent data indicate that CCR1 is a receptor that can modulate inflammatory responses either positively or negatively, depending on the microenvironment.

CCR2. This is a leukocyte MCP-1 receptor expressed by monocytes, dendritic cells, NK cells and T cells, B cells and basophils. Mice lacking CCR2 develop normally but do not recruit macrophages in an experimental inflammation model. They fail to clear infections, have smaller granulomas and show defective recruitment of monocytes–macrophages to the site of inflammation. These results indicate a role for CCR2 in macrophage function. CCR2 may be also involved in HIV infection [1,3,9,24].

CCR3. This is the receptor for chemoattractants on eosinophils and may thus be important during allergic inflammation and hypersensitivity. This receptor can be activated by MIP-1α, MIP-1β and eotaxin, RANTES, MCP-3, MCP-4, MIP-5 and the TAT protein of HIV. Eotaxin appears to be the most potent agonist of CCR3. CCR3 can also be detected on basophils, mast cells, Th2-type T lymphocytes and DCs. Eotaxin knockout mice showed only weak responses after ovalbumin challenge. Using animal models, neutralization of eotaxin resulted in a partial blockade of eosinophilia after allergen challenge [26].

CCR4. This is expressed by Th2 T lymphocytes and can be activated by macrophage-derived chemokine (MDC) and thymus and activation-regulated chemokine (TARC). This receptor may be involved in dendritic cell function, trafficking of T cells to the lymph nodes and T-cell transmigration, as well as homing of memory T cells to inflamed skin [27].

CCR5. This has become well known as a major HIV-1 co-receptor that controls susceptibility to HIV-1 infection and disease [9]. CCR5 is expressed by T lymphocytes and macrophages as well as Langerhans' cells. CCR5 can be activated by MIP-1α, RANTES, MIP-1β and MCP-1. MCP-3 however, appears to be an CCR5 antagonist. CCR5 knockout mice appear healthy. A role for CCR5 in down-modulating T-cell-dependent immune responses has been suggested. CCR5 is one of the first receptors for which use of receptor antagonists has been advocated in clinical trials in humans, in HIV infection [28].

CCR6. This mediates responsiveness of memory T cells to the chemokine LARC. CCR6 seems to be important for the migration of memory T cells and dendritic cells to secondary lymphoid organs. The chemokine MIP-3α has been shown to regulate the homing of Langerhans'-type dendritic cells to the epidermis by activating CCR6. The CCR6 ligand LARC can be released by macrophages, dendritic cells and endothelial cells. However, the human β-defensin 2 (HBD-2) has also been shown to functionally bind CCR6. HBD-2 is produced by enterocytes during infection and functions as an antimicrobial factor. It also attracts DCs and memory T cells via CCR6 activation. Together, these results indicate a role for this receptor as a link between the innate and adaptive immune systems [29].

CCR7. This is a homing receptor for B cells, T cells and DCs across high endothelial venules. CCR7 is activated by the chemokines ELC and SLC, which are expressed in the T-cell area of lymphoid tissues but not in the B-cell area. This is supported by the finding that CCR7 knockout mice show defective B- and T-cell homing, whereas defective T-cell development is not found.

CCR8. This is critically associated with the function of Th2 lymphocytes. Reports of the activation of CCR8 by various agents such as TARC and MIP-1β are controversial. Interestingly, CCR8 can be activated by viral chemokines from molluscum contagiosum [30]. CCR8 has also been described as an HIV-1 co-receptor.

CCR9. This is a recently described receptor that can be activated by TECK, a chemokine for dendritic cells, T cells and activated macrophages. It appears to be involved in the development of T cells within the thymus.

CCR10. This is a receptor for the skin-associated CC chemokine CCL27 (CTACK) that attracts skin-homing memory T cells to the site of inflammation [16].

CCR11. This is a receptor for MCP-1, MCP-2 and MCP-4. It has been described in the heart, small intestine and the lung.

CX3CR1. This is a receptor that is crucially involved in cell–cell adhesion and leukocyte trafficking. Its ligand fractalkine is a transmembrane protein that activates CX3R1 on neutrophils, monocytes, NK cells and T lymphocytes. This receptor has also been described as a co-receptor for HIV-1. Its role in the skin, however, is currently unknown.

A crucial role for chemokines and chemokine receptors in cutaneous inflammation has also been observed in several studies in which the relevant genes have been deleted by homologous recombination. For example, CXCR2 gene-deficient mice are incapable of mobilizing neutrophils *in vivo* [31]. Further results showing that CXCR2 ligand neutralization leads to impaired reactions during skin inflammation suggest a potential therapeutic strategy for the use of chemokine receptor antagonists in inflammatory skin diseases such as psoriasis. CXCR2 knockout mice show defective neutrophil recruitment, an altered temporal pattern of monocyte recruitment and altered secretion of IL-1β, indicating a role for this chemokine receptor in wound healing [32].

Recent data suggest a role for chemokines in angiogenesis. IL-8 (CXCL8) has been shown to act as a growth factor in malignant melanoma. Melanoma cells overexpress certain chemokines that activate CXCL8, indicating an autocrine tumour-promoting effect of this chemokine. Many chemokines, including CCL20/MIP-3α, have been demonstrated to display antimicrobial activity comparable to defensins.

Chemokines may also be involved in the modulation of angiogenesis during tumour growth. For instance, CXCL8 (IL-8) and CXCL10 (IP-10) are angiostatic factors, while CXCL12 (SDF-1) has been shown to act as an angiogenic factor *in vivo* [2,7,9,33]. Interestingly, CXCL12 and VEGF appear to act synergistically to regulate angiogenesis. Other chemokines such as CXCL4, CXCL9 and CXCL10 decrease angiogenesis, thereby inhibiting tumour growth. A role for chemokines in regulating blood vessel formation during chronic inflammation and injury awaits further clarification.

In summary, recent data indicate a crucial role for various chemokines in cutaneous inflammation, and receptor antagonists may prove useful in the treatment of several skin diseases including inflammation, autoimmunity, allergy, infection and tumour growth.

Proteases

Proteases constitute the largest family of enzymes, and comprise approximately 5% of the human genome, making them the largest protein family in humans. Although not known to be involved in multiple processes, proteases have in the past been regarded purely as destructive enzymes that merely degrade peptides. Proteases are in fact involved in almost all biological processes, such as embryogenesis, cell cycling, growth and differentiation, coagulation, inflammation, tumourigenesis, hair growth, secretion and tissue repair, and also assist in cell–cell communication [1–4].

Proteases can be devided into five groups, depending on the type of molecule that mediates catalytic work (serine, threonine, cysteine, aspartyl, metalloproteinases). It is important to realize that the effect of a protease is irreversible, because hydrolysis cannot be reversed. Therefore, proteases are maintained in a precursor state (zymogen) and become activated only when needed. Proteinases are involved in inflammatory processes that are not appropriately regulated. Significant tissue destruction and impairment of repair mechanisms may occur after proteinase activation, or dysfunction of protease inhibitors. One of the best examples of a crucial part played by a protease-regulated system is the blood coagulation cascade. Another example is programmed cell death (apoptosis) in which cysteine proteases (caspases) are critically involved [5].

In the skin, exogenous proteases such as Der p3 or Der p9 from house-dust mite, bacterial (e.g. V8 protease from staphylococci) or fungal proteinases (aspartyl proteases) are capable of triggering the inflammatory response in the epidermis or dermis. Among the keratinocyte-derived enzymes that may contribute to inflammation are acid phosphatase, cathepsins (acid proteases) B, C and D, mainly distributed in lysosomes with acid phosphatase, and neutral serine proteinases such as squamous cell tryptic enzyme (SCTE), squamous cell chymotryptic enzyme

(SCCE) and trypsin IV. Interestingly, enteropeptidase, the enzyme that cleaves trypsinogen and thereby activates trypsin, can be functionally expressed by keratinocytes. Keratinocytes also respond to protease inhibitors, indicating a complete proteinase-regulated machinery within the epidermis. Another enzyme, plasminogen activator, is generated throughout the epidermis, with a predominance within the granular layer.

Hereditary angio-oedema, characterized by episodic localized angio-oedema of the skin or mucosa, results from heterozygous deficiency of a protease inhibitor from the plasma, C1 esterase inhibitor (C1INH). C1INH seems to be involved in preventing excessive vascular permeability, and is an important modulator of inflammatory responses via regulation of complement activation.

Converting enzymes, such as IL-1 converting enzyme or pro-hormone convertase, are important proteinases in the switching of a pro-form of a molecule to the active state. They are especially important during the inflammatory process, where dysfunction of such enzymes may result in a disease state.

Acid phosphatase occurs in large amounts, relative to other acid hydrolases, particularly in the upper keratinizing layers of the epidermis. It probably participates in nucleic acid degradation. Hyperplasia of human skin induced by UV radiation and vitamin A application is associated with increased acid phosphatase. This increase, which also occurs in the stratum corneum, has found applications as a test for weak irritants; severe irritants result in a loss of acid phosphatase. Mild irritation of rat skin results in an increase of acid phosphatase, maximal on the third day, coinciding with acanthosis and thickening of the stratum granulosum.

Acidic protease cathepsins B, C and D occur in human epidermis. Tests in rabbits show that cathepsin D has a major role in intracellular protein digestion, and if released may degrade extracellular protein. Following irritation, proteases first degrade damaged cells on release of lysosomal enzymes, then there is activation of complement or Hageman factor, or cleavage of fibrin, inducing attraction of leukocytes, which further the inflammatory changes. A neutral protease in human skin, also present in fibroblasts, neutrophils and lymphocytes, has been shown to cleave complement and stimulate neutrophil chemotaxis in mice [6]. Thus, damage to the epidermis will initiate generation of chemotactic substances by release of proteolytic enzymes and by activation of other APPs, resulting in infiltration by neutrophils and further inflammation.

Tryptase is released by mast cells during inflammation, allergic reactions and tissue repair, and stimulates the release of pro-inflammatory cytokines (IL-6, IL-8), growth factors (GM-CSF) and other inflammatory mediators (NO, prostaglandins) [7–9]. Another protease released by mast cells during inflammation is chymase. This enzyme seems to be important as a regulator of vascular responses, leukocyte recruitment and the regulation of extracellular matrix proteins. Thus, chymase may be involved in the pathophysiology of allergic reactions, inflammation and tissue repair [10].

Many proteases are integral components of vital signalling networks. Besides their role as catalysts for extracellular matrix proteins, certain serine proteases have been demonstrated to activate specific receptors. The first protease-mediated receptor system identified was the thrombin receptor (PAR-1) [11]. Two other thrombin receptors were characterized: PAR-3 and PAR-4 [12]. Thrombin not only plays an essential part in the coagulation cascade, but additionally activates platelets and endothelial cells, thereby contributing to inflammation and tissue repair. PARs are G protein-coupled receptors with seven transmembrane domains. After activation, PARs mediate several responses involved in inflammation, such as release of cytokines, prostaglandins, NO or chemokines. Up-regulation of cell adhesion molecules on microvascular endothelial cells can be also mediated via PARs, indicating a direct role of proteases on leukocyte–endothelial interactions during inflammation [7]. *In vivo*, PAR-2 can be activated by skin-derived proteases such as tryptase and trypsin IV, leading to pruritus, oedema, plasma extravasation, up-regulation of cell adhesion molecules and promotion of the transendothelial migration of neutrophils [13–16]. Thus, activation of PARs affects all aspects of acute and chronic inflammation.

Plasminogen activation on the cell surface depends on the activation of urokinase type plasminogen activator (uPA) and its receptor. Such protease receptor families are defined as plasminogen activator receptors (also abbreviated PAR receptors). In contrast to the other PARs, these receptors are single-transmembrane receptors with protein kinase activity. One receptor, uPAR (urokinase receptor) can be activated by binding of urokinase and vitronectin [17]. Once activated on endothelial cells, urokinase receptors mediate adhesion, proliferation and migration of inflammatory cells. For example, uPAR has been demonstrated to be highly expressed on leukocytes during HIV infection, and soluble uPAR (suPAR) in the serum is an effective predictor of survival in HIV infection [18]. In the skin, uPAR has been implicated in the pathophysiology of pemphigus acantholysis [19]. uPA also activates metalloproteinases, thereby contributing to vascular damage [20]. The uPA–uPAR system is completed by the existence of plasminogen activator inhibitors (PAIs). Together, the orchestrated interaction of uPA, uPAR and PAI appears to have an essential role during inflammation, angiogenesis and cancer [21]. It is well known that protease inhibitor deficiency, or dysfunction, such as with α_1-antitrypsin, may result in airway disease [22]. An important recent finding has been that certain protease inhibitors are involved in cutaneous inflammation and disease. SPINK5, encoding

the putative multidomain serine protease inhibitor LEKTI, was recently identified as the defective gene in Netherton's syndrome [22]. LEKTI is strongly expressed in the granular and uppermost spinous layers of the epidermis, and in differentiated layers of stratified epithelia. Loss of LEKTI expression in the epidermis seems to be a diagnostic feature of Netherton's syndrome.

Protease inhibitors have been found to be effective drugs. For example, inhibitors of ACE and neutral endopeptidase may be involved in cutaneous inflammation. Moreover, HIV protease inhibitors are effective in the treatment of this infectious disease. Together, the key role of proteases in many organs including the skin and the immune system makes them attractive targets for future drug developments [23–26].

In summary, proteases along with their inhibitors and receptors have an essential role in skin homoeostasis and pathology. A well-tuned orchestra of these enzymes seems to be crucial for the maintenance of many inflammatory responses in the skin such as oedema, plasma extravasation, recruitment of leukocytes, cell–cell communication, extracellular matrix degradation, angiogenesis, cytoprotection, post-inflammatory pigmentation, spongiosis and keratinocyte desquamation. The significance of proteases to the treatment of skin diseases will be better understood once effective protease inhibitors, protease-receptor antagonists (or agonists) are available in the future.

Matrix metalloproteinases

Matrix metalloproteinases (MMPs) constitute a family of multidomain zinc endopeptidases that contain a catalytic domain with a common metzincin-like topology (Table 9.8). They are involved not only in extracellular matrix degradation, but also in a number of other biological processes. Classically, MMPs are known as key players in the regulation of the extracellular matrix (ECM), by mediating the responses of cells to their environment. By causing the proteolytic degradation or activation of a cell and the ECM, these proteases influence cell migration, proliferation and cell survival. They have overlapping activities principally on collagen, fibronectin, laminin and elastin. The activity is tightly controlled, being stimulated by inflammatory mediators or growth factors such as IL-1, TNF-α, TGF-β, EGF, FGF and PDGF, and repressed by TGF-α and IL-4. The extracellular activity is inhibited by four different tissue inhibitors of metalloproteinases (TIMP-1–TIMP-4) and by the less selective α_1-antitrypsin (α_1-proteinase inhibitor) and α_2-macroglobulin [1–4].

Twenty-eight matrix metalloproteinases (MMP-1–MMP-28), grouped according to domain structure as gelatinases, collagenases, stromolysins and matrilysin, are zinc-dependent endopeptidases present in small

Table 9.8 Vertebrate matrix metalloproteinases (MMPs).

MMP	Name	Group	Substrate
MMP1	Collagenase-1	Collagenases	Collagens I, II, III, VII, VIII, X, gelatin
MMP2	Gelatinase-A	Gelatinases	Collagens I, II, III, IV, V, VII, X, XI
MMP3	Stromelysin-1	Stromelysins	PG core protein, laminin, fibronectin
MMP7	Matrilysin-1	Matrilysins	Collagens I and IV, elastin, fibronectin, entactin, tenascin, aggrecan, vitronectin, decorin, versican, osteopontin, E-cadherin, Fas ligand, pro-TNF-α
MMP8	Neutrophil collagenase	Collagenases	Collagens I, II and III, aggrecan
MMP9	Gelatinase-B	Gelatinases	Collagens IV, V, XI and XIV, gelatin, elastin, fibronectin, vitronectin, laminin, aggrecan, versican, decorin
MMP10	Stromelysin-2	Stromelysins	Collagens III, IV and V, gelatin, elastin, fibronectin, aggrecan
MMP11	Stromelysin-3	Stromelysins	Collagin IV, gelatin, fibronectin, laminin, insulin-like growth factor-binding protein (IGFBP)
MMP12	Macrophage elastase	Metalloelastases	Collagens I, IV and V, gelatin, elastin, fibronectin, vitronectin, laminin, entactin, osteonectin, aggrecan
MMP13	Collagenase-3	Collagenases	Collagens I, II, III, IV, VI, IX, X and XIV, gelatin, fibronectin
MMP14	MT1-MMP	MT-MMPs	Collagens I, II and III, gelatin, fibronectin, tenascin, vitronectin, laminin, entactin, aggrecan, perlecan
MMP15	MT2-MMP	MT-MMPs	Fibronectin, tenascin, entactin, laminin, aggrecan, perlecan
MMP16	MT3-MMP	MT-MMPs	Collagen III, gelatin, fibronectin, vitronectin, laminin
MMP17	MT4-MMP	MT-MMPs	Gelatin, fibronectin, fibrillin
MMP18	Collagenase-4 (Xenopus)		
MMP19	RASI-1	Other MMPs	Collagen IV, gelatin, tenascin, fibronectin, aggrecan, entactin, laminin
MMP20	Enamelysin	Other MMPs	Amelogenin, aggrecan
MMP21	XMMP (Xenopus)		ND
MMP22	CMMP (chicken)		ND
MMP23	CA-MMP	Other MMPs	ND
MMP24	MT5-MMP	MT-MMPs	ND
MMP25	MT6-MMP	MT-MMPs	Collagen IV, gelatin, fibronectin
MMP26	Endometase, matrilysin-2	Matrilysins	Collagen IV, gelatin, fibronectin
MMP27			ND
MMP28	Epilysin	Other MMPs	ND

ND, not determined.

amounts in resting tissue, which are increased in normal tissue remodelling, and pathological changes including tumour infiltration and tissue repair. Secreted forms can be distinguished from transmembrane forms. Both forms have been implicated in proteolytic regulation of cell communication. TIMP-3 seems to be an inhibitor of the function of so-called ADAMs (adamalysin-like proteinases with metalloproteinase and desintegrin-like domains). Moreover, matrix-associated ADAMs exist that have a thrombospondin-like domain (ADAM-TS). In addition to TIMPs, ADAMs appear to be crucial regulators of MMP activity during skin homoeostasis and disease. For example, TACE, ADAM-10 and ADAM-9 have been shown to be functionally expressed in keratinocytes. Activation of these ADAMs resulted in increased shedding of transmembrane collagen XVII from keratinocytes, indicating that it represents a substrate for ADAMs, thereby regulating extracellular matrix function in the skin during inflammation or blistering diseases [5].

MMP activity seems to be enhanced in patients with inflammatory skin diseases such as psoriasis [6], and MMP-9 activity can be enhanced in human keratinocytes by UV irradiation [7]. Moreover, matrix metalloproteinase gelatinase B (MMP-9) coordinates and effects epithelial regeneration during healing, as demonstrated in a mouse model [8]. MMP-1 also directly influences its own up-regulation by elastin peptides in cultured fibroblasts [9], and fibroblast themselves are capable of generating MMP-2 and MMP-9 [10]. Increased levels of MMP-1, MMP-2 and MMP-13 were observed in lesional skin of inflammatory skin diseases such as stasis dermatitis. In contrast, TIMP-1 and TIMP-2 levels were diminished, indicating that MMPs are directly involved in the regulation of skin remodelling and inflammatory responses during stasis dermatitis [11].

There is little difference in the enzymes present in tissues in acute and chronic wounds, the major enzymes being MMP-2 and MMP-9 (gelatinases and pro-collagenase) and MMP-1 (collagenase) [12,13]. Keratinocyte formation of collagenase occurs rapidly (within 4–6 h) during wound healing, reaching a maximum in uncomplicated wounds on days 3–5, and then declining by about day 9 when repair is complete. Collagenase digests native collagen to short peptide chains, which become susceptible

to degradation by other non-specific proteases. At the wound edges, collagenase prepares the extracellular matrix bed for keratinocytes, and may contribute to keratinocyte migration [14–17]. There is also a decrease in the amount of TIMPs, the inhibitors of MMPs, in chronic wounds [15,18]. In addition, cytokines and tissue degradation products also contribute to impairment of healing. Fluid from acute wounds stimulates fibroblast proliferation, proteinase expression, matrix element formation and contains the cytokines PDGF and βFGF [19,20].

Lysosomal mediators

Many mediators of inflammation, particularly tissue-destructive enzymes, are derived from cellular lysosomes. Released into the cytoplasm, they result in autolysis. Extracellularly, they degrade tissue elements (e.g. collagen and elastin) and dead cells [1,2]. The enzymes also activate further mediators of inflammation in plasma or tissue fluids (e.g. the generation of kinins from kallikrein induced by the trypsin-like activity of the lysosomal proteases). Such proteases can also cleave complement C3 to activate the alternative pathway of complement.

Lysosomes are found in nearly all living cells, and comprise a semipermeable membrane surrounding a small vacuole, which contains acidic hydrolases and other enzymes and substances. There is some variation in the lysosomal substances to be found in each type of cell [1,2]. In the developing neutrophil, lysosomes are derived from the Golgi complex; in macrophages and some other cells including keratinocytes, it is believed that they are derived from the rough endoplasmic reticulum and are transferred to special areas of the smooth endoplasmic reticulum situated within the Golgi complex.

Epidermal cells have lysosomes that contain acid phosphatases, aryl sulphatase, several proteases including the acidic protease cathepsin D, and other enzymes [3–5]. One of the difficulties in examining these enzymes is the presence of inhibitors, which inactivate enzymes of the epidermal cells, and of the dermis and plasma.

The lysosomes participate in the phagocytic functions of epidermal cells, particularly active during regeneration after wounds. They are also involved in pigmentation, as melanosomes are transferred to keratinocytes by a process analogous to phagocytosis. Epidermal cell lysosomes are involved in keratinization, responses to UV light and neoplasia [3,6]. Lysosomes also appear to be involved in sebaceous secretion, as they enlarge and rupture in the process of cell disintegration.

During inflammation, as induced by a cantharidin blister, the increase in extracellular acid phosphatase and protease is attributed to release from epidermal lysosomes, because it occurs before leukocyte infiltration and is more concentrated locally than in serum. The leukocytes, particularly neutrophils, entering the lesion may be attracted by chemotactic substances generated by the activity of acid or neutral proteases, which cleave complement, kallikrein or Hageman factor. A neutral proteinase extracted from rabbit skin induced wealing within 15 min and acute neutrophil infiltration within 18 h when injected into the skin of rabbits, indicating the possible participation of epidermal cell lysosome enzymes in inflammation [7].

Respiratory burst and oxygen-dependent cytotoxicity

At high concentrations, free radicals and radical derived, non-radical reactive species are hazardous for living organisms and damage all major cellular constituents. However, at moderate concentrations, NO, superoxide anion and related reactive oxygen species (ROS) play an important part as regulatory mediators in signalling processes. Many of the ROS-mediated responses actually protect cells against oxidative stress and re-establish 'redox homoeostasis'. Higher organisms, however, have also evolved the use of NO and ROS as signalling molecules for other physiological functions. These include regulation of vascular tone, monitoring of oxygen tension in the control of ventilation and erythropoietin production, and signal transduction from membrane receptors in various physiological processes. Activation is caused by membrane stimulation, phagocytosis, immune complexes or aggregated immunoglobulins, both IgG and IgA, and IFN-γ. The generated oxygen radicals may exist only for seconds; they are potent toxic agents, although their contribution may not always be significant [1–4].

NO and ROS are typically generated by tightly regulated enzymes such as NO synthase (NOS) and NADPH oxidase, or from less well-regulated sources such as the mitochondrial electron-transport chain. The massive production of antimicrobial and tumoricidal ROS in an inflammatory environment is called the 'oxidative burst' and has an important role as a first line of defence against environmental pathogens. The physiological relevance of NADPH oxidase as a defensive agent is suggested by the observation that mice lacking the NADPH oxidase components gp91phox or p47 exhibit reduced resistance to infection [5–7].

Various forms ('species') of activated oxygen and intermediates exist: superoxide anion O^-, a precursor of toxic products, H_2O_2, MPO particularly formed in phagocytes, and hydroxyl ($HO^\bullet$) and singlet oxygen ($^\bullet O_2$) radicals, which give rise to chemiluminescence. Oxygen (O_2) alone is not toxic. H_2O_2 in small amounts is a normal cell signal molecule. Both may be converted to reactive factors. H_2O_2, particularly in the presence of iron, is converted to the very reactive hydroxyl radical $HO^\bullet$. The $HO^\bullet$ mediates a chain reaction with lipid and cyclic peroxides as the end-products, and causes cell death and membrane lysis. Furthermore, the superoxide anion of the human monocyte oxidizes low-density lipoprotein and converts it into a cytotoxin, which damages fibroblast cell lines [8].

In mitochondria, ROS are generated as undesirable side products of the oxidative energy metabolism. An excessive and/or sustained increase in ROS production has been implicated in the pathogenesis of autoimmune diseases, cancer, diabetes mellitus, atherosclerosis, neurodegenerative diseases, rheumatoid arthritis, ischaemia/reperfusion injury, obstructive sleep apnoea and many other diseases. In addition, free radicals have been implicated in the mechanism of skin ageing. There is growing evidence that ageing involves, in addition, progressive changes in free radical-mediated regulatory processes that result in altered gene expression. Finally, a crucial role of oxygen-dependent cytotoxicity in cutaneous carcinogenesis, with a decreased control of DNA synthesis and cell division, has been described [9,10].

There is a growing evidence that oxidative stress has a pivotal role in various diseases such as inflammation, tumour growth, metabolic diseases, atherosclerosis and thrombosis, and infection such as HIV. 'Mitochondrial oxidative stress' seems to be crucial in metabolic diseases and cancer, resulting in a pro-oxidative shift in the systemic thiol–disulphide redox state and elevated ROS production. In contrast, during 'inflammatory oxidative conditions', an excessive stimulation of NADPH oxidase activity by cytokines or other agents can be observed. Here, increased ROS levels or changes in intracellular glutathione levels are often associated with pathological changes indicative of a dysregulation of signal cascaded and/or gene expression, exemplified by altered expression of cell adhesion molecules [11,12].

During inflammation, NO and ROS are capable of killing microorganisms, thereby contributing to host defence. The generation of their activities is associated with the respiratory burst when cells are exposed to foreign substances. In the skin, UV radiation may—alone or following exposure to phototoxic or photoallergic chemicals—induce the activation of NO and ROS species, leading to the production of various inflammatory mediators, including cytokines and kinins. During psoralen therapy in psoriasis, the skin is exposed to UV radiation, which leads to the production of radicals. Similar effects are observed in patients with porphyria who have been exposed to UV light. In general, the poly (ADP-ribose) polymerase (PARP) pathway appears to have an important role in the regulation of inflammatory processes in the skin [13]. Some of the inflammatory activity of monocyte–macrophages, neutrophils and eosinophils is caused by free radicals. There is growing evidence that the biochemical basis for the mechanism of action of dithranol at the molecular level is related to the redox activity leading to the production of active oxygen species, which include singlet oxygen, and superoxide anion and hydroxyl

radical [14]. ROS molecules have also been implicated in regulating leukocyte–endothelial interactions. For example, adhesion of neutrophils to endothelial cells involves the stimulation of ICAM-1, and L-selectin via ROS activation [15,16].

There also exist important physiological aspects of redox regulation. The production of superoxide and NO, respectively, by these enzymes is strictly regulated by cytokines and other inflammatory mediators. Subsequently, the resulting oxidative species act as secondary messengers to control a variety of physiological responses such as vascular relaxation or hormone production [17].

Enhancement of signal transduction pathways by stimulation of ROS leads to up-regulation of expression or receptors involved in inflammation, such as the angiotensin II receptor and the EGF receptor. Furthermore, H_2O_2 has a relatively long half-life and may directly cross the cell membrane to modulate cell function. For example, ROS from activated macrophages and neutrophils may contribute decisively to the activation of antigen-specific immune responses to pathogens. Signalling pathways involving JNK, p38 MAPK, and the transcription factors AP-1 and NF-kB are particularly responsive to redox regulation. Thus, various intracellular signalling cascades are modulated by ROS molecules [18–20].

The production of ROS by non-phagocytic NADPH oxidase isoforms also plays a part in the regulation of the intracellular signalling cascade within non-phagocytic cells, including fibroblasts. Moreover, activated macrophages and neutrophils can produce large amounts of superoxide and its derivatives via the phagocytic isoform of NADPH oxidase. Stimulated neutrophils and macrophages also generate singlet oxygen by reactions that involve either MPO or NADPH oxidase, respectively. Importantly, physiologically relevant ROS concentrations can also modulate redox-sensitive signal cascades and enhance immunological functions of lymphocytes [21,22].

With regard to achieving a balanced inflammatory response, the activity of free radicals has to be rapidly terminated. Therefore, various endogenous and exogenous molecules rapidly inactivate the function of extracellular oxygen species, such as superoxide dismutase, catalase and glutathione peroxidase, free α-tocopherols and antioxidants.

In summary, ROS generated by many cells in the immune system and the skin can modulate inflammation and infection. Clinical interventions with ROS-modulating agents may help to attenuate oxidative stress that is directly attributable to inflammation.

Nitric oxide

Over the last few years, NO has been established as a versatile factor in the immune system. NO is involved in the pathophysiology and control of inflammation, infectious diseases, autoimmune processes, tumorigenesis and chronic degenerative diseases, and may be of considerable

Table 9.9 Pathophysiological role of nitric oxide in human skin.

Disease	Functions
Contact dermatitis (CD)	Modified expression in allergic and irritant contact dermatitis NOS expression in irritant CD: focal staining in epidermis and dermis
Atopic dermatitis	Clinical application of NOS inhibitor for atopic dermatitis Enhanced staining in the spongiotic area of the epidermis and of the perivascular region (inflammatory cells?)
Acute urticaria	NOS expression co-localized with inflammatory cytokines and CD23
Psoriasis	iNOS mRNA and IL-8 mRNA co-localize in keratinocytes of psoriatic skin Overexpression of iNOS in keratinocytes of psoriatic lesions NO may account for reduced incidence of infections in psoriasis
Lupus erythematosus (LE)	iNOS expression in cuneous and systemic LE. Aberrant timing of UVA-induced iNOS expression in LE patients Enhanced NO production, endothelial and keratinocyte iNOS production in LE patients
Systemic sclerosis (SSc)	Increased iNOS and eNOS expression by endothelial cells in SSc Enhanced iNOS synthesis in SSc patients Increased NO production and iNOS synthesis in mononuclear cells, endothelial cells and fibroblasts in lesional skin of SSc
Stevens–Johnson syndrome (SJS)/ toxic epidermal necrolysis (TEN)	Expression of iNOS in inflammatory cells of SJS and TEN
Sunburn erythema	Topical application of NO inhibitors protect from UVB-induced erythema UVB acts as a potent stimulator of eNOS and xanthine oxidase in human keratinocytes
Leg ulcers	Increased NOS expression in chronic leg ulcers Increased NOS activity in diabetic foot ulcers (macrophages)
Burn injury	Enhanced NO production in burning skin lesions Expression of iNOS in burn wounds (keratinocytes, capillary endothelium)
Tinea pedis	Successful treatment with a NO-liberating cream (acidified nitrate)
Molluscum contagiosum	Successful treatment with a NO-liberating cream (acidified nitrate)

eNOS, endothelial nitric oxide synthase; iNOS, inducible nitric oxide synthase; NO, nitric oxide; NOS, nitric oxide synthase.

importance in a variety of skin diseases (Table 9.9). Originally, NO was perceived as a product of macrophages activated by cytokines and generated from the amino acid L-arginine by the enzymatic activity of inducible NO synthase (iNOS or NOS2). It is now known that NO functions are considerably more complex. NO has a wide distribution in immune cells such as dendritic cells, eosinophils and neutrophils, Kupffer cells, macrophages, mast cells, microglial and NK cells, as well as in other cells that may be involved in immune reactions, such as chondrocytes, endothelial cells, epithelial cells, hepatocytes, mesangial cells, Schwann cells and vascular smooth muscle cells [1,2]. Furthermore, additionally to iNOS, different isoforms of NO synthase have been identified—endothelial NOS (eNOS or NOS3), neuronal NOS (nNOS or NOS1), both also known as constitutive NOS (cNOS)—that all operate within the immune system and catalyse the same reaction, conversion of L-arginine to NO [2]. Importantly, the activity of NO is not restricted to the site of production. As a gas it is highly diffusable and the ability of NO to form complexes allow this molecule to bridge long distances. Circulating nitrite (NO_2^-), a stable product of the NOS reaction, can be reduced to $^{\bullet}NO$, which is the substrate for the peroxidase pathways of eosinophils and neutrophils, leading to the formation of novel NO-derived oxidants at distant sites [3,4]. Therefore, NOS-negative immune cells can both produce NO and become targets of NO action.

The expression of iNOS is regulated by cytokines, while nNOS and eNOS, constitutively expressed in the cell, are activated by elevation of intracellular Ca^{2+} concentration and binding of calmodulin. In low concentrations, NO itself activates NF-κB and up-regulates iNOS, whereas high concentrations exert the opposite effect and may help to suppress NO overproduction. All three NOS isoforms are only active as homodimers. Another factor that determines NOS activity is the availability of its substrate, arginine. Generation of NO (e.g. by macrophages) depends on extracellular L-arginine even when an adequate level of intracellular arginine is present [2,5].

NO possesses many signalling functions. In the immune system, use of NOS inhibitors, NO donors and NOS knockout mice have provided evidence that NO triggers a broad spectrum of processes. NO inhibits the adhesion of platelets and leukocytes to endothelium [6], but the underlying mechanisms are not understood. It has been shown that NO variably down-regulates the expression of endothelial cell adhesion molecules such as E-selectin,

P-selectin, ICAM-1 and VCAM-1 [7,8]. NO can inhibit the expression of integrins such as LFA-1 on neutrophils [6,9,10] and, interestingly, influence the chemotactic response of leukocytes by modulating the production and activity of chemokines [2,11–13]. Additionally, NO signalling is involved in differentiation, proliferation and apoptosis of immune cells. In the thymus, deletion of T-cell receptor-activated double-positive thymocytes is, amongst other things, dependent on thymic stromal cell released NO [14–18].

Analysis of experimental autoimmune arthritis (EAA), encephalomyelitis (EAE), uveitis (EAU) and nephritis (EAN) in rodents has provided evidence that iNOS functions as a negative feedback regulator of autoimmune Th1 cell responses and thereby protects the host against immunopathological sequelae [1,19]. However, it has to be pointed out that results obtained with iNOS knockout mice, and mice treated with NOS inhibitors, do not support this view [19–21]. A possible explanation derives from work by McCartney-Francis *et al.* [21] on the streptococcal cell wall-induced arthritis model in rats, in which eNOS and nNOS appear to mediate the acute and chronic erosive joint disease, whereas iNOS helped to limit inflammation. Furthermore, a protective anti-inflammatory function of iNOS has been demonstrated in a T-cell-dependent and B-cell-mediated myasthenia gravis-like autoimmune disease [22], in local carrageenan-induced pleurisy [23] and in TNF-induced shock in mice [24].

Histamine

Histamine (2-[4-imidazolyl]ethylamine) was the first mediator of anaphylaxis to be identified, in 1932. Its pharmacological description as an endogenous substance was even earlier, in 1910 [1]. Histamine is synthesized from histidine by the specific enzyme L-histidine decarboxylase (HDC). It can be generated by some neurones, mast cells, basophils and platelets, where it is intracellularly stored in vesicles, and rapidly released upon stimulation. However, it has been shown that HDC is inducible in a variety of tissues by a mechanism coupled with the cytokine network, leading to non-classical histamine generation. Histamine, like tryptase, is one of the mediators rapidly released from mast cells during inflammation and hypersensitivity. However, recent knowledge clearly indicates that histamine is not the only inflammatory mediator released by mast cells.

Histamine exerts a powerful effect on blood vessels, causing smooth muscle contraction, vasodilatation and plasma extravasation from capillaries. Classically, histamine is released upon an antigen–antibody reaction with IgE bridging on the cell surface of mast cells. Further studies have shown that histamine release can be also triggered in an IgE-independent manner (e.g. by direct interaction of molecules with cell membrane-associated G proteins or transmembrane lipid mediators). Release of

high concentrations of histamine, as during immediate-type hypersensitivity, leads to systemic shock symptoms such as vasodilatation, oedema, smooth muscle contraction, decreased blood pressure and subsequent cardiopulmonary dysfunction. Histamine characteristically mediates itch responses, especially at the beginning of an inflammatory response by activating histamine receptors on cutaneous sensory nerves. Interestingly, histamine does not appear to be the crucial mediator of itch in atopic dermatitis patients. Thus, different mediators seem to be responsible for mediating pruritus in different inflammatory skin diseases. For example, cytokines or proteinases released during the inflammatory response may activate nerve fibres [2].

Additionally, histamine can exert direct effects on immune cells, endothelial cells and primary efferent nerve fibres via activation of histamine receptors. Four histamine receptors (HRs) have been cloned and characterized so far, which belong to the G protein-coupled receptor family with seven transmembrane domains (H_1–H_4).

Except for H_3R, which is exclusively expressed in the brain, histamine receptors are widely distributed in humans. Thus, H_4R is located in the thymus, small intestine, liver spleen, colon, bone marrow, and on peripheral blood leukocytes [3]. H_1R is found to be expressed by tissues including mammalian brain, retina, airway, skin [4], genitourinary tract, vascular smooth muscle, adrenal medulla, liver, endothelial cells, astrocytoma cells, cerebral microvessels and lymphocytes [5]. H_2R shows a similar expression pattern to H_1R, being detected in mammalian brain, pulmonary system, cardiovascular system, intestine, skin [4], endocrine and exocrine glands [6] and the immune system, in T cells [7,8], macrophage–monocytes and lymphocytes [9].

In the skin, histamine receptor-1 is localized on fibroblasts [10] and endothelial cells [11], and both H_1R and H_2R are expressed on keratinocytes [12,13]. After histamine activation, H_1R mediates several vascular responses, such as increased vascular permeability, vasodilatation and constriction of smooth muscle cells. H_2R exerts various effects on immune cells, such as mediator release from basophils, neutrophils and lymphocytes. Interestingly, H_2R augments T-suppressor cell activity, whereas H_1R activates regulatory T cells with contradictory effects. H_3R function is implicated in neuroregulation in the central nervous system.

Histamine action can be terminated by receptor down-regulation, enzymes and suppressor factors. One of the latter is histamine suppressor factor (HSF), synthesized by activated lymphocytes. Histamine also stimulates the formation by monocytes of two substances inhibiting lymphocyte migration [14]. Apart from these direct activities, histamine also enhances expression of cell receptors, and either inhibits the outgrowth of epidermis from skin slices *in vitro* or stimulates it, depending upon concentration [15]. Thus, histamine may contribute to both pro-inflammatory and to regenerative changes in the tissue, depending on the concentration of histamine, of degrading enzymes and of the receptor repertoire of the cells involved.

Histamine formation and release is regulated by several factors other than IgE, such as cytokines, prostaglandins, leukotrienes and neuropeptides. In contrast, histamine activity regulates formation of cytokines. For example, IL-1, IL-3, IL-5 and IL-8 are capable of increasing histamine synthesis and release. Histamine, through the H_2 receptor, reduces formation of IL-1 and TNF-α from endotoxin-stimulated cells in human monocytes [16]. Histamine inhibits formation of IL-2, the critical interleukin promoting formation of T-cell clones, and possibly indirectly through IL-2 inhibition it also reduces IFN-γ activity [16]. Histamine also stimulates IL-6 synthesis [16]. Thus, histamine contributes to cytokine participation in inflammation and allergy. Some cytokines are potent histamine-releasing agents, particularly the chemokine MCP-1, and to a lesser extent RANTES, MIP-1α and MIP-1β [17].

It been shown recently that histamine regulates T-cell and antibody responses by differential expression of H_1 and H_2 receptors [8]; histamine enhances Th1-type responses by triggering the histamine receptor type 1, whereas both Th1- and Th2-type responses are negatively regulated by H_2R via the activation of different intracellular signalling pathways. In mice, deletion of H_1R results in suppression of IFN-γ and dominant secretion of Th2 cytokines (IL-4 and IL-13). Mutant mice lacking H_2R showed up-regulation of both Th1 and Th2 cytokines. Mice lacking H_1R displayed increased specific antibody responses, with increased IgE and IgG1, IgG2b and IgG3, compared with mice lacking H_2R. These findings indicate an important regulatory mechanism in the control of inflammatory and immune functions through release of histamine [8].

Platelet-activating factor

PAF (1-*O*-alkyl-2-acetyl-sn-glycero-3-phosphocholine) is a phospholipid with diverse biological functions, particularly during inflammation. It is rapidly synthesized on stimulation, probably by activation of phospholipase A_2 hydrolysing fatty acid acyl groups as in arachidonic acid, followed by reacetylation. PAF binds to and activates a specific PAF receptor that is expressed by many inflammatory cells. Inactivation of PAF is regulated primarily by the rate of degradation, which is catalysed by PAF-acetylhydrolase. Beside its role as an inflammatory mediator, PAF is also capable of functioning as a hormone and transmitter in the nervous system. PAF is formed concomitantly with other arachidonic acid derivatives, the prostaglandins and leukotrienes.

In humans, PAF is synthesized by monocyte–macrophages, neutrophils, eosinophils, endothelial cells, mast cells, basophils and platelets, in response to immunological, infective or acute inflammatory mediators.

PAF stimulates platelet aggregation, and synthesis and release of mediators [1], such as serotonin, thromboxane and PAF, within minutes of activation. In neutrophils, PAF induces chemokinesis (activated mobility), chemotaxis (attraction), secretion of lysosomal products, synthesis of 12-HETE and LTB_4 and initiation of the respiratory burst [2,3]. In addition, PAF activates monocytes, in which PAF signals NF-κB translocation to the nucleus and alterations in gene expression and other functional responses [4]. Eosinophils are particularly responsive to PAF, especially *in vivo*, as are endothelial cells, in which PAF mediates contraction with resultant transient increased vascular permeability in post-capillary venules, followed by a late phase of erythema. In humans, intradermal injection has been shown to induce local eosinophilia [5] and a significant neutrophilia with a late-phase erythema [6].

PAF signals the priming and activation of leukocytes at the cell surface of activated human microvascular endothelial cells after activation. Moreover, PAF and the cell adhesion molecule P-selectin are coordinately displayed on the plasma membranes of stimulated human endothelial cells. P-selectin tethers the leukocyte to the endothelial cell, which allows PAF to bind to its receptors on the endothelial cell and on the polymorphonuclear leukocyte. This constitutes a form of juxtacrine signalling that may be a general way to spatially restrict the actions of a potent pleiotropic mediator such as PAF [7].

The PAF-receptor belongs to a subfamily of G protein-coupled receptors with seven transmembrane domains. It is expressed by many immune cells as well as epithelial cells. PAF-induced signalling is mediated via NF-κB and protein kinase C.

PAF-transgenic animals show increased mortality when challenged with endotoxin, develop melanocytic tumours of the skin, and have increased bronchial hyperreactivity. In the skin, PAF is involved in growth of melanocytic tumours and is known to mediate skin inflammation [8].

Dysregulated signalling by PAF may result in disease states. For example, developmental deficiency of PAF acetylhydrolase may lead to unregulated pro-inflammatory signalling by PAF in infants with neonatal necrotizing enterocolitis [9]. Dysregulated signalling by PAF also contributes to the severity of asthma in patients genetically deficient in PAF acetylhydrolase.

Recently, strategies with exogenous recombinant PAF acetylhydrolase or PAF receptor antagonists demonstrated that PAF is a juxtacrine signalling molecule at the surfaces of activated human platelets, which—like endothelial cells—are critical in cell–cell interactions in inflammatory and thrombotic responses [10].

Prostaglandins and leukotrienes

Prostaglandins and thromboxanes

Prostaglandins (PG) and thromboxanes (TX) comprise a diverse family of autacoids, whose synthesis is initiated by cyclo-oxygenase-mediated metabolism of the unsaturated 20-carbon fatty acid arachidonic acid to the endoperoxide intermediates, PGG_2 and PGH_2 [1]. Prostaglandins were first discovered in the 1930s by Von Euler, who investigated the blood pressure lowering potential of compounds from semen. Prostaglandins are products of cyclo-oxygenase activity on arachidonic acid, and to a much lesser extent other unsaturated fatty acids, and through intermediate products release PGE_2 and PGD_2 by different isomerases, and $PGF_{2\alpha}$ by a reductase. They are synthesized by many cell types. This leads to generation of five bioactive prostanoids: TXA_2, PGD_2, PGE_2, PGF_2 and PGI_2. These mediators are involved in processes such as inflammation, tumour growth and cardiovascular homoeostasis. Thus, cyclo-oxygenase-inhibiting agents are of potential use in a wide range of diseases. Each of the prostanoids is generated via activation of specific synthetases. Because prostanoids are either chemically or metabollically unstable, it is believed that they exert their effects very locally [2].

After release, they exert their effects by binding and activating a subfamily of eight heptical G protein-coupled receptors, defined as EP (four subtypes for PGE_2) and FP, DP, IP or TP for PGF_2, PGD_2, $PGI_{2\alpha}$ and TXA_2, respectively [3]. All these are extremely potent mediators of inflammation, active at very low concentrations. Although each receptor subtype shows the highest affinity to the prospective ligand, cross-reactivity between the family members can be observed [4]. Moreover, splice variants of certain PG receptors can be observed, leading to altered receptor function and probably disease. PG receptors signal via stimulation of IP-3, diacylglycerol, and inhibition of adenylyl cyclase or Gi.

Prostanoids and their receptors are widely distributed and have a biological role in many cell types. Prostanoids may exert synergistic but also contradictory effects on specific cell types, such as epithelial cells or smooth muscle cells. In the airways, for example, PGE_2 has a relaxing effect, whereas $PGI_{2\alpha}$ is a potent vasoconstrictor. PGE_2 shows strong immunosuppressive effects on T cells and facilitates IgE switching in B cells by synergistically acting with LPS or IL-4. $PGI_{2\alpha}$ contracts smooth muscle, and induces broncho- and vasoconstriction. It also inhibits PGE_2-mediated cutaneous permeability.

Thus, $PGI_{2\alpha}$ counteracts PGE_2 activity. In normal tissues, concentrations of both mediators seem to be balanced. Under pathophysiological conditions, however, the vasodilatator PGE_2 is increased, resulting in pro-inflammatory effects. In contrast, this balance is restored during tissue regeneration.

In the skin, PGE_2 induces vasodilatation and potentiates the pro-inflammatory effects of histamine, serotonin and bradykinin, inducing oedema, plasma extravasation, pruritus and pain [5]. Moreover, PGE_2 has important immunoregulatory functions by decreasing proliferation of Th1 cells or by stimulating the synthesis of IFN-γ [6]. This has clinical implications; for example, in patients with atopic dermatitis, who show increased synthesis of PGE_2 in peripheral blood monocytes, decreased Th1 lymphocyte proliferation and reduced synthesis of IFN-γ. PGE_2 also contributes to the synthesis of IL-4, thereby regulating IgE synthesis and affecting the Th1–Th2 balance [7,8].

In vivo, prostaglandins contribute to cutaneous inflammation, such as contact dermatitis or UV-induced inflammation, and potentiate the itch induced by histamine.

Prostacyclin (PGI_2), the common designation of epoprostenol, is the main metabolic product of arachidonic acid in vascular tissue, particularly in the endothelium [9]. It is an unstable substance with a half-life in blood of 2–3 min. PGI_2 is the most potent endogenous inhibitor of platelet aggregation, and also disperses aggregated platelets, inhibits thrombus formation, increases cutaneous bleeding time and is a strong vasodilator.

12-HETE and 15-HETE are products of arachidonic acid, converted by the 12- and 15-lipoxygenase enzymes via intermediate peroxy forms. Both are formed by fibroblasts and keratinocytes. 12-HETE is pro-inflammatory, attracting neutrophils, eosinophils and monocytes *in vitro*, and aggregates leukocytes [10]. It stimulates epidermal DNA synthesis. When applied to skin, 12-HETE induces erythema followed by neutrophil and monocyte infiltration, but not eosinophil infiltration [11]. Physiological amounts occur in psoriatic skin and after UV irradiation. As it is much less potent than LTB_4 and other chemoattractants, the significance of 12-HETE in lesions is unknown. 15-HETE is the main arachidonic acid metabolite in homogenized dermis, and is almost certainly derived from fibroblasts; it inhibits mitogen-induced DNA synthesis by T lymphocytes and 12-HETE formation by platelets and keratinocytes. It is therefore anti-inflammatory, regulating the pro-inflammatory changes mediated by 12-HETE. Keratinocytes also form 15-HETE, but the significance of this to control 12-HETE production appears unknown [12–14]. Pharmacological and genetic approaches have further defined the role of prostaglandin receptors in inflammation and immune response. EP2-deficient

mice show a loss of PGE_2-induced bronchodilatation, and EP3-deficient mice demonstrate impaired febrile responses to pyrogens and mucosal integrity. A decreased inflammatory response can be observed in EP4- and IP-deficient mice, indicating a direct role of this receptor during inflammation [15,16]. PGI_2, via IP activation, seems to be critically involved in acute oedematous responses [17]. PG receptors such as IP, EP1, EP3 and EP4 are expressed by sensory neurones and contribute to pain during inflammation.

Allergic responses are associated with an increase in prostanoid secretion. PGD_2 is a major PG released by mast cells during allergen challenge, and is abundantly produced in atopic diseases such as atopic dermatitis and asthma.

In addition to PG transmembrane receptors, the nuclear peroxisome proliferator-activated receptor-γ (PPARγ) has been identified as a prostanoid receptor. Interestingly, PPARγ can inactivate NF-κB, thereby modulating inflammatory responses [18].

Prostanoid synthesis critically depends on the action of cyclo-oxygenase. Two isoforms exist: COX-1 and COX-2. Whereas COX-1 is localized in the endoplasmatic reticulum and close to the plasma membrane, COX-2 can be found in the perinuclear region. COX-1 is constitutively expressed by most cells but can be slightly increased by growth factors, cytokines or tumour-promoting agents [19]. Although COX-1 was not thought to be involved in inflammation, COX-1-deficient mice display reduced experimentally induced inflammation such as ear oedema and allergic airway disease. COX-2 expression is inducible by various factors such as cytokines, growth factors and endotoxins. Surprisingly, COX-2-deficient mice do not exhibit marked differences in inflammatory responses as compared to wild-type mice. Thus, COX-1 may contribute more to inflammation than previously thought. Overexpression of the COX-2 gene in epithelial cells resulted in increased adhesion to the extracellular matrix, diminished E-cadherin expression, enhanced Bcl-2 levels and enhanced resistance to butyrate-induced apoptosis. Moreover, COX-1 appears to be essential for endothelial tube formation, whereas COX-2 is essential for the production of angiogenic factors. Thus, cyclo-oxygenases exert several effects on endothelial cells during inflammation and tumour growth [20].

