• Hairy leukoplakia is caused by EBV. It usually has a corrugated surface and mainly affects margins of the tongue almost exclusively. It is seen in the immunocompromised and is a complication of HIV infection. It is seen in all groups at risk of HIV infection. The condition appears to be benign and self-limiting. Leukoplakia in chronic renal failure causes similar symmetrical soft keratoses, and may be caused by EBV.

Diagnosis. There are no signs or symptoms which reliably predict whether a leukoplakia will undergo malignant change, and thus histology must be used to detect dysplasia. Scalpel or punch biopsy is therefore generally indicated. Biopsy is mandatory for those leukoplakias that exhibit the following characteristics:
• found in patients with previous or concurrent head and neck cancer;
• are non-homogeneous, i.e. have red areas and/or are verrucous and/or are indurated;
• in a high-risk site such as floor of mouth or tongue;
• focal;
• with symptoms;
• without obvious aetiological factors.

Pathology. Keratoses show, to a varying degree, increased keratin production, change in epithelial thickness and disordered epithelial maturation. Mild dysplasia is not usually regarded as of serious significance. The presence of severe epithelial dysplasia is thought to indicate a considerable risk of malignant development [18]. Pagetoid dyskeratosis is considered a selective keratinocytic response in which a small part of the normal population of keratinocytes is induced to proliferate in response to friction [19]. Pagetoid dyskeratosis has been found in 42.2% of lip biopsies, more frequent in younger patients and in women. Pagetoid cells are more common in suprabasal location and in the labial mucosa. These cells show positivity for high-molecular-weight cytokeratin and negative reaction for low-molecular-weight cytokeratin, epithelial membrane antigen, carcinoembryonic antigen and HPV. The immunohistochemical profile is different from the surrounding keratinocytes, indicating premature keratinization. The morphological features of dyskeratotic pagetoid cells are distinctive and easily recognized as an incidental finding, thus preventing confusion with other important entities including an intraepidermal tumour.

The main differential diagnoses include white-sponge naevus, leukoedema, oral koilocytoses, hairy leukoplakia, pagetoid squamous cell carcinoma *in situ* and extramammary Paget's disease of the oral mucosa.

Prognosis. Overall, around 2–5% of leukoplakias become malignant in 10 years and 5–20% of leukoplakias are dysplastic. Of leukoplakias with dysplasia, 10–35% proceed to carcinoma. There is thus clear evidence of the malignant potential of some oral leukoplakias, although some leukoplakias (15–30%) regress clinically, not only when supposed aetiological factors have been removed but also sometimes spontaneously. Malignant change to carcinoma is most frequent in women older than 50 years and in large lesions. Interestingly, leukoplakias developing in non-smokers have a higher rather than lower risk of malignant change.

At present, it is not possible to reliably predict which dysplastic lesions will progress to carcinoma and which will regress, and there is concern over observer and inter-observer variation in diagnosis of dysplasia [20,21]. Over the recent past, much effort has gone into identifying tissue markers of malignant potential [22], in particular the genetic changes that underlie oral carcinoma, resulting in the identification of biomarkers such as DNA ploidy, p53, and chromosome 3 and 9 changes that might predict neoplastic change in potentially malignant lesions [23–30].

Management. Management can be difficult, not least because of the wide extent of some lesions, their frequent admixture with areas of erythroplasia (speckled leukoplakias), and controversy as to the prognosis and long-term benefit and effects of various therapies. Indeed, no controlled studies are available [31]. Treatment therefore is empirical [32,33].

Removal of known risk factors (tobacco, alcohol and trauma) is a mandatory first step. The patient should be re-examined 3 months after instituting this. If the lesion persists, it should be removed [33–36].

Surgery (scalpel or laser excision) is an obvious option for the management of leukoplakias with a high predisposition to malignant transformation, such as leukoplakias that are:

- speckled;
- verrucous;
- from high-risk sites (e.g. floor of mouth/ventrum of tongue, or soft palate/fauces);
- in a patient with previous cancer of the upper aerodigestive tract;
- dysplastic;
- polysomic (aneuploidy or tetraploidy);
- positive for genetic markers such as mutated tumour-suppressor factor p53, or for loss of heterozygosity on chromosomes 3p or 9p—such advances in molecular biology mean that it should soon be possible to ascertain the malignant potential of leukoplakia from genetic and DNA studies.

Chemotherapy and chemoprevention are attractive possibilities [37]. Topical 0.5% bleomycin in dimethyl sulfoxide (dimethyl sulphoxide) is being evaluated [13]. Although they may induce regression of some leukoplakias and may inhibit their development, topical or systemic vitamin A derivatives, methisoprinol and calcipotriol have not been widely used because of adverse effects or their uncertain long-term consequences [38–42].

Actinic cheilitis (see p. 66.115)

Hairy leukoplakia

Aetiology. Hairy leukoplakia (HL) is seen in severe immune defects, especially HIV infection, and occasionally in the apparently immunocompetent [1,2]. HIV is not found within the genome of epithelial cells in HL and it is more likely that the features are a consequence of an opportunistic infection with EBV. It is now clear that normal human oral mucosa from HIV-negative and HIV-positive individuals may contain latent EBV [3,4].

EBV has been shown to be present in HL, especially in the upper layers of the epithelium. The oral site of predilection for HL appears to relate to the presence of EBV receptors only on the parakeratinized mucosae such as the lateral margin of the tongue. HL regresses on treatment with antivirals but fails to resolve with antifungals, despite the frequent presence of *Candida* species.

Pathology. Histological features of HL include hyperparakeratosis, hyperplasia and ballooning of prickle cells, few or absent Langerhans' cells, and only a sparse inflammatory cell infiltrate in the lamina propria.

Clinical features. HL is a white patch, usually seen on the parakeratinized mucosa of the tongue, frequently bilaterally (Fig. 66.55). The lesions are corrugated or have a shaggy or hairy appearance, are mostly symptomless and, unlike some oral keratoses, have no known premalignant potential [1,5]. The majority of the affected patients who are HIV positive appear eventually to develop AIDS. HL also occurs in HIV-negative persons [6–12].

Fig. 66.55 Hairy leukoplakia. Found mainly in HIV infection, vertical white ridges on the lateral margin of the tongue.

Diagnosis. Some of the histological features typical of HL, especially the hyperparakeratosis, can be seen in oral white lesions other than HL in HIV-infected persons [13]. Not only are there oral lesions that mimic HL in HIV infection, but lesions similar to HL can be seen in other immunocompromised persons and even in some apparently healthy individuals.

However, most cases can be distinguished from the HL of HIV infection by the absence of EBV DNA on histology and, of course, by examination for HIV serum antibody.

Treatment. HL really needs no treatment but in HIV-infected individuals may occasionally improve spontaneously or with the antiretroviral agents aciclovir or ganciclovir.

Psoriasis (see Chapter 35)

The oral mucosa appears to be rarely involved in psoriasis, with less than 100 cases reported, although there are occasionally lip lesions or white oral lesions, especially in the buccal mucosa, or lesions clinically indistinguishable from geographical tongue (sometimes termed 'annulus migrans' or 'erythema circinatum'), particularly in generalized pustular psoriasis [1–12].

Koplik's spots (see Chapter 25)

White specks may be seen in the buccal mucosa in early measles.

Pigmented lesions

Congenital lesions are described on p. 66.27. The tongue is often discoloured due to superficial staining from foods, drinks or habits such as tobacco or betel use. Localized hyperpigmented lesions are usually due to pigmentary incontinence, amalgam tattoos, melanotic macule or naevi, although melanomas, Kaposi's sarcoma and epithelioid angiomatosis must be excluded. Generalized oral mucosal hyperpigmentation is usually racial in origin and only occasionally has a systemic cause such as Addison's disease.

Furred, brown and black hairy tongue

Aetiology and pathology. Children rarely have a furred tongue in health but it may be coated with off-white debris in febrile and other illnesses.

Adults, however, not infrequently have a coating on the tongue in health, particularly if they are edentulous, are on a soft non-abrasive diet, have poor oral hygiene or are fasting. The coating appears more obvious in xerostomic and in ill patients, especially those who cannot maintain oral hygiene.

The coating in most cases appears to be of epithelial, food and microbial debris; indeed, the tongue is the main oral reservoir of some microorganisms, such as *Candida albicans* and viridans streptococci. The filiform papillae are excessively long and stained by the accumulation of squames and chromogenic microorganisms.

Habits such as tobacco and betel use, and various medicaments such as chlorhexidine or iron, can cause a black or brown superficial staining of the tongue (and teeth).

Occasionally, a brown hairy tongue may be caused by drugs that induce xerostomia, lansoprazole or antimicrobial therapy, when it may be related to overgrowth of microorganisms such as *Candida* species and may respond to withdrawal of the drug [1,2].

Clinical features. Black hairy tongue affects mainly the posterior part of the dorsum of the tongue, especially centrally (Fig. 66.56) [3,4].

Treatment. Patients with black hairy tongue may find the condition improves if they avoid habits or drugs that stain the tongue, increase their standard of oral hygiene, brush the tongue with a hard toothbrush, use sodium bicarbonate mouthwashes, chew gum or suck a peach stone. Topical tretinoin may be effective [5].

Tattoos

Amalgam tattoos are common causes of blue-black pigmentation, usually seen in the mandibular gingiva or at least close to the teeth (Fig. 66.57), or in the scar of an apicectomy where there has been a retrograde root-filling [1–3]. The amalgam associates with elastin fibres [4]. Radio-opacities may or may not be seen on radiography. Similar lesions can result if for some reason pencil lead or other similar foreign bodies become embedded in the oral tissues [5].

Radiography may help to confirm the diagnosis. Biopsy may be indicated to exclude a melanoma but otherwise these innocuous lesions can be left alone.

Deliberate tattooing is a rare cause of oral pigmentation [6,7].

Body art

Tattooing of the lower lip may occasionally be seen. A tattooed lower lip in a Sudanese woman, for example, signifies that she is married [1]. The Wodaabe people of Nigeria and Cameroon may tattoo on the skin surface at the angle of the mouth, a practice which has its basis in ritual warding-off of the 'evil eye'. Similar tattoos may be seen on Bedouin women of North Africa. Tattooing of the chin is seen increasingly in Maoris ('Moki') and tattooing inside the lip may now be seen in developed countries. Mathur and Sahoo [2] reported an instance of fatal septicaemia following the placement of tribal tattoo marks at the angle of the mouth in a Nigerian infant.

The practice of piercing oral and facial soft tissues and then placing foreign objects in the defects on a more or less permanent basis is one which has also been largely confined until recently to certain tribal groups in continental Africa and isolated Amazon regions of South America, for example the Suia and Txukahameis tribes of Brazil, but it is now not uncommon in developed countries.

Food, habits, heavy metal and drug-induced hyperpigmentation

Causes (see Table 66.11) [1–4] include:

- Foods and beverages (such as beetroot, red wine, coffee and tea) cause superficial staining.
- Confectionery (such as liquorice) causes superficial staining.
- Smoking tobacco is now a fairly common cause (smoker's melanosis) and may produce extrinsic discoloration but also intrinsic pigmentary incontinence, with pigment cells increasing and appearing in the lamina propria. This is especially likely in persons who smoke with the lighted end of the cigarette within the mouth (reverse smoking), as practised mainly in some Asian communities [5,6].
- Chewing betel may cause superficial brownish-red discoloration mainly in the buccal mucosa (and on the teeth), with an irregular epithelial surface that has a tendency to desquamate, seen mainly in women from South and South-East Asia. The epithelium in betel chewer's mucosa is often hyperplastic, and brownish amorphous material from the betel quid may be seen on the epithelial surface and intracellularly and intercellularly, with ballooning of epithelial cells [7]. Betel chewer's mucosa is not known to be precancerous but betel use predisposes to submucous fibrosis and cancer.
- Drugs such as chlorhexidine, iron salts, griseofulvin, crack cocaine, minocycline, bismuth subsalicylate, lansoprazole and hormone replacement therapy. Chlorhexidine and iron salts cause superficial staining. Drugs that cause intrinsic staining include the following [8–16].
  - Antimalarials produce a variety of colours in the mucosa, ranging from yellow with mepacrine to blue–black with amodiaquine.
  - Minocycline may cause blackish discoloration of teeth, gingivae and bone, skin, sclera and even breast milk. Minocycline can, in a minority of patients, produce blue–grey gingival pigmentation caused by staining of the underlying bone, and some intrinsic faint bluish-grey staining, mainly at the anterior teeth.
  - Busulphan, some other cytotoxic drugs, oral contraceptives, phenothiazines and anticonvulsants may also occasionally produce, or increase, brown pigmentation. Adrenocorticotrophic hormone (ACTH) therapy may also produce brown pigmentation, as may zidovudine and clofazimine.
  - Gold may produce purplish gingival discoloration. Many of the heavy metals formerly implicated in producing oral hyperpigmentation (such as mercury, lead and bismuth) are not used therapeutically now, although industrial or accidental exposure is still occasionally seen [17]. Metallic sulphides deposited in the tissues were seen especially where oral hygiene was poor, with bacteria producing sulphides that resulted in pigmentation at the gingival margin (e.g. lead line).

Management. Some drug-induced hyperpigmentation resolves on cessation of exposure to the drug and improved oral hygiene, although resolution can take months or years.

ACTH-induced hyperpigmentation

Oral hyperpigmentation may be seen in ACTH therapy, Addison's disease, Nelson's syndrome or ectopic ACTH production (e.g. by bronchogenic carcinoma). The brown or black pigmentation is variable in distribution but is seen typically on the soft palate, buccal mucosa and at sites of trauma [1–7].

Oral mucosal melanotic macule, reactive type

SYN. MELANOACANTHOMA; MELANOACANTHOSIS

Melanotic macules occasionally appear suddenly as reactive lesions following trauma [1–9]. Melanoacanthoma is a misnomer: most reported cases have been in black people as reactive lesions [4]. A hyperpigmented symptomless macule appears over a course of days or weeks. The course is benign, and some cases resolve spontaneously within 6 months.

Pigment-filled dendritic cells that appear to be melanocytes are found in the stratum malpighii but, in contrast to melanoma, basal layer melanocytes are not increased.

Excision biopsy may be indicated to exclude melanoma.

Malignant melanoma (see Chapter 38)

Oral malignant melanoma is rare. Most patients are over 50 years of age and there is a male preponderance.

Malignant melanoma may arise in apparently normal oral mucosa or in a pre-existent pigmented naevus, most commonly in the palate or maxillary alveolus [1–5]. Metastatic melanoma is rare [4]. Features suggestive of malignancy include a rapid increase in size, change in colour, ulceration, pain, bleeding, the occurrence of satellite pigmented spots, or regional lymph node enlargement. The prognosis is poor unless detected very early [2,3]. The histology may show anaplastic spindle-shaped or squamoid cells. However, the histology is quite varied and staining with dopa or antibodies may be required to help the diagnosis. Most cases are positive for S-100, tyrosinase, and Mart-1/melana-A. Lesions suspected to be malignant melanoma should not be biopsied until the time of definitive surgical excision [6–10].

Kaposi's sarcoma (see Chapter 53)

Kaposi's sarcoma (KS) is seen predominantly as a consequence of HIV infection, mainly in men who have sex with men. It appears to be associated with HHV-8 [1,2]. Up to 50% of male homosexual AIDS patients have developed oral KS, although it appears to be declining in frequency and is rare in other HIV-infected patients.

Oral KS is the first presentation of HIV in 20–60% of affected patients, often associated with oral candidiasis. KS affects the hard-palate mucosa in particular (Fig. 66.58). Up to 95% of lesions are seen in the palate, 23% in the gingiva and others on the tongue or buccal mucosa. A red-purple macule is the early lesion, progressing to a purple nodular swelling that may be extensive and ulcerated.

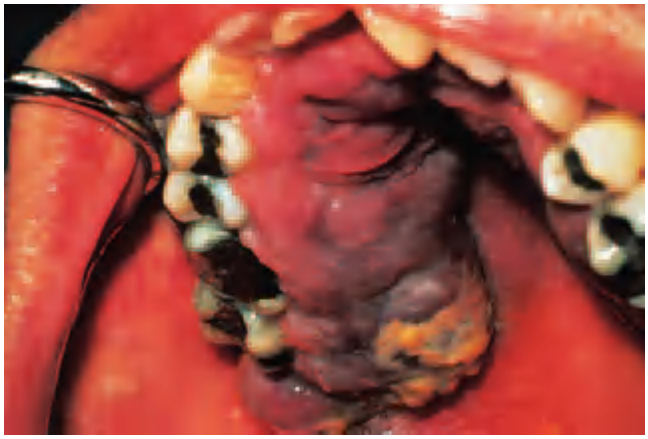

Fig. 66.58 Kaposi's sarcoma in a typical site with a characteristic purplish appearance. (Courtesy of Dr J.B. Epstein, Cancer Control Agency, Vancouver, Canada.)

Multiple lesions are common [3–6]. Lesions are often asymptomatic but more than 25% are painful and about 8% bleed. Oral KS is also occasionally seen in other non-HIV-infected immunocompromised patients.

Oral KS may regress occasionally spontaneously, or with HAART, zidovudine or systemic vinca alkaloids, etoposide or interferon, but the more usual treatment is local radiotherapy, laser removal or intralesional vinblastine. The latter produces fewer adverse effects than radiotherapy [4,7–9].

Purpura

Petechiae are usually caused by trauma, often from suction, but a bleeding tendency (as in infectious mononucleosis or HIV infection) or leukaemias must be excluded

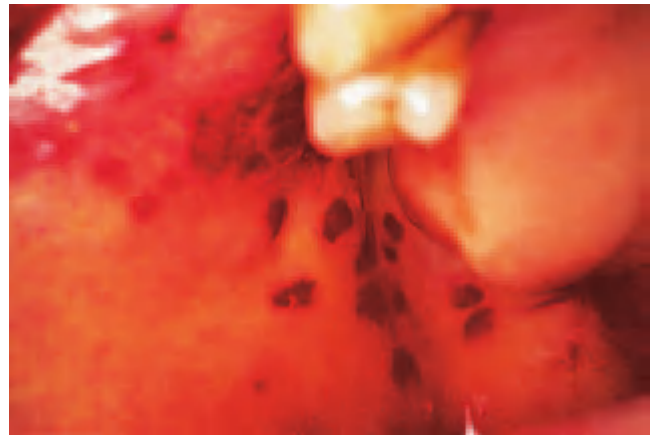

Fig. 66.59 Oral purpura in thrombocytopenia.

(Fig. 66.59). Blood-filled blisters may be seen in localized oral purpura (angina bullosa haemorrhagica) and pemphigoid, and occasionally in amyloidosis. Rarely a purpuric lesion may be seen in pigmented purpuric stomatitis [1].

Red lesions

Many oral red lesions are inflammatory in nature, although epithelial thinning (in geographical tongue) and desquamation (in desquamative gingivitis) are fairly common, and epithelial atrophy is an important cause, especially in deficiency glossitis and erythroplasia. Telangiectases are usually red and haemangiomas purplish in colour.

Benign migratory glossitis

SYN. LINGUAL ERYTHEMA MIGRANS; GEOGRAPHICAL TONGUE

Definition. A benign inflammatory condition of the tongue with map-like areas of erythema which are not constant in size, shape or location. Lingual erythema migrans is unrelated to cutaneous erythema migrans.

Aetiology. Unknown, but many patients with a fissured tongue (scrotal tongue) also have lingual erythema migrans. It is a common condition, affecting about 1–2% of the population [1,2]. A positive family history may be obtainable. HLA findings have been equivocal, with reports of associations with B15 and DR7 [3].

Some patients with lingual erythema migrans have atopic allergies such as hay fever and a few relate the oral

Fig. 66.60 Classical geographical tongue (lingual erythema migrans).

lesions to a particular food, for example cheese, or to stress. Similar oral lesions may be seen in Reiter's syndrome, generalized pustular psoriasis and acrodermatitis continua of Hallopeau [4]. Purported associations with diabetes [5] may be coincidental.

Pathology. There is epithelial thinning at the centre of the lesion with an inflammatory infiltrate mainly of polymorphonuclear leukocytes [1,2].

Clinical features. Geographical tongue may be asymptomatic or cause a sore tongue. Patients of any age may be affected but why the condition sometimes gives rise to symptoms after it has been present asymptomatically for decades is unclear [6–8].

Geographical tongue is characterized by map-like red areas with increased thickness of intervening filiform papillae. Alternatively, there are rounded, sometimes scalloped, reddish areas with a white margin (Figs 66.60 & 66.61). These patterns change from day to day and even within a few hours.

Rarely, other sites, such as the labial or palatal mucosa, are affected. The tongue is usually, but not invariably, affected simultaneously with the other sites [9].

There are no complications.

Fig. 66.61 Somewhat less obvious signs of lingual erythema migrans.

Diagnosis. Clinical examination usually suffices to differentiate the condition from LP, candidiasis, psoriasis, larva migrans or deficiency glossitis.

Treatment. Blood and urine examination may be necessary to exclude anaemia and diabetes. In those with no systemic disorder, no effective treatment is available except reassurance.

Fig. 66.62 Venous lake of the lip. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

Glossitis (see p. 66.82)

Strawberry tongue

Prominence of the lingual papillae may be seen in scarlet fever, Kawasaki disease and Riley–Day syndrome (familial dysautonomia), giving rise to an appearance similar to a strawberry.

Telangiectasia (see Chapter 51)

Oral telangiectases occur mainly in hereditary haemorrhagic telangiectasia, CREST (*c*alcinosis, *R*aynaud's, *e*sophageal, *s*clerodactyly, *t*elangiectasia) syndrome [1] (see Chapter 56), chronic liver disease, pregnancy and after irradiation.

Venous lake

SYN. VENOUS VARIX; SENILE HAEMANGIOMA OF LIP

This is a bluish-purple soft swelling, 2–10 mm in diameter, usually seen on the lower lip of an elderly person, due to a venous dilatation (Fig. 66.62). The lesion is lined by a single layer of flattened endothelial cells with a thick wall of fibrous tissue. The lesion empties on prolonged pressure [1,2].

A venous lake may be only a trivial cosmetic problem or it can bleed severely after trauma. It can be excised, but careful cryotherapy, electrocautery or treatment with an argon laser [2] can also give good results.

Proliferative vascular lesions

Benign atypical vascular lesions may exhibit cytological or architectural features that simulate angiosarcoma such that considerable caution is required in diagnosis [1]. The head and neck region is a common location particularly for lobular capillary haemangioma (pyogenic granuloma), while the lip is an especially common site for lobular capillary haemangioma [2] and intravascular papillary endothelial hyperplasia (Masson's haemangioma or pseudoangiosarcoma) [3,4]. Intravascular papillary endothelial hyperplasia is a benign, non-neoplastic, vascular lesion characterized histologically by papillary fronds lined by proliferating endothelium and probably represents an organizing thrombus. Seen mainly in the lip or tongue in females, it may simulate angiosarcoma histologically [5]. Excision suffices.

Vascular lesions such as epithelioid haemangioma, epithelioid haemangioendothelioma, spindle-cell haemangioendothelioma, acquired progressive lymphangioma, or angiosarcoma and KS may also occasionally be seen.

Varicosities

Bluish oral varicosities may often be seen in elderly patients, particularly in the ventrum and lateral margin of the tongue. They are benign and inconsequential.

Erythroplasia

Erythroplasia (erythroplakia) is a red velvety lesion level with, or depressed below, the surrounding mucosa. It is uncommon and affects patients of either sex in their sixth and seventh decades [1–3]. Erythroplasia usually involves the floor of the mouth, the ventrum of the tongue, or the

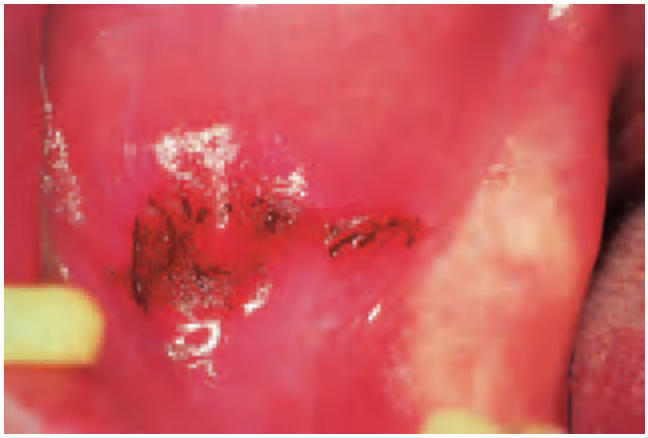

Fig. 66.63 Erythroplasia. (Courtesy of Professor R.A. Cawson, Eastman Dental Institute, London, UK.)

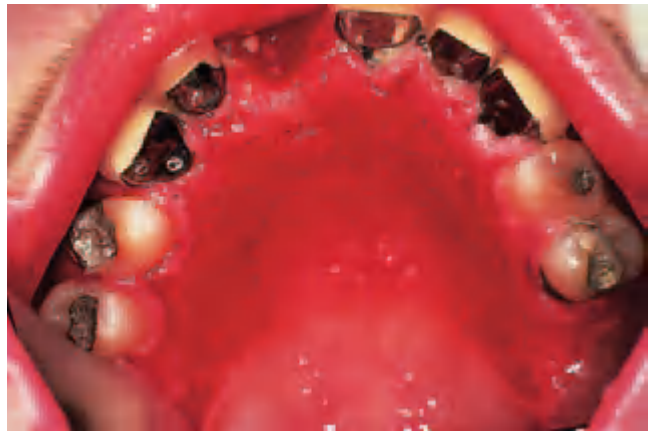

Fig. 66.64 Denture-induced stomatitis showing diffuse erythema in the denture-bearing area.

soft palate (Fig. 66.63) [1–4]. With regard to the risk of erythroplasia, a more than additive interaction has been found between tobacco chewing and low vegetable intake, whereas a more than multiplicative interaction has been found between alcohol drinking and low vegetable intake, and between drinking and low fruit intake [5].

Some 75–90% of cases of erythroplasia prove to be carcinoma or carcinoma *in situ* or show severe dysplasia. The incidence of malignant change in erythroplasia is 17 times higher than in leukoplakia.

Areas of erythroplasia should be excised and sent for histological examination.

Erythematous candidiasis

Oral candidiasis can cause erythema and soreness of the oral mucosa, with or without the more usual thrush.

Denture-related stomatitis

SYN. DENTURE SORE MOUTH

This common form of mild, chronic, atrophic oral candidiasis occurs only beneath a denture, usually a complete upper denture, and is not often sore despite its name [1,2]. Dentures worn throughout the night, or with a dry mouth, favour development of this infection with *Candida* species. It is not caused by allergy to the denture material and it is not clear why only some denture wearers develop the condition. It is a disease mainly of the middle-aged or elderly and is more prevalent in women than men. Patients appear otherwise healthy. In some studies of institutionalized elderly patients, as many as 70% have been found to have denture-related stomatitis but overall it is considerably less common, particularly in normal healthy subjects.

Denture-related stomatitis consists of mild inflammation and erythema of the mucosa beneath a denture (Fig. 66.64).

Aetiopathogenesis [5–8]. Dentures can produce a number of ecological changes, including the following:

- Changes in the oral flora.
- Plaque accumulation between the mucosal surface of the denture and the palate.
- Saliva present between the maxillary denture and the mucosa may have a lower pH than usual.
- Accumulation of microbial plaque (bacteria and/or yeasts) on and in the fitting surface of the denture and the underlying mucosa.

In some persons, the cause appears to be related to a non-specific plaque [1–4]. This plaque undergoes sequential development, and is colonized by *Candida* organisms. Although there is no increased aspartyl proteinase production from the *Candida* involved, the decreased salivary flow and a low pH under the denture probably results in a high *Candida* enzymatic activity, which can cause inflammation.

Yeasts such as *Candida* are isolated in up to 90% of persons with denture-related stomatitis but even 66% of denture wearers have them. The most frequently isolated species is *Candida albicans*. Of the *C. albicans* isolates, 75% are serotype A and 25% serotype B, a significant increase in serotype B compared with a control group of non-denture-wearing HIV-seronegative individuals with oral candidiasis. Resistogram strain-C is the most

predominant (24% of total isolates), while strain A-CDE is the least (1.5% of total isolates). Adherence of *C. albicans* to denture-base materials *in vitro* is related to the hydrophobicity of the organism. When *Candida* is involved in denture-related stomatitis, the more common terms '*Candida*-associated denture stomatitis', 'denture-induced candidiasis' or 'chronic atrophic candidiasis' are used. However, denture-induced stomatitis is not exclusively associated with *Candida* and, occasionally, other factors such as bacterial infection or mechanical irritation are at play.

Histological examination of the soft tissue beneath dentures has shown proliferative or degenerative responses with reduced keratinization and thinner epithelium.

However, it not clear why only some denture wearers develop denture-related stomatitis, since most patients appear otherwise healthy. There have been few studies. Patients with denture-related stomatitis have no serious cell-mediated immune defects but they may sometimes be deficient in migration inhibition factor and may have overactive suppressor T cells or other T-lymphocyte/phagocyte defects. Mean concentrations of serum IL-6 and tumour necrosis factor (TNF)-α are statistically significantly higher and soluble TNF receptors lower in denture wearers compared with controls but there are no differences when stomatitis is present [9].

Predisposing factors. Dental appliances (mainly maxillary dentures), especially when worn throughout the night, or with a dry mouth, are the major predisposing factor. Diabetes or a high-carbohydrate diet occasionally predispose [10–12] and HIV is a rare underlying factor.

Factors that are usually *not* significant include allergy to the dental material (if it were, denture-related stomatitis would affect mucosae other than just that beneath the appliance), trauma (the condition is more common beneath maxillary dentures than mandibular dentures, yet trauma is more common with the latter), pharmacological agents and smoking.

Clinical features. The characteristic presenting features of denture-related stomatitis are:

- chronic erythema and oedema of the mucosa that contacts the fitting surface of the denture (usually a complete upper denture);
- the mucosa below lower dentures is rarely involved;
- erythema is restricted to the denture-bearing area;
- usually there are no symptoms;
- uncommon complications include angular stomatitis, and papillary hyperplasia in the vault of the palate.

Diagnosis. Denture-related stomatitis is a clinical diagnosis; the lesions have been classified into three clinical types (Newton's types), increasing in severity.

- Type 1: a localized simple inflammation or a pinpoint hyperaemia.
- Type 2: an erythematous or generalized simple type presenting as more diffuse erythema involving a part of, or the entire, denture-covered mucosa.
- Type 3: a granular type (inflammatory papillary hyperplasia) commonly involving the central part of the hard palate and the alveolar ridge.

Management. Any underlying systemic disease should be treated where possible.

The denture plaque and fitting surface is infested, usually with *C. albicans*. This must be removed regularly. Therefore, to treat and prevent recurrence of denture-related stomatitis, dentures should be removed from the mouth at night, cleaned and disinfected, and stored in an antiseptic. Cleansing is crucial to therapeutic success [13]. Denture cleansers can be divided into groups according to their main components: alkaline peroxides, alkaline hypochlorites, acids, yeast lytic enzymes, proteolytic enzymes and disinfectants such as hypochlorite. Denture soak solution containing benzoic acid completely eradicates *C. albicans* from the denture surface as it is taken up into the acrylic resin. An oral rinse containing chlorhexidine gluconate also results in complete elimination of *C. albicans* on the acrylic resin surface of the denture, and in reduction of palatal inflammation. A protease-containing denture soak (Alcalase) is also an effective way of removing denture plaque, especially when combined with brushing. Hypochlorite is an effective anticandidal but can turn chrome cobalt dentures black.

The mucosal infection is eradicated by brushing the palate and using antifungals for at least 4 weeks. Effective agents include nystatin pastilles or suspension, amphotericin lozenges, miconazole gel or fluconazole suspension or tablets, administered concurrently with an oral antiseptic such as chlorhexidine, which itself has antifungal activity. Isolates are usually sensitive to amphotericin and nystatin but less sensitive to miconazole. Fluconazole is as effective as newer agents such as itraconazole. The cyclodextrin solution and the capsule preparations of itraconazole are equally effective adjuncts in the treatment but, because of side effects, the capsules are preferred. Miconazole lacquer or fluconazole in tissue conditioners applied to the denture fitting surface are also effective [14–16].

Surgery may be needed to excise papillary hyperplasia [17].

Acute candidiasis

Acute oral candidiasis may complicate corticosteroid or antibiotic therapy, particularly with long-term broad-spectrum antimicrobials such as used in transplant or terminally ill patients [1–3]. There is widespread erythema and soreness of the oral mucosa, sometimes with thrush, particularly noticeable on the tongue.

HIV-associated candidiasis

Candida infections in and around the mouth have increased greatly, particularly as the HIV epidemic has spread, and now other species (especially *C. krusei*) and antifungal resistance are serious clinical realities [1–4]. There may be transmission of *Candida* species from HIV-infected persons [5] and new species and clades are being recognized [6]. The most dominant oral species, in decreasing order of frequency, are:

- *C. albicans*;
- *C. tropicalis*;
- *C. glabrata*;
- *C. parapsilosis*;
- *C. krusei*;
- other *Candida* species such as *C. dubliniensis*, *C. africanus* and *C. inconspicua*;
- other genera (*Rhodotorula*, *Saccharomyces*, etc.), which are rare and transient.

Erythematous or atrophic candidiasis may arise as a consequence of persistent acute pseudomembranous candidiasis when the pseudomembranes are shed, may develop *de novo*, or in HIV infection may precede pseudomembranous candidosis. The clinical presentation is of erythematous areas generally on the dorsum of the tongue, palate or buccal mucosa. Lesions on the dorsum of the tongue present as depapillated areas. Red areas are often seen in the palate in HIV disease. There can be an associated angular stomatitis and/or thrush.

Thrush is a well-recognized feature of T-cell immunodeficiencies, particularly after the severe T-cell immunosuppression necessary for organ transplantation and in other secondary immunodeficiencies, such as leukaemia, diabetes or HIV/AIDS. It is a common and early feature of AIDS.

Furthermore, with increasing use of antimycotic therapy, especially in HIV disease, there is a shift towards not only resistant *C. albicans*, as well as the appearance of novel species, but also other species such as *C. glabrata* and *C. krusei*. Thrush is characterized by white patches on the surface of the oral mucosa, tongue and elsewhere. The lesions develop to form confluent plaques that resemble milk curds, and can be wiped off to reveal a raw, erythematous and sometimes bleeding base. Complications of oropharyngeal thrush may sometimes present as lesions of the adjacent mucosa, particularly in the upper respiratory tract and the oesophagus. The combination of oral and oesophageal candidiasis is particularly prevalent in HIV-infected patients. Antifungal therapy is indicated.

Median rhomboid glossitis

SYN. CENTRAL PAPILLARY ATROPHY OF THE TONGUE

Aetiology. This red, depapillated, rhomboidal area in the centre line of the dorsum of the tongue, just anterior to the sulcus terminalis, was formerly thought to be caused by persistence of the tuberculum impar. However, it is now thought to be associated with candidiasis [1–3]. Multiple oral lesions may occasionally be present, especially a 'kissing' lesion in the palatal vault [4,5]. Smoking, denture wearing and, occasionally, immune defects (including HIV) and diabetes predispose to this lesion [6,7].

Pathology. Histology shows irregular pseudoepitheliomatous epithelial hyperplasia that may resemble a carcinoma but it is not a malignant condition.

Clinical features. There is typically a red central lesion of somewhat rhomboidal shape anterior to the sulcus terminalis on the dorsum of the tongue (Fig. 66.65). Occasionally, there is a nodular component.

There may also sometimes be a coexistent erythematous candidiasis in the palate [4,5], which some have termed 'chronic oral multifocal candidiasis'.

Diagnosis and management. Median rhomboid glossitis is usually diagnosed on clinical grounds, although biopsy may be indicated, since some lesions are nodular and may simulate a neoplasm. It may respond to the use of antifungals and to cessation of smoking.

Fig. 66.65 Median rhomboid glossitis.

Desquamative gingivitis

This is usually caused by pemphigoid or lichen planus.

Loss of elasticity of oral tissues

Fibrosis of oral tissues can follow burns or irradiation. It may also be associated with habits such as the chewing of betel nut (areca), which predisposes to oral submucous fibrosis (see below) and may be caused by a connective tissue disorder such as scleroderma. Rarely it is occupational (polyvinylchloride workers). Epidermolysis bullosa and mucous membrane pemphigoid may cause scarring and the orofacial region is occasionally involved in multiple idiopathic fibrosis [1].

REFERENCE

Oral submucous fibrosis

Aetiology. Oral submucous fibrosis is a chronic disease of the oral mucosa that appears to be caused by exposure to constituents of the areca nut. It is found virtually exclusively in persons from the Indian subcontinent; most of

those affected chew areca nut with tobacco, betel leaf and lime [1,2].

Pathology. There is a subepithelial chronic inflammatory reaction with fibrosis extending to the submucosa and muscle. Epithelial changes range from atrophy to keratosis and there may be dysplasia.

Clinical features. Oral submucous fibrosis develops insidiously, often initially presenting with oral dysaesthesia and a non-specific vesicular stomatitis [3]. Later there may be symmetrical fibrosis of the cheeks, lips or palate, which may be symptomless and noted only as bands running through the mucosa. This can, however, become so severe that the affected site becomes white and firm, with severely restricted opening of the mouth.

Oral submucous fibrosis appears to be restricted to the mouth, although many patients are also anaemic. Oral submucous fibrosis may predispose to the development of oral carcinoma, which occurs in 2–10% of patients over a period of 10 years [4,5].

The diagnosis can be confirmed by biopsy.

Treatment. Management is difficult. Intralesional corticosteroids and jaw exercises may be useful in the early stages, but surgery may be needed to relieve the fibrosis [1,6].

Systemic sclerosis (see Chapter 56)

Oral features are common in systemic sclerosis and are generally more obvious in those with diffuse than localized scleroderma. About 70% of patients have xerostomia, and there is an increase in both caries and periodontal disease. A characteristic finding is of increased width of the periodontal ligament space of all teeth on radiography [1]. There are mandibular erosions in the angle particularly, but also in the condyle, coronoid or digastric regions. Telangiectasia may be seen and most patients have restricted oral opening with linear wrinkles of the lips [2,3].

Lumps and swellings

Lumps in the mouth range from simple anatomical variants, which can cause the patient considerable concern, to lumps caused by inflammatory, cystic (Fig. 66.66), neoplastic and other disorders (Table 66.23).

Foliate papillitis

The foliate lingual papillae may become inflamed and swell. Because of their location on the posterolateral tongue this may give undue concern about malignancy. The condition resolves spontaneously.

Angio-oedema

Oral swelling may be a feature of acquired angio-oedema. The swelling is of acute onset, may affect the lips, tongue or other areas, and is often only mild and transient, although there is always the potential for obstruction of the airway. Local anaesthetics [1] or more commonly angiotensin-converting enzyme inhibitors [2–6] may cause angio-oedema, which can occasionally be lethal [4].

It may respond to a sympathomimetic agent such as epinephrine (adrenaline) or to antihistamines.

Oral allergy syndrome

Oral allergy syndrome is the combination of oral pruritus, irritation and swelling of the lips, tongue, palate and throat, sometimes associated with other allergic features such as rhinoconjunctivitis, asthma, urticaria–angio-oedema, and anaphylactic shock, precipitated mainly by fresh foods such as fruits and vegetables, sometimes by pollens because of cross-reacting allergens [1,2]. Cooking often destroys the allergens.

It may respond to antihistamines or to a sympathomimetic agent such as ephedrine which can be taken by mouth.

Osteoma mucosae

SYN. OSSEOUS CHORISTOMA

There are rare cases of osteoma of the oral mucosa, usually in the tongue. Most have been in females in the third and fourth decades and have arisen as pedunculated, hard, painless lumps on the dorsum of the tongue immediately posterior to the foramen caecum [1–3]. They may arise from thyroid anlages. Simple excision suffices.

REFERENCES

1 Busuttil A. An osteoma of the tongue. *J Laryngol* 1977; **91**: 259–61.

Abscesses

Most intraoral abscesses are odontogenic in origin, as a final consequence of dental caries. Most abscesses discharge in the mouth on the buccal gingiva but occasionally discharge palatally, lingually, on the chin or submental region (Fig. 66.67), or elsewhere. Very occasionally abscesses follow trauma or a foreign body, or rarely are related to unusual oral infections such as actinomycosis [1], nocardiosis or botryomycosis [2]. Drainage and appropriate antimicrobials are indicated [3]. Dental

Fig. 66.67 Sinus on chin related to a dental abscess on a mandibular incisor tooth.

attention is required; dental abscesses are drained by tooth extraction, incision and drainage, or through the root canal (endodontics).

3 Luker J. A case of lingual abscess. *Br Dent J* 1985; **159**: 300.

Sarcoidosis

Isolated nodules [1,2], gingival lesions [3], facial or labial swelling [4] and salivary gland involvement are the main oral or perioral lesions of sarcoidosis, but are uncommon. However, even where the mucosa is clinically normal, patients with sarcoidosis may have characteristic changes in palatal or labial salivary gland biopsies [5].

5 Van Maarsseveen ACMTH, Van der Waal I, Stam J *et al*. Oral involvement in sarcoidosis. *Int J Oral Surg* 1982; **11**: 21–9.

Pulse granuloma

SYN. LEWAR'S DISEASE

Chronic mandibular periostitis caused by embedded vegetable matter of dietary origin is uncommon but typically presents as a submucosal lump over the lower alveolus. Histology shows amorphous hyaline material and a granulomatous inflammatory reaction [1]. Excision suffices.

REFERENCE

1 Keirby FAR, Soames JV. Periostitis and osteitis associated with hyaline bodies. *Br J Oral Surg* 1985; **23**: 346–50.

Denture-induced hyperplasia

SYN. DENTURE GRANULOMA; EPULIS FISSURATUM

Where a denture flange is overextended and irritates the vestibular mucosa, a linear reparative process may result, eventually producing an elongated fibroepithelial enlargement known as denture-induced hyperplasia [1]. The pathology is that of a fibrous lump (see p. 66.20).

Firm, leaf-like, painless swellings are seen, usually in the buccal or labial vestibule.

A denture-induced granuloma should be excised and examined histologically, if modification of the denture does not induce regression. Rarely, a denture granuloma arises because some other lesion develops beneath a denture and causes the mucosa to be irritated.

REFERENCE

1 Budzt-Jorgensen E. Oral mucosal lesions associated with the wearing of removable dentures. *J Oral Pathol* 1981; **10**: 65–80.

Mucocele (mucous cyst)

SYN. MUCOUS RETENTION CYST; RANULA; MUCOCELE; MYXOID CYST OF LIP

Superficial mucoceles are seen mainly in lichen planus. Deeper mucoceles are more common and are usually seen in the lower labial mucosa (Fig. 66.68), usually resulting from the escape of mucus into the lamina propria from a damaged minor salivary gland duct.

Fig. 66.68 Mucocele in a typical site.

They appear as painless dome-shaped, translucent, whitish blue papules or nodules [1].

Care should be taken to ensure that the lesion is not a salivary gland tumour with cystic change, especially when dealing with an apparent mucous cyst in the upper lip. The cysts can be excised but they also respond well to cryosurgery, using a single freeze–thaw cycle [2].

Buccal fat-pad herniation

Trauma may rarely cause the buccal pad of fat to herniate through the buccinator muscle, producing an intraoral swelling [1]. This usually occurs in males under the age of 4 years. Surgery is indicated.

REFERENCE

1 Fleming P. Traumatic herniation of buccal fat pad: a report of two cases. *J Oral Surg* 1986; **24**: 265–8.

Oral papilloma

Aetiology. These are caused by HPV [1].

Pathology. Histology includes acanthotic and sometimes hyperkeratotic epithelium with occasional koilocytosis.

Clinical features. Papillomas can appear anywhere in the mouth, but are most common at the junction of the hard and soft palate. The papilloma is a white or pink, cauliflower-like lesion that may resemble a wart. Papillomas of normal colour may be confused with the commoner fibroepithelial polyps, although the latter are commonest at sites of potential trauma.

Prognosis. Unlike some papillomas of the larynx or bowel, oral papillomas remain benign.

Diagnosis. Oral papillomas should be examined histologically to establish a correct diagnosis.

Treatment. Excision must be total, deep and wide enough to include any abnormal cells beyond the zone of the pedicle.

Fig. 66.69 Genital warts on the lower lip in HIV infection. (There is also a healing herpes simplex lesion on the lip.)

Warts (see Chapter 25)

Common warts (verrucae vulgaris) and venereal warts (condyloma acuminatum) are both caused by papillomaviruses [1–3]. They are rare in the mouth (Fig. 66.69) but are more common in HIV disease. None is known to be premalignant. Most can be removed by excision, cryosurgery or laser, or podophyllum or imiquimod.

Focal epithelial hyperplasia

SYN. HECK'S DISEASE

Focal epithelial hyperplasia is a rare, benign, familial disorder with no sex predisposition, characterized by multiple, soft, circumscribed, sessile, nodular elevations of the oral mucosa [1,2].

Heck's disease occurs particularly in native Americans and in Inuits in Greenland but has been reported rarely from many other countries. The prevalence in Greenland and Venezuela approaches 35% [1,3,4].

Aetiology. The papillomaviruses HPV-13 and HPV-32 appear to be causal in patients with the genetic predisposition to focal epithelial hyperplasia [5–8].

Pathology. The characteristics of focal epithelial hyperplasia are local epithelial hyperplasia, acanthosis and elongated 'Bronze Age axe' rete ridges, together with a ballooning type of nuclear degeneration. Epithelial cells have a pseudomitotic appearance.

Clinical features. Among native Americans, focal epithelial hyperplasia mainly affects children and usually involves the lower lip, whereas in the Inuit and in white people the lesions are found mainly in the fourth decade and later and often affect the tongue. This is a benign asymptomatic condition, requiring only reassurance.

Rhabdomyoma

Rhabdomyomas are rare but most extracardiac rhabdomyomas present in the mouth, typically as lumps in the floor of mouth, tongue or soft palate [1,2]. Most are seen in the sixth decade, predominantly in males. Surgery is effective provided total excision is achieved.

REFERENCES

Rhabdomyosarcoma

Some 45% of soft-tissue sarcomas in the head and neck region are rhabdomyosarcomas. The most common oral presentation is a progressively enlarging mass; some 20% have enlarged regional lymph nodes [1]. In advanced disease there may be pain, paraesthesia, trismus or loosening of teeth.

The prognosis is poor. Treatment includes cytotoxic chemotherapy, surgery and radiotherapy.

REFERENCE

1 Bras J, Batsakis JG, Luna MA. Rhabdomyosarcoma of the oral soft tissues. *Oral Surg* 1987; **64**: 585–96.

Nodular fasciitis (see Chapter 53)

Nodular (pseudosarcomatous) fasciitis affects the head and neck in 20% of cases but rarely involves the mouth [1,2].