Recently, a number of PG receptor compounds and COX-2 inhibitors have been developed. Most of these compounds are not selective but activate or inactivate several receptor subtypes [21,22]. The classic COX-inhibitor, aspirin, blocks both, but preferentially COX-1 over COX-2. In contrast, COX-2 inhibitors such as rofecoxib and celecoxib are effective anti-inflammatory agents, while showing considerably less gastrotoxicity than COX-1 inhibitors and other non-steroidal anti-inflammatory drugs.

Leukotrienes

Cleavage of arachidonic acid by 5-lipoxygenase (5-LO) releases a product that on further degradation results in several chemically related leukotrienes. The leukotrienes [21–24] are divisible chemically and biologically into two substances: LTB_4 and LTC_4. These may be further transformed into metabolites LTD_4 and LTE_4. They are formed by many cell types [21,22]. LTB_4 aggregates, attracts and stimulates chemokinesis of polymorphonuclear leukocytes, and induces exudation of plasma, but is relatively weak at contracting smooth muscle. Leukotrienes induce prolonged contraction of smooth muscle, and hence constriction of small airways. They stimulate mucus secretion and induce post-capillary oedema. LTB_4 has been isolated from the skin of patients with psoriasis and atopic dermatitis.

The 5-LO pathway leading to leukotriene formation plays a pivotal part in the pro-inflammatory cascade during inflammation [22]. For example, LTB_4 promotes neutrophil chemotaxis and adhesion to vascular endothelium through specific integrins. The cysteinyl leukotrienes cause plasma leakage from post-capillary venules and enhance mucus secretion. LTD_4 and another 5-LO-derived eicosanoid, 5-oxo-ETE, are eosinophil chemoattractants. The use of murine models in which specific genes such as '5-lipoxygenase' of the leukotriene pathway have been deleted by homologous recombination firmly support their crucial role in allergic inflammation.

5-LO has been identified as an inducer of ROS production in lymphocytes. However, our knowledge on the physiological relevance of this in redox signalling is still incomplete. The oxidized metabolites generated by 5-LO have been found to change the intracellular redox balance and to induce signal transduction pathways and gene expression. LTB_4 controls cytotoxic effector T-cell recruitment to inflamed tissues [23]. Moreover, Th2 cytokines coordinately regulate IgE-dependent cysteinyl leukotriene production by human mast cells; IL-4 induces leukotriene C4 synthase expression, and thereby regulates T-cell–mast cell interactions [24–26].

Leukotrienes exert theit effects by binding and activating specific heptical G protein-coupled receptors (GPCRs). Four receptor subtypes have been cloned and characterized. The high-affinity B-LT1 receptor on leukocytes binds LTB_4 in the subnanomolar range, and stimulates neutrophil secretion. Two subtypes of cysteinyl leukotriene receptors, CysLT1 and CysLT2, mediate the actions of LTC_4 and LTD_4. CysLT1 is found on airway smooth muscle cells and vascular endothelial cells, and promotes bronchoconstriction and up-regulation of endothelial cell adhesion molecules. However, our knowledge of the role of leukotrienes receptors under physiological and pathophysiological conditions in these tissues is far from complete.

The lipoxins are chemically and functionally different from the leukotrienes. Although LXA_4 and LXB_4 are similar in structure, these mediators display biological activities that are quite distinct. LXA_4 interactions with neutrophils involve binding sites that are not recognized by LXB_4 [27,28]. LXB_4 is a potent agonist for stimulating proliferation and differentiation of granulocyte–monocyte colonies from human mononuclear cells [29], and increases the S-phase in the cell cycle and enhances nuclear protein kinase C activity [30]; such effects have not been reported for LXA_4. However, both LXA_4 and LXB_4 selectively stimulate human peripheral blood monocytes [31] and enhance growth of myeloid progenitor cells [32].

There is increasing interest in a potential therapeutic effect of leukotriene modifiers or antileukotrienes such as 5-LO inhibitors (zileuton [Zyflo]) and CysLT1 receptor antagonists (zafirlukast [Accolate] or montelukast [Singulair]). They have been used clinically in long-term studies in asthma therapy [33]. However, there is still much debate about their clinical efficacy. Their effectiveness in exercise-induced asthma and aspirin-intolerant asthma is well documented. Clinical trials show bronchodilatory effects beyond those provided by β-agonists, as well as reduced eosinophil numbers in the sputum. On the other hand, a number of non-responding patients have been observed. This may be explained—at least in part—by non-leukotriene-dependent asthma mechanisms or by pharmacogenetic factors. Thus, leukotriene modulating agents may provide novel tools for the treatment of certain inflammatory diseases. For instance, a steroid-sparing benefit in mild to moderate asthma was described. However, whether antileukotriene agents may be of help for the treatment of inflammatory skin diseases such as urticaria and allergic reactions is still unclear [34].

Table 9.10 Neuromediators in the skin; sources and target cells of neurotransmitters/neuropeptides.

Neuromediator	Receptor	Source	Target cells/function
Acetylcholine	Nicotinergic and muscarinergic acetylcholine receptors	Autonomic cholinergic nerves, keratinocytes, lymphocytes, melanocytes	Innervation of sweat glands and arteriovenous anastomoses; keratinocyte and lymphocyte differentiation; proliferation, adhesion; migration
Catecholamine, noradrenaline	Adrenergic receptors	Autonomic adrenergic nerves, keratinocytes, melanocytes	Innervation of blood vessels, arrector pili muscles; pain transmission; regulation of activity of natural killer cells and monocytes; apoptosis induction in lymphocytes
Substance P	Tachykinin (neurokinin) receptors (NK1-, NK2-, NK3R)	Sensory nerve fibres	Mediates skin erythema, oedema, pruritus; up-regulates cell adhesion molecule expession on keratinocytes and endothelial cells; release of Il-8, TNF-α, histamine, leukotriene B4, prostaglandin D_2
Neurokinin A	Tachykinin (neurokinin) receptors	Sensory nerve fibres	Up-regulation of keratinocyte nerve growth factor expression
VIP	VPAC receptors	Sensory nerve fibres Merkel cells	Sweat secretion, vasodilatation; proliferation, migration of keratinocytes; histamine release from mast cells
PACAP	VPAC receptors	Autonomic and sensory nerve fibres, lymphocytes, dermal endothelial cells	Vasodilatation, immunomodulatory effect on T cells and macrophages; modulates mast cell function, inhibits antigen-induced apoptosis on mature T lymphocytes, down-regulates pro-inflammatory cytokines and chemokines in T cells, up-regulates cytokines and cell adhesion molecules in dermal microvascular endothelial cells
CGRP	CGRP receptors	Sensory nerve fibres	Keratinocyte and endothelial cell proliferation, stimulates cytokine production
POMC	Melanocortin receptors	Melanocytes, keratinocytes, endothelial cells, Langerhans' cells, mast cells, fibroblasts, monocytes, macrophages	Antagonizes effects of pro-inflammatory cytokines (IL-1α, IL-1β, IL-6, TNF-α, endotoxins); up-regulates Il-10; releases histamine from mast cells; regulates dendritic cell function

Neuromediators

Accumulating evidence indicates the existence of an interactive network between the cutaneous neuronal system, the neuroendocrine axis and the immune system. Neurocutaneous interactions influence a variety of physiological and pathophysiological biological functions in the skin, such as development, growth, differentiation, immunity, inflammation, pruritus and wound healing (Table 9.10). Different types of cutaneous nerve fibre release neuromediators and activate specific receptors on target cells in the skin, such as keratinocytes, mast cells, Langerhans' cells, microvascular endothelial cells, fibroblasts and infiltrating immune cells, thereby modulating inflammation.

Cutaneous neuropeptides and neurohormones include a large family of small peptides such as substance P, CGRP, somatostatin, vasoactive intestinal peptide (VIP), pituitary adenylate cyclase activating peptide (PACAP), melanocyte-stimulating hormone (MSH) and β-endorphin. Moreover, neurotrophic factors such as nerve growth factor may affect the skin. Such neuromediators can be released from both sensory and autonomic nerve fibres, which terminate predominantly in the dermis but also in the epidermis, and thus are in close anatomical proximity to a variety of different cutaneous cell types during inflammation. Additionally, several skin cells generate neuropeptide receptors during the inflammatory response. Most of them belong to the G protein-coupled heptical transmembrane receptor family coupled to heterotrimeric G proteins. Because sensory neurones also express specific receptors for neuropeptides, prostaglandins, histamine, neurotrophins, proteases and cytokines, an interactive communication network between sensory nerves and immune cells likely exists during cutaneous inflammation [1–3]. Some neuropeptides have been demonstrated to be also capable of direct activation of intracellular G proteins. Endopeptidases such as neutral endopeptidase (NEP) or ACE are transmembrane molecules that regulate neuropeptide function by degradation, thereby leading to the inhibition of neuropeptide function. They have also been shown to modulate neurogenic inflammation by limiting the effects of neuropeptides in the skin [4]. Hence, a complex network of neuromediators, neurotransmitter receptors and peptidases exist to regulate cutaneous inflammation.

The axon reflex response in the skin is complex and is dependent on the anatomical distribution of the cutaneous axon reflexes and release of different types of neuropeptide [4]. In the skin, at least 30% of the cutaneous afferent nerves belong to a subtype of sensory nerves with

dual sensory afferent and efferent function, which mediate neurogenic inflammation. Capsaicin-sensitive C-fibres, and to a lesser extent Aδ–fibres, are not only capable of transporting impulses to the central nervous system (orthodromic signal) but also release neuropeptides (antidromic signal), which result in inflammatory activities in the skin. Neuropeptides released from cutaneous nerves are capable of acting on target cells via a paracrine, juxtacrine or endocrine pathway. These target cells express specific neuropeptide receptors that are appropriately coupled to an intracellular signal transduction pathway, or ion channels that, when activated, may result in activation of biological responses such as erythema, oedema, hyperthermia and pruritus. Because of their anatomical association to cutaneous nerves, mast cells and their released products appear to play an important part in mediating neuronal antidromic responses in the skin, although the precise role of these cells in cutaneous inflammation remains to be determined.

Substance P (SP), for example, strongly induces inflammatory responses and pruritus. TNF-α release from human skin may be also induced by SP. SP is capable of mediating secretion of histamine and TNF-α from mast cells, which results in vasodilatation via activation of H_1 receptors on vascular smooth muscle cells. It may also induce the release of leukotrienes and prostaglandins. Acute immobilization stress triggers skin mast cell degranulation via SP, corticotrophin-releasing hormone and neurotensin [5]. This ties in with the frequent observation that stress, via release of certain neuropeptides, may trigger skin mast cell degranulation and influence cutaneous inflammation and pruritus. Previous studies using tachykinin NK1R antagonists indicate that cutaneous oedema can be modulated by SP via NK1R activation, and is independent of histamine effects [6].

Neuropeptides may also regulate vascular responses in the skin during inflammation. For example, PACAP is a potent vasodilatator and oedema potentiator in rabbit skin, and mediates plasma extravasation in rat skin [7,8]. PACAP is a relatively new member of the VIP–secretin-peptide family, present in autonomic and sensory nerve fibres of the spinal cord and dorsal root ganglia, where it may influence inflammation and nociception [9]. Recently, PACAP was detected in cutaneous nerve fibres coexisting with VIP, substance P or CGRP, respectively, all of which may play a part during cutaneous inflammation. PACAP produces a long-lasting depression of a C-fibre-evoked flexion reflex in rats [10]. PACAP may also be involved in immunomodulation, down-regulating pro-inflammatory responses such as IL-2 or IL-6, and up-regulating anti-inflammatory mediators such as IL-10 [11], indicating that PACAP may have a role in neurogenic inflammation of the skin.

The neuropeptide CGRP has been shown to modulate immune responses and inflammation *in vitro* and *in vivo*. In general, CGRP predominantly mediates anti-inflammatory and neurotrophic effects. CGRP regulates Langerhans' cell function [12], and increases the phagocytotic ability of macrophages, indicating a regulatory role of CGRP on monocyte–macrophage–dendritic cell function. CGRP also stimulated adhesion of human neutrophils and monocytes to HUVEC and dermal microvascular endothelial cells [13]. In addition, CGRP potentiated the accumulation of neutrophils and oedema formation induced by IL-1 [14], and induced mast cells to release TNF-α, which resulted in inflammatory effects on surrounding skin cells [15].

Somatostatin (SOM) is an inhibitor of immune responses and inflammation [16]. Additionally, it is regarded as a predominantly antiproliferative molecule, having cancer-inhibiting properties mediated by tyrosine phosphatases and inhibitory effects on proliferation of T lymphocytes [17]. The inhibitory effects of SOM may not be generalized, because SOM also stimulates histamine release of human skin mast cells. SOM and the SOM analogue angiopeptin also decrease adhesion by monocytes to unstimulated and IL-1-stimulated endothelial cells by a cyclic adenosine monophosphate (cAMP) dependent mechanism that does not involve ICAM-1. SOM may therefore attenuate recruitment of distinct leukocyte subpopulations during the initial phase of inflammation [18]. There is evidence for the participation of SOM in the pathophysiology of atopic dermatitis and mastocytosis [19–21].

Another molecule with anti-inflammatory potential is α-MSH. α-MSH belongs to the family of pro-opiomelanocortin (POMC) peptides. POMC peptides are widely distributed in the skin and are expressed by melanocytes, keratinocytes, microvascular endothelial cells, Langerhans' cells, mast cells and fibroblasts, as well as by immune cells such as monocytes and macrophages. Post-translational processing of a POMC pro-hormone generates up to eight different POMC peptides after cleavage by pro-hormone convertase 1 and 2 (PC1, PC2). α-MSH has direct immunoregulatory and anti-inflammatory effects on several cutaneous cells *in vitro* and *in vivo*. For example, α-MSH antagonizes the effects of pro-inflammatory cytokines such as IL-1α, IL-1β, IL-6 and TNF-α [22], suggesting that the immunosuppressive capacity of α-MSH is also mediated through its effects on monocyte and macrophage functions. α-MSH down-regulates the production of pro-inflammatory cytokines and accessory molecules on antigen-presenting cells, while production of suppressor factors such as IL-10 is up-regulated by α-MSH [23]. It is well established that α-MSH ameliorates contact hypersensitivity leading to hapten-specific tolerance by inducing anti-inflammatory cytokines. Thus, α-MSH may inhibit cutaneous inflammation.

The neurotransmitters acetylcholine (ACh) and noradrenaline (NA) (norepinephrine) are also involved in

inflammatory processes in the skin. ACh is released by autonomic nerves, but can be also produced by melanocytes, keratinocytes [24] and lymphocytes. It regulates different activities in keratinocytes such as proliferation, adhesion, migration and differentiation. ACh was shown to be crucial to sustain the viability of keratinocytes *in vitro*, and cholinergic drugs were capable of modulating keratinocyte function such as adhesion and motility. Both choline acetyltransferase and acetylcholinesterase appear to regulate the function of ACh in keratinocytes. Intracutaneous application of ACh has been demonstrated to modulate various inflammatory responses [25].

ACh and its derivatives exert their effects by activating nicotinergic or muscarinergic cell surface receptors. The nicotinic receptors for ACh are transmembrane ion channels. Muscarinic receptors belong to a subfamily of G protein-coupled heptical receptors, defined as m_1, m_2, m_3, m_4 and m_5 receptors. Muscarinergic as well as nicotinergic receptors are widely expressed and are involved in epithelial differentiation, cell survival of keratinocytes, and inflammation [26–28].

Catecholamines, their regulating enzymes and adrenergic receptors (ARs) have been detected in nerve fibres, keratinocytes [29] and melanocytes [30,31]. They regulate the activity of certain lymphocytes (NK cells) and monocytes, and induce apoptosis in lymphocytes. In contrast, catecholamine release may be also induced by lymphocytes such as T and B cells. During delayed-type hypersensitivity, NA may also serve as an immunoenhancing agent. α- and β-ARs have been detected in human skin. AR agonists inhibit TNF-α release from mast cells [32], and are potent inhibitors of the IgE-mediated release of tryptase mediators from human mast cells *in vitro* [33]. α and β ARs may also regulate important vascular responses in the skin such as vasoconstriction. Decreased levels of β ARs were observed in lesional and non-lesional skin of psoriasis patients [34], whereas increased levels of α ARs were observed in arterioles of patients with scleroderma [35]. NA is able to increase LPS-induced IL-6 production in human microvascular endothelial cells via ARs. Recent data suggest that catecholamines, in addition to CGRP, regulate Langerhans' cell function in the skin [36]. Together, these results clearly indicate a role for classic autonomic neurotransmitters during inflammation and the immune response.

Capsaicin (*trans*-8-methyl-*N*-vanillyl-6-nonenamide), a vanillyl-alkaloid found in chilli peppers and other solanaceae, has been used as an anti-inflammatory agent for many years. Topically applied, capsaicin elicits a rapid sensation of burning pain by selectively activating sensory C-fibres, and triggers a cascade of inflammatory events such as erythema, and release of pro-inflammatory mediators in skin and mucosa. While capsaicin at lower concentrations activates sensory nerves to release neuropeptides, repeated application renders nerves in the treated area insensitive to further stimulation at higher concentrations. This is probably caused by capsaicin receptor-mediated depletion of neuronal-derived neuropeptides within a certain subdivision of sensory nerves [37].

Chronic application of capsaicin leads to neurotoxic effects in sensory nerves, causing involution of nerve termini. Thus, constant application may have an anti-inflammatory and antipruritic effect in the skin. These effects are at least in part mediated by activation of the capsaicin (vanilloid) receptor transient receptor potential vanilloid-1 (TRPV1) [38]. TRPV1 is a non-selective cation channel with six transmembrane domains, now defined as a member of the transient receptor potential (TRP) family. The receptor can be directly activated by exposure to heat, protons and the cannabinoid anandamide (conditions seen in inflammation and injury). In the skin, TRPV1 is expressed by sensory nerves and keratinocytes, and may thus induce the release of neuropeptides, prostaglandins (PGE_2) and cytokines such as IL-8. Moreover, TRPV1 is up-regulated in keratinocytes of patients with atopic dermatitis, indicating a role of TRPV1 and its ligands in cutaneous inflammation.

Recent data suggest that proteases as neuromediators contribute to cutaneous inflammation by activating PARs. Activation of PARs by thrombin or mast cell tryptase results in vasodilatation, extravasation of plasma proteins and infiltration of neutrophils [39], by releasing neuropeptides such as CGRP and SP from sensory nerve endings. Thus, mast cells may regulate inflammatory responses in the skin by communicating with sensory nerves, not only via histamine receptors, but also via PARs. In the skin, PARs are localized in keratinocytes, endothelial cells, nerve fibres and myoepithelial cells of sweat glands. Mast cells themselves express PAR-2, indicating a potential autocrine regulatory role for tryptase in cutaneous neurogenic inflammation via activating PAR-2. *In vivo*, PAR-2 mediates oedema, plasma extravasation and up-regulation of cell adhesion molecules, and promotes the transendothelial migration of neutrophils [40], in part by a neurogenic mechanism. Finally, PAR-2 mediates pro-inflammatory responses and itch, indicating a role of PAR-2 during the pruritic response in inflammatory skin lesions [41].

Vasculature and inflammation

Adhesion molecules

Intercell and cell–substrate adhesion is an essential function of cell membranes. Adhesion molecules participate in every cell activity, although they may be latent (not expressed until the cell is stimulated) as in platelets, or expressed very transiently, as for the selectins, binding leukocytes and endothelium, or over a longer duration, as for the integrins binding basal keratinocytes to the basement membrane. Tissue growth, differentiation and repair is regulated by adhesion molecules; leukocyte recruitment and function is also dependent upon adhesion molecules. A leukocyte may sequentially express several different surface molecules during its passage through the endothelium to the site of damage, and during its period of activity at the site. Adhesion molecule expression is complex, associated with or induced by the contiguous cells or substrate, cytokines and chemokines. Adhesion molecules are classified as members of the integrin family, the selectin family and the immunoglobulin superfamily.

Integrins

Integrins, first recognized by Hynes in 1987 [1], are the best studied of all cell adhesion receptors. Integrins and their ligands are critical to tissue development, immune responses, leukocyte trafficking, cancer metastasis and haemostasis.

Table 9.11 Integrin β1 and β2 families regulating cell–cell and cell–extracellular matrix binding.

	Family	α: CD number	Ligands	Integrin occurrence/responding cells
VLA-β1				
α1β1	VLA-1	CD49a	Laminin, type IV collagen	Fibroblasts
α2β1	VLA-2	CD49b	Laminin, collagens	Keratinocytes (basal), fibroblasts, platelets
α3β1	VLA-3	CD49c	Laminin, collagen, fibronectin	Fibroblasts, keratinocytes (basal)
α4β1	VLA-4	CD49d	Fibronectin VCAM-1	Fibroblasts, leukocytes (not neutrophils), Langerhans' cells
α5β1	VLA-5	CD49e	Fibronectin	Fibroblasts, endothelium, platelets, macrophages, keratinocytes
α6β1	VLA-6	CD49f	Laminin	Fibroblasts, keratinocytes
α7β1			Laminin	
α8β1				
α9β1			Fibronectin, VCAM-1	Fibroblasts, leukocytes, Langerhans' cells
α10β1			Collagens	Fibroblasts
α11β1			Collagens	Fibroblasts
αvβ1		CD51	Fibronectin, vitronectin	Fibroblasts, keratinocytes
LEUCAM-β2 (mainly cell–cell)				
α1β2	LFA-1	CD11a/CD18	ICAM-1, -2, -3	Leukocytes
αmβ2	Mac-1	CD11b/CD18	ICAM-1, fibrinogen, C3bi	Leukocytes
αxβ2	p150.95	CD11c/CD18	Fibrinogen, C3bi	Leukocytes, endothelium
αdβ2			ICAM-3	Macrophages

See text for abbreviation definitions. β1 integrins stated to bind to basal keratinocytes may be expressed weakly in suprabasal cells of normal epidermis; expression is increased during inflammation. LEUCAM, leukocyte (cell) adhesion molecules.

Integrins are α- and β-heterodimers but are of considerable diversity, there being eight β chains and 18 α subunits; one α subunit non-covalently links with one β subunit [2], assembling into 24 distinct integrins (Table 9.11). Some α subunits (e.g. αv) may link with more than one β-chain, enabling binding to different substrata (e.g. vitronectin, fibronectin or collagen); recognition is specific for the tripeptide sequence Arg-Gly-Asp (RGD) [3]. Ligand substrates have been identified experimentally. *In vivo*, it is probable that there is diversity in adhesion molecules; a cell may vary expression of integrins depending upon the nature either of the substrate or the stimulus [2].

In addition to their roles in adhesion to extracellular matrix ligands, integrins act as links between the intracellular cytoskeleton and extracellular milieu. All integrins, apart from α6β4, link to actin, whereas the β4 subunit with its large (1000 amino acid compared to 50 amino acid) cytoplasmic domain links to intermediate filaments. Ligation of integrins initiates a plethora of signal transduction events that serve to modulate cell behaviour, including proliferation, apoptosis, gene expression, polarity and differentiation [4]. Many integrin-stimulated pathways are similar to those triggered by growth factor receptors. Knockout mice studies have helped elucidate the specific non-redundant function of each of the 24 integrins. Indeed, genes for all eight β subunits and 14 of the 18 α subunits have been knocked out and each subsequent phenotype is distinct. The phenotypes range from perinatal lethality (α3, α6, α8, αv, β4 and β8) to defects in leukocyte function (αL, αM, αE, β2 and β7), inflammation (β6) and angiogenesis (α1 and β3) [5].

The β1 chain integrins, also known as VLA (very late antigens of activation, being late in appearance on T-cell activation) bind cells to substrates (Table 9.11). The β1 integrins have important cell–cell and cell–membrane linking functions in the epidermis. The distribution of integrins in epidermal cultures is fairly consistent. The α2, α3, α5 and β1 chains are present in basal cells, particularly at cell–cell junctions; α6β4 tends to be most strongly expressed on the base of the basal cells, as is αvβ1, which is weakly and irregularly expressed. These two integrins bind to fibronectin, laminin and vitronectin of the basement membrane [3–8]. If the culture substrate in the initial stages of development is changed from laminin to collagen, the dominant integrin in the basal–substrate zone changes from α3 to α2β1 [6]. The half-life of integrins in culture is 12–15 h. Disappearance of integrins in suprabasal cells occurs because they are not replaced, and is associated with terminal differentiation. Upward cell migration from the basal layer involves loss of adhesion to the basement-membrane proteins, which precedes the decrease and loss of the α5β1 integrins and fibronectin [9,10].

In normal epidermis *in vivo*, the greatest expression of integrins is on the basal cells, either at cell–cell contacts, where α2 and α3β1 are particularly found, or the basal cell–basement-membrane interface, with α3β1 being strongly expressed and αvβ1 and α1β1 being less evident [6,11,12]. Integrin α6β4, a laminin receptor, is strongly expressed in hemidesmosomes [13]. Opinion varies about the presence of α5 on normal basal cells, or the persistence of integrins in the suprabasal layers; discrepancies in the literature may be a result of different epitope specificities

of the test antibodies, or to activation of the skin before or during sampling. The β1 chain persists on the cell surface in suprabasal layers, but at a lower level than on basal cells [3,6]. Reported identification of α2β1 and α3β1 on suprabasal cells of normal epidermis [6] may be caused by recognition of the β1 chain rather than the α chains. As described in the culture studies on α5β1, there is first loss of binding to the extracellular matrix components and then loss of the integrin during differentiation [10], with possibly greater persistence of the β1 cell–cell links.

During epidermal wound healing, there is increased expression in the wound of α2β1, α3β1, α5β1, αvβ4 and α6β4 [11,14,15]; some differences in relative expression have been reported during repair of punch-biopsy wounds [15] as compared with suction blisters [11]. The migrating keratinocytes in punch-biopsy repair strongly express α3 and β1, α6 and β4, and after day 2 α5 activity is increased. The α3 and β1 pattern extends into the unwounded peripheral tissue [15]. In suction-blister repair, the blister roof expresses clusters of several α chains and β1 and β4 chains. On day 2, the migrating keratinocytes express the normal basal cell pattern. By day 6 in the healed hyperproliferative suprabasal epithelium, α2, α3, α6 and β1 are present, and there are low amounts of αv. The α5 and β4 integrins are confined to the basal layer, and in the case of β4 also to the next layer. The staining pattern distal to the wounds is normal [11]. These changes reflect the more rapid upward and lateral migration of hyperproliferative keratinocytes, and synthesis of extracellular substances (e.g. fibronectin and vitronectin). Changes in the granulating basement membrane of full epidermal thickness wounds [15] stimulate formation of the corresponding integrins. In 7-day wounds, formation of fibronectin and tenascin is associated with expression of αvβ6, and of the specific integrins beneath the basal cells at the dermal interface [16]. Hyperproliferation of epidermal keratinocytes in psoriasis is associated with discrete clusters of suprabasal α6 and β1 [8], and also with α3 and α5, particularly at the rete ridges [17].

Avidity of integrins (β2)

Cell migration, and cell–cell or cell–substrate binding in tissue repair, are associated with increased cell adhesion, integrin avidity and cytoskeleton actin polymerization. Members of the β2 integrin leukocyte cell adhesion molecule (LEUCAM) subfamily (also known as CD11/18) are expressed on most leukocytes, becoming inactive when they are 'resting'. Leukocyte function associated antigen-1 (LFA-1) (CD11a/CD18;α1β2) illustrates the changes in conformation and increase in binding sites after activation of the cell. The adhesion molecules of mobile non-activated leukocytes do not bind to endothelial cell ligands, thus avoiding spontaneous cell aggregation and vascular damage. On leukocyte activation, rapid changes in LFA-1 promote binding to the endothelial ligands (immunoglobulin superfamily members) ICAM-1 and ICAM-2, resulting in leukocyte arrest at the site, emigration or local inflammatory change [1,2]. New epitopes appear in the α and β chains [3,4] and there is an influx of calcium ions resulting in an increase in expression of the binding sites [2,5]. Strong support for the importance of β2 to leukocyte trafficking and inflammation comes from the phenotypes of mice lacking one or more β2 integrins on their ligands (e.g. skin infections), and the genetic disease leukocyte adhesion deficiency (LAD) which results from mutations in the gene for β2 integrin. LAD patients suffer from leukocytosis and failure to recruit leukocytes to sites of infection [6]. Blockade of β2 integrins is a highly promising line of biological therapy for skin inflammation, particularly psoriasis [7].

Low-avidity integrins are not closely associated with the cytoskeleton, but upon ICAM-1 contact stimulation,

Table 9.12 Selectin family.

Molecule	Cells	Function	Activation
P-selectin			
CD62P GMP 140 PADGEM LECAM-3	Platelets, endothelial cells	Links neutrophils and monocytes to platelets and endothelium	Thrombin, histamine oncostatin M, IL-4, IL-13, free radicals, peroxides
E-selectin			
CD26E ELAM-1 LECAM-2	Endothelial cells	Links neutrophils, monocytes, and CLA^+ T-cell subsets to endothelium	IL-1β, TNF-α, LPS, substance P
L-selectin			
CD62L LAM-1 LECAM-1 $Gp90^{MEL}$ DREG	Neutrophils, basophils, eosinophils, monocytes, lymphocytes	Leukocyte rolling on endothelium. Transient arrest	Constitutive activation by endothelium

membrane protein kinase C (PKC) initiates phosphorylation of the cytoskeletal proteins, and the α and β chains of LFA-1. This results in reorganization of the vinculin, talin and α-actinin molecules that link actin fibrils to the cell membrane and the integrin, and induces polymerization of the actin fibrils, thereby increasing the cytoskeleton matrix essential to the adaptation of the cell to its environment. The changes in conformation result in increased avidity of the integrins [1,2]. Leukocyte activation results in high-avidity transformation of LFA-1, coupling to the actin intermediate proteins, and polymerization of the actin fibrils, which stabilizes binding to ICAM-1 and promotes adherence to the endothelium. Activation of integrins also stimulates cell synthesis of cytokines and receptors to chemokines, contributing to cell emigration.

Mac-1 (CD11b/CD18) on the membranes of neutrophils eosinophils and monocytes has a wider range of ligand binding than LFA-1 although it has the same β2 chain (Table 9.11). In normal cells it is inactive but, like LFA-1, the binding affinity for the endothelial cell membrane and other ligands becomes expressed on leukocyte stimulation.

Selectins

Selectins are calcium-dependent transmembrance glycoproteins with an amino-group terminal portion that binds to sialylated carbohydrate counter-receptors on other cells. Selectin binding is a key transient link between leukocytes and vascular endothelium, thereby mediating the initial steps of leukocyte tethering and rolling. The selectin family comprises three members: P-, E- and L-selectin—which are clustered on chromosome 1 (Table 9.12) [1]. Each selectin has a lectin-like domain at the amino (NH_2) terminal followed by an EGF-like domain and consensus repeats.

P-selectin. P-selectin (CD62P, GMP-140, PADGEM, LECAM-3) is stored intracellularly in the α-granules of platelets and Weibel–Palade bodies of endothelial cells [2,3]. Surface expression of P-selectin on endothelium follows fusion of Weibel–Palade bodies with the plasma membrane. This follows stimulation by histamine, IL-4, IL-13, oncostatin M or thrombin [4–6]. Expression of P-selectin occurs rapidly, within 30 min. Transient expression on endothelium contributes to early leukocyte recruitment [7]. More sustained expression of P-selectin occurs when platelets and endothelium are activated by thrombin, histamine or free radicals, resulting in adhesion of platelets to neutrophils or monocytes and further adhesion of leukocytes, which is enhanced by PAF [8–10]. Once expressed on the cell surface P-selectin is rapidly internalized by endocytosis [11].

The main ligand for P-selectin is P-selectin glycoprotein ligand-1 (PSGL-1) expressed on myeloid, lymphoid and dendritic cells [12]. P-selectin–PSGL-1 binding is crucial to

neutrophil rolling, in that targeted gene disruption of PSGL-1 abrogates this process [13]. The other P-selectin ligand is CD24, which can mediate cell rolling on inflamed endothelium independent of PSGL-1 [14]. Recently, it has been shown that adhesion of P-selectin to leukocytes activates intracellular signalling pathways [15]. For instance, adhesion to T lymphocytes leads to tyrosine phosphorylation of proteins including paxillin [16].

Soluble P-selectin has been detected in plasma but its role is uncertain.

E-selectin. E-selectin (CD62E, ELAM-1, LECAM-2) is synthesized and expressed solely by endothelium and, unlike P-selectin, is not constitutively expressed. Expression is transcriptionally regulated by TNF-α, IL-1 LPS and substance P [17–19]. Following stimulation, peak expression of E-selectin occurs within 4 h and wanes in 24–48 h [20]. E-selectin ligand-1 (ESL-1), the main receptor for E-selectin, is expressed only on myeloid cells [21]. Both PSGL-1 and L-selectin are able to bind E-selectin [22,23]. Leukocytes do not require activation to bind to E-selectin, but as a result of binding there is activation of the β_2 integrin LFA-1 receptors on neutrophils [24]. E-selectin differentiates between neutrophil and eosinophil binding through differences in amount and dimeric form of ESL-1, eosinophil binding is about half that of neutrophils [25].

E-selectin expression is detectable on dermal endothelium in all inflammatory dermatoses, indeed it is preferentially expressed in skin [26]. Cutaneous lymphocyte antigen (CLA) is a glycoprotein molecule expressed on T cells that home specifically to the skin [27]. The expression of CLA by T cells is dependent on induction of glycosylation enzymes that modify pre-existing PSGL-1 during transition of T cells from non-activated to memory phenotype [28,29]. T cells in inflammatory skin disease express CLA, whereas T cells in non-cutaneous inflammation are mainly CLA-negative [28]. The skin specificity of E-selectin–CLA binding makes this an attractive target for biological therapy of inflammatory skin disease [30]. However, a systemically administered antibody directed to E-selectin was ineffective in the treatment of psoriasis [30]. A soluble form of E-selectin is released, which can also induce β2 integrin expression on neutrophils. Levels of soluble E-selectin in plasma are increased in scleroderma, polyarteritis nodosa, SLE, psoriasis and atopic dermatitis [31]. Correlation between levels of soluble E-selectin and disease activity has been observed in atopic dermatitis, psoriasis and palmoplantar pustulosis [32,33]. Whether soluble E-selectin has any direct pathogenic role in psoriasis or is merely a reflection of skin inflammation is debatable.

L-selectin. L-selectin (CD62L, LAM-1, LECAM-1, $gp90^{MEL}$, DREG) is constitutively expressed on the surface of leukocytes during maturation, and expression persists until binding of leukocyte to endothelium [34]. L-selectin is important in the initial phases of leukocyte–endothelial cell binding (Fig. 9.5). L-selectin is unique in that it is the only selectin known to be involved in trafficking of lymphocytes into lymphatic tissue. Upon leukocyte activation (binding), L-selectin is shed from the cell surface [35]. During the later stages of the inflammatory response L-selectin is an important mediator of neutrophil recruitment [36]. Four L-selectin ligands have been identified to date:

1 *Glycosylation-dependent cell adhesion molecule-1* (GlyCAM-1): a secreted protein not found on high endothelial venules (HEV)

2 *Mucosal adressin cell adhesion molecule-1* (MadCAM-1): important in tethering and rolling of lymphocytes in the HEV of Peyer's patches in the gut

3 *CD34*: has a role in lymphocyte rolling in the tonsil

4 *Sgp200*: as for the other two selectins, PSGL-1 may also be a ligand for L-selectin.

Although selectins were originally investigated as adhesion molecules, there is now considerable interest in their role as signalling molecules. For instance, activation via cross-linking of L-selectin on leukocytes leads to up-regulation of surface expression of β1 and β2 on naïve but not memory T cells, and calcium flux in peripheral blood mononuclear cells [37–39]. In neutrophils in particular, L-selectin cross-linking leads to activation of MAP kinases involving Erk 1 and 2 activation [40].

Immunoglobulin superfamily

CAM are the ligands or counter-receptors for the integrins (Table 9.13). They have one or more immunoglobulin-like domains, hence the designation immunoglobulin superfamily, and have repeat sequences resembling those of fibronectin. Their chief function is to bind leukocytes to cells expressing them, or to endothelium to facilitate vascular emigration, or to cytokine-activated fibroblasts and keratinocytes, to aggregate leukocytes at sites of inflammation.

ICAM-1 has five immunoglobulin-like domains, and is expressed weakly on normal endothelium, but is much increased by stimulation by IL-1, TNF-α or the complement component C5a [1]. On other cells (e.g. keratinocytes and fibroblasts) ICAM-1 is not expressed constitutively, but appears following stimulation by TNF-α or IFN-γ. ICAM-2, present constitutively on endothelium, is not increased by inflammatory stimulation. The third member, ICAM-3, contains five immunoglobulin-like domains and is expressed constitutively by resting monocytes, lymphocytes and epidermal Langerhans' cells [2]. Its expression is increased upon stimulation (e.g. treatment *in vitro*) and binds with LFA-1 (CD11a/CD18). ICAM-1 contributes to leukocyte adhesion via the LFA-1 and Mac-1 β2 integrins (Table 9.13) [3]. The related VCAM-1 molecule expression is increased after cytokine stimulation, and binds the α4β1 integrin mediating extravascular migration, principally of monocytes and eosinophils. Another variant, the platelet–endothelial cell adhesion molecule (PECAM-1 or CD31), is found in platelets and at the intercellular junctions of endothelium, where it contributes to leukocyte passage from blood vessels (Fig. 9.5) [4].

Like the selectins, the extracellular regions of ICAMs and VCAM are released into tissue fluids in a soluble form (sICAM-1, sVCAM). *In vitro* studies of ICAM-1 indicate that its soluble form is released from blood mononuclear

Table 9.13 The immunoglobulin superfamily of adhesion molecules.

Adhesion molecule	Cells	Ligand/counter-receptors	Cells
LFA-3 (CD 58)	Most cell types	CD2	T lymphocytes
ICAM-1	Endothelium Fibroblasts Activated leukocytes Activated keratinocytes	LFA-1 (α1β2) Mac-1 (αnβ2)	Leukocytes Monocytes
ICAM-2	Endothelium	LFA-1	Leukocytes
ICAM-3	Activated leukocytes Dendritic cells Langerhans' cells	LFA-1	Leukocytes
VCAM-1	Endothelium Macrophages Dendritic cells Fibronectin	VLA-4 (α4β1)	Leukocytes (not neutrophils) Langerhans' cells
PECAM-1	Platelets, leukocytes Endothelium	PECAM-1, CD31	

cells, but not from epithelium, fibroblasts or endothelium. In normal persons, up to 450 ng/mL sICAM-1 is detectable in serum, but this may be increased two- or threefold in inflammation (e.g. in disorders such as diabetes, idiopathic pulmonary fibrosis and liver disease); sICAM-1 is also detectable in the synovial fluid of patients with rheumatoid arthritis [5]. sICAM-1 is significantly elevated in the serum of a number of dermatological diseases including atopic dermatitis, psoriasis and metastatic melanoma [6–8] and correlates with clinical severity in untreated disease. sICAM-2 does not exist. sICAM-3 is increased in the sera of patients with psoriasis and atopic dermatitis but is less relevant than sICAM-1 to disease activity [9]. sVCAM is present in normal sera, and is increased in cancer and inflammation, including rheumatoid arthritis. Serum levels of sVCAM are elevated in advanced cutaneous melanoma, localized scleroderma, systemic sclerosis and SLE [10–12]. The role of soluble adhesion molecules is poorly understood—they may compete in cell–cell binding or they may activate cells that possess the cognate ligand.

Adhesion molecules regulating leukocyte emigration

Leukocyte emigration at a site of inflammation is regulated by a complex sequence of interacting changes. A leukocyte rolling over endothelium is arrested by an activated endothelial cell, binds to it, and passes through an endothelial intercellular junction, attracted by chemokines and other chemotactic agents [1–4], a process known as the endothelial cell–leukocyte adhesion cascade (Fig. 9.5).

Neutrophils, eosinophils and monocytes in the blood may flow mid-stream, or roll down the endothelium, when both leukocytes and endothelium are unstimulated. Contact between the rolling leukocyte and endothelium is regulated by constitutive L-selectin (neutrophils) or by L-selectin and α4β1 integrins (eosinophils and monocytes).

On contact between the leukocyte, and endothelium activated by TNF-α, IL-1, IL-4 or LPS endotoxin, the leukocytes are rapidly activated. Differences in the integrins expressed in the leukocyte types contribute to the selectivity of the resulting leukocyte infiltrate. The initial adhesion is enhanced by other products resulting from endothelial activation: thrombin, histamine, bradykinin, H_2O_2 and LTC_4. Similarly, neutrophils become further activated by endothelial inflammatory products, particularly PAF, enhanced by platelet aggregation.

The rolling activated neutrophil is arrested by the activated endothelium. The L-selectin molecules are shed. P-selectin from endothelium and platelets is rapidly mobilized, linking the neutrophil to the endothelium; adherence is enhanced by E-selectin on the endothelium binding to sialyl Lewis groups on the neutrophils (Fig. 9.5).

Arrest is followed by firm adhesion, during which the neutrophil spreads on the endothelium, adhesion forces are progressively increased, and the neutrophil begins to respond to chemokines and other attraction agents. A rapid change occurs in the conversion of LFA-1 integrins to an avid state, to bind with ICAM-1 and ICAM-2 on the endothelium, which increases expression of ICAM-1. A second β2 integrin, Mac-1, also has functional increased activity and binds to ICAM-1 only (Fig. 9.5).

Adherence changes to migration as the neutrophil responds to IL-8, neutrophil activating peptide-2 (NAP-2), growth-regulated gene/melanoma growth stimulating activity (GRO/MGSA), C5a and other attraction agents. Vascular emigration is most evident in the post-capillary endothelium, but occurs elsewhere in the venous system with sufficient loss of vessel wall integrity. Emigration appears to be mediated by the neutrophil flowing over the ICAM molecules and inserting itself into an intercellular junction, where PECAM-1 is localized; this appears essential for passage of the cell (Fig. 9.5).

Emigration of monocytes and eosinophils is similar, but with some differences in the adhesion molecules and chemokines involved. The α4β1 integrin is expressed constitutively, and contributes to leukocyte rolling, and also to adhesion by binding to VCAM-1 [2]. Monocytes express all three of the CD11/CD18 β2 integrins, and also some ICAM-1 [5]. This may regulate the binding of monocytes to unstimulated endothelium, but adhesion to and emigration from stimulated endothelium is much stronger [5]. A greater number of chemokines contribute to monocyte and eosinophil emigration than emigration by neutrophils, particularly RANTES, MIP-1α, MCP-2 and MCP-3, and additionally MIP-1β and MCP-1 attract monocytes.

Detailed knowledge of the adhesion molecules has an application in the development of blocking ligands, which may offer the potential for control of tissue damaging inflammation.

Adhesion molecules on activated keratinocytes

Leukocytes emerging from blood vessels move through tissue and bind to activated cells by the same adhesion molecules. ICAM-1 is expressed on fibroblasts, activated thymic epithelial cells and activated keratinocytes [1–4]. As for endothelial cells, ICAM-1 is inducible on fibroblasts by IL-1, IFN-γ and TNF-α, which are cytokines activated or released in damaged tissue [4,5].

Normal keratinocytes do not express ICAM-1 when examined by usual immunohistochemical methods, although extremely small amounts are detectable by immunoelectron microscopy; this expression may be sufficient for normal leukocyte and Langerhans' cell migration but avoids leukocyte-mediated damage [6]. The expression of ICAM-1 on keratinocytes is induced by IFN-γ and TNF-α, which are products released by lymphocytes infiltrating inflamed skin [7]. Activated lymphocyte IFN-γ induces keratinocyte expression of ICAM-1 and HLA-DR, promoting inflammatory and allergic epidermal responses [8,9]. ICAM-1 expression is induced in the basal and lower suprabasal layers; decreased expression in the upper layers is associated with greater differentiation and formation of involucrin [10]. When ICAM-1 is found in the upper suprabasal layers, it probably reflects the presence of relatively undifferentiated hyperproliferative epidermis. Among the disorders in which keratinocytes express ICAM-1 are allergic contact dermatitis [11–13], irritant contact dermatitis [14], psoriasis [15,16], lichen planus, bullous pemphigoid, exanthems and urticaria [17].

Endothelin 1

Endothelin 1 (ET-1) was first identified as an endothelial cell product [1] and contributes to endothelial turnover and integrity. It is also synthesized by keratinocytes [2]. ET-1 is mitogenic for fibroblasts [3], smooth muscle cells including vascular cells [3,4], melanocytes, in which cells it also stimulates tyrosinase activity [5], and renal mesangial cells.

Growth factors from cells other than keratinocytes

Potent cytokines stimulating regeneration of skin are synthesized by cells of the dermis. TGF-α and TGF-β, PDGF and βFGF are synthesized by several types of cell, and the epidermis probably contributes only a small proportion of that synthesized in a healing lesion. Other potent cytokines are EGF, insulin-like growth factor-1 (IGF-1), IGF-2, FGF, αFGF and βFGF.

Chapter 10

Clinical Immunology, Allergy and Photoimmunology

G.P. Spickett & T. Schwarz

Overview of structure and function of immune system

[G.P. Spickett, pp. 10.1–10.29]

The immune system plays a key role in the protection of the organism against infection and has evolved in parallel with pathogens, which seek to circumvent the organism's defensive strategies. The structure and function of the immune system is complex, rivalled in complexity only by the nervous system with which it shares considerable structural and functional homology. Both organs extend through the body and are reliant on chemical mediators to transmit complex information between cells. There are complex links between the two systems, manifest by shared receptors and common mediators. The immune system is divided into innate and acquired immunity, which between them provide both immediate defence and long-term immunological memory. Both systems are interlinked to provide effective protection against infection. Disease can arise through immunodeficiency, malignancy and deviation (autoimmunity and allergy).

Traditionally, the immune system is divided into two parts, the innate or non-adaptive and acquired or adaptive, the difference being in the ability of the acquired immune system to learn from exposure to pathogens. The requirement for the innate system is to provide generic protection during the time required for the acquired immune system to generate a specific response. The main feature of the adaptive system is long-lived specific immunological memory. The two parts are linked through shared mediators (cytokines and chemokines) as well as shared receptors. In many respects, both systems amplify the other's response through released mediators.

In a short chapter it is not possible to give an in-depth view of all aspects of the immune system and the interested reader is directed to more detailed sources of information. A brief overview of the immune system follows as an introduction to the clinical aspects later in the chapter.

Innate immunity

Innate immunity describes all the body's defensive strategies that do not have the capacity for learnt responses or immunological memory. The system includes surface defences, soluble mediators and non-specific cells. These do not operate in isolation but are closely integrated with acquired immunity. Figure 10.1 gives an overview of the main features and how they are integrated.

Non-specific defence mechanisms

The non-specific defence mechanisms include the

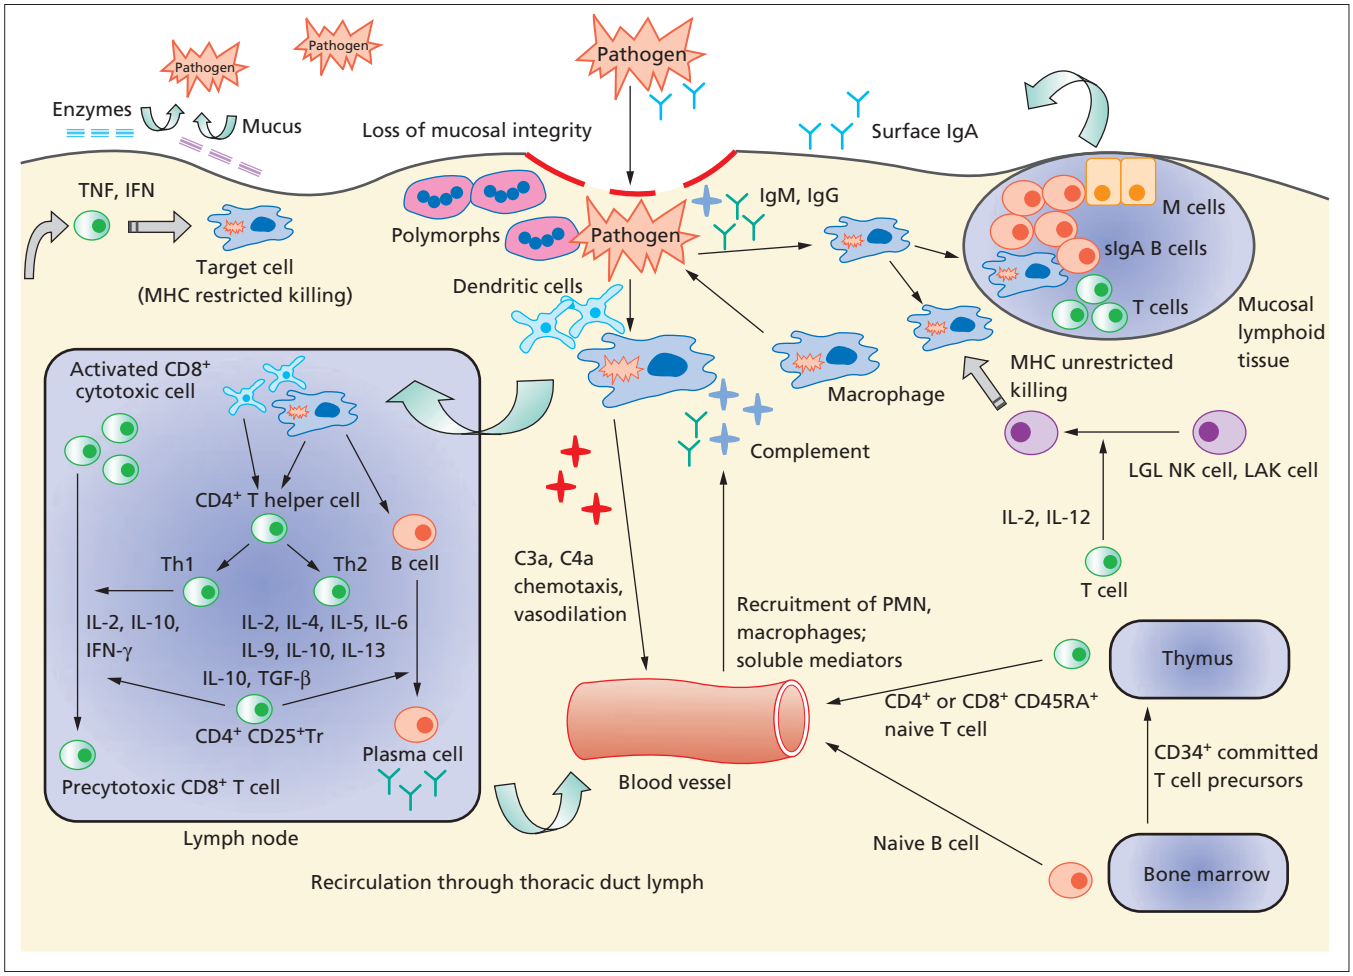

Fig. 10.1 Integration of the various aspects of the immune system, both innate and acquired, in dealing with pathogens. IFN, interferon; IL, interleukin; LAK, lymphokine-activated killer; LGL, large granular lymphocyte; TGF, transforming growth factor.

structural design of the organism, aimed at reducing the capacity for microorganisms to gain entry. These include the structure of the skin itself, together with the secretions that it produces; enzymes in tears and other secretions, such as lysozyme and complement, that have a bactericidal effect; stomach acid, which is extremely effective at reducing bacterial counts entering the upper gastrointestinal tract; and surface mucus in the respiratory tract, which traps bacteria and allows them to be removed by the ciliary escalator. The importance of these mechanisms is demonstrated in illnesses where these protective mechanisms are disrupted, for example burns lead to easy passage of bacteria into deeper tissues; Sjögren's syndrome, with reduced secretions in eyes, mouth and lungs, is accompanied by increased bacterial infections at all these sites; achlorhydria, either due to gastric atrophy or induced by drugs such as proton-pump inhibitors, is associated with reduced resistance to enteric infections and also to *Candida*; cystic fibrosis and ciliary dyskinesia both disrupt the interaction between mucus and cilia and lead to progressive and severe lung disease due to infection. These examples clearly demonstrate that these non-specific features play a significant role in host defence and cannot be replaced no matter how effective other aspects of the innate and acquired immune systems might be.