Verruciform xanthoma

Although verruciform xanthoma was originally described as a distinct oral entity, it is now also known occasionally to affect the skin and non-oral mucosae [1]. The aetiology is unknown but may be a reaction to some irritant.

The lesions consist of parakeratotic verruciform epithelium, with large foamy xanthoma cells containing slightly PAS-positive granules and abundant lipid in the lamina propria between the epithelial pegs [2].

Verruciform xanthoma is usually a solitary symptomless lesion, typically on the gingiva, with a normal, pale, reddish or keratotic surface [1,2]. Excision is only rarely followed by recurrence.

Lipoma (see Chapter 55)

Lipomas are uncommon in the mouth, comprising less than 5% of oral benign tumours [1]. They present as slow-growing, spherical, smooth and soft semi-fluctuant lumps with a characteristic yellowish colour. Most involve the buccal mucosa or floor of mouth. Occasionally, although benign, they infiltrate. Histology shows adult fat cells

gathered into lobules by vascular septa of fibrous connective tissue. Surgery is rarely indicated except for infiltrating lipomas.

REFERENCE

Myxoma

Myxomas are rare in the oral cavity. They can arise in bone or soft tissue and, although benign, are aggressive and difficult to eradicate because of the tendency to infiltrate normal tissue.

Leiomyoma

This benign tumour of smooth muscle is rare in the oral cavity but usually affects the tongue or palate.

Macroglossia

The tongue may be congenitally enlarged (macroglossia) in Down's syndrome or Beckwith–Wiedemann syndrome or where there is an angioma. It may also enlarge in angio-oedema, gigantism, acromegaly or amyloidosis.

Myeloma and paraproteinaemias

Multiple myeloma very occasionally presents with an intraoral mass or oral bleeding. Bone lesions are more common. Solitary plasmacytomas may also be seen; indeed, some 80% of these rare tumours are found in the head and neck region but typically in the nasal cavity or pharynx rather than in the mouth [1,2].

Waldenström's macroglobulinaemia

Oral manifestations in Waldenström's macroglobulinaemia include purpura, ulceration and occasional mental nerve anaesthesia [3–5].

Fig. 66.70 Macroglossia and oral petechiae in amyloidosis.

Franklin's disease

SYN. HEAVY-CHAIN DISEASE

Palatal oedema and oral ulceration have been described in a few patients with heavy-chain disease, but the former feature is not as invariable as initially described [1,2].

REFERENCES

Thrombotic thrombocytopenic purpura

This may present with oral purpura and/or spontaneous gingival haemorrhage [1,2]. Gingival biopsy is a recommended investigation [3,4].

Amyloidosis (see Chapter 57)

In primary amyloidosis the tongue is enlarged and hard. There may also be yellowish submucosal nodules, lumps or petechiae (Fig. 66.70). Rarely, there are similar deposits elsewhere (e.g. in the soft palate), jaw claudication, salivary gland swelling or xerostomia [1–5].

Secondary amyloidoses rarely involve the mouth except in the case of multiple myeloma or haemodialysis-

associated amyloid, which may occasionally produce oral nodules [6,7].

Some 10% of patients with oral amyloidosis have amyloid in their submandibular glands. Solitary intraoral amyloid is rare [8].

Congo red or thioflavine T staining of a biopsy usually confirms the diagnosis, although in extreme cases the deposits are seen on haematoxylin and eosin staining. Treatment is unsatisfactory but the underlying disease, where present, should be treated.

Table 66.25 Liver diseases.

Disease	Oral manifestations
Most liver diseases with jaundice	Bleeding tendency Jaundice
Alcoholic cirrhosis	Bleeding tendency Sialosis
Chronic active hepatitis	Lichen planus
Primary biliary cirrhosis	Sjögren's syndrome Lichen planus
Hepatitis C	Lichen planus Sjögren's syndrome

Table 66.26 Psychiatric disease.

Disease	Oral manifestations
Depression, hypochondriasis and various psychoses	Various complaints such as dry mouth, discharges, pain, disturbed taste and sensation Drug reactions Often multiple complaints Artefactual ulcers
Anxiety states	Cheek biting Bruxism (teeth grinding)
Bulimia	Tooth erosion

Table 66.24 Endocrine disorders.

Disease	Oral manifestations
Pituitary dwarfism	Microdontia Retarded tooth eruption
Congenital hypothyroidism	Macroglossia Retarded tooth eruption
Congenital hypoparathyroidism	Dental hypoplasia May be chronic candidiasis if associated immune defect
Gigantism/acromegaly	Spaced teeth Mandibular prognathism Macroglossia Megadontia (in gigantism)
Hyperparathyroidism	Bone rarefaction Brown tumours
Addison's disease	Mucosal hyperpigmentation
Diabetes mellitus	Periodontal disease Xerostomia Candidiasis Sialosis Lichen planus
Pregnancy	Gingivitis Epulis
Precocious puberty	Accelerated tooth eruption (fibrous dysplasia in Albright's syndrome)

Table 66.27 Drug effects.

Tissue	Drug effect	Drugs commonly implicated
Teeth	Discoloration	Tetracyclines
		Chlorhexidine
	Root anomalies	Phenytoin
		Cytotoxic drugs
Gingiva	Swelling	Phenytoin
		Ciclosporin
		Nifedipine
		Diltiazem
Salivary glands	Dry mouth	Tricyclic antidepressants
		Phenothiazines
		Antihypertensives
		Lithium
Taste	Disturbed	Metronidazole
		Penicillamine
Facial movements	Dyskinesias	Phenothiazines
		Metoclopramide
Mucosa	Thrush	Broad-spectrum antimicrobials
		Corticosteroids
		Cytotoxic drugs
	Ulcers	Cytotoxic drugs
		Non-steroidal anti-inflammatory agents
	Lichenoid lesions	Non-steroidal anti-inflammatory agents
	Erythema multiforme	Barbiturates
		Sulphonamides

Table 66.28 Gastrointestinal diseases.

Disease	Oral manifestations
Pernicious anaemia	Ulcers
	Glossitis
	Angular stomatitis
	Red lesions
Any cause of malabsorption	Ulcers
	Glossitis

Acquired lip lesions

Cheilitis

SYN. INFLAMMATION OF THE LIPS

Cheilitis may arise as a primary disorder of the vermilion zone or the inflammation may extend from nearby skin or, less often, from the oral mucosa (Table 66.39) [1].

REFERENCE

1 Scully C, Bagan JV, Eisen D, Porter S, Rogers RS. *Dermatology of the Lips*. Oxford: Isis Medical Media, 2000.

'Chapping' of the lips

Chapping is a reaction to adverse environmental conditions usually caused by exposure to freezing cold or to hot dry winds. The keratin of the vermilion loses its plasticity, so that the lips become sore, cracked and scaly. The affected person tends to lick the lips, or to pick at the scales, which may aggravate the condition.

Table 66.32 Primary and secondary immunodeficiencies.

Disease	Oral manifestations
Severe combined immunodeficiency	Candidiasis
	Viral infections
	Ulcers
	Absent tonsils
	Recurrent sinusitis
Sex-linked agammaglobulinaemia	Ulcers
	Recurrent sinusitis

Cyclic neutropenia	Ulcers
	Severe periodontitis
	Eczematous lesions of the face
Chronic granulomatous disease	Candidiasis
	Enamel hypoplasia
	Acute gingivitis
	Ulcers
Myeloperoxidase deficiency	Candidiasis
Chédiak–Higashi syndrome	Ulcers
	Periodontitis
Job's syndrome	Abnormal facies
Secondary immune defects	Ulcers
	Periodontitis
	Candidiasis
	Viral infections
	Malignant neoplasms
	Hairy leukoplakia

Table 66.33 Metabolic disorders.

Disease	Oral manifestations
Congenital hyperuricaemia (Lesch–Nyhan syndrome)	Self-mutilation
Mucopolysaccharidoses	Spaced teeth
	Retarded tooth eruption
	Cystic radiolucencies
	Temporomandibular joint anomalies
	Enamel defects
	Gingival hyperplasia
Niemann–Pick disease	Retarded tooth eruption
	Loosening of teeth
	Mucosal pigmentation
Mucolipidoses	Gingival hyperplasia
Hypophosphatasia	Loosening and loss of teeth
Erythropoietic porphyria	Reddish teeth
	Bullae/erosions
	Dental hypoplasia
Amyloidosis	Macroglossia
	Purpura
Vitamin B_{12} or folic acid deficiency	Ulcers
	Glossitis
	Angular stomatitis
Scurvy	Gingival swelling
	Purpura
	Ulcers
Rickets (vitamin D dependent)	Dental hypoplasia
	Large pulp chambers
	Large tooth eruption

Table 66.34 Collagen–vascular diseases.

Disease	Oral manifestations
Any collagen–vascular disease	Sjögren's syndrome
Rheumatoid arthritis	Temporomandibular arthritis
	Drug reaction (e.g. lichenoid)
	Ulcers in Felty's syndrome
	Temporomandibular ankylosis in juvenile arthritides
Lupus erythematosus	White lesions
	Ulcers
Systemic sclerosis	Stiffness of lips, tongue, etc.
	Trismus
	Telangiectasia
	Mandibular condylar resorption
	Periodontal ligament widened on X-ray

Treatment is by application of petroleum jelly and avoidance of the adverse environmental conditions.

Eczematous cheilitis

The lips are often involved secondarily to atopic eczema (see Chapter 18). The treatment is with emollients and topical corticosteroids. A potent steroid such as fludrocortisone may be required to bring the condition under control.

Contact cheilitis

Contact cheilitis is an inflammatory reaction provoked by the irritant or sensitizing action of chemicals. Many cases are caused by lipsticks or lipsalves but a large number of substances have been incriminated.

Lipsticks and lipsalves (Table 66.40). Lipsticks are composed of mineral oils and wax (which form the stick), castor oil as a solvent for the dyes, lanolin as an emollient, preservatives, perfumes and colours [1]. The dyes may include azo dyes and eosin, a bromofluorescein derivative. An eosin

Table 66.35 Miscellaneous disorders.

Disease	Oral manifestations
Sarcoidosis	Xerostomia Salivary gland swelling Heerfordt's syndrome (parotid swelling, lacrimal swelling, facial palsy) Gingival swelling
Behçet's syndrome	Ulcers like aphthae
Sweet's syndrome	Ulcers like aphthae
Reiter's syndrome	Ulcers
Langerhans' cell histiocytosis	Loosening of teeth Jaw radiolucencies
Wegener's granulomatosis	Gingival swellings Ulcers
Kawasaki disease (mucocutaneous lymph node syndrome)	Sore tongue Cheilitis
Ellis–van Creveld syndrome (chondroectodermal dysplasia)	Multiple fraena Short roots Hypodontia
Tuberous sclerosis	Enamel defects Gingival fibromatosis

Disease	Oral manifestations
Syphilis	Chancre Mucous patches Ulcers Gumma Pain from neurosyphilis Leukoplakia Lymph node enlargement Hutchinson's teeth in congenital syphilis
Gonorrhoea	Pharyngitis (occasionally) Gingivitis (occasionally) Temporomandibular arthritis (rarely)
Tuberculosis (including atypical mycobacteria)	Ulcers (rarely)
Leprosy	Cranial nerve palsies (rarely)
Lyme disease	Facial palsy
Candidiasis	White lesions Red lesions Angular stomatitis
Cryptococcosis	Ulcers
Coccidioidomycosis	Ulcers
Histoplasmosis	Ulcers (especially in immune defects)
Blastomycosis	Ulcers
Paracoccidioidomycosis	Ulcers
Mucormycosis, aspergillosis	Antral infections or ulcers (especially in immune defects)

Table 66.37 Viral infections.

Disease	Oral manifestations
Herpes simplex	Ulcers in primary infection Gingivitis in primary infection Vesicles on lips in recurrence (rarely oral ulcers)
Herpes zoster–varicella	Ulcers in chickenpox, or in zoster of maxillary or mandibular divisions of the trigeminal nerve Pain in maxillary or mandibular zoster
Coxsackieviruses and echoviruses	Ulcers in herpangina and hand, foot and mouth disease
Epstein–Barr virus (in infectious mononucleosis)	Sore throat Tonsillar exudate Palatal petechiae Recurrent parotitis (possibly) Hairy leukoplakia
Measles	Koplik's spots
Mumps	Salivary gland swelling
Papillomaviruses	Warts Papillomas Focal epithelial hyperplasia
Human immunodeficiency virus	
Common	Candidiasis Hairy leukoplakia Gingival and periodontal disease Herpes simplex infection Herpes zoster infection Papillomavirus infection Kaposi's sarcoma Aphthous-like ulcers Xerostomia
Uncommon	Infections *Cryptococcus* Mycobacteria *Histoplasma* Cytomegalovirus Others Salivary gland swelling Sjögren's syndrome-like disease Cranial neuropathies Fetal AIDS syndrome

impurity used to be an important sensitizer [2] but is now rarely if ever used. Other ingredients occasionally incriminated include azo dyes, carmine, oleyl alcohol [3], lanolin, perfumes, azulene, propyl gallate, sesame oil [4], stearates [5], shellac and colophony [6]. Sunscreens in lipstick or lipsalve (e.g. cinnamic aldehyde) can also cause contact cheilitis [7]. Phenyl salicylate and antibiotics have also been incriminated [8,9]. Petrolatum chapsticks may cause an unusual form of acne with a single row of large open comedones along the cutaneous margin of the upper lip [10].

Mouthwashes and dentrifices [11]. Sensitizers used in some toothpastes include essential oils, such as peppermint, cinnamon, clove and spearmint; carvone along with imonene, pinene, phellandrene, dipentene, cineole, linalool, and esters of dihydrocuminyl alcohol and dehydrocarveol; bactericidal agents; propolis, derived from resin collected by bees [12,13]; and tartar-control dentifrices, which contain pyrophosphate compounds [14].

Table 66.38 Neurological disorders.

Disease	Oral manifestations
Facial palsy of any cause	Palsy and poor natural cleansing of mouth on same side
Trigeminal neuralgia	Pain
Bulbar palsy	Fasciculation of tongue
Parkinsonism	Drooling
	Tremor of tongue
	Dysarthria
Neurosyphilis	Pain (rarely)
	Dysarthria
	Tremor of tongue
Cerebral palsy	Spastic tongue
	Dysarthria
	Attrition

Dental preparations. Mercury, eugenol, and plastics including epimine-containing materials can cause cheilitis [15–17].

Foods (Table 66.41). Peppermint, carvone, spearmint [18], citrus fruits [19], artichokes [20], nuts [21], pineapple [22], mangoes [23–25], asparagus [26] and cinnamon oil [27,28] occasionally cause allergic cheilitis and perioral dermatitis. The oil on the peel of citrus fruits is irritant to the skin; in addition, some sweet oranges contain a weakly phototoxic agent that can cause a reaction in pale-skinned people [29].

Miscellaneous objects. Metal hair clips, metal pencils, the cobalt paint on blue pencils [30], nail varnish [31], and the metal, wooden, nickel and reed mouthpieces of musical instruments [32–34] may cause cheilitis.

Clinical features. Lipstick cheilitis is sometimes confined to the vermilion but more often extends beyond. There

may be persistent irritation and scaling or a more acute reaction with oedema and vesiculation.

The other forms of cheilitis vary greatly in their clinical appearance. Those caused by foods commonly also involve the skin around the mouth. If a small, sucked object is responsible, the reaction may be confined to one part of the lips.

Diagnosis. If acute eczematous changes are obviously present, the diagnosis of contact cheilitis presents no difficulty. If the changes are confined to irritation and scaling, the various forms of exfoliative cheilitis must be excluded.

If an allergic reaction is suspected, patch tests should be carried out.

Treatment. Topical corticosteroids will give symptomatic relief but the offending substance must be identified and avoided.

Drug-induced cheilitis

Haemorrhagic crusting of the lips (Fig. 66.71) is a feature of erythema multiforme (particularly in Stevens–Johnson syndrome) (see p. 66.67), but cheilitis can also occur as an isolated feature of a drug reaction.

Aromatic retinoids such as etretinate and isotretinoin cause cheilitis, dryness and cracking of the lips in many patients.

Infective cheilitis

Viral. Rare viral infections such as orf [1,2] and vaccinia [3] can affect the lips.

Fig. 66.71 Haemorrhagic crusting of the lips in Stevens–Johnson syndrome.

Bacterial. Dental infection or occasionally a furuncle or carbuncle may cause swelling of the lip. Impetigo may mimic herpes labialis (see Chapter 27). Cancrum oris (fusospirochaetal infection) may cause labial and buccal necrosis [4,5].

The lip is the most common extragenital site for a primary syphilitic lesion. Most lip chancres in males tend to occur on the upper lip, in females on the lower lip. In secondary syphilis, moist, flat, papulonodular lesions (condylomata lata) often appear at the mucocutaneous junctions and on mucosal surfaces especially at the commissures [6]. The tropical treponematoses may present similarly to syphilis.

Rhinoscleroma initially affects the nasal mucosa but may spread slowly to the upper lip, producing plaques or nodules with sunken centres. The extreme hardness of the infiltrations is characteristic. The lip can appear to fuse to the alveolar process but the overlying skin and mucosa remain normal.

Protozoal. Cutaneous or mucocutaneous leishmaniasis typically causes swellings on the upper lip with later enlargement and destruction of the lip [7–10], reflecting the three stages of oedema, granulomatous proliferation and then necrosis.

Fungal. Blastomycosis and paracoccidioidomycosis are uncommon causes of chronic ulceration affecting the lip, producing very similar clinical lesions to leishmaniasis [11].

Others. Red swollen lips with fissuring and exfoliation are prominent in mucocutaneous lymph node syndrome (Kawasaki disease).

Angular cheilitis

SYN. ANGULAR STOMATITIS

Angular cheilitis is an acute or chronic inflammation of the skin and contiguous labial mucous membrane at the angles of the mouth [1].

Aetiology. Most cases in adults are due to mechanical and/or infective causes, but in children nutritional or immune defects are more prominent causes.

Infective agents. These are the major cause. *Candida* or staphylococci are isolated from most patients [2–4]. Permanent cure can be achieved only by eliminating the *Candida* beneath the upper denture [5]. Candidiasis was probably responsible for some of the cases of cheilitis attributed to allergy to denture materials, since contamination of denture material by *Candida* may cause false-positive patch-test reactions [6].

Immune deficiency, such as diabetes and HIV infection, may present with angular stomatitis. Outbreaks of acute pustular and fissured cheilitis may occur in children, particularly if they are malnourished, and in some cases streptococci or staphylococci have appeared to be causative [7].

Mechanical factors in edentulous patients who do not wear a denture or who have inadequate dentures, and also as a normal consequence of the ageing process, produce an oblique curved fold and keep the small area of skin constantly macerated. The recurrent trauma of dental flossing is a very rare cause of angular cheilitis [8].

Nutritional deficiencies, particularly deficiencies of riboflavin, folate, iron and general protein malnutrition, may produce smooth, shiny, red lips associated with angular stomatitis, a combination called *cheilosis* [1,9–11]. Crohn's disease or orofacial granulomatosis may be found in some [12].

Clinical features. Angular cheilitis presents as a roughly triangular area of erythema and oedema at one, or more commonly both, angles of the mouth (Fig. 66.72). Linear furrows or fissures radiating from the angle of the mouth (rhagades) are seen in the more severe forms, especially in denture wearers.

Diagnosis. This is usually obvious. *Candida* should be sought not only in the lesions but also beneath the denture.

Treatment. Dentures should be removed from the mouth at night and stored in a candidacidal solution such as hypochlorite. Denture-related stomatitis should be treated with an antifungal. Miconazole may be preferable

Fig. 66.72 Angular cheilitis.

treatment for candidiasis (cream applied locally, together with the oral gel) as it has some Gram-positive bacteriostatic action. New dentures that restore facial contour may help. The skin lesions should be swabbed and staphylococcal infection treated with fusidic acid ointment or cream at least four times daily.

Actinic cheilitis

SYN. ACTINIC KERATOSIS OF LIP; SOLAR CHEILOSIS

This is a premalignant keratosis of the lip caused by exposure to solar irradiation.

Fig. 66.73 Chronic actinic cheilitis with leukoplakia. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

Aetiology. Actinic cheilitis is most common in hot dry regions, in outdoor workers and in fair-skinned people (skin types I and II). The vermilion of the lower lip receives a high dose of UV irradiation because it is almost at right angles to the rays of the midday sun and is poorly protected by keratin and melanocytes. Most actinic cheilitis is seen on the lower lip of fair-skinned men in their fourth to eighth decade of life.

Pathology. Histology shows a flattened or atrophic epithelium, beneath which is a band of inflammatory infiltrate in which plasma cells may predominate [1]. Nuclear atypia and abnormal mitoses may be seen in the more severe cases, and some develop into invasive squamous carcinoma [2]. The collagen generally shows basophilic (elastotic) degeneration [3].

Clinical features (Fig. 66.73). Actinic cheilitis tends to affect the lower lip of adults who have had prolonged exposure to sunlight [4]. In the early stages there may be redness and oedema, but later the lips become dry and scaly. Later still, the epithelium becomes palpably thickened with small greyish-white plaques and, eventually, warty nodules may form. Eventually these may undergo malignant change, the possibility of which must always be considered when ulceration develops or when there are other suspect features such as:

- a red and white, blotchy appearance with an indistinct vermilion border;
- generalized atrophy with focal areas of whitish thickening;
- persistent flaking and crusting [5,6].

Diagnosis. This is clinical.

Treatment. Treatment of actinic cheilitis is required to relieve symptoms and to prevent development of squamous carcinoma.

• Topical agents: 5% fluorouracil three times daily for 10 days is suitable [7]. Topical tretinoin [8] or trichloracetic acid [9] may also be effective.
• Vermilionectomy (lip shave) [10–12].
• Laser ablation [13–16].

Following treatment, prevention of recurrence by the regular use of a sunscreen lipsalve containing *p*-aminobenzoic acid probably gives the best protection [17,18].

Particular care should be taken to protect the vermilion of the lips with adequate sunscreens in patients with photosensitivity disorders, such as xeroderma pigmentosum, and in those whose exposure to UVB is high, such as mountaineers, windsurfers and skiers.

Actinic prurigo (see Chapter 24)

Actinic prurigo is a type of familial photodermatitis, seen mainly in native Americans living at high altitudes [1,2] especially in Latin America, and in China [3]. It usually presents in young women as a photosensitive facial rash with pruritic lower lip cheilitis, and it may be associated with conjunctivitis, eyebrow alopecia and pterygia.

Actinic prurigo is due to enhanced sensitivity to sunlight and is distinguished from actinic cheilitis, which is due to prolonged and excessive exposure to UV irradiation, by the relative absence of epidermal dysplasia and solar elastosis [4]. Polymorphous light eruption is almost invariably present in the actinic prurigo of native Americans [5,6].

Treatment is with sunscreens, β-carotene, psoralen and UVA (PUVA), and antihistamines. Oral thalidomide may be tried [7].

Glandular cheilitis

Definition. Glandular cheilitis is characterized by inflammatory changes and swelling of salivary glands in the lips [1–3].

Aetiology. This is an uncommon idiopathic condition which in a few cases has apparently been familial [4]. Although it was originally thought that the condition was due to inflammation of enlarged heterotopic salivary glands, the glands are often normal in size, depth and histology [5]. It is possible that the excessive salivary secretion from minor salivary glands in this condition might be an unusual clinical response to irritation of the lip from some other cause such as actinic damage or repeated licking.

Pathology. In the milder forms there is some fibrosis surrounding the salivary glands, while in the more severe forms there may be a dense chronic inflammatory infiltrate. Only rarely do patients show genuine hyperplasia of the salivary glands or duct ectasia.

Clinical features. The onset is at any age from childhood onwards. In simple glandular cheilitis, the lower lip is slightly thickened and bears numerous pinhead-sized orifices, from which mucous saliva can readily be squeezed. The upper lip is rarely involved [6].

In the more severe suppurative form (*Volkmann's cheilitis*) the lip is considerably and permanently enlarged, and subject to episodes of pain, tenderness and increased

enlargement. The surface is covered by crusts and scales, beneath which the salivary duct orifices may be discovered. In the most severe forms there may be deep-seated infection with abscess formation and fistulous tracts.

The condition can evidently be premalignant; in some series 20–30% of cases progress to squamous cancer. This does, of course, support the suggestion that in many cases glandular cheilitis is a consequence of actinic cheilitis [5].

Treatment. Actinic cheilitis, if identified, should be treated appropriately. If the lips are grossly enlarged, excision of an elongated ellipse of tissue may be required; in other cases shave vermilionectomy may be all that is necessary. Other conditions such as atopic disease or factitial cheilitis would require different treatment.

Granulomatous cheilitis

SYN. MIESCHER'S CHEILITIS

Definition. A chronic swelling of the lip due to granulomatous inflammation of unknown cause.

Nomenclature. Melkersson in 1928 [1] described labial oedema in association with recurrent facial palsy. Rosenthal in 1930 emphasized the role of genetic factors and added scrotal tongue to the syndrome. The full syndrome has since been called Melkersson–Rosenthal syndrome [2].

In Miescher's cheilitis the granulomatous changes are confined to the lip, and this is generally regarded as a monosymptomatic form of Melkersson–Rosenthal syndrome, although the possibility remains that these may be two separate diseases.

Aetiology. The cause is unknown, but there may be a genetic predisposition to Melkersson–Rosenthal syndrome [3]; siblings have been affected and a scrotal tongue may be present in otherwise normal relatives.

There is no convincing evidence that granulomatous cheilitis is due to an infective agent. Some cases may represent a localized form of sarcoidosis [4] or ectopic Crohn's disease [5,6] or orofacial granulomatosis. There is increasing evidence that some patients with granulomatous cheilitis are predisposed to Crohn's disease [6]. In some cases, granulomatous cheilitis is followed some years later by regional ileitis [7–10]. A few patients react to cobalt [11] or to food additives such as cinnamic aldehyde [12–14] and have no extra oral lesions, although these reactions are by no means always relevant; for example, in one study only one of nine patients had a relationship between cheilitis and food intake [15].

Pathology. Biopsy of the swollen lip or facial tissues during the early stages of the disease shows only oedema and perivascular lymphocytic infiltration. In some cases of long duration no other changes are seen, but in others the infiltrate becomes more dense and pleomorphic and small focal granulomas are formed, indistinguishable from sarcoidosis or Crohn's disease. Similar changes may be present in cervical lymph nodes [16–19]. In some cases, small granulomas occur in the lymphatic walls [20].

Clinical features. The condition affects the sexes equally. The earliest manifestations usually develop in childhood or adolescence but may be delayed until middle or old age. The earliest cutaneous manifestation is sudden diffuse or nodular swellings [21] involving the upper lip, the lower lip and one or both cheeks in decreasing order of frequency [5,19]. Labial swelling occurs in about 75% and facial swelling in 50% of patients [22]. Less commonly, the forehead, eyelids or one side of the scalp may be involved. The attacks are sometimes accompanied by fever and mild constitutional symptoms, including headache and even visual disturbance. At the first episode the oedema typically subsides completely in hours or days, but after recurrent attacks the swelling may persist, and slowly increases in degree (Fig. 66.74). It gradually becomes firmer and eventually acquires the consistency of firm rubber. After some years, the swelling may very slowly regress.

A fissured or scrotal tongue is seen in 20–40% of cases. It is present from birth in some, which may indicate genetic susceptibility. There may be loss of sense of taste and decreased salivary gland secretion [19].

The regional lymph nodes are enlarged in 50% of cases [3] but not usually very greatly.

Facial palsy of the lower motor neurone type occurs in some 30% of cases. It may precede the attacks of oedema by months or years, but more commonly develops later. Although intermittent at first, the palsy may become permanent. It may be unilateral or bilateral, and partial or complete [19]. Other cranial nerves (olfactory, auditory, glossopharyngeal and hypoglossal) may occasionally be involved. Involvement of the CNS has also been reported, but the significance of the resulting symptoms is easily overlooked as they are very variable, sometimes simulating disseminated sclerosis but often with a poorly defined association of psychotic and neurological features. Autonomic disturbances may occur.

(a)   (b)

Fig. 66.74 Granulomatous cheilitis of the lower lip. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

Diagnosis. The essential feature of the syndrome is the granulomatous swelling of lip or face. In the early attacks clinical differentiation from angio-oedema may be impossible in the absence of either scrotal tongue or facial palsy. Persistence of the swelling between attacks should suggest the diagnosis, which can sometimes be confirmed by biopsy. However, the histological changes are not always conspicuous or specific.

In established cases, other causes of macrocheilia (Table 66.42) must be excluded. Ascher's syndrome associated with blepharochalasia is likely to cause confusion, although the swelling of the lip is caused by redundant salivary tissue and is present from childhood. Lymphoma is a rare differential diagnosis [23].

Treatment. Reactions to dietary components should be sought and possible antigens avoided. The injection of up to 10 mL triamcinolone (10 mg/L) into the lips after local analgesia may be effective [15,24,25]. The injections may have to be repeated every 4–6 months once a response plateau has been reached. This treatment has also been successfully combined with surgical reduction (cheiloplasty) [26,27]. The injections must be continued periodically after the surgery or there may be an exaggerated recurrence of the condition. Surgery alone is relatively unsuccessful [28].

Systemic corticosteroids are rarely indicated [29]. Not all respond [27,30] and adverse effects may be a problem. Clofazimine appears to help the majority of patients [31,32], in a dose of 100 mg twice daily for 10 days, then twice weekly for 4 months. Metronidazole may also produce resolution in granulomatous cheilitis [33,34].

Other treatments which have occasionally been helpful include long-term penicillin, erythromycin, sulfasalazine (sulphasalazine) or ketotifen.

Table 66.42 Macrocheilia: acute or chronic enlargement of one or both lips.

Acute	Chronic
Traumatic	Developmental
Infective	Familial idiopathic
Pyococcal	Double lip
Anthrax	Ascher's syndrome
Diphtheria	Lymphangioma
Primary syphilis	Haemangioma
Trichophytosis	Neurofibroma
Leishmaniasis	Mucopolysaccharidoses
Herpes simplex	Fucosidosis
Trichiniasis	Coffin–Siris syndrome
Angio-oedema	Acquired
Erythema multiforme	Post-traumatic
Actinic cheilitis	Post-infective on basis of developmental
Other forms of cheilitis	lymphatic defect
	Infective
	Tuberculosis
	Leprosy
	Rhinoscleroma
	Leishmaniasis
	Neoplastic
	Melkersson–Rosenthal syndrome
	Cheilitis glandularis
	Sarcoidosis
	Crohn's disease
	Orofacial granulomatosis

Exfoliative cheilitis

SYN. FACTITIOUS CHEILITIS; LE TIC DE LÈVRES

Exfoliative cheilitis is a chronic superficial inflammatory disorder of the vermilion borders of the lips characterized by persistent scaling (Fig. 66.75). The diagnosis is now restricted to those few patients whose lesions cannot be attributed to other causes, such as contact sensitization or light (see actinic cheilitis, p. 66.115). Many of these cases are now thought to be factitious, owing to repeated lip sucking, chewing or other manipulation of the lips [1,2]. There is no association with dermatological or systemic disease, although rare cases are seen in HIV infection. Some are infected with *Candida* species [3].

Fig. 66.75 Factitious cheilitis due to repeated lip sucking.

Most cases occur in girls or young women, and the majority have a personality disorder [4,5]. The process, which often starts in the middle of the lower lip and spreads to involve the whole of the lower or both lips, consists of scaling and crusting, more or less confined to the vermilion border, and persisting in varying severity for months or years. The patient often complains of irritation or burning, and can be observed frequently biting or sucking the lips. In some cases the condition appears to start with chapping or with atopic eczema, and develops into a habit tic.

In a large Russian series, almost half the cases had associated thyroid disease [6], but this observation has not been confirmed.

Diagnosis. Contact and active cheilitis must be carefully excluded. Chronic exfoliative cheilitis is readily contaminated by *Candida*. In such cases the clinical features are variable and may simulate carcinoma, LP or lupus erythematosus.

Treatment. Some cases resolve spontaneously [2,7] or with improved oral hygiene [8]. Reassurance and topical corticosteroids may be helpful in some cases [1], but others require psychotherapy or tranquillizers [7,9].

Plasma cell cheilitis

SYN. PLASMA CELL ORIFICIAL MUCOSITIS

Plasma cell cheilitis is an idiopathic benign inflammatory condition, characterized by dense plasma cell infiltrates in the lips and other mucosae close to body orifices [1–3]. The condition has been reported (under a wide variety of names) to affect the penis, vulva, lips, buccal mucosa, palate, gingiva, tongue, epiglottis and larynx.

Plasma cell cheilitis is the counterpart of Zoon's plasma cell balanitis (see Chapter 68). It presents as circumscribed flat or elevated patches of erythema, usually on the lower lip in an elderly person. The cause is unknown, but it responds to the application of powerful topical corticosteroids such as clobetasol, or to the intradermal injection of triamcinolone [4], or to systemic griseofulvin [5].

A similar lesion, which tends to form a tumorous mass with a hyperkeratotic surface and needs to be differentiated from extramedullary plasmacytoma [6], has been called *plasma-acanthoma* [7,8].

Lupus erythematosus

Involvement of the vermilion zone is quite common in both discoid erythematosus and SLE [1]. Discoid lupus can be premalignant, and should be treated vigorously with topical steroid ointments and sunscreens [2,3]. The cheilitis of SLE tends to be more severe, with erosions and haemorrhagic crusts.

Lupus erythematosus can be very difficult to distinguish from LP of the lips, both clinically and by histology (Fig. 66.76).

Lip fissure

A lip fissure may develop when a patient, typically a child, is mouth-breathing (Fig. 66.77). Otherwise the aetiology may be obscure, though sun, wind, cold weather and smoking are thought to predispose. A hereditary predisposition for weakness in the first branchial arch fusion seems to exist.

Lip fissures are common in Down's syndrome and the lips may also crack in this way if swollen, for example in cheilitis granulomatosa [1–4].

Clinical features. Most lip fissures are seen in males, typically median in the lower lip and chronic, causing discomfort and possibly bleeding from time to time. Contrary to the clinical impression that fissures are seen only in the lower lip, there is also a high prevalence in the upper lip.

Diagnosis. The diagnosis is clinical.

Fig. 66.77 Lip fissure.

Management. Predisposing factors should be managed. Bland creams may help the lesion heal spontaneously. Otherwise, local applications of 1–2% silver nitrate, 0.5% balsam of Peru, salicylic acid and topical antimicrobials seem less effective than excision, preferably with a Z-plasty [5–7] or cryosurgery [8].

Lip ulcer due to calibre-persistent artery

A calibre-persistent artery is defined as an artery with a diameter larger than normal near a mucosal or external surface. When such arteries occur in the gut wall (Dieulafoy malformation) they may bleed, but in the lip they tend to cause chronic ulceration that can be mistaken for a squamous cancer. The ulcer is attributed to continual pulsation from the large artery running parallel to the surface, although the exact mechanism is obscure [1,2].

Ligation of the artery appears successful [3].

Chapter 67

The Breast

D.A. Burns

The terms 'breasts' and 'mammary glands' are often accepted as equivalent, but they are not strictly synonymous, because the breasts contain tissues (fat, vessels, nerves, etc.) other than the glandular elements.

In the evolutionary sense, the mammary glands are believed to be related to the apocrine sweat glands. They develop from ectodermal mammary ridges ('milk lines'). The classical view, derived from comparative anatomy, that the mammary ridges extend from the base of the upper limb bud to the base of the lower limb bud, is now questioned. It is considered that the mammary ridge extends only over the axillopectoral area [1].

The skin of the breast does not differ structurally from that of the neighbouring chest wall, but the skin of the nipple and areola is very highly specialized. There are individual and racial variations in the size, shape and colour of the nipple and areola. The periphery of the areola contains hair follicles, and the development of coarse terminal hairs in this site may be a cosmetic problem for some women.

The nipple is glabrous. Lactiferous ducts and sebaceous glands open only at its tip. Sensory nerve end organs are also confined to the tip of the nipple. The areola has clusters of large sebaceous glands [2] and the so-called tubercles of Montgomery. These elevations on the areola are produced by the glands of Montgomery [3]. Each of these is a combined sebaceous unit and lactiferous gland, with the lactiferous duct opening into the sebaceous duct close to the areola or occasionally directly onto the areola [1]. The glands of Montgomery are an integral part of the lactiferous apparatus, secreting milk during lactation.

The development of the breasts at puberty requires oestrogens and progesterone, and, in a more minor role, insulin, growth hormone, corticosteroids and prolactin. The adult breast consists of several lobes, each of which is drained by a ductal system ending in a lactiferous duct which opens at the nipple. Each lobe contains up to 40 lobules, and each lobule 10–100 alveoli, the basic secretory units [1].

The breasts enlarge during pregnancy, and the veins become prominent. The areolae also enlarge and become darker. This pigmentation decreases after parturition but does not fade completely.

Although most of the more serious diseases of the breast come within the province of the surgeon, the gynaecologist or the endocrinologist, there are some diseases which affect only the breast skin and are wholly the concern of the dermatologist, and others which may involve the skin and present difficult problems in differential diagnosis.

Supernumerary breasts or nipples [1,2]

Supernumerary (accessory) breasts (polymastia) and the far more common supernumerary nipples (polythelia) usually develop along the course of the milk lines. Accessory glandular tissue most frequently occurs in the axillae [3], but rarely breast components occur in other sites [4–6].

Accessory breast tissue may consist of nipple, areola or glandular tissue singly, or in any combination (Fig. 67.1). The condition is very common in women, with an incidence of around 2–4%, although in the majority of cases the accessory nipple is insignificant, appearing as a small brown papule, usually on the chest wall, just below the breast. Much more rarely, the condition occurs in men, and in one case a fully developed breast was located on the posterior aspect of the thigh of a male [7]. A familial incidence is sometimes noted [8,9].

Polythelia has been found in association with various rare genodermatoses [10–17]. A suggested association between the presence of supernumerary nipples and urinary tract anomalies in children [18–20] prompted debate about whether to investigate the renal tract in children with supernumerary nipples and no other obvious anomaly [21,22]. However, more recent publications have not demonstrated an association between supernumerary nipples and urinary tract malformations [23,24].

The Simpson–Golabi–Behmel syndrome is an X-linked overgrowth syndrome caused by deletions in glypican 3. It is characterized by a specific facial appearance, supernumerary nipples, polydactyly, midline defects and mild mental retardation [25].

An accessory nipple is usually recognized if the diagnosis is considered, but is often otherwise confused with a pigmented naevus. If functional breast tissue is present, enlargement at puberty or in pregnancy may be embarrassing or painful. Simple excision is advisable, as carcinoma may occur.

Breast hypertrophy

Unusually large breasts may be problematic for a number of reasons, and postural abnormalities, backache and psychological disturbance may prompt referral to a plastic surgeon for a reduction mammaplasty. A dermatologist may be consulted about associated problems such as submammary intertrigo.

Breast enlargement in the setting of human immunodeficiency virus (HIV) infection is a relatively recently described phenomenon. It may be a component of the lipodystrophy syndrome (lipomastia), or there may be true gynaecomastia (see below). Breast ultrasonography allows these two states to be differentiated [1].

1 Qazi NA, Morlese JF, King DM *et al*. Gynaecomastia without lipodystrophy in HIV-1-seropositive patients on efavirenz: an alternative hypothesis. *AIDS* 2002; **16**: 506–7.

Gigantomastia (macromastia)

Gigantomastia is a condition in which the female breasts enlarge rapidly until they reach a tremendous size. The overlying skin may become inflamed, oedematous and tender, and there may be striae or even severe ulceration [1]. The condition may occur at puberty [2–4] or during pregnancy [1,5]. The aetiology is obscure, but a suggested cause is increased sensitivity of the breast tissue to normal levels of circulating hormones.

The condition is occasionally familial [6].

Penicillamine therapy can also cause gigantomastia [7,8].

Bromocriptine may be of benefit in patients in whom the condition occurs during pregnancy, but in many patients, and certainly in pubertal cases, reduction mammaplasty is usually required.

Gynaecomastia [1–4]

Gynaecomastia, which may be defined as benign enlargement of the male breast caused by proliferation of the glandular components, can occur as an isolated defect or as a manifestation of a wide range of different pathological states in which it may be a valuable diagnostic sign. The multiplicity of syndromes associated with gynaecomastia reflects the complexity of the hormonal mechanisms concerned in breast enlargement. The patient complains of enlargement of the breast, which may be unilateral or bilateral, and is often tender.

Gynaecomastia can be distinguished from fatty enlargement of the breast in obesity (pseudogynaecomastia) by grasping the breast between thumb and forefinger and moving the digits up towards the nipple with the patient supine. In gynaecomastia a rubbery, mobile, disc-like mound will be felt beneath the areola.

Oestrogens stimulate and androgens inhibit development of breast tissue, and gynaecomastia occurs as a result of a disturbance of the ratio of free androgen to free oestrogen, with a relative increase in oestrogen levels. Peripheral conversion of androgens to oestrogen by aromatization contributes to oestrogen production. Local susceptibility of hormone receptors or local hormone conversion presumably play a role in unilateral gynaecomastia.

The histopathological changes [5] are related to the duration of gynaecomastia and not to its cause. At early stages, there are active proliferating ducts in a vascular fibroblastic stroma. Later, there is progressive fibrosis and hyalinization, and the number of ducts is reduced.

Gynaecomastia may be either physiological or pathological. Some of the causes are listed in Table 67.1.

Physiological gynaecomastia

There are three peaks in the age distribution of physiological gynaecomastia. It occurs in most male neonates due to transplacental passage of oestrogen from the mother. It is usually bilateral, but may be unilateral, and it regresses spontaneously. Some enlargement of the breast occurs at puberty in about 38% of normal boys [6]. The peak incidence is around the age of 14 years. It is unilateral in about 25% of cases. The degree of enlargement is usually slight, but may be sufficient to cause embarrassment and

anxiety. Spontaneous regression usually takes place within a few months, but the enlargement occasionally persists for 2–3 years.

Gynaecomastia also appears to be frequent over the age of 65 years, increasing with age.

Gynaecomastia in endocrine disorders

Gynaecomastia occurs in a very wide range of endocrine disorders. Primary or secondary reduction of testicular androgen production is of special importance. Some tumours of the testis are associated with gynaecomastia, notably seminoma, Leydig cell tumour, Sertoli cell tumour and certain teratomas.

Gynaecomastia occurs in most men with Klinefelter's syndrome, and there is an increased risk of breast cancer in this syndrome [7,8], although other causes of gynaecomastia are not associated with an increased risk of cancer [1].

In other endocrine disorders, gynaecomastia is less common, but may occur in association with tumours or hyperplasia of the adrenal gland, pituitary tumours and hyperthyroidism [9].

Gynaecomastia in nutritional, metabolic, renal and hepatic disease

Gynaecomastia may occur during starvation or on resumption of a more adequate diet after prolonged starvation [10].

Chronic renal failure and haemodialysis may also be associated with gynaecomastia [11–13], although the incidence of gynaecomastia in dialysis patients has decreased in recent years.

Hepatic cirrhosis is usually listed as a cause of gynaecomastia, but one study found that palpable gynaecomastia was not a uniform feature in advanced cirrhosis, and that its prevalence was similar to that in a non-obese, non-cirrhotic, age-matched control population [14].

Gynaecomastia occasionally occurs in association with erythroderma [15].

Drug-induced gynaecomastia [16–33]

Drugs which may produce gynaecomastia are listed in Table 67.2.

They produce their effect by different mechanisms, for example spironolactone and cimetidine are antiandrogens, and neuroleptic drugs produce hyperprolactinaemia (Fig. 67.2). Testosterone might act by peripheral aromatization to oestrogens.

True gynaecomastia, as opposed to breast hypertrophy secondary to lipodystrophy syndrome, can occur with all currently available classes of antiretroviral agents. The mechanism responsible is unclear, but it has been proposed that it may be related to improvement in the T-helper cytokine response after starting highly active antiretroviral therapy (HAART) [28]. Cytokines produced

Fig. 67.2 Gynaecomastia in a man taking stilboestrol for carcinoma of the prostate.

during the immune restoration process have an effect on breast tissue, resulting in gynaecomastia. Once immune restoration has occurred, the cytokine levels fall, and the gynaecomastia resolves spontaneously.

Finasteride treatment of male androgenetic alopecia may be associated with gynaecomastia [29,30], and it has also been recorded in individuals who have used oestrogen-containing hair preparations [31,32] and in a men's hairdresser who had massaged the scalps of his balding customers with an oestrogen-containing lotion [33].

Management of gynaecomastia [3]

In the majority of patients, history and examination will suggest the likely cause of the gynaecomastia. Careful examination for underlying disease and a full drug history are required, particularly if the gynaecomastia is symptomatic, progressive or of recent onset in an adult, but it should be remembered that a large proportion of otherwise normal men have some slight gynaecomastia.

In unilateral disease, particularly in older men, breast cancer should be excluded.

Spontaneous resolution occurs in many 'physiological' cases, or following cessation of the causative drug when it is drug related.

For patients with considerable breast discomfort, or if the condition is severe enough to cause embarrassment, treatment with tamoxifen, clomiphene or danazol has been employed.

In extreme cases, subcutaneous mastectomy or liposuction may be performed by a plastic surgeon.

Black galactorrhoea

Galactorrhoea is sometimes caused by drugs such as phenothiazines. In one patient taking perphenazine, the

droplets of milk were stained black, due to the concomitant administration of minocycline for acne [1]. The pigment which produces the black discoloration of breast milk in women taking minocycline is thought to be due to an iron chelate of minocycline within macrophages [2].

Hypomastia or amastia [1]

Very small breasts are fairly common in otherwise normal women, in whom they may cause considerable psychological distress. There is some evidence of an association between hypoplastic breasts (defined as a breast size of 200 mL or less) and mitral valve prolapse [1].

Becker's naevus is occasionally associated with unilateral breast hypoplasia [2,3], possibly as a result of high androgen-receptor activity on the affected side, and with areolar hypoplasia in males [4,5].

Unilateral symbrachydactyly and ipsilateral aplasia of the sternal head of the pectoralis major muscle, aplasia of the breast and absence of axillary hair, are features of the *Poland syndrome* [6].

Breast hypoplasia or aplasia is a feature of the *AREDYLD* (acrorenal field defect, ectodermal dysplasia, and lipoatrophic diabetes) *syndrome* [7].

Morphoea [1]

If morphoea occurs on the chest wall prior to or during breast development, severe hypoplasia of the breast may result [2,3] (Fig. 67.3).

A feature of generalized morphoea is sparing of the nipples and areolae. Christianson *et al*. [4] noted that the skin was pinched or squeezed like 'rising biscuits on a platter' (Fig. 67.4).