Soluble factors

The main soluble factors involved in host defence are the components of the complement and kinin cascades, which are linked through shared regulatory components also with the clotting cascade. There are three pathways of complement activation (Fig. 10.2): the classical pathway, triggered by interaction of an antibody–antigen complex with C1q; the lectin pathways, triggered by binding of mannose-binding lectin (MBL) to mannose residues on bacterial surfaces; and the alternate pathway, triggered by interaction of lipopolysaccharides of appropriate surface charge with alternate pathway proteins. The alternate pathway is also responsible for the 'tick-over' low-level activation of the complement system. All three pathways

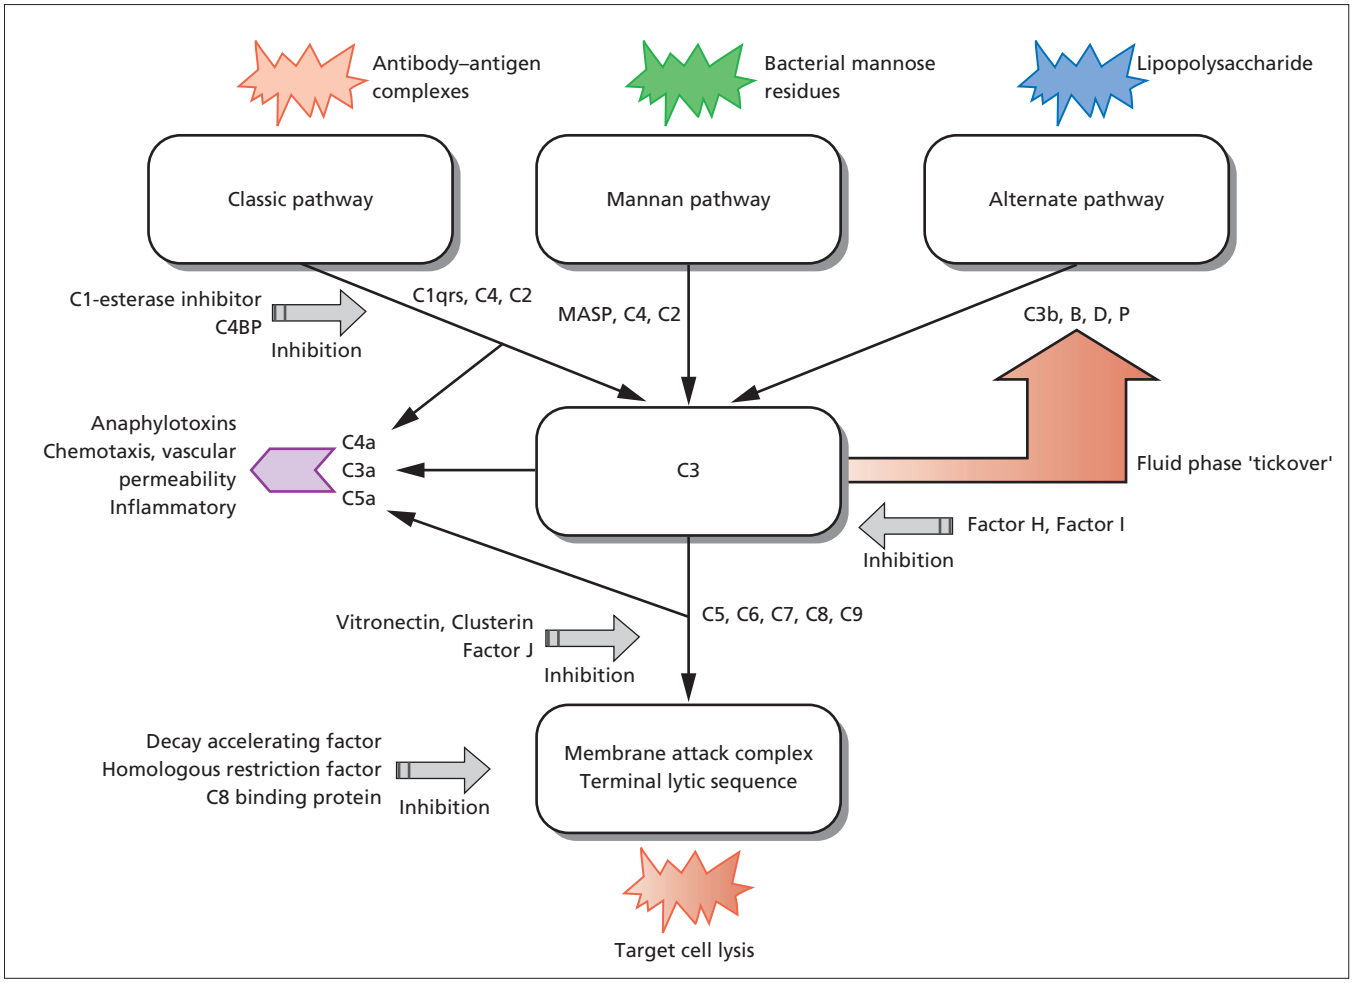

Fig. 10.2 Pathways of complement activation and their control. MASP, mannan-binding protein associated serine protease.

converge at the level of C3 to activate the terminal lytic sequence, which inserts a pore comprising the C5–8 proteins and polymerized C9. These pore-forming proteins are structurally very similar to the proteins produced in natural killer (NK) cells and cytotoxic T cells. Complement is a major opsonin, and the presence of C1q and C3 on bacterial surfaces increases phagocytosis through binding to complement receptors. Activation of the complement system also increases recruitment of phagocytic cells by the split products released during activation, i.e. C4a, C3a and C5a, the anaphylatoxins, which increase vascular permeability and are chemotactic for neutrophils. A specific receptor for C5a (CD88) has been identified that activates cells via tyrosine phosphorylation and MAP kinases.

Complement receptors play a crucial role in linking the innate and acquired systems. Complement receptor 1 (CR1, CD35) is widely expressed on neutrophils, macrophages, follicular dendritic cells and B cells. Its presence on phagocytic cells is directly coupled to the process of phagocytosis, while on follicular dendritic cells it plays a pivotal role in antigen trapping and therefore persistence of antigen for subsequent presentation to T cells and B cells to maintain immunological memory. On B cells it is involved in activation and also in presentation of antigen to T cells. It is present on erythrocytes and is therefore involved in the removal of immune complexes to the spleen for subsequent phagocytosis and destruction. CR2 (CD21, EBV receptor) is expressed mainly on B cells, and forms part of the B-cell antigen receptor complex with surface immunoglobulin, CD19 and the immunoglobulin α chain (CD81). CR2 binds C3 degradation fragments iC3b and C3d, and co-ligation of these with antigen to the B-cell receptor reduces the threshold for B-cell activation 100-fold. CD21 is also essential for the development and maintenance of B1 ($CD5^+$) B cells, which are involved in the spontaneous production of IgM and play a role in recognition of lipid antigens. It is also a receptor for soluble CD23, an autocrine B-cell growth factor involved in IgE production. CR3 and CR4 are β integrins, expressed on phagocytic cells and directly involved in signalling for phagocytosis.

The complement system is an enzymatic cascade of proteases, with each step providing amplification. There are key checkpoints at which regulatory proteins act to ensure that the process is controlled. C1-esterase inhibitor inhibits C1r and C1s and also mannan-binding protein (MBP)-associated serine protease from the lectin pathway, as well as acting as a regulatory protein in the clotting and kinin cascades. Factor H is an inhibitor of C3 and C4-binding protein inhibits activated C4; these are both large molecules with multiple binding sites and are therefore capable of inactivating multiple activated complement proteins simultaneously. Both also act as co-factors for factor I, an inhibitor of activated C3 and C4. Deficiency of factor H has been associated with haemolytic–uraemic syndrome. Newly described regulators of the terminal lytic sequence include vitronectin, clusterin and factor J, which interact mainly with C5b67. Host cells also have regulatory proteins (CD55, decay-accelerating factor; CD59, homologous restriction factor 20; C8-binding protein) expressed on their surface to prevent accidental bystander destruction. In paroxysmal nocturnal haemoglobinuria, there is a somatic clonal mutation in the *pig*A gene that prevents these proteins from being expressed through disruption of the transmembrane glycolipid tail, leading to production of erythrocytes susceptible to complement-mediated lysis.

Deficiency of nearly all components of the complement system has been described, and most lead to increased susceptibility to infection, particularly with *Neisseria* species. The significance of MBP deficiency is uncertain, as deficiency alleles have been identified in healthy subjects. It is thought likely that MBP deficiency is only clinically important when other aspects of the humoral immune system are defective.

The kinin cascade is also a critical pathway in inflammation, particularly in rhinitis and asthma, and also in generation of angio-oedema in hereditary angio-oedema. The end-product of the cascade is bradykinin, which acts through specific bradykinin receptors on smooth muscle, endothelial cells, neurones and synovial cells. C1-esterase inhibitor and α_2-macroglobulin inhibit activated kallikrein and therefore inhibit bradykinin production; C1-esterase inhibitor also inhibits factor XIa in the clotting cascade and Hageman factor in the kinin cascade. Carboxypeptidase N breaks down bradykinin to des-arg-bradykinin, which retains some vasoactive properties: deficiency of carboxypeptidase N has been reported as a cause of angio-oedema. Des-arg-bradykinin is inactivated by angiotensin-converting enzyme (ACE), which explains why angio-oedema and cough are common complications of therapy with ACE inhibitors. Experimental drugs such as icatibant and FR173657 are available that block bradykinin receptors, and may therefore have a major role in the management of angio-oedema.

The pentraxin family of molecules includes C-reactive protein (CRP) and serum amyloid A (SAA). These are acute-phase proteins and bind directly to microbial polysaccharides as well as matrix proteins. CRP also scavenges DNA released from dead cells by binding to chromatin. It binds to C1q, thus facilitating the removal of the DNA–immune complex. CRP is clearly an essential molecule, as deficiency has never been reported.

Defensins are newly described small polypeptide molecules with a direct ability to lyse bacteria. The α-defensins are produced in neutrophils and also in gastrointestinal Paneth cells, while the β-defensins are produced by epithelial cells of the airway and the urothelium.

Many cells of the innate system produce inflammatory compounds derived from the arachidonic acid pathway. These include the prostaglandins, thromboxanes and leukotrienes. These agents have a diverse array of inflammatory properties, including increasing vascular permeability, local blood flow, chemotaxis of neutrophils and smooth muscle constriction, and effects on platelets. The different metabolic pathways include mutually antagonistic agents, prostacyclins and lipoxins. Abnormalities of the enzymes of the synthetic pathways for prostaglandins account for the adverse effects of aspirin in some individuals. The pharmaceutical industry has been active in producing inhibitors of leukotriene synthesis, inhibitors of lipoxygenase (Zileuton) and 5-lipoxygenase activating protein being the most effective, while drugs such as montelukast and zafirlukast are leukotriene antagonists that are effective in asthma but also in urticaria and other inflammatory conditions.

Cellular components

Polymorphonuclear leukocytes (neutrophils) play a critical role in the immediate defence against bacteria. They develop in the bone marrow under the influence of the specific cytokines SCF, IL-3, G-CSF and GM-CSF. The bone marrow contains a large reserve pool of mature cells, which can be released by stress such as infection; 60% of bone marrow capacity is devoted to neutrophil production. Neutrophils remain in the circulation for only a few hours before emigrating into tissues. Abundant expression of leukocyte adhesion molecules, such as L-selectin, P-selectin and cutaneous lymphocyte antigen (CLA), ensures the margination of neutrophils along the endothelial surface. In the presence of activating and chemotactic factors binding to specific surface receptors such as *N*-formylmethionine-containing peptides derived from bacteria, platelet-activating factor (PAF), the chemokines MIP-1α, RANTES and IL-8, and the anaphylatoxins C3a and C5a, adhesion to the endothelium takes place. This process involves integrins of the CD11/CD18 family, with subsequent emigration and migration of neutrophils to the site of inflammation, following the chemotactic gradient. Phagocytosis is stimulated by binding of antibody to

Fc receptors and complement to complement receptors, leading to the formation of the phagocytic vacuole. Fusion of the vacuole with the primary neutrophil granules then exposes the bacterium to an array of enzymes and bactericidal proteins, including myeloperoxidase, lysozyme, elastase, cathepsin G, proteinase-3, azurocidin and α-defensins. Three types of granule are recognized: specific granules containing the enzymes, gelatinase granules containing predominantly gelatinase and NADPH oxidase, and secretory granules. Inducible enzyme systems also contribute, producing nitric oxide and superoxide. The oxidative burst that forms superoxide is produced by the NADPH oxidase system, a multicomponent enzyme. Genetic deficiencies of the subunits of this enzyme cause the X-linked and autosomal forms of chronic granulomatous disease. In X-linked chronic granulomatous disease (63% of cases) mutations occur in the gp91-phox protein, while the autosomal forms are due to mutations in p47-phox, p22-phox and p67-phox. Myeloperoxidase is responsible for the production of hypochlorous acid, a potent oxidizing agent formed from hydrogen peroxide and chlorine; myeloperoxidase deficiency has been reported and leads to increased infections. Neutrophils have multiple bactericidal pathways, so defects in one pathway will not necessarily lead to failure to kill bacteria. Neutrophils are also biosynthetically active, secreting an array of cytokines and chemokines, including tumour necrosis factor (TNF)-α, IL-1, IL-12, interferon (IFN)-γ, transforming growth factor (TGF)-β and IL-8, that amplify the inflammatory response.

Macrophage–monocytes are the mononuclear phagocytic cells, also derived from the bone marrow and under similar differentiation control to neutrophils. They are longer lived than neutrophils and are actively migratory, being found in all tissues in the body. Control of migration is similar to neutrophils, although there are a range of chemokines specifically involved in recruitment, such as MCP-1, MDC, PF4 and MIP-1α. As well as expressing complement and Fc receptors, enabling them to phagocytose immune complexes, they also express an array of scavenger receptors, including lipopolysaccharide (LPS) receptor, CD14 and Toll-like receptors (TLR), which bind LPS complexed with soluble CD14. Other TLR bind proteolytic cleavage fragments from the complement and kinin systems. Activation through TLR leads to oxidative burst and release of the cytokines IL-1 and TNF-α, which drive the systemic inflammatory reaction, stimulating the acute-phase response and causing pyrexia via effects on the hypothalamus. Macrophages have similar enzyme systems to neutrophils, although the activity of the NADPH oxidase system is lower. Macrophages can act as antigen-presenting cells (APCs) and major histocompatibility complex (MHC) class II antigens on the cell surface are upregulated by activation. These cells play an essential role in type IV delayed-type hypersensitivity reactions, as part of granuloma formation, often with cell fusion to create multinucleate giant cells. This is mediated through IFN-γ. Mutations in the IFN-γ receptor, leading to either non-expression or expression but loss of function, have been associated with increased susceptibility to mycobacterial infection, due to failure of macrophage function despite good T-cell immunity. Defects in the receptor for IL-12, which is involved in the induction of IFN-γ, also lead to a similar clinical picture.

Macrophages, together with dendritic cells, form an essential bridge between the innate and acquired immune systems. Phagocytosis of antigen by macrophages leads to internalization, digestion of antigen and re-expression of derived peptides on the cell surface bound to MHC class II antigens. This provides essential stimulation to $CD4^+$ T cells. Dendritic cells do have a direct phagocytic capacity but acquire antigen through transfer from macrophages, with which they form tight complexes during the immune process.

Eosinophils are derived from the same bone marrow lineage as neutrophils, but differentiate under the influence of IL-5. Their main role in host defence is against parasitic infections. Their granules contain eosinophil peroxidase, the Charcot–Leyden crystal protein, a cytotoxic phosphatase, eosinophil cationic protein (ECP), major basic protein and eosinophil-derived neurotoxin. The latter is an important mediator of the neuropathy seen in Churg–Strauss syndrome. Eosinophils have surface receptors for IgE (low affinity, CD23), IgG Fc receptors and complement receptors. Recruitment to sites of inflammation is through similar use of selectins and integrins. The anaphylatoxins and PAF are chemotactic and there are specific eosinophil chemoattractants of the chemokine family, eotaxin-2 and eotaxin-3. Activation of the eosinophil leads to an oxidative burst and production of leukotrienes as well as an array of cytokines, including IL-1, IL-6, TNF-α and the chemokine IL-8, thus promoting an acute inflammatory reaction. Release of eosinophil granule components contributes to the lung damage in asthma, and promotes the chronic phase of inflammation through the release of cytokines active on lymphocytes. MHC class II is expressed, indicating that the cells can also function as APCs.

Mast cells are derived from a distinct lineage of bone marrow cells and express high levels of high-affinity IgE receptors on their surface. Mast cells also express receptors for C3a and C5a, as well as multiple chemokine receptors, ensuring that they are attracted to sites of inflammation regardless of the initiating event. Similar adhesion molecules are expressed as on neutrophils and eosinophils. Their granules contain large amounts of histamine, heparin, tryptase and TNF-α. Cross-linking of the IgE receptor by allergen triggers degranulation. Mast cells produce both leukotrienes and prostaglandins, contributing to the inflammatory response, and also synthesize

IL-3, IL-4, IL-5 and GM-CSF. Mast cells in lung and gastrointestinal mucosa can be differentiated from those in skin and gastrointestinal submucosa by the presence of chymase in the latter.

Basophils are circulating cells with similar properties to tissue mast cells and have high-affinity receptors for IgE. Despite this, they are derived from the same bone marrow precursor as eosinophils, whereas mast cells are a distinct lineage. Basophils circulate for several days in the bloodstream. They produce leukotrienes but not prostaglandins. Basophils are about a 100-fold more sensitive to activation via the IgE receptor compared with mast cells, and are also more sensitive to non-IgE stimuli, including *N*-formyl-methyonyl-leucylphenylalanine (fMLP), C3a and C5a, and phospholipase A. They appear to be involved in the late phase of allergic reactions in tissues and produce IL-4 and IL-13, which increase synthesis of IgE. Interestingly, the release of these cytokines is dependent on the calcineurin pathway, which can be inhibited by ciclosporin A and tacrolimus, accounting for the effectiveness of these drugs in treating allergic reactions.

NK cells are large granular lymphocytes derived from bone marrow precursors. Their granules contain perforin, a cytotoxic protein closely related to complement proteins of the terminal lytic sequence. Although of lymphocyte lineage, these cells do not express CD3/T-cell receptor (TCR) complexes on their surface, nor do they rearrange their TCR genes. Some cells express CD8, but mainly they express CD16, a low-affinity IgG Fc receptor, and CD56, a variant of the neural cell adhesion molecule. They express a range of specific NK-cell receptors, including NKp46 and NKG2D (binds to MHC class I chain-related A and B molecules, MICA and MICB), and cytotoxicity is enhanced by exposure to IL-2. It is thought that the default for NK cells is to kill cells that they come into contact with, unless the cells express sufficient levels of MHC class I antigens to interact with killer-inhibitory receptors (KIRs) expressed on the surface of NK cells. Binding of MHC class I to KIRs is independent of the presence of bound peptide. There are a variety of different KIRs, some of which recognize non-classical MHC antigens (HLA-E, HLA-G). This reactivity explains the abundance of NK cells in the placenta that express high levels of non-classical MHC, NK cells being involved in tolerance to the fetal allograft. Expression of IgG receptors enables them to kill antibody-coated targets via antibody-dependent cell-mediated cytotoxicity. They produce IFN-γ, TNF-α and GM-CSF, contributing to the acute inflammation and stimulating T-helper type 1 (Th1) responses in the acquired system (see below). NK cells contribute to tumour surveillance, seeking out cells with reduced class I expression, and also provide protection against viral infections, as viruses often block surface expression of MHC class I antigens, preventing T-cell recognition. Very rare primary NK-cell deficiency has been reported, with increased susceptibility to all types of herpesviruses. Functional abnormalities of NK cells are seen in the X-linked lymphoproliferative syndrome, due to SLAM—associated protein (SAP) deficiency, and in Chédiak–Higashi syndrome.

Acquired immunity

The key features of the acquired immune system are (i) the responses that develop are specific to a particular pathogen or antigen; and (ii) there is long-lived immunological memory that persists after the first encounter. This is manifest in the antibody responses to antigen on first exposure, where the response is small and comprises predominantly IgM (primary immune response), whereas re-challenge after a suitable interval leads to a large and predominantly IgG response (secondary immune response). The process is accompanied by an expansion of the antigen-reactive cells, together with the generation of long-lived memory B cells. A similar process takes place in T cells. During the process somatic mutation takes place in the antigen receptors to enhance the affinity of the receptor for the antigen. The immune system is a dynamic surveillance system, with constant recirculation of the constituent cells through the bloodstream, tissues and lymphoid tissue. The lymph nodes and spleen remain the primary sites of encounter with antigen-bearing APCs and are also the sites of major antigen-driven proliferation. The recirculation process is tissue specific and targeted through specific receptors expressed on vascular endothelium.

Components of acquired immunity

The key components of the acquired immune system are the B cells, which produce antibody, and the T cells, which serve helper, cytotoxic and regulatory functions. Both have specific receptors based on recombination of multiple genes to give an enormous range of potential specificities. Both cell types use the recombinase-activating genes (*RAG-1* and *RAG-2*) to carry out this process. The antigen receptors on T and B cells differ in their recognition requirements. Antibody binds to conformational epitopes in whole molecules and these will not usually be contiguous, but are represented as surface binding sites on the target molecule. In contrast, the TCR recognizes short linear peptide sequences (7–15 amino acids), only in the context of binding of the peptide to MHC antigens. These linear sequences may be anywhere in the molecule but are usually deeply buried within the structure and not accessible on the surface. This means that B cells can be stimulated by free antigen whereas T cells in the main require processed antigen, presented by antigen-presenting cells (APCs) such as macrophages and dendritic cells. As B cells themselves express MHC class II antigens, they can function as APCs, presenting peptides to $CD4^+$ T cells

in return for help through T-cell cytokine production. Both T-cell and B-cell antigen receptors occur in clusters with co-receptor molecules, which confer additional recognition functions (complement, MHC class), and transmembrane signalling molecules linked to cascades of intracellular enzymes. Activation signals are usually delivered by phosphotyrosine kinases, while inhibitory signals dephosphorylate tyrosine.

B lymphocytes develop in the marrow and then migrate to secondary lymphoid tissue, where they encounter antigen. Antigen-stimulated B cells develop into plasma cells, producing quantities of serum immunoglobulins that are representative of the surface antibody receptor of the cell. B cells exist in two forms, B1 and B2, distinguished by their pattern of surface antigens. B1 cells have low/absent surface IgD, CD45, CD23 and can be $CD5^+$ (B1a) and $CD5^-$ (B1b). B1 cells are long-lived cells producing naturally occurring low-affinity antibodies, usually IgM, against bacteria and autoantigens. Early in life a high percentage of cells are B1, but this falls with age; however, it is this population that is expanded in most chronic lymphocytic leukaemias. B2 cells are 'conventional' B cells and have high levels of surface IgM and IgD as well as CD45 and CD23, but do not express CD5.

Serum immunoglobulins comprise five classes, IgM, IgD, IgG, IgA and IgE (in order of expression), determined by the heavy chain. Each can have either κ or λ light chains. IgD functions primarily as a surface receptor and has no known function as a secreted molecule. High levels have been associated with a syndrome of recurrent fevers, arthritis and infections (hyper-IgD syndrome) that appears to be caused by a defect in mevalonate kinase. IgM exists as a membrane receptor and as a soluble pentameric form, in which the five IgM molecules are joined by a J chain. IgM is the antibody produced in the first phase of an immune response. IgG exists as four subclasses, and comprises by concentration the major serum immunoglobulin. IgG1 and IgG3 are mainly antiprotein antibodies, while IgG2 is mainly antipolysaccharide. IgG4 is present only in low concentrations and its precise role is uncertain, although it and other subclasses do not necessarily give rise to clinical disease; measurement of IgG subclasses is therefore not a useful predictor of underlying humoral immune deficiency. In Sjögren's syndrome, IgG1 is preferentially increased in the polyclonal elevation of IgG seen in this condition; the other subclasses are relatively reduced. IgA exists in two forms, IgA1 (the predominant serum form) and IgA2. IgA is the antibody of mucosal surfaces, and is secreted in the form of dimers and trimers, with an associated J chain. In the process of secretion, which involves active transport through the epithelial cells mediated by the poly Ig receptor, a secretory piece is added, which slows the rate of breakdown. Secretory piece deficiency has been reported very rarely. In the absence of IgA, IgG and IgM can be transported to the mucosal surface and provide effective protection. Thus selective IgA deficiency may be asymptomatic in respect of infection, although it increases the risk of developing a range of autoimmune diseases, including coeliac disease and connective tissue diseases. IgE is primarily involved in antiparasite immunity, acting as a passively adsorbed receptor on mast cells and basophils. Serum concentrations are extremely low in comparison with the other classes of immunoglobulins.

Mature T cells develop in the thymus from T-lineage committed precursors derived from bone marrow. In the thymus, the process of development of functional TCRs takes place in an analogous way to the process in B cells. As well as the TCR, the cells also develop the co-receptor molecules of the CD3 complex (five separate chains) and CD4 and CD8 surface expression. In the periphery, T-cell function is defined to a certain extent by expression of CD4 and CD8, which define the class of MHC recognized. $CD4^+$ T cells are 'helper-effector cells', which recognize predominantly MHC class II antigens and thus interact mainly with a restricted array of MHC class II-positive cells, such as B cells and APCs, or other cells which may have induced class II, e.g. thyrocytes during thyroiditis. Functions ascribed to $CD4^+$ T cells include provision of T-cell help through cognate interactions and cytokine release to B cells and also cytotoxicity towards class II-bearing targets. $CD8^+$ T cells recognize MHC class I antigens, which are expressed on all cells except erythrocytes, and are particularly involved in the recognition of virally infected targets. These cells are actively cytotoxic, using the same enzymes found in NK-cell granules (perforins and granzymes). T cells also perform regulatory functions, cross-suppressing other types of T cells (see below).

Structure and development of the immune system

Although diffused throughout the body, the immune system functions as an integrated organ in much the same way as the nervous system, with which it shares a number of key molecular concepts. However, the immune system has an enormous task as the surface area of the skin is about 2 m^2, that of the lung 100 m^2 (the size of a football pitch) and that of the gastrointestinal tract 400 m^2 (four football pitches!). The mucosal surfaces have to be 'painted' with a contiguous film of secreted IgA. This explains why the total daily production of IgA is tenfold higher than that of IgG, even though the serum level of IgA is five times less than that of IgG.

Primary lymphoid tissue

The primary lymphoid tissue comprises the sites in which lymphocytes and other cells involved in immunological function develop. In humans this comprises the yolk sac

and fetal liver during embryogenesis, with seeding of pluripotent precursors to the bone marrow. These stem cells may be either $CD34^+$ or $CD34^-$, although in clinical transplantation CD34 is used to enrich for stem-cell activity. B-cell development takes place in the bone marrow while committed T-cell precursors, which are $CD7^+$, migrate to the thymus. In birds the bursa of Fabricius and in lagomorphs the sacculus rotundus and the appendix are specific organs involved in the generation of B cells and are analogous to the thymus. However, humans do not appear to have homologous structures. In all these organs there is a complex interaction between stromal epithelium and developing immunocytes, with production of key growth factors by the epithelial cells and presentation of self-antigens involved in tolerance induction.

B-cell development takes place in the bone marrow in humans, with 10^9 new B cells produced each day. During the process of B-cell development, the immunoglobulin genes undergo rearrangement to form the basis of the enormous repertoire of antibodies. This process is dependent on the presence of the recombinase enzymes *RAG-1/RAG-2*. Recombination occurs first in the heavy-chain genes, involving the V, D and J regions. There is a significant wastage as 50% of cells fail to produce viable recombinations. Initially the cells produce a membrane form of the μ heavy chain, which appears on the surface, coupled with the surrogate light chains, V pre-B and λ5. At the same time the invariant chains Igα and Igβ are also produced and combine on the surface as part of the receptor complex. The role of the surrogate light chains is purely to allow expression of the heavy chain and to permit the continued development of the B cell, with recombinations of the κ and λ light chains, and the expression of a fully formed receptor. During this process, the other components of the receptor complex (CD19 and CD21) also appear, and cells become dual positive for surface IgM and IgD. B-cell development is a complex process, and defects in some of the essential enzymes and genes have been identified as causing primary immunodeficiencies. These include deficiencies of surrogate light chain, μ chain, Igα BLNK (B cell linker protein) and BTK (B cell tyrosine kinase), which give B-lineage specific defects, while *RAG-1/RAG-2* defects cause severe combined immunodeficiency (SCID) due to their involvement in TCR rearrangement. Use of knock-out mice has enabled rapid strides to be made in the assessment of the enzymes critical to B-cell development. It is likely that further genetic abnormalities will be described in humans.

Within the thymus, committed T-cell precursors undergo rearrangement first of their TCR β genes; *RAG-1/RAG-2* are critical for this process. In order for the gene product to be expressed a surrogate α chain, invariant TCR pre-α, is produced that permits the next stage of α-chain rearrangement. A small proportion of cells produced do not express αβ TCR but express γδ TCR. Failure to rearrange a functioning β chain leads to cell death. It has been calculated that the process of gene rearrangement can lead to 10^8 potential recombinations. Numerous genes are involved in the control of this process, including *Ikaros* and *Notch-1*. During this process, expression of CD44 (hyaluronate receptor) is lost and expression of CD25 (low-affinity IL-2 receptor) is gained. Cells then express CD3 and both CD4 and CD8 (dual-positive cells), and lose one or the other as development proceeds to become either $CD4^+$ or $CD8^+$ T cells. The enzyme ZAP-70 kinase is essential to this process and genetic deficiency of this enzyme leads to failure of production of $CD8^+$ T cells and reduced numbers of $CD4^+$ T cells; this disorder is a variant of SCID. The T cells then leave the thymus as naive T cells. During the process of T-cell development two key processes take place: positive selection of T cells that recognize self-MHC, and negative selection of those that recognize self-peptides. As the recombination process is essentially random, the majority of developing T cells do not develop appropriate TCRs. Cells that do not recognize MHC die by 'neglect' while those that recognize self-peptides are stimulated to proliferate and die (activation-induced cell death or apoptosis). Accordingly the thymus has a huge turnover of T cells, the majority of which die *in situ*. Any failure in the process of eliminating self-peptide reactive T cells contributes to later development of autoimmune disease.

Failure of thymic development has been described and is due to as yet uncharacterized gene defects located at chromosome 22q11, which control the development of the branchial arches and pouches; this leads to failure of T-cell production as well as cardiac abnormalities. The severe form with immunodeficiency is recognized as DiGeorge's syndrome, analogous to the nude mouse mutation. However, milder variants without immunodeficiency are also identified: velocardiofacial syndrome and conotruncal anomaly face syndome.

Although early dogma denied the possibility of extrathymic generation of T cells, it is now clear that certain specific classes of T cells can develop independently of the thymus. These include intestinal intraepithelial lymphocytes, which are usually γδ TCR^+ and often express an unusual homodimeric ααCD8. Extrathymic γδ TCR^+ cells appear to have specificity for non-protein phosphate-containing antigens, particularly triphosphate nucleic acids and hydrocarbon phosphates derived from mycobacteria. Recognition of these antigens does not appear to require conventional processing and the cells can recognize whole antigen.

Secondary lymphoid tissue

Spleen

The largest lymphoid organ is the spleen, containing about 25% of the body's lymphocytes, and comprises

white pulp surrounding central arterioles (peri-arteriolar lymphoid sheath) and red pulp through which blood is filtered. Red pulp contains sinusoids with abundant macrophages, which are important in stripping off immune complexes bound to the surface of red cells and also for removing aged red cells. The white pulp comprises both T and B cells and also contains follicles comprising mainly B cells. In primary follicles the B cells are predominantly resting cells, whereas in secondary follicles a change in morphology identifies the presence of germinal centres, where active B-cell development takes place in response to antigenic stimulation. This process is stimulated by the presence of APCs and activated T cells expressing high levels of CD40 ligand (CD154). The marginal zone occurs at the interface of red and white pulp and contains a distinct population of B cells, expressing surface IgM but little IgD.

Lymph nodes

Lymph nodes occur in chains beginning at the extremities and are linked by lymphatic channels that eventually coalesce to form the thoracic duct, which drains into the left subclavian vein. Flow along the lymphatics is centripetal, draining lymph containing antigen, inflammatory mediators and cells to regional lymph nodes and thence to the general circulation. Lymph enters the cortex of the node, filtering through the kidney-shaped node to leave by the medulla. The cortex comprises the mainly B-cell area with primary and secondary follicles, as in the white pulp of the spleen, while the medullary area comprises mainly T and B cells in the process of emigration from the node. However, T cells and APCs are spread through the whole structure of the lymph node and the paracortical area surrounding the B-cell follicles is rich in T cells, macrophages and dendritic cells. Specialized follicular dendritic cells are found in the follicles and are responsible for holding antigen on their surface to provide continuous stimulation of B cells recruited into the follicle. These cells have abundant Fc receptors for IgG and use passively bound antibody to sequester antigen in abortive endocytic vacuoles called iccosomes, which protect it from proteolytic degradation. This feature explains why antibody levels decline but not usually to zero after a secondary immune response, as there is continuous restimulation from the sequestered antigen.

Specialized lymphoid tissue is present in the upper respiratory tract, including the tonsils and adenoids (Waldeyer's ring). These are particularly rich in B cells and have a structure similar to lymph nodes. Absence of tonsillar tissue in a small child should always raise suspicion of a B-cell deficiency, particularly a genetic abnormality such as X-linked agammaglobulinaemia, in which mature B cells cannot be produced. The tonsils atrophy in early adult life and it is most unusual to see persistent tonsillar tissue in adults over the age of 25. The gut is well supplied with lymphoid tissue in the form of Peyer's patches, located in the lamina propria, particularly around the ileum, and containing many follicles. Isolated follicles also occur scattered through the lamina propria. The surface epithelium overlying the follicles and Peyer's patches is modified with the presence of M cells, which take up particulate antigen and express MHC class II antigens. Peyer's patches contain all the elements found in peripheral lymph nodes, except that a high proportion of the differentiated B cells express IgA. As well as the defined structures, the lamina propria also contains large numbers of free-ranging lymphocytes, including IgA^+ B cells, and specialized intraepithelial lymphocytes, mainly $CD8^+$ or $CD4^-CD8^-$ T cells. However, there is an increased proportion of $\gamma\delta$ TCR^+ cells with cytotoxic activity. The lymphoid structure in the lower respiratory tract is less well developed, although small aggregates similar to Peyer's patches may be found. The difference is related to the burden of microbes in the two sites, as the lung under normal conditions is relatively free of infection, with most foreign material trapped in the upper airway or removed by the mucociliary escalator.

In the skin there are Langerhans' cells, scattered through the stratum malpighii. These are potent APCs, migrating in the lymph to the regional lymph nodes to stimulate B and T cells and secreting IL-1 and chemokines. Keratinocytes are also directly involved in immune responses through the production of cytokines, including IL-1, IL-6, TNF-α and TGF-β. As noted below, blood vessels in the skin express specific receptors for recruiting skin-homing lymphocytes that express CLA.

Lymphocyte trafficking

A key feature of immune function is the traffic of lymphocytes and other cells involved in the immune response from sites of storage or rest to sites of inflammation. As an estimate of the size of the population of cells on the move, the total number of lymphocytes is estimated at 10^{12} while 10^{11} are in circulation at any one time. Recruitment of lymphocytes into secondary lymphoid tissue occurs through specialized vessels in lymph nodes, the high endothelial venule (HEV); 80% of the lymphocytes enter lymph nodes using the HEV, with the remaining 20% arriving in afferent lymph from tissues. Entry is controlled by expression of L-selectin (CD62L) on the lymphocyte and its cognate receptor on the HEV. The integrins of the lymphocyte function antigen (LFA-1) family are also crucial in neutrophil trafficking but are less so for lymphocytes, which can use other cognate pairs; clinical deficiency of LFA-1 family members leads to an inability of neutrophils to leave the circulation. A range of different receptors occurs on lymphoid tissue in different tissues and the skin that allow selective recruitment of either naive cells or cells that have

been primed to antigens occurring in these locations. For example, binding of L-selectin to the mucosal addressin MAdCAM causes recruitment of naive cells to Peyer's patches, while the interaction of an $\alpha_4\beta_7$ integrin with MadCAM and vascular cell adhesion molecule (VCAM)-1 recruits naive cells to Peyer's patches but memory cells to the lamina propria of the gut. Interaction of CLA and E-selectin on endothelium in skin recruits memory cells to the skin. Binding of lymphocyte very late antigen (VLA)-1 to VCAM-1 attracts lymphocytes to inflammation, as does interaction of lymphocyte CD44 with hyaluronate. Chemokines and their receptors are also involved, such as secondary lymphoid chemokines, which bind to T cells bearing CCR7; fractalkine, expressed on HEV is also a potent chemoattractant for T cells. T and B cells have discrete and non-overlapping patterns of chemokine responses, and are therefore recruited to different areas within the lymph nodes. Many other molecules involved in cellular adhesion have been identified and it is thought that other molecular pairs exist which confer additional tissue specificity on lymphocytes. Once memory cells are recruited in one area, they are thought to retain that homing response for the reminder of their life.

As well as deficiencies of LFA-1 such as leukocyte adhesion molecule deficiency (LAD)-1, clinical examples of other adhesion molecule deficiencies have been described. LAD-2 is caused by a defect in fucosylation that leads to an inability of the receptors for selectins to bind to their cognate molecules, causing recurrent infections, neutrophilia and mental retardation. These patients can be treated successfully with oral fucose. A clinical deficiency of E-selectin has also been described, with recurrent infections but no neutrophilia.

Lymphocyte function, activation and regulation

Antigen presentation

Professional APCs, including macrophages and dendritic cells, undertake antigen presentation to T cells and B cells that express MHC class II antigens constitutively and to other cells on which class II can be induced by inflammation. Although dendritic cells are not phagocytic, they can take up processed antigen transferred from macrophages via pinocytosis in clathrin-coated pits and receptor-mediated endocytosis. Antigen presentation through the class II (or exogenous) pathway targets antigen to the $CD4^+$ T cells. Newly synthesized class II molecules are directed to the endosomal compartment by the invariant chain Ii where they are loaded with peptides. A peptide sequence in Ii called CLIP blocks the peptide-binding groove in the class II molecule until it reaches the endosome, where the enzyme DM removes it. The peptide-binding groove in class II is open-ended, allowing peptides to overhang the ends, provided that the correct sequence binds in the middle. Once loaded, the class II molecule is transferred to the cell surface. The process is a continuous one, and class II is recycled off the surface and can be reloaded with peptide.

Antigen presented via the class I (or endogenous) pathway is loaded in a different compartment, the endoplasmic reticulum, with proteolysis taking place in proteosomes in the cytosol and governed by ubiquitin. The peptide-binding groove on class I has closed ends, which means that the peptide has to be exactly the right length and sequence to bind. Trimming of over-length peptides is carried out in the cytosol by leucine aminopeptidase. The proteins involved in peptide loading are the TAP (transporter associated with antigen processing) proteins. Once correctly loaded, the class I molecule is inserted in the endoplasmic reticulum membrane in association with calnexin and then with β_2-micoglobulin. Finally, a large multimolecular complex is formed and transported to the Golgi body and then to the surface membrane. Any class I molecules not loaded with peptide are destroyed prior to transfer to the Golgi. Evidence for recycling is less clear than for class II.

A third pathway of antigen presentation exists, based on the non-MHC molecular family CD1, which is coded separately from MHC but has similarities to class I, including the use of β_2-micoglobulin as a light chain. CD1 molecules also present antigen to T cells, although the antigens are predominantly lipids, particularly those derived from mycobacteria. At least four isoforms are known, each with different lipid specificities. Loading of CD1 molecules with lipid takes place in the endocytic pathway.

B cells

Mature B cells leaving the bone marrow circulate through the blood and tissues or enter lymph nodes directly via HEVs, where they form the follicles. On encounter with antigen and with T cells recognizing components of the same antigen, the B cells are stimulated to proliferate and to develop further to plasma cells. Two further key processes are involved: class switching, in which the B cell changes the heavy chain associated with a given antibody binding specificity; and somatic hypermutation, which permits an increase in affinity of the antibody (affinity maturation).

Class switching allows the immune system to develop IgG and IgA responses from the initial primary IgM response. This process depends on the interaction of CD40 on the B cell with CD40 ligand (CD154) on activated T cells. Genetic defects in CD154 lead to the X-linked hyper-IgM syndrome, where there is failure of the class switch and IgG and IgA antibody are not produced but high levels of IgM are produced. CD40 is also expressed on APCs and hence T-cell function is also impaired, leading to the typical occurrence of opportunistic infections such

as *Pneumocystis carinii* pneumonia and cryptosporidiosis. One of the enzymes involved in class switching is activation-induced cytidine deaminase (AID); mutations in this enzyme give rise to autosomal hyper-IgM syndrome. Other enzymes involved are the Ku family of DNA phosphokinases, which are targets in the autoimmune process in systemic lupus erythematosus (SLE).

Affinity maturation only takes place in B cells proliferating in the germinal centres, and occurs at hotspots within the variable regions of heavy and light chains, targeting residues that form part of the antibody-binding site. The process is random, and it appears that the enzyme AID is also involved in this process. The process is actively driven by exposure to antigen: cells that hypermutate to produce antibodies of lower affinity are less stimulated and will therefore cease to proliferate, whereas those with higher affinity will continue to receive positive feedback stimuli.

Memory B cells have a different phenotype from naive B cells, expressing high levels of CD27, a member of the TNF-receptor gene family. Conversion to memory phenotype is dependent on the CD40–CD40 ligand interaction in the presence of IL-4. Subsequent activation of memory B cells can take place through interaction of CD27 with its ligand, CD70, expressed on activated T cells; IL-2 and IL-10 augment this process. Naive B cells can be induced to plasma cell formation through OX40 and its interaction with OX40 ligand on T cells.

B-cell responses to antigen have been divided on the basis of requirement for T-cell help. T-dependent antigens include most proteins; T-independent (TI) antigens are mostly polysaccharide antigens. TI-1 antigens include LPS and endotoxin, which at low doses stimulate B cells directly to produce specific antibody, but at high doses stimulate polyclonal B-cell proliferation through interaction with specific receptors. TI-2 antigens such capsular polysaccharides only stimulate specific antibody production. For all TI responses, however, responses are greater in the presence of T cells, so T-cell independence is relative.

Regulation of B-cell activation takes place through negative feedback loops of cytokines produced by activated B cells. It is also thought that the production of idiotypic antibodies, i.e. antibodies that bind to the antigen-binding site of other antibodies, form complex regulatory networks that down-regulate antibody production. Rheumatoid factors are antibodies that recognize the Fc regions of other antibodies; these also appear during infections and are thought to play a role in control of the immune response, presumably by forming immune complexes, which are known to switch off antibody production when present in high concentrations. This explains why antibody responses to antigens are much reduced in small children when maternal antibody is still present. This normal occurrence of rheumatoid factors during the immune response explains why measurement of rheumatoid factors as a diagnostic screening test is usually unhelpful unless a patient has obvious clinical rheumatoid arthritis.

T cells

Recent T-cell emigrants from the thymus are naive and are distinguished by expression of high levels of CD45RA. After antigen exposure the phenotype changes, with reduction in CD45RA and expression of CD45RO. CD45RA and CD45RO are isoforms of the leukocyte common antigen CD45 and are generated by alternate splicing of the RNA transcript. Exposure to antigen via the TCR/CD3 complex must occur in the context of the appropriate co-stimulatory molecules for T-cell activation to occur. If exposure to antigen occurs in the absence of co-stimulation, then non-responsiveness to the antigen is generated (anergy) or the cell is switched to the apoptotic pathway. The best-known co-stimulatory molecule is T-cell CD28. This interacts with B7.1 (CD80) and B7.2 (CD86) expressed on APCs. As noted above, interaction between CD40 and CD40 ligand is also important. ICOS is another T-cell co-stimulatory molecule that interacts with B7RP-1 to activate T cells. Conversely, a related T-cell molecule, cytotoxic T lymphocyte-associated antigen (CTLA)-4, binds to B7.2 and leads to inhibition of T-cell activation. Surface receptors for cytokines are also required for T-cell activation. Mutations in the common γ chain for cytokine receptors leads to SCID. The intracellular kinase cascade is complex, and is being unravelled through studies on knock-out mice and human genetic immunodeficiencies. The kinase JAK-3, linked upstream to cytokine receptors and downstream to STAT kinase, is critical since defects in this molecule also lead to SCID. Other defects in intracellular signal transduction occur in Wiskott–Aldrich syndrome, where mutations in the *WASP* gene interfere with signalling through the rho-GTPases; ataxia telangiectasia, in which a phosphatidylinositol 3-kinase is defective; and the X-linked lymphoproliferative syndrome in which the defect is in the SAP protein. Intracellular calcium is essential for activity of some of the kinases and this is controlled via the calcineurin pathway, which provides the target for ciclosporin A and tacrolimus, immunosuppressive drugs that prevent T-cell activation.

Apoptosis plays a key role in the control of lymphocyte activation and the prevention of autoimmunity. Two processes exist: apoptosis triggered by lack of signals (intrinsic cell death pathway, controlled by Bcl) and apoptosis triggered by activation via CD95. CD95 is expressed on T cells activated via the TCR/CD3 complex. Interaction of CD95 ligand with CD95 (fas) on the T cell activates the caspase pathways and leads to DNA fragmentation. The importance of this pathway is demonstrated in the Canale–Smith syndrome, in which there are defects in the apoptotic pathways at the level of either CD95 or the caspases. The syndrome is characterized by excessive

uncontrolled lymphoproliferation accompanied by features of autoimmunity.

$CD4^+$ Th cells have been divided on the basis of cytokine production, and latterly chemokine receptor expression, into Th1 and Th2 cells. Th1 cells are involved primarily in 'help' for cytotoxic or cell-mediated T-cell responses, while Th2 cells are predominantly responsible for the support of antibody-mediated responses, including IgE-mediated allergic responses. There is cross-regulation of the two subsets, with Th1 cytokines down-regulating Th2 cells and vice versa. Th1 cells produce IL-2 and IFN-γ, while Th2 cells produce IL-4, IL-5, IL-9, IL-10 and IL-13. Th1 responses require signalling through the IL-12 receptor and the IFN-γ receptor; in the absence of function in these pathways, Th1 responses essential for handling mycobacteria are abolished and recurrent infection occurs. Polarization of naive $CD4^+$ T cells to either a Th1 or Th2 response occurs through the release of cytokines from the cells of the innate system, such as macrophages, NK cells, mast cells, eosinophils and basophils. Conversely, the cytokines released by activated Th1 and Th2 cells further stimulate the innate cells. IL-9 appears to have an important role in governing the class switch in B cells to IgE production. In evolutionary terms, the Th2–IgE axis plays an important role in the control of parasitic infections, particularly worm infections of the bowel. One proposal for the increasing prevalence of allergic disease suggests that the disappearance of parasitic worm infections in developed countries releases the IgE system to respond inappropriately to other antigens.

$CD8^+$ cytotoxic T (Tc) cells have also been divided into two populations based on cytokine production: Tc1 produce IFN-γ, while Tc2 produce IL-4 and IL-5. Two discrete mechanisms are used by Tc cells for killing targets recognized via interaction of target cell class I with the CD3/TCR/CD8 complex. Co-stimulation is required for optimum killing activity, especially via CD2 and LFA-1 (CD11a/CD18). The first pathway triggers cell death in the target using the fas–fas ligand pathway of apoptosis, as discussed above. The other pathway uses granzyme and perforin, exocytosed from granules in the Tc. Perforin forms pores in the target cell membrane and allows the entry of granzymes into the cell, which complete cell destruction. Under certain circumstances $CD4^+$ T cells can also be shown to possess cytolytic activity.

A third class of T cells has been described that plays an important role in down-regulation and control of activated T cells. These are sometimes called Th3 or T-regulatory cells, not to be confused with the old concept of 'suppressor cells'. The role of CTLA-4 in inhibiting activation has already been noted. IL-10 and TGF-β produced by these T cells is also inhibitory. No clear phenotype has been identified, but these cells, in some models, are $CD45RB^{hi}$. $CD4^+CD25^+$ T cells have also been shown to be suppressive. As fas is also up-regulated during T-cell activation, this provides another mechanism for control of the immune response.

Overview of immunological disease

Immunological disease can arise as a result of genetic deficiency of key components, hyperreactivity (allergy/hypersensitivity), immune deviation (autoimmunity) and immunological malignancy. In addition, there are changes in immunological function arising from extremes of age, malignancy in other organs, pregnancy and environmental exposures (e.g. cigarette smoke, drug administration).

Understanding immune-mediated disease is dependent on understanding both the development and function of the immune system. However, multiple mechanisms may be active. For example, in primary immunodeficiencies due to genetic defects, there is often aberrant immunological development that leads to autoimmunity and eventually in many cases to lymphoid malignancy.

Immunodeficiency

Immunodeficiency is subdivided into primary and secondary (Tables 10.1–10.3). Over the last 10 years an increasing number of genetic abnormalities of the immune system have been described. A key feature is the lack of correlation between the genetic abnormalities and the clinical phenotype. In some cases this is due to the redundancy within the immune system, allowing compensatory mechanisms to provide protection. Some immunological diseases that are classified as 'primary' do not yet have a clearly defined genetic basis, such as common variable immunodeficiency, selective IgA deficiency and specific antibody deficiency. Most primary immunodeficiencies are rare, in contrast with secondary immunodeficiency, which is common and becoming increasingly so due to widespread use of immunomodulating drugs to control immune-mediated disease.

Primary immunodeficiency

Primary immunodeficiency is defined as immunodeficiency due to genetic defects or where no secondary cause can be identified. Advances in molecular genetics over the last 10 years have meant that clinically well-described syndromes have been identified genetically, increasing our understanding of the immune system through natural knock-out experiments. This has also led to a re-evaluation of some diseases, for example X-linked hyper-IgM syndrome, previously thought to be a B-cell defect, is now known to be a T-cell defect impairing B-cell development.