(a) (b)

Silicone breast implants and autoimmune disease

In the early 1990s, a major controversy arose about a possible relationship between silicone gel breast implants and subsequent development of connective tissue disease. Although the most common specific disease was scleroderma, many cases had a non-specific syndrome. Because of safety concerns, the US Food and Drug Administration imposed a moratorium on the use of such implants in 1992. The UK Medical Devices Directorate reviewed the scientific evidence relating to connective tissue disease and silicone gel breast implants, and in April 1992 presented a report to an independent Expert Advisory Group. The Group concluded that, on the basis of all available data, there was no evidence of an increased incidence of connective tissue disease associated with silicone gel breast implants [1]. An Independent Advisory Committee in Canada concluded that there was an absence of evidence establishing that women with silicone gel implants were more likely than those without such implants to have autoimmune disorders [2]. The issue provoked intense medicolegal activity.

Although a retrospective cohort study of 395 542 female health professionals, involving self-reported data, suggested a small increased risk of connective tissue diseases among women with breast implants [3], numerous controlled epidemiological studies did not demonstrate any statistically significant association between a recognized connective tissue disease and silicone breast implants [4], and three meta-analyses of the data failed to show an association [5–7]. However, the controversy continued [8,9]. Further studies showed no evidence of an association [10,11], and the UK Independent Review Group on Silicone Gel Breast Implants concluded that these implants were not associated with any greater health risk than other surgical implants, and that if there was any risk of connective tissue disease it was too small to be quantified [12]. At about the same time as this report was issued, a settlement of the medicolegal issues was proposed [13].

Rudimentary nipples

The association of absent or rudimentary nipples with abnormalities of the scalp and ears has been reported as an autosomal-dominant trait [1–3].

Rudimentary nipples are also a feature of the ablepharon–macrostomia and Barber–Say syndromes, whose other features include absence of the eyelids or ectropion, macrostomia, ear anomalies, redundant skin, abnormal genitalia and hypertrichosis in the Barber–Say syndrome [4,5].

Adnexal polyp of neonatal skin [1,2]

This is a small, usually solitary, tumour which occurs mainly on the areola of the neonate. It is firm and pink, but becomes dry and brown and falls off within a few days of birth. Histologically, it contains hair follicles, eccrine glands and vestigial sebaceous glands. A survey in Tokyo showed that the condition occurred in 4% of 3257 newborn infants.

Inverted nipple

Inverted nipple is common, affecting up to 10% of adult females [1], and potentially leading to functional problems with breastfeeding, and psychological distress. There are three main causes: congenital, periductal inflammation and tumour infiltration. It is also important to remember that in postmenopausal women it may result from the involutional process of periductal fibrosis. In most cases, the abnormality is congenital, and the fault lies in failure of the normal eversion process [2]. The lactiferous ducts are shortened and there is a reduction in the amount of dense connective tissue which is present beneath a normal nipple [3]. The abnormality is usually bilateral, but may affect only one nipple.

Many women with inverted nipples are able to breastfeed without difficulty, probably because the nipple itself plays a relatively small part in the anatomical aspects of suckling, as the infant makes a 'teat' from the surrounding breast tissue as well as the nipple [2].

If inverted nipples pose a cosmetic problem, surgical correction may be considered. Numerous techniques have been described, suggesting that none is ideal. Procedures which involve division of the lactiferous ducts are probably more effective, but breast function is destroyed. One of the more recent suggestions, which preserves breast function, involves piercing the base of the nipple and inserting a stainless steel barbell of a type employed in decorative body piercing [4].

The duct ectasia/periductal mastitis complex [1]

A number of pathological processes contribute to the clinical features of this complex. These features include nipple discharge, subareolar abscess, mammary duct fistula and nipple retraction. It is a rare occurrence in males, but has been described in association with HIV infection [2].

Hyperkeratosis of the nipple and areola

On the basis of reported cases, hyperkeratosis of the nipple and areola is considered to be a rare condition. The classical Levy-Franckel classification includes three categories [1,2]: as an extension of an epidermal naevus, in which involvement tends to be unilateral and both sexes may be affected; in association with ichthyosis, in which involvement is bilateral and both sexes are affected; a naevoid type, usually bilateral, and occurring predominantly in women in the second or third decade of life. Pérez-Izquierdo *et al*. [3] suggested an alternative classification of two types: (i) idiopathic or naevoid (unilateral or bilateral); and (ii) secondary, local (unilateral or bilateral)—acanthosis nigricans, verrucous naevus or seborrhoeic keratosis; systemic (bilateral)—dermatosis, ichthyosis, malignant lymphomas, Darier's disease, chronic eczemas; or drug-related—diethylstilboestrol, spironolactone. Another classification, proposed by Mehanna *et al*. [4], includes a suggestion that the term 'naevoid' should be replaced by 'idiopathic'.

Whether described as naevoid or idiopathic, there is a distinct entity of verrucous thickening and brownish discoloration of the nipples and areolae which occurs predominantly in women in the second or third decade of life [5], in the absence of associated skin disease. It is usually bilateral, although unilateral involvement has been described [6,7], and it occasionally occurs in men [8]. Histology shows hyperkeratosis, filiform acanthosis and papillomatosis and keratin plugging.

Hyperkeratosis of the nipples may also occur in association with ichthyosis, ichthyosiform erythroderma, acanthosis nigricans, Darier's disease (in association with other skin lesions, but also described as an isolated presenting phenomenon [9]), and T-cell lymphoma [10,11]. It has also been described in men with carcinoma of the prostate treated with oestrogens [12,13].

An appearance resembling verrucous naevi around both areolae has been described as a manifestation of inadequate hygiene [14].

Suggested treatments for naevoid hyperkeratosis include topical retinoic acid [3], topical calcipotriol [15], cryotherapy [6] and the carbon dioxide laser [16].

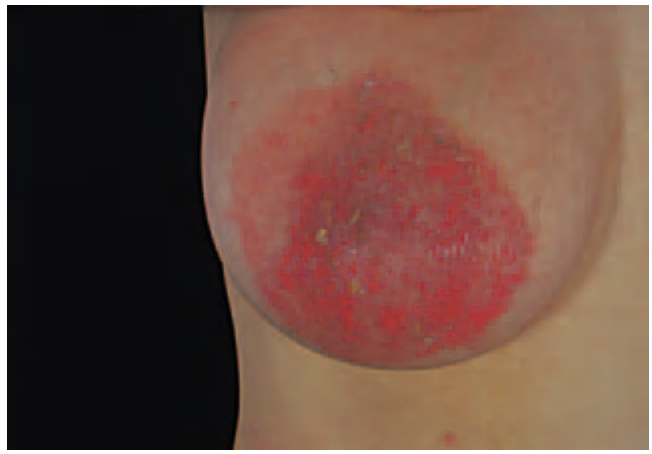
Eczema of the nipple and areola

Although eczema of the nipple and areola occurs mainly in women (Fig. 67.5), it is an occasional occurrence in men (Fig. 67.6); it may be unilateral or bilateral [1,2]. Often no cause can be established, although there is an association with atopy [3].

Contact dermatitis is a possibility, and allergic contact dermatitis of the nipples has been reported in a breast-feeding woman using a beeswax nipple protector [4], and two others applying Roman chamomile ointment [5].

(a)



(b)

Fig. 67.5 (a, b) Severe bilateral nipple eczema in a young woman.

Irritation from friction must also be considered (see the section on jogger's and cyclist's nipple, below), and unilateral nipple dermatitis in three women with large asymmetrical breasts was attributed to friction between the larger breast and the seam of the brassiere cup [6].

Treatment of nipple eczema is with mild to moderate potency topical steroids.

The intermittent course, more severe itching, indefinite margin and lack of distortion of the nipple help to distinguish eczema from Paget's disease (Chapter 36, Fig. 67.7). Erosive adenomatosis of the nipple (see p. 67.11) may have an eczematous appearance, and a case of clear cell acanthoma presenting as nipple eczema has been described [7]. If the diagnosis is at all doubtful, biopsy should be performed, particularly if there has been no response to topical steroids.

'Cracked' nipples in lactation

Many women experience discomfort, irritation and fissuring of the nipples early in the puerperium when they are trying to establish breastfeeding. Anatomical features, such as relatively flat nipples, contribute to the development of this problem. Mastitis and deep abscesses may occur due to penetration of the broken skin by pyogenic bacteria. The problem is, in essence, one of friction and irritancy resulting from vigorous suckling, and can be eased considerably by the judicious use of gentle cleansing and emollients such as white soft paraffin.

Jogger's and cyclist's nipples [1,2]

Long-distance runners of either sex may suffer from irritation of the nipples caused by prolonged friction against a shirt. The problem is more pronounced in women who do not wear a brassiere. The condition is self-healing; prevention includes the application of petrolatum or powder to the nipples to reduce friction, and the use of a sports brassiere.

Cyclists may suffer from cold injury to the nipple as evaporation of perspiration and wind chill combine to lower the temperature of the nipple on a cold day [3]. Pain, which may last for several days, soreness and tenderness are the result. Cycling jackets made of wind-resistant fabric offer a solution.

Nipple piercings

Body piercing has been practised in some societies since antiquity, but it has usually been confined to the ears and nose. In recent years it has become 'fashionable' in Western countries, and devotees indulge not only in piercings on the face and ears, but also the genitalia and nipples. In a recent study of American undergraduates, 3% of males and 6% of females had pierced nipples [1]. Of these, 21% had experienced trauma or bleeding and the piercing had been removed in a third (mainly male).

Nipple piercings may cause problems either due to trauma or infection [2,3] or the development of allergy to the metal. Lactiferous ducts may be damaged when the nipple is pierced, but this does not appear to lead to problems with breastfeeding [4].

Tassel ornaments suspended from the breasts have

been popular in some cultures, particularly in the Middle East, for many generations. Some dancers have their nipples pierced to accommodate a ring from which ornaments are suspended and this can cause breast duct ectasia [5].

Artefactual breast disease

There are relatively few reports of artefactual breast disease, but the features of reported cases are as varied and bizarre as factitial lesions elsewhere on the body [1–6].

Vasculitis of the breast

Vasculitis affecting breast tissue is rare. It may occur as part of a systemic vasculitis, or as localized disease.

There are several reported cases of polyarteritis nodosa presenting as tender breast nodules [1,2], and breast lesions may also be a feature of Wegener's granulomatosis, sometimes as an initial manifestation [3,4].

Lupus panniculitis

SYN. LUPUS ERYTHEMATOSUS PROFUNDUS; LUPUS MASTITIS [1–4]

Lupus panniculitis can result in breast nodules, which may be mistaken for carcinoma. Lesions are usually chronic and disfiguring. The treatment of choice is antimalarial therapy.

Sarcoidosis of the breast [1–5]

Although involvement of the breast with sarcoidosis is rare, it is important to be aware of its occurrence, as it mimics breast carcinoma. It can present as solitary or multiple, unilateral or bilateral subcutaneous masses, which may be associated with other manifestations of the disease or occur as an isolated phenomenon. Lesions may be fixed or mobile, tender or non-tender, and with or without palpable axillary lymphadenopathy.

Erosive adenomatosis of the nipple [1–5]

SYN. BENIGN PAPILLOMATOSIS OF THE NIPPLE; FLORID PAPILLOMATOSIS OF THE NIPPLE DUCTS; PAPILLARY ADENOMA OF THE NIPPLE; SUBAREOLAR DUCT PAPILLOMATOSIS; SUPERFICIAL PAPILLARY ADENOMATOSIS

Definition. A complex benign tumour arising from the lactiferous ducts of the nipple.

Incidence. This is an uncommon tumour, which occurs mainly in middle-aged women, but it can occur at any age [6], and occasionally in males [7–9]. In one case, the lesion developed 10 years after treatment for carcinoma of the prostate by bilateral orchidectomy and diethylstilbestrol [10].

Pathology [1,4,11–14]. The lesion consists of tubules, with an inner layer of columnar cells and an outer layer of cuboidal myoepithelial cells. A major feature is the presence of superficial keratocysts lined by both squamous and columnar epithelium, and filled with keratin flakes and an eosinophilic material, apparently secreted by the columnar cells. The cysts seem to reproduce the terminal portion of the nipple duct system. Within some of the superficial cysts or ducts, foreign-body giant cells may be seen. Some degree of intraluminal growth (intraductal papillomatosis) is present in many cases. This ranges from small papillary epithelial tufts to almost complete occlusion of the lumina by solid epithelial plugs, and there may be evidence of apocrine decapitation secretion. The overlying epidermis may show acanthosis and hyperkeratosis.

The major histopathological diagnostic pitfall is confusing erosive adenomatosis with sweat gland tumours, and as it may also be difficult to differentiate from papillary breast carcinoma, immunohistological techniques are of value in demonstrating the layer of myoepithelial cells [12,13].

Clinical features. These are variable. The condition may start with a blood-stained or serous discharge, and the nipple may be enlarged, eroded, crusted or eczematous. There may be a small nodule on the nipple, and the symptoms may be worse in the premenstrual phase. The condition is commonly misdiagnosed as Paget's disease or eczema. It is usually unilateral, but bilateral involvement has been reported [15,16], and it has been described in an accessory nipple [17].

Treatment. Excision is curative—either simple local excision, or partial or complete resection of the nipple, depending on the size of the tumour [18]. There are reports of successful treatment by cryosurgery [19] and Mohs surgery [20].

Breast telangiectasia

White [1] described a 77-year-old man with bilateral patches of perfectly circular, symmetrical telangiectasia of the areolae. The condition had been present for as long as he could remember, with no associated abnormalities.

Blue areolae were one feature of a familial disorder named 'hereditary acrolabial telangiectasia' [2], and Schlappner and Shelley reported a 35-year-old woman with symmetrical essential telangiectasis of the breasts, recurrent aphthous stomatitis and hypersplenism [3].

Mammary duct fistula [1]

SYN. RECURRENT SUBAREOLAR ABSCESS

This condition typically occurs in a young adult woman who has a history of recurrent abscesses in a breast which

have been treated by surgical drainage or have discharged spontaneously. There is typically partial inversion of the nipple and a scar or scars at the edge of the areola.

The condition is treated by passing a probe into the opening of the discharging sinus, along the track of the fistula, and out of the nipple. The fistula is then laid open (fistulotomy) and left to heal by granulation, or the whole tract is excised (fistulectomy) and the wound allowed to granulate.

Breast abscess [1]

Breast abscesses may be classified as lactational (occurring in the puerperium) and non-lactational. The majority of lactational abscesses are caused by *Staphylococcus aureus*, and present as a painful, red, swollen breast, associated with fever.

Non-lactational abscesses include subareolar abscess, which is seen mainly in women in their reproductive years in association with the duct ectasia/periductal mastitis complex, and peripheral abscess, which occurs as a typical inflammatory breast abscess in postmenopausal women. The former is associated with a mixed bacterial spectrum, and the latter with *S. aureus*. Lactational abscesses are now uncommon in comparison with the frequency of non-lactational lesions [2].

Breast cancer (Fig. 67.8)

This common and important condition lies in the province of the surgeon rather than the dermatologist, but all physicians have a duty to detect and diagnose early breast cancer, which can sometimes be discovered on routine examination. Inspection and palpation of the breasts should be included in any full examination. The breasts should be inspected with the arms by the side, above the head and pressing on the hips, because in some cases these manoeuvres will demonstrate a visible mass, or a change in contour of the breast, or early retraction or dimpling of the skin caused by a breast cancer. The dermatologist should also remember that redness or oedema of the breast skin can be due to underlying cancer. Breast cancer can also cause flattening, broadening or inversion of the nipple. It is important that all four quadrants of the breast, including the axillary tail and axillary lymph nodes, should be palpated.

Fig. 67.8 Advanced carcinoma of the breast.

The dermatologist should examine the breasts carefully in all patients presenting with skin disease which may be associated with systemic malignancy, for example acanthosis nigricans or dermatomyositis.

The term *peau d'orange* is applied to dimpled oedematous or indurated skin resembling the surface of an orange. The finding of peau d'orange should lead to an intensive search for underlying carcinoma. Rarely, it occurs in the absence of any clinically palpable tumour. It has also been reported as a complication of anasarca, nephrotic syndrome and cardiac failure [1].

Breast cancer frequently involves the skin, and there are several different clinicopathological types of cutaneous involvement [2]. These include Paget's disease of the nipple, inflammatory metastatic carcinoma (carcinoma erysipeloides), carcinoma en cuirasse, telangiectatic metastatic carcinoma, nodular metastatic carcinoma, alopecia neoplastica, carcinoma of the inframammary crease and metastatic mammary carcinoma of the eyelid. Carcinoma metastatic to the eyelids is a rare phenomenon, and breast carcinoma is responsible for a sizeable proportion of these cases. Involvement may be unilateral, with the right eyelids affected more frequently than the left [3], or bilateral [4,5]. In many of the reported cases, the histology has shown prominent histiocytoid features [2].

Pigmented primary carcinoma of the breast is rare, and may mimic malignant melanoma clinically and histologically [6,7]. Metastatic melanoma may be responsible for inflammatory changes in breast skin [8].

Other conditions which may mimic breast carcinoma include postsurgical lymphoedema [9] and sarcoidosis [10].

Virgili *et al*. [11] described four patients with what were thought to represent cutaneous tumour-related granulomatous lesions following mastectomy for carcinoma of the breast. The lesions developed on the arm on the same side as the previous mastectomy.

Breast cancer in men

Breast cancer in men is relatively rare, accounting for around 0.2% of all cancers in men in the USA and less than 1% of all cases of breast cancer [1].

Risk factors include conditions associated with reduced testicular function, excess oestrogen exposure, Klinefelter's syndrome [2], and a family history of breast carcinoma. Case–control studies indicate that the disease is commoner in black men and in those who have never married [3].

The mean age of presentation is 60–65 years, and is approximately 5 years older than that for breast carcinoma in women.

As in women, the clinical features include a breast mass, which is typically subareolar, nipple inversion and nipple discharge (Fig. 67.9). Infiltrating ductal carcinoma is the predominant histological type. Paget's disease may be the presenting feature [4,5].

Basal cell carcinoma of the nipple [1–4]

This is a very rare lesion. It can occur in either men or women, usually in old age. It usually presents as a red, eczema-like patch of the nipple or areola and runs a long, indolent course. Biopsy is essential to differentiate it from Paget's disease.

Paget's disease, which is a marker of an underlying breast carcinoma, is discussed in Chapter 36.

Hair sinus of the breast

Hair sinus of the periareolar area of the breast has been observed in women engaged in sheep shearing (roustabout's breast) and hairdressing [1] (Fig. 67.10), and in canine beauticians whose work leaves them covered in dog hairs [2]. The lesions are similar to the interdigital pilonidal sinuses which may occur in barbers and dog groomers [3]. The histology shows a granulomatous reaction. Repeated breast abscesses in female sheep shearers may provoke concern about the ability to breastfeed or even lead to women contemplating mastectomy. This problem prompted the manufacture, in New Zealand, of a protective brassiere, the Baa Bra [4].

Seborrhoeic warts

SYN. BASAL CELL PAPILLOMAS (Chapter 36)

These are particularly common in the submammary creases in middle-aged or elderly women, often in association with intertrigo (Fig. 67.11). Seborrhoeic warts may also occur as sharply demarcated papules or plaques on the nipple and areola [1].

REFERENCE

Mondor's disease (Fig. 67.12)

SYN. SCLEROSING PERIPHLEBITIS OF THE CHEST WALL

Mondor's disease is usually regarded as an obliterative phlebitis affecting the thoracoepigastric, lateral thoracic or superior epigastric vein. It occurs mainly between the ages of 30 and 60 years and affects women much more frequently than men [1,2]. Risk factors cited for the development of the condition include large, pendulous breasts, strenuous physical activity, direct trauma, breast surgery and infection near the affected vessels. Breast cancer is an occasional cause [3], and mammography is recommended even when no mass is palpable [4–6]. Mondor's disease has characteristic mammographic and sonographic features [5,6]. It has also been described in association with metastatic axillary adenopathy 2 years after radical mastectomy for breast carcinoma [7], and in a patient with metastatic lung cancer in the breast [8].

In a case of recurrent Mondor's disease of the thoracoepigastric vein, resolution occurred after excision of a lipoma which was in close proximity to the vein [9]. It is a rare occurrence in pregnancy [10,11].

Other rare causes include intravenous drug abuse, following use of the breasts as injection sites [12], jellyfish stings [13] and a lupus erythematosus-like syndrome probably induced by procainamide [14]. However, often no cause is apparent.

Rarely, the condition is bilateral [14], and in one such case potential aetiological factors included breast surgery,

the use of oral contraceptives, hereditary protein C deficiency and anticardiolipin antibodies [15].

There may be some tenderness or discomfort, but there are often no symptoms until the patient discovers a red linear cord running from the lateral margin of the breast, crossing the costal margin and extending to the abdominal wall. The cord is 2–3 mm in diameter and is attached to the skin but not to the deep fascia. It is usually only a few centimetres long, but may extend to 30–40 cm. The symptoms subside in a few weeks and there are no known complications.

Other conditions which may involve the breast

Vitiligo sometimes shows a striking symmetrical involvement of the breasts.

Psoriasis may be provoked by the trauma of suckling.

Pityriasis rosea commonly presents with a herald patch on the breast, and has been reported as a localized eruption on one breast [1].

Chapter 68

The Genital, Perianal and Umbilical Regions

C.B. Bunker & S.M. Neill

Introduction

A number of common skin diseases affect the umbilical, perianal, genital and genitocrural skin only incidentally, and may present in these areas with unusual features. These will be dealt with briefly or by cross-reference to their full description elsewhere. However, those conditions that are entirely or predominantly confined to these regions are discussed in detail.

General approach to the patient and the problem

Clinical assessment begins with the history and examination. Patients with anogenital symptoms may be embarrassed and present late, or present to specialties (urology, gynaecology, general or colorectal surgery, genitourinary medicine) where training and experience are not focused on dermatological diagnosis and management.

Itching, rashes and tumours are the major components of general dermatology and the anogenital area is not spared. The pruritic diseases that may affect the anogenital region are listed in Tables 68.1–68.3. Itch occurring in the absence of specific diagnostic skin lesions is not usually confined to the anogenital area, but if so it should not be labelled as psychogenic until all possible causes have been excluded. The intensity with which itch can be perceived in the anogenital area may be a result of the vagaries of cortical representation afforded the region in the sensorium as well as anxiety about exposure to sexually transmitted disease and anogenital cleanliness.

Kaposi's sarcoma
Langerhans' cell histiocytosis
Carcinoma erysipeloides

The symptomatology of anogenital dermatology is more extensive than the standard symptomatic presentation of skin disease. This obliges the clinician to elicit symptoms resulting from sexual dysfunction (e.g. preputial dysfunction—soreness, pain, bleeding or tearing on intercourse) and the components of sexual function (erection, lubrication, libido, ejaculation, orgasm, fertility), urinary dysfunction (frequency, discharge, dysuria) or colorectal symptomatology (pain, bleeding, discharge).

History taking must involve attention to the sexual history (orientation, marital status, last sexual activity (when; how—vaginal, oral, anal; contraception), regular partner(s), partner symptomatology) and drug history (topical and systemic, prescribed and over-the-counter). The personal and family history of atopy, psoriasis and seborrhoeic dermatitis is often relevant. Smoking habits should be documented; smoking is a risk factor for anogenital cancer.

Complete examination is mandatory because common diagnoses will be reached with the assistance of important signs at extragenital sites. Often the patient will not have had his/her genitalia or perineum examined. The practice of anogenital dermatology demands careful inspection and often requires internal examination and urinalysis. Drawings are made and photographs obtained. Signs are described in conventional and specific terms (e.g. posthitis, phimosis).

Intertrigo describes any dermatosis occurring in skinfolds; frictional abrasion and a degree of epithelial loss may result in erosion that renders the site especially susceptible to secondary infection (e.g. with *Candida*). Causes are listed in Tables 68.4 and 68.5.

Pigmentary change is common. Causes of anogenital hypopigmentation and leukoderma include striae, vitiligo, lichen sclerosus, viral warts, leukoplakia and post-inflammatory changes (Table 68.6). Rarer causes include

Post-traumatic
Lichen planus
Herpes simplex
Fixed drug eruption

Candida, extramammary Paget's disease, mycosis fungoides and melanoma. Common causes of anogenital hyperpigmentation include tattoos, purpura, lentigines, naevi, pseudoacanthosis nigricans and post-inflammatory changes (Table 68.7). Rarer or potential causes include Addison's disease, Nelson's syndrome, genital melanosis, Laugier–Hunziker syndrome [3], Peutz–Jeghers syndrome [4,5], LAMB syndrome (lentigines, atrial myxoma, mucocutaneous myxoma, blue naevi) [6,7], LEOPARD syndrome, Ruvalcaba–Myhre–Smith syndrome [8,9], acanthosis nigricans, acral lentiginous melanoma, drugs and metals. Both post-inflammatory hypo- and hyperpigmentation are possible after acute and chronic inflammation from diverse causes; both may be more pronounced in ethnically darker skin. Lichen planus, fixed drug eruptions and recurrent herpes simplex are the common causes of post-inflammatory hyperpigmentation. Genital trauma from a zipper injury can lead to macular pseudolentiginous lesions on the glans and shaft of the penis.

A mucosal white patch or plaque is sometimes called leukoplakia (Table 68.8). This is not a diagnostic term, and it is unhelpful as it evokes connotations from oral medicine of premalignancy or even frank neoplasia.

Anogenital ulceration requires meticulous elucidation. The principal causes are benign aphthae, sexually transmitted and non-sexually transmitted infection, cancer and artefact. Tables 68.9 and 68.10 list all the causes. Several causes can co-present, especially in HIV/AIDS.

Lymphogranuloma venereum
Syphilis—primary chancre
Squamous carcinoma

Commonly required investigations include microbiology or virology of a swab or smear, scrapings for fungal microscopy and culture, scrapings for mite identification, skin biopsy, Wood's light to demonstrate vitiligo and erythrasma, and blood tests (e.g. ASOT, HLA B27, HIV). Investigations pertinent to the evaluation of sexually transmitted diseases are not discussed further, but it bears re-emphasis that if a diagnosis of a potentially sexually transmitted disease is reached (warts, molluscum contagiosum, herpes simplex, scabies, pediculosis) then the patient should be referred for a genitourinary opinion and advised to inform their partner(s) so that they may be screened also.

The opinion of another specialist may be necessary and should be sought as dictated by the urological, gynaecological, colorectal or genitourinary situation. Combined clinics are the ideal.

Genitocrural dermatology

Introduction

The genitocrural folds represent a region of the body that is particularly prone to intertrigo and flexural forms of common dermatoses, probably because of koebnerization. Moisture and friction also lead to maceration and fissuring, and secondary infections readily supervene. Vegetating reactions can prove resistant to treatment. Itch may be prominent in psoriasis, infections and infestations of the area. Crab louse and *Oxyuris* infestation must be excluded as primary causes of rash. Lichenification occurs readily.

Inflammatory dermatoses

Intertrigo

Intertrigo is a generic name for an inflammatory dermatosis involving the body folds, notably those of the submammary and genitocrural regions. There may be no clear distinction between constitutional and infective causes (listed in Tables 68.4 & 68.5). Physical factors such as obesity, sweating, friction, incontinence and faecal soiling may cause erythema or fissuring, and render the skin vulnerable to the effects of other agents. Initially, it is marked by soreness or slight itching, and a superficial mild erythema of the apposed surfaces. Secondary infection occurs rapidly, and the condition is then perpetuated as an infective dermatitis. In eczematous subjects this will take on the physical characteristics of eczema; in others, the infection may progress to crusting, pustular or vegetating lesions. The organisms concerned are *Staphylococcus aureus*, rarely the haemolytic streptococcus, *Escherichia coli*, *Proteus* spp. and, occasionally, *Pseudomonas aeruginosa*. In infants, diabetics and the obese, yeasts are often present. Latent diabetes should be borne in mind when the disease is refractory to treatment. Overtreatment may compound the irritation or lead to a sensitization dermatitis.

Candidosis and contact dermatitis are differentiated by the history, the appearance and microscopic examination. The diffuse macerated erythema, often with fissures at the apex of the fold and without a sharply defined edge, distinguishes intertrigo from psoriasis and dermatophytosis, although scrapings and culture should always be

undertaken. Mistakes in diagnosis arise from failure to recognize that two or more aetiological factors may co-exist [1]. In India, *Trichosporon* species, which normally cause white piedra trichomycosis, have been implicated in causing cutaneous lesions resembling genitocrural intertrigo [2]. Langerhans' cell histiocytosis (see Chapter 52) has a predilection for the perineum or inguinal regions [3] and is a rare cause of genitocrural intertrigo; likewise extramammary Paget's disease. Congenital syphilis may present as intertrigo in an infant.

In the early stages, the condition can be controlled by avoidance of friction and tight clothing. Driving or sitting for long periods should be avoided. In severe cases, the patient must rest in bed, preferably with groins unclothed and bedclothes lifted by a cradle, the apposed skin surfaces being kept apart with appropriate dressings. Obesity, diabetes and incontinence should receive attention. Wet dressings are often useful initially in acute cases, and may be followed by bland or mild antibacterial creams or lotions. The aniline dyes and magenta paints still have a place in therapy. In general, lotions, paints and powders are more acceptable than creams. Nystatin, hydroxyquinoline and imidazoles can be applied alone or with topical steroids for a few days.

Genitocrural dermatitis

Lichen simplex is a result and/or cause of severe and spasmodic itch; the psychological mechanisms involved are similar to those discussed in relation to pruritus vulvae and pruritus ani. The 'giant' form of lichenification described by Pautrier [4] may be extremely resistant to treatment. Local treatment with corticosteroid applications is supplemented by reassurance, rest and sedation. All factors provoking local itching must, as far as possible, be removed.

Contact dermatitis (see Chapters 19–21) may present suddenly with pruritus, oedema and erythema, or insidiously as a gradual intensification of a pre-existing dermatitis. Sensitization to applied medicaments, contraceptives or, in men, industrial or other contact agents transferred by hand may be responsible for allergic contact dermatitis, especially if the scrotum and thighs are also affected. Irritant contact dermatitis is common and caused by excessive or exuberant use of soap and toiletries. A good example is nappy (diaper) rash where urine, occlusion, friction and *Candida* contribute to the clinical presentation. Classically, the convex surfaces are affected and the flexures are spared, distinguishing it from psoriasis [5]. Nappy rash has become much less common with the availability of absorbent disposable paper napkins. A severe erosive form (Jacquet's dermatitis) is still occasionally seen in children with urinary or faecal incontinence.

Constitutional eczema should be considered in the differential diagnosis of napkin erythema in an infant (see Chapter 14). In adults, the genitocrural and lower abdominal folds are likely to be involved in seborrhoeic or intertriginous dermatitis.

Miscellaneous

Psoriasis and lichen planus are recognized by their special characteristics, although the diagnosis may be difficult when they arise in an exclusively flexural distribution. In the flexures and at anogenital sites, seborrhoeic dermatitis and psoriasis may be indistinguishable.

Impetigo herpetiformis frequently starts in the groin with small inflammatory yellowish green pustules, which rupture to produce scabs and crusts. Acrodermatitis enteropathica and the acquired zinc deficiency syndrome may well be overlooked as causes of genitocrural dermatitis. The distinction of Jacquet's eruption from congenital syphilis and from the exuberant plaques and nodules of infantile gluteal granuloma [5,6] is important. Hidradenitis suppurativa usually involves the area widely, although localized lesions are sometimes seen.

All forms of pemphigus and pemphigoid (especially pemphigus vegetans [7] and pyodermite végétante [8]) affect this region, and juvenile pemphigoid and pemphigoid gestationis affect it selectively and sometimes exclusively. Pemphigus vegetans must be distinguished from vegetating forms of pyoderma, which are not uncommon in the groins, and from blastomycosis and other mycoses, verrucoid forms of tuberculosis and granuloma inguinale. Mucous membrane (cicatricial) pemphigoid [9] may affect the groin. Benign familial pemphigoid (Hailey–Hailey disease) affected the groins or genitalia in 14 out of 21 patients in one series [10]. It can involve the groins in isolation. Secondary infection with herpes simplex has been reported after treatment with retinoids [11]. Very rarely, papular plaques similar in appearance to genital warts have been reported. Darier's disease (see Chapter 34) involving the flexures is mild in most patients but does occur in the vast majority. It can be very sore and malodorous. The intertriginous features are similar to those of Hailey–Hailey disease. There have been several reports of a genital, inguinal and perineal eruption, with clinical and histological similarity to Darier's disease and Hailey–Hailey disease, called genitocrural papular acantholytic dermatosis. The patients had no rash elsewhere, no family history and negative immunofluorescence [12]. Subcorneal pustular dermatosis extends outwards from the inguinal folds as flaccid pustules, rapidly rupturing to form gyrate and circinate crusted lesions. Dystrophic forms of epidermolysis bullosa may cause separation of the skin during delivery or, if less severe, bullae and erosions at these sites of friction.

Epidermal necrolysis may present as desquamation, sometimes involving the whole region. Severe erythema multiforme involves the genital or anal mucosa in half of the cases. Necrolytic migratory erythema also extends in waves from this area [13].

Infections

Erythrasma

Erythrasma (see Chapter 27) is a common genitocrural infection, especially of the male. It is caused by *Corynebacterium minutissimum*, an organism that is normally a commensal but which in warmer climates may become pathogenic. Tawny, slightly scaly plaques are seen on the upper inner thighs. In the inguinal folds, erythrasma may present as an intertrigo and can be macerated and eroded. It is not usually very itchy, but can be slightly sore. Lesions are usually also found in the axillae or toe webs. It may coexist with *Trichophyton rubrum* [1] and candidosis. Pruritus ani has also been reported [2]. Erythrasma is a clinical diagnosis confirmed by demonstration of coral pink fluorescence under Wood's light (resulting from a porphyrin elaborated by the bacterium). Treatment is with topical clindamycin, erythromycin or an imidazole, or with oral erythromycin. It is prone to recur.

Candidosis

Candidosis (thrush) presents as an intertrigo. Symptoms of burning and soreness are more common than itch. Coalescent red patches or plaques involve the folds, often with superficial erosions. Pustulosis extends out onto the skin of the abdomen, buttocks or thighs from the irregularly marginated intertriginous lesions. It can be a primary infection, particularly in infants, and in pregnancy and diabetes, but *Candida* may be more often a secondary pathogen in anogenital dermatoses. Observing the signs of candidosis or demonstrating the presence of the organism does not prove that it is the cause of all the symptoms and signs. *Candida albicans* is such a ready opportunist because it is a part of the resident flora of the gastrointestinal tract and may be retrieved from intertriginous areas, including the preputial folds, in the absence of symptoms and signs. A search for an underlying dermatological or medical cause should be undertaken. The symptoms and signs of *Candida* may be more florid than the underlying predisposing cause. Obesity predisposes to candidal intertrigo but medical causes include diabetes mellitus, iatrogenic immunosuppression and systemic antibiotic treatment. Although oropharyngeal candidosis is almost invariably found in HIV infection, anogenital candidosis is not generally associated, perhaps because it is overlooked or because many patients take long-term imidazole antifungals orally.

Underlying disease should be identified and treated, and predisposing factors rectified. Treatment includes topical nystatin, clioquinol or an imidazole, often very usefully combined with hydrocortisone or a moderately potent corticosteroid. If the infection is severe, an oral imidazole may be indicated.

Tinea cruris

Tinea (see Chapter 31) is a common disease of the groins and is usually caused by *Trichophyton rubrum*. It is generally rare in women, but occurs more frequently in hot climates. Spread occurs onto the thighs, buttocks and pubis. Many patients have been previously misdiagnosed and/or partially treated with topical corticosteroids and/or topical antifungal agents. Tinea and *Candida* may complicate other dermatoses such as psoriasis. Tinea incognito/occulta is therefore common. There is a fine peripheral scaling (eczema marginé of Hebra). Cases have been described in infants [3].

Microscopy will confirm the clinical diagnosis, and in tinea incognito/occulta there are numerous fungal elements.

Dermatophyte infection of the anogenital skin usually requires oral treatment with griseofulvin, terbinafine or itraconazole. Topical treatments often fail because the anatomical complexity of the area makes topical treatment difficult, and there may be reinfection from concomitant involvement of feet or hands, toe or finger nails.

Miscellaneous

Bacterial or candidal infections complicate intertrigo, eczema, napkin erythema, scabies and many tropical diseases. Vincent's organism, *Pseudomonas aeruginosa* and a wide variety of Gram-negative organisms are commonly found. Gangrenous ecthyma of infants may, very rarely, affect the inguinocrural area. Bullous impetigo occurs in

childhood, often secondary to scabies. Giant condylomata acuminata may infiltrate the groin [4]. Gangrene has followed operations for inguinal hernia [5]. Sacral herpes zoster may present with groin lesions and retention of urine or constipation.

Phthiriasis pubis is sometimes overlooked as a cause of pruritus in the female. In the hirsute male, the infestation may be widespread. Oxyuriasis can cause localized urticaria as well as pruritus. Scabies in children is diffuse, and the inguinal glands are often enlarged from secondary infection. Seabather's eruption and 'seaweed dermatitis' affect the bathing trunk area.

Schistosomiasis and amoebiasis cause phagedenic necrosis, fistulae and pseudoelephantiasis, and may also give rise to granulomas and condylomatous masses [6]. Onchocerciasis causes depigmentation, nodules, atrophy, lymphadenopathy and a 'hanging groin' [7]. Trichosporosis is a common cause of genitocrural intertrigo in India, with symptoms of itching or burning. Scaly papules may accompany the intertrigo. Coexisting dermatophyte, *Candida*, trichomycosis and erythrasma infection may be found. Dequalinium chloride is applied topically for treatment [8]. Trichomycosis presents with malodour and discolored broken hairs [9], which should be distinguished from those of trichorrhexis nodosa, caused by repeated scratching [10]. Blastomycosis, actinomycosis and other deep fungal infections (see Chapter 31) simulate tuberculosis, but are more prone to form fissures, sinuses and vegetating or exuberant granulomatous lesions. They are distinguished by histological and bacteriological examination.

Among chronic infections, tuberculosis, tertiary syphilis and leishmaniasis are diagnosed by their characteristic features, which are described elsewhere. Congenital syphilis can be overlooked as a cause of genitocrural intertrigo in an infant. In tropical countries, tuberculous inguinal lymphadenopathy may be a cause of genitocrural lymphoedema. Amoebiasis involves the groins and perineum by extension from the anus.

Sexually transmitted diseases are fully discussed in Chapters 27 and 30. Granuloma inguinale affects the genitalia in less than half of cases, causing coalescing nodules, serpiginous ulcers and fungating masses. The buboes and fistulae of lymphogranuloma venereum are characteristic. Vulval (rarely scrotal) lymphoedema and elephantiasis may occur in both diseases.

Miscellaneous

In the 'short bowel syndrome', kwashiorkor-like changes include an 'enamel paint skin' [1]. Dowling–Degos disease (reticulate pigmented anomaly of the flexures) involved the flexures in eight out of 10 patients [2], but may be restricted entirely to the vulval skin [3].

Acanthosis nigricans almost invariably affects the groins. Pseudoacanthosis nigricans can present as a macerated intertrigo and with secondary infection. These can be distinguished from each other and from lichenification in pigmented skins by a rubber silicone impression technique [4]. Calcinosis involving the upper inner thighs may resemble pseudoxanthoma elasticum [5].

The following entities are encountered in the genitocrural area. Angiomas and angiokeratomas—diffuse angiomas or lymphangiomas may cause irregular subcutaneous swellings; angiokeratoma corporis diffusum may be a feature of several very rare congenital diseases affecting lysosomes, with the pinhead-sized lesions of Anderson–Fabry disease (α-galactosidase deficiency) occurring around the lower limb girdle and upper thighs from the navel to the knees. Epidermal naevi are not uncommon. Seborrhoeic warts may be mistaken for viral warts [6] or Bowenoid papulosis, as may melanocytic naevi or acrochordons. Papilliferous naevi and skin tags often become large and pedunculated on the inner aspect of the thighs. Inguinogenital epidermoid cysts may become infected; lesions containing molluscum contagiosum have been described [7]. Pilar cyst, including giant forms, is much rarer [8].

Pubic hair problems are relatively rare in men, whereas women may be troubled by hirsutism or pili incarnati. Alopecia areata rarely affects this region alone. Vitiligo is common in the groins.

Extramammary Paget's disease can involve the genitocrural folds and present as an intertrigo.

Carcinoma erysipeloides (from anogenital disease) [9] is probably more common in the genitocrural area than reports would suggest. Carcinoma of the cervix, bladder and prostate may be the cause [10].

Male genital dermatology

Introduction

Male patients with non-venereological and non-urological skin problems commonly present to genitourinary or urology clinics where the training and expertise are not orientated to adequate dermatological diagnosis and treatment [1].

Careful dermatological evaluation, including a full history and complete examination, usually allows confident clinical differential diagnosis. A biopsy and other investigations are sometimes indicated. It is important to consider the possibility of sexually transmitted disease or a urological disorder and refer accordingly; combined clinics are useful.

History taking and the primary symptomatology of anogenital dermatology are discussed on pp. 68.1–68.4. It may be necessary actively to elicit symptoms caused by sexual dysfunction, and it should be remembered that male sexual function amounts to more than erectile potency; libido, ejaculation and orgasm are the other components [2].

Complete examination is mandatory to elicit important signs at extragenital sites. The physical examination of the male at any age is incomplete without examination of the genitals and scrotum (but this is frequently not carried out in general clinical settings) and urologists teach that there are three primary reasons for careful examination of the scrotum: pain, swelling and absence of contents. The presence or absence of the prepuce, phimosis or paraphimosis should be sought and the foreskin retracted gently (if present). The gluteal and crural folds should be parted to allow adequate inspection. Sometimes it is useful to elicit dermatographism of the inner thighs. Urinalysis completes the physical examination.

Findings specific to the male genitalia include phimosis, paraphimosis, balanitis and posthitis. Phimosis ('muzzling') refers to a non-retractable foreskin. The literature can be confusing; Rickwood [3] has defined it as scarring of the tip of the foreskin. There are several possible causes of phimosis (Table 68.11). In adults, phimosis is usually the consequence of disease processes. It has also been attributed to titanium formulated in proprietary topical preparations [4]. Diabetes was diagnosed in 36% of men between 17 and 59 years of age presenting with phimosis of less than 2 years' duration, with no specific preputial pathology identified histologically [5]. In boys, the histological findings may be normal in nearly half of those circumcised [6].

Kaposi's sarcoma

Table 68.12 Causes of paraphimosis. (After Bunker [7]. © 2004, with permission from Elsevier.)

Acute contact urticaria
Acute allergic contact dermatitis
Lichen sclerosus

Paraphimosis refers to a foreskin fixed in retraction. Although some authors have used the term to describe a foreskin that is tight in retraction around the flaccid penile shaft, 'waisting' may be a better term [7]. Rickwood [8] has said that paraphimosis results from abuse not disease of the foreskin, but some medical causes can be identified (Table 68.12).

Balanitis is inflammation of the glans penis; posthitis is inflammation of the prepuce [9]. Balanoposthitis means inflammation of the glans and prepuce and can be regarded as a special form of intertrigo (Tables 68.13 & 68.14). By definition therefore, balanoposthitis cannot occur in the circumcised male. Generally, dermatologists feel that balanitis, posthitis and balanoposthitis are probably more commonly caused by inflammatory and precancerous dermatoses than do genitourinary physicians, who teach that most cases are caused by infection, usually with *Candida* [10,11]. However, the evidence for *Candida* as a cause for balanoposthitis is not strong [12].

General aspects of anogenital ulceration are discussed on pp. 68.3–68.4 and in Tables 68.9 and 68.10. The principal causes of male genital ulceration are sexually transmitted and non-sexually transmitted infection, cancer and artefact [13]. Several causes can co-present, especially in HIV/AIDS. Dorsal perforation of the prepuce is a recently highlighted complication of several ulcerative penile diseases, sexually and non-sexually acquired, as listed in

Table 68.15 [14,15]. Penile necrosis is a rare but devastating presentation with an important differential diagnosis.

Special investigations appropriate to anogenital cases are discussed on p. 68.3. In genitourinary clinics, application of 3–5% acetic acid to the penis is used as an aid to the clinical diagnosis of viral warts and is held to reveal subclinical infection [16], but is not in routine use in dermatological practice. Human papillomavirus (HPV) polymerase chain reaction (PCR) screening suggests that the acetowhite test is not very specific [17–19]. A penis biopsy can be highly informative in selected cases [20]. It is safe to use small amounts of adrenaline in the local anaesthetic. Beware of the distal ventral midline area where the urethra is very close to the skin surface. It is often not necessary to suture a punch biopsy site.

Structure and function of the male genitalia

The penis is the male organ of urinary elimination and sexual function for the insemination of the female. The prepuce and its secretions provide physical and immunological protective functions, and it has erogenous properties (e.g. the penile dartos muscle and the corpuscular receptor-rich ridged band), but none of these is indispensible for erogenous function in copulation [21]. The scrotum maintains the testes at the ideal temperature for spermatogenesis. The male genital structures are illustrated in Fig. 68.1. The anatomical position is that of full penile erection.

The anatomy is explained by the embryology [22]. At about the third week of fetal development, mesenchymal tissue from the primitive streak forms cloacal folds

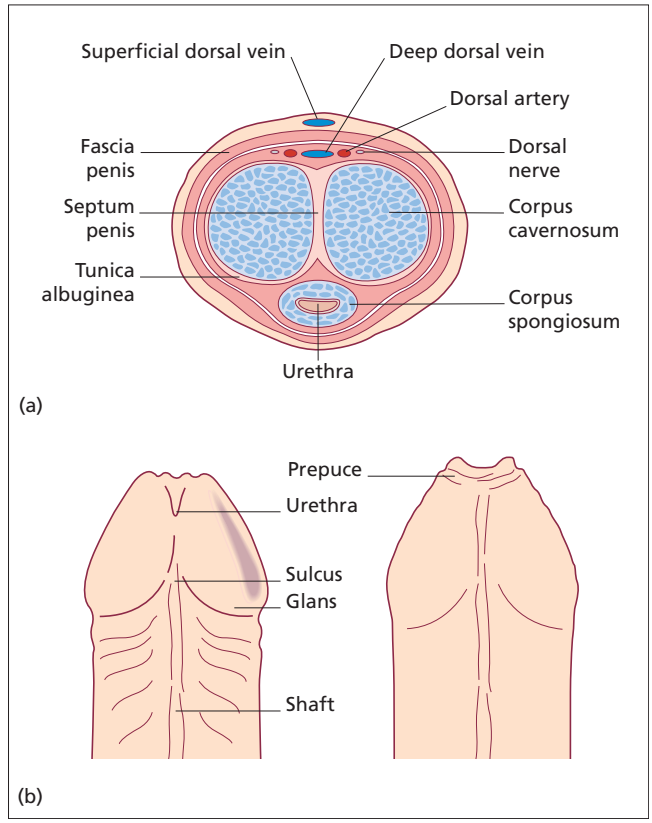

Fig. 68.1 (a) Cross section of the body of the penis. (b) Circumcised and uncircumcised glans penis. (Adapted from *Last's Anatomy*, 9th edn. Reproduced from Bunker CB. *Male Genital Skin Disease*, © 2004, with permission from Elsevier.)

around the cloacal membrane, joined anteriorly and cranially to form the genital tubercle, posteriorly and caudally to form an annulus. The cloacal membrane is thus divided into urogenital and anal membranes craniocaudally, and lateral genital swellings appear as precursors of either the scrotum or labia majora.

Fetal and testicular androgens then induce lengthening of the genital tubercle to form first an urethral groove and then the urethral canal. The urethral epithelium of the penis is therefore derived from endoderm. Initially, it is incomplete cranially where the glans has developed from the genital tubercle. The glandular urethra and the meatus form from an invading canalizing cord of ectoderm. The scrotal swellings fuse posteriorly at about 14 weeks but are empty until birth.

The prepuce [21] is formed by a midline fusion of ectoderm, neuroectoderm and mesenchyme, resulting in a pentalaminar structure consisting of (from the inner layer outwards) squamous mucosal epithelium, lamina propria, dartos muscle, dermis and glabrous skin. The preputial fold progressively extends, but there is also an ingrowth of a cellular lamella. It then fuses with the mucosa of the glans. The female analogue is the clitoral hood.

The anogenital area is densely endowed with eccrine and apocrine sweat glands. Also in plentiful number are holocrine sebaceous glands, usually in association with hair follicles but also occurring as free glands at some sites such as the anal rim or around the coronal sulcus (Tyson's glands). These secretions exist to lubricate hair, lubricate the mucocutaneous junctions to assist in the voiding of excreta and protect the epithelia from irritation and to lubricate the penis for sexual activity (probably mainly the retraction of the foreskin rather than the penetration of the vagina).

Pubic hair appears in puberty as vellus hair that is focally replaced by terminal hair. The pattern of pubic hair in men is different from that in woman, and its distribution varies widely between men. McGregor [23] defined three patterns (Fig. 68.2). Generally, the abdominal wall, pubic mound, groins, scrotum and perineum are hairy but the natal cleft, perianal skin, distal penile shaft, prepuce and glans are hairless.

The pattern of keratinization of the epithelium is different throughout the anogenital area, particularly at the mucosal junctions, the prepuce and distal penile shaft and the glans in the circumcised male. The spectrum of differentiation of the male urogenital tract is manifest in the expression of differing epithelial cytokeratins [24].

Normal variants

Normal male genital variants include pigmentary variation, hair variation as above, skin tags, pearly penile papules, sebaceous prominence (Fig. 68.3), melanocytic naevi, prominent veins, angiomas and angiokeratomas, common congenital abnormalities and circumcision.

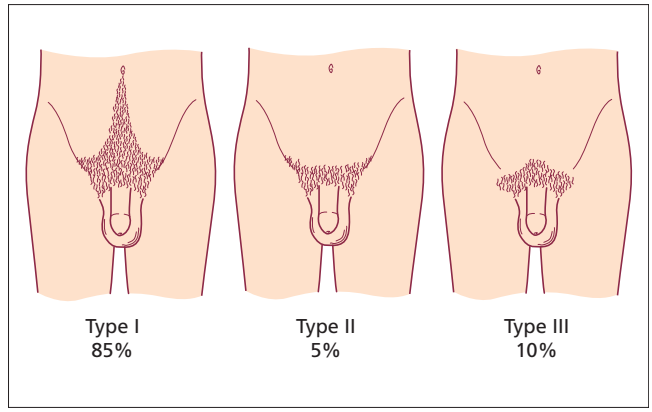

Fig. 68.2 Normal distribution of pubic hair in men. (After McGregor [23]. Reproduced from Bunker CB. *Male Genital Skin Disease*, © 2004, with permission from Elsevier.)

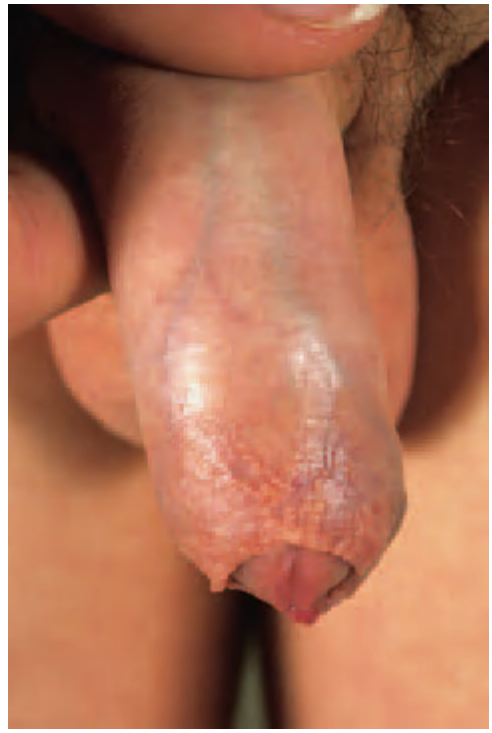

Fig. 68.3 Prominent sebaceous glands on the penis. (Courtesy of Dr F.A. Ive, Durham, UK.)

Skin tags are common in the groins, especially of obese men. They may catch on clothing, bleed and become infected. Treatment is by electrocautery or scissor amputation and cautery. Fibrosed haemorrhoids result in perianal skin tags. Larger, fleshier, more oedematous skin tags should arouse the suspicion of Crohn's disease. They can predate gastrointestinal disease by several years. Sigmoidoscopy and biopsy should be considered [25].

Pearly pink penile papules [26] are common; they may be found in up to 50% of men [27]. They present as flesh-coloured smooth rounded 1–3 mm papules, occurring predominantly around the coronal margin of the glans,

Fig. 68.4 Pearly penile papules. (Courtesy of Dr D.A. Burns, Leicester, UK.)

rarely on the glans, in rows or rings (Fig. 68.4). Ectopic lesions on the penile shaft have been reported [28]. They are frequently mistaken for warts and misdiagnosed as Tyson's or ectopic sebaceous glands of Fordyce. The patient is often an anxious adolescent. The histology is that of angiofibroma. The lesion is analogous to other acral angiofibromas such as adenoma sebaceum, subungual and periungual fibromas, fibrous papule of the nose, acquired acral angiofibroma and oral fibroma [29]. Reassurance is usually sufficient but cryotherapy and laser treatment can be effective [30, 31].

Sebaceous gland prominence, Tyson's glands, sebaceous hyperplasia and ectopic sebaceous glands of Fordyce are all virtually synonymous, common, normal variants of the skin of the scrotal sac and penile shaft, but they may cause concern to the patient. Fordyce's condition also commonly affects the vermilion border of the lips. Naevoid linear lesions on the penile shaft have been seen [32]. The glans can be affected [33]. Reassurance is usually all that is required, but dysmorphophobia can occur.

Congenital and acquired melanocytic naevi are common. It is possible that naevi on the penis occur more frequently in patients with the atypical naevus syndrome, but this has not been formally documented. Genital epithelioid blue naevus is very rare [34]. Divided or 'kissing' naevus (analogous to the entity recognized on the eyelids) has been reported, with one component located on the glans and the other on the distal penile shaft or prepuce, separated by uninvolved skin across the coronal sulcus [35]. Large 'bathing trunk' naevi frequently involve the anogenital area and pose significant management problems (see Chapter 38).

Prominent veins are common, if not universal, and occasionally give rise to concern. Vascular white spots are sometimes seen on the glans, and are possibly analogous to Bier's spots seen on the palms and forearms.

Cherry Campbell de Morgan angiomas may, unusually, be confined to the genitalia. Angiokeratomas on the

Fig. 68.5 Scrotal angiokeratoma of Fordyce (Courtesy of Dr D.A. Burns, Leicester, UK.)

genitalia have also confusingly been given the Fordyce eponym (Fig. 68.5). They are multiple, rarely solitary, blue to purple, smooth, 2–5 mm papules on the scrotum or penile shaft, rarely the glans. Angiomas and angiokeratomas may bleed following trauma. The differential diagnosis includes angiokeratoma corporis diffusum, acquired capillary and cavernous haemangiomas, Masson's tumour, glomus tumour, epithelioid haemangioma, bacillary angiomatosis, Kaposi's sarcoma and epithelioid haemangioendothelioma. Hyfrecation, electrocautery or laser ablation [36] can be offered, but lesions recur. Many patients are content with reassurance and a biopsy is not usually necessary.

The foreskin

The prepuce has been present in primates for 65–100 million years. It is usual for it to be adherent to the glans at birth. Four per cent of boys have a retractable foreskin at birth, 15% at 6 months, 50% at 1 year and 80–90% at 3 years; the process should be complete by 17 years [21]. The foreskin varies in length and retractability: 'short' and 'long' variants are seen.

Circumcision

Circumcision has been performed for religious, cultural or medical reasons throughout history [37]. Worldwide, it

has been estimated that approximately 25% of men have been circumcised [38]. Routine neonatal circumcision is controversial [39]. The UK General Medical Council (GMC) undertook a review of infantile circumcision in 1997, which 'demonstrated widely conflicting views in society that neither doctors nor the GMC can resolve' [40].

During infancy, circumcised boys have a higher incidence of penile problems than the uncircumcised, but after infancy the situation is significantly reversed [41,42]. Many have concluded that circumcision protects men from cancer of the penis and urinary tract, and sexually transmitted infections including HIV [43]. However, the incidence of penis cancer is low in countries where circumcision is uncommon [44], so other factors are important in penile carcinogenesis (see pp. 68.36–68.38). Also, the effects of circumcision on the other outcomes may be small [45] (e.g. urethritis may be more common in the circumcised, whereas ulcerative disease is more common in the uncircumcised). Circumcision protects men from inflammatory genital dermatoses including psoriasis, seborrhoeic dermatitis, lichen planus and lichen sclerosus [46].

Circumcision is important in the management of disorders of the penis and the foreskin, including dermatological disease. However, variability exists between clinicians in the indications for circumcision, especially in children. They include true phimosis, recurrent balanoposthitis, lichen sclerosus, penile lymphoedema, intraepithelial neoplasia and carcinoma.

The consensus is that circumcision has insignificant adverse effects on health, but it is not risk or complication free: bleeding, infection, adhesions, fistula, keloid, concealed or buried penis, amputation, excision of excessive penile skin, meatal stenosis, meatitis and meatal ulcer, cysts, chordee, hypospadias and epispadias, amputation neuromas, abnormal sexual behaviour, psychological distress and dysmorphophobia [47–53]. 'Uncircumcision' describes preputial restoration performed throughout history for various reasons [54,55].

Congenital and developmental abnormalities

Congenital and developmental anomalies are common because of the complicated embryogenesis and subsequent sexual differentiation of the anogenital region. The dermatologist may not be called upon to make a primary diagnosis, but needs to be aware of anatomical and functional abnormalities because these additionally predispose the area to dermatoses and infections.

Naevi are discussed above. Other common abnormalities include meatal pit, sacral pit, hypospadias [56], median raphe cysts, canals and sinuses, and ambiguous genitalia.

Other rare anomalies include hypospadias variants, epispadias, penile hypoplasia, mucoid or urethral cysts, dermoid cyst, juvenile xanthogranuloma, buried penis, urethral atresia, penoscrotal transposition, congenital lymphoedema, giant prepucial sac, megaprepuce, accessory scrotum, haemangiomas, strawberry naevus, os penis, true aposthia and faun tail [7].

Trauma and artefact

Penile haematoma and rupture

The genitals may be readily traumatized by sexual activity. The penis is very vascular but haematoma formation and 'fracture' (penile rupture) are quite rare [1]. Pain, swelling and deformity associated with the history of a cracking noise during strenuous or contorted intercourse characterize the diagnosis. Splitting of the tunica albuginea of the corpus cavernosum can result in urethral damage, haematoma and retention. The prognosis is generally good but Peyronie's disease can occur [2]. Injection of drugs for erectile dysfunction can be complicated by haematoma.

Sclerosing lymphangitis

Non-venereal sclerosing lymphangitis/penile venereal oedema/Mondor's phlebitis/localized penile (venereal) lymphoedema/penile lymphocoele presents with a serpiginous mass in the coronal sulcus. The lesion usually arises after prolonged or frequent sexual intercourse with a passive or unenthusiastic partner; subsequent sexual activity may result in tenderness and enlargement. The circumferential scar left by circumcision may be a predisposing factor. There may be spontaneous resolution, or surgical excision may be needed [3]. It is not known whether lymphangitis or phlebitis is the cause [4]. True phlebitis of penile and scrotal veins has been reported in three patients, one of whom had been injured by a golf ball but the others were idiopathic [5]. Thrombophlebitis of superficial penile and scrotal veins is analagous to Mondor's phlebitis of the chest wall (see Chapter 67), but it may be associated with polyarteritis nodosa and thromboangiitis obliterans [6]. Penile thrombophlebitis has been misdiagnosed as Peyronie's disease, and has also been the initial manifestation of a paraneoplastic migratory thrombophlebitis resulting from pancreatic cancer [7].

Strangulation of the penis

The penis may be strangulated by ring devices [8] , including vacuum erection equipment [9], condom rings [10], rubber bands, string, rings (washers), nuts, bushes and sprockets, which are placed deliberately on the penis by the patient for masturbation or by his partner to prolong erection [11,12]. In boys, strangulation can occur following experimental use of rubber bands or string or thread to control enuresis, or resulting from encoiled hair after circumcision [13]. Penile strangulation—the tourniquet syndrome—causes pain, swelling, urethral fistula, pseudoainhum, gangrene and amputation.

Foreign body

Self-instrumentation of the external genitalia may have an autoerotic, psychiatric, therapeutic (relief of itch [14], aiding voiding, cleaning) or accidental aetiology [15]. Complications include frequency, haematuria, abscess, retention, fistulae and calculi. The diagnosis is made by palpation and radiography. Endoscopic removal is usually possible for foreign bodies below the urogenital diaphragm.

Glass beads, spheres of plastic or small round smooth stones (even pearls) may be introduced under the skin of the penis for erotic reasons, causing clinical and radiographical confusion. If oil, petroleum jelly or silicone is

used then a paraffinoma, silicone granuloma or (sclerosing) lipogranuloma can result. In the Philippines, this practice is called 'bulleetus', in Sumatra 'persimbraon', in Korea 'chagan ball' and in Thailand it is called 'mukhsa' or 'tancho' [16].

Extrusion of a testicular prosthesis has been reported to cause scrotal ulceration because of a sinus tract [17].

Lipogranuloma

Mineral oil, petroleum jelly and silicone introduced into the genital skin can elicit lipogranuloma. Most cases are self-induced, either to create testicular prostheses or to increase penile size, enhance sexual pleasure, mutilate or malinger, although some may be accidental [18,19]. One patient injected his penis with an industrial high-pressure pneumatic grease-gun [20]. Endogenous fat liberation is a possible mechanism and idiopathic cases have been reported, predominantly from Japan [21].

Dermatitis artefacta

Dermatitis artefacta on the genitalia does occur. Lesions are typically geometrical, angulated and rectilinear. Sometimes they are induced by needles, knives or cigarette burns, and extraneous foreign material may be introduced into the skin (lipogranuloma and silicone granuloma are discussed above).

Psychotic patients may mutilate their genitalia, as can transvestites [22], but non-psychotic genital self-mutilation can also occur. Australian aborigines slit the penis—open the urethra ventrally, creating hypospadias—and this is called subincision [23]. Ritual female circumcision in Islam, and male circumcision in the Jewish culture, Islam and Western society may be perceived as similar practices.

Biopsy and other investigations may be necessary to exclude penile cancer. It is important also to consider pyoderma gangrenosum, which is rare but frequently omitted from the differential diagnosis of penile ulceration by non-dermatologists.

Child abuse

Physical and sexual child abuse should be suspected in the differential diagnosis of cutaneous disease of the anogenital area in children (Table 68.16), but signs should be interpreted with caution and re-examination should be avoided [25–29]. Child abuse may be erroneously suspected (Table 68.17) when the anogenital area is involved by a dermatosis or a diarrhoeal illness [30].

The significance of anogenital warts in suggesting possible child sexual abuse is controversial. However, early recognition as a marker for child sexual abuse is in the child's long-term best interest [31].

Miscellaneous

Sometimes the penis is bitten by another individual or an animal [32]. Purpura and ecchymoses may develop after oral sex ('love bites') or the use of vacuum erection devices [33]. Degloving injuries can occur in accidents with industrial or agricultural equipment [34]. Electric burns are rare [35]. Sex aids can result in abrasions, eczema and ulceration. Anogenital tattoos are commonplace [36].

Localized gangrene of the scrotum and penis resulting from arterial embolization with particulate matter complicating accidental femoral self-injection of heroin in an addict has been reported [37].

Inflammatory dermatoses

Urticaria and dermographism

These are usually generalized eruptions (see Chapter 47) but it has been proposed that they may account for some of the symptomatology in some patients with unexplained genital itching (and pruritus ani—see below). Stroking the inside of the thigh might induce a weal; indeed, stroking can cause itching without any discernible redness or wealing [1,2]. Contact urticaria is discussed below. Lisinopril has been reported to cause genital angio-oedema [3].

Fig. 68.6 Scrotal lichen simplex. (Courtesy of Dr F.A. Ive, Durham, UK.)

Eczematous dermatoses

Itching and lichenification, particularly around the scrotum, are common presenting problems. Contributory factors include pre-existing dermatoses such as xerosis, atopy and psoriasis, sedentary occupations, motor car and aeroplane travel, and tight underclothing and trousers.

Irritation is a key adverse exogenous influence to which anogenital sites are vulnerable, and sweat, sebum, desquamated corneocytes, dirt, excreta, sexual secretions, clothing, detergents, toiletries, cosmetics, contraceptives and some therapeutic topical treatments are all potential irritants.

Frequently underrated are the effects of overwashing and the excessive use of soap and toiletries, especially in the presence of skin symptoms or urinary or bowel problems, and particularly if patients feel that they might have been exposed to a sexually transmitted disease.

Lichen simplex

Lichen simplex is common around the male genitalia. It is not usually a flexural condition but can be seen on the penile shaft and scrotum (Fig. 68.6). Giant forms (of Pautrier) occur, giving a pineapple appearance [4]. The skin may be broken by excoriations and become secondarily impetiginized or colonized by *Candida*.

Treatment follows the lines of management above and below relating to irritants. There is emphasis on the relief of scratching, soap substitution and moisturization are recommended and the area occluded if possible with a bland dressing—wet if the skin is fiercely eczematized. A potent topical corticosteroid ointment can be used for a few days and then tailed off. Preparations containing tar or combinations of antibacterial and anticandidal and antifungal agents are also useful. Two cases of extensive

giant lichen simplex of the scrotum have been successfully treated by hemiscrotectomy [4].

Irritant contact dermatitis

Anogenital irritants are discussed above and listed in Table 68.18. Friction [6], maceration, overwashing, concomitant anorectal or urological disease are the chief influences. There may be an association with atopy; Birley [7] diagnosed irritant dermatitis in 72% of patients presenting to a genitourinary clinic with 'balanitis' (probably meaning balanoposthitis) of whom a possible 67% had a history of atopy, but none of these patients was patch tested. An irritant scrotal dermatitis in cellists has been described [8]. Topical 5-fluorouracil used to treat keratoses at extragenital sites has caused genital irritant dermatitis [9]. Acute or chronic, sterile or superinfected (with staphylococci or *Candida*, or both), eroded or hyperkeratotic presentations are seen, depending on the scenario. A good example is nappy (diaper) rash (see Chapter 14).

Management follows lines similar to those for pruritus ani (see p. 68.87). Irritants should be identified and eliminated or reduced. Advice is given about soap substitutes, moisturizers, towels and toilet paper. Topical corticosteroid ointments, with or without antibiotic and anticandidal agents, are employed to control the dermatitis. Oral antihistamines are useful. Topical local anaesthetics should be avoided because of the risk of sensitization. Occasionally, secondary infection may be severe; a swab should be taken and oral antibiotics and oral antifungals prescribed.

A more acute picture (itch, burning or pain, swelling, erythema, vesiculation) may occur if highly irritant chemicals in high concentration are accidentally or deliberately used on the genitalia. Patients with a genital rash who are frightened that it may have been sexually acquired will sometimes self-treat with unsuitable preparations and in the process increase their morbidity and conceal an underlying sexually transmitted disease or dermatosis. Treatment is with potassium permanganate soaks, very potent topical corticosteroid creams (sometimes systemic corticosteroids) and systemic antibiotics.

Allergic contact dermatitis

The risks of allergic contact dermatitis of the genital skin come about from: (i) direct contact with the allergen (e.g. medicaments—even coal tar allergy has been reported [10]), contraceptive usage and prosthetic limbs in amputees [11]; or, very rarely, (ii) transfer of allergen (e.g. urushiol as in poison oak, poison ivy and poison sumac dermatitis) to the genitalia [12] and possibly subsequent exposure to sunlight (e.g. psoralens from fig or citrus plants, as in phytodermatitis); and (iii) involvement in a more generalized eczematous response (e.g. to a medicament or dressing used on venous eczema or ulceration, as in the autosensitization/secondary spread/secondary generalization syndrome).

Acute or chronic eczematous symptomatology appears approximately 1 week after first contact with the allergen if previously unsensitized, or within a few hours if already allergic. The patient may present with pruritus ani [13] or paraphimosis [14]. More immediate symptomatology and acute erythema and angio-oedema suggest a contact urticaria, which can occur with some of the rubber constituents of condoms and gloves [15].

The principles of management are the identification of the potential allergen (Table 68.19) and its likely source, and then its elimination. There may be clues to these factors at presentation but subsequent patch testing is often required. Following patch testing, Bauer *et al.* [16] made a final diagnosis of allergic contact dermatitis in 35% of patients with anogenital skin problems. Allergic contact dermatitis can persist even with the withdrawal of the trigger allergen. Management is otherwise as for irritant contact dermatitis, lichen simplex and pruritus ani (see above and p. 68.87).

The most common relevant sensitivities are to rubber, contraceptives, preservatives and fragrances in toiletries

and medicaments, and the active agents (antibiotics, steroids, anaesthetics) in medicaments.

Genital rubber dermatitis is not confined to young sexually active male condom users and their partners [17–20]. Incontinent men who use external urinary collection devices (Paul's tubing) are also at risk. Latex allergy may be a problem in patients with spinal cord injury using rubber products for the management of urinary difficulties; life-threatening anaphylactic reactions have occurred [19]. Condoms made from lamb caecum are available for rubberallergic patients but they may provide less protection against sexually transmitted disease than latex. Creating hypoallergenic condoms by washing in an ammonium solution to remove the residues of the accelerator chemicals that actually cause the hypersensitivity has proved unsuccessful [21]. Patients may become sensitized to the spermicide [17].

Celandine juice [14] and clothing dye dermatitis of the scrotum [22] have been reported.

Atopic dermatitis

Genital skin disease caused by atopic dermatis (AD) is not uncommon but rarely occurs in isolation, unlike other common chronic dermatoses such as seborrhoeic dermatitis and psoriasis. It is not known how genital AD is related to circumcision, sexual activity and sexually transmitted disease. Evidence of atopy was found in a possible 67% of a total of 72% of patients diagnosed as having irritant dermatitis from a consecutive series of men presenting to a genitourinary clinic with 'balanitis'—probably balanoposthitis [6]. AD in HIV/AIDS is discussed in Chapter 26.

Radiodermatitis

Radiodermatitis (see Chapter 76) is not usually a diagnostic challenge or a therapeutic problem in the acute stage after radiotherapy to the anogenital skin for skin disease or internal cancer. In the chronic state, there may be pruritus together with the typical poikiloderma. Radiotherapy confers a long-term increased risk of skin cancer, especially basal cell carcinoma. There is concern that radiotherapy for Bowen's disease or erythroplasia of Queyrat may increase the subsequent risk of invasive carcinoma.

Seborrhoeic dermatitis

Genital involvement is frequent with this common dermatosis. The groins and penis may be the only sites involved. A good history (including family history) and careful examination of other sites typically affected aid the diagnosis. On the scalp, the face, in the flexures and at anogenital sites seborrhoeic dermatitis and psoriasis may be indistinguishable. Seborrhoeic dermatitis in HIV/AIDS is discussed in Chapter 26.

Diagnosis is established on clinical grounds, including response to therapy, and it is not usually necessary to perform a biopsy.

No treatment may be required other than reassurance that it is not sexually transmitted or related to poor hygiene. However, treatments that diminish the *Malassezia* load and reduce irritation and eczematization can be successfully and safely used long term. These include topical antifungals (such as clioquinol, nystatin and imidazoles) as ointments, creams, lotions or shampoos, and mixtures of the same agents with mild and moderately potent topical corticosteroids used alongside emollients and soap substitutes. In severe cases, patients with concomitant seborrhoeic folliculitis, or in patients with HIV/AIDS, treatment with an oral imidazole and/or an oral tetracycline may be suitable.

Psoriasis

Approximately 2% of the population are said to have psoriasis but it is possible that many more than 2% of men may have or have had anogenital psoriasis at some time; it is certainly a common anogenital diagnosis in isolation.

Psoriasis and its clinical manifestations are discussed in Chapter 35; the relationship of psoriasis with HIV/AIDS is discussed in Chapter 26. Anogenital presentations of psoriasis may be vague in symptomatology and nonspecific on examination. It is not usually itchy; significant itch should arouse suspicions of another dermatosis such as an eczematous dermatitis or tinea. Soreness occurs with superinfection, especially with *Candida*. Other typically affected sites should be examined for signs of the disease. Genital appearances may be challenging to interpret, especially in the uncircumcised patient, because a mucosal site is affected rather than keratinized skin. The diagnosis is usually easier in the circumcised male where the morphology is similar to extragenital lesions.

Inverse pattern psoriasis refers to the manifestation of the disease on intertriginous skin in the axillae, natal cleft, gluteal folds, groins and in the preputial sac and on the glans of the uncircumcised male, where its occurrence is probably brought about by the Koebner phenomenon.

Usually, the diagnosis of psoriasis is clinical, but a biopsy may be necessary (e.g. of a solitary mucosal lesion in an uncircumcised individual) to distinguish psoriasis from Zoon's balanitis, lichen planus, erythroplasia of Queyrat or Kaposi's sarcoma. Bowen's disease and extramammary Paget's disease may be misdiagnosed as psoriasis when there are single or several foci on the penile shaft and/or in the groins.

Topical treatment includes emollients, soap substitutes, corticosteroids combined with antibiotic and antifungal agents or weak tar solutions. Strong crude tar preparations should be avoided at this site given that anogenital skin has a propensity to increased absorption of topical agents and because of the risk of genital cancer; one of the first

occupational diseases described was scrotal carcinoma in chimney sweeps. Dithranol is usually avoided in this region. The vitamin D analogue calcipotriol can be helpful. Topical ciclosporin (100 mg/mL in wet dressings three times daily) has been advocated [23]. Phototherapy is contraindicated because of the risk of anogenital cancer. Severe anogenital psoriasis can be an indication for systemic treatment.

Reiter's disease or syndrome (part of the same continuum as psoriasis in genetically predisposed individuals) is discussed in Chapter 35. Characteristic, sometimes severe, involvement of the penis (circinate balanitis) occurs. The penile lesions have the same histopathology as psoriasis [24].

Zoon's balanitis

Aetiology. Zoon's plasma cell balanitis (ZB) is a disorder of the middle-aged and older uncircumcised male [1,2], although an analogous condition has been reported to afflict the vulva (see p. 68.59), mouth, lips [3] and epiglottis [3,4]. Since Zoon's original reports there have been many accounts in the literature but the aetiology remains uncertain.

The evidence suggests that ZB is a chronic, reactive, principally irritant mucositis brought about by a dysfunctional prepuce. Retention of urine and squames between two tightly apposed and infrequently and inadequately separated and/or inappropriately bathed, commensally hypercolonized, desquamative, secretory epithelial surfaces leads to a disturbed 'preputial ecology' and excessive frictional trauma (ZB is often located on the dorsal aspect of the glans and/or the adjacent prepuce, sites of maximal friction on foreskin retraction) and irritation by urine [5–7]. There is no evidence of an infectious cause, and immunohistochemical findings suggest that ZB represents a non-specific polyclonal tissue reaction [8,9], consistent with an irritant mucositis.

Clinical features. The presentation is classically indolent and asymptomatic, although staining of the underclothes with blood has been reported [10]. Well-demarcated, glistening, moist, bright red or autumn brown patches involve the glans and mucosal prepuce [7], with sparing of the keratinized penile shaft and foreskin (Fig. 68.7). The urethra (fossa navicularis) may be involved. Other signs include dark red stippling—'cayenne pepper spots'—and purpura with haemosiderin, solitary or multiple lesions of differing sizes (guttate or nummular), characteristically symmetrical about the axis of the coronal sulcus and 'kissing'. Although vegetative and nodular presentations have been recorded, atypical or unusual morphology should be viewed with great suspicion and biopsied.

Histopathology. The classic histology is of epidermal attenuation with absent granular and horny layers, and diamond- or lozenge-shaped basal cell keratinocytes with sparse dyskeratosis and spongiosis. There is a band of dermal infiltration with plasma cells of variable density. Extravasated erythrocytes, haemosiderin and vascular proliferation are also seen. Although Zoon stressed the presence of the plasma cell infiltrate in this condition, the plasma cell numbers can be very variable [7,11].

Differential diagnosis. The differential diagnosis includes erosive lichen planus, psoriasis, seborrhoeic dermatitis, contact dermatitis, fixed drug eruption, secondary syphilis, histoplasmosis [12], erythroplasia of Queyrat [13] and Kaposi's sarcoma. A confident clinical diagnosis is not always possible or safe [6], so a biopsy is advisable and the

Fig. 68.7 Zoon's balanitis. Symmetrical moist erythema of glans and prepuce. (Courtesy of Dr C.B. Bunker, with permission from Medical Illustration UK, Chelsea & Westminster Hospital, London, UK.)

pathologist should be asked to look for concomitant disease. Frank cases of lichen sclerosus, lichen planus, Bowenoid papulosis and penile cancer often appear to have ZB-like changes on clinical examination and on histology. In other words, the signs of ZB may be secondary to underlying preputial disease. It is likely that some of the clinical and histological variants that have been reported [14–16], and a recent claim that ZB *per se* is a premalignant condition in a single case report [17], are a consequence of this phenomenon. ZB indicates a dysfunctional foreskin and a more sinister dermatosis may be concealed.

Treatment. Although ZB can improve with altered washing habits and the intermittent application of a mild or potent topical corticosteroid (with or without an antibiotic and anticandidal agent), it usually persists or relapses. Definitive curative treatment is circumcision [7]. Again, the pathologist should be asked to examine the whole specimen for signs of another underlying dermatosis. It has been claimed that the carbon dioxide laser is effective [18].

Lichen sclerosus

Aetiology. Lichen sclerosus is discussed in Chapter 56. The aetiopathogenesis is not known. Poorly understood are the predilection for the genitalia generally (in males, particularly the uncircumcised [1]), the association with organ-specific autoimmune disease and the propensity to progress to squamous carcinoma [2–5]. HPV (types 6, 16 and 18) is present in 70% of cases of childhood penile lichen sclerosus [6,7], but the epidemiology and clinical tenor of lichen sclerosus is not that of an infectious or sexually transmitted disease [5,8]. Anatomical abnormality and trauma seem to be contributing factors [5,9]. Specifically, lichen sclerosus has been related to hypospadias and its repair [10]. The presence of the histopathological features of lichen sclerosus in a percentage of acrochordons (skin tags) has led to the suggestion that occlusion of flaccid skin is a pathogenic factor [11].

Clinical features. Lichen sclerosus of the penis may be asymptomatic, but diverse, often vague, symptomatology is usually encountered [12]. Patients may describe itching, burning, bleeding, tearing, splitting, haemorrhagic blisters, any manner of symptoms signifying sexual dysfunction or dyspareunia, discomfort with urination and narrowing of the urinary stream, and/or be concerned about the changing anatomy of their genitalia [5]. Other presentations are non-retractile foreskin (phimosis)

Fig. 68.8 Lichen sclerosus causing phimosis. (Courtesy of Dr D.A. Burns, Leicester, UK.)

Fig. 68.9 Lichen sclerosus. White plaques and haemorrhagic areas on the glans. (Courtesy of Dr D.A. Burns, Leicester, UK.)

(Fig. 68.8), foreskin fixed in retraction (paraphimosis) and urinary retention, even renal failure.

Genital, like extragenital, lichen sclerosus can manifest as atrophic leukodermic patches or plaques, or lilac, slightly scaly patches with telangiectasia and sparse purpura (Fig. 68.9). Predominant purpura, bullae, erosions and ulceration may be encountered [5,13,14]. The signs may be subtle, with meatal 'pin hole' narrowing, slight tightening of the retracted prepuce because of sclerotic plaques and bands, with or without difficulty in retraction—incomplete paraphimosis or 'waisting' (Fig. 68.10) or they may be florid, with severe changes caused both by the lichen sclerosus and by associated Zoon's balanoposthitis-like changes: adhesions, loss of anatomical definition and dissolution or effacement of the normally sharply defined architectural features, especially of the frenulum and the coronal sulcus. Changes resulting from ZB may be more florid than the underlying lichen sclerosus. Post-inflammatory hyper- and hypopigmentation are occasionally seen.

Whereas posthitis xerotica obliterans refers to chronic damage to the prepuce by lichen sclerosus, balanitis xerotica obliterans (BXO) properly describes involvement of the glans penis (although the term has been used imprecisely). BXO can be a consequence of other scarring dermatoses such as lichen planus and cicatricial pemphigoid [15].

Genital lichen sclerosus is more common than extragen-

Fig. 68.10 Lichen sclerosus. Sclerotic band of the prepuce causing 'waisting'. (Courtesy of Dr C.B. Bunker, with permission from Medical Illustration UK, Chelsea & Westminster Hospital, London, UK.)

ital or oral disease, but there may (rarely) be concomitant involvement of these sites. In adults, anogenital lichen sclerosus is said to be about 10 times more common in women than men. Perianal disease seems rare in the male. The involvement of the anterior urethra can be serious: 29% of patients undergoing urethroplasty for urethral stricture had pathological evidence of lichen sclerosus [16].

The first report of genital lichen sclerosus in boys appeared only in 1977 [17], and lichen sclerosus may be much more frequent than is generally supposed in young boys. The development of secondary phimosis in school-age boys is highly suggestive of lichen sclerosus [18]. In the older male, persistent primary phimosis or the secondary development of phimosis in a previously retractable foreskin may be related to lichen sclerosus [5].

Most cases of genital lichen sclerosus can be diagnosed clinically. Lichen planus and the much rarer mucous membrane pemphigoid are in the differential diagnosis. A biopsy should be performed if there is clinical doubt or if the lesion is eroded or verrucous.

Histopathology. The histology is classic (see Chapter 56). The occasional association of endarteritis led originally to the usage of the term 'obliterans' [19]. In two cases in boys, a dermal lymphohistiocytic and granulomatous phlebitis has been found, and one also had evidence of HPV [20]. A garland-like basal lamina has been found ultrastructurally [21]. Sometimes, lichen sclerosus may be difficult to differentiate from lichen planus, and criteria to assist, in the vulva, have been proposed by Fung and LeBoit [22].

Treatment. Guidelines for the management of lichen sclerosus have been published by the British Association of Dermatologists [23]. A very potent topical corticosteroid (used under supervision) is effective [24]. The plasticity of the epithelium at this site seems to allow significant remodelling, with the relief of phimosis, improvement of incomplete phimosis or waisting, improvement in the histological changes and avoidance of circumcision [5,12]. Secondary candidal and bacterial infection should be treated. There are reports of the efficacy of long-term systemic antibiotic therapy (penicillin and azithromycin) in cases of lichen sclerosus thought to be associated with *Borrelia* infection [25,26]. Testosterone propionate ointment, oral stanozolol, freezing with ethyl chloride, liquid nitrogen cryotherapy, carbon dioxide laser and adrenocorticotrophic hormone (ACTH) have been used with variable success [5].

If medical treatment is not possible or fails, then surgery may be indicated. Circumcision, frenuloplasty, meatotomy and sophisticated plastic repair, depending upon the clinical presentation, can be offered. In boys, complete circumcision is the treatment of choice because all affected tissue is removed and any secondary involvement of the glans probably regresses or resolves [18]; it is the unproven impression that this phenomenon also occurs in most adult patients. Lichen sclerosus can recur in donor grafts from unrelated sites [13,27]. Carbon dioxide laser circumcision has been advocated [28].

Squamous carcinoma of the penis is the most serious potential complication of lichen sclerosus; *in situ* change can occur often after long periods [5,29]. A risk of 4–9.5% has been claimed, depending on length of follow-up; the latent period may be one to three decades [30–32]. Verrucous carcinoma (Buschke–Löwenstein tumour) has been associated with previous lichen sclerosus [33,34]. Carcinoma complicating lichen sclerosus constituted one-third of all cases of penile cancer seen by Campus *et al.* [35] and, of 20 patients with penile squamous cell carcinoma (SCC) studied by Powell *et al.* [36], 11 had a clinical history and/or histological evidence of lichen sclerosus. Involvement of the glans penis confers a greater risk [32].

The effect of medical and surgical treatment on the subsequent incidence of penile cancer is not known [37,38]. Liatsikos *et al.* [39] report SCC of the glans developing in one of eight patients followed-up after circumcision for lichen sclerosus. Patients should be followed-up long term, especially if circumcision has not been performed or if symptoms persist or recur after any form of treatment.

Lichen planus

Aetiology. Lichen planus is discussed in Chapter 42. It is a common inflammatory dermatosis with a particular predilection for the mucosae [1]. The aetiopathogenesis of lichen planus is not known. Drugs can cause a generalized lichenoid eruption; a case of a lichenoid drug eruption confined to the penis resulting from propranolol has been reported [2].

Clinical features. Lichen planus can present in, and remain localized to the anogenital area, including the groins and perianal skin. Like the classical disease at other sites, it presents as itchy red–purple papules, also as patches or plaques and annular lesions (Fig. 68.11) or as phimosis [3]. The Koebner phenomenon may partly explain the orogenital predilection [4].

Fig. 68.11 Lichen planus. Papules and annular lesions with Wickham's striae on the glans and shaft. (Courtesy of Dr C.B. Bunker, with permission from Medical Illustration UK, Chelsea & Westminster Hospital, London, UK.)

Occasionally, an erosive form is encountered. There is a male equivalent of the vulvovaginal syndrome of Hewitt—the genito-gingival syndrome—with chronic erosive gingival and genital lesions [5]. In most cases, anogenital lichen planus is self-limiting, although some patients relapse and remit. Adhesions can form. Post-inflammatory hyperpigmentation can persist for months or years. A case of paraneoplastic lichen planus with orogenital and cicatrizing conjunctival involvement in a patient with thymoma has been reported [6].

Chronic mucosal erosive lichen planus is associated with a risk of progression to SCC but most reports concern oral lichen planus. SCC may complicate hypertrophic lichen planus of the glans penis [7,8].

Lichen nitidus has an affinity for the penis. It can be difficult to diagnose because the signs may be subtle, even when the lesions are widespread.

The differential diagnosis of anogenital lichen planus includes psoriasis, ZB, lichen sclerosus, viral warts, Bowenoid papulosis and porokeratosis. A biopsy is frequently necessary for diagnostic purposes and in the

follow-up of cases of chronic anogenital disease if erosive, ulcerative or verrucous features arouse concern about the development of SCC.

Treatment. Potent and ultrapotent topical corticosteroids usually suffice for treatment. Patients are told to continue with the treatment until the lesions are non-itchy and flat; they are warned about post-inflammatory hyperpigmentation. Topical and oral ciclosporin have been used [9,10]. Circumcision may be necessary for phimosis [11] and should be considered in refractory erosive disease [12]. The rationale being that the abolition of koebnerization influences and facilitates resolution of the lichen planus. Photodynamic therapy was used inadvertently in one patient with lichen planus of the glans penis, to good effect [13].

Ulcerative disease and penile necrosis

Aphthous ulceration of the penis and scrotum can occur, including in HIV/AIDS (see Chapter 26), but specific exclusion of sexually transmitted diseases and consideration of other causes of genital ulceration, especially Behçet's syndrome, is necessary. The causes are obscure and the histology is non-specific.

Five cases of spontaneous scrotal ulceration in young, previously fit men have been described [1]. Histology showed non-specific vasculitis, and spontaneous resolution occurred. This entity may be related to idiopathic scrotal panniculitis and fat necrosis. This condition is distinct from other causes of the acute scrotum in prepubertal boys. It presents as acute tender, sometimes painful, swelling (classically, but not always, after swimming in cold water). Masses may be palpable in the scrotal wall. Otherwise, the boy is well, with no fever or leukocytosis. Idiopathic scrotal necrosis in a 2-month-old boy has been documented by Sarihan [2], where trauma, extreme cold and Fournier's gangrene were excluded. Management is expectant and conservative [3,4]. In adults, one case of idiopathic scrotal panniculitis has been reported [5] and another associated with pancreatitis [6].

Subtle or severe orogenital ulceration can occur in erythema multiforme or the Stevens–Johnson syndrome (see Chapter 74).

Behçet's disease is discussed in Chapter 66. Recurrent genital ulceration is not mandatory for the diagnosis; if patients do not have genital ulceration then they must have ophthalmic and dermatological involvement or a positive pathergy test [7]. In practice, there are many patients who have an incomplete syndrome. Other anogenital manifestations include epididymitis and urethritis [8], spontaneous haematocoele from venous rupture resulting from lymphocytic venulitis [9] and erectile dysfunction [10]. The genital ulcers in men can be very painful and occur anywhere on the anogenital area, including the perianal skin. Generally, they are larger, deeper, fewer and less recurrent than those in the mouth. Patients with relapsing polychondritis and Behçet's disease have been reported, and the acronym MAGIC (mouth and genital ulcers with inflamed cartilage) syndrome has been proposed [11,12]. The histology of Behçet's disease is usually non-specific and does not enable it to be distinguished from idiopathic aphthae, although sometimes necrotizing vasculitis can be present.

Degos' malignant atrophic papulosis (see Chapter 48) has caused penile ulceration, which preceded the development of the rash and eventual fatal involvement of other organs, despite aggressive treatment [13].

The hypereosinophilic syndrome involves the skin in up to 50% of cases, with orogenital ulceration, erythroderma and urticaria [14]. It may occur in HIV infection.

Penile necrosis has a wide differential diagnosis (Table 68.20). Many of the causes are discussed in this or other sections.

Two cases of necrobiosis have been reported presenting as erythematous ulcerated lesions of the glans penis. One patient was diabetic and had lesions on the legs [22]; the other had penile lesions only and was treated with oral pentoxifylline [23].

There are a number of case reports of pyoderma gangrenosum (see Chapter 49), including the variant superficial granulomatous pyoderma, involving the penis and scrotum in adults and children (where the anogenital area is a site of predilection as well as the head and neck)

Table 68.20 Causes of penile necrosis. (After Bunker [15]. © 2004, with permission from Elsevier.)

Decubitus ulcer
Spider bite
Priapism
Embolism
Strangulation and tourniquet syndromes
Vacuum erection device
Vasculitis [16]
Diabetes mellitus [17,18]
Chronic renal failure [19]
Thrombocytopenia
Polycythaemia
Cryoglobulinaemia
Coagulopathy [20]
Pyoderma gangrenosum
Calciphylaxis
Ecthyma gangrenosum
Fournier's gangrene
Herpes simplex
Leukaemia
Mucormycosis (in acute myeloblastic leukaemia) [21]
Warfarin
Fixed drug eruption

(Fig. 68.12) [24,25]. Genital pyoderma gangrenosum may occur following local trauma such as urological surgery [26], or complicate ulcerative colitis [27] or chronic lymphocytic leukaemia, or it may be idiopathic [28–31]. Pyoderma gangrenosum is a diagnosis made when other causes of purulent ulceration, such as infection (sexually acquired and exotic), malignancy and artefact have been excluded.

Calciphylaxis (see Chapter 59) is a rare and serious complication of chronic renal failure in which extending ischaemic gangrenous necrosis affects acral tissues and sometimes the thighs, buttocks and genitals [32–34].

Pilonidal sinus

Pilonidal sinus very rarely affects the penis, but when it does it is usually in the coronal sulcus. Some of the reported cases have been complicated by actinomycosis [1,2] and another has been associated with a dermoid cyst [3].

Penile acne

There is no literature on this condition but it is occasionally encountered. Patients have comedones, papules, pustules and inflammatory nodules of the proximal shaft of the penis. The differential diagnosis should include chloracne (see Chapter 43). Patients respond to conventional treatment for acne.

Peyronie's disease

Peyronie's disease [1,2], which affects middle-aged and older men, is a localized fibrotic disorder involving tissue immediately adjacent to the erectile tissues. It presents with pain and curvature on erection, a sensation of a cord within the penis, palpation of a lump or knot, decreased erection distal to the plaque, interference with intercourse and progressive impotence. It may be subclinical in many men, given that 23% of autopsies have shown histological evidence of the condition [1]. Psychological complications and marital difficulties occur. The penis curves towards the lesion, with dorsal curvature being most common. Peyronie (a physician to Louis XIV) described nodules as 'rosary beads' but plaques vary in size. It has been associated with systemic sclerosis [3], and such patients may have penile Raynaud's phenomenon [4]. It has occurred as a complication of the use of a vacuum erection device [5], but in most men the cause is unknown. Some evidence has been advanced for an autoimmune pathogenesis [6].

The differential diagnosis includes congenital curvature, fibrosis secondary to trauma or urethritis and abscess, syphilitic gumma, lymphogranuloma venereum, and infiltrative tumours (e.g. lipogranuloma). Penile thrombophlebitis as the initial presentation of a paraneoplastic migratory thrombophlebitis resulting from pancreatic cancer has been misdiagnosed as Peyronie's disease [7].

In some men there may be spontaneous regression. Treatments include intralesional corticosteroid injection [8], including delivery by Dermojet [9]. Surgery is avoided, but some specialized techniques are available [10]. Symptomatic relief has been claimed following iontophoresis of drugs such as dexamethasone, lidocaine (lignocaine) and verapamil [11].