The type cell or protein affected by the defect determines the likely clinical sequelae. In most cases this will include infection, although other problems such as autoimmunity and malignancy also arise.

Table 10.1 Summary of immune defects.

B-cell defects
X-linked agammaglobulinaemia
μ-chain deficiency; surrogate light-chain deficiency
SWAP-70 deficiency
Hyper-IgE syndrome (includes secondary neutrophil disorder)
CD79a (Igα chain) deficiency
BLNK deficiency
T-cell defects
Wiskott–Aldrich syndrome (*WASP* gene mutations)
Ataxia telangiectasia (*ATM* mutations)
Chronic mucocutaneous candidiasis (AIRE, FOXP3 deficiency)
X-linked hyper-IgM (CD40 ligand deficiency); autosomal hyper-IgM syndrome
Cartilage–hair hypoplasia
Idiopathic CD4 T-cell lymphopenia
Combined defects
Severe combined immunodeficiency (*RAG-1*/*RAG-2* mutations, common γ-chain deficiency; CD3ε deficiency)
Adenosine deaminase deficiency
Purine nucleoside phosphorylase deficiency
DNA repair defects (DNA ligase IV); Bloom's syndrome; xeroderma pigmentosum
Canale–Smith syndrome (autoimmune lymphoproliferative syndromes; fas, fas-ligand, caspase deficiencies)
X-linked lymphoproliferative syndrome (SAP deficiency; includes NK disorder)
MHC class I and MHC class II deficiency
Neutrophil defects
Chronic granulomatous disease (X-linked, autosomal)
Cyclic neutropenia
Leukocyte adhesion molecule deficiency (LAD-1, LAD-2)
Chédiak–Higashi syndrome (including NK cells)
Complement defects
C1–9 deficiency, properdin deficiency
C1-esterase inhibitor deficiency
C4-binding protein deficiency
Factor H deficiency
Unclassified
Common variable immunodeficiency
Selective IgA deficiency
Specific antibody deficiency
Hyper-IgD syndrome (mevalonate kinase deficiency); periodic fever syndromes (TNF-receptor associated protein deficiency)

Investigation for primary immunodeficiency is an increasingly complex field and specialist advice from an immunologist interested in this type of disorder is required at an early stage to assist with both diagnosis and management.

Secondary immunodeficiency

Secondary immunodeficiency represents the most likely type of immunodeficiency that will be encountered by clinical practitioners. The causes are extensive but can be categorized according to primary triggers. In most cases the effects are on T and B cells, although some triggers lead to damage to neutrophils and other parts of the innate immune system, leading to a more complex immunodeficiency. The dermatological manifestations tend to be cutaneous infection and an increase in cutaneous neoplastic change, often at multiple sites. Investigation may be required to prove the cause, but in most cases identification of the primary cause is enough to explain the problem.

Autoimmunity and allergy (hypersensitivity)

These represent overactivity of the immune system. In the case of allergy this is directed against external antigens (allergens), while in autoimmunity the targets are host antigens. Gell and Coombs originally classified the pathogenic mechanisms and no one has produced a better classification since (Table 10.4). However, it is worth noting that pathological reactions frequently involve more than one mechanism so the classification represents a simplification of the true nature of immunological disease.

Allergic disease

Atopic disease in particular is now thought to be a complex phenomenon, with both immediate type I and delayed type IV mechanisms active at different times within the evolution of the disease process. This applies particularly to asthma and has important ramifications for therapy. Previously, treatment has focused on the immediate responses in the airway, while ignoring the T-cell-mediated damage, which is not apparent until secondary lung fibrosis occurs due to T-cell-stimulated collagen deposition. Thus although good initial control is obtained, the disease gradually progresses to irreversible lung disease. Adapting treatment to deal with all the pathogenic mechanisms involved is therefore critical.

In clinical practice, classification of a disease is dependent on demonstrating the presence of appropriate components of the immune response, such as allergen-specific IgE, autoantibodies and complement abnormalities. However, detection of abnormal T cells is more difficult, except in the context of patch-testing for contact hypersensitivity.

The development of allergic disease is multifactorial. In principle, however, allergens are no different to any other antigen in the way in which they are processed and presented to T cells. The propensity to develop a Th2–IgE response appears to be genetically controlled, although more than one gene is involved. Candidate genes include those for the Th2 cytokines IL-4, IL-5 and their receptors, IgE and MHC antigens. Allergic reactions are commoner in developed countries, although allergic sensitization occurs in all populations. However, in communities in developing countries it appears that the cytokines

Table 10.2 Dermatological consequences of some primary immunodeficiencies.

	Key clinical features	Dermatological features
B-cell defects		
X-linked agammaglobulinaemia	Bacterial infections of upper and lower respiratory tracts, joints, gastrointestinal tract	Cutaneous bacterial infection
Common variable immunodeficiency	Bacterial infections of upper and lower respiratory tracts, joints, gastrointestinal tract; autoimmunity; granulomatous disease, lymphoma; nodular lymphoid hyperplasia	Cutaneous bacterial infection, vitiligo, alopecia, cutaneous granulomas
Hyper-IgE syndrome	Eczema, staphylococcal infections of skin and lung (pneumatoceles), osteopenia	Extensive impetigo, recurrent boils
T-cell defects		
Chronic mucocutaneous candidiasis (including APCED: autoimmune polyendocrinopathy, candidiasis and ectodermal dysplasia, due to *AIRE* gene mutations)	Chronic candidiasis; endocrinopathy; systemic infections with bacteria, mycobacteria and herpesviruses	Candidiasis of nails, Norwegian scabies
Wiskott–Aldrich syndrome (mutations in *WASP* gene)	Thrombocytopenia, small platelets, recurrent bacterial and viral infections, eczema, lymphoma	Eczema (distribution atypical compared with atopic eczema); often infected; cutaneous viral infections, papillomavirus, molluscum contagiosum (both extensive)
Ataxia telangiectasia	Cerebellar ataxia (progressive), cutaneous telangiectasia, viral and bacterial infections	Cutaneous viral infections, papillomavirus, molluscum contagiosum (both extensive); telangiectasia (conjunctivae, ears especially)
Cartilage–hair hypoplasia	Short-limbed dwarfism, fine hair, recurrent bacterial infections	Abnormal (fine) hair
Combined immunodeficiencies		
Severe combined immunodeficiency (all variants)	Early onset of infections: bacterial, viral, fungal	Rashes (Omenn variant, maternofetal engraftment)
DNA repair defects (xeroderma pigmentosum, Nijmegen breakage syndrome)	Malignancy, recurrent infections	Keratoses, cutaneous malignancy
Neutrophil disorders		
Chronic granulomatous disease	Bacterial and fungal infections	Cutaneous bacterial infections, ulceration of mouth
Cyclic neutropenia	Bacterial and fungal infections	Cyclic mouth ulceration (gingivitis)
Rare disorders		
Chédiak–Higashi syndrome and Griscelli's syndrome	NK cell defect, abnormal neutrophils, recurrent infections, lymphohistiocytosis	Silver streaks in hair, oculocutaneous albinism
Dyskeratosis congenita	Malignancy, bone marrow failure, recurrent infections (bacterial) with hypogammaglobulinaemia	Cutaneous pigmentation, nail dystrophy, oral leukoplakia
Anhidrotic ectodermal dysplasia	Respiratory infections	Hypohidrosis, abnormal dentition
Papillon–Lefèvre syndrome	Recurrent bacterial infections, impaired neutrophil function	Hyperkeratosis and pyoderma
Complement disorders		
C2 deficiency	SLE-like disease, recurrent bacterial infections	Extensive cutaneous lupus erythematosus
C1-esterase inhibitor deficiency	Angio-oedema	Angio-oedema without urticaria
C4-binding protein deficiency	Angio-oedema, features of Behçet's syndrome	Angio-oedema, ulceration

NK, natural killer; SLE, systemic lupus erythematosus.

produced as a result of endemic infections suppress the clinical manifestations of allergic disease. Where food allergens are concerned, it appears that exposure at times when the immune system is relatively immature in the first 2 years of life can lead to inappropriate responses. This may be augmented by the fact that many of the foods concerned contain naturally occurring lectins (e.g. wheat-germ agglutinin, peanut agglutinin), which have profound proliferative effects on lymphocytes. Exposure to infections in early childhood also has a protective effect against the development of allergic disease, as demonstrated in German children brought up on farms (hygiene hypothesis). Changes in the way we live are also important, for example the move to centrally heated, double-glazed houses with poor ventilation and fitted carpets provide optimum growth conditions for house-dust

Table 10.3 Causes of secondary immunodeficiency.

Infection
Human immunodeficiency virus
Epstein–Barr virus and other herpesviruses
Measles, rubella, influenza
Chronic bacterial sepsis, tuberculosis
Parasitic and protozoal infections
Drugs
Immunosuppressive drugs: corticosteroids, cyclophosphamide, azathioprine, ciclosporin A, tacrolimus, sirolimus, mycophenolate (all affect T- and B-cell function)
Biologicals: anti-CD3, anti-CD4, anti-CD52, anti-TNF (Etanercept)
Anticonvulsants: phenytoin, valproate, carbamazepine (hypogammaglobulinaemia, neutrophil dysfunction)
Carbimazole (agranulocytosis)
Chloramphenicol, penicillins (aplastic anaemia)
Transfusion therapy (blood components, including intravenous immunoglobulin)
Malignancy
Lymphoma, leukaemia, myeloma and other plasma cell dyscrasias, myelofibrosis (neutrophil dysfunction)
Solid tumours
Physical
Irradiation
Plasmapheresis, immunopheresis
Surgery (especially if thoracic duct damaged)
Medical/metabolic
Diabetes mellitus, glycogen storage disease (neutrophil dysfunction)
Chronic renal failure
Protein-losing enteropathy
Myotonic dystrophy
Nutritional deficiency (iron, zinc, vitamin B_{12})
Miscellaneous
Asplenia
Burns
Toxins (alcohol, cigarettes, solvents)
Extremes of age (prematurity, old age)
Pregnancy

TNF, tumour necrosis factor.

mites. Keeping pets indoors also contributes, although there is some evidence that keeping pets can have a protective effect against pet allergy. Other environmental factors include changes in diet, for example peanuts are now a common source of protein whereas they were rarely consumed 30 years ago, and the contribution of pollution, especially diesel fumes.

Autoimmune disease

Autoimmunity can arise through failure of the initial negative selection process for T and B cells or it can occur through the breaking of peripheral tolerance. As pathogens have evolved in parallel with humans, they have developed antigenic structures similar to those present in their preferred host, in order to reduce the risk of elimination by the immune system. Accordingly there is a risk that the immune response may generate both antibodies and effector T cells that are cross-reactive with self components, for example coxsackieviruses and diabetes mellitus, *Klebsiella* and HLA-B27$^+$ arthritis. Evolutionary selection pressure will determine that individuals who can respond to pathogens with an effective immune response will survive, even though this may be at a later cost of autoimmune disease. The pathogen will eliminate those whose immune response fails. The need to present such antigens then drives the evolutionary pressure on the selection of certain MHC haplotypes in stable populations and accounts for the widely differing patterns of MHC antigens in different parts of the world. Today's long-distance travel means that this equilibrium is disturbed: individuals are exposed to pathogens whose antigens cannot be presented effectively because those infected do not possess the appropriate MHC molecules. Other genes also contribute to the generation of autoimmunity, for example there is an increased incidence of autoimmunity in complement deficiencies and a high

Table 10.4 Gell and Coombs classification of immunological reactions.

Gell and Coombs classification	Immunological mechanisms	Examples of clinical disease
Type I (immediate hypersensitivity)	Allergen-specific IgE, mast cells, histamine, leukotrienes, Th2 cells, cytokines involved in IgE production (IL-4), eosinophil production (GM-CSF, IL-3, IL-5)	Anaphylaxis, urticaria (some types), allergic rhinoconjunctivitis, asthma (immediate but not chronic)
Type II	IgG-antibody mediated, direct effects (complement-mediated lysis), Th2 cells	Antibody-mediated autoimmune disease (thyroid, haemolytic anaemia, thrombocytopenia, myasthenia gravis, etc.)
Type III	Immune complex disease, IgG and IgM antibodies, complement, complement receptors	Serum sickness, SLE (abnormal complement, complement receptors), complement deficiency (abnormal immune complexes)
Type IV (delayed hypersensitivity)	T-cell mediated, Th1 cells, cytokines (IL-2, IFN-γ, TNF-α), macrophages, CD8$^+$ cytotoxic T cells	Contact (delayed-type) hypersensitivity, eczema, graft rejection

GM-CSF, granulocyte–macrophage colony-stimulating factor; IFN, interferon; IL, interleukin; SLE, systemic lupus erythematosus; TNF, tumour necrosis factor.

incidence of autoimmunity in defects of apoptosis such as fas deficiency and caspase deficiency. Autoimmunity may also be triggered by the release of sequestered antigen from privileged sites (e.g. the eye) and by the generation of neoantigens by chemicals and toxins (e.g. autoimmune haemolytic anaemia caused by penicillins). One suspects that the root cause of most autoimmune diseases will be infection, although like a hit-and-run accident the culprit is long gone even though the effects of the 'accident' may be lifelong.

Immunity at extremes of age

The immune system is incompletely developed at birth: while all the components are present, the acquired immune system requires antigen exposure to develop the full repertoire of both T- and B-cell antigen receptors through recombination and somatic mutation and class switching. While this process takes place, protection is provided for the first 6 months of life by maternally transmitted antibody, transferred across the placenta by an active process in the last trimester. Breastfeeding also provides important amounts of IgA for protection of the gut. Stimulation to the acquired system can be provided by either natural infection or programmes of immunization. However, virulence factors in certain classes of bacteria, notably pneumococci, *Haemophilus influenzae* and *Neisseria meningitidis*, are capsular polysaccharides. These antigens are difficult for the immune system to recognize in the first 2 years of life, hence the high incidence of invasive disease caused by these organisms in this age group. Normally the bulk of antipolysaccharide antibody is IgG2 subclass. Interestingly, this defect can be bypassed by covalently conjugating the polysaccharide antigen to a protein, with the immune system producing a protective but mainly IgG1 antibody response to the polysaccharide. As the immune system ages, this inability to recognize polysaccharide antigens returns and there is a second peak of disease in the older population.

Ageing of the immune system is not chronologically related. Studies of the immune system in the elderly have been hampered by the need to define healthy elderly, free of other illness and medication. In fact the immune system remains remarkably effective, with good vaccine responses in the healthy elderly. However, protection of at-risk groups is less effective by virtue of their coexisting disease. Thus targeting influenza vaccine at those with, for example, chronic respiratory disease or chronic lymphocytic leukaemia targets the vaccines at those least able to respond. It was previously assumed that beyond the age of about 25 years, the ability of the immune system to reconstitute from thymus and bone marrow declined rapidly. However, newer evidence has shown that thymus is capable of functioning well into old age, albeit with a reduced capacity for generation of mature T cells. Much of the immune dysfunction of the elderly is related to other disease processes, either directly or through their treatment. Immune regulatory function becomes less effective with age and this is manifest by increasing levels of rheumatoid factors and other autoantibodies, usually in the absence of clinical disease. Low-level monoclonal gammopathies also develop due to failure to suppress antibody-producing clones at the end of an immune response. These may remain stable for decades, although the current view is that all will eventually develop into myeloma, given sufficient time.

Immunity and malignancy

The immune system has an important role to play in immune surveillance for malignancy through the activities of NK cells (see above) and in control of established tumours through infiltrating cytotoxic T cells. Tumours often escape immune surveillance and cytotoxicity by loss of key antigens on the cell surface or production of immunosuppressive mediators. Tumours of the immune system, either lymphomas (including chronic lymphocytic leukaemia) or myelomas, have a direct effect on immunological responsiveness, with reduction in humoral immunity especially and an increase in bacterial infections. In the case of lymphomas, the abnormalities of humoral immune function may persist for years after apparently curative therapy. The importance of the acquired immune system in tumour control is well demonstrated by the significant increase in cutaneous tumours seen in patients treated with immunosuppressive drugs such as ciclosporin and cyclophosphamide over long periods.

Overview of diagnostic testing for immunological and allergic disease

Accurate immunological diagnosis depends on access to appropriate immunology laboratory services. Such services need to be run to high quality standards, verified by external peer review inspection. In the UK this is carried out by Clinical Pathology Accreditation (CPA). Laboratories are inspected at regular intervals to ensure compliance with agreed standards. These standards verify the organization, testing and reporting of laboratory testing. Participation in external quality assurance for the tests offered is essential, although rarely requested tests may not have national schemes in place. Under these circumstances the laboratory must satisfy itself that it is taking reasonable steps to quality assure the results. In all cases laboratories should run internal controls with defined parameters and only report results when these internal controls meet their predetermined values. Clinical governance standards require clinicians to assure themselves that they are using appropriate diagnostic services. Where academic departments are providing in-house tests for diagnostic clinical

use, they have the responsibility, under product liability legislation, for any errors or problems arising from the assay. It is essential therefore that scrupulous internal quality control data are collected, together with validation data.

Good clinical practice requires that test selection should be appropriate to the disease under investigation. The laboratory is responsible for selecting the most appropriate methodology and ensuring that clinicians have a clear understanding of the performance of the test, through derivation of normal ranges appropriate to the population under study and interpretative comment. Each laboratory for each test should define normal ranges, although in practice nationally established ranges may be used. Ranges should be adjusted for age, sex and racial background.

Immunochemistry

Immunochemistry covers the measurement and identification of serum proteins, including abnormal ones. Usually this is undertaken using automated analysers, which are readily quality controlled. International standards have been established for all major serum proteins, and there are long-established external quality assurance schemes. Results in principle should vary little from laboratory to laboratory.

Allergy tests (Table 10.5)

Total IgE and allergen-specific IgE are readily measured in the diagnostic laboratory. However, total IgE levels correlate poorly with the allergic symptomatology; elevated levels suggest inheritance of the atopic tendency but do not predict the form this may take. Levels greater than 1000 kU/L are usually seen in atopic eczema. Levels more than 50 000 kU/L are seen in the hyper-IgE syndrome. However, levels in the range 10 000–50 000 kU/L may be seen in either condition and the differential diagnosis is then dependent on associated clinical and immunological features. Levels of total IgE within the normal range do not exclude severe allergic disease, although this is usually mono-allergenic. Total IgE levels are geometrically rather than normally distributed and there is considerable variation in ranges with age. It is essential to check that the laboratory has reported the appropriate range for age.

Allergen-specific IgE can be detected by many techniques, although the earliest technique was the radioallergosorbent test (RAST): this acronym has entered common usage as a term for allergen-specific IgE. Few, if any, laboratories use this technique now, having moved to colorimetric or fluorimetric assays. These assays tend to be expensive. Direct testing by skin prick is cheaper and is the preferred method of testing, provided that staff experienced in the technique are available. Results of skin prick testing are operator dependent. Correlation between skin prick testing and RAST is dependent on the allergen. For inhalant allergens and strongly allergenic food allergens, such as shrimp, peanut and tree nuts, there is good correlation. In the case of fruit allergens, as seen in the oral allergy syndrome, RAST results are unreliable and should not be used. Of those patients with latex allergy, 15% will have negative RAST results. RAST for drug allergy, with the exception of suxamethonium, is also unreliable and skin prick or intradermal testing is required. Newer assays include the Flow-CAST, and assays of stimulated histamine release compare well in some respects but are very expensive in comparison with existing tests. Allergy testing should be targeted to allergens identified on the basis of clinical symptoms, as routine screening with extended panels often leads to positive results of uncertain clinical significance, which is confusing to clinicians and patients alike. Very high total IgE levels (> 1000 kU/L) have always been suspected of causing false-positive reactions in RAST, especially to food allergens, although most modern assays seem to be less susceptible to this effect. Biological cross-reactivity is also common, where similar allergenic proteins occur in many species of plant or animal. This may be clinically relevant, for example prawn allergy in patients allergic to house-dust mite, or irrelevant, as in the detection of IgE to wheat

Table 10.5 Allergy tests.

	Advantages	Disadvantages
Skin prick tests	Cheap Results available in 15 min Useful positive and negative reinforcement Can be used with *ad hoc* allergens (e.g. fresh foods, drugs)	Cannot be done in patients receiving antihistamines, calcium channel blockers, phenothiazines, or those with extensive eczema Inadvisable as first-line test in patients with suspected anaphylaxis to test reagents (except where resuscitation facilities available) Requires skilled staff for reproducible results
Radioallergosorbent test (RAST)	Clinically useful for inhalants and some foods only Automated analysis Can be used in patients where skin prick testing is contraindicated	Expense (staff and analyser) Results not immediately available No reinforcement of clinical message Not suitable for many allergens (fruits, drugs)
Flow cytometric tests	Research tools	Very expensive, labour-intensive

Table 10.6 Patterns of immunoglobulins.

Pattern of immunoglobulins and electrophoresis	Clinical associations
IgG, IgA, IgM all low; electrophoresis shows agammaglobulinaemia	X-linked agammaglobulinaemia (children), light-chain myeloma (elderly), gross unselective nephrotic syndrome (all serum proteins reduced), burns, immunosuppressive drugs (excess), acute severe bacterial infection
IgG and IgM normal, IgA absent; electrophoresis normal	IgA deficiency; may be associated with IgG subclass deficiency and specific antibody deficiency. Also associated with gluten sensitivity (dermatitis herpetiformis, coeliac disease), connective tissue diseases
IgG and IgA low/absent, IgM normal/low; electrophoresis shows reduced γ region	Common variable immunodeficiency, protein-losing enteropathy; selective nephrotic syndrome (albumin reduced)
IgG and IgA low/absent, IgM high/normal; electrophoresis shows reduced γ region	Hyper-IgM syndrome, acute viral infection (repeat in convalescence)
Raised IgG; IgA and IgM low; electrophoresis shows monoclonal band on background of reduced γ region	IgG myeloma, lymphoma
Raised IgA; IgG and IgM low; electrophoresis shows monoclonal band on background of reduced γ region	IgA myeloma
Raised IgM; IgG and IgA low; electrophoresis shows monoclonal band on background of reduced γ region	Waldenström's macroglobulinaemia, lymphoma
IgG, IgA and IgM low; electrophoresis shows monoclonal band on background of reduced γ region	IgD or IgE myeloma, light-chain myeloma with free light chains in serum (also think of AL amyloid)
Raised IgG, normal/raised IgA, normal IgM; electrophoresis shows polyclonal increase in γ	Chronic infections (bacterial, viral), chronic inflammatory disease (RhA, SLE), sarcoidosis, autoimmune hepatitis
Very raised IgG (predominantly IgG1), raised IgA and IgM; electrophoresis shows polyclonal increase in γ	Sjögren's syndrome, hypergammaglobulinaemic purpura
Very raised IgM, normal IgG or IgA; electrophoresis shows polyclonal increase in γ region with or without small IgM bands	Primary biliary cirrhosis
Very raised IgA, normal/raised IgG, normal IgM; polyclonal increase in γ with β–γ bridging	Liver disease, especially cirrhosis due to alcohol

RhA, rheumatoid arthritis; SLE, systemic lupus erythematosus.

in patients allergic to grass pollen. Interpretation of results is therefore dependent on a clear understanding of the patient's history.

Mast cell tryptase is a useful marker of mast cell degranulation and can therefore be used to discriminate between acute allergic reactions and non-immunological mimics. It is a stable protein whose levels remains elevated for up to 24 h after a reaction and is easily and reliably measured on a clotted blood sample. ECP has also been used to demonstrate activation of eosinophils, particularly in the context of asthma, where it has been proposed as a useful marker of chronic eosinophilic inflammation. Unfortunately it is less stable than mast cell tryptase, and has a strict sampling protocol involving timed centrifugation, which renders it useless for diagnostic use.

Mast cell tryptase is also helpful in suspected mastocytosis, although 24-h urinary methylhistamine is probably more sensitive, albeit more awkward to collect. At present, the only commercial assay for urinary methylhistamine has been withdrawn by the manufacturer.

Immunoglobulins (Table 10.6)

Automated analysers, using nephelometry or turbidimetry, can measure serum immunoglobulins and IgG subclasses accurately and reproducibly. The only indications for measurement of these parameters are the investigation of suspected immunodeficiency, liver disease, lymphomas and plasma cell dyscrasias. Normal ranges must be age specific and in adults the range for IgM is also modified by sex, with the lower limit of normal for IgM being higher in females than males. Measurement of immunoglobulins should always be accompanied by electrophoresis, both as an internal quality control and also to permit the detection of paraproteins (monoclonal immunoglobulins). If the latter are detected, then immunofixation should be carried out to identify the nature of the band, and urine requested for analysis for free light chains (Bence Jones proteins). Paraproteins may react abnormally with antisera used for the quantification, leading to falsely low or high results. This may be due to polymerization of the paraproteins or the presence of monomeric, as opposed to pentameric, IgM. Paraproteins should therefore also be quantified by scanning densitometry.

Cryoglobulins and cryofibrinogen

Cryoglobulins are abnormal immunoglobulins that precipitate at a higher temperature than normal (Table 10.7). Normal immunoglobulins may precipitate from serum that is cooled to 4–6°C, but cryoglobulins precipitate at temperatures found in the extremities, i.e. above 26°C,

Table 10.7 Cryoglobulins.

Type	Composition	Associations
I	Monoclonal immunoglobulin	Myeloma, Waldenström's macroglobulinaemia, lymphoma
II	Monoclonal immunoglobulin with rheumatoid factor activity, precipitate contains both monoclonal and polyclonal immunoglobulins	Myeloma, Waldenström's macroglobulinaemia, lymphoma, mixed essential cryoglobulinaemia (HCV infection), subacute bacterial endocarditis, connective tissue diseases
III	Polyclonal immunoglobulins with rheumatoid factor activity	Chronic infections, chronic inflammatory diseases

HCV, hepatitis C virus.

causing obstruction to small blood vessels and a vasculitic-looking rash on cooler parts of the bodies, typically the hands and feet but also nose and ears. The higher the temperature at which they precipitate, the worse the symptoms will be. The appearance of cutaneous vasculitis on extremities, particularly in cooler weather, should always raise suspicions of cryoglobulins. The detection of a type II cryoglobulin in the absence of evidence for myeloma should raise the possibility of hepatitis C infection; complement C4 is invariably markedly reduced. Pyroglobulins are extremely rare and precipitate when the temperature is raised. Cryofibrinogen is an abnormal fibrinogen precipitated by cold; the significance of cryofibrinogen is less certain, but it is often associated with malignancy. Cryoglobulins are often confused with cold agglutinins, which are antibodies that agglutinate erythrocytes in the cold and are strongly associated with *Mycoplasma* infection.

Detection of cryoglobulins requires a clotted blood sample to be taken and kept at 37°C until clot retraction has taken place; in practice this means transporting samples in a vacuum flask containing water at 37°C. Cryofibrinogen can be detected in samples containing ethylenediamine tetra-acetic acid (EDTA); heparin should not be used because some fibrinogens are heparin insoluble.

Specific antibodies

Specific antibodies to bacterial, viral and fungal allergens are useful diagnostic tests for the assessment of the appropriateness of the humoral immune response. Tests can be carried out to exposure antigens and to deliberate challenges with vaccines (no live vaccines should be used in patients with any form of known or suspected immunodeficiency). The use of polysaccharide antigens such as pneumococcal capsular polysaccharide is particularly valuable as a robust test for humoral immune deficiency, as failure of responsiveness may occur even when total immunoglobulins and IgG subclasses are normal.

Precipitating antibodies to fungi are useful as diagnostic tests for fungal infection, although chronic mucocutaneous candidiasis is often accompanied by very high levels of *Candida* precipitins despite poor or absent T-cell responses, demonstrated by delayed hypersensitivity testing or *in vitro* antigen-specific T-cell proliferation (see below).

Complement assays

Complement components C3 and C4 are usually measured routinely by nephelometry or turbidimetry and can be assayed rapidly. Both are acute-phase proteins and will rise in chronic infection or inflammation by about 10%. C4 null alleles are common, resulting in reduced C4; as there is an ancestral gene duplication there are two C4 genes (four alleles), C4A and C4B. As a rule of thumb, two null alleles give a C4 level at the lower end of the normal range, while three null alleles give a level of half the lower end of the normal range, assuming there is no excess consumption. Factor B, from the alternate pathway, can be measured by automated analyser, although in routine practice this adds little useful clinical information. MBP from the lectin pathway can also be readily measured but the clinical utility is uncertain, except in the investigation of recurrent infections, where deficiency in MBP may be a co-factor with other immunological deficiency.

There is no role for measurement of immune complexes. Immune complexes can be readily detected in normal healthy individuals and the assays are difficult to standardize. Measurement of stable complement breakdown products such as C3d is more valuable as a determinant of complement turnover (Table 10.8).

Investigation of complement component deficiencies, which are associated with increased susceptibility to neisserial infection and atypical SLE-like disease, should be undertaken with haemolytic assays of complement that test both the classical and alternate pathways: CH_{100}/CH_{50} and $APCH_{100}$/$APCH_{50}$. These assays demonstrate intact complement cascade pathways through lysis of red cells. In the case of CH_{100}/CH_{50}, antibody-coated red cells are used to fix complement via the classical pathway; for the alternate pathway $APCH_{100}$/$APCH_{50}$, guinea pig erythrocytes are used, which can uniquely bind the alternate

Table 10.8 Patterns of complement abnormalities.

Complement pattern	Associated conditions
C3, C4 raised	Acute phase: infection, inflammation
C3, C4 reduced, C3d increased	Increased complement turnover via classical pathway (antibody or MBP mediated)
C3 reduced, C4 normal/high, C3d increased	Increased complement turnover via alternate pathway (endotoxin) Post-streptococcal glomerulonephritis (up to 6 weeks); C3 nephritic factor (> 6 weeks: type II membranoproliferative glomerulonephritis)
C3 normal, C4 reduced, C3d normal	C4 null alleles, C1-esterase inhibitor deficiency, C4-nephritic factor, mixed essential cryoglobulinaemia (HCV)

HCV, hepatitis C virus; MBP, mannan-binding protein.

pathway components. Both tests rely on an intact terminal lytic sequence. Both tests must be done in parallel to identify the site of any deficient component. Reduced haemolytic function will be seen where there is excessive complement consumption, although absent haemolysis will be found where there is a component deficiency. The exception is C9 deficiency, which permits slow haemolysis via the membrane attack complex C5–8. This deficiency is rare in Caucasians but is common in Japan. Individual components can then be measured depending on which part of the complement cascade is likely to be affected. It is difficult to identify C2 deficiency, which often presents with atypical cutaneous lupus (Ro antibody positive), because active lupus without C2 deficiency will reduce C2 levels due to activation of the classical pathway by antigen–autoantibody complexes. Ideally one needs to carry out testing at a time when clinical disease is quiescent, although this is often difficult to achieve.

C1-esterase inhibitor deficiency leads to a clinical syndrome of angio-oedema *without* urticaria, i.e. hereditary angio-oedema, an autosomal dominant condition. There is no value in screening patients for C1-esterase inhibitor deficiency where typical urticaria is seen. Patients with hereditary angio-oedema all have reduced C4 levels even between attacks; during attacks, C4 levels become undetectable. Measurement of C1-esterase inhibitor is therefore unlikely to be helpful if C4 is normal. Individuals with type I hereditary angio-oedema (85%) have a non-functioning C1-esterase inhibitor gene, while in type II (15%) there is a point mutation at the enzyme active site, leading to loss of function of the protein. Both immunochemical and functional assays for C1-esterase inhibitor are available. Angio-oedema has also been reported as a consequence of the rare deficiency of C4-binding protein.

Acquired angio-oedema may be seen in the older population, in association with the presence of paraproteins or autoimmune disease. In such cases checking for autoantibodies associated with SLE and measuring immunoglobulins and performing serum electrophoresis will give clues to the underlying diagnosis. C2 levels are said to be reduced in hereditary angio-oedema but normal in acquired angio-oedema, but this is not reliable.

Acute-phase proteins

Measurement of acute-phase proteins is an essential part of the investigation of sick patients. Measures of the acute phase include erythrocyte sedimentation rate (ESR), plasma viscosity, CRP, orosomucoid (α_1-acid glycoprotein), SAA and albumin. However, these measures are *not* interchangeable, and more than one marker is usually required. Albumin is a negative acute-phase protein, i.e. serum levels decrease during the inflammatory process. Transferrin behaves similarly. Most other proteins increase during an inflammatory process, although the increase may only be of the order of 10%, for example C3 and C4. In selecting suitable measures for clinical use, it is essential to choose markers that are easily measurable (preferably with automated equipment) and cheap and which have a wide dynamic range, i.e. there is a large difference between normal and abnormal values. The ESR has a dynamic range of 15 (10–150), while the CRP has a dynamic range of 100 (4–400). SAA has a similar dynamic range to CRP but is a less widely available and more expensive test, so has little additional value. Orosomucoid has a dynamic range of 2 so is unsuitable for routine use, although it has been previously supported as a more specific marker in inflammatory bowel disease. There is, however, no evidence that it performs better than CRP. Plasma viscosity has been promoted as equivalent to ESR but also has a poor dynamic range (2); its use is specifically for investigation and monitoring of hyperviscous states occurring in myeloma, especially IgA myeloma, and Waldenström's macroglobulinaemia.

Contrary to popular belief, CRP and ESR are not interchangeable. The relationship between ESR and CRP is similar to that between HbA_{1c} and glucose. The ESR rises only slowly after the onset of an acute insult and remains raised for several weeks after, being largely dependent on serum fibrinogen levels, a long-lived circulating protein. CRP on the other hand rises within hours and has a short half-life (6–8 h), meaning that levels also fall rapidly after a successful therapeutic intervention. Accordingly, CRP is appropriate for day-to-day monitoring, whereas ESR changes little in this time frame. At any given time,

CRP gives a picture of events of the previous 12 h, while ESR clarifies events of the previous 2 weeks. There are diseases, such as active SLE, where the two markers move asynchronously, with a significantly elevated ESR but little if any rise in CRP, unless infection is also present. Occasional patients have been described whose CRP range is reset, so that their acute-phase response takes place within the 'accepted' normal range. This is seen sometimes in giant cell arteritis, and makes monitoring difficult.

Detection of autoimmunity

Detection of the presence of autoantibodies can be performed by direct or indirect immunofluorescence (usually the cheapest and easiest method), solid phase assays, enzyme-linked immunosorbent assay (ELISA) and radioimmunoassay and, in some cases, flow cytometry. In all cases it is essential that the assay system has an appropriate threshold to reduce the risk of false-positive results. A number of autoantibodies may be found at low levels in apparently healthy individuals (e.g. rheumatoid factors, anti-Ro antibodies) and the prevalence of incidental positives rises with increasing age.

Nuclear and related antigens

A very large range of nuclear antigens have been identified as targets for autoimmune processes. Not all of these have identifiable clinical utility. Table 10.9 identifies the most important antigens and their clinical significance. Most of these can be detected by immunofluorescence using either rodent tissue or a human epithelial cell line (Hep2) (Fig. 10.3). Hep2 cells have the advantage of having a large nucleus in which patterns of staining can be readily identified. Genetically modified Hep2 cells are also available, engineered to have higher levels of expression of Ro antigen. Rodent tissue tends to have low levels of Ro antigen and it is also saline soluble so can be lost during the staining procedure. When rodent tissue was used exclusively for the detection of antibodies to nuclear antigens, this loss of Ro accounted for the high percentage of patients classified as antinuclear antibody-negative lupus. The increased use of Hep2 cells has significantly reduced the number of lupus patients in whom no antinuclear antibodies can be detected. Antibodies to extractable nuclear antigens were originally identified by counter-current immunoelectrophoresis; however, with the availability of cloned recombinant antigens, solid

Table 10.9 Nuclear and related antigens.

Staining pattern on rodent liver and Hep2 cells	Antigens recognized	Clinical associations
Homogeneous nuclear staining	dsDNA	SLE
	Histones (H2A, H2B)	SLE, drug-induced LE
	Mi-2	Steroid-responsive dermatomyositis
Fine speckled nuclear staining	Ro (52 kDa, 60 kDa antigens, distinguished using immunoblotting)	Sjögrens's syndrome, SLE
	La (48 kDa protein)	Primary Sjögrens's syndrome, SLE
Coarse speckled nuclear staining	U1-RNP	Undifferentiated connective tissue disease (anti-dsDNA and anti-Sm negative)
	Sm (B′/B and D proteins shared between U1, U2 and U4–U6 RNPs)	SLE
	Nuclear matrix (coarse speckles indicates multiple proteins)	SLE, undifferentiated connective tissue disease
Atypical speckled nuclear staining	Scl-70	Systemic sclerosis (severe form)
Nucleolar staining	RNA Pol I (speckled nucleolar staining)	Diffuse systemic sclerosis
	PM-Scl (PM-1) (homogeneous nucleolar staining)	Myositis–scleroderma overlap
	Fibrillarin (clumpy nucleolar staining)	Systemic sclerosis (lung and heart but few joint problems)
Cell-cycle-specific nuclear speckles	PCNA	SLE
Centromere (dividing cells)	CENA, CENB, CENC	Limited scleroderma (CREST syndrome)
Fine cytoplasmic speckled staining	tRNA synthetases (Jo-1, PL-7, PL-12, EJ, OJ)	Myositis (antisynthetase syndrome)
Coarse cytoplasmic speckled staining	Signal recognition peptide	Myositis
Ribosomal staining	rRNP	SLE (nephritis)
	Ribosomal P protein	SLE (cerebral)

CREST, calcinosis, Raynaud's phenomenon, (o)esophageal involvement, sclerodactyly, telangiectasia; dsDNA, double-stranded DNA; LE, lupus erythematosus; PCNA, proliferating cell nuclear antigen; RNP, ribonucleoprotein; SLE, systemic lupus erythematosus.

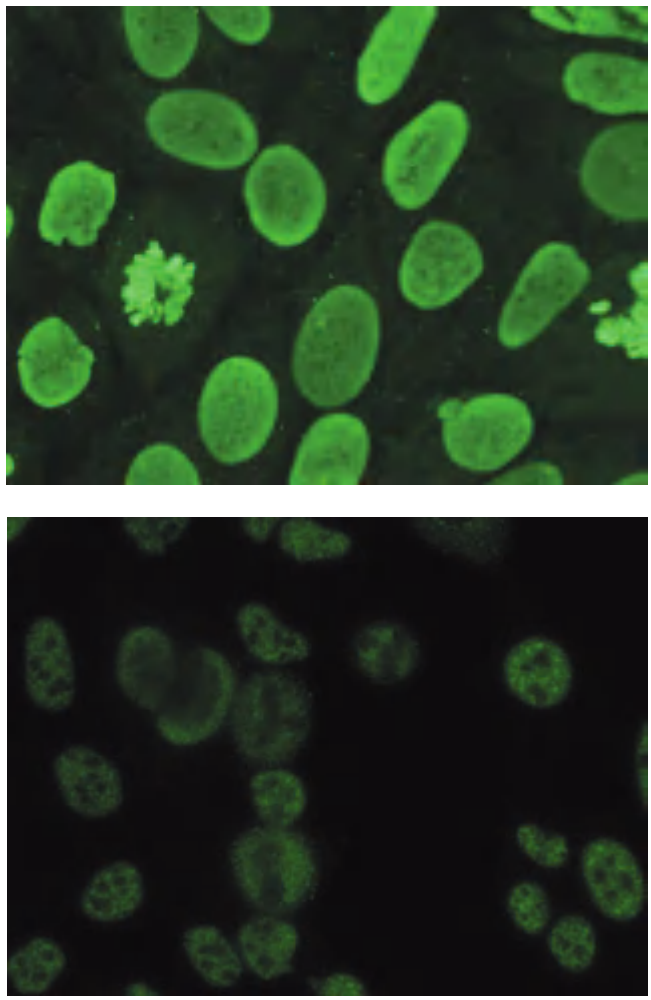

Fig. 10.3 (a) Homogeneous antinuclear antibody demonstrated by indirect immunofluorescence on Hep2 cells. (b) Coarse speckled pattern seen with anti-RNP antibodies on Hep2 cells.

phase assays are widely used to identify specificities of nuclear antibodies. The wide variety of different assays has meant that there is often no good agreement between the different assays and there is no currently accepted 'gold standard'. Similar problems have arisen with antibodies to double-stranded DNA (dsDNA), although here the gold standard has been the Farr assay; ELISA does not always produce satisfactory results due to degradation of dsDNA to single-stranded DNA or reverse-wound DNA (Z-DNA). Immunofluorescence on *Crithidia* has been proposed as a suitable test for dsDNA as its kinetochore contains pure dsDNA. The assay is, however, relatively insensitive and is now less widely used.

Detection of antibodies to nuclear components is diagnostically valuable. However, with the exception of antibodies to dsDNA, serial monitoring of antibody titres or arbitrary ELISA units provides no clinically useful information. Changes in levels of dsDNA antibodies do have some predictive value: a rising titre frequently heralds relapse, while a falling titre is usual where therapy has been successful. However, the absolute value has no relevance to disease activity. It is likely that there are subgroups of dsDNA antibodies, as not all patients with SLE develop renal disease. Currently available diagnostic tests do not yet distinguish these different anti-DNA antibodies.

The significance of the titre of an antinuclear antibody is dependent on the age of the patient: low-titre and clinically insignificant antibodies are seen in healthy elderly patients; conversely, low-titre antibodies are often significant in children. Laboratories should provide age-specific ranges.

Antinuclear antibodies of varying specificities and sometimes in high titre have been reported in association with infection, especially adenovirus and Gram-negative bacteria. Antibodies to dsDNA are rarely found under these circumstances. It is critically important to interpret the laboratory results in the light of the full clinical picture. Similarly, antibodies can appear in association with malignancy. In some cases, these markers are useful identifiers of paraneoplastic phenomena (anti-Hu, anti-Yo, anti-Ri in neurological disease).

ANCA antigens and the diagnosis of vasculitis

The detection of antineutrophil cytoplasmic antibodies (ANCA) has been an important step forward in the diagnosis of autoimmune vasculitis. The substrate for detection is ethanol-fixed human neutrophils. Other fixation techniques such as formaldehyde and acetone are not reliable and should not therefore be used. Three patterns are recognized: cytoplasmic granular staining (C-ANCA), atypical cytoplasmic staining (X-ANCA) and perinuclear staining (P-ANCA). As the latter can be difficult to distinguish from nuclear staining, Hep2 cells should also be used as a control for the presence of nuclear antibodies. Target antigens have been identified: proteinase 3 is the main target antigen for C-ANCA and myeloperoxidase is the main antigen for P-ANCA. Solid phase confirmatory assays are now available for these antigens. Other target antigens that have been identified include cathepsins, lactoferrin and neutrophil elastase. It is important to identify X-ANCA, as laboratories frequently confuse this pattern (which is not associated with antibodies to proteinase 3) with a true C-ANCA.

Of patients with Wegener's granulomatosis, 85% have C-ANCA, 10% P-ANCA and 5% will be seronegative. Of patients with Churg–Strauss syndrome, 10% have C-ANCA and 60% P-ANCA. In microscopic polyangiitis, 45% have C-ANCA and 45% have P-ANCA.

ANCA may also be seen in non-vasculitic conditions, including inflammatory bowel disease and sclerosing cholangitis. Prolonged neutrophil activation, as in infection, may also cause ANCA to appear, for example in cystic fibrosis. Careful interpretation of results is therefore

required. It appears that ANCA do not appear as part of the ageing process, and therefore their detection in the elderly is likely to be significant. There is no correlation between disease severity and ANCA titre, although rising titres are thought to herald relapse. IgA ANCA have been reported in some IgA-related vasculitides such as Henoch–Schönlein purpura and IgA nephropathy, although the significance of this is uncertain.

Rheumatoid factor

As previously noted, rheumatoid factors are seen as part of the normal immune response to infection. They also occur in the ageing population, without clinical significance, and as a specificity of monoclonal proteins (often with cryoglobulin properties). Although the assay is widely requested, its utility as a screening test is nil. Its major value is as a predictor of severe extra-articular disease in those patients with known clinical rheumatoid arthritis, where high levels of rheumatoid factors are predictive.

Other organ-non-specific antigens

Immunofluorescence using composite tissue blocks containing kidney, liver and stomach will also identify other organ-non-specific antibodies such as mitochondrial antibodies (primary biliary cirrhosis), liver–kidney microsomal antibodies (drug-induced hepatitis), ribosomal antibodies (see Table 10.9), smooth muscle antibodies (autoimmune hepatitis) and gastric parietal cell antibodies (pernicious anaemia).

Organ-specific antigens (including skin)

Organ-specific autoantibodies can be detected by direct immunofluorescence on biopsies and also by indirect techniques using animal tissues (primate or rodent). These include autoantibodies against endocrine tissues, as seen in the autoimmune polyglandular syndromes, some of which are associated with chronic mucocutaneous candidiasis (Table 10.10).

Autoantibodies to skin (see Chapter 41) are detected on primate oesophagus by indirect immunofluorescence. Titres and serial monitoring do not appear to have any great clinical significance. The same substrate is also used to detect endomysial antibodies of the IgA class, as a diagnostic test of high sensitivity and specificity in gluten-sensitive enteropathy, including dermatitis herpetiformis. As coeliac disease is associated with an increased incidence of IgA deficiency, screening for IgA deficiency is required; under these circumstances, IgG endomysial antibodies carry the same diagnostic significance. The target antigen has been identified as tissue transglutaminase, and solid phase assays for antibodies to this enzyme are available. There is no evidence that these are diagnostically superior to endomysial antibodies. Gliadin antibodies (IgG and IgA) are non-specific tests that should not be used for the diagnosis of gluten-sensitive enteropathy. Endomysial antibodies disappear gradually when strict gluten avoidance is instituted, but reappear after gluten challenge; they are therefore valuable as a tool to monitor compliance.

Autoimmunity in urticaria

It has been claimed that a significant proportion of patients (up to 35%) with chronic urticaria may have autoantibodies to the α subunit of the IgE receptor, and a further 5–10% may have autoantibodies to IgE itself. Unfortunately the solid phase assays used to demonstrate the presence of these autoantibodies have lacked appropriate controls. Studies using immunoblots have confirmed that such autoantibodies may occur but have shown them to be commonly present in low concentrations in the serum of otherwise healthy individuals and also at higher titre in patients with blistering skin diseases and connective tissue diseases. Their clinical utility is doubtful and there are no commercial validated assays available.

A small proportion of patients with chronic urticaria have hypocomplementaemic urticarial vasculitis. These patients have systemic features and may also suffer from angio-oedema, ocular inflammation and chronic obstructive pulmonary disease in the absence of a smoking history. It may be associated with evidence of an underlying connective tissue disorder. C3 and C4 are usually reduced and autoantibodies to the collagenous region of C1q can be demonstrated, although these are also found in

Table 10.10 Autoimmune syndromes.

Syndrome	Major criteria	Minor criteria
Type I (autoimmune polyendocrinopathy, candidiasis, ectodermal dysplasia)	Candidiasis, adrenal failure, hypoparathyroidism	Gonadal failure, alopecia, malabsorption, chronic hepatitis
Type II (Schmidt's syndrome)	Adrenal failure, thyroid disease, type I diabetes mellitus	Gonadal failure, vitiligo, non-endocrine autoimmunity (myasthenia gravis)
Type III	Thyroid disease	Type I diabetes mellitus *or* pernicious anaemia *or* non-endocrine autoimmunity (myasthenia gravis)

patients with SLE (especially if glomerulonephritis is present) who do not have urticarial lesions. However, all patients with clinical features of hypocomplementaemic urticarial vasculitis have the antibody. Routine assays are available for anti-C1q antibodies, although these are prone to interference from immune complexes and DNA fragments.

Cellular tests

Delayed-type hypersensitivity testing

In vivo testing for type IV reactions is commonly practised in dermatology departments in the form of patch testing for contact dermatitis. This is a useful and reliable test, and is the type IV counterpart of skin prick testing. Allergens are applied under aluminium discs taped to the back for 48 h and then removed. Allergen-specific T cells are then recruited by allergen-bearing APCs in the epidermis, accumulating over the next 48–72 h. The infiltrate is palpable, and there is often blistering and inflammation at the site due to cytokine release and recruitment of inflammatory cells. In the case of photo-allergy, allergens are applied in duplicate, with one panel being exposed to UV light after removal of the discs, while the duplicate panel is protected from light.

Variants of this type of test include the well-known Heaf test for T-cell immunity to *Mycobacterium tuberculosis*, in which a multipronged applicator introduces purified protein derivative (PPD) into the dermis. Similar tests are used by clinical immunologists to test for T-cell immunity to *Candida* and other protein antigens, as part of the work-up for suspected T-cell immunodeficiency. Access to antigens in a form suitable for (unlicenced) clinical use limits the usefulness of this type of testing.

Cell marker analysis (whole blood) (Table 10.11)

Lymphocyte subpopulations in peripheral blood are readily measurable. This test is carried out by flow cytometry, ideally using a single platform instrument capable of producing absolute counts for the major lymphocyte populations. There is a wide range of available surface markers, but in clinical practice a relatively restricted panel provide all the required information. This type of testing has no intrinsic diagnostic value in the absence of a clear clinical question, such as whether a child has immunological features compatible with SCID. Testing lymphocyte subsets is often carried out as a surrogate (without informed consent) for retroviral disease. As well as being ethically unjustified, this is inappropriate because changes in $CD4^+$ T cells are seen in a wide range of acute and chronic viral infections as well as in acutely sick patients and are not specific to human immunodeficiency virus (HIV) disease. In patients with known HIV infection, monitoring of cell counts provides important information on risks of opportunistic infections, as different infections appear at different points in the decline of the $CD4^+$ T-lymphocyte count. Monitoring is also important in assessing the immune reconstitution seen in response to treatment with highly active antiretroviral therapy. Patients on immunosuppressive therapy with cytotoxic agents should in the first

Table 10.11 Surface markers on leukocytes.

Surface marker	Cell type	Examples of abnormalities
CD19 (or CD20)	B lymphocytes	Absent in X-linked agammaglobulinaemia, BLNK deficiency and B^- SCID; reduced in common variable immunodeficiency
CD16/56	NK cells	Elevated in acute infections; rare deficiency reported
CD3	T cells	Reduced/absent in severe combined immunodeficiency
CD4	T helper cells	Reduced in viral infections including HIV
CD8	T cytotoxic cells	Raised in acute/chronic viral infections; reduced/absent in ZAP-70 deficiency
CD25	IL-2 receptor	Expression measured on $CD4^+$ cells as marker of T-cell activation (inflammation and infection)
MHC class II (DR common)	Constitutively expressed on B cells, activation marker on T cells	Measured on $CD4^+$ cells as marker of T-cell activation (inflammation and infection); absent in class II MHC deficiency
MHC class I (W6/32, common)	All nucleated cells	Absent in MHC class I deficiency
CD45RA	Naive T cells	Monitoring reconstitution post BMT
CD45RO	Memory T cells	Monitoring reconstitution post BMT
CD11a,b,c/CD18	Adhesion molecules (lymphocytes, neutrophils)	Leukocyte adhesion molecule deficiency type I
CD15	Adhesion molecule (macrophages, neutrophils)	Leukocyte adhesion molecule deficiency type II
CD21/CD35	Complement receptors (with CD11b, c) on phagocytic cells and B lymphocytes	Complement receptor deficiency

BLNK, B-cell linker protein; BMT, bone marrow transplantation; HIV, human immunodeficiency virus; IL, interleukin; MHC, major histocompatibility complex; NK, natural killer; SCID, severe combined immunodeficiency.

instance be monitored with absolute lymphocyte counts obtained from a standard full blood count, but if very low counts occur then checking the subpopulations is helpful for determining whether any additional prophylaxis against infection is required.