Drug reactions

The penis is a site of predilection for fixed drug eruption, like the face and extremities (see Chapter 73). The symptoms are itch or burning. The eruption is acute with a swollen plaque, sometimes with central blister formation, erosion and ulceration. Gruber *et al.* [1] describe the case of a man with known sensitivity to co-trimoxazole who developed a penile fixed drug eruption after intercourse with his wife while she was taking the drug for a sore throat. The differential diagnosis includes herpes simplex and erythema multiforme.

Ulceration has been reported following the inadvertent subcutaneous injection of papaverine for the treatment of erectile impotence [2]. Dequalinium is a topical antibacterial that was used for the treatment of impetigo and moniliasis in the 1950s and 1960s, but it caused a necrotizing balanitis with ulceration when used for the treatment of balanitis in uncircumcised men [3]. Warfarin necrosis can affect the genitalia [4]. All-*trans*-retinoic acid has been reported to induce scrotal ulceration in a patient with acute promyelocytic leukaemia [5]. Foscarnet is a recognized cause of genital ulceration in HIV-infected patients [6–8]. Erosion following the use of topical steroids has been seen.

Miscellaneous

It is not unusual for the herald patch of pityriasis rosea to appear on suprapubic skin or in the groin. Incomplete or limited presentations (e.g. affecting the pelvic girdle) are not rare, although careful examination may elicit another patch on the neck or in the axilla.

Bottomley and Cotterill [1] have described an acutely tender erythematous scrotum associated with zinc deficiency in a patient with Crohn's disease. Necrolytic migratory erythema can be localized to the genitalia [2].

Autoimmune bullous diseases such as pemphigus can involve the penis (the glans is the usual site) (Fig. 68.13), but very rarely in isolation [3]. Pemphigus vegetans presenting with a 4-year history of indolent tender balanitis, where the glans penis was involved with a moist vegetative plaque with beefy red erosions separating irregular hyperkeratotic mounds, has been reported [4]. Linear immunoglobulin A (IgA) disease commonly involves the mucosae. Mucosal lesions of bullous pemphigoid are uncommon; their presence suggests another diagnosis or an underlying neoplasm. Pelvic girdle lesions are often seen, but rarely in isolation.

Cicatricial pemphigoid or (benign) mucous membrane pemphigoid is a rare variant of bullous pemphigoid in which blisters affect the skin and the mucous membranes. Skin lesions are usually less widespread than in bullous pemphigoid and they may heal with scarring. Oral lesions predominantly involve the palate and gingivae, but there may be oesophageal involvement with dysphagia, and conjunctival disease can lead to blindness. Involvement of the penis may be with blisters, erosions, ulcers, transcoronal adhesions, scarring and phimosis [5,6]. Although direct immunofluorescence is usually positive, circulating antibodies to the basement membrane zone are rarely found. The disease often responds poorly to oral steroids,

Fig. 68.13 Pemphigus of the penis. (Courtesy of Dr F.A. Ive, Durham, UK.)

but dapsone or other sulpha drugs such as sulphamethoxypyridazine can be effective. Regular haematology screening is mandatory with dapsone because of the risk of agranulocytosis.

One patient with Darier's disease developed an HPV 16-associated squamous carcinoma of the scrotum during oral isotretinoin treatment; he had not previously had radiotherapy to the genitocrural area [7]. Genitocrural papular acantholytic dermatosis can involve the penis, as can granuloma annulare. Erythematous smooth, round and linear nodules are described in the latter. Most patients are uncircumcised. Extragenital granuloma annulare is uncommon in these patients.

Occasionally, patients with generalized cutaneous sarcoid present with genital lesions [8]. Tender erythematous induration of the distal shaft of the penis and several yellowish subcutaneous nodules on the glans have been described [9]. A case presenting with penile ulceration has been reported [10]. Importantly, sarcoid can masquerade as testicular malignancy [11–13].

A granulomatous lymphangitis may be found histologically in the investigation of penile lymphoedema [14]. It can be a rare feature of the Melkersson–Rosenthal syndrome. Crohn's disease can involve the penis and scrotum [15–20].

A soft-tissue mass in the penis associated with systemic amyloid has been reported [21]. Primary amyloid of the

urethra is very rare indeed, but accurate diagnosis is essential, as its presentation simulates carcinoma, with dysuria, bloody discharge and tender induration of the penis [22], or as an obstructive voiding syndrome, with tender periurethral masses and irregular urethral strictures [23].

One case each of eccrine syringofibroadenomatosis with penile involvement manifesting as a balanoposthitis [24], benign mucinous metaplasia with a prepucial 0.6 cm papule replacing the superficial epidermis [25], and mucinous syringometaplasia with an ulcerated papule on the shaft of the penis [26] have been reported.

Acute scrotum is a clinical syndrome defined as acute painful swelling of the scrotum or its contents, usually in boys, accompanied by local signs and general symptoms [27]. The critical differential diagnosis is torsion of the testis or spermatic cord. Other causes include idiopathic scrotal oedema, epididymitis, orchitis, hernia and haematocoele. Thromboangiitis obliterans has been found in two cases [28]. Acute scrotal swelling may be a physical sign of primary peritonitis in children and infants [29] or secondary peritonitis resulting from appendicitis, healed meconium peritonitis in the neonate, haemoperitonitis (ruptured spleen) and pseudotorsion resulting from ventriculoperitoneal shunts inserted for hydrocephalus that have migrated into the scrotum from the peritoneum. Acute idiopathic scrotal oedema usually affects children aged 4–12 years old. Allergy, infection (umbilical sepsis), trauma, insect bites, urinary extravasation and Henoch–Schönlein purpura have all been considered as causes. It is rare in adults, but cases in association with septic diabetic foot have been reported [30].

Henoch–Schönlein purpura/anaphylactoid purpura may affect the genitalia. Ureteritis, renal pelvic haemorrhage and pain and swelling of the spermatic cord have been reported. The incidence of scrotal involvement ranges from 2 to 38%. In some cases, the presentation has masqueraded as testicular torsion, resulting in unnecessary surgical exploration. Ultrasonography can help to distinguish between them [31]. However, testicular torsion can also be a serious complication of Henoch–Schönlein purpura [31].

Acute haemorrhagic oedema of childhood may present as tenderness, redness and swelling of the penis and scrotum with the development of more widespread haemorrhagic lesions [32]. The differential diagnosis includes acute febrile neutrophilic dermatosis, erythema multiforme, Henoch–Schönlein purpura and child abuse. The prognosis for complete recovery is excellent. Acute inflammation of the scrotum in patients with familial Mediterranean fever can occur [33]. It is manifested by pain, erythema and swelling, fever, leukocytosis and elevated erythrocyte sedimentation rate (ESR). It may occur in isolation or accompanying peritonitis. The differential diagnosis includes torsion, orchitis and epididymitis in boys.

Polyarteritis nodosa may be associated with testicular and epididymal involvement, with scrotal pain and swelling. In one case these were the sole presenting features and testicular biopsy provided the diagnosis [34–36].

Non-sexually transmitted infections

Staphylococcal cellulitis

Cellulitis may affect the penis. Piercing and genital jewellery predispose to infection. Cellulitis and abscess formation can complicate cysts, sinuses and fistulae and sexually transmitted infections. The exact relationship between episodes of acute infection and chronic penile oedema (CPL; see below), which often is complicated by cellulitis, is uncertain.

Anogenital infection in patients with malignant disease is serious, and potentially life-threatening necrotizing fasciitis and Fournier's gangrene may occur.

Streptococcal dermatitis/perianal cellulitis

This syndrome in children [1] probably also has a corollary in adults [2], but it is much more common in boys in whom, if the penis is involved, there may be dysuria, erythema and swelling of the penis and balanoposthitis.

Chronic idiopathic penile oedema

Chronic penile lymphoedema (CPL) is a relatively rare, reactive, disfiguring condition that causes sexual dysfunction and phimosis [3]. It has previously been called tumorous lymphoedema or elephantiasis verrucosa nostra [4]. Evidence of streptococcal infection may be present, and this could lead to irreversible lymphatic damage, whereas other cases seem idiopathic, and are perhaps brought about by primary hypoplastic lymphatics. Some patients have another penile dermatosis. Few cases of CPL have been reported before [3,5,6], and the aetiopathogenesis may have been misunderstood. Penoscrotal oedema has also been attributed to continuous ambulatory peritoneal dialysis [7], amputation of septic limbs in diabetes [8], acute necrotizing pancreatitis [9] and streptococcal infections [10]. Penile venereal oedema has been associated with gonococcal and herpes infection, and scabies infestation, and resolves after treatment of the underlying disease [11]. Similarly childhood penile oedema is self-limiting [12].

Filariasis and pelvic mass lesions should be excluded. Imaging of lymphatic channels is not particularly helpful [13]. It is possible that cases of CPL are related to any of the above factors and/or temporally unrelated but repetitive sexually transmitted disease. Persistent lymphatic insult from whatever cause could result in an inflammatory process affecting genital and pelvic vessels and nodes. Therefore all cases of penoscrotal oedema should be treated aggressively at first presentation, because the more chronic the genital lymphoedema the more difficult it is to treat, both medically and surgically [14]. The aim of treatment of CPL must be prophylaxis against further infective episodes and aggressive treatment of relapses.

Patients with CPL present with chronic swelling of the penis, foreskin, scrotum, pubic mound, buttocks and thighs, which may be warm and red. There may be intercurrent attacks of cellulitis and/or erysipelas with systemic upset.

Acute attacks require admission to hospital and treatment with systemic broad-spectrum antibiotics; a short course of prednisolone may also be helpful. Long-term treatment with erythromycin, clarithromycin or ciprofloxacin appears to improve and stabilize the process, and improves the appearance and function of the penis. The success of this approach argues the importance of infection as a factor in the perpetuation if not initiation of the process. Medical control with antibiotics then allows surgical intervention in the form of circumcision. Plastic repair may be necessary after excision of affected tissue [15,16].

Ecthyma gangrenosum

Ecthyma gangrenosum has a predilection for the acral and anogenital regions, and may affect the penis in isolation, leading to gangrene [17]. The prognosis is poor. A case has been reported that was probably caused by direct arterial septic embolization of the penis from femoral heroin injection [18].

Fournier's gangrene

Fournier's gangrene is analogous to necrotizing fasciitis and Meleney's gangrene. In 1883, the Parisian dermatologist Alfred Fournier described five cases of spontaneous genital gangrene and ulceration, but Baurienne (1764) probably first reported this condition [19]. The disease begins with urethral or appendageal polybacterial infection. Most of the organisms isolated are resident urethral or lower gastrointestinal flora, and most patients have mixed infections. In children, staphylococci and strepto-

Polyarteritis nodosa
Necrolytic migratory erythema
Vascular occlusion syndromes
Warfarin necrosis

cocci are most commonly isolated [20]. A necrotizing vasculitis, possibly exotoxin-mediated, ensues with devastating consequences for involved skin, subcutis, fascia and muscle. It is held to be the human counterpart of the local Shwartzman phenomenon [21,22]. Painful erythematous swelling of the genitals (a black spot may appear on the scrotum [23]), perianal or lower abdominal skin with no suppuration but marked systemic toxicity (may be absent in children [20]), and urinary retention, is a typical presentation. Necrosis of skin and deeper tissues can occur rapidly, and there is a very high mortality unless the diagnosis is made promptly and radical mangement undertaken. Plain X-rays may show soft-tissue gas [24]. Predisposing factors are listed in Table 68.21. Preceding surgery, including vasectomy and instrumentation, especially in patients with the listed risk factors, is particularly important. The differential diagnosis is given in Table 68.22.

If a diagnosis of Fournier's gangrene is made, radical surgical débridement of all affected tissue is undertaken and broad-spectrum systemic antibiotic therapy initiated. Plastic repair can be undertaken if the patient survives. Hyperbaric oxgen and high-dose systemic steroid treatment have been used [22,26,27]. Children can be treated with more conservative surgery, and the mortality rate is lower [20,28]. In adults, the mortality is approximately 25%.

Trichomycosis pubis

Trichomycosis pubis causes asymptomatic yellow, red or black micronodules around hair shafts [29]. Pubic and axillary hair may be involved. The skin is normal but the sweat may be discolored. Trichomycosis pubis is rare in Western dermatological practice but is common in the Middle East [30], and may occur concomitantly with trichosporosis in India [31]. It is caused by *Corynebacterium* spp. The differential diagnosis includes true mycoses such as white or black piedra. Treatment is with topical benzoic acid, salicylic acid, clindamycin or naftifine [29].

Tuberculosis

Tuberculosis of the penis is rare [32] but important given the resurgence of the disease. Primary penile ulceration (solitary and multiple), with or without inguinal lymphadenopathy, caused by sexual infection or contact with infected clothing may occur [33], or the ulceration may be secondary to tuberculosis elsewhere (e.g. the lung) [34]. A cold abscess (presenting as erectile impotence) has been reported [35]. Tuberculides have involved the penis, including in isolation [36].

Non-syphilitic spirochaetal ulcerative balanoposthitis

This condition is recognized in the Tropics and South Africa, presenting as large serpiginous foul-smelling ulcers in uncircumcised men, associated in some with non-tender inguinal lymphadenopathy. Treatment is with penicillin or metronidazole [37].

Yaws

An ulcerated, crusted and papillomatous lesion has been reported on the prepuce as part of disseminated early yaws (with other skin lesions elsewhere) in a patient in an endemic region. Several family members were also infected. The genital lesion probably arose from autoinnoculation [38].

Candidosis

Genitourinary physicians maintain that *Candida* can be the cause of urethritis and balanoposthitis [39]. The glans penis and prepuce may be eroded. *Candida* of the penis (with a prevalence of approximately 10% of that of vaginal candidosis) has attracted very little research interest [40].

Candida may be more often a secondary pathogen than a sexually acquired infection. Observing the signs of candidosis, or demonstrating the presence of the organism, does not prove that it is the cause of all the symptoms and signs. An underlying dermatological or medical cause should be excluded. The symptoms and signs of *Candida*

may be more florid than the underlying predisposing cause. Medical causes include diabetes mellitus, iatrogenic immunosuppression and systemic antibiotic treatment. Although oropharyngeal candidosis is almost invariably found in HIV infection, candidal balanoposthitis is not generally associated, perhaps because it is overlooked or because many patients take long-term imidazole antifungals orally.

Candida albicans is such a ready opportunist organism because it is a part of the resident flora of the gastrointestinal tract and may be retrieved from intertriginous areas, including the preputial folds, in the absence of symptoms and signs. Candidal balanoposthitis could be a sexually transmitted disease that may have an affinity for the anatomically or physiologically abnormal penis, or in individuals predisposed by other factors or disease, and where there is chronic vaginal or anal carriage in a partner. Screening should be performed for other sexually transmitted diseases.

Diagnosis is discussed in Chapter 31. Underlying disease should be identified and treated, and predisposing factors rectified. Treatment includes topical nystatin, clioquinol or an imidazole, often very usefully combined with hydrocortisone or a moderately potent corticosteroid. In severe disease, an oral imidazole may be indicated.

Tinea

Tinea of the penis or scrotum is uncommon and when it occurs it is usually associated with crural disease. Rarely encountered is the occurrence of tinea on the glans penis as a seat of itch or pain, and producing an erythematous patch or a crop of scaly papules [41–46]. Penile tinea in India has been associated with occlusion resulting from the wearing of a langota—a T-shaped piece of cloth tied over the genitalia [43].

Deep fungal infections

Although histoplasmosis is a common cause of disseminated fungal infection in the USA, urological and anogenital disease, usually ulceration and adenopathy in an ill patient, is rare [47,48]. An otherwise well man with a small warty nodule on the glans penis has been reported [49]. One patient with a penile ulcer transmitted the disease venereally to his wife [50].

In blastomycosis, although the genitourinary (prostate and epididymis) tract is involved in 20–30% of cases [51], involvement of the genital skin is rare. However, lesions of the prepuce and perianal skin have been recorded [52,53].

Paracoccidioidomycosis can be the cause of scrotal swelling and genital nodules and erosions [54].

Miscellaneous

Bacillary angiomatosis (see Chapter 26) is important in the differential diagnosis of AIDS-related Kaposi's sarcoma. A case in which the presenting tender red nodules affected the scrotum and groins has been published [55].

The penis is rarely affected by pityriasis versicolor and probably almost never in isolation [56,57]. Occasionally, the anterior pelvic girdle is the site involved.

One case only of superficial phaeohyphomycosis manifesting as multiple, 1–3 mm, pigmented papules, resembling seborrhoeic keratoses, on the scrotum of an HIV-positive patient has been described. Microscopy showed a mass of mycelia, and two dematiaceous fungi were cultured [58].

Occasionally, genital herpes simplex may be acquired non-sexually (e.g. during contact sports such as rugby football [59]). A phenomemenon of chronic erosive and verrucous herpes as part of immunoreconstitution disease has been described in HIV infection [60].

Sacral herpes zoster is discussed in Chapter 25. Lesions may be found on the scrotum and penis, and urinary retention and constipation can occur.

Amoebiasis can rarely present as a painful ulcerative balanitis, with swelling, frequency, dysuria and retention in tropical countries [61]. Self-inoculation from concomitant intestinal infection, by heterosexual intercourse where the female partner has amoebic vaginitis, or by sodomy, are the putative mechanisms. Amoebiasis as the cause of genital ulceration should lead to the suspicion of underlying HIV infection [62].

Cutaneous leishmaniasis can affect the genitalia [63,64]. An erythematous scaly plaque on the glans has been reported [65] and post-kala-azar dermal leishmaniasis of the penis and scrotum is encountered. Rarely, genital skin lesions may lead to the diagnosis of schistosomiasis. They occur because ova shed by worms enter the perineal vessels [66]. The papules and nodules may be skin-coloured, pink or brown, scattered or grouped, affecting the penis and scrotum. They can spread onto the perineum and around the anus, and may develop into soft warty vegetating lesions. Ulceration is rare and, even more rarely, concomitant carcinoma has been reported [67].

The anogenital consequences of onchocerciasis are 'leopard skin' hypopigmentation (the scrotum is commonly involved), ileal crest and scrotal nodules, 'hanging groin', and scrotal enlargement [68,69]. The differential diagnosis of the scrotal enlargement includes bancroftian filariasis [68]. Other filarial infections can lead to mild hydrocoele or gross elephantiasis. Filariasis can cause secondary lymphangiectasis. Excision, grafting and genital reconstruction can be undertaken [70].

Dermatological aspects of sexually transmitted disease

Syphilis

Syphilis (see Chapter 30) is endemic throughout the world. It is enjoying a resurgence in homosexual men. All manifestations of syphilis can affect the genital region [1]. Balanoposthitis can complicate and obscure penile chancre. The granulomatous gumma may affect the genital area as an ulcer, a white plaque or as an atrophic scar. Pseudochancre redux describes gummatous (tertiary stage) recurrence at the site of the primary chancre [2]; it is very rare.

Viral warts

Circumcised men are more likely to have genital warts than the uncircumcised [3]. The risk of acquiring genital warts is significantly reduced by using condoms [4]. Clinically inapparent disease may present as balanoposthitis [5]. Subclinical or latent genital HPV infection may be 100 times more common than classical condylomas [6]. The 5% acetic acid test is not a very specific aid to the identification of warts or dysplastic lesions [7]. Congenital and acquired immunosuppression increases the susceptibility of the anogenital region to HPV infection and progression to dysplasia and frank malignancy [8].

The clinical diagnosis of HPV infection is usually certain but condylomata lata (secondary syphilis), lichen planus, molluscum contagiosum, Bowenoid papulosis and pearly penile papules enter the differential diagnosis. Solitary lesions have a wider differential diagnosis, including giant condyloma, squamous carcinoma and transitional cell carcinoma of the distal urethra, which can present as a warty lesion at the urethral meatus [9]. Biopsy should be performed if there is diagnostic doubt or dysplasia. Patients with anogenital warts and their partners may require full sexually transmitted disease and sometimes colorectal assessment.

Molluscum contagiosum

Molluscum contagiosum is discussed in Chapter 25. Young men are commonly seen with penile and pubic lesions and it is assumed that this is a sexually transmitted infection, but this may not always be the case.

Table 68.23 Causes of penile and scrotal ulcers in HIV infection.

Pseudomonas
Syphilis
Chancroid
Herpes simplex
Penicilliosis
Amoebiasis
Fournier's gangrene
Squamous cell carcinoma
Kaposi's sarcoma
Drugs (e.g. foscarnet)

Human immunodeficiency virus infection

Ulcerative genital disease is a risk factor for HIV [10], but anogenital ulceration may be a consequence of HIV infection (see Chapter 26) [11]. Table 68.23 lists the main causes. Biopsy, with special stains and culture, is mandatory. Other genital problems in HIV, such as psoriasis, warts, intraepithelial neoplasia, squamous carcinoma and Kaposi's sarcoma, are discussed elsewhere.

Phthiriasis

Phthiriasis (see Chapter 33) can present with marked genital and pubic itching with few overt physical signs, or as an infected genitocrural and pubic eczema that conceals the underlying primary signs. In hirsute men, the abdomen, chest, axillae and thighs may also be involved. Screening for other sexually transmitted diseases should be offered to the patient and partner(s).

Scabies

Scabies may present with anogenital itch, 'folliculitis' (including of the buttocks) and penile, scrotal and pubic nodules (Fig. 68.14). The patient must be told to advise close physical contacts and family to be treated simultaneously.

Benign tumours

The following entities are all encountered in the male genital area: angiomas and angiokeratomas, and angiokeratoma corporis diffusum; basal cell papillomas may be mistaken for viral warts [12] or Bowenoid papulosis, as may melanocytic naevi; inguinogenital epidermoid cysts may become infected: lesions containing molluscum contagiosum have been described [13]; pilar cyst, including giant forms, is much rarer [14].

Median raphe cysts

Congenital cystic median raphe anomalies may remain unobtrusive until adulthood. Cystic or nodular and linear

Fig. 68.14 Papules on the penis in scabies. (Courtesy of Dr C. White, University Hospital of North Durham, Durham, UK.)

swellings of the ventral penis occur near the glans. In adolescence or adulthood they may become traumatized or infected with staphylococci, gonococci or *Trichomonas* and present as tender erythematous purulent nodules [1]. Histologically, they are either dermoid or mucoid, depending on their embryology or epithelial lining [15]. Very rarely, the basal epithelial lining of the cysts may contain melanocytes, imparting a brown-black pigment to the lesion [16].

Mucoid cysts

These are rare lesions that present from birth or childhood as small flesh-coloured mobile cystic papules or nodules with no punctum, commonly on the ventral glans or foreskin, rarely in the perineum. They can be asymptomatic, become infected or interfere with intercourse. The histological features suggest that they arise from ectopic urethral tissue during embryological development [17].

Scrotal calcinosis

Scrotal calcinosis is a relatively common benign idiopathic disorder presenting as solitary or multiple, hard, smooth, white papules or nodules on the scrotum, rarely the penis (Fig. 68.15). Interestingly, these lesions are much rarer on the vulva [18]. Occasionally, they may become secondarily inflamed or infected following trauma.

Fig. 68.15 Scrotal calcinosis. (Courtesy of Dr D.A. Burns, Leicester, UK.)

Their occurrence was first described by Hutchinson [19]. Their origin has been debated: they have been said to arise from epidermoid cysts, eccrine duct milia, eccrine epithelial cysts, dystrophy of the dartos muscle, trauma and the presence of foreign bodies [1,20–30]. Scrotal calcinosis may occur after meconium peritonitis, with leakage of meconium through the processus vaginalis, and in testicular tumours such as teratomas, gonadoblastomas and Leydig cell tumours [27]. In endemic areas of onchocerciasis, calcified scrotal cysts may be caused by the living or dead nematodes, and patients have evidence of the disease elsewhere [31,32]. Onchocercal nodules are more common on the iliac crests and the rib cage (see Chapter 32).

The unsightly and embarrassing lesions can be treated by incision and eventration under local anaesthesia.

Verruciform xanthoma

Verruciform xanthoma mainly affects the mouth (see Chapter 66). The genitalia are the next most frequently involved, where it presents as a painless, yellow-brown or red, verrucous, sessile or papillary plaque. Fewer than 20 cases have been reported [33]. The histological findings are hyperkeratosis, focal parakeratosis, acanthosis and fat-filled foam cells in the papillary dermis. Verrucous xanthoma is thought to represent epidermal degeneration, with keratinocyte lipid then taken up by dermal macrophages [34] or fibroblasts to form the foam cells. HPV 6 has been implicated in one case [35]. Treatment is by surgical excision.

Miscellaneous

Naevus comedonicus of the glans penis, generally devoid of pilosebaceous structures, has been reported [36].

Keloid is rare, but can complicate circumcision [37,38], and other surgery and trauma [39,40]. Keloid has been

simulated on the dorsum of the penis by chronic oedema caused by a condom catheter [41].

Dermoid cyst affecting the penis, presenting with pain, swelling and suppuration from abscess formation, has been reported [42].

Acanthosis nigricans almost always affects the groins. In pseudoacanthosis nigricans, the associated obesity is almost always responsible for associated intertrigo and skin tags.

Some cases of multiple syringoma localized to the penis have been described, mimicking genital warts or lichen planus [43–46].

Other benign tumours that have been reported rarely to affect the anogenital area include apocrine cystadenoma [47,48], mixed syringocystadenoma papilliferum and papillary eccrine adenoma occurring in a scrotal condyloma [49], dermatofibroma [50], giant cell fibroblastoma (scrotum) [51], connective tissue naevi (scrotum) [52], fibrous hamartoma of infancy (scrotum) [53], leiomyoma [50,54], genital smooth muscle hamartoma (scrotum) [55], neurofibroma, neurilemoma, granular cell myoblastoma [50,56–58], varicosities (venous lakes), acquired capillary and cavernous haemangioma of the penis have been described [50] (other angiomatous lesions are very much rarer, and controversy exists as to whether they represent a true neoplasm, herniation of the corpus spongiosum or vascularization of a haematoma or thrombus [59]), Masson's vegetant intravascular haemangioendothelioma [60], angiokeratoma circumscriptum of Mibelli [61], glomus tumour [50,62], port-wine stain, strawberry naevus [63–65], epithelioid haemangioma [66], epithelioid haemangioendothelioma [50,67], angiolymphoid hyperplasia with eosinophilia/Kimura's disease (penis and spermatic cord) [68,69] and lymphangioma circumscriptum [70,71].

Precancerous dermatoses

Squamous hyperplasia

Such lesions consist of white patches or plaques. Although it is the most common epithelial abnormality found in association with invasive squamous carcinoma of the penis, histologically there is *no* cytological atypia; acanthosis and orthokeratotic hyperkeratosis are found [1].

Penile horn

It is rare for cutaneous horn to affect the penis [2]. The underlying causes include pseudoepitheliomatous micaceous and keratotic balanitis [3], verrucous carcinoma [4–6] and squamous carcinoma [7]. Chronic inflammation and recent circumcision for long-standing phimosis are said to be important predisposing factors. The lesion is premalignant or, in one-third of cases, malignant at presentation, with squamous carcinoma the underlying pathology. Treatment should be dictated by precise diagnosis achieved by adequate excision and histology of the whole lesion. Follow-up is mandatory because recurrence may occur.

Porokeratosis

Genital porokeratosis of Mibelli is rare, but classical lesions have been found on the penis and scrotum. Ulceration may occur [8]. Porokeratosis may be confused with psoriasis, Bowen's disease, granuloma annulare or lichen planus; biopsy differentiates these conditions [9]. Topical 5-fluorouracil can be used [10].

Pseudoepitheliomatous micaceous and keratotic balanitis

Pseudoepitheliomatous micaceous and keratotic balanitis (PEMKB) is a rare penile condition. It presents as thick scaly micaceous patches (possibly a cutaneous horn) on the glans penis in older uncircumcised men [3,11]. Histological examination shows hyperkeratosis, parakeratosis, acanthosis, prolongation of the rete ridges and mild lower epidermal dysplasia, with a non-specific dermal inflammatory infiltrate of eosinophils and lymphocytes. Some consider that PEMKB is a form of locally invasive verrucous carcinoma [12], others that it is a variant of lichen sclerosus [13]. Metastastic spread has not occurred except where there was a penile horn [14], and in one patient who developed an aggressive soft-tissue sarcoma of the penis [15]. Recurrence is common. Topical 5-fluorouracil, radiotherapy and surgery are the principal treatment choices [3].

Erythroplasia of Queyrat, Bowen's disease of the penis and bowenoid papulosis

Erythroplasia of Queyrat (EQ), Bowen's disease of the penis (BDP) and bowenoid papulosis (BP) are three clinical variants of carcinoma *in situ* of the penis [16–18]. Penile intraepithelial neoplasia (PIN—corresponding to cervical, vulval and anal intraepithelial neoplasia; CIN, VIN and AIN) is the term favoured by some, and may be a convenient umbrella term, but there is no formal consensus on clinicopathological classification (particularly

Fig. 68.16 Bowenoid papulosis. (Courtesy of Dr D.A. Burns, Leicester, UK.)

'grade') and clinical utility. An alternative expression 'squamous intraepithelial lesion' (SIL) has been proposed, and qualified by the descriptor 'high-' or 'low-grade' [19]. EQ, BDP and BP all describe disorders of the penis predominantly in uncircumcised white men, although EQ has been recorded in a circumcised man [20]. CIN, VIN and AIN are terms analogous to PIN.

Although EQ and BDP are synonymous in describing carcinoma *in situ* of the penis, BD is used to refer to squamous carcinoma *in situ* at other cutaneous sites. EQ should be used to describe red shiny patches or plaques of the mucosal penis (glans and prepuce of the uncircumcised). BDP should be used to describe red, sometimes slightly pigmented, scaly patches and plaques of the keratinized penis. This distinction has not always been made in the literature. BP is analogous to, but clinically different from, EQ and BDP. The term should be used to describe multiple warty lesions, which are often pigmented in keratinized sites, and more numerous and more inflamed at mucosal sites (Fig. 68.16). BP lesions are less papillomatous, smoother topped, more polymorphic and more coalescent than common genital viral condylomata acuminata, and occur in younger, sexually active men, as opposed to the patches or scaly plaques of EQ and BDP, respectively, seen in older men. BP may be associated with a lesser risk of squamous carcinoma than EQ and BDP. It is associated with HPV infection (especially HPV 16) and HIV infection. Voltz *et al.* [21] found anogenital warts in 16% of all HIV-positive males, nearly half of whom showed histological signs of intraepithelial neoplasia.

The aetiology of EQ, BDP and BP is unknown. Local carcinogenic influences in uncircumcised men such as poor hygiene, smegma, trauma, friction, heat, maceration, inflammation, phimosis, dermatoses such as lichen sclerosus and smoking (tar metabolites in urine) have been proposed [22], as have HPV, particularly in BP [23]. BP is probably virus-induced epithelial dysplasia associated mainly with HPV 16, but other types have been found [24,25]. Recently, EQ has been shown to be associated with co-infection with the rare epidermodysplasia verruciformis-asssociated HPV 8 and the genital high-risk HPV 16 [26]. There is a high prevalence of PIN in male sexual partners of women with CIN [27,28], but many patients with PIN have consorts with no evidence of warts or CIN. Immunosuppression is important: 50% of HIV patients with anogenital warts had squamous carcinoma *in situ* on histology [21]. Nothing is known about the influence of immunogenotype. The evidence confirming that EQ/BDP may result in squamous carcinoma has been reviewed comprehensively [22,29]. The risk of progression of BP to invasive squamous carcinoma is not known, but is probably low in the absence of other risk factors, especially immunocompromise. The grade of the intraepithelial neoplasia and the development of invasive carcinoma are related to age [30]. *p53* mutations do not appear to be important in male genital carcinogenesis [31].

Some patients with these lesions may be quite young [32]. There may be several foci of BDP or EQ and they may occur concomitantly. The non-specificity of the clinical appearances makes for an important differential diagnosis, which includes psoriasis, lichen sclerosus, erosive lichen planus, ZB and extramammary Paget's disease. The differential diagnosis of BP includes lichen planus, common warts, seborrhoeic warts, naevi and condylomata lata. A biopsy is indicated in instances where the clinical diagnosis is uncertain. Aynaud *et al.* [33] have suggested that shrewd clinical interpretation predicts which lesions will show squamous carcinoma histologically and which will contain oncogenic HPV. Occasionally, it may be necessary to perform a second biopsy if the initial histology is inconclusive. It has been suggested that, where glans and shaft are both involved, the glans may be the preferential biopsy site. On histological examination, there are the features of an intraepithelial carcinoma.

Treatment. Treatment depends on many factors. Circumcision removes a major risk factor for cancer and provides extensive tissue for histology. Topical 5-fluorouracil as a 5% cream is a well-established conventional option for the treatment of BD, EQ and BP [17] but there have been no clinical trials.

Other treatments include cryosurgery, curettage and electrocautery, excisional surgery, radiotherapy (controversial), Mohs' micrographic surgery, laser and photodynamic therapy. Topical imiquimod is under evaluation [34,35]. Patients presenting with these conditions should be counselled and screened for HPV and other sexually transmitted diseases, including HIV infection. This advice should be extended to sexual partners. Follow-up should be long term [17,30].

Squamous carcinoma

Genital squamous carcinoma is sometimes called epidermoid carcinoma. The aetiology is not clearly understood but HPV is implicated [1,2]. Diagnosis and management can present difficulties. Squamous carcinoma should be suspected in all nodulo-ulcerative genital disease, especially in the context of lichen sclerosus, lichen planus, hidradenitis suppurativa, intraepithelial neoplasia and immunocompromise. Genitourinary and urological assessment should be sought. Proctoscopy and sigmoidoscopy are necessary to exclude anorectal cancer. Suspect lesions should be biopsied.

Carcinoma of the penis

Incidence and aetiology. Carcinoma of the penis accounts for less than 1% of deaths from cancer in the USA (100 per year in the UK, and unchanged over several decades) but constitutes 10–20% of tumours seen in males in either underdeveloped countries or in areas where early circumcision is not routinely practised [3–6].

The earliest stages of penis cancer and precancer form a spectrum of disease [7]. Although some penile cancers arise *de novo*, others develop from premalignant states, which may be misdiagnosed or may be difficult to diagnose [8], and there are the issues of multifocality and field change [9] to acknowledge.

The precise aetiology of the types of PIN, verrucous carcinoma and frank invasive squamous carcinoma of the penis is unknown, as is their precise relationship to the various types of precursor lesion. However, Cubilla *et al*. [10] have defined several types of preceding epithelial abnormality: squamous hyperplasia and SIL (squamous, basaloid or warty, high or low grade).

The presence of a foreskin confers cancer risk (Table 68.24). Circumcision appears to protect against penile carcinoma [11–13], unless the circumcision was performed for penile disease [14,15]. However, there have been very rare cases in Jews and others circumcised at birth [16–18].

Carcinoma of the penis is more common in males in either underdeveloped countries or in areas where early circumcision is not routinely practised [4,19], but the incidence of penis cancer is low in Japan and Denmark,

Table 68.24 Risk factors for squamous carcinoma of the penis.

Uncircumcised
Phimosis
Poor hygiene
Chronic irritation, inflammation, scarring
Smoking
Lichen sclerosus
Lichen planus
Human papillomavirus
HIV
Squamous hyperplasia
Bowen's disease
Erythroplasia of Queyrat
Bowenoid papulosis
Giant condyloma/verrucous carcinoma
Photochemotherapy
Iatrogenic immunosuppression
Renal transplantation
Systemic lupus erythematosus

where circumcision is rare [20,21], so other factors are important in carcinogenesis.

Phimosis and balanitis are known risk factors for penile cancer [3,11,22–24]. Poor personal and sexual hygiene [12] and phimosis may lead to the retention of smegma and development of balanitis. However, the carcinogenicity of human smegma has not been ascertained [25] and it is not widely appreciated that phimosis is a physical sign and not a diagnosis. Hence, there may be more in the carcinogenic propensity of phimosis than simply physical retention of smegma.

Lichen sclerosus is a common cause of phimosis in males and it predisposes to penile carcinoma [26–30]. Powell *et al.* [31] found that half of patients with penis cancer had a clinical history and/or histological evidence of lichen sclerosus. Chronic erosive and hypertrophic lichen planus are premalignant conditions, and lichen planus is a cause of phimosis [32,33]. An underlying skin disorder was found in 22 out of 23 patients with vulval squamous carcinoma [34].

Chronic irritation and inflammation or scarring are all risk factors for squamous carcinoma of the skin generally and the penis is no exception; penis cancer complicating a burn scar has been reported [35]. Quantifying the malignant potential of the precancerous dermatoses, BDP, EQ and PIN, is not possible, but they are acknowledged risks for penile cancer [36–38].

Smoking is a risk factor, independent of phimosis, for penile carcinoma [23], and is also a recognized risk factor for anal [39] and cervical cancer [3]. Smoking may cause squamoepithelial cancer, not only in parts of the body in contact with smoke but also at distant sites by dissemination of carcinogens in the circulation or in secretions [40,41]. The presence of tobacco-specific nitrosamines in the preputial secretions of rats has been demonstrated [42].

Penile carcinoma is a complication of psoralens and UVA therapy (PUVA) [43,44], and posssibly other treatments for psoriasis [45,46]. The photodye treatment of genital herpes simplex ceased in the 1970s because of the occurrence of BDP in young men who did not have other risk factors for erythroplasia [47]. However, increased UV exposure of the genitals from sunlamps and sunbeds had not led to an increase in genital skin cancer in the USA by 1986 [48].

Although penile cancer is associated with multiple sexual partners and previous sexually transmitted disease, including HIV, the epidemiological features are not those characteristic of a sexually transmitted disease [25]—unlike carcinoma of the cervix and, to a lesser extent, anal carcinoma [49]. In cervical cancer, the evidence is that it is a sexually transmitted disease and that HPV is the aetiological agent [50–52]. Yet penile cancer puts wives and consorts at risk of cervical cancer [53], there is a high prevalence of PIN in sexual partners of women with CIN [54,55] and PIN can be found in men being screened for HPV infection [56].

HPV is implicated [1,2], but its role is still uncertain, as many patients with penis cancer have no evidence of infection. Oncogenic HPV types 16 and 18 have been incriminated [24,57–65]. In Brazil, Villa and Lopes [59] found HPV 18 in seven out of 18 penile squamous carcinomas and, in Argentina, Picconi *et al.* [65] found HPV DNA in 71% of 65 penis cancers, 81% of which were 'high-risk' HPV with predominance of HPV 18. Gregoire *et al.* [66] associated HPV with higher grade, more aggressive squamous carcinomas of predominantly the glans penis showing basaloid changes. The overall frequency of HPV in penile squamous carcinoma suggests [10,66] that a proportion of these cancers can arise from HPV-associated SIL. As in vulval cancer [67,68], a bimodal hypothesis of HPV-related and non-HPV-related causation has evolved [10,69].

Penis cancer has been reported to complicate immunosuppression in renal transplantation [70] and HIV infection [71].

Clinical features. Itch, irritation, pain, bleeding, discharge, ulceration or the discovery of a mass are the presenting symptoms of squamous carcinoma. There is often a long history of preceding problems with the penis and foreskin manifest as dyspareunia, balanoposthitis or phimosis and dysuria. Irregular nodular and ulcerative morphology is found on examination (Figs 68.17 & 68.18) and there may be background BDP, EQ and BP, lichen sclerosus or lichen planus. Phimosis should be regarded as a sinister situation, not least because it does not allow complete inspection and palpation of the glans and coronal sulcus. The inguinal lymph glands must be palpated, although in penile cancer only 50% of enlarged glands will be found to contain tumour [4]. The concomitant presence of sexually

Fig. 68.18 Squamous carcinoma. Severe background lichen sclerosus. (Reproduced from Bunker CB. Skin conditions of the male genitalia. *Medicine* 2001; **29**: 9–13, by kind permission of The Medicine Publishing Company.)

transmitted diseases and immunocompromise should be excluded [72]. The differential diagnosis includes the manifestations of intraepithelial neoplasia (and the differential diagnosis of these), erosive or ulcerative sexually transmitted disease, basal cell carcinoma, Kaposi's sarcoma, pyoderma gangrenosum and artefact. Genitourinary and urological assessment should be sought.

Histopathology. Diagnosis is confirmed histologically. A biopsy should be of adequate size and depth, and it may be necessary to sample several sites. The biopsy(ies) may need to be performed by a urologist under general anaesthesia. Patients who have negative or equivocal biopsies, but who have risk factors or in whom there is a high index of suspicion, should be followed-up closely and rebiopsied if indicated.

Histologically, squamous carcinoma manifests tongues of invasive atypical keratinocytes penetrating the dermis, and contains foci of aberrant and ectopic keratinization called squamous pearls [23]. Background histological signs of lichen sclerosus are commonly found in penile cancer in men, as in vulvar cancer [73]. Verrucous carcinoma is discussed below. Spindle cell carcinoma of the penis is a very rare variant [74]. Telomerase activity is high in penis cancer [75].

Cubilla *et al.* [9] have identified four histological types of squamous carcinoma of the penis:

1 *Superficial spreading* (42%): a biphasic infiltrative and radially extensive carcinoma *in situ* contiguously involving several anatomical sites or compartments (glans, coronal sulcus, foreskin, even urethra)

2 *Vertical growth* (32%): unifocal high-grade deeply invasive, unassociated with carcinoma *in situ*

3 *Verrucous* (18%): low-grade, papillary or endophytic (see below)

4 *Multicentric* (8%): two or more independent primary tumours without contiguous field change.

These observations have implications for the pathogenesis of the different types, and in determining management in individual cases.

Carcinoma of the scrotum

Squamous carcinoma of the scrotum has been recognized in chimney sweeps (exposed to carcinogens in soot) [1], mule spinners (exposed to carcinogens in lubricating oils for the spinning jenny in the cloth industry), Persian nomads (who travelled with pots of burning charcoal between their legs) and Indian jute oil processors [2–6]. Oil-mist exposure in industry continues to be widespread and, apart from scrotal cancer, has been associated with other cutaneous problems (such as contact dermatitis and oil acne) and respiratory diseases, including cancer [7].

Other individuals at risk of scrotal squamous carcinoma include those with a history of psoriasis treated with arsenic, coal tar, UVB and PUVA [8–13], previous radiotherapy treatment [8], scrotal HPV infection, hidradenitis suppurativa and multiple cutaneous keratoses and epitheliomas [14–17]. Rarely, black men may be affected [18].

The presentation of scrotal carcinoma is similar to that of penis cancer, with itch, irritation, pain, bleeding, discharge, ulceration or the discovery of a lump, and irregular nodular and ulcerative clinical features. A pigmented squamous carcinoma of the scrotum has been reported [19]. The differential diagnosis includes the manifestations of intraepithelial neoplasia (and the differential diagnosis of these), erosive or ulcerative sexually transmitted disease, basal cell carcinoma, Kaposi's sarcoma, pyoderma gangrenosum and artefact. The diagnosis is confirmed by biopsy.

Treatment of squamous carcinoma

The treatment of anogenital squamous carcinoma is not generally the province of the dermatologist. The overriding general principle is to offer adequate surgical excision, including circumcision, for disease of the penis. The penile surgery may need to be radical, total or partial, depending on location and extent [20–22]. To minimize residual sexual dysfunction, conservative plastic techniques are increasingly used [23], as are laser treatment [24] and Mohs' micrographic surgery [25–28] for squamous carcinoma of the penis, but the concepts of field change and the implications of infection by HPV and multifocality must be considered. Combination chemotherapy has been used for palliation and proposed for adjuvant treatment of carcinoma of the penis, but remains under evaluation [29].

Lymphatic or haematogenous dissemination of genital cancer dictates individualized multidisciplinary treatment. The management of ilioinguinal lymphadenopathy is controversial [20,22,30].

The prognosis of penis cancer relates to the extent of inguinal lymphadenopathy [31,32] and involvement of the corpus [33]. It does not correlate with HPV status [34]. The prognosis for scrotal carcinoma is not good, despite apparently adequate primary surgical treatment: the 5-year mortality is 50–60% [3,4].

Penile cancer puts wives and consorts at risk of cervical cancer [35]. In black men who develop penile cancer there is a substantial risk (18%) of the later development of a second primary malignancy [36].

Verrucous carcinoma/giant condyloma/Buschke–Löwenstein tumour

Buschke–Löwenstein tumour and verrucous carcinoma can probably be regarded as synonymous. They represent verrucous low-grade well-differentiated squamous carcinoma. It is perhaps more accurate and more clinically useful to consider giant condyloma as a separate HPV-related entity with a better prognosis, but controversy exists [1–7].

Verrucous carcinoma is rare. It produces dramatic polypoid or cauliflower-like clinical lesions (Fig. 68.19). Presentation as a penile cutaneous horn has been described [8,9]. Although locally deeply invasive, the tumour is well demarcated from surrounding tissue and is unlikely to metastasize. Both sexes can be affected.

Fig. 68.19 Gross condylomas of Buschke–Löwenstein of the penis. (Courtesy of Professor R.M. MacKie, Glasgow University, Glasgow, UK.)

A specific aetiology for verrucous carcinoma of Buschke–Löwenstein has not been unequivocally identified, but an origin from genital warts is likely. HPV types 6 and 11 are the most commonly associated [1,3,4,10–16]. A patient taking ciclosporin for psoriasis developed a verrucous carcinoma containing HPV 6 and 16 [17]. Multiple HPV types were found in a transplant patient [18]. Tumours containing several HPV types may be mixed, containing verrucous carcinoma adjacent to squamous carcinoma [19]. Cases emanating from background lichen sclerosus have occurred [20,21]. Chronic hidradenitis suppurativa may rarely be a predisposing factor [22].

If verrucous carcinoma is suspected, then a deep surgical biopsy must be planned. The tumour has a different histology from squamous carcinoma, showing deep lobular invaginations of well-defined proliferative epithelium consisting of typical clear pale keratinocytes [23]. Frank squamous carcinoma [24] and foci of invasive squamous carcinoma [25] have been reported in some cases of anogenital verrucous carcinoma. Ultrastructurally, verrucous carcinoma is distinct from condyloma acuminatum but similar to SCC [26].

Clinical, histological and virological differences may distinguish verrucous carcinoma (potential for aggressive lethal behaviour) from Buschke–Löwenstein tumour and giant condyloma (no malignant potential) and this distinction should direct treatment [3,4,11,13,16].

Surgical excision is the treatment usually recommended (e.g. glansectomy [27] or penectomy). Mohs' micrographic surgery [28–30], cryotherapy [31], laser treatment [32], interferon-α [33–36], radiotherapy [37] or bleomycin [38] are alternatives.

The prognosis is poor because the tumour can continue to grow and invade locally, causing death by exsanguination from femoral arterial invasion or cachexia [39]. Even with treatment, recurrence and progressive malignant transformation do occur [40,41], so follow-up is necessary.

Other malignant neoplasms

Extramammary Paget's disease

Extramammary Paget's disease (EMPD) presents as irritating, itchy, burning, red scaly patches or plaques that may be solitary or multifocal. EMPD can occur anywhere in the anogenital area, including the glans penis, and may be multicentric [1–3]. An 'underpants' pattern of erythema has been reported in a number of patients [4]. EMPD is frequently misdiagnosed as psoriasis or eczema [5], or Bowen's disease. Subclinical EMPD has been documented, where the skin looks normal macroscopically but is involved microscopically. EMPD behaves indolently, spreading by local extension and metastasis [6,7].

The concurrence of genital and extragenital EMPD is extremely rare, but overt and latent axillary EMPD can coexist and change daily in association with penile and pubic EMPD [8]. Also very rare is depigmented EMPD of the genitalia, evoking the differential diagnosis of vitiligo, hypopigmented mycosis fungoides and lichen sclerosus [9]. A focus of cutaneous squamous carcinoma has been reported complicating genital EMPD [10].

Diagnosis is by biopsy. Histological examination shows nests of large vacuolated cells with circular nuclei and foamy pale cytoplasm in the epidermis (Paget's cells). Dermal involvement signifies a poor prognosis. Pagetoid dyskeratosis can be found in a number of benign lesions such as naevi, skin tags and lentigines [11]. Pale cells resembling Paget's cells can be seen incidentally in benign papular intertriginous conditions, and in nearly 40% of prepuces sent for histological examination following circumcision for phimosis [11–13]. Anogenital Paget's disease can be accompanied by epidermal hyperplasia similar to fibroepithelioma of Pinkus [14]. Immunohistochemical and enzyme histochemical evidence points to sweat gland epithelium as the source of Paget's cells in EMPD [15]. The distribution along the 'milk line' has led to the suggestion that the 'clear cells of Toker' are the histogenic precursors of both clear cell papulosis and mammary and extramammary Paget's disease, respectively [9]. HPV is not present [16], but the c-erbB-2 oncoprotein may have a role in the pathogenesis of EMPD [17].

Mammary Paget's disease is an epidermal manifestation of an underlying breast adenocarcinoma [18]. EMPD is found in areas rich in apocrine sweat glands, such as the axillae and anogenital region. EMPD can also be associated with an underlying malignancy [6]. In a large series, 24% of patients had a proximate cutaneous adnexal adenocarcinoma, 12% were found to have a concurrent, and another 17% to have a non-concurrent internal malignancy [19].

Although properly regarded as a type of carcinoma *in situ*, EMPD may itself become invasive and metastatic [20–22]. There may be subjacent carcinoma (e.g. in periurethral glands) [23] or distant carcinoma (e.g. prostate [24] or bladder [25]), or both (e.g. periurethral glands and bladder [26]). Pagetoid epidermal invasion of inguinal cutaneous metastatic mesothelioma of the tunica vaginalis of the testis has been reported [27].

Treatments used for EMPD include cryotherapy and topical 5-fluorouracil [28], wide excisional surgery [20], micrographic surgery [29,30], radiotherapy [7,31] and photodynamic therapy [32].

Malignant melanoma

This is a very rare condition of the penis (fewer than 100 cases reported). It is estimated to account for 1–1.5% of all malignancies of the penis [1,2] and less than 0.15% of all melanomas [3]. Melanoma is even rarer on the scrotum, with only four cases appearing in the literature [4,5].

Genital melanoma presents as a pigmented macule or as a pigmented or amelanotic papule or nodule (possibly developing from a lentiginous area or pre-existing dysplastic naevus), which may ulcerate or bleed [1,2,6–14]. Patients are usually middle-aged or older, although it has been reported in a boy [15]. It is exceedingly rare in Asians and has not been reported in black people (although a case of melanoma of the urethra has been seen) [16].

Sixty to 70% of lesions occur on the glans. There may be a family history of melanoma and other atypical or 'dysplastic' naevi on examination. The inguinal and other nodes, as well as the abdomen, should be palpated. Forty to 50% of patients have lymphatic or other metastatic dissemination at the time of presentation. Clinically atypical lesions should be biopsied and the histology critically reviewed [7,11]. Malignant melanoma of any histological subtype may be encountered [17].

Treatment is by primary excision. Subsequent management depends on the Breslow thickness of the lesion and complete clinical staging. Radical surgery and chemotherapy may be needed, but the prognosis is poor for all melanomas that have already metastasized [1,15,18].

Kaposi's sarcoma

Solitary Kaposi's sarcoma (KS) of the penis was very rarely seen before the HIV epidemic and cases are still occasionally seen in HIV-negative patients [19,20], but genital KS is essentially an HIV-associated problem. It presents as a dull red patch or plaque of the glans or prepuce, or anywhere else on the penis or scrotum, perineum or perianal skin in one of its classic forms: purple, slightly scaly patches or plaques, nodules or ulcerative lesions [21]. More atypical presentations that have been seen include engorgement with hypervascularity [22], penile lymphoedema [23] and phimosis. The differential diagnosis includes cellular naevus, histiocytoma, angioma, angiokeratoma, pseudo-Kaposi's sarcoma [24], bacillary angiomatosis and melanoma.

Miscellaneous

Although basal cell carcinoma is the most common type of skin cancer, it is rare in the anogenital area, although over 100 cases have been reported [25], including one case report of fibroepithelioma of Pinkus affecting the base of the penis [26]. A case of multiple erosive scrotal basal cell carcinomas with metastasis has been described [27].

Fibrosarcoma, haemangiopericytoma, leiomyosarcoma, malignant fibrous histiocytoma, epithelioid sarcoma, dermatofibrosarcoma protuberans and spindle cell sarcoma may occur, presenting as painful or painless nodules, masses or swelling with dysuria and erectile difficulties (e.g. masquerading as Peyronie's disease) [19,28]. Other rarities include Merkel cell carcinoma [29], malignant eccrine poroma [30], malignant schwannoma [19,31] and solitary reticulohistiocytic granuloma of the scrotum [32].

Involvement of the penis with Langerhans' cell histiocytosis is very rare; a fleshy papule on the dorsal penis and primary penile ulceration have been reported [33].

Mycosis fungoides can be confined to or concentrated in the genital region. Localized perianal involvement has been described [34].

Although lymphoma is the most frequent secondary tumour of the testis, it is rare in other parts of the male urogenital tract [19]. Penile lymphoma can present as painless subcutaneous nodules, erythematous swelling and ulceration [35–37]. There may be no evidence of systemic lymphoma. A fungating nodular scrotal lymphoma has been reported [38], as have scrotal and penile ulceration resulting from leukaemic infiltration [39,40].

Metastases to the penis are rare, but several hundred cases have been reported [41]. They are usually secondary to cancer of the urogenital tract [42] or gastrointestinal system, or other common cancers such as of the lung [43], and present with pain, swelling, priapism, urinary symptoms or haematuria. A very rare cause is secondary melanoma [41].

Miscellaneous

Pigmentary change is dealt with in the general introduction on pp. 68.2–68.3, and causes of anogenital hypo- and hyperpigmentation are listed in Tables 68.6 and 68.7.

Penile melanosis

Pigmented macules are not uncommon on the glans and shaft of the penis [1]. They are benign but, because they may be large or enlarging, with irregular edges and multifocal and variegated pigmentary patterns, they arouse concern about atypical melanocytic proliferation and acral lentiginous melanoma. Such clinical concerns should lead to biopsy [2]. Post-inflammmatory hyperpigmentation (e.g. lichen sclerosus, lichen planus) may be the cause in many patients. Some cases have been associated with previous treatment with anthralin, or PUVA therapy for psoriasis, or diabetes [3,4]. On histological examination there may be increased basal epidermal pigmentation, with or without benign lentiginous melanocytic hyperplasia, or an increase in basal melanocyte number. Breathnach *et al.* [5] have proposed that depigmentation is an essential element of penile melanosis and demonstrated melanocytic hyperplasia in areas of hyperpigmentation.

Penile melanosis is the term for lesions without lentiginous hyperplasia [4,6]. Revuz and Clerici [6] proposed the grouping of penile melanosis, vulvovaginal melanosis and the predominantly oral mucosal hyperpigmentation of the Laugier–Hunziker syndrome under the umbrella of essential melanotic hyperpigmentation of the mucosa. Lenane *et al.* [7] used the term genital melanotic macules.

Patients ask for treatment of penile melanosis as it is unsightly and embarrassing. Laser treatment may help [8].

Hypopigmentation

Striae as a consequence of growth or weight surges are common around the pelvic girdle or represent a complication of topical corticosteroid application [9]. Initially, they are often purple-red in colour. Vitiligo is a commonly observed affliction of the male genitalia, although patients may be unaware of it and clinicians might not always observe it [10].

Acral lentiginous melanoma is very rare but important [11,12].

Pain and swelling

Some presentations of many entities can be painful but generally pain is an unusual presentation for a dermatosis. Swelling is more common and may be painful or not. A common factor in many but not all causes of swelling may be oedema or lymphoedema. Causes of anogenital lymphoedema and penoscrotal swelling are listed in Tables 68.25–68.27.

Iatrogenic swellings and lymphoedema

Congenital defects of the inguinal canal and other non-inguinal peritoneal leaks can lead to scrotal and penile swelling as a manifestation of dialysate oedema in patients with end-stage renal failure treated by continuous ambulatory peritoneal dialysis [7]. Genital oedema is

Hypertrophic scars
Wide scars
Proximal penile hump (thick hair-bearing Y flap)
Low-hanging penis
Loss of fat
Nodules
Deformed shaft

commonplace in intensive care units, because of the practice of maintaining a raised right heart filling pressure. Radical cancer surgery and/or radiotherapy to the anogenital area and the lymphatics can cause swelling because of lymphoedema, early or delayed [8]. Chronic oedema, resembling keloid, of the penis has been caused by a condom catheter for neurogenic bladder [9].

Increasingly, patients seek plastic surgery to the penis [10] for psychosexual reasons (e.g. dysmorphophobia) but surgery can result in significant complications (Table 68.28).

Idiopathic lipogranuloma

Cases of characteristic, spontaneously resolving, painless, Y-shaped swelling of the scrotum embracing the penile root, with sclerosing eosinophilic lipogranuloma on histology and electron microscopy (but no exogenous lipids) and associated with blood eosinophilia (one patient had arthralgia), have been reported from Japan [12].

Priapism

Priapism is defined as the prolonged painful erection of the penis, unassociated with sexual desire and not relieved by ejaculation. Although not predominantly a dermatological concern, it has an important differential diagnosis. The principal causes are listed in Table 68.29. It results in impotence in more than 50% of those affected [3,4] and can lead to gangrenous penile necrosis [5].

Levine *et al*. [1] distinguish veno-occlusive priapism from arterial priapism. Veno-occlusive priapism results from persistent obstruction to venous outflow from the lacunar spaces. It is a potential vascular emergency because, as the corporeal bodies expand to maximal volume, an obstructed outflow causes decreased arterial inflow, with the potential for ischaemia, pain, fibrosis and hence impotence. Arterial priapism is usually secondary to trauma, such that a damaged cavernosal artery causes unregulated blood flow to the lacunar spaces; it is thus non-ischaemic [1].

Dermatological non-disease, dysaesthesia and chronic pain syndromes

'Dermatological non-disease' may be the diagnosis where there is a paucity or even absence of primary dermatological signs to account for florid symptomatology. Genital symptoms include itching, excessive redness, burning and discomfort—in some cases so severe that it prevents the patient from sitting down. Dysmorphophobia, depression and psychosis may be present, and attempted suicide is a real risk in such patients [1,2].

Itching of the urethra may lead to insertion of a foreign body into the urethra in an attempt to relieve the sensation [3], or this might be done for sexual gratification.

Patients with symptoms of itching, burning and pain localized to the penis or scrotum are not uncommonly encountered. The skin is usually completely normal. The situation is analogous to vulvodynia in women, and terms such as penodynia and scrotodynia have been coined to describe the syndrome in men. Doxepin, amitriptyline and paroxetine can afford some relief.

Fisher [4] has defined the red, burning scrotum syndrome as 'persistent redness of the anterior half of the scrotum that may involve the base of the penis . . . usually accompanied by a persistent itching or burning sensation and hyperalgesia'. It is a chronic condition that is resistant to treatment and its cause is unknown [4,5]. Accompanying the erythema there may be telangiectasia. It is related to idiopathic penile and scrotal pain syndromes [6]. Prednisolone and antidepressants have given some relief to some patients.

Localized dermatographism should be sought by stroking the inside of the thigh, because such patients may be helped by oral antihistamine treatment.

The possibilities of zinc deficiency and necrolytic migratory erythema should be entertained.

Chronic urogenital and rectal pain syndromes include penile pain (penodynia), scrotodynia, orchialgia, prostatodynia, coccygodynia, proctalgia fugax, perineal pain, the descending perineum syndrome and vulvodynia

[7–9]. The neuroanatomy of the pelvis is complicated and the neurophysiological basis of the pathogenesis of these syndromes is poorly understood, but their clinical presentations are well recognized. The differential diagnosis is addressed above.

A diagnosis of a chronic pain syndrome implies the prospect of considerable psychological morbidity. Treatment is challenging and only empirical at best. Most agree that invasive and irreversible procedures should be avoided if at all possible. Multidisciplinary management is recommended [6].

Hair disorders

Alopecia areata can affect the pubic hair, but usually as part of more widespread involvement as in alopecia universalis. Loss of pubic hair occurs in secondary syphilis and has been reported in primary systemic amyloid [1]. Trichotillomania of the pubic hair has been described [2,3].

Female genital dermatology

Introduction

Disorders of the vulval epithelium have proved confusing to the many and varied specialists who have been involved in their diagnosis and treatment. The difficulty has arisen because the majority of the problems are dermatological and the specialists—gynaecologists, urologists, paediatricians and genitourinary physicians—have had little or no training in dermatology. The problem is compounded by the fact that the normal characteristics of common diseases at this flexural site are lost or modified, making the diagnosis difficult even for an experienced dermatologist. Over the years, classifications of vulval disorders have been devised to help, but unfortunately these have only resulted in further confusion. There is no need for a separate classification for vulval disorders, as the current classifications that exist for dermatology and pathology can be used [1,2].

Dystrophy, leukoplakia and kraurosis vulvae have all now been abandoned as diagnostic terms [3]. Over the years, the term leukoplakia has unfortunately had the sinister implication that it always represented a premalignant condition [4], but now leukoplakia is used as a descriptive term only and may represent anything from a patch of lichen simplex to an SCC. Similarly, squamous cell hyperplasia is not a diagnosis but a histological description, and can be seen in many disorders including psoriasis, candidosis and hypertrophic lichen planus.

Vulval clinics have been an important step forward in the diagnosis and management of women with vulval problems [5,6]. These clinics ideally should be multidisciplinary with input from dermatology, gynaecology, genitourinary medicine and pathology. It is important that there are links with other specialists including paediatricians and plastic surgeons, as well as psychologists and psychosexual therapists.

The development of these clinics has been extremely important, not only for improved patient care but also for the valuable interdisciplinary education of the doctors involved.

An accurate diagnosis depends on a thorough history, examination of the affected skin and skin at extragenital sites, and pertinent investigations. The history must include the chief complaint, how long it has been present, how the problem changes in certain circumstances (e.g. variation with the menstrual cycle), what treatment has been prescribed and what were the effects of the treatment. A drug history is important, and should include direct questioning about over-the-counter oral and topical medications, oral contraceptives and hormone replacement therapy (HRT). The latter two are included in this direct questioning as patients do not always consider these as medications, particularly if the HRT is in a topical formulation. A personal and family history of autoimmune disease, atopy or psoriasis should be established, and any known skin sensitivities. The patient should also be asked about vaginal discharge, urinary symptoms and bowel function. Finally, as the vulva is important for normal sexual function, it is important to include relevant questions on problems with intercourse where appropriate.

The complaint of irritation has many meanings and it is sometimes helpful to ask the patient exactly what they mean by the term. It may be the sensation of itch, dryness, pain, burning or rawness. This point is important as a

patient with itch will scratch or rub the skin, and the response will be lichen simplex or lichenification, whereas with discomfort or pain there will be no such change as the patient avoids touching the area.

Lichen simplex and lichenification. Lichen simplex and lichenification are terms used to describe the exaggerated normal rhomboidal patterning of the skin surface. Lichen simplex is used to describe the changes seen on apparently normal skin secondary to itching and rubbing, although the provoking symptom of itch may be initiated by a low-grade dermatosis such as psoriasis or seborrhoeic eczema. The term lichenification is used for similar changes arising on a background of a visible dermatosis.

The lesions of lichen simplex tend to be in one isolated area, usually on the labia majora or mons pubis. They are well defined, with a pale grey or white surface.

The histological changes of lichen simplex and lichenification are similar, except that there are the changes of the background dermatosis in the latter. There is hyperkeratosis, acanthosis, a prominent granular layer, lengthened rete ridges and a chronic inflammatory dermal infiltrate. In addition, lamellar thickening of the papillary dermis and perineural fibrosis can be seen. Twelve cases of what was termed multinucleated atypia of the vulva have been reported [7], but this is thought to be a non-specific change found in lichenified skin [8,9].

Treatment of the underlying dermatosis will usually resolve the lichenification. In cases of lichen simplex with no underlying dermatosis, the treatment is the application of a potent topical steroid to encourage a disruption of the itch–scratch cycle. A soap substitute should be introduced and possible irritants avoided. If these measures are unsuccessful, patch testing should be performed to exclude the possibility of an unsuspected allergen.

The examination is often very embarrassing for the patient, so it must be carried out sympathetically to ease any tension. It is important that there is good lighting, and a means of magnification. The skin and the mucosae are examined in the anogenital area for changes in colour, epithelial integrity and texture. If there is scarring this will be seen in loss of characteristic features (e.g. introital narrowing, loss of the labia minora or sealing of the clitoral hood). The examination must also include examination of other flexural sites and mucosae, the scalp and nails. It is also useful to determine if the patient exhibits dermographism [10]. The vagina and cervix should be examined in patients who have dermatoses that affect mucosal surfaces and in patients with symptoms of dyspareunia, vaginal discharge or postcoital bleeding. Investigations are determined by the specific problem and include microbiological assessment. The investigation of the common bacterial or fungal problems can be easily performed by a dermatologist but if an exotic bacterial or sexually transmitted infection is high on the differential diagnosis, it is important to involve a genitourinary physician in the investigation and work-up of these patients and their partners. A biopsy is important, particularly in cases where there is no response to treatment. If a biopsy is performed, it is important to let the pathologist know what area has been biopsied, as the vulva is a mucocutaneous junction and the normal histological changes of a mucosal epithelium differ significantly from those of cornified epithelium and may be misinterpreted as pathological changes. Other investigations include those performed routinely for skin problems elsewhere (e.g. patch testing, examination with Wood's light, Tzanck smears). Some investigations are not the usual remit of the dermatologist but are necessary in patients with anogenital dermatoses, and will include a cervical smear and proctoscopy.

On occasions, the vulval changes are not caused by a primary problem of the vulval skin but are the secondary consequences of pathology at another site (e.g. an irritant vulval dermatitis resulting from a vaginal discharge because of cervical, uterine or vaginal pathology).

Table 68.30 Causes of vaginal discharge.

Physiological
Ovulation
Iatrogenic
Medications (e.g. tamoxifen, oral contraceptive pill)
Infective
Candidosis
Bacterial vaginosis
Cervicitis
Inflammatory
Lichen planus
Mucous membrane pemphigoid
Pemphigus
Erythema multiforme
Stevens–Johnson syndrome
Vaginal adenosis
Cervical erosion
Neoplastic
Langerhans' cell histiocytosis
Vaginal, uterine or fallopian tube tumours

Diagnosis and management of vaginal discharge

The diagnosis usually falls into one of the following categories: physiological, iatrogenic, infective, inflammatory or neoplastic (Table 68.30).

Physiological

Between 5 and 10% of women complaining of vaginal discharge do not have an infection. The discharge may be caused by an excess physiological secretion of mucus, usually resulting from a cervical erosion or an increase in the amount of vaginal transudate. The discharge is thick,

with a grey-white appearance, and is odourless and non-irritant. Vaginal pH is normal.

Iatrogenic

This is usually secondary to medications that have an effect on the vaginal epithelium (e.g. tamoxifen, which has an oestrogenic effect on the vagina); oral contraceptive pills can cause a cervical erosion and an increase in vaginal discharge.

Infective

This is the most common cause of a vaginal discharge, and a pH greater than 6 is highly predictive of an infectious cause [11]. Bacterial vaginosis is the usual diagnosis [12]. The patient complains of excessive grey watery discharge, associated with a 'fishy' malodour, which is worsened with intercourse. Vulval irritation is slight or absent in this group, and the smell is the most distressing symptom. The condition is invariably associated with infection by a small aerobic Gram-negative rod known as *Gardnerella vaginalis*, after its discoverer Gardner [13]. It would appear that this organism alone is incapable of causing infection, and non-specific vaginitis is now regarded as a complex interrelationship between *Gardnerella* and anaerobic species of bacteria [14], two of which belong to the genus *Mobiluncus*. The fishy odour of the discharge can be accentuated by the addition of an alkali such as 10% potassium hydroxide (the Whiff test). A wet mount of a vaginal smear in saline will identify 'clue cells'. These are vaginal epithelial cells with a granular cytoplasmic appearance and indistinct cellular outlines. This indistinct border is caused by the attachment of the small Gram-negative rods to the cell [15]. Bacterial vaginosis is not always sexually acquired—its incidence is equal in virginal and sexually active groups [16,17]. This type of abnormal bacterial colonization may be associated with preterm delivery and late miscarriage in pregnant patients [18]. Treatment is with metronidazole 400 mg twice daily for 5 days or 2 g as a single dose.

Patients with infective cervicitis will also present with an increased vaginal discharge. The four most common pathogens involved are *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Trichomonas vaginalis* and herpes virus hominis. *Chlamydia trachomatis* has been grown from the cervices of 50% of women with mucopurulent cervicitis [19]. The main symptoms are discharge, deep pelvic pain and dyspareunia.

Infestation with thread worms, *Enterobius vermicularis*, has also been recorded as a cause of a vulvovaginitis [20].

Inflammatory

Vaginal or cervical ulceration and erosion resulting from inflammatory conditions can give rise to an increased vaginal discharge. The most common inflammatory conditions are lichen planus and pemphigus [21]. The diagnosis is often missed, particularly if these sites are affected in isolation. There is a chronic odourless discharge, which may be blood-tinged. The patient will also complain of postcoital bleeding if she is sexually active. An accurate diagnosis requires a biopsy, and immunofluorescence studies should be performed both on tissue and serum. Examination of eyes and mouth may help if the patient also has disease at these sites. Treatment requires topical steroids in the form of foams or pessaries that are currently used for inflammatory bowel disease.

Neoplastic

Tumours of the fallopian tubes, uterus, cervix and vagina may all cause an increased vaginal discharge. Rarer causes of a chronic vaginal discharge include Langerhans' cell histiocytosis.

Management of vulval disorders depends upon the diagnosis, but general measures include the use of a soap substitute and avoidance of irritants (e.g. bubble baths, shampooing hair in the bath). If there is an incontinence problem, a barrier ointment helps to protect the skin. Weak potassium permanganate solution or Burow's solution can be used when there is erosive disease. Topical steroids are best used in an ointment formulation to avoid the irritant effect of preservatives and alcohol. Many of the patients are elderly and may have difficulty treating themselves. It is often helpful to take time in the clinic, using a mirror, to explain exactly where the treatment should be applied.

Structure and function of the female genitalia

The vulva is the collective term for the structures that comprise the female external genitalia. Anatomically, it is the region known as the urogenital triangle, bounded anteriorly by the symphysis pubis, the pubic rami laterally and the transverse perineal body posteriorly. The vulval structures included within this area are the mons pubis, paired labia majora and labia minora, clitoris and vulval vestibule. The epithelia that cover the vulva change from skin on the outer aspects to mucosa on the innermost region.

The mons pubis lies in front of and above the upper part of the symphysis pubis. It is softly rounded because of a thick cushion of subcutaneous fat. The epithelium is densely covered in hairs and possesses all the adnexal structures usually found in skin.

The labia majora are paired rounded folds of skin and are the homologue of the scrotum. They extend downwards and backwards from the mons pubis and meet posteriorly in the midline to form the posterior commissure, which lies approximately 2 cm anterior to the anus. The epithelium is similar in structure to that on the mons pubis in that there is a thick layer of adipose tissue and a dense distribution of hair on the outer surfaces of the labia. Hair is absent from the inner surfaces but numerous sebaceous glands remain. The inner aspects of the labia majora fuse into the outer aspects of the labia minora laterally, forming the interlabial sulci. The labia majora enclose an elliptical fissure which is known as the pudendal cleft—this contains the vestibule with the openings of the vagina and urethra.

The labia minora are the equivalent of the prepuce, and part of the ventral portion of the penis and the floor of the spongy part of the male urethra. They are paired pendulous folds, which lie between the labia majora and the vulval vestibule. Anteriorly they split into two folds on each side, which fuse in the midline. The superior folds cover the clitoris like a hood, forming the prepuce of the clitoris, and the lower folds fuse on the inferior aspect of the clitoris, forming the clitoral frenulum. Posteriorly, the labia minora fuse to form the fourchette, and sometimes form a depression in the midline, the fossa navicularis. The labia minora possess little subcutaneous fat. Their epithelium lacks hair but there are numerous sebaceous glands and sweat glands. The epithelium is cornified but its barrier function is not as effective as skin elsewhere.

The clitoris is the homologue of the penis and contains all the vascular and muscular structures found in its male counterpart. The end of the clitoris is surmounted by a small rounded tubercle, the glans clitoris.

The vestibule is usually considered as part of the vulva, although many anatomy books refer to it as the vestibule of the vagina. It is the area that lies between the labia minora and contains the openings of the urethra and vagina. The vaginal opening is partially closed by the hymen. When the hymen is ruptured, its remnants form rounded crenulations, the hymenal caruncle. The fold between the hymenal caruncle and the vestibular floor is the nymphohymenal sulcus. Sometimes a clear line of demarcation between the labia minora and the epithelium of the vestibule can be seen, Hart's line. The vestibule is a mucosal epithelium and lacks hairs and sebaceous glands. On each side, the duct of the major vestibular gland, Bartholin's gland, can be seen sited between the hymenal ring and posterior part of the labium minus. The ducts of the minor vestibular glands, Skene's glands, open on either side of the urethral orifice. The epithelial surface is usually smooth, but occasionally tiny frond-like papillae may be seen distributed symmetrically laterally and posteriorly on the vestibule (Fig. 68.20). These vestibular papillae are a variant of normal and not related to HPV infection.

Normal flora

The skin of the perineal area has a higher pH, temperature and degree of humidity than skin elsewhere and, because of its proximity to the vagina and rectum, harbours many of the flora from these sites [1,2]. The main resident organisms are micrococci, diphtheroids and lactobacilli. Lactobacilli are probably the most common organisms, particularly on the labial mucosa, as the glycogenated epithelium of the vagina, under the influence of oestrogen, encourages colonization by them. The lactobacilli in turn metabolize the glycogen to lactic acid, which keeps the vaginal pH at approximately 4.5, restricting the growth of many organisms.

Normal variants

Angiokeratomas are small vascular 1–4 mm papules found on the labia majora [1]. They vary in colour from red to blue-black and are normally asymptomatic, but can become quite large and bleed if traumatized, particularly in pregnancy.

Sebaceous gland hyperplasia is seen on the inner aspects of the labia majora and labia minora where the glands do not usually have an associated hair unit. The glands open directly onto the surface, and may be very prominent and numerous. The yellow uniform papules are often best seen when the skin is stretched. Prominent and numerous glands may be associated with pruritus. Occasionally, they can become very large and be mistaken for a sebaceous gland adenoma [2].

Vestibular papillomatosis is the term used to describe the occasional normal finding of myriad tiny filiform or soft frond-like projections on the vestibular epithelium and inner aspects of the labia minora. These lesions have had various names in the past, including papillomatosis labialis, hirsuties papillaris [3], hirsutoid papillomas of the vulva [4], vestibular papillae [5], pseudocondylomas, vestibular microwarts and vulval squamous papillomatosis [6]. The last two suggest that HPV is implicated but the evidence now suggests that the known HPV types are not associated with these papillae [7–9]. Clinically, vestibular papillae are unlike the lesions induced by HPV as they are symmetrically arranged and each papilla has a solitary base. Histologically, problems arise if the pathologist is unaware that the tissue is the vestibule, which has heavily glycogenated epithelial cells that become vacuolated on processing and may resemble koilocytes. The problem is also compounded by the fact that koilocyte-like lesions can be found on vulval biopsies but these are not necessarily associated with HPV infection [10]. Currently, it is believed that this entity is a normal variant and the female equivalent of pearly penile papules.

Varicosities of the labial veins may occur unilaterally in association with limb varicosities, or appear in pregnancy. The other changes in pregnancy include a fall in the pH and increased pigmentation. At the menopause, vascularity decreases and the sebaceous glands become less active.

Congenital and developmental abnormalities [1]

Ambiguous external genitalia

In some individuals, the external genitalia are not phenotypically characteristic of either male or female. An attempt at classification of these abnormalities is based on aetiology and clinical syndromes; there are three main groups [2,3]:

1 Female hermaphroditism
2 Male pseudohermaphroditism
3 Abnormal external genitalia in females may also be associated with abnormalities of the upper reproductive tract or urinary system [4].

Labial problems

There may be persistence of most caudal elements of the milk line in the labia majora, and there is great variation in the size and symmetry of normal labia minora. There may be very marked hypertrophy of the labia minora, some cases of which are examples of neurofibromatosis [5].

Labial adhesions may occur as an inherited familial trait [6] or in association with abnormal sexual differentiation. In general, most occur in the neonatal period and early infancy, and usually divide spontaneously by the time the child is 6 years old. No intervention is necessary unless there is a problem with urination. Some cases of labial adhesions result from lichen sclerosus.

Accessory labioscrotal folds are rare in women and are divided into two types, depending on whether or not there is an associated perineal lipoma [7].

The clitoris may be absent because of a failure of the genital tubercle to fuse, remain hypoplastic [8] or be enlarged because of congenital adrenal hyperplasia. The Lawrence–Seip syndrome, which is a congenital generalized lipodystrophy with the onset of insulin-resistant diabetes around the time of puberty, may also result in clitoral hypertrophy. There are clitoral tumours that may mimic genital sexual ambiguity (e.g. haemangioma, neurofibroma, lipoma [5,9–11]).

Virilization of the external genitalia may also occur with maternal ingestion of testosterone or synthetic progestogens in the first trimester, and if taken later in pregnancy there may be clitoral hypertrophy alone.

An imperforate hymen is usually discovered at puberty and is caused either by failure of the epithelial cells of the hymen to degenerate or by scarring after an inflammatory reaction in the hymen at birth.

Trauma and artefact

Factitial dermatitis

There are various causes of vulval trauma, including accidental injury, obstetrical tears, damage at the time of surgery in a nearby site and coital and sexual mutilation, both cultural and self-induced [1–3].

Nymphohymenal tears induced by sexual intercourse are not uncommon and may mimic the symptoms of vulval vestibulodynia (see p. 68.82).

Sclerosing lipogranuloma [4] is a granulomatous response induced artefactually.

Female genital mutilation [1]

Ritual and cultural female genital mutilation (FGM), although banned in most European countries, is still forced on millions of women worldwide [2,3], particularly in Africa and in some countries where there is a large Muslim population. However, it is not practised in certain Muslim countries, including Saudi Arabia [4]. Although it is unusual in Western society, many cases are now being seen in the UK because of the rise in immigration of women who have had previous FGM.

There are four types of operation performed, which vary according to the country and culture:

1 *Circumcision*: removal of the clitoris or the clitoral hood (Sunna circumcision).

2 *Excision*: removal of the clitoris and part or all of the labia minora.

3 *Infibulation*: removal of the clitoris, labia minora and partial removal of the labia majora. The introitus is then sutured leaving a tiny opening for urination and menstruation.

4 Another type includes a variety of different practices. It might involve cauterization, applying corrosive material, piercing or cutting of the clitoris, surrounding skin or vagina.

FGM may be carried out at any age from the neonate to the adolescent. It is often performed without an anaesthetic in unhygienic circumstances. There may be damage to the urethra and vagina at the time of the operation, and later there may be severe damage to the urethra, bladder or anal sphincter during delivery in those that have had infibulation. Many of the women who have had FGM

experience difficulties with sexual intercourse, urination and pregnancy and seek help in the clinics of their new country of residence, where unfortunately many of the health care professionals have not encountered their specific problem [5]. There are now a number of clinics being set up to deal specifically with these patients. The initial findings of a specialized clinic set up by a central London maternity unit found that many of the patients referred to them for problems in pregnancy were reluctant to volunteer the fact that they had been circumcised, and less than 10% refused to continue the tradition of FGM [6].

Dermatological manifestations of sexual abuse of children

Childhood sexual abuse is not the usual domain of the dermatologist, but occasionally it can be encountered when a dermatological opinion is sought on a genital skin problem. Lichen sclerosus and other dermatoses can be mistaken for sexual abuse [1–4], but sometimes the sexual abuse may be the initiating or exacerbating factor of the dermatological condition [5]. The possibility of sexual abuse sometimes has to be considered in a child whose lichen sclerosus, despite appropriate treatment and compliance, has not responded as expected. Sexual abuse always has to be excluded in the child who presents with a sexually transmitted disease [6,7], but conditions such as molluscum contagiosum, bacterial vaginosis [8] and genital warts are not necessarily indicative of sexual activity, and can be acquired by non-sexual means [9,10]. Genital warts in children may carry both genital and skin-type viruses [11]. If gonorrhoea or semen is found the situation is clear-cut, with the exception of neonatal infection and gonococcal eye disease [12]. Herpes simplex of the prepubertal genitalia is relatively uncommon [13] and sexual transmission may be implicated in both HSV-1 and -2 infections [14]. In a review of six cases, sexual abuse was proved in four. In the two innocently acquired cases, HSV-1 infection of the oral cavity immediately preceded the genital signs [15].

There are strict protocols for the examination and assessment of a child who is suspected to be a victim of sexual abuse [16]. It is important that this evaluation is carried out by a skilled specialist, usually a paediatrician [17].

HIV has rarely been reported as being transmitted by sexual abuse of children [18,19], but direct transmission is possible, and sexual abuse may be a risk factor for HIV in later life [20–22].

Inflammatory dermatoses

Eczema

Atopic eczema can involve the vulva but the eczematous dermatoses affecting the vulva in isolation are seborrhoeic

eczema, irritant contact dermatitis and allergic contact dermatitis.

Seborrhoeic eczema

This condition has both eczematous and psoriasiform features, sometimes making differentiation between it and psoriasis difficult. The inguinal and genitocrural folds, labia majora, mons pubis, perineal body and perianal skin are the usual sites involved. Vulval involvement may be associated with skin changes on the scalp and changes at other flexural sites. Histological examination is not always helpful, as there may be features of both eczema and psoriasis. There is moderate acanthosis with slight spongiosis and a mild dermal inflammatory infiltrate.

Irritant contact dermatitis

The barrier function of the vulval skin is impaired, as measured by transepidermal water loss [1], and there is an increased susceptibility to irritant contact eczema [2,3]. The problem may occur because of the dampness and maceration secondary to a heavy vaginal discharge, or increased contact with urine in the incontinent patient. Contact with irritant chemicals in topical agents, particularly cleansing agents, bubble baths, disinfectants, lubricants, perfumed products, deodorants and medicaments (e.g. 5-fluorouracil, podophyllotoxin and dequalinium), may all be responsible for an irritant dermatitis.

Allergic contact dermatitis

In spite of the frequent use of topical agents in the vulval area, allergic contact dermatitis is extremely rare in clinical practice. However, high incidences of contact dermatitis in vulval dermatoses have been reported [4,5]. An explanation for these unexpected high incidences may be that the patients in the studies had perianal skin involvement as well as vulval involvement, and allergic contact dermatitis to topical medicaments is more frequently encountered in perianal skin. One study has shown a higher incidence of positive patch tests in patients with anogenital dermatoses if both the genital and perianal areas are involved, compared with dermatoses affecting the genital skin alone [6].

There are reports of allergy to vaginal preparations and an intrauterine device [7–9], sanitary wear [10] and condoms [11]. Oestradiol may rarely cause a localized allergic contact dermatitis at a transdermal patch site, or generalized contact dermatitis with oral therapy [12].

Allergic contact urticaria

The two most common causes of contact urticaria in the vulvovaginal area are latex and semen [13], and there is usually a history of atopy [14]. Seminal fluid usually induces an urticarial immediate type I reaction and rarely produces a type IV contact allergy. There are reports of mixed sensitivities: one patient was allergic to semen and latex and another to her husband's semen and sweat [15,16]. However, semen itself may not be the responsible allergen, the problem being caused by a medication or other allergen carried in the seminal fluid [17–19]. Specific immunotherapy against semen has been successfully employed on occasion [20]. A fixed eruption to seminal fluid has been reported [21], and familial allergy to semen [22].

Psoriasis

The pattern of psoriasis affecting the anogenital skin is

Fig. 68.21 Fissured psoriasis in the natal cleft.

most frequently flexural. The areas involved include the genitocrural folds, mons pubis, outer aspects of the labia majora, the perianal skin and the natal cleft (Fig. 68.21). The characteristic silvery scaling is absent in these occluded sites and the main clinical picture is intense erythema with a well-defined margin. Rarely, there may be some scarring associated with vulval psoriasis with loss of the labia minora and fusion of the clitoral hood.

The histology is not always typical, and there may be marked spongiosis and papillary oedema.

Reiter's disease (circinate ulcerative vulvitis)

Circinate balanitis is well recognized but the corresponding vulvitis is much rarer [1–4]. The lesions may be eroded, ulcerative or scaly. Histologically, the changes are of those seen in pustular psoriasis [5], with hyperkeratosis, parakeratosis, psoriasiform hyperplasia, an absent granular layer and collections of polymorphs in the epidermis.

Fig. 68.22 White patches of lichen planus in the interlabial sulci.

Lichen planus [1–3]

Lichen planus (LP) can affect the vulva in isolation or at the same time as a generalized outbreak, when approximately 20% of patients will have genital lesions. The vulval lesions are similar to those seen at other sites and may be violaceous or erythematous papules, white (Fig. 68.22) or annular plaques, and erosions with or without a lacy white border. These lesions may all ulcerate. Wickham's striae occur infrequently (Fig. 68.23). If the vulva is affected in isolation, the disease is more often erosive, with most of the lesions around the labia minora, clitoris and clitoral hood. Confluent white and red patches will also be seen in this variant. A careful examination of the oral mucosae is helpful, as LP be may found on the tongue, palate, gingivae and lateral buccal mucosae.

The other clinical forms of vulval LP include the following.

1 *Pigmented flexural lichen planus* (Fig. 68.24). This variant of LP can affect the vulval area, particularly the mons pubis, the inguinal and genitocrural folds. The characteristic and striking finding is brown pigmented patches, some so deeply pigmented that they resemble melanocytic naevi. If the disease is seen in the early stages, a violaceous erythema is also observed. This form of LP is also found in the inframammary areas and axillae.

Fig. 68.23 Delicate white striae of lichen planus, with the labia minora flattening and fusing into the surrounding skin.

Fig. 68.24 Patches of pigmented flexural lichen planus.

2 *Vulvovaginal–gingival lichen planus* (VVG-LP) (syndrome of Hewitt and Pelisse; desquamative vaginitis). This distinctive erosive form of LP is clinically very similar to mucous membrane pemphigoid [4,5]. In the past, many cases labelled desquamative vaginitis were probably this entity [6,7]. VVG-LP principally affects the inner aspects of the labia minora, vestibule and vagina. The condition is chronic and painful, and there is an increase in vaginal discharge, dysuria, dyspareunia and postcoital bleeding. Clinically, the epithelia are eroded and often there is a distinctive fine white lacy border. There may be marked loss of architecture (Fig. 68.25). The anal margin may also be involved. The vaginal lesions are velvety red erosions or bright red, glazed erythema, which is friable and bleeds when touched. Vaginal synechiae and adhesions develop, leading in some cases to vaginal stenosis. The cervix may also be involved [5,8,9]. Oral LP lesions can occur at any site, but the characteristic finding is an intense erythema of the gingivae, which may be asymptomatic (Fig. 68.26). Unusual extragenital lesions have been described on the conjunctiva [10], lachrymal gland canal [11], oesophagus [12–15] and the auditory canal [16]. The manifestations of this syndrome do not necessarily all occur synchronously.
3 *Lichen planopilaris* has been described on the vulva [17].

Histopathology. On cornified epithelium there is hyperkeratosis, irregular acanthosis with a typical saw-tooth appearance of the rete pegs, an increased granular layer, and disruption of the basal layer with a closely apposed dermal band-like lymphocytic infiltrate. The acanthosis and hyperkeratosis are marked in the hypertrophic form and, because of the chronicity of this form, the characteristic band-like infiltrate is not obvious but will be found focally. Eosinophilic colloid bodies may be seen. Immunofluorescence studies reveal uneven staining of the basement membrane zone for fibrinogen and IgM, cytoid bodies and, on occasion, IgG or IgA.

Differential diagnosis. The main differential diagnosis is usually lichen sclerosus, but mucous membrane pemphigoid and morphoea could also be included. In some cases, the differentiation between lichen sclerosus (LS) and LP can be extremely difficult, even impossible, as the two diseases share so many features in common [18,19]. If a definite diagnosis cannot be made on a combination of clinical, histological and immunofluorescence findings and response to treatment, it is perhaps best to allocate the case as an overlap of the two disorders. Frequently, there are cases of LP misdiagnosed as Zoon's vulvitis.

Fig. 68.25 Lichen planus: vulval aspect showing glazed erythema and distortion of the architecture, with a remnant of the left labium minus and buried clitoris above it.

Fig. 68.26 Lichen planus. Intense glazed erythema of gingiva.

Treatment. First-line treatment is with potent topical steroids. If the vagina is involved, a topical steroid can be introduced with a vaginal applicator, or steroid foams or suppositories that are available for inflammatory bowel conditions can be used [20,21]. Topical retinoids are useful for hyperkeratotic and hypertrophic LP, and recently topical tacrolimus has been used [22]. Other treatments tried with variable success include oral steroids, oral and topical retinoids, methotrexate [23], ciclosporin [24] and azathioprine.

Zoon's vulvitis

It is likely that plasma cell vulvitis (PCV; vulvitis

circumscripta plasmacellularis) is not a single disease entity but represents a reaction pattern to another inflammatory condition. A plasma cell-rich infiltrate in a vestibular biopsy may be a misleading finding, because plasma cells are commonly found in inflammatory conditions of the vestibule as it is a mucosal epithelium.

Many of the cases are examples of unrecognized dermatoses such as LP, and in others the persistent change may represent a chronic post-inflammatory phenomenon.

The first descriptions of the female equivalent of ZB were by Garnier and Zoon [1–3]. The lesions described in these reports were erythematous patches with a glazed appearance, with the histological findings of a plasma cell-rich dermal infiltrate and no cytological atypia. The disorder followed a chronic but benign course. The disorder appears to be less common in women, and in one series of 20 cases there was only one female [4].

Most of the reports of this condition in women describe the lesions in the vestibule and labia minora, whereas the typical site in men is the glans and prepuce. The glans clitoris is rarely, if ever, affected.

Histology. The criteria needed to make the diagnosis have varied in the literature, and there is some doubt whether PCV is a distinct clinicopathological entity, as many of the reports of vestibular Zoon's are probably LP [5].

The essential features are epidermal thinning, absent horny and granular layers and distinctive lozenge-shaped keratinocytes with widened intercellular spaces; in the dermis there is a dense inflammatory infiltrate composed largely of plasma cells, with dilated blood vessels and usually much haemosiderin. Russell bodies and dermal–epidermal splitting have also been described [6].

Treatment. Treatment depends on the underlying inflammatory dermatosis responsible for this histological change. In the majority of cases this is LP, and a potent topical steroid should be tried. If the inflammatory phase of disease has resolved and the patient is complaining of a sensation of rawness or burning, then topical 5% lidocaine can be effective. Finally, a barrier ointment such as Vaseline petroleum jelly may offer some relief if there is an irritant component to the problem.

Chronic vulval purpura

It is not uncommon to find patients with purpuric patches, often at the vestibule, in which haemosiderin and plasma cells are found without any specific epidermal change, and the term chronic vulval purpura may be a more accurate description [7]. An association with lichen aureus has been suggested, as pressure factors are thought to be relevant in the extravasation of blood [8].

Lichen sclerosus [1–6]

Lichen sclerosus (LS) was first described as a variant of LP with a tendency to affect the genital area. The old terms leukoplakia, leukoplakic vulvitis and kraurosis vulvae were clearly applied to examples of LS or LP, and the use of these terms led to confusion. The term vulval dystrophy was introduced in the 1960s in an attempt to overcome the problems in distinguishing and classifying vulval dermatoses characterized by pallor and scarring [7]. This terminology unfortunately proved unsuccessful in its objectives, as its use discouraged attempts to differentiate between disorders such as LS, LP and mucous membrane pemphigoid. In 1983, the Terminology Committee of the International Society for the Study of Vulvovaginal Dermatoses recommended a new classification with discontinuation of the term dystrophy [8]. The term vulval squamous cell hyperplasia was introduced with this classification (see p. 68.49).

Aetiology and pathogenesis. The aetiology is still unknown but there is mounting evidence that LS is a genetically determined autoimmune disorder. A positive family history is recognized [9] and the disorder has been described in twins, both identical [10] and non-identical [11]. An association of LS in females with other autoimmune disease has been noted [12–14]. Attempts to establish a specific HLA linkage in patients with LS were initially inconclusive [15] but a later study has shown an increased incidence of DQ7 [16]. Similar findings have been reported in LS in girls [17].

The role of *Borrelia burgdorferi* as an aetiological trigger is controversial. A study in the UK showed no evidence histologically of spirochaetes but did show 'cocci' with a Fite stain, which later proved to be mast cells when stained with toluidine blue [18].

Clinical features. LS can affect females of any age, but the majority of patients are either prepubertal or menopausal. There is still uncertainty whether LS in prepubertal girls

Fig. 68.27 Oedema and ecchymosis of lichen sclerosus.

Fig. 68.28 Lichen sclerosus. Pallor and atrophy of the vulval skin with loss of the labia minora and burying of the clitoris.

remits spontaneously at puberty. The presenting symptom is usually itching, which is often severe and distressing.