It is important to remember that analysis of peripheral blood lymphocytes provides a snapshot of lymphocytes in transit only, and gives no information about immunological processes going on in other tissues. Furthermore, there are circadian changes in blood lymphocytes, so the timing of samples has a significant effect on cell counts; this is particularly important for serial monitoring.

More extensive panels are used for the identification of leukaemias and this is usually done in parallel with examination of bone marrow. Here absolute counts are not necessary as the phenotype of the bulk population is required.

In vitro proliferation assays

In vitro T-cell function testing is complex, labour-intensive, time-consuming and difficult to quality control. Lymphocytes must be purified from blood by density gradient centrifugation and set up in sterile culture for periods of 3–7 days. Accordingly, its use is restricted to diagnosis and monitoring of primary immunodeficiencies. Abnormalities in these assays are not necessarily translated into clinical symptoms. The gold standard is still tritiated thymidine uptake. Alternative methods using flow cytometry have been developed based on analysis of cellular DNA content and expression of activation markers such as CD69 and transferrin receptor, but these do not provide the same information or have the same clinical correlations as tritiated thymidine incorporation. Panels of polyclonal stimuli are used that activate T or B cells at different points in the cascade, enabling the cellular location of defects to be identified. These include phytohaemagglutinin A, pokeweed mitogens and concanavalin A, plant lectins that bind to oligosaccharides on cell surface proteins; anti-CD3 (± IL-2), which mimics activation via the TCR; and phorbol esters, which activate the intracellular enzyme protein kinase C in the presence of calcium (calcium ionophores are used). Antigen can also be used but as the frequency of antigen-specific T-cell precursors in peripheral blood is very low, responses are very small compared with polyclonal stimuli. Typically, *Candida* antigens, tetanus toxoid and viral antigens such as those from herpes simplex virus (HSV), cytomegalovirus (CMV) and varicella-zoster virus (VZV) are used.

Results are expressed in counts per minute (cpm) and also as a stimulation index (SI) calculated by comparing the control incorporation with the stimulated incorporation. It is essential that a medium control is always performed and that a normal healthy control is run in parallel as a reagent check. There is a large range of normal responses and laboratories should develop their own acceptable ranges. However, as a general principle polyclonal stimuli should give an SI greater than 10, while for antigen an SI of 2–4 is acceptable.

Other functional assays have been developed for the flow cytometer, including assays for apoptosis, valuable in the Canale–Smith syndrome, and activation-induced expression of CD40 ligand (CD154), valuable in the X-linked hyper-IgM syndrome.

Neutrophil function tests

Robust assays exist for the identification of defects of neutrophil oxidative metabolism. The historic assay is the nitroblue tetrazolium reduction test, which was performed as a slide assay. This has been modified by the application of similar fluorescent dyes for use on the flow cytometer. Similarly, flow cytometric assays exist for measuring neutrophil and macrophage phagocytosis, using fluoresceinated opsonized bacteria. However, these assays are highly susceptible to the clinical state of the patient, and abnormal results are obtained in patients with active or recent infection. Assays of neutrophil chemotaxis are described but these are impossible to standardize and there is such a wide range of 'normal' results that interpretation of clinical results is no better than guesswork.

Cytokine assays

Measurement of cytokines by solid phase assays is well established as a research tool. However, measurement of cytokines in clinical material has not been shown to be diagnostically helpful as the assays are unreliable when used in this way, mainly due to the natural occurrence of soluble cytokine receptors and anticytokine antibodies in body fluids that interfere with binding. The use of surrogates such as CRP is more robust. Cytokine production *in vitro* can be used as an adjunct to T-cell proliferation assays. Intracellular cytokine production can be measured using the flow cytometer, and cytokine production can be tied to particular cell types by simultaneous surface staining with monoclonal antibodies. There seems to be little gain in clinically useful information over and above that derived from lymphocyte subset analysis.

Molecular immunology

The use of molecular genetic techniques to identify immunoglobulin and TCR gene rearrangements has been essential in developing the understanding of lymphoproliferative conditions. These techniques can be as easily applied to solid tissue extracts as to peripheral blood cells. Flow cytometric methods have also been used to identify clonality of T cells in peripheral blood by examining Vβ chain usage with panels of monoclonal antibodies.

Immunological therapy

Immunological therapy has for many years rested on a small group of cytotoxic drugs supplemented with corticosteroids. These remain important, but advances in our understanding of basic immunology and parallel technical advances have opened the door to new and exciting immunological therapies with potentially fewer side effects. Nonetheless, steroids and cytotoxics will remain important for the foreseeable future.

Corticosteroids

These have both anti-inflammatory and immunosuppressive effects. The anti-inflammatory effect is mediated by increased production of lipomodulin, an inhibitor of phospholipase A_2, the enzyme essential to the formation of the arachidonic acid pathway metabolites involved in inflammation (leukotrienes and prostaglandins). Phagocytosis is also inhibited, and production of IL-1 and TNF-α is reduced. At higher doses, steroids are lymphotoxic, via increased apoptosis. Lymphocyte proliferation is inhibited and cytokine production is reduced, especially by Th1 cells.

Methotrexate

Methotrexate is a folate antagonist, used in weekly (low) doses as an immunosuppressant. It is converted to long-lived intracellular polyglutamate metabolites, which are potent inhibitors of dihydrofolate reductase; this accounts for the cumulative toxicity. However, it is not clear if this activity accounts for the immunosuppressive and anti-inflammatory activities. One suggested mechanism is blockade of transmethylation reactions, with increased lymphotoxic concentrations of *S*-adenosyl-homocysteine (one of the toxic metabolites that accumulates in adenosine deaminase deficiency, a cause of SCID). Another postulated mechanism involves the inhibition of aminoimidazole carboxamide ribonucleotide (AICAR) transformylase, which leads to an increase in cellular AICAR riboside, which also inhibits adenosine deaminase and leads to an increase in adenosine, a powerful inhibitor of lymphocyte proliferation and cytokine production that acts via specific adenosine receptors.

Azathioprine

Azathioprine, a pro-drug of 6-mercaptopurine, inhibits DNA synthesis and also the purine salvage pathway. Its conversion to thio-IMP suppresses the conversion of IMP to AMP, and metabolism of thio-IMP to thioguanine leads to the latter's incorporation into, and consequent damage to, DNA. Azathioprine has a broad range of immunological activities: reduced NK-cell function, reduction in $CD8^+$ T cells, inhibition of lymphocyte proliferation and cytokine production, inhibition of antibody responses (primary > secondary) and impaired neutrophil chemotaxis. Side effects are related to levels of the enzyme thiopurine methyltransferase (TPMT). Patients with a homozygous deficiency of TPMT are highly susceptible to prolonged bone marrow toxicity from even tiny doses of azathioprine, whereas heterozygotes can tolerate reduced doses of the drug with care. Checking red cell TPMT levels before treatment allows identification of those who will develop severe toxicity so they can be spared a trial of therapy. Long-term use may cause a persistent profound lymphopenia and severe hypogammaglobulinaemia.

Other drugs operating on these pathways are fludarabine and cladribine. These have been mainly used in the treatment of haematological malignancies, but their potent immunosuppressive effects are likely to be of considerable value in managing autoimmune disease, with appropriate tailoring of the doses.

Mycophenolate mofetil

Mycophenolate is a potent inhibitor of the enzyme IMP dehydrogenase and therefore works on both *de novo* purine synthesis as well as purine salvage, i.e. the same pathways affected by azathioprine. Its range of effects is therefore very similar to azathioprine. In addition, the reduction in the guanine nucleotide pool decreases the synthesis of oligosaccharide chains on surface receptors involved in adhesion and migration.

Cyclophosphamide

Cyclophosphamide is a pro-drug converted by the liver into phosphoramide mustard, an alkylating agent that acts on guanine residues in DNA and which increases cross-linking of DNA strands, thus preventing DNA replication and transcription. It is a potent inhibitor of lymphocyte proliferation, reducing antibody production, particularly primary antibody responses. It is more active against $CD4^+$ T cells, and has minimal effects on NK cells. Significant lymphopenia occurs on treatment with cyclophosphamide, and prophylactic antibiotics to prevent opportunistic infections are recommended.

Leflunomide

This is a pro-drug that is converted *in vivo* into a potent inhibitor of the enzyme dihydro-orotate dehydrogenase, an enzyme required for the synthesis of pyrimidines. It prevents lymphocyte proliferation. As T cells are dependent on *de novo* synthesis of pyrimidines, they are uniquely sensitive to leflunomide. At high doses it is also thought to

inhibit tyrosine kinases, inhibiting the cascade linked to the IL-2 receptor. It has a very long half-life, as it is highly protein bound.

Hydroxychloroquine and mepacrine

The actions of the antimalarials are not entirely certain, although they reduce the production of cytokines, particularly the pro-inflammatory cytokines IL-1, TNF-α and IFN-γ. They are also concentrated into lysosomes, where they alter the pH and interfere with antigen processing.

Thalidomide

Thalidomide is a potent inhibitor of TNF-α production by monocytes, interfering with gene transcription. It also decreases adhesion molecule expression and inhibits IFN-γ production through preferential stimulation of Th2 cells. Oxpentifylline has similar but weaker properties.

Ciclosporin, tacrolimus and sirolimus

Ciclosporin binds to cyclophilin, an intracellular peptidyl-prolyl *cis-trans* isomerase, and the resulting complex inhibits cytoplasmic calcineurin, a calcium-activated serine–threonine phosphatase. This in turn prevents dephosphorylation of NF-AT (nuclear factor of activated T cells), which normally binds to DNA to enhance the transcription of IL-2 and other cytokines, and CD40 ligand in activated T cells. Dephosphorylation prevents the normal translocation of NF-AT from cytoplasm to nucleus, and inhibits the production of IL-2 and other molecules normally associated with activation of T cells. T cells are particularly sensitive to the effects of ciclosporin, because of low levels of calcineurin. NK cells and B cells are also affected by ciclosporin. The effect is reversible, so overenthusiastic immunosuppression can be rapidly reversed if required. Monitoring of trough blood levels is possible and enables doses to be accurately controlled; levels required for control of autoimmune diseases are lower than those required to prevent allograft rejection.

Tacrolimus binds to a similar peptidyl-prolyl *cis-trans* isomerase, FKBP12, and this has a similar effect on calcineurin. Clinically and immunologically, the effects of tacrolimus are similar to those of ciclosporin.

Sirolimus (rapamycin) also binds to FKBP12, but appears to inhibit an enzyme called mTOR, which is involved in transmission of signals via the IL-2 receptor. Sirolimus and ciclosporin appear therefore to be able to act synergistically by inhibition both of IL-2 production and signalling via IL-2.

Topical formulations of these drugs and related novel compounds are now being introduced for use in immunologically mediated skin disease.

Biological therapy (monoclonal antibodies, chimeric molecules, cytokines, cytokine antagonists, intravenous immunoglobulin)

There has been great interest in the use of monoclonal antibodies for the treatment of disease. The first agent used clinically was a murine anti-CD3 (Muromonab), although its use was limited by its murine origin, which usually led rapidly to the development of neutralizing antibodies. However, it was recognized as a potent immunosuppressive agent and used in clinical allograft rejection. Genetic engineering of monoclonal antibodies now allows the murine binding site to be inserted into a human immunoglobulin framework, while retaining its original specificity. This reduces but does not completely abolish the antimouse response. Antibodies to the panleukocyte antigen CD52 are potent immunosuppressive agents (Campath), producing a prolonged lymphopenia. Many surface molecules are now the targets of experimental monoclonal antibody therapies. Particular targets of interest are the co-stimulatory molecules B7–CD28 and CD40–CD40 ligand. Because of its inhibitory nature, CTLA-4 has also been used in the form of a hybrid fusion molecule with human immunoglobulin.

An alternative strategy has been to target the cytokines or their receptors. The most effective examples of this have been the use of the humanized anti-TNF monoclonal antibody Infliximab and the TNF-receptor Ig Fc fusion protein etanercept, both of which are highly active in suppressing TNF-based inflammatory reactions such as Crohn's disease and rheumatoid arthritis. There has been concern, however, that use of these agents may increase autoimmunity and also susceptibility to infection, particularly mycobacterial infection. Other cytokine antagonists, such as the naturally occurring IL-1 receptor antagonist, which binds to IL-1 receptor but does not signal, are also being tested in clinical trials. Other targets for monoclonal antibodies in trials include IL-6 and IL-8.

There is a long history to the administration of cytokines in pharmacological doses, starting with IL-2, as adjuncts to chemotherapy for malignant disease. However, the benefits have been small and the side effects considerable. There may be some benefit from IL-2 in common variable immunodeficiency, used in a pegylated form to lengthen the circulating half-life, and in acquired immune deficiency syndrome (AIDS), to improve T-cell function. Administration of IFN-γ has been shown to be beneficial in chronic granulomatous disease, although the precise mechanism of action is unclear. IFN-α is valuable in treatment of chronic hepatitis C infection, with best results coming from combination therapy with the antiviral ribavirin. On the whole, however, cytokine therapy has been a disappointment. This is partly due to the considerable cytokine redundancy, with overlapping

functions from multiple cytokines, and partly because most of the cytokines act as short-range messengers; also, the total cytokine and chemokine milieu that a cell experiences determines its response. The same cytokine may therefore have different effects depending on which other cytokines are present. This scenario is difficult to replicate by pharmacological administration of single cytokines.

High-dose intravenous immunoglobulin is widely used as an immunomodulatory agent for autoimmune disease. It is likely that multiple mechanisms of action are involved, including modulation of cytokine release and function, antiproliferative effects, suppression of antibody production via idiotypic antibodies, inhibition of complement-mediated tissue damage and Fc receptor blockade. Problems with this type of therapy are that it is in short supply and has to be derived from human material, which poses risks of infection; the risks of transmission of prion disease are as yet unquantified. It has been widely used, including the treatment of bullous skin diseases, resistant urticaria and atopic dermatitis. None of these uses are yet licensed. In a shortage, priority for supplies should be given to its use in licensed indications and in properly conducted clinical trials.

Physical therapy (plasmapheresis, photopheresis, irradiation, immunoadsorption)

Plasmapheresis provides a rapid way of removing pathogenic autoantibodies. However, it must be combined with immunosuppressive therapy, as there is usually a rebound increase in autoantibody levels immediately following plasmapheresis. Modifications of plasmapheresis include the use of specific immunoadsorption columns in the extracorporeal circuit. These columns comprise a biocompatible substrate to which either protein A or specific antigen is coupled, enabling specific antibodies to be removed without removing essential antibodies necessary for host defence against pathogens. A further development is the use of photopheresis, in which psoralen-like drugs are administered and the extracorporeal circuit is then irradiated with UV light; this provides a potent method of suppression of lymphocytes. The main drawback of these methods is the need for expensive equipment and trained staff.

Low-dose irradiation is also immunosuppressive in doses below those used in the management of malignant disease. This can prove valuable where there is localized immunological disease, for example locally aggressive Wegener's granulomatosis.

Allergy therapy

The mainstay of symptomatic allergy relief is the reduction of mediator output by the use of steroids and mast-cell stabilizing drugs such as disodium cromoglycate and nedocromil, and the antagonism of released mediators by the use of antihistamines and leukotriene antagonists.

Reduction or abolition of allergic reactivity can be undertaken by specific allergen immunotherapy, using purified and standardized allergen extracts. The precise mechanism by which tolerance is induced is unclear. Initially, IgE levels increase before declining slowly. IgG4 antibodies are also produced and may have a blocking role. Alterations in T-cell function are also likely. The process is slow and optimum schedules have yet to be established. Maintenance therapy is required usually for several years. Most therapy is given by injection but there is some evidence that the sublingual route can be used, albeit requiring much larger doses of allergen. It is, however, very effective for seasonal allergic rhinitis due to grass and tree pollens, and is also effective for house-dust mite, cats (but not dogs) and venoms. There is some risk of anaphylaxis and therefore the treatment is suitable only for hospital use by experienced personnel. Current trials are investigating the use of peptides derived from key allergens as a way of inducing T-cell tolerance and therefore abolishing the IgE response. The peptides induce tolerance when injected because they are not presented in the correct way with co-stimulation. This effect may be enhanced by co-administration of IL-12 or IL-18, which induce IFN-γ and bias the immune response towards Th1.

Monoclonal antibodies to IgE have also been introduced into clinical trials with some success. These have been tested first in asthma, where the effects are modest, probably because non-IgE mechanisms are also prominent, but are likely to be more effective in rhinitis. Significant reductions in circulating IgE levels have been documented.

Transplantation

Stem cell transplantation after bone marrow ablative therapy as a treatment for severe autoimmune disease refractory to conventional immunosuppressive therapy is now being undertaken. Diseases include juvenile chronic arthritis and other severe connective tissue diseases such as scleroderma.

Further reading

The field of immunology is a colossal one and provision of up-to-date references in a textbook that takes 2 years from submission to publication is impossible. Accordingly, the list below indicates useful immunological references that provide more detailed discussion of the topics covered. Photoimmunology

[T. Schwarz, pp. 10.29–10.37]

It is more than 25 years since the discovery that ultraviolet (UV) radiation can influence the immune system. Since then, numerous studies in the field of photoimmunology have tried to identify the biological impacts of UV-induced immunosuppression and the underlying mechanisms. The immunosuppressive effects of solar radiation are mostly due to medium-wavelength UV (UVB, 290–320 nm). Accordingly, the vast majority of photoimmunological studies have used UVB. There is recent evidence that long-wavelength UV (UVA, 320–400 nm) can also affect the immune system, although its effects are less pronounced. Hence, in this section the term UV refers mostly to UVB. If other spectra (e.g. UVA or UVC) have been used, they are mentioned specifically.

UV radiation induces local and systemic immunosuppression

Initial evidence that UV radiation influences the immune system was provided by the observation that UV radiation inhibits the immunological rejection of transplanted tumours. Skin tumours induced by chronic UV exposure in mice are highly immunogenic since they are rejected following transplantation into naive syngeneic hosts [1]. However, if the recipient animal is treated with immunosuppressive drugs, the inoculated tumours are not rejected but grow, implying that the rejection is immunological in nature. Rejection can also be prevented when the recipient mice are exposed to UV radiation instead of immunosuppressive drugs, clearly indicating that UV radiation can act in an immunosuppressive fashion (Fig. 10.4).

A similar effect can be observed in another immunological *in vivo* model, namely the induction of contact hypersensitivity (CHS). CHS represents a particular kind of delayed-type hypersensitivity response, induced by epicutaneous application of low-molecular-weight chemical compounds. Since these substances have to bind to proteins to exert antigenic features, they are called haptens. Painting of haptens on areas of skin that have been exposed to low doses of UV radiation (~ 1 J/m^2) does not induce CHS, whereas administration of the same compound to an unexposed site causes a normal CHS response [2]. Inhibition of CHS induction by UV radiation is associated with a reduction in the number of Langerhans' cells at the site of exposure [2,3]. Langerhans' cells are the key APCs in the skin and thus this finding indicates that UV radiation interferes with antigen presentation. Since the areas of hapten application and UV exposure are identical, this type of immunosuppression is called local (Fig. 10.5).

Local immunosuppression seems to be genetically determined in mice since suppression is only observed in particular strains (e.g. C3H/HeN, C57BL/6), while other strains (C3H/HeJ, Balb/c) respond with normal sensitization despite UV exposure. Accordingly the former are called UV-susceptible, the latter UV-resistant [4]. The phenotypic traits of UV resistance and susceptibility are inherited in a polygenic fashion; the relevant loci for polymorphic alleles are LPS and TNF-α [5]. Accordingly, TNF-α appears to be involved in the inhibition of CHS by low-dose UV radiation, since UV-mediated local

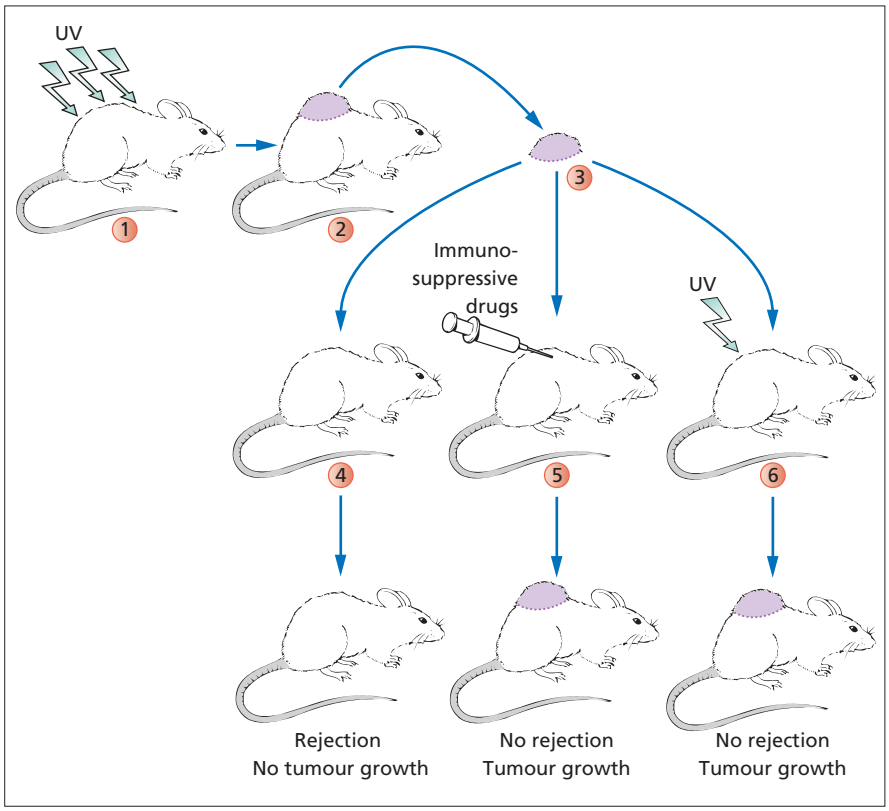

Fig. 10.4 UV radiation inhibits the rejection of immunogenic skin tumours. Chronic UV exposure (1) induces skin tumours (2). Upon transplantation (3), these tumours are rejected by naive syngeneic recipient mice (4). If recipient mice are treated with immunosuppressive drugs (5) or exposed to UV radiation (6), these tumours are not rejected but grow.

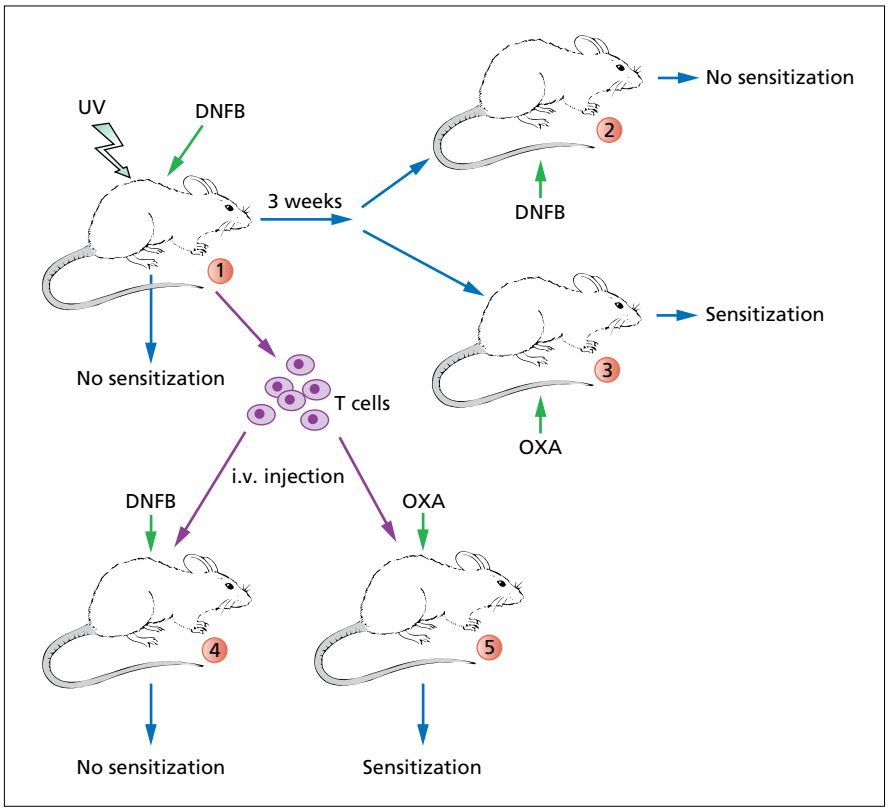

Fig. 10.5 UV radiation induces hapten-specific tolerance that can be adoptively transferred. Application of the hapten dinitrofluorobenzene (DNFB) on to UV-exposed skin does not result in sensitization (1). Reapplication of DNFB to non-UV-exposed skin of the same mice 3 weeks later again does not cause sensitization (2), indicating that tolerance has developed. However, animals can be sensitized against the unrelated hapten oxazolone (OXA), indicating that tolerance is hapten-specific (3). Intravenous injection of T cells obtained from mice that received DNFB on UV-exposed skin inhibits sensitization against DNFB of recipient mice (4). However, recipients can be sensitized against OXA (5), indicating that transfer of suppression is hapten-specific.

immunosuppression can be inhibited by the injection of neutralizing antibodies to anti-TNF-α [6]. However, since TNF-receptor-deficient mice can be immunosuppressed by UV radiation additional factors, other than TNF-α, might be involved in UV-induced local suppression [7].

Higher doses of UV in the range of 2 kJ/m^2 can also affect immune reactions initiated at distant non-UV-exposed sites. Accordingly, CHS cannot be induced in mice exposed to high doses of UV radiation even if the hapten is applied at unirradiated sites [8]. This type is called systemic immunosuppression. Systemic immunosuppression is certainly mediated by mechanisms other than local immunosuppression. The question as to how UV radiation could interfere with the induction of an immune response at a distant non-UV-exposed area of skin has remained unanswered for a long time. It is now clear that UV radiation stimulates keratinocytes to release immunosuppressive soluble mediators, which enter the circulation and cause systemic immunosuppression.

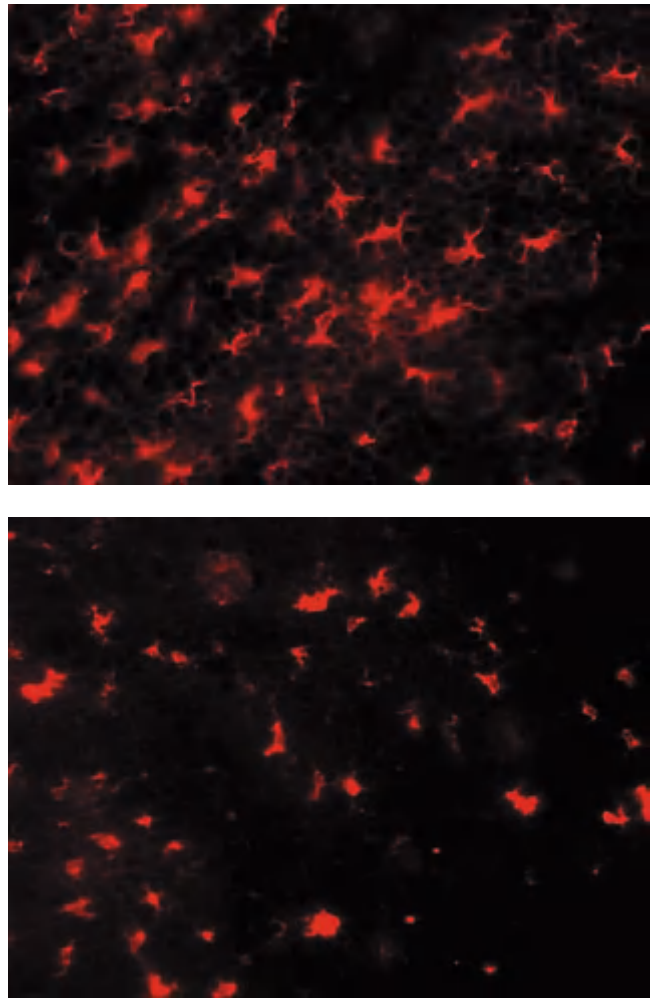

Fig. 10.6 UV radiation depletes Langerhans' cells from the epidermis. (a) In a sheet preparation of normal murine skin, numerous Langerhans' cells can be detected by staining with an antibody against MHC class II (Ia) molecules. (b) The number of Langerhans' cells is remarkably reduced upon UV exposure (2 J/m^2).

Effect of UV radiation on antigen presentation

Within the epidermis, dendritic Langerhans' cells are the major APCs [1]. Exposure of skin to UV radiation results in a profound depletion of Langerhans' cells, which seems to be responsible for inhibition of the induction of CHS following UV irradiation [2] (Fig. 10.6). Depending on the UV dose applied, the disappearance of Langerhans' cells may be due to emigration out of the epidermis and/or the induction of apoptotic cell death. In addition, UV radiation suppresses the expression of MHC class II surface molecules and adenosine triphosphatase (ATPase) activity in Langerhans' cells [3]. Both markers, particularly MHC class II, are used to identify Langerhans' cells in the epidermis. Furthermore, UV radiation alters the antigen-presenting capacity of Langerhans' cells [4]. Inhibition of expression of the adhesion molecule intercellular adhesion molecule (ICAM)-1 by UV radiation may be responsible for impaired adherence of Langerhans' cells and T cells. Accordingly, inhibition of antigen presentation by UV radiation has been proven both *in vitro* and *in vivo*. Injection of antigen-loaded Langerhans' cells or dendritic cells that have been exposed to UV radiation does not result in sensitization, while injection of antigen-pulsed cells mounts an immune response [5]. In addition, UV-exposed APCs are unable to induce a response *in vitro*, e.g. proliferation in the mixed leukocyte reaction [6]. *In vitro*, UV exposure differentially affects Langerhans' cells in their capacity to stimulate different subsets of CD4$^+$ T-cell clones. While UV-treated Langerhans' cells are unable to stimulate T-cell clones of the Th1 type, their ability to stimulate Th2 clones is unaffected [7]. This may explain

why UV radiation preferentially suppresses Th1-mediated immune responses.

Other APCs such as human peripheral blood-derived dendritic cells exposed to UV radiation and splenic dendritic cells from UV-treated mice have also been found to be significantly impaired in their ability to stimulate allogeneic T cells. This indicates that UV-induced suppression of APC function is not specific for Langerhans' cells. UV radiation suppresses the expression of the co-stimulatory B7 surface molecules CD80/86. CD80/86 are expressed on Langerhans' cells and other APCs and play an important role in interactions between APCs and T cells. UV radiation down-regulates the expression of CD80 and CD86 on human Langerhans' cells *in vitro* and of CD80 on blood-derived dendritic cells *in vitro* [8,9]. Reactive oxygen species may also be involved in the impairment of APC function by UV radiation since the antioxidative enzyme catalase prevents the inhibitory effect of UV radiation [10]. Antigen presentation, however, may also be suppressed indirectly by UV radiation via the release of immunosuppressive cytokines and neuropeptides such as IL-10 or calcitonin gene-related peptide, respectively [11]. In addition, the photoproduct *cis*-urocanic acid interferes with antigen presentation.

UV radiation induces immunological tolerance

Application of haptens on to UV-exposed murine skin does not result in the induction of CHS. If the same contact allergen is applied several weeks later to an area of skin that was not exposed to UV radiation, again no CHS response is induced [1]. This indicates that the initial application of the hapten on to UV-exposed skin induces long-term unresponsiveness (see Fig. 10.5). However, the mice are not generally immunosuppressed by the initial UV exposure since an immune response against another, unrelated, hapten can be perfectly induced in these animals. This indicates that the immunological unresponsiveness caused by UV radiation is hapten-specific, a state called hapten-specific tolerance. Induction of UV-mediated tolerance can be observed also in the model of systemic immunosuppression [2]. Long-term immunosuppression by UV radiation can also be observed in the tumour transplantation model. UV exposure suppresses rejection of transplanted skin tumours. If mice are treated for several weeks with repeated doses of UV radiation and then treatment is stopped, the animals remain susceptible to tumour challenge for at least 1 year, perhaps for the rest of their lives [3]. UV-induced tolerance appears to be mediated via the generation of hapten-specific T-suppressor cells.

UV radiation induces T cells with regulatory/suppressor activity

UV radiation-induced hapten-specific tolerance appears to be due to the induction of T cells with inhibitory/suppressor activity. Injection of splenocytes, from mice that have been tolerized by application of a hapten on to UV-exposed skin, into naive syngeneic mice renders the recipients unresponsive to this particular antigen [1]. Immune responses against other non-related antigens are unaffected (see Fig. 10.5). Transfer of suppression is mediated via T cells since depletion of T cells from splenocytes is associated with a loss of transfer. Thus, sensitization in combination with UV exposure induces the generation of T cells with hapten-specific suppressor activity. Transfer of tolerance can be observed in both local [1] and systemic [2] models. Nevertheless, different types of T cells seem to be involved. In the systemic form of UV-induced suppression, transfer of tolerance is mediated by the induction of antigen-specific $CD3^+CD4^+CD8^-$ suppressor cells [3]; in the local form of suppression, both $CD4^+$ and $CD8^+$ cells appear to be involved. These differences may be due to the different systems used dependent on the strain of mice,

the type of haptens and the UV doses applied. When UV-induced suppressor T cells are transferred intravenously not into naive but into sensitized mice, the immune response in the recipients is unaffected [4]. This indicates that suppressor T cells only suppress sensitization but are not active once antigen-specific memory T cells have been induced and thus are not suppressive during the elicitation of an immune response.

Although the adoptive transfer experiments appear convincing, attempts to purify and clone these transferred cells have been unsuccessful. For this reason, the term 'suppressor T cell' was almost banned in general immunology and the entire concept of UV-induced tolerance and suppressor cells drawn into question by many immunologists [5].

The subject of suppressor T cells experienced a renaissance by the finding that chronic activation of both human and murine $CD4^+$ T cells in the presence of IL-10 induces $CD4^+$ T-cell clones that release high levels of IL-10, low levels of IL-2 and no IL-4 [6]. These antigen-specific T-cell clones suppress the proliferation of $CD4^+$ T cells in response to antigen, and prevent a T-cell-mediated colitis in an immunodeficient mouse model of this condition [6]. This $CD4^+$ T-cell subset is referred to as T-regulatory cell 1 (Tr1). These cells exhibit very low proliferative capacity, and offer an explanation as to why cloning of regulatory/suppressor T cells may be difficult or even impossible.

Another subset of $CD4^+$ regulatory T cells is characterized by the constitutive expression of the α chain of the IL-2 receptor (CD25). After antigen-specific activation, $CD4^+CD25^+$ T cells suppress immune reactions both *in vitro* and *in vivo* in an antigen-non-specific way [7]. There is also evidence that $CD4^+CD25^+$ T cells may be involved in the mediation of UV-induced tolerance. The area of regulatory T cells is currently one of the most extensively studied subjects in general immunology and future studies will increase knowledge about mediation of tolerance and active suppression. Whether these T cells are termed suppressor or regulatory seems to be more a semantic issue. The term 'regulatory T cell' is usually preferred since the existence of these cells is becoming accepted even by those investigators who previously denied the existence of suppressor T cells.

The detailed mechanism by which UV-induced regulatory/suppressor T cells mediate suppression still remains to be determined. There is evidence that particular surface molecules like CTLA-4 [8] and the apoptosis-related receptor CD95/Fas [9,10] may be critically involved. NK T cells appear to play a role in UV-induced suppression of tumour immunity [11]. UV-induced NK T cells suppress a delayed-type hypersensitivity reaction against tumour antigens. In addition, they support the growth of inoculated UV-induced tumour cells which are rejected in normal mice. This indicates that NK T cells may play a critical role in regulating the growth of UV-induced skin cancers.

UV radiation induces the release of immunosuppressive mediators

The finding that mice exposed to higher doses of UV radiation cannot be sensitized, even when the antigen is applied to an area of skin which has not been exposed to UV [1,2], clearly indicates that UV radiation has the capacity to suppress the immune system in a systemic manner. How the events occurring at the irradiated site lead to a suppressed response to an antigen applied at a distant area of non-UV-exposed skin remained unresolved for some years. Keratinocytes have been recognized as a potent source of various soluble mediators, including immunostimulatory and pro-inflammatory cytokines. Cytokine release by keratinocytes can be effectively induced by UV radiation [3]. UV radiation, however, may also stimulate the release of immunosuppressive mediators since intravenous injection of supernatants obtained from UV-exposed keratinocytes into naive mice renders the recipients unresponsive to hapten sensitization [4]. Therefore, UV-induced keratinocyte-derived immunosuppressive mediators may enter the circulation and inhibit immune responses at areas of skin not directly exposed to UV radiation, explaining the phenomenon of systemic immunosuppression.

Several mediators seem to be involved in UV-induced immunosuppression. The major player appears to be IL-10. IL-10, whose release by keratinocytes is induced by UV radiation [5], abrogates the ability of Langerhans' cells

to present antigens to Th1 clones and even tolerizes them [6]. Injection of IL-10 into an area of skin where hapten has been applied prevents the induction of CHS and induces hapten-specific tolerance [7]. In turn, injection of an anti-IL-10 antibody into UV-irradiated mice prevents systemic UV-induced suppression of the induction of delayed-type hypersensitivity [5]. Furthermore, IL-10 induces a shift from a Th1 to a Th2 response; this may explain why UV radiation inhibits primarily Th1 immune reactions and favours development of Th2 reactions [8].

IL-12 is a cytokine that induces a Th1 immune response and may be regarded as a counterbalance to IL-10 [9]. Thus, it is not surprising that IL-12 has the capacity to prevent UV-induced immunosuppression. Injection of IL-12 before UV exposure enables sensitization even if the antigen is applied on to UV-irradiated skin [10–12]. Even more importantly IL-12 is able to break established UV-induced tolerance, since injection of IL-12 into UV-tolerized mice renders these animals susceptible to the antigen against which they were tolerized [10,12]. Other soluble mediators besides IL-10 that appear to be involved in UV-induced immunosuppression include TNF-α [13,14], IL-4 [15], prostaglandin E_2 [15], calcitonin gene related peptide [16] and α-melanocyte-stimulating hormone [17].

Involvement of urocanic acid in UV-induced immunosuppression

Urocanic acid (UCA) is an epidermal chromophore involved in mediating UV-induced immunosuppression [1]. UCA is generated in the metabolic pathway of the essential amino acid histidine. It accumulates in the epidermis because epidermal cells are devoid of the necessary enzymes to further catabolize UCA. Two tautomeric forms of UCA exist: *trans* (E)-UCA and *cis* (Z)-UCA. The predominant isoform in the epidermis is *trans*-UCA. Upon UV exposure, UCA is photoisomerized from *trans*- into *cis*-UCA. Tape-stripping of the epidermis, which removes the majority of UCA, prevents UV-induced suppression of the induction of CHS, indicating that *cis*-UCA is involved in photoimmunosuppression [2]. Furthermore, injection of *cis*-UCA partially mimics the immuno-inhibitory activity of UV radiation [3]. Vice versa, anti-*cis*-UCA antibodies restore particular immune responses after UV exposure [4]. *cis*-UCA also inhibits the presentation of tumour antigens by Langerhans' cells [5]. This effect can be reversed by IL-12 [6]. In addition, injection of *cis*-UCA antibodies reduces the incidence of UV-induced skin tumours in a photocarcinogenesis model, indicating the involvement of *cis*-UCA in the generation of UV-induced skin cancer [6].

UV radiation induces immunosuppression in humans

The vast majority of studies in the field of photoimmunology have been performed *in vivo* in animal, usually murine, models. Although numerous *in vitro* studies have been performed with human cells, the key questions are whether the observations made in animal models are relevant to humans and whether humans are immunosuppressed by UV radiation in a similar fashion. In fact, UV radiation appears to suppress the induction of CHS. Even tolerance can be induced, although according to one study only in 10% of people [1]. Tolerance was hapten-specific, since the individuals revealed pronounced CHS responses upon subsequent immunization with another, unrelated hapten [1]. Other studies reported that a higher proportion of subjects developed tolerance when the hapten was applied on areas of skin exposed to erythemogenic doses of UV [2]. However, it is certain that some people can be immunosuppressed by UV radiation. This implies that as in the murine system UV-susceptible and UV-resistant individuals may exist. It remains to be determined whether the UV-susceptible population is at higher risk of developing skin cancer. Indeed, sensitivity to sunburn appears to be associated with susceptibility to UV radiation-induced suppression of cutaneous cell-mediated immunity in humans [3]. Recently, UV-induced immunosuppression has started to be used as a tool to evaluate the potency of sunscreens [4,5].

Molecular targets mediating UV-induced immunosuppression

Nuclear DNA is a perfect chromophore for both UVB and UVC radiation. UV radiation primarily induces two types of DNA lesions: pyrimidine dimers and (6-4)-photoproducts. Thus UV-induced DNA lesions have been regarded as the major and, for a long time, the only molecular target through which UV radiation exerts its biological effects. UV-induced DNA damage also appears to be critically involved in signalling photoimmunosuppression. The first functional evidence for this assumption was provided by an opossum model that has the ability to remove UV-induced DNA damage via photoreactivation, a DNA repair process induced by visible light [1]. Application of haptens on to UV-exposed skin of these animals does not result in the induction of CHS. In contrast when the animals are exposed to visible light, which induces DNA repair immediately after UV irradiation, sensitization is inducible, indicating that UV-mediated DNA damage is a major trigger for photoimmunosuppression [1].

This conclusion is supported by studies using DNA repair enzymes applied topically in a liposome-based cream. Application of T4N5 endonuclease, a bacterial DNA repair enzyme, restores the immune response when applied immediately after UV exposure [2]. Similar findings were obtained in humans when the repair enzyme photolyase was applied topically [3]. In addition, UV-induced release of the immunosuppressive cytokines IL-10 and TNF-α can be inhibited and reduced, respectively, by the application of T4N5 endonuclease [4,5]. Furthermore, lower doses of UV radiation are required to obtain equal suppression of an immune response in mice deficient in DNA repair (XPA knock-out mice) when compared with wild-type mice that exhibit normal DNA repair capacity [6]. Together, all these data strongly support DNA damage as an important inducer of UV-induced immunosuppression.

Despite clear-cut evidence for the crucial role of UV-induced DNA damage in photoimmunosuppression, there are indications that UV radiation may also affect cytoplasmic and membrane targets [7]. UV radiation can directly trigger surface receptors by inducing either their oligomerization [8] or phosphorylation [9]. UV radiation may also mediate its immunosuppressive effects by affecting targets at the cell membrane, since it prevents both IFN-γ and IL-2 from exerting particular biological effects via interference with the signal transduction of these two important immunostimulatory cytokines [10,11]. In addition, the involvement of *cis*-UCA indicates that UV-induced immunosuppression can be mediated independent of DNA damage. The relative contribution of the extranuclear signalling pathways in photoimmunosuppression remains to be determined, since UV-induced DNA damage appears to be the predominant signalling event.

UVA-induced immunosuppression

The biologically most active part of the solar spectrum is UVB (290–320 nm) since it is primarily responsible for the induction of inflammation, carcinogenesis and immunosuppression. Hence, it is perhaps unsurprising that the vast majority of photoimmunological studies have used UVB sources. However, this does not mean that UVA has neither biological effects nor the ability to modulate the immune system.

Recently, an increasing number of studies have addressed the photoimmunological properties of UVA. Similar to UVB radiation, broad-band UVA (320–400 nm) can suppress the induction of CHS in the murine model; however, in contrast to UVB, UVA has to be dosed daily for 4 weeks [1]. Under these conditions UVA exposure can induce tolerance [1]. An oxidative pathway appears to be involved in UVA-induced immunosuppression since UVA-mediated inhibition of antigen presentation can be prevented by the addition of glutathione, which exhibits antioxidative properties [2]. Besides reactive oxygen species, nitric oxide may also contribute to the modulation of the immune response by UVA since inhibitors of nitric oxide prevent UVA-induced depletion of Langerhans' cells from the epidermis [3]. When comparing the effect of solar-simulated, UVB and UVA radiation on the suppression of the immune response to recall antigens in humans, UVB radiation appeared to be less immunosuppressive than solar-simulated radiation but followed the same time course. In contrast, UVA radiation-induced immunosuppression turned out to be transient, becoming less effective with subsequent UVA exposures, indicating that an adaptive mechanism may exist [4]. In a similar vein, under particular conditions UVA radiation even appears to abrogate or prevent immunosuppression from UVB radiation [5]. This effect seems to be mediated via IFN-γ [6].

Studying the immunosuppressive effects of UVA is more complicated than UVB since UVA can be separated into UVA-2 (320–340 nm) and UVA-1 (340–400 nm). This has to be taken into account when comparing studies. In the broad-band UVA range (320–400 nm), the immunosuppressive properties are mostly allocated to the short-wave UVA-2, since this spectrum is more related to UVB radiation. However, there are also indications that UVA-1 may affect the immune system since UVA-1 exposure of human skin results in Langerhans' cell depletion and reduction of epidermal APC function [7]. Further studies addressing the photoimmunological effects of UVA-1 are urgently needed since UVA-1 has been advertised as completely free of side effects, which appears not to be the case. More recently, UVA-1-induced immunosuppression has been used to determine the UVA-1 filtering capacity of sunscreens [8].

Implications of UV-induced immunosuppression

The biological implications of UV-induced immunosuppression may be several-fold. In experimental models it has been demonstrated that UV radiation can inhibit the protective immune response against viral, bacterial and fungal infections. The infectious agents most frequently used to study these phenomena are HSV, *Listeria*, *Leishmania*, mycobacteria and *Candida* [1]. Based on these studies there is clear-cut evidence that UV radiation can

compromise an immune response against these agents in both a local and a systemic fashion. These models have contributed in an essential way to the further understanding of how UV radiation suppresses the immune system. However, from daily clinical practice we know that acute and severe exacerbations of infectious diseases following solar exposure are extremely rare in humans. The only exception is HSV infection in which recurrences are frequently observed after solar exposure. Therefore, at this stage, the clinical implications of UV-induced immunosuppression for infectious diseases may be limited.

The immune system not only protects against infection but also against malignancy. Transformed cells, particularly in the early stages, can be recognized as 'foreign' and attacked by the immune system (tumour immunology). This may specifically apply to both non-melanoma skin cancer and malignant melanoma. There is clear evidence of an association of susceptibility to skin cancer and immunosuppression. Chronically immunosuppressed individuals, like transplant patients, exhibit a significantly increased risk of developing skin cancer [2]. This risk certainly increases with cumulative UV load. In addition, the ability of UV radiation to negate host defences against skin tumours has been convincingly demonstrated in various experimental animal models [3]. Furthermore, restoration or even enhancement of an immune response, e.g. by topical or systemic application of immunomodulators (interferons, imiquimod), has become an established alternative therapeutic option for the treatment of skin cancer. Taken together, the immunosuppressive impact of UV radiation is probably much more relevant for carcinogenesis than for the exacerbation of infectious diseases.

It is striking that UV radiation at low doses can suppress an immune response [4]. Thus, one may speculate that a certain degree of immunosuppression may be beneficial. The skin is an organ that is constantly exposed to potential allergens; in addition autoimmune responses may be generated within the skin [5,6]. Hence, it is tempting to speculate that a certain degree of regular immunosuppression by daily solar exposure may prevent the induction of these immune responses.

However, the immunosuppressive effects of UV radiation can also be exploited therapeutically. Phototherapy is a major therapeutic strategy in the treatment of inflammatory skin disorders (see Chapter 24). Although the mechanisms underlying the beneficial effects of solar/UV exposure in certain diseases remain to be determined, it is obvious that the immunosuppressive properties are essential in this respect [7]. Accordingly, the majority of dermatoses (e.g. psoriasis and atopic dermatitis) that can be treated with immunosuppressive drugs respond favourably to phototherapy.

Chapter 11

Wound Healing

J.A. McGrath & S.M. Breathnach

Biological aspects of wound healing

[S.M. Breathnach, pp. 11.1–11.10]

Introduction

Maintaining skin integrity is vital for humans and animals to protect against dehydration, bleeding and ingress of microorganisms. In order to do this, animals have evolved a sophisticated mechanism of wound healing to plug the gap quickly, re-epithelialize over the defect and rapidly replace the lost dermis with new matrix. The final product is not normal skin, for adult human skin does not regenerate, but rather is a repair in the form of a scar, which is visible on the skin surface.

Adult wound repair consists of a series of overlapping stages [1], beginning with aggregation and degranulation of platelets, blood clotting and the formation of a fibrin plug (eschar), which initially fills the wound. This is followed by the inflammatory phase, where initially polymorphonuclear leukocytes appear, which stimulate the recruitment of monocytes, macrophages and lymphocytes that kill microorganisms and secrete a wide variety of growth factors and cytokines, which modulate the remaining wound healing response. These immune cells invade the fibrin-filled wound space and, together with fibroblasts and blood vessels from the deep fascia and surrounding dermis, begin to lay down a temporary matrix of granulation tissue consisting initially of a proteoglycan-, glycosaminoglycan- and fibronectin-rich tissue, which serves as a guiding substratum for the migrating and proliferating cells. Cellular behaviour and coordination of the wound response is controlled during this granulation phase by a wide range of growth factors, extracellular matrix molecules and their receptors. There are extensive cell–cell and cell–matrix interactions. The CXC chemokine interferon-γ (IFN-γ) inducible protein-9 acts as a mediator of epidermal–dermal communication during wound repair [2]. Epidermal cells proliferate and move down the edge of the wound until they reach the new granulation tissue, where they dissect between the overlying fibrinous eschar and the underlying granulation tissue to close the wound. At the same time, the wound contracts predominantly by forces exerted by contractile elements contained within myofibroblasts. The transitory granulation tissue phase ends as immune cells, fibroblasts and endothelial cells undergo apoptosis, while the remaining fibroblasts lay down collagen (mostly types I and III), a process that continues for some time. In the final remodelling stage of wound healing, the matrix is remodelled with a decrease in the relative levels of fibronectin, glycosaminoglycans, proteoglycans and type III collagen and an increase in the levels of predominantly type I collagen, which is organized into thick bundles and extensively cross-linked to form the mature scar.