The classical lesions seen on the extragenital skin are ivory white papules and plaques with follicular delling. Anogenital disease tends to be characterized by flatter lesions of atrophic whitened epithelium, which may become confluent, extending around the vulval and perianal skin in a figure-of-eight configuration. There may also be oedema, ecchymosis, bullae, erosions and ulceration (Fig. 68.27). The sites most commonly affected are the genito-crural folds, the inner aspects of the labia majora, labia minora, clitoris and clitoral hood. Vestibular involvement is rare and vaginal lesions do not occur, as LS seems to spare non-cornified stratified squamous epithelia (mucosal epithelium). Perianal lesions occur in approximately 30% of female patients, in contrast with men who do not seem to develop perianal involvement. Extragenital lesions occur in 10% of women with vulval disease. The extragenital areas may be truncal, at sites of pressure, upper back, wrists, buttocks and thighs. The Koebner phenomenon has also been reported at sites of radiotherapy [19], scar tissue [20], vaccination [21] and congenital haemangioma [22]. Facial [23], scalp [24] and nail involvement [25,26] have been recorded.

Lesions of LS in the oral cavity are extremely rare. Many of the reports of oral involvement in the literature have often not been confirmed histologically [27] and may have been examples of LP. It is not uncommon for patients with vulval LS to have coexistent oral LP [28].

The author (SMN) has seen two cases of oral LS, confirmed histologically, and both were on the tongue. This is one of the few sites in the mouth that has cornified stratified squamous epithelium.

LS is a scarring dermatosis and the changes that can occur on the vulva include loss of the labia minora, and sealing over of the clitoral hood, burying the clitoris (Fig. 68.28). Introital narrowing resulting from anterior and posterior labial fusion sometimes results in a tiny opening into the vestibule. Milia may occur [29].

Histology. The classic histology is a thinned epidermis with flattening of the rete pegs. The underlying dermis is hyalinized and there are often extravasated red cells. Below the hyalinized area is a band-like zone of chronic

inflammatory cells. There is an absence of elastic fibres in the upper dermis. There have been attempts to grade the histological appearances [30] but there is probably little correlation between the timing of a lesion and its histological appearance [31].

In some cases the epidermis is thickened, and this is LS with squamous cell hyperplasia. It is found in approximately 30% of cases of LS in association with vulval SCC [32].

There are abnormalities of the basement membrane, but it is uncertain whether these are a primary or secondary event [33]. Immunofluorescence studies are usually negative or demonstrate non-specific fibrin deposition at the dermal–epidermal junction. There is also an alteration of the elastin and fibrillin in the affected dermis [34].

Differential diagnosis. Vitiligo, mucous membrane pemphigoid, LP and morphoea may present with a similar clinical appearance. There can be clinical and histological overlap between morphoea, LP and LS, and they may represent a spectrum of disease rather than three distinct conditions [35,36].

Lichen sclerosus and vulval malignancy

There is undoubtedly an association between vulval SCC and LS that was probably underestimated in the past (Fig. 68.29) [37]. The incidence of SCC developing on LS in clinical practice is of the order of 4% or less [1]. However, in retrospective reviews of pathological specimens of vulval carcinoma, histological evidence of LS is found in approximately half of the cases [37–40]. These series included patients presenting with SCC as well as those on long-term follow-up. A longitudinal cohort study of 211 patients showed that the number of invasive SCCs significantly exceeded that in an age-matched group [41]. It is not known whether good control of LS reduces this risk.

There appears to be a bimodal pattern for vulval SCC. In younger women the tumour is associated as a rule with oncogenic types of HPV and intraepithelial neoplasia, and in the older woman with a chronic dermatosis without evidence of HPV infection [42–44].

The histological patterns associated with SCC arising on LS include epithelial hyperplasia and differentiated intraepithelial neoplasia (dysplastic changes that are confined to the basal layers) [45].

LS has been reported in association with verrucous carcinoma [46,47], basal cell carcinoma [48] and melanoma [49]. However, malignant melanoma is known to be difficult to diagnose in the presence of LS [50], and the validity of the case report of an association between malignant melanoma and LS was questioned [51]. However, the original authors upheld their view.

Fig. 68.29 Squamous cell carcinoma arising on a background of lichen sclerosus.

Treatment [52,53]. The current and recommended treatment for uncomplicated LS is the potent topical corticosteroid, clobetasol propionate. There are no randomized controlled trials providing evidence for any particular corticosteroid or treatment regimen being more effective than any other. The regimen recommended by the author (SMN) for a newly diagnosed case is initially clobetasol propionate once nightly for 4 weeks, then alternate nights for 4 weeks, and twice a week for a further month. A 30-g tube of clobetasol propionate should last 12 weeks, and the patient is then reviewed. The clobetasol propionate is then used as and when required to control itching. Most patients seem to require 30–60 g annually. A proportion of patients go into complete remission and do not require further treatment. Others will continue to have flares and remissions and they are advised to use clobetasol propionate as required. A soap substitute is also recommended and an information sheet on LS, including instructions for the use of the topical steroid, is provided.

Topical testosterone currently has no role in the management of LS. It is expensive and is not as effective as clobetasol propionate [54].

Surgical excision is not necessary in the management of most cases of LS and it should be used exclusively for the management of functional problems caused by post-

inflammatory scarring [55,56], premalignant lesions and malignancy.

Crohn's disease

Anogenital lesions occur in approximately 30% of patients with intestinal Crohn's disease, either as a direct extension of active intestinal disease or as metastatic disease. Vulval disease may present many years before intestinal involvement, and in some cases there is vulval oedema only, with no evidence of granulomatous inflammation [1,2]. The more usual presentation is ulceration, abscess, sinus and fistula formation, with a granulomatous histology. There may be deep linear fissures (knife cut sign) along the skin creases.

A separate form of vulval granuloma akin to the orofacial lesions seen in Melkersson–Rosenthal syndrome has been described [3,4].

Ulcerative and bullous disorders

Any of the blistering disorders of the skin can occur on the vulva and vagina, either as part of the generalized disease or in isolation. Diagnosis can be more difficult in the latter case.

There are many causes of vulval ulceration and some features are important in narrowing down the differential diagnosis. It is helpful to divide them into acute and chronic types.

Acute genital ulceration

Benign aphthae

Many eponymous names have been assigned to acute vulval ulcers and several of these disorders are probably examples of benign aphthae. Reiter's syndrome may be associated with an ulcerative vulvitis [1].

Benign aphthae of the vulva may or may not occur with concomitant oral lesions. The age of onset is in childhood, about the age of 6 years, and there may be a family history. The lesions are usually multiple and small, and less commonly solitary or few and larger—referred to as giant aphthae. Herpetic infection should be excluded. There are often premenstrual exacerbations once the menarche is reached. The aetiology remains unknown.

The lesions are superficial and painful, with a yellow base surrounded by a red areola. They are distributed most frequently on the labia minora, and heal quickly (Fig. 68.30).

Fig. 68.30 Solitary benign aphthous ulcer of the left labium minus.

Sutton's ulcer (periadenitis mucosa necrotica recurrens) was originally reported in the mouth [2] but vulval lesions have also been given this label. The ulcer is characterized as being solitary, painful and recurring [2]. This type of ulceration, in the light of today's knowledge, would now be regarded as an example of benign aphthosis or a manifestation of Behçet's syndrome. Lipschutz's ulcer, described 2 years after Sutton's report, encompassed three types of ulcer (ulcus vulvae acutum), two of which today would be assigned to either aphthous ulceration or Behçet's syndrome. Only one is still regarded as being a separate entity [3]. This remaining form of ulceration is sometimes associated with a systemic infection such as infectious mononucleosis [4,5], typhoid or paratyphoid fever. Epstein–Barr virus (EBV) has been isolated from the ulcers [6], and there is one case of a mistaken diagnosis of lymphoma [7]. The Lipschutz-type ulcer usually affects adolescent girls and has a rapid onset. The ulcer may be very deep and large, and has a surrounding red areola and a thick adherent slough. It is most often solitary on one side of the vulva, usually the inner aspect of the labium minus, but lesions may occur bilaterally. Healing is spontaneous, but may take several weeks and leaves some scarring.

Treatment includes analgesics, potassium permanganate soaks and the application of a topical steroid with or without a topical tetracycline. In very severe ulceration, a short course of oral steroids may be required.

Erythema multiforme

The pattern of recurrent acral erythema multiforme is rarely associated with genital lesions, whereas oral lesions are nearly always present. The vulva is affected in Stevens–Johnson syndrome, often with erosions.

Bullous fixed drug eruptions

These are less common (or less commonly recognized) on the vulva than on the penis, where the commonly implicated medications include paracetemol and tetracycline. It is now rare to see cases involving phenolphthalein, sulphonamides and barbiturates.

Chronic genital ulceration

Any chronic ulcer of the genital mucosa must be considered malignant until proved otherwise. The differential diagnosis of chronic ulceration includes the diseases listed below, which are discussed fully in the relevant sections of this and other chapters.

1 *Genetic.* Epidermolysis bullosa, Hailey–Hailey disease and Darier's disease may all be responsible for chronic recurring ulceration. Exacerbations may follow friction, infection, irritants and herpes simplex infections.

2 *External trauma.* Nymphohymenal tears, dermatitis artefacta and radiation damage. Nymphohymenal tears may occur with sexual intercourse but most heal spontaneously. They tend to occur around the nymphohymenal sulcus, usually in the inferior segment at the 5 and 7 o'clock positions (Fig. 68.31). Those that do not heal can be excised radially.

3 *Malignancy.* The two most common malignant ulcers of the vulva are squamous cell carcinoma and basal cell carcinoma. Melanoma may also present as an amelanotic ulcerating nodule. Langerhans' cell histiocytosis may present with vulval and vaginal ulceration.

4 *Infection.* Chronic infective ulcers occur in tuberculosis, actinomycosis and other deep mycoses. The late stages of lymphogranuloma venereum cause ulceration and scarring.

5 *Inflammatory.* LS, LP and lupus erythematosus can all cause chronic ulceration. Pyoderma gangrenosum may be mistaken for malignancy on the vulva [8]. Hidradenitis suppurativa and Crohn's disease can sometimes be difficult to distinguish, particularly if they occur together. Pilonidal sinuses have been recorded on the vulva and clitoris [9].

Several of the autoimmune bullous diseases affect the vulva. Juvenile pemphigoid, mucous membrane pemphigoid (Fig. 68.32), pemphigus vulgaris and vegetans may all present with vulval and vaginal ulceration.

Fig. 68.31 Tear of the right inferior aspect of the nymphohymenal sulcus.

Non-sexually transmitted infections

Bacterial infections

Staphylococci

Staphylococcus aureus is usually the causative agent in infective folliculitis, boils and abscesses of the vulva. It is often associated with an underlying problem (e.g.

Fig. 68.32 Erosions in vulval mucous membrane pemphigoid.

diabetes, immunosuppression). Pseudofolliculitis is a sterile folliculitis that may follow shaving and is caused by the newly regrowing hairs inducing an inflammatory reaction. It is a foreign body reaction and results in changes from mild inflammation to the formation of abscesses and sinuses. A staphylococcal folliculitis on the buttocks may occur secondary to the pruritus induced by intestinal infestation with pin worm.

An exotoxin associated with phage group 1 staphylococci has been implicated in production of the collapse, fever and morbilliform rash seen in the toxic shock syndrome. Although the syndrome occurs most commonly in menstruating women who use tampons, the association is not exclusive.

Histology. The impetiginous lesion shows subcorneal pustules filled with neutrophils and some spongiosis, with a moderate inflammatory response in the papillary dermis.

The acute folliculitis may be superficial with a subcorneal pustule present at the follicular opening, or deep and associated with a perifollicular abscess, and destruction of the follicle wall and sebaceous gland. Chronic deep intrafollicular abscesses may have the additional features of fibrosis and foreign body giant cells.

Streptococcal infections

Beta-haemolytic Lancefield group A bacteria may be the cause of vulval cellulitis. The erythema and oedema may be extreme, and vesicles and bullae develop. There are usually associated systemic signs. The infection arises at sites of trauma where there is a wound and it is commonly seen following a vulvectomy with lymphadenectomy. If there is residual lymphoedema then further attacks of cellulitis are more common. Streptococcal dermatitis usually affects the anogenital area of children [1].

Synergistic bacterial gangrene

This severe and rapidly extending disease is caused by the synergistic effect of a microaerophilic streptococcus and *Staphylococcus aureus* (see Chapter 27).

Hidradenitis suppurativa

This is dealt with fully in Chapter 27, but mention is made here as staphylococcal and streptococcal infection have a secondary role. The primary problem is an abnormality of the follicular epithelium of the apocrine gland ducts, which starts with a spongiform infundibular folliculitis [2]. *Streptococcus milleri* is often found as a secondary pathogen [3].

Histology. This is characterized by distension and inflammation of apocrine ducts, with polymorphs in and around the ducts. The apocrine glands may become necrotic, with an infiltrate of lymphocytes, plasma cells and macrophages. Sinuses are lined by keratinized epithelium. Fibrosis and a foreign body reaction with granulomatous changes are common. Pseudoepitheliomatous hyperplasia may be seen, and at least nine cases of SCC have been reported—two of these were in females with buttock lesions [4].

Treatment is with long-term antibiotics, and in some cases oral isotretinoin may be helpful. The important differential diagnosis is Crohn's disease, but hidradenitis suppurativa and Crohn's disease may coexist [5,6].

Gram-negative bacilli

Pseudomonas aeruginosa is a common problem in patients with bladder problems but it is not a cause of vulvovaginitis. There has been a report of blue staining of napkins in infants with this infection [7].

Despite its name, *Trichomycosis* is caused by species of corynebacteria, which lead to red, yellow or black nodules on the shafts of the axillary and pubic hairs (see Chapter 27). Histological examination shows that these nodules consist of concretions of bacteria. The hair shafts may be damaged [8].

Diphtheria, caused by *Corynebacterium diphtheriae*, is rare in developed countries. Vulval infection takes the form of ulcers, often with a greyish membrane. It has been described in children [9,10] and in adults [11,12].

Mycobacterial infections

Vulval tuberculosis, caused by *Mycobacterium tuberculosis*, is uncommon in the UK. It may occur by means of haematogenous spread from foci outside the genital tract, by distal spread from the upper genital tract, or as a primary exogenous infection contracted from sputum or sexual intercourse. Vulval tuberculosis has been reported in a renal transplant patient [13], and three cases were described in a series of 26 patients with genital tuberculosis [14]. Genitourinary tuberculous infection is more common in HIV-positive subjects. In a primary infection the initial lesion may be inconspicuous, the main feature being a caseating lymphadenopathy. In other cases the lesions are masses or nodules that may ulcerate and lead to lymphoedema [15]. Bartholin's gland may be involved [16].

Leprosy (see Chapter 29)

The female genital tract may be involved in infection by *Mycobacterium leprae* [17], but vulval lesions are rare [18]. Pubic hair may be lost [19].

Higher bacterial infection

Higher bacteria is the name assigned to those bacteria that, like filamentous fungi, are capable of forming true branches. They include the genera *Streptomyces*, *Actinomyces* and *Nocardia*.

Actinomycosis

The Gram-positive acid-fast organisms responsible for actinomycosis are predominantly *Actinomyces israelii* and *Actinomyces gerencseriae*. They may colonize intrauterine devices and are usually asymptomatic, but invasion of the genital tract can occur [20,21]. Genital infection usually arises from bowel disease [22]. Lesions of the vulva alone have been reported [23].

Mycoplasmas

Mycoplasma hominis and *Ureaplasma urealyticum* are found in the vagina and rarely cause disease. There are rare reports of *M. hominis* being isolated from cases of Bartholin's abscess [24,25].

Abscesses of Bartholin's gland may be caused by pyococcal organisms, gonococcus and *Chlamydia trachomatis* [26]. In one study, only 21 of 109 cases were caused by staphylococci, whereas 50 were caused by *Escherichia coli* and 46 by *Streptococcus faecalis* [27]. The abscess results from distal blockage of the duct. The patient presents with fever, malaise and a tender swelling arising posterior to the origin of the labium minus. Episodes of bartholinitis may be mild and recurrent until fibrosis supervenes.

Fungal infections

Candidal vulvovaginitis

Candida and *Torulopsis* are both yeasts that can infect the vulva and vagina. *Torulopsis* accounts for very few

infections, whereas *Candida albicans* is the most frequently isolated.

Candida albicans is dimorphic, with both yeast and mycelial forms. It is a non-pathogenic commensal in the intestinal tract in 30% of the normal population. Infection in women is usually a vulvovaginitis. Changes in host factors are probably responsible for transition to pathogenicity, and are generally not directly associated with sexual contact. Factors related to cell-mediated immunity are doubtless important, but as yet are ill-understood. Pregnancy, diabetes, possibly oral antibiotics, high-dose oestrogen oral contraceptive pills and immunosuppression may all be predisposing factors. The primary infection arises in the vagina, causing inflammation and a heavy white curdy discharge, which then leads to a secondary vulvitis with well-demarcated sheets of erythema on the outer aspects of the vulva, sometimes extending on occasions into the genitocrural folds and perianally. There may be a scaly or vesiculopustular edge. Beyond this edge lie grouped or isolated superficial small pustules, which rupture rapidly, leaving a slightly scaly periphery. In all cases of candidal vulvovaginitis, but particularly in the middle-aged patient, late-onset diabetes should be considered, and appropriate tests carried out.

Diagnosis is confirmed by direct microscopy and culture.

Treatment of vulvovaginal candidiasis requires vaginal pessaries or creams and/or oral imidazoles.

In some cases of vulval eczema and psoriasis, *Candida* is cultured from skin swabs, but the candidal overgrowth is a secondary problem arising on a background of an inflamed epithelium. Treating the dermatosis alone with a topical steroid will usually resolve the problem, without the addition of anticandidal agents.

Dermatophyte fungi

Dermatophyte infections of the vulval skin are uncommon in cooler climates. The sites affected are usually the inguinal folds and perianal area. The causative agents are *Trichophyton rubrum* or *Epidermophyton floccosum*. The vulval epithelium in the adult seems to be relatively immune to dermatophyte infections. The lesions are erythematous and scaly, with a spreading raised circinate edge. Folliculitis is also seen, particularly in the perianal area. Tinea incognito may also occur perianally following the injudicious use of a topical steroid in the presence of an unrecognized dermatophyte infection. The diagnosis is usually made by direct microscopy and culture of skin scrapings, and treatment is usually oral terbinafine or griseofulvin because the skin is hair-bearing.

Miscellaneous

Pityriasis versicolor classically occurs on the trunk, but in severe widespread infection there may be vulval involvement [1,2].

The black and white forms of piedra (trichosporosis) are caused by *Piedraia hortai* and *Trichosporon beigelii*, respectively, the latter acting synergistically with a corynebacterium. The hair-bearing parts of the vulva can be affected with black and white nodules along the hair shafts [3]. The diagnosis is made by microscopy and culture.

Vulval phycomycosis has been described [4]. Subcutaneous infections occur in children and young adults. Histologically, the epidermis is unremarkable but subcutaneously there are deep granulomatous masses containing hyphae.

There is one case report of chromomycosis (chromoblastomycosis) affecting the vulva [5].

Cryptococcus neoformans can induce painless ulceration of the vulva in the immunosuppressed patient [6].

Infections with protozoa

Infection with *Trichomonas vaginalis* causes a frothy malodorous greyish green watery discharge, and a bright red vaginal mucosa studded with petechiae. The vaginal discharge may cause a secondary vulvitis, with erythema and swelling of the vestibule and labia minora. Colonization of the urethra and paraurethral glands often occurs. The diagnosis is made by microscopic examination of wet preparations and culture.

Treatment is with metronidazole 400 mg twice daily for 5 days or 2 g in a single dose.

The flagellate protozoan *Leishmania tropica* causes cutaneous, mucocutaneous and visceral forms of leishmaniasis. The vulva is mainly affected by the cutaneous form, which is endemic in areas of the eastern Mediterranean, Asia Minor and India; and to a lesser extent by the mucocutaneous form, found in Central and South America. An example of sexual transmission from post-kala-azar dermal leishmaniasis has been reported [1]. Transmission of infection is usually by sandflies. The lesions are nodular or ulcerative.

Entamoeba histolytica is found worldwide and intestinal amoebiasis may be transmitted from the bowel to other areas including the genital tract, although such involve-

ment is rare [2]. It appears as warty or ulcerative masses of the vulva, perineum and cervix. Live amoebae may be recovered from scrapings, or the organism seen as a small eosinophilic body in an inflammatory histological reaction.

Vulval schistosomiasis is usually caused by *Schistosoma haematobium*. The lesions are chronic, scarring and granulomatous, and may ulcerate and calcify [3–5].

Histologically, there is inflammation surrounding the organisms and their remains, with granuloma formation and many eosinophils. Ova may be found in the vagina, urine and faeces.

Viruses

Three groups of viruses are important causes of infection in the genital area: the poxviruses, papillomaviruses and herpesviruses. Other viruses seldom give rise to distinctive clinical pictures, although vulval lesions may occur as part of a generalized viral infection.

Genital HPV infection and herpes simplex are discussed later in the section on sexually transmitted infections (see p. 68.70).

The most common poxvirus is mollusum contagiosum virus, two types of which have been identified. There is no relationship between virus type and anatomical distribution of lesions [1]. Vulval lesions in childhood are common and usually acquired innocently, but they are more likely to be acquired sexually in adults. Lesions are often found on the mons pubis and labia majora, and if inflamed they may mimic folliculitis. The clinical diagnosis is straightforward when there are multiple pearly lesions with an umbilicated centre, but solitary large lesions can cause diagnostic problems. It is the solitary giant lesion that may miss immediate diagnosis until it is biopsied. Lesions of molluscum contagiosum can be profuse and large in immunosuppressed women, especially in those with AIDS. The condition is more fully described in Chapter 26.

Other poxvirus infections of the vulva are rare, but there are isolated reports of orf [2] and cowpox [3].

Herpes simplex (see below).

Varicella-zoster virus. This may also affect the vulva if the third sacral dermatome is involved. It may be accompanied by bowel and bladder dysfunction [4].

Epstein–Barr virus. This has been found rarely in genital ulcers at the time of infectious mononucleosis [5–7]. EBV may also be shed from the cervix [8] but there is no link with vulval malignancy [9].

Cytomegalovirus (CMV). CMV inclusions were seen in a biopsy and a positive culture for CMV was obtained in an infant with congenital HIV disease who presented with pustular and ulcerative lesions on the perineum [10].

Malakoplakia of the vulva [1–4]

Malakoplakia (meaning 'soft plaque') is a granulomatous response to infection. It is not usually caused by one specific agent but the organisms involved include *Escherichia coli*, *Pseudomonas* and *Staphylococcus aureus*. Malakoplakia most often affects the urinary or gastrointestinal tract but cutaneous lesions may occur on the vagina, vulva and perineum. Involvement of Bartholin's gland has been described [5]. The lesions include persistent plaques, ulcers, nodules and sinuses. There is often underlying immunosuppression, the aetiology of which may include malignancy, dermatomyositis [6], lupus erythematosus, rheumatoid arthritis and organ transplantation [7].

Histopathology. There are confluent sheets of histiocytes with eosinophilic granular cytoplasm and small eccentric nuclei. Round, sometimes laminated structures are found with these cells and are known as Michaelis–Gutmann bodies. The histiocytic infiltrate may be mixed with neutrophils, lymphocytes and plasma cells, with associated granulation tissue. Electron microscopy of malakoplakia shows that the histiocytes contain numerous

phagolysosomes within which there may be occasional intact and partly digested bacteria.

Sexually transmitted disease

A brief outline of the main sexually transmitted diseases that can affect the vulval skin is given below. Fuller descriptions of the individual diseases are given elsewhere (see Chapters 25–27 and 30).

Herpes simplex virus

Once this sexually transmitted DNA virus is acquired it lies dormant in dorsal root ganglia and can give rise to recurrent symptomatic lesions. It exists in two types: I and II. Type I usually affects non-genital sites and type II is responsible for 50–80% of genital infections. Ninety-five per cent of infections are acquired sexually and the rest are cases of autoinoculation or non-sexual contact. The lesions are typically painful vesicles or ulcers, which are often multiple in primary infection but are fewer and usually localized to one side with recurrences. There may be prodromal symptoms of tingling or tender enlarged inguinal nodes. Paraesthesiae may occur, affecting S2–4, which may lead to urinary retention. Pain and oedema may also lead to retention, particularly in primary infections. It is important to obtain a definite diagnosis with a positive culture of HSV and it is necessary to perform the test as soon as the blisters arise, as the virus is harder to culture from older lesions. However, a negative test does not exclude an infection with HSV.

The treatment is either oral aciclovir 200 mg five times daily for 5 days, valaciclovir 500 mg twice daily for 5 days or famciclovir 250 mg three times daily for 5 days.

Suppressant therapy is sometimes required for patients with frequent recurrences (six or more in a year).

Human papillomavirus infection

HPV is a small DNA virus, and is discussed in more detail in Chapter 25. Those that most commonly infect the vulval skin are HPV 6, 11, 16 and 18. The warty lesions are known as condylomata acuminata. Extensive vegetating masses can cover the vulva and perianal area, particularly in diabetes, pregnancy and immunocompromised patients. Patients with genital warts should be screened for other sexually transmitted diseases. Secondary syphilis may also present with extensive papulosquamous lesions and has to be considered in the differential diagnosis.

Types 16 and 18 are linked with cervical and anogenital intraepithelial neoplasia and SCC.

The histology of genital warts is characterized by the koilocyte, a vacuolated squamous cell with a basophilic and pyknotic nucleus in the upper part of the epidermis; it is important not to confuse it with the heavily glycogenated clear cells of vestibular epithelium. Other histological features are elongated dermal papillae, acanthosis, a prominent granular layer often containing koilocytes, and a stratum corneum of variable thickness.

Treatment. Podophyllotoxin is the recommended initial treatment. It is applied twice daily for 3 consecutive days each week for 4 weeks. This treatment is contraindicated in pregnancy because of the theoretical risk of teratogenicity. Diathermy, hyfrecation, topical trichloroacetic acid, cryotherapy and carbon dioxide laser have been used with variable success. These treatments are successful in patients where the lesions are few or filiform in morphology.

The new immune response modulating cream, imiquimod, is now used for resistant cases or patients with extensive lesions. This has to be used with care as it also induces an inflammatory response in patients who have a background dermatitis. It should not be used in patients who have benign vulval aphthous ulcers.

In pregnancy, only cryotherapy or destructive techniques with cautery or hyfrecation can be used safely.

Gonorrhoea

The urethra, cervix and rectum may be infected by *Neisseria gonorrhoea* and spread occurs to the endometrium and fallopian tubes. Vulval involvement is rare in adults, and infection is sited in the paraurethral and Bartholin's glands, resulting in painful abscess formation. In children, the infection is usually a result of sexual abuse, and an acute vulvitis may develop [1].

Syphilis

The causative organism is *Treponema pallidum* and vulval lesions may occur in both early and late syphilis. The primary chancre is an ulcerative lesion and is usually accompanied by unilateral or bilateral lymphadenopathy. In secondary syphilis, condylomata lata, flat-topped warty papules, affect the vulva, as may also mucous patches,

which are greyish white moist-looking lesions. Gummas, which are a manifestation of tertiary syphilis, are extremely rare on the vulva, and clinically they occur as either single or multiple swellings or nodules.

Bullous, papular, papulosquamous lesions and mucous patches occur on the vulva in early congenital syphilis and condylomata lata may develop later.

The diagnosis of syphilis is made by dark ground microscopy, immunofluorescence of scrapings or serology.

Histologically, the findings are very variable but, typically, early lesions show inflammation with perivascular plasma cells and lymphocytes together with an endarteritis. There is marked epithelial hyperplasia in lesions of condylomata lata, with a prominent perivascular lymphocytic and plasma cell infiltrate.

Chancroid [2]

This sexually transmitted disease, caused by *Haemophilus ducreyi*, is rare in the UK [2] as it is normally found in tropical and semitropical countries, although the incidence is falling in Africa [3]. Single or multiple small tender ulcers appear on the labia majora, perineum and perianal area, and may also affect the vagina and cervix. The inguinal lymph glands are involved in half of cases and the adenitis is unilateral in most. Buboes develop, which are fluctuant, and rupture leaving extensive ulceration. Co-infections with *Treponema pallidum* or HSV are frequent [4].

Diagnosis may be confirmed by culture of scrapings from the ulcer base or aspirated pus. Microscopy of scrapings or pus will show Gram-negative coccobacilli. PCR may also be used. The histological features include epithelial hyperplasia adjacent to the ulceration, with three relatively distinct zones at the base of the ulcer. The superficial zone consists of a thin band of neutrophils, fibrin and necrotic debris; the middle zone of oedema with thin-walled, dilated and vertically orientated blood vessels; and the deep zone of a dense perivascular infiltrate of lymphocytes and plasma cells. A Giemsa or Brown–Brenn stain may reveal organisms in the superficial zone staining blue or red, respectively.

Treatment. Azithromycin, ceftriaxone, ciprofloxacin or erythromycin can be used. The recent guidelines issued by the Communicable Disease Centre (CDC) should be consulted (http://www.cdc.gov/std). Special considerations should be given to patients with HIV infection.

Donovanosis [5]

SYN. GRANULOMA VENEREUM; GRANULOMA INGUINALE

The causative organism is *Calymmatobacterium granulomatis*, formerly known as *Donovania granulomatis*. The disease is sexually transmitted and found in New Guinea, India, South Africa and Brazil. Papules or nodules break down to form ulcers with a rolled edge. Large areas are involved, and granulomatous masses may involve any part of the genitocrural area, although the lymph nodes themselves are not affected. The vagina and cervix may be involved. Scarring and lymphoedema may ensue.

Histopathology shows epithelial hyperplasia adjacent to the ulcer, sometimes with spongiosis and intraepithelial neutrophilic abscesses, and a dense dermal or submucosal infiltrate with neutrophilic abscesses surrounded by plasma cells, histiocytes and lymphocytes. The organisms occasionally are visible with silver stains, which show intracytoplasmic inclusions (Donovan bodies), seen as black oval or rod-shaped structures in the cytoplasm of histiocytes. The organisms are more reliably demonstrated on smear preparations than tissue sections.

Chlamydia **(lymphogranuloma venereum)**

Chlamydia trachomatis is a Gram-negative intracellular bacterium that is an obligatory parasite. The serovars L1–3 cause lymphogranuloma venereum, which occurs in tropical and subtropical countries. The incubation period varies from a few days to a few weeks. A small papule develops on the vulva, usually at the fourchette, heals quickly and is followed weeks later by striking lymphadenopathy. The nodes may form a suppurative mass that heals with scarring, leading to lymphoedema, which may be gross. Generalized chronic infection leads to abscess and fistula formation, and finally genital and anal strictures and elephantiasis.

Rectal lesions present as a proctocolitis with subsequent stricture formation.

The histology of the vulval ulcers is non-specific, but the affected nodes show epithelioid cells and giant cells, and later stellate abscesses develop that are surrounded by epithelioid cells, granulomatous tissue and plasma cells. Fibrosis and necrosis are seen in chronic lesions.

Benign tumours and tumour-like lesions of the vulva [1,2]

Most of the tumours that arise on the anogenital skin are similar to those that occur on the skin elsewhere. Fibromas arise from deeper connective tissue structures, particularly

those surrounding the introitus and perineal body. They usually occur on the labia majora, are often pedunculated or pendulous, and can attain a very large size. Fibroepitheliomatous polyps (skin tags) are usually solitary and appear as soft wrinkled polypoidal nodules. There is a fibrovascular connective tissue core covered by squamous epithelium, which may be atrophic or, more commonly, mildly acanthotic and hyperkeratotic. Cellular atypia is occasionally seen in the stromal cells. Lipomas develop from the fatty tissue of the labia majora, but there have been reports of localization to the clitoris [3], as has also been reported with haemangiomas [3,4,].

Two types of lymphangioma may occur on the vulva: lymphangioma circumscriptum, which are localized thin-walled vesicles [5], and cavernous lymphangioma, which arise in childhood and present as a soft compressible mass, which, although usually located in the labia minora, can involve the whole of the vulva [6]. Acquired lymphangiectasia is discussed on p. 68.81.

Melanocytic naevi include junctional, intradermal and compound types, which generally share the same clinical and histological features as naevi at other sites of the body, with the exception that in premenopausal women vulval naevi sometimes have atypical histological features [7]. The atypia may extend into the adnexal structures, but the overall symmetry of the lesion, with cellular maturation in the deeper dermis, should help to distinguish it from a truly malignant lesion. Sometimes, differentiation from melanoma can be difficult and evaluation by an experienced dermatopathologist may be necessary.

Epidermal cysts of the vulva may develop from epithelial implants following surgical trauma, from epidermal inclusions occurring at fusion sites during embryogenesis, or from obstructed sebaceous gland ducts that have undergone squamous metaplasia. They may be single or multiple, and occur most commonly in the labia majora. Steatocystoma may present as a solitary cyst in the vulval region [8]. Calcified nodules have been recorded [9].

Syringomas

These are considered to be adenomas of the intraepidermal eccrine sweat gland ducts. They do not require treatment as they are usually asymptomatic, although there may be pruritus [10]. Vulval syringomas are multiple, bilateral and symmetrical, although a solitary lesion may occur. One case was reported that had the typical histological features of a syringoma mixed with pilosebaceous elements [11].

Papillary hidradenoma

This sweat gland adenoma with apocrine differentiation occurs almost exclusively in the anogenital region of middle-aged white women. It has been associated with anogenital glands [12]. It is a firm asymptomatic papule or nodule, which can occasionally be painful, and occurs most commonly on the labia majora, interlabial sulcus, lateral surfaces of the labia minora or perineal region [13]. Although usually single, there are occasionally multiple lesions. Curiously, when they are multiple all the lesions tend to develop on one side of the vulva. In most patients, the covering epidermis remains intact, but in a proportion the elevated epithelium may become ulcerated [14].

Malignant change within a papillary hidradenoma has been reported: apocrine carcinoma [15] and adenosquamous carcinoma [16].

Fox–Fordyce disease

In this condition, described in detail in Chapter 45, the apocrine ducts become blocked, with retention of sweat. Itchy skin-coloured papules appear on the mons pubis, labia majora, axillae and on the breast. They develop around the time of puberty and there are menstrual exacerbations. There is some improvement in pregnancy and after the menopause.

Mucinous cysts

Mucinous cysts of the vulva are not uncommon. They are usually found in the vestibule where they develop secondary to obstruction of the duct of one of the many minor vestibular mucus-secreting glands. The cysts are of urogenital sinus origin and not, as was once thought, of Müllerian origin [1,2].

Bartholin's duct tumours

These are very rare and there is debate as to whether they are true neoplasms or better regarded as examples of hyperplasia or hamartoma [1,2].

Neurofibroma and neurofibromatosis

Vulval neurofibromas may occur either as solitary lesions with no other features of neurofibromatosis, or as part of generalized neurofibromatosis. In one series, 18% had vulval lesions [1]. Vulval neurofibromas have also been described as one component of a localized neurofibromatosis of the female genitourinary tract [2,3]. Some cases have led to confusion by mimicking an intersex problem [4–7].

Glomus tumour

There are rare reports of this tumour on the labia minora giving rise to dyspareunia [1,2].

Leiomyoma

Vulval leiomyomas are uncommon [1,2], and there is no association with uterine leiomyomas. It is unclear whether these tumours originate from the smooth muscle of the vulval erectile tissue, from the muscular elements of the round ligament, or from the myoepithelial cells of Bartholin's gland.

Vulval leiomyomas occur during the reproductive years and usually present as well-circumscribed painless non-tender nodules or swellings in the labia. Lesions may enlarge in pregnancy. A clitoral leiomyoma can cause a mistaken diagnosis of an intersex disorder. A clitoral leiomyoma associated with a leiomyoma of the oesophagus has been reported [3].

Rarer tumours include granular cell myoblastoma [1,2], which present as flesh-coloured, occasionally pedunculated or ulcerated lesions. Verruciform xanthomas have a predilection for the oral mucosa and the genital skin. They are rare on the vulva [3,4]. Clinically, they present as solitary plaques or warty lesions and vary in colour from yellow to grey or pink. There is acanthosis, papillomatosis and parakeratosis, and the presence of foamy macrophages in the papillary dermis and tips of the elongated rete ridges distinguishes this entity from a viral wart. Nodular fasciitis presents as a painless mass and has rarely been reported on the vulva [5].

Urethral caruncle and urethral prolapse, which are common, can sometimes be mistaken for neoplasms. A urethral caruncle occurs in postmenopausal women as a red fleshy lesion around the urethral meatus and is a chronically inflamed eversion of the urethral mucosa. It may measure from a few millimetres to a few centimetres in diameter and is usually asymptomatic; it may cause dysuria or bleeding if ulcerated. Histologically, it is essentially the same as a pyogenic granuloma, showing a highly vascular connective tissue with a heavy inflammatory infiltrate of lymphocytes and plasma cells. Enmeshed in

this inflamed stroma are varying quantities of glandular structures or solid islands of urethral epithelium.

Prolapse of the urethra may occur at any age. Histologically, there is marked oedema of the underlying connective tissue, and the overlying urethral mucosa may be focally ulcerated. The underlying stroma shows marked vascular distension and engorgement, often with thrombosis. The epithelial inclusions typically seen in a urethral caruncle are not present.

Precancerous dermatoses

Vulval intraepithelial neoplasia

This term was introduced by the International Society for the Study of Vulvovaginal Diseases (ISSVD) to replace the previous terms dystrophy with atypia, Bowen's disease, bowenoid papulosis, erythroplasia of Queyrat and squamous carcinoma *in situ* [1–3]. It is defined as loss of the normal orientation and architecture of the epithelium with cellular atypia. It was also graded into VIN1–3, according to the percentage of the epithelium involved. This classification also included EMPD and melanoma *in situ*. There are now proposals to change this classification, reserving the term VIN exclusively for squamous cell dysplasia that has a risk of malignant transformation. This would not include Paget's disease or melanoma *in situ*. The newer terminology for VIN also recommends abolishing the current grading system. The three tier grading of VIN is often misleading [4,5], as many cases of VIN1 with basal atypia are not truly premalignant but reparative (e.g. LP). The important VIN with malignant potential is that with atypia involving two-thirds to full thickness of the epithelium (undifferentiated VIN [VIN2 and VIN3]), or severe atypia confined to the basal layers with fairly normal differentiation of the upper layers (differentiated VIN). The rete ridges may be long and forked, with keratin pearls. This change on a background of LS/LP represents either very early invasive disease or heralds its imminent onset.

Undifferentiated vulval intraepithelial neoplasia

SYN. BOWEN'S DISEASE; BOWENOID PAPULOSIS; CARCINOMA IN SITU; CARCINOMA SIMPLEX

There is a complete loss of cellular stratification throughout the epidermis, with large hyperchromatic cells, dyskeratosis, multinucleated cells and numerous typical and atypical mitoses. Originally, two distinct histological types of VIN were described: bowenoid, characterized by individual cell keratinization and abnormal cellular differentiation; and basaloid, with atypical parabasal cells extending throughout the full thickness of the epithelium. However, both types can sometimes be found in the same histological section so it is no longer considered helpful to distinguish the two.

Multifocal anogenital disease is strongly associated with the oncogenic papillomaviruses, particularly HPV 16 and 18, and almost exclusively occurs in smokers [6,7]. The condition is caused by a failure of the host to mount an immune response to the HPV. Patients who are immunocompromised have a higher incidence of this problem, but the majority of young women with this problem do not have an identifiable immunodeficiency. In addition to being multifocal, VIN may be associated with multicentric disease, with lesions of intraepithelial neoplasia involving the cervix, vagina and perianal skin. Up to two-thirds of patients with VIN have a current or past history of CIN [8].

Clinically, the lesions of intraepithelial neoplasia can be solitary or multiple. The morphology of the lesions is also very diverse, with lesions that resemble viral warts, plaques that may be shiny and smooth, skin-coloured, red or white, or others that are warty and pigmented and resemble seborrhoeic keratoses [9,10]. Less commonly, the lesions may be large and papillomatous, particularly perianally, where they may be polypoid. The main symptom is pruritus, which can be severe and troublesome (Figs 68.33–68.35).

Vaginal involvement is uncommon. Initially, it was felt that BP could be distinguished histologically from Bowen's disease but time has proved this not to be the case.

The risk of progression to invasive disease is estimated as 10% or less in multifocal disease, but this risk is higher in immunocompromised patients, particularly with perianal disease [11] and in the older woman with a solitary plaque [12].

There also have been reports of vulval cancer in patients with Fanconi's anaemia [13,14].

Treatment. This is tailored to the individual patient's needs. In the case of a solitary lesion that is amenable to simple excision, this is the treatment of choice. In the woman with extensive disease, surgery would be mutilating physically and distressing psychologically, and does not guarantee a cure as the risk of recurrence is significant

Fig. 68.33 Vulval intraepithelial neoplasia. Erythematous patches with one warty plaque inferiorly on the inner aspect of the right labium minus.

[15,16]. Such patients require regular and long-term follow-up, with biopsies of suspicious areas. Thick or polypoid lesions should be excised, as early invasive changes are difficult to detect in these areas [17]. Cryotherapy is not effective, but 5-fluorouracil can be used successfully for lesions of the labia minora, vestibule and clitoral area [16]. It is not effective on the hair-bearing parts of the vulva, probably because of the deep adnexal structures, which can all be involved. Laser vaporization has a high recurrence rate, particularly if the hair-bearing parts of the vulva are involved, and there is the additional danger that early invasive disease may be missed and therefore inappropriately treated. It is also extremely painful postoperatively.

As VIN is a multicentric problem, the other sites that need to be monitored are the cervix, vagina and perianal area. If there is perianal disease, anoscopy should be performed to exclude involvement of the anal canal.

Vulval malignancy [1]

The most common malignancy by far is SCC, followed by basal cell carcinoma, adenocarcinoma, melanoma and verrucous carcinoma.

Squamous cell carcinoma

Aetiologically, there appear to be two types of vulval squamous cell carcinoma [2–5]. The first and largest group occurs in elderly women on a background of a chronic dermatosis such as LS or LP. The second type, which accounts for approximately 40% of cases, occurs in younger women and is associated with intraepithelial neoplasia associated with oncogenic-type HPV infection. A link with HPV has not yet been established with the first group [6].

In the 1990s, the staging of vulval cancer was replaced by a combined clinical and surgical staging [7]. One of the reasons for this change was to remove the term microinvasive carcinoma of the vulva, as at that time its definition was misleading. In this new classification, stage I tumours are less than 2 cm diameter and are further subdivided into Ia and Ib. Ia are lesions with less than 1 mm depth of invasion. There are some difficulties as to how this measurement should be made. The most recent recommendation is to measure from the dermal–epidermal junction of the nearest dermal papilla to the deepest point of invasion [8]. Lymph node dissection is mandatory for all lesions greater than 1 mm but can be avoided in those with stage Ia. There are three histological types of SCC: keratinizing, basaloid and warty carcinomas.

Keratinizing tumours are those seen in the older women, which are not HPV-related, and the basaloid and warty tumours are those found in younger women with HPV-related VIN.

There is also an adenoid variant of SCC with acantholysis in the centres of some of the infiltrating nests, producing cystic spaces lined by cubocolumnar nests. These pseudocysts do not contain mucin, which differentiates them from adenosquamous cell carcinoma.

Treatment. Surgical excision is tailored to the individual, and is determined by the size and site of the tumour.

The overall 5-year survival is approximately 75%, which rises to 90% or greater in those with no nodal metastases. The main reason for failure of treatment is the inability to control lymphatic and distant metastases, lymphatic spread being the most important factor. The vulval lymphatics drain to the inguinal and femoral nodes and from there to the pelvic nodes. Central lesions (those placed near the clitoris, urethra, vagina, fourchette and perianal area) have a bilateral lymphatic drainage, and it is important in these cases that the inguinofemoral nodes on both sides are excised. Radiotherapy is used as an adjuvant in patients with positive nodes and in those with inoperable tumours. It is also sometimes used as a primary treatment in tumours of the anus and urethra, to reduce their size before surgery and to try to preserve sphincter function.

Verrucous carcinoma

SYN. GIANT CONDYLOMA OF BUSCHKE–LÖWENSTEIN

This tumour occurs in older women, and many arise on a background of LS [1]. There is also a strong relationship to vulval condylomas. Clinically, the lesions appear as a warty plaque or cauliflower-like tumour, which can ulcerate and become extremely large (Fig. 68.36).

Fig. 68.36 Verrucous carcinoma on a background of lichen sclerosus.

The histological changes include epidermal acanthosis, with large bulbous rete ridges which compress and push down the underlying stroma. There is very little cellular atypia and the few, if any, mitoses are confined to the basal layers. Koilocytes are usually present. Lymph node and distant metastases occur rarely.

Treatment is wide local excision. Radiotherapy is not used as it is associated with a worse prognosis, probably because it can induce anaplastic transformation [2]. Oral retinoids may also be helpful [3].

3 Mehta RK, Rytina E, Sterling JC. Treatment of verrucous carcinoma of vulva with acetretin. *Br J Dermatol* 2000; **142**: 1195–8.

Basal cell carcinoma

Vulval basal cell carcomas are not uncommon and present as an eroded plaque, which may be pigmented. Less commonly, the tumour may form a nodule or ulcer. They occur most frequently on the labia majora (Fig. 68.37) [1].

Fig. 68.37 Basal cell carcinoma: lower left labium majus.

Histologically, the appearances are identical to BCCs seen elsewhere. Inadequate excision accounts for a high recurrence rate and metastases to regional lymph nodes [2]. Mohs' surgery is often recommended to ensure adequate local excision [3,4].

Adenocarcinoma

Primary adenocarcinoma unrelated to underlying glandular adnexae is exceedingly rare. The lesion usually presents as a painless subcutaneous nodule which, as it expands, becomes fixed and painful. The tumour can invade deeply into fat, muscle or bone and may be associated with a Bartholin's gland abscess. Adenocarcinoma may be associated with EMPD.

Many of the mucinous carcinomas that arise are possibly of cloacal origin [1].

There is one report of a mucinous carcinoma with neuroendocrine differentiation [2].

Melanoma

Vulval melanomas account for approximately 5% of vulval malignancy. Any of the variants of melanoma may occur on the vulva, and the clinical and histological features are the same as for melanomas elsewhere (Fig. 68.38). However, in one cohort of 219 patients, 27% of lesions were amelanotic [1,2]. Melanomas at this site carry the same prognosis according to the Clarke level of invasion, the Breslow thickness and the presence or absence of a vertical growth phase. They may be mistakenly diagnosed as EMPD.

Vulval extramammary Paget's disease

EMPD is fully discussed in Chapter 36. EMPD is a rare dermatosis, and is distinct from Paget's disease of the nipple, which is always associated with underlying breast neoplasia. The vulva is the most common site for EMPD, which is subdivided into primary and secondary disease. Primary, or cutaneous EMPD, is an intraepithelial adenocarcinoma arising in the epidermis or the epithelia of the local skin appendages. Secondary EMPD is epidermal involvement from a non-cutaneous internal neoplasm, either by direct extension or metastasis. The two most common tumours associated with secondary vulval EMPD are anorectal adenocarcinoma and urothelial carcinoma of the bladder or urethra. Other associated tumours reported include cervix, endometrium and ovary [1,2].