Acute wound healing proceeds quickly and with few problems in the vast majority of cases. Clearly, the speed of wound healing depends upon many factors, including the size of the wound (incisional or excisional), blood supply to the area, presence of foreign bodies and microorganisms, age and health of the patient, nutritional status of the patient, drugs that the patient may be taking and a variety of systemic diseases. Oxygen plays a critical part in wound healing [3,4], as does nitric oxide [5,6]. Leptin may be another regulator of wound healing [7]. Wound healing is subject to regulation by a large number of different cytokines and growth factors [8,9]. Oestrogens promote wound healing, while androgens inhibit it [10–13]. Opioid peptides may also favour wound healing [14].

Sometimes, the wound-healing process does not proceed normally and chronic wounds result. The most common forms of chronic wounds in humans include venous ulcers, diabetic ulcers and pressure sores. In each of these cases there is normally an underlying pathology, such as venous insufficiency in the case of venous ulcers, or abnormal microvascular patterns and high blood sugar levels in diabetic ulcers. These underlying pathologies create a situation whereby the wound-healing response cannot go to completion. Thus, for example, in the case of venous stasis ulcers, there is often a chronic ischaemia–reperfusion injury resulting in high levels of local cytokines, complex cuffs forming around the blood vessels and increased levels of wound proteases, particularly elastase, and decreased levels of protease inhibitors such as tissue inhibitor of matrix metalloproteinases (TIMP) [15–17]. In the case of diabetic ulcers, there are often extensive abnormalities in the microcirculation, thickening of the blood vessel wall, thrombi and areas of focal necrosis [18]. In such chronic wounds, it is necessary to treat the underlying pathology if long-term non-recurrent healing of the ulcer is to be achieved. Understanding the molecular pathogenesis of these chronic wound-healing states can lead to novel therapeutic targets for pharmacological intervention (e.g. exogenous administration of protease inhibitors or fibronectin).

The wound-healing response can also be disrupted by excessive healing (adverse scarring), which is represented at the extremes by hypertrophic scars or keloids. These excessive wound-healing states result from the abnormal deposition of connective tissue within the healing wound, such that the scar is elevated and may extend beyond the boundaries of the original wound. Excessive scarring shows a clear genetic basis with racial tendencies (e.g. it is more common in black and oriental people than it is in white people).

Finally, the acute wound-healing response varies with the age of the individual. Wounds made on very early embryos heal by complete regeneration, while wounds made on later embryos or early fetuses (in the middle trimester of pregnancy) display scar-free healing but absence of regeneration of dermal appendages. Comparison between postnatal and fetal wound healing has revealed differences in inflammatory response, cellular mediators, cytokines, growth factors, extracellular matrix modulators, tyrosine phosphorylation patterns and homoeobox gene expression [19,20]. Wounds in children and young adults often heal quickly with excessive scarring, while elderly patients show specific disruptions in the wound-healing cascade, such as elevated levels of proteases, altered ratios of growth factors and their receptors and a slower rate of healing but often with enhanced quality (reduced scarring). Age-related changes in the inflammatory reponse to wounding have been reported [21]. Wounds heal more quickly if patients are relieved of stress [22].

Despite the fact that the various phases of wound healing overlap, it is convenient to consider the principal cellular and molecular mechanisms regulating the basic biology of wound healing under three phases: inflammation and the immune response, re-epithelialization, and angiogenesis and matrix remodelling.

Inflammation and the immune response

Following wounding, there is almost immediate release of inflammatory mediators from damaged cells, degranulating platelets or resident tissue macrophages and mast

cells. Furthermore, wounding causes a transient permeabilization of cells near the wound margin, with the rapid exchange of extracellular and intracellular ions, resulting in the switching on of early response genes in such cells within seconds following wounding. These mediators initially cause arteriole dilatation, resulting in an increased blood flow into the wound area. This process is further aided by growth factors such as vascular endothelial growth factor (VEGF), which causes hyperpermeability of endothelial cells [1]. This results in an influx of fluid and plasma components into the wound space, while inflammatory cells adhere to the vascular endothelium and migrate through the vascular wall into the wound. Neutrophils are the predominant initial inflammatory cells recruited to the wound, which together with platelets release a complex mixture of cytokines and growth factors. These stimulate the further influx of monocytes and lymphocytes, the proliferation of monocyte precursors within the wound and their differentiation into mature macrophages [2]. The chemokine CXCR2 has been shown by studies in knockout mice to be important in the neutrophil and monocyte recruitment as well as in wound closure [3].

Platelets respond very quickly, and when they reach the wound they adhere through selectin and integrin receptors [4], degranulate and release a variety of factors, including thromboxanes, prostaglandins, 12 lipoxygenase products, serotonin, adhesive glycoproteins including fibrinogen, Von Willebrand factor, fibronectin and thrombospondin and growth factors including platelet-derived growth factor (PDGF), epidermal growth factor (EGF) and transforming growth factor-β1 (TGF-β1). These factors both contribute to the initial fibrin plug that closes the wound and modulate subsequent cellular behaviour, including attachment, migration, proliferation and matrix deposition. However, wound closure, angiogenesis and collagen synthesis are not significantly impaired in thrombocytopenic mice [5].

These signals from the wound site, together with changes in vascular permeability, cause leukocytes to pavement in the blood vessels, undergo rolling and attachment to activated endothelial cell selectins and integrins [6–8]. Neutrophils, recruited early in wound healing, are responsible for destroying invading bacteria by phagocytosis and release of free oxygen radicals and proteolytic enzymes, which may cause further tissue damage and inflammation. Once in the wound, neutrophils may be activated by cytokines such as granulocyte–macrophage colony-stimulating factor (GM-CSF) and tumour necrosis factor-α (TNF-α), complement or proteases such as thrombin. The neutrophils do not subsequently re-enter the circulation but are eliminated by macrophage phagocytosis or apoptopic cell death, following by phagocytosis by surrounding cells and macrophages [9]. The lifespan of neutrophils in the wound depends on the presence of survival factors, such as GM-CSF and interleukin 2 (IL-2). Monocytes and macrophages are recruited in large numbers to the healing wound as neutrophil numbers begin to decline. Classic studies by Leibovich and Ross [10] demonstrated the importance of these cells in wound healing; experimental depletion of wound macrophages resulted in prolonged inflammation and delays in fibroblast proliferation, matrix deposition and subsequent wound closure. By contrast, exogenous application of blood-derived monocytes to wounds can result in accelerated healing. The transition from a resting to an active state in monocytes and macrophages is controlled by cytokines such as TNF-α and IFN-γ, as well as bacterial products such as lipopolysaccharide. Monocytes and macrophages produce a range of cytokines in response to pro-inflammatory signals, including TGF-β and TGF-α, and fibroblast growth factor (FGF) 1 and 2. The interactions between these growth factors and monocyte/macrophage differentiation/activation is complex and often self-regulatory. Thus, TGF-β1 acts as a pro-inflammatory cytokine early in the wound-healing phase, as it is chemotactic to immature monocytes, which are recruited to the wound site, and synthesize and secrete more TGF-β1 (TGF-β1 has a self-inducing response element within its promoter). However, TGF-β1 is anti-inflammatory to mature or activated monocytes/macrophages, because it inhibits their activation and modulates receptor expression [11,12]. Thus, it can be seen that the same growth factor, TGF-β1, can have completely opposite effects, depending on the state of differentiation/activation of the cell, which in turn may be regulated by other growth factors or extracellular matrix molecules. Wound healing is delayed in immunodeficient TGF-β1 knockout mice [13].

In addition to the production of cytokines, wound macrophages also produce a range of extracellular matrix molecules, which, together with fibrinogen and fibrin from the blood clot, matrix molecules from degranulating platelets, recruited fibroblasts and endothelial cells, form the granulation tissue or provisional matrix. This provisional matrix is rich in molecules, such as fibronectin, vitronectin, thrombospondin, tenascin and proteoglycans such as dermatan, chondroitin and heparan sulphate. It acts as an early scaffold for the re-establishment of the dermis and for the migration of epidermis as it promotes both cell migration and proliferation [14]. Regulation of this provisional matrix is complex, and achieved partially through control at the transcriptional level, for example with alternative splicing of the primary transcript for fibronectin resulting in embryonic-like cellular fibronectins being deposited within the wound space, which better facilitate cell migration and proliferation [15].

Pro-inflammatory cytokines such as TNF-α and IFN-γ can stimulate the production of chemokines by endothelial cells [16]. These chemokines (e.g. IL-8, IL-10, PF-4,

MIP-1α, MIP-1β, RANTES and MCP-1) attract lymphocytes to the wound area, and may have a role in the progression of healing to fibrosis [17]. These lymphocytes include both B and T lymphocytes, and there is growing evidence that the particular type of T-lymphocyte response (Th1 or Th2), each characterized by a different profile of cytokine secretion, may be one of the factors underlying abnormal fibrosis and scarring. Human γ/δ T lymphocytes express and synthesize connective tissue growth factor (CTGF), known to regulate fibrogenesis and wound healing [18]. The type of T-lymphocyte response itself may be determined by the profile of growth factors in the early wound. Thus, for example, natural killer (NK) cell migration out of blood vessels is promoted by VEGF but inhibited by FGF-2 [19]. IL-6 also has a crucial role in wound healing, probably by regulating leukocyte infiltration, angiogenesis and collagen accumulation [20].

These early inflammatory responses are vital to the wound-healing process: clearing the wound of foreign antigens such as bacteria, and supplying combinations of growth factors and extracellular matrix molecules, which orchestrate the subsequent healing of the provisional matrix by providing the signals and scaffold for fibroblast, endothelial and keratinocyte influx. Inflammatory cells such as monocytes and macrophages decrease towards the end of the inflammatory phase, largely through apoptosis resulting from diminution of the levels of survival factors (e.g. specific cytokines and matrix molecules) [21].

Re-epithelialization

During the inflammatory period, the process of re-epithelialization commences, with consequent alterations in the differentiation and kinetics of surrounding keratinocytes [1]. These surrounding keratinocytes alter their differentiation state and adhesion profile, become migratory, move across the provisional wound matrix, protect themselves against the hostile elements within the wound matrix (e.g. proteases, reactive oxygen species), proliferate to provide replacement cells and, once temporary epithelial cover is established, redifferentiate back into a normal epidermis with stem cells in the correct spatial orientation.

Following wounding, there is immediate stimulation of the tyrosine phosphorylation of numerous cellular proteins, with activation of p21ras, mitogen-activated protein kinases, extracellular signal-regulated kinases 1/2, c-Jun NH2 terminal kinase, and p38 mitogen-activated protein kinase, and consequent increased phosphorylation of their respective substrates, c-jun and activator transcription factor 1 [2]. Syndecan appears to be important in keratinocyte activation [3]. TNF-α stimulates transcription of the PPARβ (peroxisome-proliferator-activated receptor β) gene via an activator protein-1 site in its promoter and it also triggers the production of PPARβ ligands in keratinocytes, with subsequent up-regulation of the expression of integrin-linked kinase and 3-phosphoinositide-dependent kinase-1, which phosphorylates protein kinase B-α (Akt1) [4]. Akt1 activity suppresses apoptosis and ensures the presence of a sufficient number of viable keratinocytes at the wound margin for re-epithelialization. GM-CSF [5], IL-1 and keratinocyte growth factor-2, also described as FGF-10, stimulate keratinocyte growth [6,7]. Keratinocytes in the basal layer some 300–400 cell diameters away from the wound margin proliferate extensively; such proliferation peaks within 1–2 days post-wounding and then falls back again to reach basal levels about 14 days post-wounding. Suprabasal cells derived from this extensive

proliferation roll over the attached basal cells to form new basal cells at the wound margin, a process repeated by successive basal cells until re-epithelialization is complete. Keratinocyte growth factor activates keratinocyte migration and stimulates hyaluronan synthesis, which also promotes keratinocyte migration [8]. p38 signalling is important in keratinocyte outgrowth from human skin explant cultures [9].

Keratinocytes at the wound edge undergo crawling and spreading, while wound contraction and sliding of the epithelial sheet by actin cable formation also contribute to wound closure and re-epithelialization. The migrating keratinocytes initially form an invading spur that moves downwards between the eschar and normal dermis, digesting the granulation tissue *en route*. Once beneath the eschar and necrotic tissue, keratinocytes from behind the front edge of the spur move bilaterally towards each other across the top of the newly formed wound matrix. Thus, the keratinocytes effectively dissect the fibrinous eschar from the underlying granulation tissue, a process achieved in part by the predilection of the keratinocyte to attach and migrate on fibronectin but not on fibrin or fibrinogen [10]. Fibrin promotes keratinocyte migration indirectly by exposing plasminogen to migrating cells, and also selectively disrupts adhesion of differentiated keratinocytes [11].

The keratinocytes that migrate to close the wound show extensive phenotypic changes. The K1 and K10 cytokeratin filaments of the cytoskeleton, which hold the differentiated keratinocyte in a rigid suprabasal phenotype, are replaced by the flexible cytokeratins K6 and K16 [12]. Expression of these cytokeratins is strongly stimulated by growth factors such as EGF, TGF-α and TGF-β present at high levels within the provisional matrix [13]. As the keratinocytes migrate, they express collagenases and urokinase-type plasminogen activator, an enzyme that converts the inactive proteases secreted by granulocytes and fibroblasts such as plasminogen and procollagenase into their active forms [14–16]. Up-regulation of urokinase plasminogen activator induced by hypoxia results in increased keratinocyte migration [17]. This up-regulation is mirrored by the concurrent up-regulation of plasminogen-activator inhibitors, which control the extent of plasminogen activation [18]. This suggests a key role for the plasmin–plasminogen system in wound healing, an assertion given experimental weight by wound-healing studies on mice with targeted disruption of the plasminogen gene [19]. These mice show substantial delays in wound re-epithelialization and the aberrant persistence of fibrin within the wound matrix, demonstrating the importance of the plasminogen–plasmin system for fibrin removal during wound healing. The wound-healing phenotype could be reconstituted by addition of exogenous plasminogen or by deletion of the fibrinogen gene.

Cells migrating through the granulation tissue express different integrins. Thus, α5, β1, αV and β5 integrins, the primary keratinocyte receptors for fibronectin and vitronectin, are up-regulated in migrating keratinocytes during re-epithelialization [20]. Expression of these integrins may be induced by TGF-β1 [21]. These integrin switches on both keratinocytes and fibroblasts surrounding the wound are in part responsible for the early lag phase in wound healing, as the cells become primed to enter the provisional matrix. Once re-epithelialization is complete, the keratinocytes switch from the vitronectin/fibronectin receptor (αVβ5) to the tenascin/fibronectin receptor (αVβ6), a switch that may be involved in the redifferentiation of the epidermis, as the β6 integrin has been associated with epithelial remodelling during development and tumourigenesis [22].

A number of growth factors promote keratinocyte proliferation and migration, including FGF-7, FGF-1 and FGF-2, insulin-like growth factor-1 (IGF-1), EGF, TGF-α and hepatocyte growth factor (HGF) [23]. These factors are up-regulated usually in the dermis near the sites of keratinocyte proliferation, while the proliferating keratinocytes up-regulate receptors for such growth factors [24]. Furthermore, these factors stimulate enhanced re-epithelialization when added exogenously to wounds [25–29]. Equally, keratinocytes produce a large number of cytokines and growth factors including interleukins, TGF-β and TGF-α, EGF, PDGF, GM-CSF and TNF-α [30]. Co-culture and other experiments demonstrate that keratinocytes can stimulate growth-factor production by underlying dermal cells, and that such factors then act back on the epithelial cells themselves. Thus, a complex set of reciprocal epithelial–mesenchymal interactions is continuously ongoing during the wound-healing process. For example, keratinocytes can stimulate FGF-7 production by underlying dermal cells, which then acts specifically on the overlying epithelial cells via the FGF-7 receptor. The FGF-7 is up-regulated in dermal cells at the wound edge, while the receptor is up-regulated in the overlying epidermis [31–33].

The migrating keratinocytes must also markedly alter their adhesive interactions with each other. Alteration in the expression of cell adhesion molecules and desmosomes is effected by the cytokine profile, but probably the earliest signal to change keratinocyte adhesive interactions is the rapid shift in extracellular ionic balance that occurs post-wounding. Thus, damage to cells causes an alteration in the ratios of magnesium and calcium ions, which induces keratinocytes to adopt a migratory phenotype [34].

In normal skin, the basement membrane separates the epidermis from the dermis. Following wounding, this dermal–epidermal junction must be reconstituted as part of the re-epithelialization process. Basal lamina components, such as type IV collagen, laminin and heparan sulphate, are synthesized and deposited into the

dermal–epidermal junction by both the fibroblasts and the keratinocytes. It is thought that most of the molecules are contributed by the fibroblasts, while the keratinocytes organize the molecules into their correct structure and orientation [35]. The early basement membrane is often punctate and poorly organized, but the molecules are deposited synchronously with re-epithelialization. Maturation and organization of the basement membrane, including the establishment of hemidesmosomes and type VII collagen anchoring fibrils, occur later after the epithelial cells are present; the basement membrane is thought to be of predominantly epithelial origin [36].

Angiogenesis

Neovascularization is an important part of granulation tissue formation, and is stimulated early in the inflammatory process. Angiogenesis, in response to tissue injury, is a dynamic process that is highly regulated by signals from both serum and the surrounding extracellular matrix (ECM) environment [1,2]. VEGF, angiopoietin, FGF and TGF-β are among the most potent angiogenic cytokines. Laminins are the major non-collagenous ECM constituents of endothelial basement membrane produced by human dermal microvascular endothelial cells. Laminin 10 is highly expressed in blood vessels around skin wounds. Laminin 8 promotes dermal endothelial cell attachment, migration and tubule formation. Integrins

with either β1 or αv subunits are the major cellular surface receptors for ECM molecules and mediate the interactions between cells and ECM during wound angiogenesis.

During angiogenesis, endothelial cells degrade the vessel basement membrane and surrounding matrix, migrate, proliferate and form new blood vessels [3]. Thus, angiogenesis results from sprouting of existing dermal vessels surrounding the wound. In larger wounds, there is also evidence for *in situ* vasculogenesis caused by the differentiation of angioblast precursors derived from the blood [4]. Growth factors involved in the stimulation of angiogenesis *in vivo* include FGF-1 and FGF-2, VEGF, neuropilin-1, EGF, TGF-α, TGF-β1, TGF-β2 and TGF-β3, activin, PDGF and CTGF [5–11]. These growth factors act by increasing the expression of proteases or protease activators at the leading edge of the endothelial cells, by stimulating endothelial cell proliferation and by increasing vascular permeability [12,13]. Matrix metalloproteinases may have both pro- and antiangiogenic activities [14]. Many angiogenic growth factors are potentiated by heparin. Adequate revascularization of the wound is essential for healing; ineffective angiogenesis results in impaired wound healing. Indeed, it is the appearance of the capillary loops that gives the provisional matrix its red granular appearance, from which is derived the name granulation tissue. At the end of the provisional matrix phase, the numbers of blood vessels within the healing wound decrease by a process of apoptosis, probably induced by depletion of vascular survival factors, such as VEGF, and the appearance of pro-apoptopic factors such as TGF-β [15].

Fibroblast recruitment, matrix synthesis and scarring

The fibroblasts migrate into, and proliferate within, the provisional wound matrix, depositing as they do additional extracellular matrix molecules [1]. Most wound fibroblasts are derived from proliferation of fibroblastic stem cells in the deep dermis and the septae of the underlying fat; relatively few cells are derived from the margins of the surrounding dermis. Like the keratinocytes, they alter their integrin profile, expressing receptors for fibronectin and down-regulating receptors for collagen during the early phases of migration [1,2]. During the early stages of provisional matrix deposition, collagen synthesis in the surrounding unwounded skin is suppressed, while fibronectin synthesis is enhanced [3]. Fibroblasts within the provisional matrix secrete and assemble a complex extracellular matrix. Initially, this consists predominantly of fibronectin, proteoglycans and glycoproteins, but later consists of mature type I collagen bundles. The ratio of collagen types during wound healing varies, the early wound being characterized by elevated levels of type III collagen, whereas later in healing type I collagen predominates. Minor collagens, such as types 12 and 14, as well as proteoglycans such as decorin, are also present in the early healing wound and play a key part in collagen fibril organization. The degree of collagenous cross-linking also varies with time after wounding: the early wound has fewer and more immature cross-links compared with the later wound, which has extensive mature cross-links resulting in a more insoluble collagenous matrix. Many growth factors stimulate fibroblast proliferation, migration and extracellular matrix synthesis, including the TGF-β family [4,5], IGF-1, PDGF [6] and CTGF. These growth factors act in various ways—autocrine, paracrine, intracrine and matricrine—to regulate many of the events during dermal healing. There is extensive cross-talk between the extracellular matrix-derived signals and growth factor signalling in this process. Thus, for example, clustering of integrin receptors on the fibroblast leading edge leads to associated clustering of growth factor receptors, which then interact with the growth factors bound to the matrix.

The early granulation tissue is characterized by specialized fibroblasts called myofibroblasts, which show elevated levels of α-smooth muscle actin, and are morphologically

and functionally intermediate between fibroblasts and smooth muscle cells [7]. These myofibroblasts are induced by growth factors such as TGF-β1 but interestingly not by TGF-β3. Myofibroblasts may contribute to the contractile forces involve in wound contraction, and their persistence can lead to abnormal scar contracture. Normally, myofibroblasts are preferentially eliminated during the apoptopic phase of wound healing that results in resolution of the granulation tissue [8]. The Smad family of proteins mediates signal transduction of the TGF-β superfamily, and TGF-β induces fibroblast contraction necessary for efficient wound healing [9]. Turnover of the extracellular matrix is facilitated by a range of proteases and protease inhibitors, including plasmin, matrix metalloproteinases, hyaluronidase and elastase [10]. Levels of these active proteases are carefully and focally controlled both by growth factors and by proteolytic inhibitors such as TIMP and syndecans [11]. IL-10 is an inhibitory factor for the remodelling of the ECM during wound healing [12].

As healing proceeds, the numbers of fibroblasts, endothelial and inflammatory cells decrease, and the predominantly collagenous matrix becomes organized into thicker, more heavily cross-linked bundles. This marks the establishment of the mature scar. Scars continue to remodel for a long time after wounding, and cannot be considered to be in a steady-state condition until at least 2 years post-wounding—often longer. Cutaneous scarring is defined as a macroscopic disturbance of the normal structure and function of the skin architecture, resulting from the end-product of a healed wound [13,14]. Scarring may manifest itself as an elevated or depressed site, with an alteration of skin texture (e.g. hard), colour (e.g. hypermelanotic), vascularity, nerve supply, reflectance and biomechanical (e.g. elasticity) properties. Histologically, dermal scars are characterized by thickened epidermis with a flattened dermal–epidermal junction, and an abnormal organization of the dermal matrix into parallel bundles of scar-tissue collagen, as opposed to the normal basket-weave appearance of dermal collagen. The scar collagen fibres are usually smaller, more densely packed and often have higher proportions of type III collagen and fibronectin compared with surrounding normal skin. Elastin appears early in the wound-healing process but then disappears (presumably because of the activity of elastase) to reappear again later in the scar [15]. However, the elastin is abnormally organized into fragmented and chaotic structures, as opposed to the normal elastin fibre arcades that characterize normal dermis [15]. Epidermal appendages such as hair follicles and sebaceous glands never regenerate in a scar, although experimental addition of dermal papillae fibroblasts to a wound can induce hair follicle formation [16]. Proliferative scarring or chronic wounds may result from overexpression or dysregulated activity of the fibrogenic isoforms of TGF-β [17–19]. All three isoforms of TGF-β, and its receptors, are strongly expressed in adult wounds, but not in fetal wounds, which do not scar [20]. Hypertrophic scars contain increased numbers of epidermal Langerhans' cells [21], and keloid scars may have elevated levels of VEGF [22].

The severity of scarring can be assessed clinically using visual analogue scales, and the severity of macroscopic scarring correlates with histological abnormalities predominantly in the epidermis and in the papillary dermis [23]. Interestingly, experimental studies show that the morphology and severity of scarring is established early in the wound-healing process [24–27]. Thus, addition of antiscarring therapies, such as neutralizing antibodies to TGF-β1 or exogenous TGF-β3, have to be applied at the time of, or shortly after wounding to demonstrate their maximum antiscarring effects many months later [24–27]. It is likely that this timing reflects the underlying biology; early alterations to the cytokine profile can have profound effects later on by influencing autocatalytic and amplification processes. Furthermore, manipulation of the cytokine profile in the early phases of wound healing, when there are only a small number of signalling systems, is likely to produce more dramatic effects than subsequent manipulations later in wound healing, when a large number of interacting and functionally redundant cytokine signalling networks have been established. These biological data have considerable clinical significance. Thus, it is likely that scar-preventing therapies will be applied at the time of, or shortly after wounding (in most cases they will be applied topically by the physician), and only a small number of applications may be required. The current antiscarring therapies include neutralizing antibodies to TGF-β1, TGF-β2 and TGF-β3 itself, or prevention of TGF-β activation by mannose-6-phosphate [24–27]. Scarring is a major clinical problem resulting in adverse cosmesis, loss of function particularly if over joints, and interference with growth in children. Furthermore, scarring is a major clinical problem in nearly every organ or tissue; for example, scarring in the eye (cornea or retina) can lead to blindness, scarring in the central nervous system (CNS) inhibits neuronal reconnection, scarring in the abdomen and pelvis often leads to strictures and adhesions, and scarring in muscle and joints leads to adverse function and ankylosis. Interestingly, the principles of antiscarring therapy based on manipulation of the proportion of proscarring versus antiscarring cytokines appear to hold good for all body systems, as well as for chronic human fibrotic diseases, such as glomerulonephritis or liver fibrosis, indicating that studies in the skin may have a wider clinical application.

Age-related changes in wound healing

Wounds even of a very substantial size created in certain lower vertebrates (e.g. amphibians) heal by complete regeneration. By the same token, wounds made in early (first-trimester) embryos also heal by complete regeneration [1]. However, these wounds tend to be made before the skin has established even a simple differentiated structure. During the second trimester, experimental studies in numerous animals have shown that late embryonic and early fetal dermal wounds heal with the absence of scarring, but without the regeneration of dermal appendages such as hair follicles or sebaceous glands [2–4]. This scar-free embryonic wound healing then gradually turns into a scarring healing phenotype during the last trimester and after birth. Wounds in children and young adults heal quickly but with poor scars (excessive scarring). There are many differences between scar-free embryonic wound healing and scar-forming adult wound healing, such as alterations in matrix components, cellular proliferation and differentiation, immune cell recruitment and growth factor profiles [4]. However, the real question is, which of these cellular and molecular differences between scar-free and scar-forming healing are central to the scar-free phenotype, and which are simply epiphenomena [5]? One major difference is the degree of inflammation elicited in an embryonic wound that heals in a scar-free fashion [4,6]. The embryonic and fetal immune system is not as well developed, and consequently there are far fewer inflammatory cells at the wound site; those that are present are at different stages of differentiation and activation compared with adult wound healing. Consequently, the growth factor profile at the embryonic wound site is different, with reduced levels, for example, of TGF-β1 and TGF-β2 [3]. These observations of scar-free fetal healing have led to experimental studies of adult wounds to try and mimic the fetal situation [7–9]. Exogenous application of neutralizing antibodies to TGF-β1 and TGF-β2 or exogenous addition of TGF-β3 or mannose-6-phosphate, which prevents activation of TGF-β1 and TGF-β2, to the recently created wound (just before, at the time of, or shortly after wounding) results in adult incisional wounds that heal with reduced or absent scarring [7–9]. These interesting experimental findings have now been translated into putative human therapies, which are undergoing evaluation in clinical trials.

Interestingly, ageing during adult life also brings alterations to the wound-healing process [10]. Many studies of human age-related changes in the wound-healing profile are methodologically flawed because of failure to control for concurrent morbidity and disease [10]. However, experimental investigations on health status in defined human subjects of varying ages have shown profound alterations in the wound-healing process with age [10]. Elderly subjects heal their wounds more slowly, with a reduced inflammatory response, an altered cytokine profile and an increased level of active proteases [11–16]. Of major interest is the observation that, in normal ageing skin, the levels of proteases such as matrix

metalloproteinases and elastase increase, while the levels of proteolytic inhibitors (e.g. TIMP) decrease, tipping the balance towards proteolytic digestion of the dermis [13–15]. This may account for some of the age-related changes seen in normal skin structure. It may also predispose certain individuals to ulcer formation, as chronic venous ulcers are characterized by an excessive proteolytic profile [13]. By contrast, the quality of wound healing in elderly subjects is markedly improved: there is reduced scarring. In part, this correlates with the altered inflammatory and growth factor response, which to some extent mimics that seen during embryonic life [11,12]. These ageing studies have also shown marked differences between how males and females heal their wounds, and between the healing of pre- and postmenopausal females [17]. In general, postmenopausal women heal more slowly but with a better scar quality than premenopausal women [17]. Exogenous therapeutic addition of topical oestrogen to the healing wounds of postmenopausal women causes a marked acceleration of wound healing and reverses the age-related changes in speed and quality [17]. Thus, topical and systemic hormonal treatment of healing wounds is a therapeutic strategy to accelerate healing in the elderly.

Clinical aspects of wound healing

[J.A. McGrath, pp. 11.10–11.25]

Acute wounds result from a breach in the integrity of the skin, which occurs with incisional and excisional surgical wounds and traumatic skin injury including burns. At a cellular level, acute wounding results in activation of mitogen-activated protein kinase pathways and activator-protein 1 [1].

Healing by primary intention refers to wounds where the edges have been brought into apposition by sutures, which is possible when there is a good blood supply and no contamination or necrotic debris. Optimal healing requires the wound edges to be everted, carefully aligned and free from tension. Epidermis will cross the gap by 24 h, but by 5 days the tensile strength is only about 5% that of normal skin. Thus, sutures help to take some tension off the wound. Buried absorbable sutures are helpful in reducing dead space and supporting the wound for longer, as the tensile strength is still only about 20% that of normal skin at 3 weeks [2].

Healing by secondary intention occurs when a wound is allowed to heal from the edge without surgical closure [3], so re-epithelialization is a crucial process. The depth of the wound is critical to the manner of healing. In a partial thickness wound, not only will part of the dermis remain intact, but retention of critical regions of hair follicles and other skin appendages will also provide a rapid source of epidermal regeneration. The density of skin appendages therefore influences the rate of healing. In contrast, full-thickness wounds will have lost dermal and appendageal components and can only be healed from the wound edge, requiring a stimulation of granulation tissue; a mixture of proliferating microvasculature, fibroblasts and the deposition of matrix components. Wound contraction occurs after 1–2 weeks, via activated fibroblasts or myofibroblasts, which decreases the surface area to be closed. Different body sites vary in the results of secondary intention healing, concave surfaces being better than convex, and the face being better than extremities.

In open wounds, the normal water-retaining properties of the skin are lost, and the inflammatory exudate on the surface dries to form a crust or scab. This acts as a barrier to external infection, but it prevents epidermal migration across the surface of the wound. A wound that is kept moist by an appropriate dressing will epithelialize faster

than a wound that has been allowed to form a crust. Accelerated epithelial healing under an occlusive non-permeable dressing is associated with a gelatinous coagulum containing fibrin and fibronectin, which provides a suitable matrix for epidermal cell migration [4].

Tertiary healing or delayed primary closure [5] involves allowing some healing by secondary intention and then closing the wound primarily. This may be indicated when infection is present and needs to be cleared by antibacterial treatment, or skin grafting is intended. Delaying primary closure in this way reduces morbidity, but does not delay the development of wound strength [6]. Indeed, there is some evidence that by the 60th day, wounds healed by delayed primary closure are considerably stronger than those closed immediately [7]. This may be because of better oxygenation and blood flow with delayed closure [8].

Burns

Thermal injuries affecting the epidermis only are known as first-degree burns but, when the dermis is involved, second-degree (partial thickness) and third-degree (full-thickness) burns are incurred. The extent of injury is determined by the rule of nines [1,2]. The head and upper limbs are each 9% of the total body surface area (TBSA), whereas each lower limb, the anterior and posterior trunk is 18% TBSA. A minor burn is either superficial or involves less than 20% TBSA. The speed of healing of dermal burns depends on the number of viable hair follicles and other appendages. Deep burns result in severe scarring and contractures, so surgical practice has evolved to excise burn wounds and close with a skin graft as soon as practicable. Full-thickness burns are chalky white or charred, dry and anaesthetic, whereas more superficial burns are non-blanching, erythematous, wet and extremely painful.

Wound healing in burns is affected by particular complications of the burn injury in the cutaneous vasculature [3]. The depth of burns tends to increase after 24–48 h as a result of progressive vascular occlusion. Thermal injury produces a zone of coagulative necrosis surrounded by an area of hyperaemia, as histamine release after burning gives initial vasodilatation followed by bradykinin-mediated vasoconstriction. Leukocyte adhesion to vessel walls produces progressive thrombotic occlusion, which causes extension and deepening of the burn. Continued leukocyte activation leads to free-radical-mediated tissue damage, and produces prolonged inflammation for 1–4 weeks, which prevents healing. Release of proteases from leukocytes, keratinocytes and macrophages also delays healing by inactivating growth factors, and by destroying newly regenerating tissue.

In a circumferential burn, early escharotomy may be needed to prevent ischaemia. Otherwise, after removal from the heat source for thermal burns, or copious washing for chemical burns, early wound management [4] involves application of a suitable dressing for 2–3 days until the wound depth is clarified. One per cent silver sulfadiazine cream is widely used in burns units, but biological dressings such as human allografts or porcine heterografts are very effective in reducing pain. Occlusive dressings may be helpful on small burns, but are not practical for large-surface-area burns.

Surgical excision down to bleeding with immediate grafting is the treatment of choice on any burn not likely to heal in 2–3 weeks. Tangential excision and split-thickness sheet or mesh grafts are used. Significant blood loss (200 mL/1% TBSA) from these procedures must be replaced. Pressure garments are widely used to prevent excessive scarring, as are silicone gel sheets and occlusive membranes.

Chronic wounds

The series of biological events that close any defect in the skin may be impaired by factors interfering with inflammation, angiogenesis, re-epithelialization and wound remodelling. Most wounds will have a tendency to heal, however long standing, but this process may be very slow and suffer from many complications. Recurrent injury over a previous scar, as in a leg ulcer or pressure sore, and recurrent breakdown following healing, can give rise to chronic skin wounds or ulcers that appear to have lost the capacity to heal. Although the mechanisms of skin

ulceration are understood, the biological profile of the chronic wound is not clear.

The chronic wound environment may, for example, be deficient in stimulatory growth factors, growth factor receptors or proteolytic enzymes required for growth factor activation, or may be overproducing any of these factors [1,2]. Growth activation in the edge of a wound bed is particularly associated with overexpression of TGF-α, heparin-binding epidermal growth factor (HB-EGF) and EGF receptor [3]. The chronic wound may produce a hostile microenvironment to cells requiring activation in the wound-healing process. Chronic wound fluid has been shown to decrease proliferation of fibroblasts, endothelial cells and keratinocytes, in contrast to acute wound fluid, which stimulates growth [4]. Wound fluid from venous ulcers contains active collagenases and degraded fibronectin and vitronectin, and decreases cell adhesion. Fibrin accumulates in chronic wounds (unlike acute wounds), and forms complexes that may bind or inactivate other molecules such as growth factors.

Metalloproteinases (MMPs) are pro-enzymes requiring activation [5]. Three classes of MMPs are collagenases, gelatinases and stromelysins, single-chain proteins the production of which is stimulated by soluble factors and matrix proteins, and inhibited by TIMP [6,7]. There may be abnormalities of MMPs and TIMP in the chronic wound [2,8,9]. Collagenases are probably important in tissue remodelling following healing. Keratinocytes in the edge of a chronic wound are stimulated to produce collagenase by type I collagen.

Keratinocytes in chronic wounds fail to migrate across a wound bed despite a hyperplastic epithelium, and may lack specific matrix proteins in the wound bed to permit cell movement. Keratinocytes migrate most effectively on fibronectin, usually present in the wound bed, and on type I and IV collagens, but not on laminin [10]. Keratinocyte mesenchymal interactions therefore require a vascularized appropriate matrix, and they are impaired in chronic persistent wounds.

The chronic wounds that pose the most significant clinical problems are chronic leg ulcers and pressure sores. These wounds are also of high economic importance, as caring for them consumes a huge amount of health care resources [11].

Leg ulcers

Leg ulcers are becoming more common as the population ages, as they particularly afflict the elderly. Prevalence figures suggest up to 1% of the population in Europe is affected. The health care cost of non-healing ulcers is immense, in view of the high use of community nursing resources. The most common cause of leg ulcers (80–90%) is chronic venous insufficiency, with arterial disease and diabetic neuropathy accounting for the majority of the remainder (Table 11.1).

Venous ulcers result from valve incompetence in the perforating veins connecting superficial and deep venous systems, so that venous pressure does not fall during exercise and as a result capillary proliferation occurs [1]. An increased permeability to macromolecules produces a pericapillary fibrin cuff, which binds growth factors and matrix proteins and may impede oxygenation [2]. Trapped leukocytes occluding capillaries may add to tissue ischaemia through the release of inflammatory mediators that increase vascular permeability [3]. The skin develops purpura resulting from extravasated red cells, and pigmentation from collections of haemosiderin and melanin. Eczematization is followed by induration and dermal fibrosis giving 'lipodermatosclerosis'. Ulceration then develops above the malleoli as an irregular craggy area, which initially heals but has a high recurrence rate. The

resultant scarring, repeated episodes of infection and chronic lymphoedema tend to promote the chronicity of ulceration [4,5] (Fig. 11.1). The most important factor in the aetiology of venous ulcers is venous hypertension, resulting from valve incompetence, loss of calf muscle pump, or both. Venous thrombosis may also lead to venous hypertension. In familial cases of venous leg ulcers there may be an inherited resistance to activated protein C, leading to thrombosis and subsequent ulceration. Most cases of activated protein C resistance are caused by a specific mutation in exon 10 of the clotting factor V gene, known as the factor V Leiden mutation [6]. Less commonly, a polymorphic variant in the prothrombin gene (G20210A) may also be associated with increased risk of venous leg ulceration [7].

Arterial ulceration tends to occur in patients with other symptoms and signs of peripheral vascular disease, such as intermittent claudication, rest pain and loss of pulses. The ulcers are punched out with a demarcated border, usually with a dry base, and tend to occur at acral sites such as the tips of toes or over bony prominences. Ischaemic ulcers are extremely painful, especially at night. They may have a livid haemorrhagic edge, or a necrotic surface.

Diabetic ulcers are most commonly associated with diabetic neuropathy, although microvascular occlusive disease may also contribute [8–11]. They often result from unnoticed injury on the plantar surface of the foot, particularly over bony prominences, and are prone to infection. Healing tends to be slow and difficult to achieve with underlying osteomyelitis, so amputation is an unfortunately common outcome. Neuropathy may be associated with paraesthesia, anaesthesia and pain. Light touch, vibration and then position sense is usually lost in the affected foot. Little is known about how endothelial and metabolic abnormalities in diabetes affect wound repair. Hyperglycaemia may affect neutrophil activity. Loss of neuropeptide homoeostasis may be relevant, as intact neurosensory activity is essential for inflammation.

Pressure ulcers

Pressure ulcers are areas of local necrosis developing when soft tissue is compressed between a bony prominence and a rigid external surface [1–4]. The mean capillary pressure in healthy individuals is 25 mmHg, and external compression with pressures of 30 mmHg will occlude blood vessels so that tissues become anoxic and undergo ischaemic necrosis. Toleration of high tissue pressures depends on the patient's health and the extent and time of application, but short intervals of pressure relief will allow longer resistance. Any patient who is severely and acutely ill can develop pressure sores, because dehydration and hypotension will add to tissue destruction. Patient immobility is the major risk factor, but loss of sensory perception, including loss of consciousness, will contribute; the elderly infirm and neurologically disabled being most affected with pressure sores. General ill health, ischaemic heart disease, peripheral vascular disease, low blood pressure and high temperature all increase risk. Patients with poor nutrition, particularly with hypoalbuminaemia and low vitamin and zinc levels, have an increased risk of full-thickness ulceration. Drugs that suppress sensation, mobility or blood flow may be

Table 11.2 Staging of pressure sores.

I	Redness not resolving on relief of pressure
II	Loss of skin layers including epidermis and partial thickness of dermis
III	Full thickness with loss of subcutaneous tissue

aggravating factors, as is incontinence. Mattress positioning and quality can contribute. Relieving shear forces by positioning and protecting skin with lubricant or suitable dressings (e.g. polyurethane films) to prevent sticking is therefore essential.

The depth of ulcer is used to classify pressure sores, and there are a number of classification systems (Table 11.2). Eighty per cent are superficial and 20% deep, but even superficial sores will progress if left unrelieved. The most common sites are the areas of highest compression in the supine patient: 60% of all sores are over the sacrum (Fig. 11.2a), while the ischial tuberosities, greater trochanter and heel (Fig. 11.2b) account for 15%. Less common sites are elbows, knees, ankles and occiput. Heels erode when individuals sit immobile with heels supported. Early active mobilization not only relieves pressure, but also increases blood flow and muscle tone. When pressure is relieved, sores go through a process of débridement, where necrotic slough forms a hard dry black eschar. This later separates by natural proteolysis, followed by wound contraction, re-epithelialization and scar remodelling. The pathology of the pressure ulcer shows wedge-shaped infarcts of the subcutaneous tissue, capillary obstruction by microthrombi, and endothelial cell swelling and necrosis, with widespread inflammation.

Infection and osteomyelitis may follow wound breakdown, but significant tissue infection will be associated with redness, heat, oedema and tenderness, and systemic features such as leukocytosis, fever and pain, with an offensive exudate. Rapid débridement is particularly important in those at increased risk of infection, such as diabetics and the immunosuppressed.

Complications of wound healing

Hypertrophic scarring

Keloids and hypertrophic scars are abnormal fibrous reactions to trauma, inflammation, surgery or burns in predisposed individuals, particularly in Afro-Caribbean skin, and most occur between the ages of 10 and 30 years. Hypertrophic scars remain restricted to the original wound, but keloids extend beyond the original wound and rarely regress. Trauma, skin tension and hormones are aetiological factors. Most keloids commence within a year of trauma in areas of highest skin tension: on the upper back, shoulders, anterior chest and upper arms. Reducing wound tension by orientating the wound along lines of relaxed tension may reduce scar formation. Familial predisposition to keloid formation is suggested by reports of recessive and dominant inheritance, but no human leukocyte antigen (HLA) association or polymorphic variants in TGF-β genes have been found [1]. Some skin diseases give keloidal scarring, including acne conglobata, acne keloidalis nuchae, hidradenitis suppurativa and certain infections such as chickenpox.

Keloids present clinically because they are disfiguring, painful or pruritic, especially when actively growing. The clinical course is variable, with keloids appearing from

weeks to months after the initiating lesion, growing to exceed the wound limits and then stabilizing. Suppurative necrosis occasionally complicates the lesion from vascular damage or pilosebaceous occlusion, particularly in acneiform lesions. Keloids seldom regress spontaneously, but may soften in the elderly.

Hypertrophic scars are distinguished from keloids by growth course and outcome. They occur soon after the trauma or inflammation, are limited to the site of the wound and regress in months to years, but may be difficult to distinguish from keloids in their early actively growing phase. Pathological distinction is not easy. Normal healing involves fibroplasia following the inflammatory phase. In keloids, this is progressive and forms nodular vascular proliferations surrounded by fibroblasts. These nodules transform into avascular collagenous bundles with persistent swirls of fibroblasts; myofibroblasts are prevalent in active keloids. The collagen bundles are randomly aligned and not orientated to the skin surface, whereas in normal scars the bundles lie parallel to the epithelial surface. There are suggestions from *in vitro* studies that abnormal collagen cross-linking, degradation or regulation by TGF-β may be involved in the pathogenesis [1–4]. Other cellular changes identified include alterations in α1β1 integrin collagen receptor expression [5] and in the regulation of fibroblast apoptosis [6]. *In vitro* studies also suggest that keloid keratinocytes may also influence keloid fibroblasts (and normal fibroblasts) to increase procollagen I and III gene and protein expression [7].

Treatment of keloids and hypertrophic scars initially involves intralesional corticosteroid injection, although hypopigmentation and local subcutaneous atrophy are possible local side effects. Mechanistically, triamcinolone acetonide has been shown to directly stimulate basic fibroblast growth factor (bFGF) expression and to inhibit TGF-β1 production [8], changes that are both recognized to reduce scarring. However, repeated injections of corticosteroids are always necessary, and seldom completely successful. Surgical therapy with excision or enucleation has a high recurrence rate in the absence of adjunct therapy, such as intralesional steroids, radiotherapy, pressure devices, silicone gels or other less proven agents including intralesional IFN-γ, IFN-α2 and retinoids. Prevention by minimizing trauma and surgery in predisposed individuals is important, as most treatments are unsatisfactory, although surgery combined with radiation has the lowest recurrence rates [9]. Other possible treatment options include laser therapy (585-nm pulsed-dye or Nd : YAG), electron beam irradiation, cryotherapy, intralesional 5-fluorouracil, intralesional verapamil and topical imiquimod [10–16]. *In vitro* studies suggest that the anti-inflammatory drug lysine acetylsalicylate also decreases proliferation and extracellular matrix gene expression (procollagen I and II) in keloid fibroblasts [17].

Wound infection

Traumatic wounds may contain necrotic eschar and non-vital tissue or foreign material, which predisposes to bacterial contamination. Colonization of wounds with microorganisms can give a local concentration of organisms without overt tissue infection, which nonetheless mediates adverse events in the wound following binding of microorganisms to tissue, multiplication of organisms and triggering of a host immune response. Wounds that contain more than 10^5 bacteria per gram of tissue are likely to lead to clinical infection [1]. Bacteria compete for metabolites (glucose and oxygen), release toxins and proteases (leading to cell damage), and activate complement (prolonging inflammation). Patients with systemic problems

such as diabetes mellitus, steroid therapy, increasing age, local ischaemia and immunosuppression are more prone to develop infection. Fibronectin in the wound bed is known to predispose to bacterial adhesion.

Chronic wounds are especially prone to infection [2–5], partly because of the underlying pathology and the common presence of necrotic debris, where superinfection with Gram-negative and anaerobic organisms gives a characteristic offensive odour. There is no evidence that bacterial contamination will delay healing [6], but systemic antibiotic treatment will be required for evidence of tissue cellulitis, with spreading redness, oedema, pain and tenderness around the wound. Wound swabs are commonly positive for Gram-negative bacilli, particularly *Pseudomonas* and *Proteus*, and the other common pathogen is *Staphylococcus aureus* (56% leg ulcers and 51% pressure sores [2]). The isolation of *Bacteroides* may be associated with impaired healing. Bacterial counts are often elevated under occlusive dressings, and there is no good explanation for the low incidence of clinical infection, although limiting exogenous pathogenic organisms by the barrier of the dressing may play a part [4,7,8]. In recent years, emergence of multiple antibiotic resistance of methicillin-resistant strains of *Staphylococcus aureus* (MRSA) has become a major clinical problem worldwide [9]. At a cellular level, the key determinant of the broad-spectrum beta-lactam resistance in MRSA strains is the activity of the penicillin-binding protein 2a (PBP2a) [10].

Patients with chronic wounds are frequently treated with oral antibiotics when suspected of clinical infection, which predisposes to the development of organism resistance. Widespread use of ciprofloxacin for its anti-*Pseudomonas* activity has given rise to resistant isolates from leg ulcers [5].

Other local factors influencing wound healing

Dessication of the wound allows the formation of a dry eschar, leading to slower re-epithelialization. Indeed, covered acute wounds resurface up to 40% faster than those exposed to the air [1]. A moist wound environment also encourages more rapid angiogenesis and dermal repair [2–4]. Occlusion of chronic wounds may also increase healing rate over the first 4 weeks.

Haematoma formation may impede wound healing because of local tissue hypoxia as well as providing a medium for accumulation and growth of bacteria and other microorganisms [5]. Haemostasis is therefore important in surgical procedures, as is good wound handling because crushed tissue or over-tight sutures may cause ischaemia and promote inflammation and secondary infection.

Foreign bodies in wounds tend to lower pH, reduce oxygen tension and activate complement, thereby delaying wound healing [2,5].

Contact dermatitis may develop to a variety of topical antimicrobial preparations applied to wounds, especially to neomycin [5]. Less common allergens include gentamycin, hydrogen peroxide and hexachlorophene. Potential sensitizers include ethyl alcohols, chlorhexidine, quarternary ammonium compounds and benzoyl peroxide. Superimposed contact dermatitis usually delays wound repair and some vehicles of topically applied medications may also affect epithelialization [6].

Wound healing and ageing

Wound healing in the elderly progresses more slowly, and it is thought that all phases of the wound-healing process are affected, with decreased proliferative responses, delayed angiogenesis, delayed remodelling and slower re-epithelialization [1–6]. Age-related reductions are seen in keratinocyte and fibroblast migration (especially in poorly oxygenated wounds), integrin function, actin cytoskeletal organization and inflammatory chemokine responses [7–10]. Incisional wounds in older individuals have a lower tensile strength, and postoperative surgical

dehiscence rates are higher [11]. However, elderly patients do successfully heal after major surgery, such as open heart surgery, and so the differences from younger individuals are not contraindications to surgical procedures. Other factors adversely affecting wound healing, such as peripheral vascular disease, cardiac problems and poor nutrition, are also more likely to occur in the elderly.

Superficial wounds heal more slowly among the elderly: dermabrasion (healed in 10 days for 25-year-olds and 21 days for 75-year-olds); suction blisters on the forearm (3.6 weeks mean for the young and 5.4 weeks for the elderly to return completely to normal) and split-thickness wounds, such as donor sites, all show the same pattern. Meshed autografts greatly accelerated healing (10 days) compared with vaseline gauze (10–36 days) in the treatment of donor sites in the elderly, which suggests that reducing the need for re-epithelialization is of considerable benefit [12]. New techniques of wound healing, such as cultured epidermal grafts, are particularly applicable to the elderly, but care must be taken to treat vigorously underlying medical conditions.

Systemic factors affecting wound healing

Systemic diseases, including vascular disorders (e.g. congestive cardiac failure, hypertension, atherosclerosis, venous insufficiency or lymphoedema), as well as metabolic disorders (e.g. chronic renal failure, chronic liver disease or diabetes mellitus) may all interfere with wound healing.

Underlying unrecognized or untreated diseases may also retard healing. For example, ulceration of the skin may result from ischaemic necrosis secondary to a primary vasculitis such as polyarteritis nodosa, rheumatoid vasculitis or neutrophilic inflammation such as pyoderma gangrenosum. Although the early stages of such lesions often have a prominent haemorrhagic component, they may result in indolent chronic ulcers. The site and distribution of lesions are often a clue to the underlying pathology, as are signs of inflammation, haemorrhage or undermining of the edge. Vasculitic lesions particularly affect acral sites and areas of impaired vascularity, and signs of livedo or palpable purpura may be present. Although lesions in necrotizing venulitis may be in the stasis areas, they will also occur on arms, legs and buttocks. Active treatment of the underlying disease will often stimulate surprisingly rapid healing, and intralesional steroids in the edge of a chronic wound help even chronic pyoderma gangrenosum lesions. Genetic abnormalities may also contribute to impaired wound healing, in particular abnormalities of connective tissue, as found in Marfan's syndrome, Ehlers–Danlos syndrome and prolidase deficiency.

Malignancy may be relevant to impaired wound healing, either because of ulceration occurring within a tumour or because malignancy arises on a background of chronic ulceration. Non-melanoma skin cancers, both basal cell and squamous cell carcinomas, may ulcerate. Many of these lesions will be on sun-exposed sites, but they may be extensive in patients exposed to carcinogens, and lesions on the legs may be misdiagnosed, although this is a common site of actinic lesions in women. A malignant ulcer will continually grow in size, be irregular in shape and usually have a thickened edge. The site may be atypical for a chronic ulcer, which provides an important clue. A diagnostic biopsy of the edge should always be considered in any ulcer increasing in size. Excision and grafting will often be required on the lower leg. Malignant change can develop in a chronic non-healing ulcer, and will cause failure to heal and progressive enlargement. Again suspicion is raised by changes in the ulcer edge and size, and a diagnostic biopsy is indicated. Malignancy arising in chronic ulcers following burn injuries is referred to as Marjolin's ulcer; the tumour is usually a squamous cell carcinoma [1].

Protein malnutrition is a major factor affecting wound healing, and malnourished patients have an increased risk of surgical complications [2]. Surgery, trauma or sepsis may lead to relative protein deficiency and a negative nitrogen balance. Angiogenesis is inhibited, and fibroblast proliferation and collagen synthesis are impaired; these abnormalities are reversed on protein replacement. Nutritional support also maintains immune function, decreases the risk of infection and facilitates wound healing, especially in cancer patients. Serum levels of albumin, transferrin and IGF-1 are indicators of the status of protein stores [3].

Vitamin deficiency may have adverse effects on wound healing, particularly in the case of vitamins A, C and K. Vitamin A modulates cell differentiation and can reverse inhibitory effects of glucocorticoids on healing of some wounds. Lack of vitamin A also compromises epithelialization, collagen synthesis and inflammation [4]. Vitamin C deficiency seriously impairs the speed and strength of wound healing because of markedly reduced collagen synthesis, formation of fragile capillaries and decreased resistance to infection [5]. Vitamin K is essential in the synthesis of blood clotting factors II, VII, IX and X. Deficiency of vitamin K impairs haemostasis and may result in haematoma formation.

Trace element deficiency usually occurs in combination with other deficiencies, particularly in chronic malabsorption and alcoholism. Zinc is a component of many coenzyme complexes, and severe deficiency results in abnormal lymphocyte function, increased susceptibility to infection and delayed wound healing [6]. Zinc-deficient wounds are also abnormally weak. Although zinc metabolism and distribution may be abnormal in patients with non-healing leg ulcers, zinc supplementation probably only accelerates healing in zinc deficiency. Iron deficiency interferes with wound healing by causing anaemia and tissue hypoxia, but also interferes with bacterial killing, increasing the risk of wound infection. Clearly, most deficiency states are multiple and it is difficult to distinguish which deficiency is causing the problem in healing. Local nutritional problems are also of importance in consideration of delayed healing, and loss of an adequate blood supply accounts for the bulk of the 'non-healing wounds' seen in clinical practice, including decubitus ulcers and ulcers of the lower legs resulting from various types of vascular disease.

Drugs, such as corticosteroids, reduce DNA synthesis in the epidermis and induce morphological changes in fibroblasts [7,8]. In addition, it is well established that they induce dermal atrophy (probably by inhibiting synthesis of collagen) and retard re-epithelialization. It is therefore not surprising that long-term administration of these drugs either systemically or topically impedes the healing of wounds, and predisposes both to wound dehiscence and to chronic ulceration. Other drugs such as anticoagulants, cytotoxic agents, aspirin, colchicine, penicillamine, ciclosporin and phenylbutazone [9–11] may have adverse effects on wound healing, from direct effects on cells taking part in the healing process (as in cytotoxic agents), effects on vascularization or the enhancement of infection.

Principles of treating wounds

Measurement

There are a number of essential measurements that are required to assess the primary pathology, such as Doppler studies of arterial pressure. However, progress in ulcer treatment is difficult to assess clinically at visits, often by multiple different health care personnel, and accurate wound measurement is required to establish the area, shape and volume of the wound. Serial photography and computerized planimetry are not possible to use in standard practice in the community, so tracings on plastic films are widely used. Deep flask-shaped pressure ulcers are particularly difficult, but the volume of fluid under an occluding membrane can be roughly measured. Research studies use laser Doppler assessment of blood flow, ultrasound measurement of depth and direct measurement of arterial or venous pressures.

Compression bandaging

Compression bandaging and elastic stockings are of proven benefit in reversing the effects of chronic venous hypertension, by raising the local hydrostatic pressure and reducing superficial venous pressure [1–4]. Indeed, a systematic review of venous leg ulcer compression bandaging trials has found that compression increases ulcer healing rates compared with no compression, that multilayered systems are more effective than single layer dressings, and that high compression is more effective than low compression [5]. The compression increases flow velocity, and results in the restoration of fibrinolysis and breakdown of fibrin cuffs. The optimal external pressure of 35–40 mmHg may not be tolerated, but lower pressures may enhance ulcer healing. It is essential not to deliver such levels of pressure to an ischaemic leg, as necrosis or gangrene may result [6], and so Doppler pressures should be measured and the ankle brachial pressure index must be greater than 0.8. Traditional crêpe bandaging,

Fig. 11.3 Application of a four-layer bandage.

etc., provides little external compression, but newer short-stretch and high-performance bandages are much more effective. There is variation in pressure according to the technique of the user. A large community programme tested a four-layer bandaging technique (Fig. 11.3) designed to deliver sustained consistent compression for a week between dressing changes (crêpe/Velband/Elset/Coban) [1]. The excellent healing rate (80% of ulcers in 12 weeks) in this study has led to the widespread adoption of the technique in the UK, but the success rates depend on the local clinical profile; specialist wound-care units often collect patients who have failed all conventional treatments.

Organization of wound-care services

The delivery of currently available wound-care management is not uniform, and many basic items, such as a wide range of compression bandages, are not readily available in the community. There has therefore been a movement to provide wound-care units, with an integrated hospital-based wound clinic interacting with primary care clinics in the community, thus upgrading community nursing. Wound-care nurse specialists are playing a major part in developing these services. They should improve wound-healing rates in the community and also ensure that only patients with wounds requiring special expertise, such as skin grafting, vascular surgery or medical treatment, are referred to more expensive hospital facilities.

Topical therapy

Antiseptics. As clinical infection was thought to retard wound healing, it has been common practice in the past to use antiseptic antibacterial agents to cleanse wounds. However, the advent of systemic antibiotics for infection control has led to a reappraisal of antiseptic usage, as they have now been shown to retard re-epithelialization and slow healing [1,2].

Saline dressings can be used to irrigate and clean a wound, removing cellular and bacterial debris, and are safe but pharmacologically inactive. Hexachlorophene and chlorhexidine are tissue toxic, and painful to apply to open wounds. Hydrogen peroxide is rapidly broken down to give molecular oxygen and, as with sodium hypochlorite, is rapidly inactivated by tissue exudate, although the physical effervescence may help surface débridement. Povidone–iodine solution is also toxic in high concentrations, but can maintain bactericidal activity at low concentration. As iodine can cause contact dermatitis, it should be used with caution.

Silver sulfadiazine compounds are widely used in burn care, being effective against *Staphylococcus aureus* and *Pseudomonas aeruginosa*, and possibly having an effect by enhancing epithelialization [3].

Antibiotics. Topical antibiotics have also been used to reduce tissue infection in wounds and are often incorporated into dressing materials, but they are frequent causes of contact dermatitis, particularly neomycin and gentamycin. Use of systemic antibiotics for true tissue infection is now preferred, particularly with the development of antibiotic-resistant organisms. Mupirocin appears to

sensitize infrequently but, as it may be effective in multi-resistant *Staphylococcus aureus* (MRSA), it should not be generally used. Topical antibiotic use should be strictly limited.

Benzoyl peroxide. In the pig, the application of 20% benzoyl peroxide suspension in a lotion base greatly increased the rate of re-epithelialization [4], whereas a 50% suspension retarded healing. Wounds treated with 20% benzoyl peroxide show a pronounced giant cell infiltrate and a highly vascular granulation tissue, and it has been suggested that the ability of benzoyl peroxide to enhance wound healing is related to its ability to attract macrophages and histiocytes into the wound. It may also be related to the release of molecular oxygen, as hyperbaric oxygen is known to facilitate healing in superficial and full-thickness wounds.

Traditional. Honey mixed with butter was applied to wounds by the Ancient Egyptians as 'Balm of Gilead', and both honey and cane sugar are still used by traditionalists as wound dressings [5,6]. Cane sugar containing sucrose, which is not metabolized outside the gastrointestinal tract, prevents bacterial growth by decreasing the available water, and it has also been claimed that it might stimulate granulation tissue [7]. A systematic review of randomized trials of topical honey in superficial burns and wounds has concluded that confidence in a conclusion that honey is a useful treatment for superficial wounds and burns is low, but that there was biological plausibility [8].

Wound débridement

When there has been ischaemic necrosis or progression in a chronic ulcer, necrotic debris may accumulate on the surface of a wound. Surgical débridement under local or general anaesthetic may be required to promote healing. Medical treatment for hydrating the slough, so it can be removed easily, can be performed by application of aqueous (or potassium permanganate) compresses or continual irrigation. Interactive hydrogel and hydrocolloid dressings may be beneficial. Proteolytic enzymes such as streptokinase must be used carefully to prevent damage to viable epithelia, but newer agents are more specific. The two enzymes most commonly used in Europe are fibrinolysin/desoxyribonuclease and collagenase. Studies in necrotic ulcer animal models have shown the effectiveness of collagenase in wound débridement but no clinical efficacy for fibrinolysin/DNAse in this model [1]. Proteolytic enzymes derived from Antarctic krill have also been shown to be effective in wound débridement [2]. Maggots have made a recent reappearance on the therapeutic scene [3]. Sterile maggots of the green bottle fly, *Lucilia (Phaenicia) sericata*, are used for débridement. Up to 1000 maggots are introduced into the wound and left for 1–3 days. One advantage of this therapy is that the maggots effectively separate necrotic from living tissue, thereby making subsequent surgical débridement much easier [4].

Wound dressings

Wound dressings protect the surface of wounds and prevent bacterial and viral contamination of healing wounds. Studies have shown that occlusive dressings maintaining a moist environment have beneficial effects on wound healing through accumulation of endogenous growth factors in wound fluid, and other biological effects on angiogenesis, generation of granulation tissue and re-epithelialization [1–5]. The main concern about wound occlusion has been a perceived increased risk of tissue infection, and indeed occlusion of wounds can lead to higher bacterial counts. However, rates of tissue infection are low and there appears to be no impairment of re-epithelialization [6].

Synthetic dressings are divided into several categories, based on physical properties. These comprise: polyurethane films, hydrogels, hydrocolloids, foams and alginates. In addition, newer dressings have emerged that have specific clinically relevant qualities. These include: collagens, hydrofibres, antimicrobial dressings, débriding agents, odour-absorbing dressings, biosynthetic dressings and hyaluronic acid dressings [7]. Clinical indications for optimal selection of appropriate dressings are outlined in Table 11.3.

Table 11.3 Selection of appropriate wound dressings.

Types of wound	Suitable dressings
Acute	
Abrasions, lacerations	Films, hydrocolloids, thin foams
Catheter or cannula sites	Films
Burns	Hydrocolloids, hydrogels, biosynthetic dressings
Donor sites	Films, hydrocolloids
Dermabrasion, chemical peels	Hydrogels
Surgical wounds	Films, hydrocolloids, hydrogels, alginates
Chronic	
Venous ulcer	
Heavy exudates	Foams, alginates, hydrofibres
Moderate exudates	Hydrocolloids, foams
Mild exudates	Hydrogels, hydrocolloids
Malodorous	Foams, alginates, hydrocolloid charcoal
Arterial	Hydrogels
Neuropathic	
Moist	Hydrogels, alginates, hydrofibres
Dry	Hydrogels, hydrocolloids
Pressure ulcers	
Stage I	Films, thin hydrocolloids
Stage II–III	Hydrocolloids, foams, hydrogels, débriding agents
Stage IV	Alginates, hydrofibres, débriding agents

Films (e.g. Opsite®, Bioocclusive®, Tegaderm®) are thin polyurethane transparent sheets. They are often coated with adhesive to stick to the margins of the wounds. Films are useful for superficial wounds or as dressings around catheter sites (wounds that are only mildly exudative as they cannot absorb exudate). Care must be taken when removing film dressings because new epithelium can easily be stripped [8–10].

Hydrogels (e.g. Intrasite®) are translucent jelly-like non-adhesive materials that maintain a moist environment. They are semi-permeable to gas and water vapour and are available as sheets, impregnated into gauze or in spray bottles. They are suitable for mildly exudative wounds because they absorb only a small amount of exudate, and a secondary dressing is required. Hydrogels often have a soothing and cooling effect because the cross-linked polymers tend to entrap water and reduce the skin surface temperature by up to 5°C.

Hydrocolloids (e.g. Granuflex®) comprise an opaque mixture of adhesive absorbent polymers and gelling agents such as sodium carboxymethylcellulose. They adhere well to the wound edge and have an impermeable polyurethane backing. Hydrophilic particles in the dressing interact with the wound exudate to form a yellow gel next to the wound. This can be confused with a purulent wound discharge, but the acidic microenvironment forms an antibacterial and antiviral barrier and is helpful in wound débridement. Hydrocolloid dressings can adhere to any dry or moist site, allowing the patient to bathe or shower. Side effects from these dressings include an increased amount of granulation tissue and tissue maceration [11,12].

Foams (e.g. Allevyn®) are absorbent opaque polyurethane sheets that are permeable to gas and water vapour. They may be of variable thickness and are suitable for moderately or heavily exudative wounds, although foam dressings may stick and be difficult to remove if the exudate dries out.

Alginates (e.g. Kaltostat®) are made from brown seaweed and are highly hydrophilic, changing from fibrous to gel form on absorbing water. Indeed, alginates can absorb up to 20 times their own weight. The ingredients include calcium salts of alginic, mannuronic and guluronic acids. When exposed to sodium-rich solutions (such as wound exudate) calcium and sodium ions interchange resulting in increased amounts of free calcium. This leads to amplification of the normal wound clotting cascade. Alginates are available in sheets or rope forms and are suitable for dressing heavily exudative wounds, deep wounds and cavities. In addition, they can be easily moved without damage to the wound surface when well hydrated [12].

Collagen dressings are made from cowhide and are available as sheets, pads, particles or gels. Sometimes they are also combined with alginates or hydrogels. These dressings accelerate wound healing by providing a collagenous matrix to enhance cell migration during wound healing.

Hydrofibres are extremely absorbant, up to three times more so than alginates. The absorbant material is composed of carboxymethyl cellulose fibres that form a soft gel when exposed to heavily exudative wounds.

Antimicrobial dressings are designed to counter the antihealing effects of bacterial colonization in chronic wounds. While it is recognized that topical antimicrobials

in high concentration interfere with wound healing, antiseptics such as povidone–iodine 0.001% have been shown to maintain bactericidal activity but without any cytotoxic effects on the healing wound. Slow-release iodine preparations such as cadexomer–iodine are suitable for chronic venous ulcers [13]. Silver compounds have also been shown to prevent chronic wound colonization by bacteria.

Débriding dressings in the form of chemical or enzymatic looseners can be used to remove necrotic tissue, often to supplement hydrocolloid dressings.

Odour-absorbing dressings are based on activated charcoal that absorbs bacterial breakdown products. These dressings are often combined with foam, alginate or hydrocolloid dressings.

Biosynthetic dressings comprise a polyurethane film or silicone membrane with collagen peptides added as a biological component. These dressings are suitable for temporary coverage of burns wounds.

Hyaluronic acid dressings are made of biodegradable absorbent bipolymers that form a hydrophilic mesh with the wound exudate. Hyaluronic acid accelerates granulation tissue formation and re-epithelialization and these dressings help stabilize the clot and attract inflammatory cells crucial to the wound-healing process.

Other pharmacological agents

Fibrin cuffs around cutaneous microvasculature are associated with impaired fibrinolysis; therefore stanozolol, an anabolic steroid that enhances fibrinolysis, was suggested as an agent to treat lipodermatosclerosis [1]. Although early studies suggested improvement, there is no evidence of benefit in established ulceration.

Pentoxifylline also increases fibrinolysis, decreasing blood viscosity, increasing red cell deformity and inhibiting platelet aggregation, and limited studies suggest benefit (e.g. at a dosage of 400 mg three times daily in chronic venous ulcers [2]).

Prostaglandins E1 and I2, calcium-channel blockers such as nifedipine, and serotonin antagonists such as ketanserin, show conflicting results in peripheral vascular disease and venous ulceration [3]. Some calcium-channel blockers may also have a direct effect on keratinocyte migration [4].

Ascorbic acid is a co-factor for proline hydroxylase necessary for collagen synthesis, but it is of doubtful benefit in patients who are not vitamin-deficient. In accordance with the Pauling concept that most individuals do not have enough vitamin C in their diet, large dietary supplements of ascorbic acid were given to a group of patients with pressure sores in a double-blind study; considerable increase in the rate of healing was noted in the treated group [5]. Ascorbic acid has also been shown to have an important function in the preparation of *in vitro* skin substitutes, with direct effects on epidermal barrier formation, basement-membrane integrity and the quality of skin contracture after grafting [6].

The precise role of zinc in wound healing is at present unclear. Early studies claiming that systemic zinc therapy accelerated wound healing in humans and other animals have been supported by some workers and refuted by others [7]. This discrepancy may be partly explained by studies that have shown that systemic zinc reduces the healing time in patients with venous and arterial leg ulcers, but only if the patients are initially zinc-deficient. Topical zinc is also unlikely to have a major effect [8,9]. Nevertheless, zinc does appear to have an important antioxidant role in skin [10], and mutations in the zinc transport gene, *SLC39A4*, have recently been demonstrated in the zinc-deficiency disorder, acrodermatitis enteropathica, an autosomal reccessive condition associated with chronic superficial skin ulceration and poor wound healing [11].

Treatment of wounds with oxygen has been considered to be helpful in some wounds, although recent studies have focused on the state of the redox environment of wounds and the role of nitric oxide in wound repair [12,13]. Nitric oxide is a small radical, formed from the amino acid L-arginine by three distinct forms of nitric acid synthase. The inducible form (iNOS) is synthesized in the early stages of normal wound healing, and experimental knockout of the gene leads to delayed wound healing. By contrast, improved wound healing can be obtained by the addition of nitric oxide or arginine to wounds. Nitric oxide has also been shown to regulate collagen synthesis,

cell proliferation and wound contraction [12]. Although not yet of practical therapeutic value, manipulation of nitric oxide in skin may have future pharmacological relevance to improving normal or abnormal wound healing.

Skin grafts

Pinch grafts and split-thickness skin grafts

For pinch grafts, small (2–3 mm^2) pieces of partial thickness skin can be removed under local anaesthetic, as an outpatient procedure or by a specialist nurse within the home, and planted across the wound bed to form islands for re-epithelialization with greatly increased healing (Fig. 11.4). The time-consuming nature of the procedure is the major problem, but repeated grafts can be performed, and the donor sites heal very rapidly. The approach may benefit both arterial and venous leg ulcers, and its suitability for primary care settings has been demonstrated [1].

For split-thickness skin grafts, a large sheet of partial thickness skin is removed using a dermatome. The plane of cleavage may be variable, either within the papillary or reticular dermis. The graft is usually meshed before application as this tends to reduce the chances of the graft subsequently detaching as a result of the wound exudate. Split-thickness skin graft donor sites are often painful.

In vitro-prepared skin grafts

The feasibility of growing human keratinocytes in culture was first established in 1975 [2] and the possibility of expanding a small donor site up to 10 000-fold led to the application of cultured keratinocytes for grafting [3]. Grafts established from the patient's own skin (autografts) or from allogeneic donors (allografts) have subsequently been formulated for clinical use (Fig. 11.5).

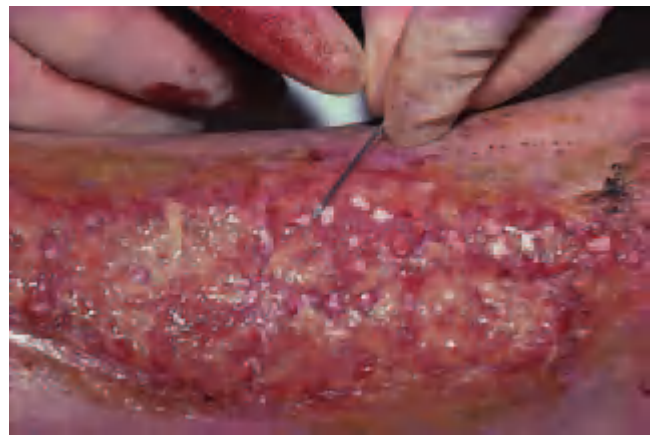

Fig. 11.4 Application of pinch grafts to a leg ulcer.

The earliest clinical use was to treat major burns patients, and the translucent sheets became a permanent stable epidermis, visible after 12–14 days [4]. The resulting graft remained fragile, and remodelling of the dermis occurred only slowly [5]. The incorporation of a dermal connective tissue in the graft on the wound bed appears to enhance graft take [6]; therefore areas of take are now much improved. Cultured epidermal autografts have also been used to treat deep dermal naevi [7], vitiligo and chronic leg ulcers [8], where repeated grafting from passaged cultures is a major advantage. The use of polymer delivery systems, such as hyaluronate membranes, allows earlier grafting than previously possible. Epithelial cell grafts can also be used in the oral cavity [9], mastoid cavity [10], urethra [11] and genital mucosa. Allografts of cultured keratinocytes do not survive long term [12–14], but have been shown to have a wound-healing effect in chronic leg ulcers [15], probably because of the production of appropriate growth factors and extracellular matrix proteins. Keratinocyte allografts have also been used in tattoos [12], donor sites [12], burns [13] and facial dermabrasion wounds.

Keratinocytes can also be subcultured onto a complex matrix or dermal substitute to form skin equivalent cultures, varying from fibroblast-contracted collagen gels [16] to de-epidermalized dermis. These have been used to treat burns, tattoos and leg ulcers and patients with junctional epidermolysis bullosa [17]. Allogenic skin equivalents also appear to promote healing of chronic ulcers, and a number of these products are now commercially available.

Growth factors to augment wound healing

All cells involved in the wound-healing process (inflammatory cells, epidermal keratinocytes and mesenchymal cells) can synthesize a wide range of membrane-bound and free growth factors, whose effects are mediated by specific growth factor receptors for each family of growth factor. Growth factors are multifunctional and have differing effects on different cell types, and can induce expression of other cytokines and their receptors in an autocrine and paracrine fashion. Growth factor activity can also be regulated via ECM components and proteolytic activation, so the net result of growth factor profiles in a wound bed will differ temporally according to the cascade of cytokine release and also with the wound type. The addition of exogenous growth factors in pharmacological amounts may have measurable effects in wound-healing models, but can be disappointing in the clinical arena, as complex synergistic and antagonistic effects may result in a different net result [1–4]. Furthermore, bacterial superinfection of wounds may completely obliterate any possibility of a useful therapeutic response from the exogenous growth factors.

In animal models, a number of growth factors have positive effects on granulation tissue formation and angiogenesis, including PDGF, FGFs [5] and TGF-β. PDGF and TGF-β have also been shown to increase tensile strength of a wound [6]. EGF appears to enhance epithelialization as well as having mesenchymal effects [7–9]. Growth factors appear to have measurable effects but are of dubious clinical benefit. EGF, for example, demonstrated a 15% acceleration in healing in donor sites. A crude extract of platelet releasate has also been reported to enhance wound healing [10]. Conversely, use of the antiparasitic drug, suramin, which is known to inhibit binding of TGF-β, PDGF, bFGF and EGF to receptors, has been shown to retard wound repair. PDGF is currently the only licensed recombinant growth factor for treating recalcitrant wounds, and its usefulness in the management

of chronic neuropathic diabetic ulcers has been demonstrated in clinical trials [11].

Endogenous overproduction of growth factors may be associated with poor long-term cosmesis or impaired wound healing, and therefore neutralizing the effects of growth factors may be a desirable therapeutic intervention. The role of TGF-β in mediating scarring has been blocked in animal models by neutralizing antibodies and binding agents such as mannose-6-phosphate [12]. The potential clinical usefulness of these agents is currently being evaluated in normal and abnormal scar formation.

Chapter 12

Genetics and Genodermatoses

J.I. Harper & R.C. Trembath

Genetics and disorders of the skin

Progress in the field of genetics in medicine continues at an astonishing rate. Most of the known single-gene disorders (e.g. genodermatoses) have at least been mapped to a particular chromosomal region and, in ever-increasing number, the causal genes have been isolated and studied (Table 12.1). In contrast, progress towards unravelling the molecular genetic basis of the more common and complex disorders (e.g. psoriasis and atopic eczema) has been somewhat slower. However, recent progress with the human sequencing effort together with radically improved computerized analytical strategies offer the prospect of progress in understanding the pathogenesis of these important dermatological disorders. The extraordinary rate of such developments has contributed to the parallel progress in understanding of the fundamental aspects of human skin characteristics. In combination, this revolution offers enormous opportunity and excitement for future research, together with the prospect of improved therapies for skin disease.

The Human Genome Project, an international effort to describe the entire human genetic sequence (3×10^9 bases), has hit targets ahead of expectation, and the recent release of the first draft [1] has necessitated a radical readjustment of the likely number of human genes within the genome (35 000–40 000), representing half the number predicted at the time of publication of the last edition of this book [2]. The genome sequences of a range of other organisms, including the nematode worm *Caenorhabditis elegans*, the fruit fly *Drosophila melanogaster* and the mouse, have now been completed. These act as important models for exploring gene structure and function in relation to tissues or the whole organism and have been extensively investigated in relation to a number of important genodermatoses.

The Internet provides the most satisfactory window on all this activity and a number of the more informative sites are listed below.

- UK Human Genome Mapping Project Resource Centre (http://www.hgmp.mrc.ac.uk). Access to a wide range of databases and resources for genetic studies, including links to PubMed.
- The National Center for Biotechnology Information (http://www.ncbi.nlm.gov). Main entry point for information about the Human Genome Project.
- Mutation Database, Cardiff (http:// www.uwcm.ac.uk/uwcm/mg/hgmd0.html).
- Online Mendelian Inheritance in Man (OMIM) (http://www.ncbi.nlm.nih.gov/omim/). OMIM is a catalogue of the 6000 known human Mendelian characters with skin manifestations, and was created by Dr Victor McKusick of Johns Hopkins Hospital, Baltimore, USA. OMIM is an excellent starting point for acquiring up-to-date information on human Mendelian characters or *phenotypes*. Each character is given a six-digit MIM number, which is widely used to identify inherited disorders in the medical literature. The first digit of the MIM number indicates the mode of inheritance (historical): 1, autosomal dominant; 2, autosomal recessive; 3, X-loci or phenotype; 4, Y-loci or phenotype; 5, mitochondrial loci; and 6, autosomal loci or phenotypes added after 1994.

Table 12.1 (*cont'd*)

Chromosome site	MIM number	Disease	Gene symbol	Gene/gene product
9q22.3	278700	Xeroderma pigmentosum, group A	278700 *XPA*	Xeroderma pigmentosum, group A
9q31	132800	Epithelioma, self-healing, squamous 1, Ferguson-Smith type Basal cell carcinoma	132800 *MSSE*, *ESS1*	Epithelioma, self-healing, squamous 1, Ferguson-Smith type
9q31	109400	Basal cell naevus syndrome	109400 *NBCCS*, *BCNS*	Naevoid basal cell carcinoma syndrome
9q34	191100 606690	Tuberous sclerosis 1 Lymphangioleiomyomatosis	605284 *TSC1*, *LAM*	Hamartin (tuberous sclerosis 1 gene)
9q34.1	187300	Hereditary haemorrhagic telangiectasia 1	131195 *ENG*, *END*, *HHT1*, *ORW*	Endoglin
9q34.1	161200 137750	Nail–patella syndrome Nail–patella syndrome with open-angle glaucoma	602575 *LMX1B*, *NPS1*	LIM homeobox transcription factor 1, β
9q34.2–q34.3	130010 130000	Ehlers–Danlos syndrome type II Ehlers–Danlos syndrome type I	120215 *COL5A1*	Collagen V, α1 polypeptide
10pter–p11.2	266500	Refsum's disease	602026 *PHYH*, *PAHX*	Phytanoyl-CoA hydroxylase
10q11	133540 278800	Cockayne's syndrome 2, type B De Sanctis–Cacchione syndrome	133540 *ERCC6*, *CKN2*, *COFS*	Excision repair, cross-complementing rodent repair deficiency, complementation group 6
10q22	603553	Haemophagocytic lymphohistiocytosis, familial, 2	170280 *PRF1*, *HPLH2*	Perforin
10q22.1	176801	Gaucher's disease, variant form	176801 *PSAP*, *SAP1*	Prosaposin (sphingolipid activator protein 1)
10q23.1	203300	Hermansky–Pudlak syndrome	604982 *HPS1*	HPS gene 1
10q23.31	158350	Cowden's disease	601728 *PTEN*, *MMAC1*	Phosphatase and tensin homologue (mutated in multiple advanced cancers 1)
10q24.1	601859	Autoimmune lympho-proliferative syndrome Squamous cell carcinoma, burn scar-related, somatic	134637 *TNFRSF6*, *APT1*, *FAS*, *CD95*	Tumour necrosis factor receptor superfamily, member 6
10q24.3	226650	EB, generalized, atrophic, benign	113811 *COL17A1*, *BPAG2*	Collagen XVII, α1 polypeptide
10q25.2–q26.3	263700	Porphyria, congenital erythropoietic	606938 *UROS*	Uroporphyrinogen III synthase
10q26	123500 123150 123790 101600 101200	Crouzon's syndrome Jackson–Weiss syndrome Beare–Stevenson cutis gyrata syndrome Pfeiffer's syndrome Apert's syndrome	176943 *FGFR2*, *BEK*,*CFD1*, *JWS*	Fibroblast growth factor receptor 2 (bacteria-expressed kinase)
11p15.5	130650	Beckwith–Wiedemann syndrome	600856 *CDKN1C*, *KIP2*, *BWS*	Cyclin-dependent kinase, inhibitor 1C (p57, Kip2)
11p15	603467	Fanconi's anaemia, complementation group F	603467 *FANCF*	Fanconi's anaemia, complementation group F
11p15	605561		605561 *PKP3*	Plakophilin 3
11p12–p11	278740	Xeroderma pigmentosum, group E, DDB-negative subtype	600811 *DDB2*	Damage-specific DNA-binding protein 2, 48 kDa
11q11–q13.1	106100	Angio-oedema, hereditary	606860 *C1NH*, *HAE1*, *HAE2*	Complement component-1 inhibitor

(*continued*)

Table 12.1 (*cont'd*)

Chromosome site	MIM number	Disease	Gene symbol	Gene/gene product
11q12–q13	278740	Xeroderma pigmentosum, group E, subtype 2	600045 *DDB1*	Damage-specific DNA-binding protein 1, 127 kDa
11q12–q13	147050	Atopy	147050 *IGER*, *APY*	IgE responsiveness, atopic
11q13	147138	Asthma, atopic, susceptibility	147138 *MS4A2*, *MS4A1*, *FCER1B*	Membrane-spanning four domains, subfamily A, member 2 (Fc fragment of IgE, high affinity I, receptor for, β polypeptide)
11q14–q21	203100 103470 606952	Albinism, oculocutaneous, type IA Waardenburg's syndrome/albinism, digenic Albinism, oculocutaneous, IB	606933 *TYR*	Tyrosinase
11q14.1–q14.3	245000 245010	Papillon–Lefèvre syndrome Haim–Munk syndrome	602365 *CTSC*, *CPPI*, *PALS*, *PLS*, *HMS*	Cathepsin C
11q21	604391	Ataxia telangiectasia-like disorder	600814 *MRE11A*, *MRE11*, *ATLD*	Meiotic recombination 11, *Saccharomyces cerevisiae*, homologue A of
11q22.3	208900	Ataxia-telangiectasia Lymphoma, B cell non-Hodgkin's, somatic	607585 *ATM*, *ATA*, *AT1*	Ataxia-telangiectasia mutated (includes complementation groups A, C, D and E)
11q23–q24	225060 225000 225000	Ectodermal dysplasia, Margarita Island type Zlotogora–Ogur syndrome Cleft lip/palate ectodermal dysplasia syndrome	600644 *HVEC*, *PVRL1*, *PVRR1*, *PRR1*	Herpesvirus entry mediator C (poliovirus receptor-related 1; nectin)
11q23.3	176000	Porphyria, acute intermittent Porphyria, acute intermittent non-erythroid variant	176000 *HMBS*, *PBGD*, *UPS*	Hydroxymethylbilane synthase
12p11	602861		602861 *PKP2*	Plakophilin-2
12q11–q13	146800	Ichthyosis bullosa of Siemens	600194 *KRT2A*, *KRT2E*	Keratin-2A
12q11–q13	600231	Palmoplantar keratoderma, Bothnia type	600231 *PPKB*	Palmoplantar keratoderma, Bothnia type
12q11–q14	600376	Hereditary haemorrhagic telangiectasia 2	601284 *ACVRL1*, *ACVRLK1*, *ALK1*, *HHT2*	Activin A receptor, type II-like kinase 1
12q13	158000	Monilethrix	602153 *KRTHB1*, *HB1*	Keratin, hair, basic, 1
12q13	158000	Monilethrix	601928 *KRTHB6*, *HB6*	Keratin, hair, basic, 6
12q13	113800 600962 607602 148700 146590 607654	Epidermolytic hyperkeratosis Keratoderma, palmoplantar, non-epidermolytic Cyclic ichthyosis with epidermolytic hyperkeratosis Keratosis palmoplantaris striata Ichthyosis hystrix, Curth–Macklin type Keratosis palmoplantaris striata III	139350 *KRT1*	Keratin-1
12q13	193900	White sponge naevus	123940 *KRT4*, *CYK4*	Keratin-4
12q13	131900 131760 131800 131960	EB simplex, Koebner type EB simplex, Dowling–Meara type EB simplex, Weber–Cockayne type EB simplex with mottled pigmentation	148040 *KRT5*	Keratin-5

(*continued overleaf*)

Table 12.1 (*cont'd*)

Chromosome site	MIM number	Disease	Gene symbol	Gene/gene product
12q13	167200	Pachyonychia congenita, Jadassohn–Lewandowsky type	148041 *KRT6A*	Keratin-6A
12q13	167210	Pachyonychia congenita, Jackson–Lawler type	148042 *KRT6B*	Keratin-6B
12q13.11–q13.2	108300 132450	Stickler's syndrome type I Epiphyseal dysplasia, multiple, with myopia and deafness	120140 *COL2A1*	Collagen II, α1 polypeptide
12q23–q24.1	124200 101900	Darier's disease Acrokeratosis verruciformis	108740 *ATP2A2*, *ATP2B*, *DAR*	ATPase, Ca^{2+} dependent, slow twitch, cardiac muscle 2
12q23.2–q24.1	175900	Porokeratosis, disseminated, superficial, actinic, 1	175900 *DSAP1*	Disseminated superficial actinic porokeratosis 1
12q24.1	163950 115150	Noonan's syndrome 1 Cardio-facio-cutaneous syndrome LEOPARD syndrome	176876 *PTPN11*, *PTP2C*, *SHP2*, *NS1*	Protein tyrosine phosphatase, non-receptor-type, 11
13q11–q12	124500 148350 148210 602540	Vohwinkel's syndrome Keratoderma, palmoplantar, with deafness KID syndrome Hystrix-like ichthyosis with deafness	121011 *GJB2*, *CX26*, *DFNB1*, *PPK*, *DFNA3*, *KID*, *HID*	Gap junction protein, β2, 26 kDa (connexin 26)
13q12	129500	Ectodermal dysplasia 2, hidrotic	604418 *GJB6*, *CX30*, *DFNA3*, *HED*, *ED2*	Gap junction protein, β6 (connexin 30)
13q12	605068		605068 *WASF3*, *WAVE3*, *SCAR3*	Wiskott–Aldrich syndrome protein family, member 3
13q12–q14	603165	Dermatitis, atopic, susceptibility	605844 *ATPD5*	Dermatitis, atopic, 5
13q12.3	227660 605724	Fanconi's anaemia, complementation group B Fanconi's anaemia complementation group D1	600185 *BRCA2*, *FANCB*, *FANCD1*	Breast cancer-2, early onset
13q33	278780	Xeroderma pigmentosum, group G	133530 *ERCC5*, *XPG*	Excision repair, complementing defective, in Chinese hamster, number 5
14q11.2	242300 242100 242300	Ichthyosis, lamellar, AR Ichthyosiform erythroderma, congenital Self-healing collodion baby	190195 *TGM1*, *ICR2*, *LI1*	Transglutaminase 1 (K polypeptide epidermal type I, protein-glutamine γ-glutamyltransferase)
14q32.1	219100 123700	Cutis laxa, AR Cutis laxa, AD	604580 *FBLN5*	Fibulin 5

Nosology of genetics in skin disease

The terms 'familial', 'inherited' and 'congenital' are frequently misunderstood and misused. *Familial* refers to the clustering of a disorder, with more close relatives affected than predicted by the population prevalence of the condition. *Inherited* disorders require the transmission of genetic variants from one generation to the next. The term *congenital* simply means that the character was present at or detectable before birth; such abnormalities may not be genetically determined, and include developmental defects due to environmental infectious agents (e.g. rubella) and deformations arising from physical insults (e.g. amniotic bands). Only a proportion of inherited disorders reveal themselves at birth (i.e. are congenital), with many having their onset in later life. Such age dependence may result from a wide number of factors, including maturation of cells or tissue-specific functions, exposure to exogenous agents or accumulation of a noxious substance. A further and important example of adult age of onset is provided by hereditary cancer syndromes, such as neurofibromatosis (NF) type 2, in which a second mutation impacting upon the normal allele of a so-called *tumour-suppressor gene* (e.g. *Merlin*) is required to lead to tumour formation. Such a mutation occurs as a 'somatic' change.

Of the inherited skin abnormalities, the largest group is the single-gene disorders, which require an alteration in the function of a gene and are known commonly as the genodermatoses. The inheritance patterns for classical genodermatoses are illustrated in Figs 12.1–12.4. Each disorder is relatively uncommon, and more detailed descriptions of a number of important examples are presented in this chapter and elsewhere. Predisposition to the more common skin disorders, including atopic eczema and psoriasis, is determined by the action of more than one gene, with significant evidence for further modulation by environmental factors. Such disorders display complex patterns of clustering in families, and are referred to as *multifactorial*. Chromosomal abnormalities, either in number (*aneuploidy*) or form (*translocation*, *complex rearrangements* or *microdeletions*) are important to the clinician, particularly if the patient presents a range of abnormalities including mental retardation. However, chromosomal anomalies rarely present solely with dermatological problems and hence are only briefly mentioned.

The study of rare disorders, including the genodermatoses, has also provided insight into fundamental aspects of human genetic principles and mechanisms. Essential terms and principles are described, with the intention of helping the reader understand relevant genetic concepts referred to throughout this book and to aid in the interpretation of the rapidly emerging literature in this field [1–4].

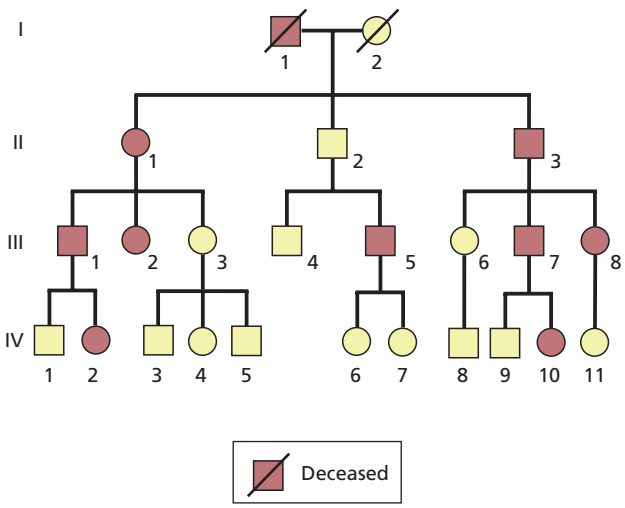

Fig. 12.1 Autosomal dominant (AD) inheritance.

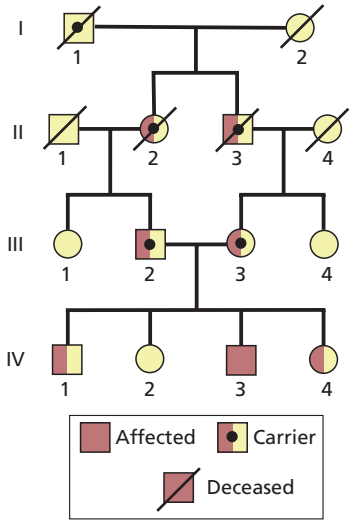
1 AD disorders affect both males and females.
2 Affected individuals are heterozygous for the abnormal allele.
3 Affected person will usually have an affected parent, apart from the recipients of new *de novo* mutations.
4 On average, 50% of the children of an affected parent will be affected.
5 The age of onset and severity of a disorder may be variable and the affected individual may remain without signs or symptoms well into adult life.
6 Some AD disorders show reduced penetrance, i.e. a person who inherits the gene does not develop the disorder, e.g. individual II2. In this situation an unaffected individual cannot be completely reassured that he or she will not transmit the disorder to their children.

Examples:
acute intermittent porphyria
epidermolysis bullosa (some forms)
ichthyosis (some forms)
neurofibromatosis
tuberous sclerosis
hereditary haemorrhagic telangiectasia



1. AR disorders affect both males and females.
2. Affected individuals are homozygous for an abnormal allele and typically are born to unaffected parents.
3. On average, 1 in 4 of the children of heterozygous parents will be affected.
4. Typically, no family history is seen.
5. Consanguinity increases the risk of an AR disorder because both parents are more likely to carry the same mutant allele, inherited from a common ancestor.
6. The offspring of an affected person will be healthy heterozygotes and can be affected only if the other parent is also a gene carrier. This is unlikely except in consanguineous marriages or in ethnic groups in which particular alleles are common (e.g. isolated populations).
7. AR disorders are often severe; for example, many of the inborn errors of metabolism are AR.

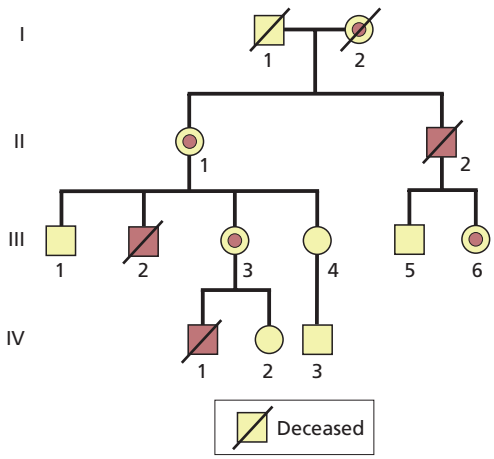
Examples:
epidermolysis bullosa (the more severe forms)
ichthyosis (the more severe forms)
acrodermatitis enteropathica
phenylketonuria
xeroderma pigmentosum

Fig. 12.2 Autosomal recessive (AR) inheritance.

Principles of medical genetics

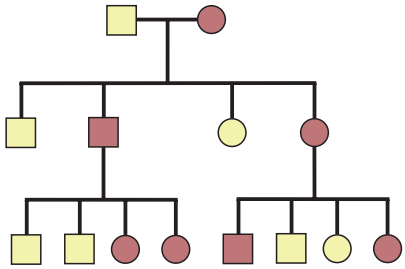
Inherited characteristics are transmitted from one generation to the next by chromosomes, composed of double-helix strands of DNA. A *gene* is a sequence of bases in DNA encoding a polypeptide. The precise position of the gene on a genetic map is known as its *locus*. In females, the 46 chromosomes found in most somatic cells present in homologous pairs; hence two copies of every gene exist, one maternal and the other paternal in origin. In males, the Y chromosome only pairs with the X chromosome at the pseudo-autosomal region. *Meiosis* is the process of cell division by which male and female gametes (germ cells) are produced. Alternative genes at a single locus are called *alleles*. An individual with two different alleles at a particular locus is *heterozygous*; where both alleles are identical,

Fig. 12.3 X-linked recessive (XLR) inheritance.



1. Usually only males are affected.
2. The disorder is transmitted through healthy female carriers; occasionally a heterozygous female may show some features of the condition (as a result of non-random X inactivation).
3. A female carrier will transmit the disorder to half her sons, and half her daughters will be carriers.
4. When a male is affected, all his daughters will be carrier heterozygotes.
5. The trait cannot be transmitted from father to son.
6. An XLR condition should be considered when the family history indicates affected males in different generations of the same family. Family history is not always positive as new *de novo* mutations are fairly common.

Examples:
anhidrotic ectodermal dysplasia
Fabry's disease
Menke's syndrome
ocular albinism



1 An XLD disorder will give rise to a disorder in both hemizygous males and heterozygous females.
2 Affected males will transmit the disorder to their daughters, but not to their sons.
3 Affected females will transmit the disorder to half their sons and half their daughters.
4 In some disorders the condition is lethal in hemizygous males; so only female patients are encountered in clinical practice.

Examples: incontinentia pigmenti
X-linked form of oro-facial-digital syndrome

Fig. 12.4 X-linked dominant (XLD) inheritance.

the individual is described as *homozygous* at that locus. Genes on the X chromosome are not one of a pair in males and when such a gene is abnormal in a male, the term *hemizygous* is used. Nuclear DNA accounts for 99.995% of the total genetic pool. As with all complex mammalian genomes, the human sequence is made up of considerable amounts of repetitive DNA (Fig. 12.5). The total number of genes is now estimated to be approximately 35 000, with an average size, including introns, of between 10 and 15 kb.

An allele is regarded as *dominant* (Fig. 12.1) if it manifests as a phenotype when present on only one member of the chromosome pair (heterozygous state) and as *recessive* (Fig. 12.2) if it must be present at both corresponding loci (homozygous state) before it can exert its full effect. Hence, it is apparent that the terms 'dominance' and 'recessivity' refer to a phenotypic characteristic rather than a gene [1].

Those genes borne on chromosomes other than the sex chromosomes (X and Y) are known as *autosomal*. Characters controlled by genes borne on the X or Y chromosomes are termed *sex-linked* (Figs 12.3 & 12.4). The Y chromosome is much smaller than the X chromosome. The great majority of sex-linked genes are exclusive to the X chromosome, having no active counterpart on the Y chromosome. For these traits the term 'recessive' applies to males who carry only one (mutant) allele. Females who carry X-linked mutations are typically heterozygous and

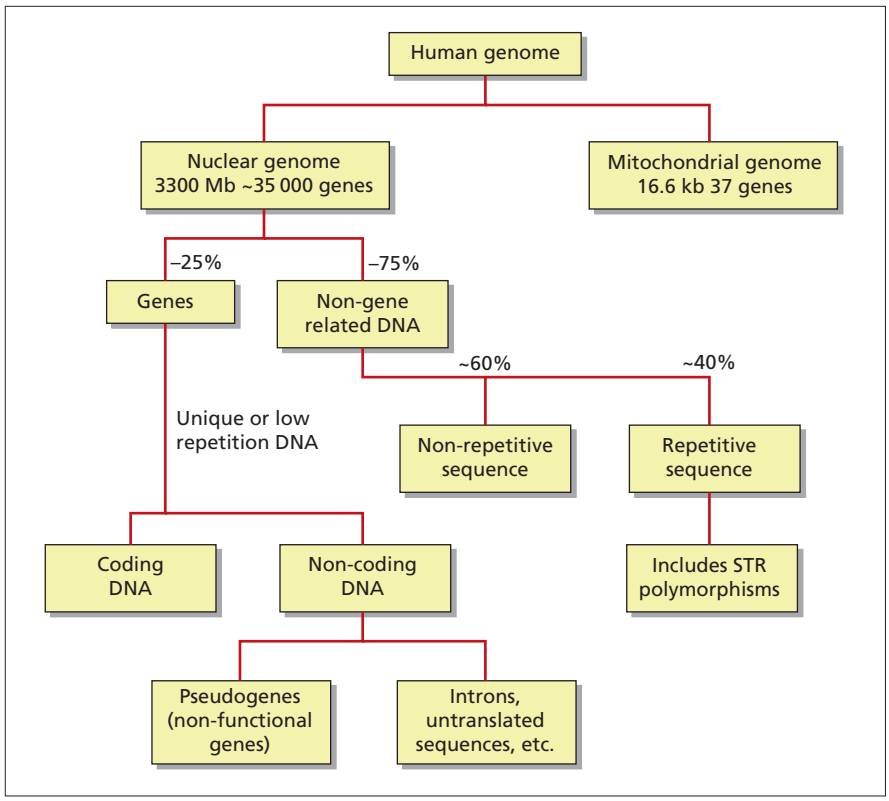


Fig. 12.5 Human genome organization.

with rare exceptions, including markedly skewed X inactivation, display no clinical abnormalities.

A region of homology sufficient for pairing between the X and Y chromosomes exists on the end of the short arm of the X chromosome, known as the *pseudo-autosomal region*, enabling sex-linked transmission comparable to autosomal traits [2]. Genes that are Y-linked are primarily involved in male sex determination (e.g. *SRY* gene controlling the testis determining factor) or spermatogenesis. Girls affected with MIDAS syndrome (microphthalmia, dermal aplasia and sclerocornea) and showing anomalies of the genitalia may display an *SRY*-positive status, indicating a translocation between the pseudo-autosomal region of Xp and Yp [3]. Hairy pinnae is another phenotype that is Y-linked [4].

The effects of a mutant allele are not necessarily constant; the degree to which the effects are variable is a measure of the *expression* of the character in question, and the frequency with which a gene produces any effect at all is a measure of its *penetrance*.

In addition to nuclear DNA, mitochondria contain a circular chromosome comprising 14 protein-coding regions [5]. The mitochondrial DNA codes for enzymes involved in the respiratory chain and oxidative phosphorylation. Mitochondrial disorders are essentially muscular, neurological and ophthalmological diseases and transmission is almost exclusively matrilineal [6].

Genetic heterogeneity

Genetic heterogeneity is the term used to describe clinically similar disorders (phenotypes) that result from different genetic defects. The concept of genetic heterogeneity is important for several reasons: (i) disorders that appear the same can be due to entirely different molecular defects, with a different natural history and requiring different treatment; (ii) for accurate genetic counselling, as defects may have different inheritance patterns; and (iii) because genetic heterogeneity plays a significant role in common complex disease states. Different alleles at the same locus (allelic) and genes at different loci (non-allelic) can give rise to similar phenotypes. Recognizing this, one can differentiate similar disorders by careful clinical distinction, as Wells and Kerr [7] did in distinguishing between autosomal dominant and X-linked ichthyosis. The use of both clinical findings and family history has helped to delineate heterogeneity in the epidermolysis bullosa and Ehlers–Danlos syndromes. Xeroderma pigmentosum illustrates phenotypic homogeneity but with marked genetic heterogeneity, with at least seven different genetic variants.

Mutations and disease

Most mutations are spontaneous and unexplained; however, certain factors such as mutagenic chemicals and ionizing radiation can increase the rate. In the absence of such agents, the mutation rate is of the order of 1 bp substitution for every 10^9–10^{10} bp replicated. If a mutation occurs in a somatic cell (*somatic mutation*), only the descendants of that cell are affected and there will be no transmission of the abnormality to further generations. Only mutations occurring in the gametes or their precursors can be transmitted to offspring.

Normally, replication of DNA is accurate but mutations can occur, either induced by exposure to mutagenic agents or spontaneously through errors in the process of DNA replication and repair during meiosis.

Mutations that impinge on the function of a gene most commonly occur within the coding regions (exons) and may alter the amino-acid sequence and hence structure and function of the protein (Fig. 12.6). In addition to gross structural chromosomal changes, submicroscopic alterations including substitutions (replacement of a single nucleotide by another), deletions (loss of one or more nucleotides) and insertions (addition of one or more nucleotides) may occur. Single-base substitutions, often referred to as point mutations, have been most extensively characterized (see Cardiff Human Mutation Database). The majority are either missense or nonsense mutations. These mutations alter a codon so that either a different amino acid is encoded (missense), or a codon specifying an amino acid in a normal individual is altered to code for the stop codon TGA, leading to premature termination of the protein (nonsense). Deletions and insertions (up to 20 bp of DNA) other than multiples of three will lead to disruption of the reading frame for RNA translation, resulting in a frameshift mutation and premature termination (Fig. 12.6). Point mutations may also affect splicing, the process by which mature messenger RNA (mRNA) is produced from RNA that has been transcribed directly from the gene [1].

Two-hit progression to tumour formation

Through pioneering observations on the familial and sporadic occurrence of rare tumours, Knudson [8] proposed that germ-line mutation of one allele of a tumour-suppressor gene, while required to explain an autosomal dominant pattern of inheritance, was not in itself sufficient to lead to tumour formation. Hence, in a target tissue, acquired mutations known as somatic mutations need to occur and lead to complete loss of function of the gene. Molecular genetic evidence to support this important concept has recently emerged for a number of disorders, including NF1 and tuberous sclerosis.

Contiguous gene syndromes

Large genome deletions may involve several neighbouring

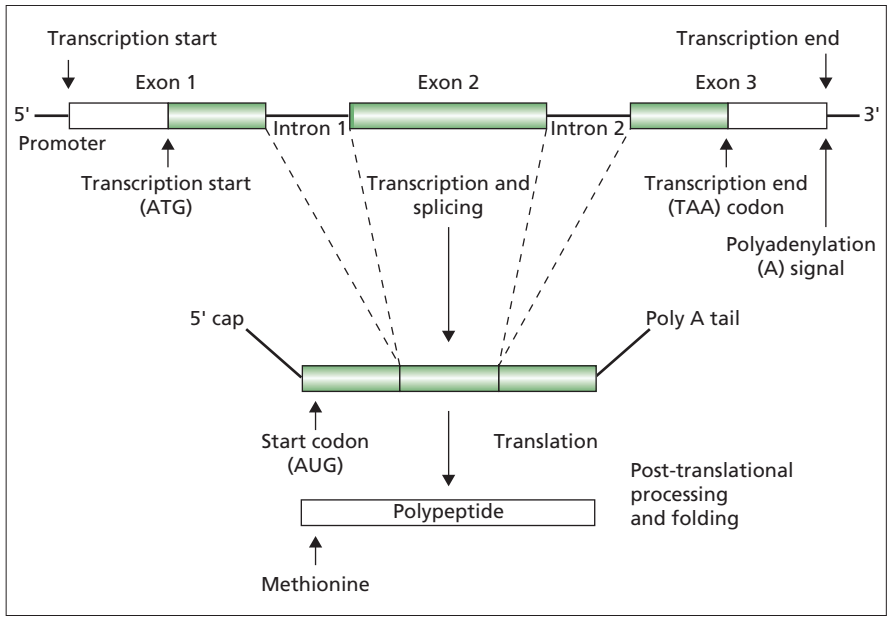

Fig. 12.6 Features of a typical human structural gene.

genes, for example a well-established 'set' of contiguous gene disorders involve the steroid sulphatase locus (Xp22.3). Deletions of different sizes and location within Xp22.3 give varying combinations of X-linked ichthyosis, Kallman's syndrome (hypogonadotrophic hypogonadism and anosmia), chondrodysplasia punctata, ocular albinism, mental retardation and short stature [9].

Functional impact of mutations and polymorphisms

Mutations exert their effects by leading to a loss or gain of function of the gene's protein product. In general, loss-of-function mutations lead to either reduced activity or complete loss of the protein. Gain-of-function mutations result in either increased levels of expression or the acquisition of a new function of a protein. The term 'mutation' has traditionally been applied to genetic variation causative of a Mendelian disorder. As further studies are undertaken to unravel the genetic contribution of common and complex disorders, understanding the subtle functional consequences of all genetic variation, including polymorphisms, will be increasingly important [1].

High-throughput genetic analysis

Studies of human genetic disease have been substantially facilitated by the introduction of rapid and increasingly low-cost methods of DNA analysis. Genome-wide screens of polymorphic markers and global analysis of gene transcripts can readily be achieved. DNA microarray represents one emerging technology likely to impact on the application of molecular genetics to clinical dermatology. A microarray or DNA chip represents multiple DNA sequences immobilized on a solid surface, using either a photolithographic process or simple 'spotting' of DNA sequences onto a glass slide. Such chips allow high-throughput parallel analysis, which can be used to uncover point mutations in single genes or larger genomic deletions, as well as detecting changes in gene expression associated with disease states or response to treatment.

Mosaicism, lyonization and the lines of Blaschko

Mosaicism [13] describes an individual with two or more cell lines of different genotypes derived from the same zygote. In health, all females exhibit functional mosaicism with regard to their X chromosomes. One of the two X chromosomes in the cells of normal females undergoes inactivation at an early stage of embryonic development (12–16 days after fertilization), a process known as lyonization [10]. The inactive X remains condensed as a densely stained mass of chromatin known as the Barr body. For each somatic cell it is random whether the paternal X or the maternal X is inactivated, but the choice is fixed for all subsequent descendants of that cell. Thus, a female has a mixture of two populations of cells, some of which have an active paternal X chromosome and some of which have an active maternal X chromosome. The relative proportions vary from female to female (even in identical twins) due to the randomness of the inactivation process. As a result of lyonization, the heterozygous state of various X-linked gene defects may give rise to a mosaic pattern of cutaneous lesions, which conforms to the system of lines on the skin first described by Blaschko in 1901 [11] (Fig. 12.7). The original description by Blaschko referred to a 'system of lines on the human skin which the

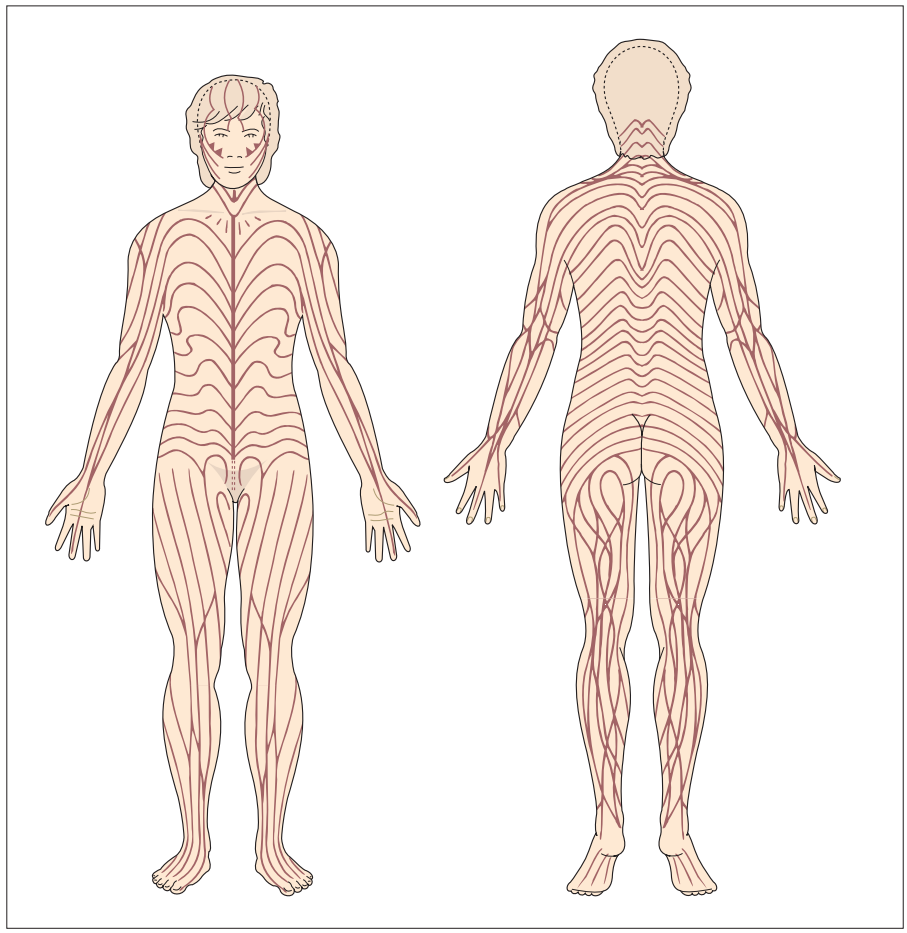

Fig. 12.7 Blaschko's lines as illustrated in his 1901 article 'A system of lines on the surface of the human body which the linear naevi and dermatoses follow'.

linear naevi and dermatoses follow'. Many naevoid skin lesions display an arrangement following these lines. The lines do not correspond to any known nervous, vascular or lymphatic structures, but represent the developmental growth pattern of the skin [12].

Many genetic skin diseases reflect mosaicism, with mutation occurring after fertilization (post-zygotic). Important features to be considered in mosaicism and their impact on phenotype relate to the proportion of cells that harbour the mutation and tissue distribution. In general, the greater the proportion of cells that are abnormal, the greater the severity of the resultant phenotype. Furthermore, phenotype is influenced by the portion of mutant cells in a specific tissue. If a mutation has little impact on the normal function of the tissue, the phenotypic consequences are likely to be minimized. Women heterozygous for the gene of X-linked recessive ichthyosis do not display any mosaic pattern of skin changes, and it has been suggested that some genes on the X chromosome may escape inactivation [13,14].

It is likely that all naevi reflect genetic mosaicism [15]. Streaky or patchy pigmentary skin changes may be a clue to the presence of mosaicism. The pigmentary patterns associated with mosaicism are reviewed by Happle [16].

Gonadal mosaicism and recurrence risk

An autosomal dominant trait may occur in more than one sibling, even though both parents are apparently unaffected. This phenomenon may be explained by gonadal mosaicism, due to the presence of a mutation in germ-line but not somatic cells [17]. Evidence of gonadal mosaicism exists in tuberous sclerosis [18], bullous ichthyosiform erythroderma [19] and NF1 [20]. Gonadal mosaicism for the X-linked disorder incontinentia pigmenti has been reported in a healthy male [21].

Genomic imprinting

This term is used to describe the phenomenon whereby a DNA sequence derived from one parent acts in a different way compared with that derived from the other parent [22,23]. Imprinting (coding or non-coding) carries a signal or imprint that indicates to nuclear transcription machinery the parent of origin for that sequence. For the majority of the human genome, no distinction is made between paternal and maternal copies, with the exclusion of polymorphic variation. The molecular basis of imprinting is thought to be methylation, the process whereby a methyl

group (CH_3) is added to DNA nucleotides (typically cytosine). Methylation is usually associated with reduced levels of expression of a gene, and for certain genes is applied exclusively to either the paternal or maternal copies. Examples of dermatological disorders subject to imprinting include familial glomus tumour [24] and Albright's hereditary osteodystrophy [25], and the phenomenon may also play a role in the genetic basis of atopy [26,27] and psoriasis [28].

Uniparental disomy

For the vast majority of individuals, one chromosome of a pair has been inherited from each parent. Rarely, uniparental disomy may occur when an offspring receives both copies of a chromosome pair from one of its parents. For some chromosomes this results in recognizable phenotypes, for example uniparental disomy of the maternal copies of chromosome 15 leads to Prader–Willi syndrome. For other chromosomes, uniparental disomy does not appear to be of obvious phenotypic value, unless by chance the identical chromosomes harbour a recessive mutation, which would then be present in the homozygous state [29,30].

Twin spotting

This hypothesis has been proposed, based on the genetic concept of somatic recombination, to explain the frequent coexistence of two separate and distinct naevi, for example a telangiectatic naevus and naevus anaemicus and phacomatosis pigmentovascularis [31–33]. Twin spotting has been extensively studied in plants and animals.

Genome sequence and analysis of inherited disorders

Completion of the human genome sequencing effort has led to phenomenal progress in gene mapping techniques, with thousands of DNA markers now available, each defined and covering all chromosomes. The reagents have greatly facilitated linkage studies within families with Mendelian disorders. Linkage analysis questions whether each DNA marker co-inherits with the disease more often than expected by chance. The statistical test of linkage is the logarithm of the odds (lod) score. A lod score of 3 or greater is accepted as significant evidence of linkage, whereas a score of –2 excludes linkage at that location. The traditional DNA marker is a *restriction fragment length polymorphism* (RFLP) analysed by Southern blotting of restricted (digested) DNA, with the fragments detected by a radioactive probe. Most genetic markers are now detected rapidly by polymerase chain reaction (PCR)-based methods of analysis, exploiting an abundant class of DNA sequence variation known as simple tandem repeats or single nucleotide polymorphisms. *Gene tracking* is the term given to the use of a known linkage between a marker and a disease locus to predict the genotype at the disease locus in a particular family member, such as in asymptomatic carrier testing or prenatal diagnosis. Linkage studies are just the first step in positional cloning of a disease gene. Table 12.1 details genes of relevance to dermatology. For more detailed reviews of the subject the reader is referred to Chapter 8 and reference [1].

Genetic linkage, linkage disequilibrium and disease association

Alleles at gene loci residing close to each other on the same chromosome remain linked in transmission so long as the chromosome remains intact; however, during reduction division (meiosis), such linkages may be disrupted if *crossing-over* occurs. The closer two gene loci are situated on a chromosome, the less likely they are to be separated by crossing-over and the more likely they are to be inherited together. Two such gene loci are said to be linked and it is possible to demonstrate genetic linkage in a family using appropriate genetic markers. When two alleles occur together more frequently, or less frequently, in a population than would have been expected from the individual allele frequencies, they are said to be in *linkage disequilibrium*. This may arise as a result of a recent mutation or for a particular combination of DNA sequences, which may have, for example, a selective advantage and hence achieve disequilibrium by natural selection. Linkage disequilibrium is one important cause of disease association.

The nail–patella syndrome is a clinical example of a disorder that shows genetic linkage with the blood group ABO locus; the ABO and the disease gene loci are both situated on chromosome 9. Because of eventual crossing-over, over a number of generations recombination will occur, leading to different affected families; alternatively, independent mutations causing nail–patella syndrome may arise *de novo*. Thus, there is genetic linkage between the loci for blood groups and nail–patella syndrome, but no association with a particular blood group. Genetic linkage is a phenomenon demonstrable within families. In contrast, association due to linkage disequilibrium is a phenomenon demonstrated by comparing a population of affected individuals with a control population [1].

Histocompatibility antigens and disease association

Human leukocyte antigens are glycoproteins on the cell surface of most nucleated human cells. These differ in subtle ways from person to person and uniquely fingerprint each person's cells. These fingerprints allow a person's immune system to recognize if a given cell is its own. The importance of the human leukocyte antigen (HLA) system has been highlighted by the need to match donors and recipients in the transplantation of human tissues.

The HLA region is located on the short arm of chromosome 6, referred to as the major histocompatibility complex (MHC). A person inherits HLA as a set, one set (haplotype) from each parent. There are at least four or five genetic loci that produce HLA, termed A, B, C, D and DR (in order of their discovery not their location), and their gene products are called HLA-A, HLA-B, HLA-C, HLA-D and HLA-DR. Each locus has multiple allelic determinants (polymorphism). Each allele at each locus controls an antigen, which is identified by a number placed after the letter of that series, for example HLA-A1, HLA-B5. The letter 'w' in front of a number indicates that its specificity was studied in an international workshop, and continues to undergo further definition.

HLAs that code at the A, B and C loci are determined by serological cytotoxicity methods, whereas those occurring at the D locus are detected by the mixed lymphocyte reaction. The HLA-DR antigens are serologically determined and are similar, if not identical, to the D locus antigens. DNA-based methods for typing at all HLA loci are now available.

The association of an HLA with a given disease means that there is a higher incidence of that antigen in a group of patients with the disease than in a group of people without the disease. There are various ways in which the presence of a particular HLA might be involved in the pathogenesis of a disease.

1 *Molecular mimicry*. An infective agent may have a similar configuration to the HLA, so that the agent is then not attacked by the body's defence system. Alternatively, the agent might differ only slightly from the HLA, so that antibodies are produced that attack both the infective agent and the cells containing the HLA, thus inducing autoimmune damage.

2 *Receptor effects*. Many chemicals, including drugs and toxins, bind to the cell surface before they are taken into the cytoplasm. Since HLAs are present on the cell surface, they could modify the binding of these potentially toxic substances, and the specificity for such binding may be determined, at least in part, by DNA variation for HLA molecules.

3 *Genetic linkage*. The HLA may be close to another gene on the same chromosome that produces a disease, either directly (e.g. due to an enzyme deficiency) or indirectly due to an effect on the immune response, which may be abnormally enhanced, leading to autoimmunity, or abnormally decreased, leading to infection.

The association between an HLA and a particular disease is rarely absolute. Ankylosing spondylitis is strongly associated with the B27 antigen, but some patients with this disease are B27 negative and many patients with B27 do not develop ankylosing spondylitis. There are many

Table 12.2 Some skin diseases known to be associated with particular human leukocyte antigens (HLA).

Disease	Antigen	Relative risk
Dermatitis herpetiformis	B8	15
	Dw3/DRw3	> 15
Pemphigus	DRw4	10
Reiter's disease	B27	35
Behçet's disease	B5	10

	B17	5
	B37	5
	Cw6	12
	Dw7	10
Psoriatic arthropathy (central)	B27	10
Psoriatic arthropathy (peripheral)	Bw38	9

There is a genetic predisposition to pemphigoid (herpes) gestationis; 90% of patients express either HLA-DR3 or HLA-DR4 [5].

possible explanations for this, including the role of environmental factors or triggers, such as chemicals or infective agents, in disease causation. Non-HLA-linked genes are probably also important, including some that may confer resistance to disease. The relative risk is the numerical answer to the question 'How many times is a person with a given HLA phenotype more likely to develop a given disease than a person without that HLA phenotype?' The relationship between HLA and skin disease is the subject of several reviews [1–4] (Table 12.2).

Genetic counselling [1–3]

Advice to parents or prospective parents must be based on an accurate diagnosis and a detailed family history. It is essential to establish a diagrammatic representation of the family pedigree. Genetic counselling depends upon the recurrence risk to parents of having an affected child. The risk that any pregnancy will produce a child with a serious abnormality is about 1 in 50 (2%). A risk greater than 10% is high, whereas a risk of less than 5% is considered low. However, the impact such a risk has upon a couple or extended family depends on the severity of the disorder and any prior experience relatives may have of a condition. The offspring and recurrence risks for known forms of Mendelian disorders are illustrated in Figs 12.1–12.4.

Many different definitions of genetic counselling have been proposed, but all include the concept of a process of communication, where patients or relatives are informed of the probability of developing or transmitting a genetic disorder. This process should also include discussion about the consequences of such disorders and the possibilities for disease prevention. Hence, it is apparent that counselling is a complex process that requires a range of skills, which increasingly includes integration of complex information regarding DNA analysis. However, it remains important to realize that it is the burden of disease rather than the precise numerical value of risk that concerns most patients and prospective parents. Genetic counselling has recently emerged as a distinct specialty in medicine and many dermatology centres work in close collaboration over the provision of accurate and comprehensive advice.

Chromosomal disorders

Chromosomal disorders may be due to abnormalities of chromosome number or structure and may involve autosomes or sex chromosomes. Somatic cells are *diploid*, with a complement of 46 chromosomes, whereas gametes (ova and sperm) are *haploid*, with only 23 chromosomes following reduction division in meiosis. Numerical abnormalities that involve the gain or loss of one or more chromosomes are known as aneuploidies. Structural chromosome rearrangements result from chromosome breakage with subsequent reunion in a different configuration. They may be balanced or unbalanced, depending on whether or not gain (or loss) of genetic material occurs. Approximately 7.5% of all conceptions have a chromosomal disorder, but most of these are spontaneously aborted, so the birth frequency is 0.6%. Among early spontaneous abortions, the frequency of chromosomal disorders is 60%, whereas in late spontaneous abortions and stillbirths the frequency is 5%. Chromosomal abnormalities generally cause multiple congenital malformations. Children with more than one physical abnormality, particularly if retarded, should undergo chromosomal analysis as part of their investigation. Chromosomal disorders are incurable but can be reliably detected by prenatal diagnostic techniques. Amniocentesis or chorionic villous sampling should be offered to women whose pregnancies are at increased risk, namely women over the age of 35 years and couples with an affected child.

Autosomal chromosome defects

Down's syndrome [1–3]

SYN. MONGOLISM

Down [1] described this syndrome in 1866. In 1959 it became the first recognized chromosomal anomaly [4]. It is the most common autosomal abnormality, with a frequency of about 1 per 700 live births [5].

Aetiology [2]. Most cases (95%) result from trisomy of chromosome 21, in which the extra chromosome is derived by non-disjunction at meiosis usually from the mother; the incidence of this type rises with maternal age. Less common, and clinically indistinguishable, is the type that shows no relation to maternal age and is sometimes familial. The affected child has the normal number of 46 chromosomes but one of the clinically normal parents carries a translocation of part of chromosome 21. A few patients are themselves mosaics and tend to have less marked physical stigmata and higher intelligence [6].

Pathology. Congenital heart defects are common and the brain is small with flat convolutions. Renal tract anomalies are less common.

Immunological defects are frequent. Autoimmune disease is common in Down's syndrome, T-cell function is impaired and the atopic state is often associated [7]. There is an increased risk of developing acute leukaemia, usually under the age of 5 years.

The lichenified patches of skin show no distinctive pattern, with hyperkeratosis, acanthosis and a dermal inflammatory infiltrate.

Clinical features [8]. The facial appearance often permits a clinical diagnosis. The head is small, the face flat, the nose short and squat and the ears small and misshapen. The eyes are usually conspicuously mongoloid, with slanting palpebral fissures. The eyelids are thickened and the eyelashes short and sparse. Epicanthic folds are frequent in early childhood but tend to become less noticeable with age. The iris tends to be hypoplastic and may show light areas in its outer third (Brushfield's spots). The limbs are stumpy and the joint ligaments lax. The fingers are short and cone-shaped and are sometimes webbed. The little finger is often curved. The presence of these features varies in affected individuals, and a diagnostic index has been proposed [9].

Mental retardation is a serious complication: the IQ is usually less than 50, and if it is not mosaicism should be suspected. Congenital heart malformations, especially endocardial cushion defects, are present in 40%, and duodenal atresia may occur. Other complications include cataracts (2%), epilepsy (10%), hypothyroidism (3%), leukaemia (1%), atlantoaxial instability (2–3%) and recurrent respiratory infections. When serious malformations are present, death during infancy is usual, but otherwise life expectancy is little reduced. Down's syndrome accounts for about one-third of all moderate and severe mental disability in children of school age. Most will walk and develop simple language. Puberty is often delayed and incomplete, with adult heights about 150 cm. Presenile dementia commonly supervenes after 40 years of age.

The skin is normal at birth and in early childhood is soft and velvety [8,10]. Between the ages of 5 and 10 years it becomes increasingly dry and less elastic, and by the age of 15 over 70% show generalized xerosis of mild to moderate degree, with evidence of accelerated skin ageing [11]. Patchy lichenification is present in some 30% under 10 years and more than 80% over 20 years of age. The patches resemble lichen simplex and most commonly occur on the upper arm, the wrists, the fronts of the thighs, the back of the ankle and the back of the neck, and are probably correctly regarded as manifestations of atopic dermatitis, the incidence of which some authorities [10] have considered to be low.

A chronic follicular papular eruption of the presternal and interscapular regions is frequently present, consistent with *Malassezia* folliculitis. In a clinical trial, oral itraconazole produced a significant clinical improvement accompanied by a decrease in the skin *Malassezia* count, but relapse occurred when therapy was discontinued and was accompanied by a return of the *Malassezia* yeasts [12].

The hair may be normal but is often fine and may be hypopigmented. The prevalence of alopecia areata is high and it tends to be extensive and persistent [7,13]. The teeth are hypoplastic and late to erupt. Fissuring and thickening of the lips are frequent and increase in prevalence and severity with age [14]. The tongue is scrotal in almost all cases. Elastosis perforans serpiginosa [15,16] and syringomas, especially in adult females with Down's syndrome [17,18], occur more often than in normal subjects.

Skin infections, angular cheilitis, chronic blepharitis and a purulent nasal discharge are common. There is a high prevalence of onychomycosis [7,19]. The cheeks are often red. The peripheral circulation is poor, acrocyanosis is frequent and livedo reticularis is often conspicuous throughout the year, on the thighs, buttocks and trunk.

Dermatoglyphic features include a single flexion crease on the fifth finger, the simian palmar crease and an increased incidence of ulnar loops on the fingers.

There is no evidence that the prevalence of other dermatoses is significantly different in individuals with Down's syndrome compared with individuals with mental retardation from other causes. Psoriasis runs its normal course, although an unusual hyperkeratotic form has been described [20]. Acral lentiginous melanoma has been described in association with Down's syndrome [21].

Trisomy 18 [1–3]

SYN. EDWARDS' SYNDROME

This is the second most common multiple malformation syndrome. It occurs in about 1 per 3000 live births; 95% of affected fetuses abort spontaneously. Parental nondisjunction at either the first or second meiotic division results in the extra copy of chromosome 18. Rarely, a parental translocation is responsible. Occasionally, mosaicism is seen with a milder phenotype and can give rise to pigmentary skin changes, as seen in hypomelanosis of Ito [4,5]. The syndrome comprises severe mental deficiency, a characteristic skull shape with a small chin and prominant occiput, low-set malformed ears, clenched hands with overlapping index and fifth fingers, single palmar crease, 'rocker-bottom' feet and a short sternum. Malformations of the heart, kidneys and other organs are frequent. Cutaneous features include cutis laxa of the neck, hypertrichosis of the forehead and back, and capillary haemangiomas. Fingerprints show a distinctive low-arch dermal ridge pattern. Death within a month occurs in 30%. Only 10% survive beyond the first year and these infants show profound developmental delay.

Trisomy 13 [1–4]

SYN. PATAU'S SYNDROME

The incidence of trisomy 13 is 1 per 5000 live births. Nondisjunction at either the first or second meiotic division in either parent may cause trisomy 13. In about 20% of cases, one parent is a translocation carrier. In about 5% of patients, mosaicism is present. The characteristic features of the syndrome are mental retardation, sloping forehead reflecting underlying holoprosencephaly (a developmental defect of the forebrain), eye defects including microphthalmia or anophthalmia, cleft palate and cleft lip, low-set ears, 'rocker-bottom' feet, cardiac defects and a variety of other visceral abnormalities. Survival for more than 6 months is unusual. Cutaneous features include vascular anomalies, especially of the forehead, hyperconvex nails and localized defects of the scalp. Cutis laxa of the neck has also been reported. The palm print shows a distal palmar axial triradius.

Other autosomal abnormality syndromes

Although the syndromes to which these autosomal abnormalities give rise include distinctive craniofacial malformations, they do not exhibit constant or frequent dermatological features, apart from abnormal dermatoglyphics. Other chromosomal disorders are reviewed elsewhere [1,2].

Chromosome 4, short-arm deletion syndrome [3]

These children have microcephaly, mental retardation, hypospadias and multiple malformations, such as cleft lip and/or palate, low-set ears and pre-auricular pits. There are scalp defects in some cases.

Chromosome 5, short-arm deletion syndrome [4–6]
SYN. CRI DU CHAT SYNDROME

This is a clinically heterogeneous syndrome. The patients are mentally deficient microcephalics with a cat-like cry. In some cases a pre-auricular skin tag accompanies low-set malformed ears. There may be premature greying of the hair.

Long-arm 18, deletion syndrome [7]

Hypoplasia of the mid-face gives these children deep-set eyes. The antihelix is very prominent and there are multiple skeletal and ocular abnormalities. Eczema has been reported to occur in 25% of cases.

Sex chromosome defects

Turner's syndrome [1,2]

Turner's syndrome is defined as a gonadal dysgenesis due to a missing or structurally defective X chromosome. In 1938, Turner described this syndrome in seven girls [1].

Aetiology [2]. The frequency of Turner's syndrome is 1 per 2500 female births [3]. In some 80% of cases there are 45 chromosomes with an X0 sex chromosome complement. Such cases are chromatin negative in buccal smears. It is assumed that the missing chromosome was lost before or at fertilization. The incidence of 45X was reported to be increased in the offspring of teenage mothers [4], but in a study from Denmark there was no significant relation between mother's age and risk of Turner's syndrome [5].

Most of the remaining 20% of cases are chromatin positive. Some have 46 chromosomes but with partial deletion of one X chromosome [6]. Such individuals may not differ significantly in their phenotype from the common X0 but they may appear more normal [7]. Other cases have shown mosaicism of various types (XX/X0 or XXX/X0) [8].

Pathology [8]. In place of the normal gonads, ovarian streaks are present that are composed of stroma-like cells and quiescent germinal epithelium without follicular activity or germ cells. However, both follicles and germ cells have occasionally been present.

Lymphangiographic studies have shown hypoplasia of cutaneous and subcutaneous lymphatics [9].

A lack of feedback inhibition by hormones from the defective ovaries produces elevated levels of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) in the serum by 5 days of age [10].

Clinical features [7,11–13]. Turner's syndrome results in early spontaneous loss of the fetus in over 95% of cases. Severely affected fetuses who survive to the second trimester can be detected by ultrasonography, which shows cystic hygroma, chylothorax, ascites and hydrops.

Growth failure is a consistent finding at birth in infants with Turner's syndrome, which begins in early gestation and is well established by mid-pregnancy [14]. The diagnosis may be suggested in the newborn by redundant neck skin and peripheral oedema. However, the diagnosis is usually made later as a result of investigation for short stature and primary amenorrhoea.

The characteristic clinical features of Turner's syndrome include small stature; a broad shield-shaped chest with widely spaced nipples; a wide carrying angle of the arms; a webbed neck (pterygium colli); a low posterior hairline; low, misshapen ears; high, arched palate; cutis laxa, especially on the neck and buttocks; short fourth, and sometimes fifth, metacarpals and metatarsals; hypoplastic nails; and a tendency to keloidal scar formation.

Individuals with Turner's syndrome have increased numbers of melanocytic naevi and therefore have an increased risk for melanoma [15]. Lymphangiectatic oedema of the hands and feet may be present at birth and clear in the first 2 years. Skeletal abnormalities are a common feature [6], but are also very variable. Among the most frequent are cubitus valgus, kyphoscoliosis and epiphyseal defects and pathological fractures. Cardiovascular abnormalities [16] are present in some 25% of cases, especially coarctation of the aorta. Ocular defects, squints or ptosis, are also a feature of some cases. Intelligence is usually normal, although a few girls have educational problems.

Endocrinological investigations reveal an increased output of pituitary gonadotrophins accompanied by low oestrogen levels. Thus there is usually primary amenorrhoea

with failure to develop full secondary sexual characteristics. Some patients menstruate and, exceptionally, may be fertile. Adrenal androgens are present, and pubic and axillary hair may be present in the absence of other manifestations of normal pubertal development. A few examples are known [17] in which otherwise typical Turner's syndrome (X0 chromosome complement) is accompanied by some degree of genital virilization and hirsutism.

Diagnosis. Diagnosis may be made prenatally by amniocentesis [5]. The somatic abnormalities may suggest the diagnosis in infancy or childhood, but if they are inconspicuous or absent, the diagnosis may be unsuspected until puberty. Increased urinary excretion of FSH supports the diagnosis, which can be confirmed by examination of buccal smears supplemented by chromosome studies.

Treatment. Oestrogen replacement will allow the development of secondary sexual characteristics but does not seem to influence stature or infertility. Treatment with human growth hormone may improve the ultimate adult height; long-term, randomized, controlled studies are in progress [18]. Melanocytic naevi may grow more rapidly during growth hormone therapy [19]. Therefore, individuals with Turner's syndrome, especially those on growth hormone therapy, should have periodic skin examinations and be advised on the regular use of sunscreens [15].

Klinefelter's syndrome [1,2]

Aetiology. The frequency of Klinefelter's syndrome is 1 per 600 male births [2]. In buccal smears the nuclei are chromatin positive and indistinguishable from those of the normal female, but in cultures there are seen to be 47 chromosomes with an XXY sex chromosome complement [3]. The differentiation of the developing gonad proceeds along male lines but the testis fails to develop fully, and many seminiferous tubules are replaced by fibrous tissue. Leydig cells are present in normal or increased numbers.

Clinical features [1,2,4–6]. There are no clinical manifestations before puberty, which occurs at the normal age. The testes are small and fail to produce adult levels of testosterone, which leads to poorly developed secondary sexual characteristics and infertility. Hair growth on the trunk, limbs and face tends to be below average. Psychiatric disorders are common but mental deficiency is not. Some patients retain eunuchoid body proportions. They are tall, obese and may develop gynaecomastia. Associated features include osteoporosis [7] and taurodontism (vertical enlargement of the molar pulp chamber) [8]. Various minor dermatoglyphic changes have been recorded [9].

An association between systemic lupus erythematosus (SLE) and Klinefelter's syndrome has been postulated [10], and this is interesting in view of the fact that SLE is more frequent in women than men and that oestrogens may provoke SLE in some patients [11]. In a case report of SLE in a hypogonadal male with Klinefelter's syndrome treated with testosterone in doses sufficient to normalize the serum level of this hormone to the adult male range, haematological and serological abnormalities, including elevated levels of anti-DNA antibodies and depressed complement levels, returned to normal within 9 months of increasing the testosterone dose [12].

There are two reports of incontinentia pigmenti in boys with Klinefelter's syndrome [13,14]. As incontinentia pigmenti trait is usually lethal in males, it has been proposed that the second X chromosome protects against fetal death.

Patients with Klinefelter's syndrome have an increased risk of developing leg ulcers, especially in combination with hyperpigmentation or atrophie blanche [15,16]. Some authors have attributed the cause of leg ulceration to venous insufficiency, others have implicated increased

activity of plasminogen activator inhibitor 1 [17]. It seems likely that androgens may protect against the development of leg ulcers, because ulcers are more common in women than men, and it may be relevant that men who do develop leg ulcers tend to be taller, heavier and less fertile than age-matched control subjects [18].

Testosterone replacement therapy will improve secondary sexual characteristics, but infertility is the rule, except in mosaics.

Diagnosis. The association of gynaecomastia with small testes and otherwise apparently normal genitalia should suggest the diagnosis, which is supported by finding an increased urinary excretion of gonadotrophin. The diagnosis is confirmed by chromosome studies.

Other abnormalities of the sex chromosomes

XXYY [1]

These individuals show many of the main features of Klinefelter's syndrome, including sparse body hair. Additional features reported are multiple cutaneous angiomas, acrocyanosis and early peripheral vascular disease.

XYY syndrome [2]

These patients are phenotypic males, often tall and with, perhaps, an increased incidence of severe acne (see Chapter 43). They may be mentally retarded, and have a reputation for aggressive behaviour [3], not accepted by all authorities. There is no evidence of increased secretion of FSH or LH [4].

XXXXY syndrome [5]

These patients, of low birth weight, are slow to grow physically and are mentally defective. There are multiple skeletal defects of which limited elbow pronation is the most characteristic. The ears are large, low-set and malformed. There is hypogenitalism. No consistent dermatological defects are reported, but some patients have hypotrichosis.

Fragile X syndrome [6–8]

Fragile X syndrome is associated with a folate-sensitive fragile site in band Xq27.3 due to a triplet DNA repeat that is expanded and unstable. Subjects have mental retardation and mild dysmorphic features, with mild connective tissue abnormality that leads to fine skin, hyperextensible joints and flat feet. Males are more commonly affected than females. The disorder is common, with about 1 in 2000 children affected.

Noonan's syndrome (MIM 163950) [1,2]

This syndrome, which occurs in both sexes, phenotypically resembles Turner's syndrome but the karyotype is

usually normal (46XY or 46XX) [1,3]. Chromosomal abnormalities have been found in only a few cases. One such child had both Noonan's syndrome (NS) and DiGeorge's syndrome, with a deletion within chromosome 22q11 [4]. Many cases appear to be sporadic, although autosomal dominant inheritance has been frequently reported [5].

Clinically, the patients are of short stature and have a broad short neck, which may be webbed. The facies shows a characteristic association of hypertelorism, blepharoptosis, epicanthic folds and a small chin. Skeletal defects are frequent. Congenital heart defects, such as pulmonary stenosis and cardiomyopathy, may be present. Intelligence may be normal but some degree of mental retardation is usual. Children with NS tend to be clumsy, stubborn, irritable and have communication difficulties [6]. In 70% of males, the testes are undescended. Lymphoedema of the feet and legs is common and more severe than in Turner's syndrome [7]. Orbital oedema is sometimes seen and can be an unusual presentation of NS [8]. Widespread leukokeratosis of the lips and gingiva has been described [9]. The hair is usually coarse, light coloured and curly, with a low posterior hairline. Downy hypertrichosis may occur on the cheeks or shoulders. Pubic hair is scanty in the male and beard growth is poor [10]. Ulerythema oophryogenes may be a cutaneous marker for NS [11,12]. Evidence has now emerged that one form of NS, that which maps to 12q24.1, is due to mutations in *PTPN11*, a gene encoding the non-receptor protein tyrosine phosphatase SHP2, which contains two Src homology-2 (SH2) domains [13]. Tartaglia *et al.* [13] found that mutations in the *PTPN11* gene accounted for about half the patients studied. Mutations in the neurofibromin gene (*NF1*), which is the site of mutations causing classic NF1, have been found in neurofibromatosis–Noonan syndrome. Acute leukaemia has been reported in a few cases of NS [14]. After germline mutations in *PTPN11* were demonstrated in NS, a search has been performed for defects in *PTPN11* in myeloid disorders, including cases of juvenile myelomonocytic leukaemia (JMML) in children with NS. Specific mutations in *PTPN11* associated with isolated JMML occur as somatic changes and have never been observed as germ-line defects, leading to speculation that these molecular defects have a greater functional impact and may be associated with embryonic lethality.

Patients with overlapping features of NF1 and NS have also been described (see p. 12.32).

In contrast with Turner's syndrome, short stature and infertility are not constant features. The diagnosis of NS must be suspected in all patients labelled as Turner's syndrome if they are of normal height, mentally retarded, have a cardiac valve defect or manifest normal gonadal function. Individuals with NS who are of short stature may benefit from treatment with growth hormone [15].

Familial multiple tumour syndromes

The neurofibromatoses

The neurofibromatoses comprise several distinct genetic disorders that lead to the formation of tumours surrounding nerves and a variety of other pathological features, the two main forms being NF1 and NF2. The most common type (NF1) is characterized by multiple café-au-lait macules and the occurrence of neurofibromas along peripheral nerves. The second type (NF2) is characterized by the occurrence of vestibular schwannomas (acoustic neuromas), usually bilateral, as well as meningiomas and other tumours of the nervous system. The spectrum of these disorders has been reviewed [1–6].

Neurofibromatosis 1 (MIM 162200)

SYN. VON RECKLINGHAUSEN'S NEUROFIBROMATOSIS

Definition, history and aetiology [7–9]. In 1882, Friedrich von Recklinghausen published a monograph describing this disease and pointing out that the skin tumours were derived from peripheral nerves [10]. In retrospect, Virchow [11] first reported a family with more than one affected member. It is now recognized that NF1 is an inherited neuroectodermal abnormality, characterized by

Fig. 12.8 Neurofibromatosis: axillary freckling and multiple neurofibromas.

Fig. 12.9 Neurofibromatosis: extensive neurofibroma of the foot.

the presence of six or more café-au-lait spots, axillary freckles, multiple neurofibromas and Lisch nodules (pigmented iris hamartomas) (Figs 12.8–12.10). The mode of inheritance is autosomal dominant, with 100% penetrance by the age of 5 years [9,12]. Sporadic cases result from a high gene mutation rate [7–9]. The prevalance has been estimated at about 1 in 2500–3300 births [9]. Incomplete or monosymptomatic forms are frequent.

Fig. 12.10 Neurofibromatosis: Lisch nodules (pigmented iris hamartomas).

The gene for NF1 is located on chromosome 17 [13,14]. The *NF1* gene has now been cloned and encodes a protein named neurofibromin [15–17]. The gene spans 335 kb and has at least 59 exons, producing four major alternatively spliced transcripts. It is widely expressed in a variety of human tissues. The neurofibromin protein shows significant regions of similarity to the GTPase-activating protein and is capable of down-regulating Ras activity. The majority of *NF1* germ-line mutations alter the reading frame or insert a premature stop codon. No hotspot for mutation has been identified. The impact of these mutations is to reduce the amount of neurofibromin produced by cells. Further investigation supports the contention that the *NF1* gene acts as a suppressor of tumour activity, with a variety of somatic inactivating mutations identified in neurofibromas, in keeping with the classical Knudson 'two-hit' hypothesis of tumour genesis. The random acquisition of somatic mutation partly explains the delayed age of onset of the tumours associated with NF1 and the variability of expression [18]. Mouse models with disrupted *NF1* genes have been shown to have an increased susceptibility to certain tumours, giving further support to the role of the *NF1* gene as a tumour suppressor [19,20]. Neurofibromin has been shown to be present in both keratinocytes and melanocytes in normal adult human skin [21].

Mast cells are increased in neurofibromas and may be involved in the development and growth of these tumours by producing several growth factors, such as histamine and tumour necrosis factor-α (TNF-α) [22,23].

Pathology. Cutaneous neurofibromas are derived from peripheral nerves and their supporting structures, including neurilemmal cells. Ultramicroscopically, they are seen

to consist of arborizing Schwann cells in collagenous interstitial tissue. The fibroblast-like cells in cutaneous neurofibromas are thought to be derived from factor XIIIa and HLA-DR-positive connective tissue cells in peripheral nerves [24]. In both café-au-lait spots and clinically unaffected skin, giant pigment granules are sometimes found in epidermal cells and melanocytes [25–29]. They are rarely found in McCune–Albright syndrome, and never in normal skin. They can, however, be found in other conditions, and their presence cannot be regarded as pathognomonic.

Clinical features [7,8,30–32]. A diagnosis of NF1, according to the National Institutes of Health Consensus Development Conference Statement [33], is based on two or more of the following criteria:
1 six or more café-au-lait macules of over 5 mm in greatest diameter in prepubertal individuals and over 15 mm in greatest diameter in postpubertal individuals;
2 two or more neurofibromas of any type or one plexiform neurofibroma;
3 freckling in the axillary or inguinal regions;
4 optic glioma;
5 two or more Lisch nodules;
6 a distinctive osseous lesion such as sphenoid dysplasia or thinning of the long bone cortex with or without pseudoarthrosis;
7 a first-degree relative (parent, sibling, offspring) with NF1 by the above criteria.

Café-au-lait macules are sharply defined, light-brown patches that vary in size from 0.5 to 50 cm, although the majority are 10 cm or less in size. Café-au-lait spots are the first feature of the disease to appear in all children [8,34]. In a population study, parents noted café-au-lait macules for the first time at 4 years of age or less in all affected children and within the first year of life in 82%. The macules increase in size and number during the first decade. Blue–red macules and pseudoatrophic macules also occur [35].

Cutaneous neurofibromas (or mollusca fibrosa) are soft lilac-pink tumours, sessile and dome-shaped, sometimes pedunculated, most numerous on the trunk and limbs; hundreds may be present, ranging from a few millimetres to several centimetres in diameter. In women, they are prominent on the areola of the breast. Small firm nodules may develop in relation to peripheral nerves. The *plexiform neurofibroma* is a diffuse elongated fibroma along the course of a nerve, frequently involving the trigeminal or upper cervical nerves and usually noticeable within the first 2 years of life. *Elephantiasis neurofibromatosa* is a similar diffuse neurofibromatosis of nerve trunks associated with overgrowth of the subcutaneous tissue and of the skin, which is wrinkled and pendulous and may produce gross disfigurement. Neurofibromas may also involve the viscera and blood vessels.

Freckling occurs frequently in the axillae, when it is virtually pathognomonic [36]. It is present in about 70% of affected subjects and appears a little later than the café-au-lait spots, the youngest case in one series being 3 years old [34]. It may also occur in other intertriginous areas.

There may also be darker pigmented patches over an underlying plexiform neurofibroma, and if these extend to the midline, it may indicate that the tumour involves the spinal cord [37].

Lisch nodules (pigmented iris hamartomas) appear as dome-shaped lesions found superficially around the iris on slit-lamp examination. They occur in over 90% of patients and increase with age [8,34]. They are asymptomatic but help to confirm the diagnosis. They do not occur in segmental or bilateral acoustic NF [31].

Oral lesions are present in 5–10% of cases, as papillomatous tumours of palate, buccal mucous membrane, tongue and lips, or as macroglossia, which is usually unilateral [38].

Kyphoscoliosis occurs in 2% of cases and the early-onset, high-level lesions may progress inexorably, leading to cardiorespiratory disease, unless aggressive surgery is performed. Pseudoarthrosis involving the tibia or radius occurs in 1%, but may be asymptomatic [31].

Short stature and macrocephaly [39] are also features of the condition.

Other organs. The severity of cutaneous involvement gives no reliable indication of the extent of the disease in other organs. Between 25 and 30% of children may exhibit learning difficulties [34,40] and physical development may be impaired. Speech impediments, hypertelorism and headaches are also common [31,41]. Endocrine disturbances of many types may be associated [42]: precocious puberty, acromegaly [43], Addison's disease, hyperparathyroidism, gynaecomastia and phaeochromocytoma. Renovascular hypertension may occur in children [44,45]. Osteomalacia when present is the result of a congenital defect of the renal tubules.

Involvement of the lower urinary tract [46] may give rise to urinary symptoms. Constipation occurs due to dysfunction of the colonic musculature. Gastrointestinal lesions may also cause recurrent haemorrhage or obstruction.

There is a high prevalence of cardiovascular abnormalities [47,48] and NF1 can be complicated by pulmonary hypertension [49].

Neurological manifestations are found in some 40% of patients [38,50]. The most common solitary intracranial tumour

is an optic nerve glioma; astrocytomas and schwannomas also occur. Tumours may arise in peripheral nerves and within the spinal cord. Intracranial tumours may cause epilepsy, although fits may occur in the absence of any demonstrable focal lesion.

Sarcomatous change within a neurofibroma varies from 1.5 to 15% of cases, more often in deeper than in cutaneous lesions [34,51]. It is rare before the age of 40 years, but has occurred in early childhood. Growth is often slow and metastasis late, but local recurrence is frequent. In contrast, malignant peripheral nerve sheath tumours are highly aggressive [52]. Malignant change may occur simultaneously in several lesions. Enlargement or pain should suggest the possibility of malignant change, although rapid enlargement may follow haemorrhage.

Other malignant diseases associated with NF include Wilms' tumour, rhabdomyosarcoma, several types of leukaemia [53], retinoblastoma [54] and malignant melanoma [55].

Pruritus may be a symptom of NF. The presence of large numbers of mast cells in the skin in this condition, and the response of the itching to antihistamines, suggest that histamine is the cause of the pruritus [37]. In addition, a beneficial effect of the mast cell blocking agent ketotifen has been reported [22].

Epidermodysplasia verruciformis has been reported in a man with NF1 [56].

Course and prognosis [7,31,38,57]. The course of the disease varies considerably in individual patients and the majority will never develop major complications. Characteristically, café-au-lait spots are present at birth or, more commonly, develop in early childhood. Cutaneous neurofibromas appear during childhood and increase rapidly in number at puberty. However, lesions may be present at birth and become progressively more extensive. Although early onset and rapid progression before puberty usually indicate a poor prognosis, minimal cutaneous involvement in the young child does not necessarily imply a favourable course, although many cases remain limited. Extensive involvement of the urinary or gastrointestinal tract or the central nervous system carries a poor prognosis. Very rarely, the disease may be so extensive at birth as to be incompatible with survival.

Pregnancy, in which unexplained hypertension frequently occurs, sometimes appears to induce rapid progression of existing lesions and the development of new ones [31,58].

At presentation, a detailed clinical assessment is essential and must include examination of all other members of the family. Investigations should include a neurophysiological assessment, a skeletal survey, audiography and slit-lamp ocular examination. Parents and siblings should also have their eyes examined for the presence of Lisch nodules. It is recommended that individuals with NF1 have an annual clinical review, which must include measurement of blood pressure. Further investigations will depend upon the detection of complications. Magnetic resonance imaging (MRI) should be performed in children who have macrocephaly or who demonstrate focal neurological signs or symptoms. Routine cranial imaging is the subject of debate. The detection of an asymptomatic brain lesion will increase patient and parental anxiety and would not alter clinical management. Patients with NF should be monitored by a number of different specialists, with one physician acting as the coordinator. The ideal situation is a multidisciplinary clinic, now established in a number of centres.

Long-term follow-up information on cohorts of NF1 patients has shown a reduced life expectancy related to the development of malignancy and other complications, such as hypertension due to renal artery stenosis or phaeochromocytoma [59–61].

Diagnosis. Diagnosis is established on the basis of clinical criteria. Molecular genetic testing is feasible, but the large size of the gene and wide range of pathogenic mutations have so far impeded the development of a clinical diagnostic test [62]. Cutaneous neurofibromas are clinically and histologically distinctive, although a plexiform neurofibroma in an infant can clinically resemble a congenital melanocytic naevus. Café-au-lait spots, usually the earliest manifestation in children, are present in 10–20% of normal individuals and about 35% of patients with McCune–Albright syndrome [7,25]. If only one or two are present, they have little diagnostic significance in the absence of other signs or of a family history of the disease; if six or more are present, the probability of NF is high. Identification of the *NF1* gene means that prenatal/presymptomatic diagnosis for this disease is now possible, with greater than 95% accuracy in families with a suitable structure [34]. However, in a disorder showing such varied expression and complications, the decision to undergo prenatal diagnosis is far from clear. Prenatal diagnosis is not an option for approximately 50% of cases who represent new mutations.