The differentiation between primary and secondary disease is not always straightforward clinically and sometimes relies on immunohistological investigations [3,4].

Additional changes to the vulval EMPD classification have been proposed, based on aetiology [5]. The primary and secondary categories are retained, but each is divided into three types. The primary intraepithelial disease, primary with invasion, and EMPD as a manifestation of an underlying primary adenocarcinoma of a vulval skin appendage or subcutaneous vulval gland. The secondary category has three groups according to the tumour from which it arises: EMPD secondary to anorectal adenocarcinoma, EMPD secondary to urothelial carcinoma and EMPD secondary to an adenocarcinoma or related tumour at other sites.

It is important to distinguish primary from secondary EMPD as management depends on the correct diagnosis.

Clinical features. Clinically, the lesion is typically a moist red oozing plaque, which looks like impetiginized eczema or psoriasis. The associated symptoms include pruritus and burning (Fig. 68.39).

Histopathology. There is frequently epidermal hyperplasia. The epidermis is infiltrated with pale-staining Paget's cells. The Paget's cells are PAS-positive and diastase-resistant, and stain with Alcian blue and markers for the simple keratins. In the lower epidermis, the tumour cells may compress the basal cells.

Treatment. In primary EMPD, excision of visible disease is often recommended for treatment and to exclude underlying appendageal adenocarcinoma. Sometimes in the very elderly, with extensive disease or recurrence after vulvectomy, this is not always an option that the patient wishes to accept. Patients should be regularly monitored, and topical steroids can be used if there is troublesome pruritus. Topical 5-fluorouracil, bleomycin and imiquimod have been used, as well as oral retinoids, with some

Fig. 68.39 Extramammary Paget's disease.

success. The recurrence rates are high after carbon dioxide laser and radiotherapy.

In secondary disease, the treatment is directed predominantly at the associated carcinoma.

Other malignancies

Langerhans' cell histiocytosis

The anogenital skin may be one of the sites involved in disseminated Langerhans' cell histiocytosis (LCH), but lesions may occur at this site only. Perianal ulceration is the most common presentation in adults and children [1,2], and genital involvement is more common in women [3,4]. The lesions may be plaques, nodules, erosions, ulcers or pustules. The Letterer–Siwe form consists of a seborrhoeic dermatitis-like eruption on the intertriginous zones and scalp. Some of the lesions may be purpuric.

Lymphomas

Non-Hodgkin's lymphoma of the vulva is more frequently reported [1,2] than Hodgkin's lymphoma [3]. Non-Hodgkin's lymphoma has also been reported post-transplantation [4] and in association with HIV infection [5].

Miscellaneous tumours

There are a few reports of vulval dermatofibrosarcoma protuberans on the labia majora [1], slow-growing liposarcoma [2], epithelioid sarcoma [3], Merkel cell carcinoma [4] and Bartholin's gland carcinoma [5].

Miscellaneous

Pigmentary disorders

Hypopigmentation

As at other sites, this can be naevoid, a post-inflammatory problem or vitiligo.

Hyperpigmentation

The increased pigmentation may be caused by haemosiderin, which results in a reddish brown discoloration. It is the result of extravasation of red blood cells and is seen in capillaritis, urethral caruncle, lichen sclerosus, Zoon's vulvitis and chronic vulval purpura. However, increased pigmentation is more commonly related to melanin. There is considerable variation in the distribution and amount of melanocytes and melanin in the normal vulva, depending on site, age, ethnicity and hormonal status.

Post-inflammatory pigmentation may follow any inflammatory dermatosis, particularly if there has been a disruption of the dermal–epidermal junction and in darker skins. It is a common sequela of LP and sometimes LS.

Vulval melanosis. Intense macular hyperpigmentation of vulval skin can be difficult to categorize, and a biopsy is essential for an accurate diagnosis and to exclude malignant melanoma (Fig. 68.40a) [1]. If the lesions are widespread and accompanied by oral pigmentation, they may be considered as examples of Laugier–Hunziker syndrome [2,3]. The term vulval melanosis is used for those cases where there is extensive macular pigmentation affecting the vulval skin, with the histological changes of basal hypermelanosis and a slight increase in the number of melanocytes. There may also be some pigmentary incontinence, but there is no abnormal junctional melanocytic proliferation (Fig. 68.40b) [4–8]. There have been other suggested terms: idiopathic lenticular mucocutaneous pigmentation [9] and genital lentiginosis, particularly if there is melanocytic hyperplasia [10].

The accepted view is that vulval melanosis is a benign condition, but there are no long-term follow-up studies reported. Therefore, most clinicians advise continuing observation, using photographs or diagrams as an aid.

Lentigines. Vulval lentigines may be sporadic or part of a syndrome (e.g. LAMB syndrome) [11,12]. There is an increase in the number of basal melanocytes, with increased melanin in the epidermis and stratum corneum. Pigment-laden macrophages are found in the papillary dermis, and the rete ridges are elongated.

Acanthosis nigricans. This condition is usually associated with insulin resistance and rarely with malignancy. Initially, the appearance is of a dark and velvety thickening of

(a)

(b)

Fig. 68.40 (a) *In situ* melanoma. (b) Vulval melanosis.

the skin in the genitocrual folds and upper inner thighs, which later becomes warty. Skin tags may also occur.

A fixed drug eruption leaves behind residual hyperpigmentation. Some laxatives are reduced in the bowel to dithranol and this may stain the skin in contact with faeces and lead to a reddish brown discoloration of the urine and vaginal secretions [13,14]. Trichomycosis and chromidrosis may cause some discoloration.

Necrolytic migratory erythema

This rare dermatosis occurs on the genital skin and lower abdomen and is almost always associated with an underlying pancreatic glucagonoma, although there are exceptional cases where it is not [1].

REFERENCE

Vulval oedema, lymphoedema and lymphangiectasia

Oedema, hereditary angio-oedema [1] and dermographism [2] may all involve the vulva. Vulval oedema may be the only manifestation of Crohn's disease [3].

Lymphoedema occurs when there is impairment of the lymph drainage and it is a frequent complication following surgery and lymphadenectomy for vulval carcinoma. Lymphangiectasia is acquired dilatation of the skin lymphatics secondary to obstruction of the lymphatic vessels. It is most frequently reported following treatment of cervical carcinoma with surgery and/or radiotherapy [4–6]. Lymphangiectasia may be very profuse in Crohn's disease and carbon dioxide laser treatment can be used in patients with troublesome lymphorrhoea [7]. Repeated episodes of cellulitis may also result in lymphangiectasia, but there may be an underlying abnormality of the lymphatics that predisposed the patient to the cellulitis initially. Lymphangiectasia may be mistaken clinically for viral warts [8].

Endometriosis

Endometriosis occasionally occurs on the vulva or in the vagina as a direct implantation. The condition may follow a previous surgical procedure [9,10], and in episiotomy scars after delivery [11,12]. It presents as firm bluish nodules, which become tender or bleed during menstruation. Clear cell adenocarcinoma has arisen in vulval endometriosis [13].

Genital papular acantholytic dyskeratosis

This was first described in 1984 [14], and is characterized by the presence of multiple papules or, less frequently, a single papule or plaque-like lesions on genital skin [15–18]. Cases with disseminated lesions have been described [19]. The histological changes are similar to those seen in Darier's disease or Hailey–Hailey disease, but there is no positive family history or evidence of these diseases at other sites. It is considered a distinct entity, although it may represent a forme fruste of Hailey–Hailey or Darier's disease.

Vulval pain syndromes

Vulvodynia

The term vulvodynia was first introduced in 1983 by the ISSVD to categorize those patients who complained of a chronic sensation of burning or rawness of the vulval skin [1]. Initially, vulvodynia included several subcategories [2], but these proved unsatisfactory in the light of further experience [3].

A diagnosis of vulvodynia should be strictly reserved for those patients who have the symptoms of pain or discomfort for 3 months or more in the absence of any visible abnormality or explanation that would account for their symptoms. If any active dermatosis or dermographism is found that could account for the symptoms then that condition is the diagnosis rather than vulvodynia.

Advances in the last decade have improved our knowledge and understanding of pain in general, and the existence of complex regional pain syndromes is now well recognized. Chronic pain syndromes are rarely caused by primary psychiatric disorders as originally thought, but are the result of peripheral and/or central neuronal sensitization.

In the 1990s it was felt that vulvodynia fulfilled many of the criteria of a complex regional pain syndrome. In clinical practice there appeared to be two major types of vulvodynia: vestibulitis and dysaesthetic vulvodynia. The main differentiation between the two was that vestibulitis was characterized by pain localized to the vulval vestibule that was precipitated by touch alone, whereas dysaesthetic vulvodynia was diffuse vulval pain that occurred spontaneously and which might or might not be aggravated by touch. The term vestibulitis was unfortunate and misleading as it suggested an inflammatory condition.

The 1999 meeting of the ISSVD recognized that there was a need for further changes in the nomenclature to fit in with the classification used for chronic pain syndromes elsewhere. It was suggested that the term dysaesthetic vulvodynia be retained for vulval pain that was diffuse, constant and spontaneous. Localized pain triggered by touch alone, previously termed vestibulitis, would be referred to by the newer and more accurate term vestibulodynia. It was also proposed that in those cases where the pain is localized at another site that this should be specified (e.g. clitorodynia if the pain is localized to the clitoris). There will probably be further terminology as our knowledge about these chronic pain syndromes increases.

Vestibulodynia

SYN. VESTIBULITIS

The term vulval vestibulitis was first defined as a triad of clinical signs and symptoms that included dyspareunia, vestibular tenderness to light touch and erythema of the vestibular epithelium [4]. This syndrome was certainly recognized earlier and terms such as focal vulvitis, hyperaesthesia of the vulva and vestibular adenitis had been used to describe the condition. It is usually a disorder of younger women, who present with the complaint of secondary dyspareunia. Most patients give a history of a precipitating event and some recall that it started during a particularly stressful time. Vestibulitis it is not an inflammatory condition [5], and for this reason alone vestibulodynia is a better term. There is no evidence to support an association with chronic infection with either *Candida* or HPV. The aetiology remains unknown and it is currently best categorized as a chronic pain syndrome [6]. The majority of patients affected by vestibulodynia are psychologically normal but they do have higher anxiety and somatization scores [7,8]. Patients also seem more susceptible to irritants, not only on the vulval skin but also at other sites (e.g. hand dermatitis, poor tolerance to earrings if made of base metals). However, patch testing is usually negative [9]. It is important to assess if the patient is dermographic, as dermographism may mimic or exacerbate vulvodynia. Sometimes it is helpful to perform an examination after recent intercourse as nymphohymenal tears, fourchette fissuring and herpes simplex infection can all be overlooked as the cause of recurrent vulval pain precipitated or exacerbated by intercourse.

Dysaesthetic vulvodynia

Dysaesthetic vulvodynia is most frequently seen in older, postmenopausal women who are often not sexually active and there is usually no precipitating event. The pain is spontaneous and often occurs independently of touch. Many of these patients are depressed, but it is difficult to establish whether this is a primary phenomenon or secondary to chronic pain. Much of the literature on the psychological profiles of patients with vulvodynia is difficult to interpret, as very often the distinction between vestibulitis and dysaesthetic vulvodynia is unclear. Dysaesthetic vulvodynia is a frequent problem following inflammatory conditions of the vulva, particularly the vestibule. It is seen most frequently following LP, when the patient still has symptoms despite the fact that the

dermatitis has responded to treatment. The use of 5% lidocaine ointment usually resolves this problem.

Some of the younger patients who develop dysaesthetic vulvodynia initially had vestibulodynia.

Treatment. Management requires an unrushed and sympathetic consultation, with time spent explaining the problem of pain syndromes and the rationale for the planned treatment. Initially, topical agents are used, which include a soap substitute, avoidance of irritants and regular application of the local anaesthetic 5% lidocaine ointment. The other topical 'caine' anaesthetics should be avoided because of the risk of contact sensitivity, which is rare with lidocaine. If the patient is dermographic, an oral antihistamine should be added. If the topical measures are of no benefit or only partially effective, a tricyclic antidepressant may be used for its central action on pain. Alternative medications include gabapentin and carbamazepine. If there are secondary psychological or sexual issues, the input from a specialist in this field will be important. Biofeedback may improve some patients, particularly if there is associated vaginismus [10]. The patients may also wish to join a self-support group; in the UK this is the Vulval Pain Society.

Perineal and perianal dermatology

Introduction

Dermatologists should be able to assess the area competently and know when to involve colleagues in other disciplines. The perineum involves the perianal skin, groins and scrotum or vulva.

Pruritus ani is a symptom, not a diagnosis, unless qualified as constitutional or idiopathic, and, in roughly half of patients with pruritus ani, a cause will be established after dermatological evaluation [1–6]. The topic is discussed at length below (see p. 68.85).

Inflammatory and infectious disorders of the area may be difficult to differentiate. The presence of an infective condition in this area may overlie and disguise a more important lesion of the colon or rectum [7].

The differential diagnosis of anogenital ulceration is addressed on p. 68.3 and in Tables 68.9 and 68.10. Many banal conditions take on a vegetating appearance in this area, especially in hot humid climates and in the presence of infection. For these, the term dermatitis vegetans can be used.

Elephantiasis forms of progressive tuberculosis [8] and syphilis are now seldom seen, but deep fungal infections must not be overlooked.

Anal and perianal symptoms and signs in homosexual males [9] have become of greater significance because of the increasing prevalence of AIDS [10–12]. Whatever the presentation of the patient, it is important to look for infective conditions and suspect the possibility of two or more concomitant diseases. Painful lesions of the anus in homosexual men are common [13], and may include traumatic lesions and herpes genitalis. Anorectal sepsis, including chronic intersphincteric abscesses, anal fistulae, fissures and ulcerated haemorrhoids were seen more frequently in a group of male homosexuals than in heterosexuals [14]. Anal intraepithelial neoplasia may be clinically subtle and invasive carcinoma is not rare. The dermatology of HIV infection is discussed generally in Chapter 26, and of the perianal and anal area below.

Structure and function

The anus is principally for the evacuation of faeces from the gastrointestinal tract [1], but may also be an organ of sexual utility.

The deep natal cleft, the inguinal (crural) folds and the infragluteal folds are special sites because they are areas where two layers of skin come into close apposition. Together these sites function as part of the hinge between the lower limbs and the trunk, as well as abutting the mucocutaneous junctions of anus and genitalia. The natal cleft is deep and firmly fixed to underlying fibrous and fascial tissues, and its sides are steep and closely apposed. Mucous discharges, excreta and moisture are retained easily within it. Proximity to the genital organs and anus give it a special physical and psychological importance.

The perineum is endowed with numerous eccrine sweat glands whose function is retained after lumbar and thoracolumbar sympathectomies. Sweating may be caused by an alternative parasympathetic sudomotor pathway from the fourth sacral anterior root. Apocrine glands are present but many are functionless. A variable number of sebaceous glands are present both in pilosebaceous units and as individual 'free' sebaceous glands at the transitional part of the anal canal.

The cloacal membrane is where ectodermal and endodermal tissues are in direct apposition caudally in the embryo. The separation into urogenital membrane and anal membrane with the formation of the perineum at about 7 weeks of gestation is brought about by the separation of the cloacal portion of the hindgut by the urorectal septum growing caudally between the allantois anteriorly and the hindgut posteriorly, thus partitioning the cloaca into the urogenital sinus anteriorly and the anorectal canal posteriorly. The anal membrane disintegrates at about 9 weeks to open into an ectodermal anal pit formed in the posterior cloacal folds.

Congenital and developmental abnormalities

Gross anomalies will be seen only incidentally by the dermatologist because of skin complications. Minor abnormalities such as haemangiomas, skin tags and papilliferous acanthomas are common on the inner sides of the thighs and infragluteal region. Pigmented, hairy naevi may involve one or both buttocks. Involvement of the buttocks with atypical naevi is a feature of the dysplastic naevus syndrome.

Developmental cysts, fistulae, sinuses and tumours

These are not uncommon, and frequently become infected. They may be mistaken for hidradenitis suppurativa or furuncles. Dermoid cysts occur on or adjacent to the perineal raphe and scrotum. Cloacal sinuses form fistulae from the anus to the adjoining skin; others involve the urethra and perineum.

Chordoma cutis

Chordomas [2] arise from the embryonic precursor of the axial skeleton, the notochord. They can involve the skin of the perineum, sacral area and buttocks by direct extension, recurrence or metastasis. They present as single or multiple, smooth, skin-coloured, non-tender nodules. Sacrococcygeal pain of a persistent nature may precede the diagnosis for years, in a manner that may mimic the presentation of sacral cysts [3], and require scanning procedures to differentiate between them.

Miscellaneous

Congenital hypertrichosis over the midline in the lumbosacral area—faun tail—is a sign of underlying spinal dysraphism (e.g. spina bifida occulta). Pilonidal sinus is discussed on p. 68.88.

3 Van Kleft E, Van Vyve M. Chronic perineal pain related to meningeal cysts. *Neurosurgery* 1991; **29**: 223–31.

Trauma and artefact

Anal trauma is not uncommon. The two most common causes of acute painful anal ulceration in homosexual men are trauma and herpes simplex. Primary syphilis, chancroid, lymphogranuloma venereum, granuloma inguinale and amoebiasis, in decreasing order of frequency, are much less common [1]. Foreign bodies are occasionally inserted into the rectum. Anogenital tattoos have become commonplace [2].

Pressure sore

Pressure sores (decubitus ulcers) in the sacral area are common. In elderly, debilitated or bedridden patients, a persistent patch of erythema on the sacral or ischial region is a sign of impending ulceration. Squamous carcinoma is a potential complication, as with all chronic ulceration.

Umbilical artery catheterization

Unilateral skin necrosis of the buttock has been reported following indwelling umbilical artery catheterization [3–5], probably resulting from thrombosis leading to

occlusion of the inferior gluteal artery. A similar case was caused by misdirection of the tip of the arterial catheter [6].

Child sexual abuse

The significance of anogenital warts in suggesting possible child sexual abuse is controversial. However, early recognition as a marker for child sexual abuse is in the child's long-term best interest [7].

Inflammatory dermatoses

The causes of perianal inflammation in infants are dealt with in Chapter 14. In adults, inflammation may result from the coexistence of several factors: haemorrhoids, anal discharge, proctitis, the presence of fissures or the effect of scratching. Five common conditions cause diagnostic difficulties: seborrhoeic dermatitis, psoriasis, contact dermatitis, lichen simplex and mycotic infections. *Oxyuris* infestation is sometimes postulated but seldom confirmed in adults. Phthiriasis pubis must be excluded.

The lesions of seborrhoeic dermatitis are brownish red, with branny or large, greasy scales towards the edge, extending beyond and outside the fold, and involving other areas of the body.

Psoriasis has a smooth glazed surface and a dull red hue, and is often fissured; other signs of the disease are nearly always present.

Contact dermatitis is markedly inflamed, and has an ill-defined spreading border. Irritant dermatitis results mainly from detergents; allergic dermatitis can have many causes (Table 68.19). In 43 suspected cases, neomycin (27%) and 'caine mix' (24%) were the most frequent offenders; quinolines (7%), lanolin (7%) and ethylenediamine (5%) were less common [1]. When resulting from a medicament, the hands may be involved. Other reports concern biocide preservatives and fragrances in moistened toilet tissue [2–5], lidocaine [6,7] and tetracaine (amethocaine) hydrochloride [8] used in topical antipruritics for piles, and Mitomycin C [9]. The role of food allergy in causing perianal symptoms is debatable [10]. Anoreceptive homosexual men may be susceptible to condom hypersensitivity.

Gross lichenification (lichen simplex) simulates psoriasis but is usually unilateral, except when it involves the perianal area. It may occur as a small, intensely irritable area, localized to the edge of the anus in one site, which is indicated exactly by the patient.

Tinea corporis presents classical signs unless there has been prior use of topical corticosteroids, which modify the features and thus create diagnostic confusion.

In all cases of perianal and perineal inflammation, the urine should be tested for sugar, and swabs and scrapings examined for organisms. A vaginal or rectal examination is mandatory. Any irregularity of the bowels that causes straining or soiling should be corrected.

Pruritus ani

The symptom complex of pruritus ani has many causes: it is not a diagnosis unless qualified as constitutional or idiopathic. Fifty per cent of patients with pruritus ani will have a cause after dermatological evaluation [1–6]. Pruritus ani is seen especially in middle-class middle-aged white males [7]. It occurs less frequently in females, either alone or with pruritus vulvae. It can be associated with most forms of anal disease and with skin conditions involving the perianal area. The contributory factors are complex and may complement or perpetuate each other. Anal itching occurs to a variable degree with any inflammatory or eczematous condition of the skin of that area, with anal fissures, whatever their aetiology, and with malignant tumours. Mycotic infection often causes intense pruritus, and diabetes must be excluded in all severe or persistent candidal infections. Threadworm

infestation is a well-recognized cause in childhood and occasionally in adults. Idiopathic anal itching, in which there is no obvious primary dermatological cause, is discussed further here. Lichenification, excoriation and secondary bacterial and candidal infection (induced by scratching) can supervene, and a contact dermatitis can be caused by overwashing and treatment, both self-directed and physician-prescribed.

The common factor linking most cases of pruritus ani is faecal contamination [2,8]. Faeces are themselves irritant and may generate perianal itch [8,9]. The itch may be triggered by a bowel movement or wiping with toilet paper, but often occurs at night, waking the patient from sleep. Faeces also contain potential allergens and endopeptidases of bacterial origin [10,11]. In the presence of pre-existing skin disease (e.g. seborrhoeic dermatitis or flexural psoriasis), or even in the absence of visible disease, these enzymes are capable of inducing both itching and inflammation [12].

Pruritus ani may be associated with anal leakage resulting from coexisting anal disease or an exaggerated recto-anal inhibitory reflex [13] and anal sphincter dysfunction [14], or be precipitated by broad-spectrum antibiotics and diarrhoea. Hypertrophy of anal papillae is probably not relevant [15]. Many patients have a dermatosis and some will have irritant or allergic contact dermatitis [16–18].

Psychological factors often contribute to pruritus ani, particularly when the itching appears to be out of proportion to the changes observed. However, as Whitlock [19] points out in a careful review, the evidence is unsatisfactory, except perhaps in primary lichen simplex. Psychosexual connotations of suppressed homosexuality do not withstand critical assessment. It is quite understandable, however, that prolonged pruritus ani can lead to tension, irritability or depression, and the treatment of this is an important part of the management of the condition. Idiopathic pruritus ani has been attributed to stress and anxiety and sedentary occupations.

The causes of faecal contamination are as follows (more than one factor may be operative).

Difficulty in cleansing the area. This may be caused by the following factors:

1 *Simple obesity*: poor ventilation and maceration have an additional role.

2 *Frequency of defaecation*: patients with a colostomy never suffer from perianal itching. Patients with pruritus ani are rarely constipated, although they may sit long at stool owing to faulty training techniques, with resultant prolapse or haemorrhoids and soiling [2,14,20]. Patients frequently admit to two or more motions a day. They are often tense individuals in whom everyday problems induce a profound colonic reflex, resulting in defaecation and soiling.

3 *Anatomical factors*: it is often noted that the anus is deeply placed. The association of this 'funnel anus' with marked hirsutism causes mechanical problems in the maintenance of hygiene.

Anal leakage. This may result from the following factors:

1 *Local causes*: such as haemorrhoids, perianal tags or fissures, which interfere with the efficient functions of the anus.

2 *Primary anal sphincter dysfunction*: anal canal manometry studies have shown that leakage of infused saline occurs early [13], and in one common group of patients the sphincter relaxes in response to rectal distension in a more rapid and profound manner than in a control group [14]. The arrival of faeces or flatus in the rectum may then regularly result in reflex faecal soiling.

Bacterial contamination. This is frequently a secondary cause, but rarely a primary cause alone. However, cross-infection of staphylococci may occur (e.g. between the ears and the anus).

Food and drink. The role of ingested metabolites or food chemicals in inducing pruritus ani is still uncertain and virtually unexplored, but anecdotal evidence in individual cases is sometimes compelling [21].

Clinical features. Clinical features vary somewhat, with possible contributions from the effects of rubbing, secondary infection, contact dermatitis or an underlying psoriatic diathesis.

1 Lichen simplex may be present in a 'pure' form, often localized to a small area at the edge of the anus or slightly away from it. The perception of itch from 'easily alerted' nerve endings is more acute in those of anxious temperament or at times of psychic trauma or fatigue.

2 A more general area of maceration, lichenification and fissuring—the 'mossy bank' anus—may be present. The architecture of the anal margin may be distorted by haemorrhoids, tags, oedema and infection. There is usually a gross degree of discharge [14].

3 Features of acute eczema may be caused by secondary infection of possibly minimal seborrhoeic dermatitis or psoriasis, or by contact dermatitis. The last mentioned should always be suspected when there has been any sudden change of pattern or intensity of a rash. The fingers may also be involved. One of the most common offenders is the 'caine' group of drugs [22], often self-prescribed.

4 Intense erythema with no obvious features of eczema may occur. This tends to vary in intensity over short periods, and probably represents the pruritic stage of the next group.

5 There may be no visible abnormality at the time of examination. These patients may have noticed erythema at times, or intense itching, and commonly give a story of

an intermittent sensation of wet anal margins and slight faecal soiling. It is in this group that dyskinesia of the sphincter appears to be a primary factor.

Diagnosis. A full history is essential and a search for underlying disease must be carried out. It is important to exclude staphylococcal infection, folliculitis, erythrasma, *Candida*, tinea, warts and thread/pinworms, and to establish whether there are other underlying skin diseases such as psoriasis [23], atopic dermatitis, LP, LS or EMPD [15]. Anal fistulae are particularly prevalent in chronic pruritus ani [24]. However, the majority of patients with piles, skin tags, fissures, warts, diarrhoea or faecal soiling do not itch [3]. Systemic diseases that have been associated with pruritus ani include lymphoma, pellagra, hypovitaminosis A and D and diabetes mellitus [4].

A rectal examination and referral for proctoscopy and sigmoidoscopy may be indicated [25]. In the young, threadworms should be sought with the Sellotape test or by stool examination for parasites. Patch testing is helpful to explore sensitivity to lanolin, medicaments, rubber, perfumed paper, etc.

Treatment. Management [2] begins with attention to the patient's washing habits. Soap is replaced with a suitable substitute and a moisturizer prescribed. A moisturizer (others recommend talcum powder) should be applied after each wash. A barrier preparation can be pre-applied to the perianal skin before the bowels are opened. Washing after defaecation in a bidet is preferable to wiping with toilet paper, if possible. Rubbing with toilet paper should be discouraged and dabbing recommended. Premoistened toilet papers should be avoided because of the potential irritancy of the moisturizing agent, which may be alcohol, and the risk of developing allergic sensitivity to fragrance or preservative components. Underwear should be loose and preferably made of cotton. Patients are best advised not to use topical anaesthetics in order to avoid sensitization to their constituents [26].

Coffee consumption might be curtailed [21]. Any other foods, such as nuts, that provoke the pruritus should be excluded from the diet, and a high-fibre diet should be encouraged if there is any history of constipation or haemorrhoids [27].

Local applications should be mild and soothing. A topical corticosteroid/antibiotic/antifungal preparation is useful for acute episodes. A wick of bandage impregnated with hydrocortisone 1% and silicone 10% inserted in the natal cleft is anti-inflammatory and lubricating. Other treatments that have been advocated include zinc paste with 1–2% phenol, St Mark's lotion, half-strength Castellani's paint, weak (0.05–0.25%) silver nitrate solution (if wet), cryotherapy, oral antihistamines, corticosteroid suppositories, intralesional triamcinolone, a 10-day tapering course of prednisolone, and intralesional methylene blue, with or without marcaine/epinephrine/xylocaine [3,4,28,29]. Caution should be exercised with topical steroid treatment because the anal skin is 'quasi-occluded' and is easily damaged by fluorinated corticosteroids.

Concomitant proctological disease (haemorrhoids, fissures, anal spasm and occult mucosal prolapse) should be treated, if found [30]. When active pathology such as fissures, haemorrhoids or anal spasm are present, surgery will be needed. Lord's stretch procedure [31] has proved helpful. The long-term results are particularly satisfactory in those patients with strong ultra-low-pressure waves [27]. However, it may not always relieve the pruritus [32]. Simple excision of anal tags is unhelpful in relieving symptoms [15].

Some authorities see a psychosexual significance in pruritus ani in men [19], and this may rarely require attention. Patients should be reassured that they do not have cancer [1].

Danthron erythema

This form of irritant contact dermatitis per rectum is caused by the use of a laxative containing danthron [1,2]. It is seen in those with Hirschsprung's disease or encopresis, and sometimes in elderly incontinent patients [2–4]. Danthron (1,8-dihydroxyanthroquinone) is reduced in the large bowel to 1,8-dihydroxyanthron, which is the active agent [2]. This is chemically identical to dithranol, and the lesions produced by faecal incontinence are equivalent to dithranol 'burns'. A bizarre livid erythema in the perianal area, groins, thighs and buttocks, with sharp outlines, corresponds to the area of contact with the faeces. Danthron erythema is easily differentiated from other causes of perianal or inguino-crural lesions.

Lichen sclerosus et atrophicus

The perianal skin is rarely affected alone, but is involved in up to two-thirds of the cases in which the vulva is affected [5], forming a characteristic figure-of-eight distribution. One case of carcinoma has been reported [6]. Perianal LS is rare in males.

Anal fissure

Small erosions and fissures may occur in the sulcus beneath oedematous haemorrhoids or in any area of dermatitis. The presence of even a small fissure in an area of dermatitis maintains the pruritus and prolongs the course.

A true anal fissure is a midline linear perianal ulcer; 90% posteriorly, 10% anteriorly. Many are idiopathic; the cause is probably related to defaecation of hard stool causing pressure trauma and necrosis, or it may be a postoperative complication. Sexually transmitted diseases and Crohn's disease should be excluded. Intense pruritus, pain, bleeding, mucous discharge and constipation constitute the symptomatology. On examination there may be a 'sentinel pile' at the anal pole of the ulcer. Management is surgical: proctoscopy is mandatory if the aetiology is in doubt, and especially if the fissure extends to the anal margin or within. Benign fissures are superficial and not indurated, but when persistent they may be painful and cause bleeding, especially in the elderly. Unless they heal quickly under treatment, a biopsy should always be performed to exclude malignancy.

Small erosions and excoriations frequently heal with treatment for anogenital pruritus. If they are hidden between haemorrhoids or anal tags, protective pastes are helpful. Fissures in psoriasis and seborrhoeic dermatitis are difficult to heal, particularly in the natal cleft. If the underlying disease is satisfactorily controlled, the lesion will heal without special attention. Intralesional corticosteroids may be effective in non-infective inflammatory conditions.

Anal fistula

A perianal fistula is a communication between the anal canal and the perianal skin. Most are on the midline posteriorly, but there may be multiple openings. The origin is from infection and abscesses within the anal glands, but Crohn's disease, foreign body and tuberculosis are classic causes and hidradenitis suppurativa is an important differential diagnosis. Squamous carcinoma is a rare complication. The presentation is usually of pruritus ani related to seropurulent discharge but there may be pain resulting from abscess formation. Surrounding skin may be indurated. Management is surgical.

Pilonidal cyst/sinus

Pilonidal sinus probably derives from the perineal pilosebaceous unit and precursor pits (not the common congenital sacral pits) associated with trapped hairs [7,8]. Clinically, pilonidal sinus constitutes part of the 'follicular–occlusion tetrad' alongside hidradenitis suppurativa, acne conglobata and dissecting cellulitis of the scalp. Symptoms include itch, pain, recurrent abscess, purulent discharge and persistent nodule. Pilonidal sinus occurs in the midline. The sacrococcygeal location is the most common site but it can occur on the pubis, anterior perineum and, very rarely, the penis. It may present as a nodule or cyst, often with a pigmented or hairy surface, which ruptures and quickly becomes infected (Fig. 68.41). The sinus usually extends to the sacrum and causes sacrococcygeal fistulae with deep ramifications. This heals if the track is thoroughly cleaned. Treatment is surgical [8,9]. Squamous carcinoma can supervene [10].

Hidradenitis suppurativa

Hidradenitis suppurativa ('chronic perianal pyoderma' in Japan) (see Chapter 27) can give rise to all degrees of inflammation and scarring. Friction and pressure accentuate the inflammatory changes that invade the fat and cause further granulomatous change extending widely over the buttocks and thighs. Persistent perineal sinuses are frequent, and deep lesions cause anal fistulae. In mild cases, only a few isolated lesions are present. Secondary bacterial invasion, often from the gut [1], is an important complicating factor. Seven cases have been associated with an oestrogen–progesterone contraceptive pill [2].

There is a clinical spectrum overlapping with chronic folliculitis (e.g. of the buttocks and 'penile acne'). In established hidradenitis, bridged comedones, folliculitis and furunculosis, deep burrowing discharging sinuses, nodules, cysts, fluctuant abscesses, scarring and fibrosis in the groins and axillae, the natal cleft and buttocks [3] may all be present. Some patients may also have conglobate acne, dissecting cellulitis and pilonidal sinus. Hidradenitis is more common in black and Mediterranean individuals. It affects the axillae preferentially in women and the perineum in men. A urethral–cutaneous fistula and phimosis have been reported [4]. Scarring from the disease and its treatment can be extensive. The morbidity of hidradenitis may be severe, interfering with sitting, sleeping, walking, defaecation and sexual activity, and responsible for depression. Disease that has persisted for more than 20 years carries a significant risk of progression to SCC [5–7] and rarely verrucous carcinoma [8].

Differential diagnosis. Hidradenitis is usually a clinical diagnosis. Swabs should be taken for bacteriological evaluation and to guide therapy, but the patient should be fully evaluated for sexually transmitted diseases should the presentation be in any way suspicious. An important differential diagnosis of acneiform disease presenting at any site is chloracne (see Chapter 43). A biopsy may be necessary to exclude carcinoma or Crohn's disease. Perineal Crohn's disease mimics hidradenitis, with its granulomatous inflammation, ulceration and fistula formation, but it is less painful. Also, the disease is absent from the axillae and it is rare for patients to be free of overt gastrointestinal symptoms. Very florid perianal disease can be seen in myeloma and leukaemia [9], and in homosexual men and in AIDS [10].

Mild or localized forms are frequently misdiagnosed as furunculosis or 'infected cysts', and confusion occurs with severe acne, developmental fistulae and lymphogranuloma venereum. The relatively painless recurrences in the same or other sites, and oblique sinuses that end in soft swollen inflamed nodules, are characteristic.

Treatment. This is challenging [11]. Small localized sinuses may be phenolized successfully, and early lesions may respond to intralesional corticosteroids. However, this treatment may have to be repeated, and recurrent or extensive lesions may require a more radical approach. Marsupialization (as with pilonidal sinuses) [12] and diathermy destruction of the affected tissue have been very successful in some cases, even those involving the scrotum. Treatment with carbon dioxide laser, with secondary intention healing, is very effective [13,14]. The use of Silastic foam dressing may facilitate healing [15]. Otherwise, plastic surgery with complete excision of all the involved skin may be required [16]. Long-term antibiotic therapy (erythromycin, flucloxacillin, ciprofloxacin, metronidazole) is often given 'blind', but is seldom of lasting value, although elimination of specific secondary invaders such as *Streptococcus milleri* [1] has given good

results. Oral prednisolone can be used alongside antibiotics to control intercurrent exacerbations. More recently, isotretinoin (1 mg/kg) for 6–8 months has been used with mixed results, but is occasionally helpful in difficult cases [17,18]. Antiandrogen therapy has yet to be evaluated.

Crohn's disease

SYN. REGIONAL ILEITIS

It is a well-known aphorism that Crohn's disease can affect any part of the gut and its cutaneous borders from the mouth to the anus. The cutaneous manifestations of Crohn's disease are listed in Table 68.31. Perianal disease may occur in up to 75–90% of patients [7,8]. Table 68.32 lists the perianal features of Crohn's disease [9]; it includes those common to most chronic diarrhoeal illnesses such as pruritus ani, skin maceration, and erosions with secondary infection. Perianal manifestations of Crohn's disease in childhood are a major cause of morbidity, but only rarely progress in a destructive manner (Fig. 68.42) [9].

Table 68.31 The cutaneous manifestations of Crohn's disease [1–6].

Erythema nodosum
Anal and perianal lesions
Spreading ulceration of perineum and buttocks after colectomy
Skin changes around ileostomies and colostomies
Genital lesions
Balanitis, posthitis and granulomatous lymphangitis
Vulval lesions
'Sarcoid' type lesions in remote sites
Pyoderma gangrenosum
Granulomatous cheilitis
Epidermolysis bullosa acquisita
Non-specific changes resulting from malabsorption

Table 68.32 Perianal features of Crohn's disease.

Pruritus ani
Maceration
Erosion
Secondary infection
Skin tags
Fissures
Anal stenosis
Fistula-*in-ano*
Abscess
'Metastatic' granulomatous plaques

Clinical features. The skin tags of Crohn's disease are larger, thicker and harder than ordinary tags. Deep undermined angulated fissures with cyanotic edges may fuse to form 'flying buttress' skin bridges, characterized by relative lack of pain. Fistulae are less common than fissures; they may be asymptomatic even when multiple. Pain usually means that an abscess has formed because of blockage of a fistula. Multiple external openings can be encountered all over the buttock, on the scrotum and on the thigh; a distinctive sign is the cyanotic hue of the indurated skin. Anal stenosis, faecal incontinence and carcinoma are complications [10].

Clinical diagnosis may be achieved based on symptoms, signs and investigation results (e.g. radiography and gut biopsy) consistent with Crohn's disease. Any anal lesion in a patient who is known to be suffering from Crohn's disease is likely to be perianal Crohn's [11]. Difficulty arises when the anogenital disease represents the first manifestation. Histologically positive perianal disease of all clinical types may predate frank gastrointestinal Crohn's disease by several years [12], including in children [9]. The relative lack of pain, multiplicity of lesions, oedema of skin tags and eccentricity of fissures are important pointers [11]. Biopsy of skin lesions is helpful, and sigmoidoscopy and biopsy of intestinal mucosal lesions is mandatory. Swabs should be taken and the patient fully evaluated for sexually transmitted diseases should the presentation be in any way atypical.

Differential diagnosis. The differential diagnosis includes the causes of pruritus ani and non-specific anal fissures and fistulae. Similar, although less extensive, lesions occur, but much less commonly, in ulcerative colitis, and only very rarely in diverticulitis [2]. Hidradenitis suppurativa presents with nodules, sinuses and purulence but is more painful; other sites may be involved and severe acne is often present. Similarily florid perianal disease can be seen in myeloma and leukaemia [11]. Proctitis, perianal ulceration, abscess, fissure and fistula are prevalent in homosexual men and those with HIV/AIDS [13,14]. Perineal pyoderma gangrenosum has been misdiagnosed as Crohn's disease. A solitary granulomatous nodule, with or without ulceration, carries a differential diagnosis that includes sarcoid, schistosomiasis, leishmaniasis, tuberculosis, atypical mycobacterial infection, deep fungal infection, granuloma inguinale, lymphogranuloma venereum, chancroid, amoebiasis and syphilis. Florid condylomata acuminata [15], anorectal carcinoma presenting with an ischiorectal abscess [16] and other mucocutaneous malignancies (basal cell carcinoma, Kaposi's sarcoma and amelanotic malignant melanoma) may rarely be encountered.

Treatment. The treatment of the anogenital manifestations of Crohn's disease depends to some extent on the treatment of active intestinal disease. Local measures include soaks with potassium permanganate and aluminium acetate, potent or very potent topical corticosteroid/antibiotic combinations and oral antibiotics (as for hidradenitis). A role has been advocated for long-term oral metronidazole (20 mg/kg/day in divided doses) [17,18]. Perianal abscess may respond to sulfasalazine and anal fissure to prednisolone and azathioprine [5]. The surgical philosophy is conservative [3,9]. Resection of the affected segment of bowel does not always cure the lesions or prevent their recurrence, especially at ileostomy or colostomy sites.

Miscellaneous

Radiodermatitis is occasionally encountered following previous treatment for *in situ* or frank carcinoma or, decades ago, pruritus ani. LP involving the buttocks and perianal region is extremely irritable and may become excoriated or hypertrophic; LP must be considered in the differential diagnosis of pruritus ani and perianal fissures. Solitary involvement of the perianal skin may occur (Fig. 68.43).

Behçet's disease occasionally presents with multiple shallow ulcers and fissures of the anal margin.

Fig. 68.43 Perianal lichen planus. (Courtesy of Dr F.A. Ive, Durham, UK.)

Calciphylaxis sometimes affects the thighs and buttocks [1–3].

Acrodermatitis enteropathica should be considered in the differential diagnosis of perianal eczema, psoriasis or candidosis in the paediatric setting, or in the presence of gastrointestinal disease causing malabsorption syndromes (e.g. Crohn's disease), extensive gastrointestinal surgery such as small intestinal bypass, malnutrition in alcoholism and recent prolonged parenteral nutrition where zinc supplementation may not have been optimal. A reticulate eczematous eruption may be found on the extensor aspects of the limbs in alcoholics but has also been reported to affect the perianal and scrotal skin [4,5]. Other deficiency diseases with some similarity to acrodermatitis enteropathica are pellagra, maple syrup urine disease and neonatal citrullinaemia.

Benign mucosal pemphigoid (cicatricial pemphigoid) [6] may affect the groin, perineum and perianal skin, and may cause anal stenosis. The drug clonidine may have been responsible in one case [7]. Pyodermite végétante can be distinguished by the histology and by immunofluorescence studies. Ulcerative colitis may be present [8].

The anus is involved in about 5% of cases of Stevens–Johnson syndrome. A connection has been recognized between epidermolysis bullosa acquisita [9] and inflammatory bowel disease, particularly Crohn's disease [10–12].

Fixed drug eruption may produce striking pigmentation. Prolonged use of potent topical corticosteroids causes a dusky erythema, atrophy or induration.

Primary systemic cutaneous anosacral amyloid

This has a predilection for the anogenital region, particularly the sacrum, in elderly Japanese people [1–3]. Moderately pruritic pigmented macules and glossy hyperkeratotic lesions fan out in lines from the anus. There are no systemic changes. Amyloid deposits are seen in the upper reticular dermis and around hair follicles. It is thought to represent an ageing process.

Infections

Folliculitis and furunculosis

The anogenital area, particularly the buttocks and thighs of men, can be susceptible to infection with *Staphylococcus aureus*. Severe involvement with furunculosis and abscesses suggests an overlap with hidradenitis suppurativa. Although the high temperature and humidity of this area, combined with pressure [1] and friction, encourage colonization by staphylococci, primary pyococcal infections are now uncommon in countries with cultural or acquired habits of cleanliness. The perineal carriage of staphylococci [2] may not cause local lesions in the host, but is especially important in acting as a reservoir from which

Hidradenitis suppurativa
Crohn's disease
Staphylococcal cellulitis
Streptococcal cellulitis
Gonococcal cellulitis
Fournier's gangrene and necrotizing fasciitis
Extramammary Paget's disease
Carcinoma erysipeloides (bladder and prostate)

S. aureus may be disseminated to other sites or to eczematous lesions elsewhere. In adults, the carriage rate is of the order of 13–22%; in neonates it may be higher. Some persons are better 'dispersers' of staphylococci than others, and the organisms may remain (and even increase) after washing. The risk of dispersion of staphylococci from this site is of obvious importance in hospital operating theatres, where attempts have been made to minimize it by the provision of special clothing [3]. Nasal carriage, diabetes and immunodeficiency should be considered. Bacterial perianal infection is commonly seen in leukaemic patients [4].

Staphylococcal cellulitis

Cellulitis and abscess formation can complicate cysts, sinuses and fistulae. The differential diagnosis is given in Table 68.33.

Anorectal infection in patients with malignant disease is serious and potentially life-threatening [6]. Although some cases of anorectal cellulitis will respond to antibiotics alone, necrotizing fasciitis and Fournier's gangrene are risks. Swelling and fluctuance signifying abscess formation may develop late. It is difficult to decide on the timing of surgery. Perianal infiltration, ulceration or abscess occurs in 5% of haematological malignancies and may rarely be the presenting feature [7].

Streptococcal dermatitis/perianal cellulitis

This syndrome in children [8] probably has a corollary in adults [9]. A child may present with pruritus, painful defaecation, anal soreness and redness (without nappy/diaper rash) and satellite pustulosis of the buttocks. Examination of the anus shows a pronounced, sharply demarcated, boggy erythema and causes discomfort to the child. Rarely, there may be a systemic presentation with fever and rash [10]. It is much more common in boys, and the penis may be involved. An association with acute guttate psoriasis has been reported [11,12]. Group A β-haemolytic streptococci is the usual cause, although *S. aureus* has been retrieved from one child who also had satellite pustules on the buttocks [13]. Proctocolitis has occurred [14]. Perianal disease may be misinterpreted as sexual abuse [15]. Streptococcal infection of the upper respiratory tract in other members of the family may be found. Communal bathing has been blamed for outbreaks. Treatment is generally with systemic penicillin or topical mupirocin, or erythromycin if clinically less acute [16].

Perianal abscess

Perianal/anorectal/ischiorectal abscess presents with painful swelling and suppuration and is commonly complicated by anal fistula. The likeliest cause of perianal abscess is infection of the anal glands but trauma (e.g. impacted fish bone), diabetes and anal cancer predispose to its development. Crohn's disease, hidradenitis, tuberculosis and *Enterobius vermicularis* [1] should be considered.

Ecthyma gangrenosum

Gram-negative organisms are seldom pathogenic unless the balance of the skin flora is grossly disturbed. *Pseudomonas aeruginosa* may be found in deep ulcers and fissures. Ecthyma gangrenosum has a predilection for the anogenital (and acral) extremities. The prognosis is poor. Ill patients with leukaemia may develop a necrotizing anorectal ulcer caused by *Pseudomonas*, presenting with severe anal

pain, anorectal ulceration and septicaemia. Anorectal ulceration may be the portal of entry of the infection or a consequence of it [2]. The mortality is high.

Thread/pinworms

Thread/pinworms can cause pruritus ani. Excoriations, eczematization and impetiginization may be present, sometimes away from the site of infestation on the buttocks and upper thighs, particularly in the younger child. However, often there are few physical signs. Perianal abscess may occur very rarely [1].

Common mycoses

Candidosis causes a bright red, glazed area, often with outlying small pustules, and may spread to the groins or natal cleft. Microscopy and culture distinguish it from other fungal infections, and from psoriasis and pyococcal infections.

The well-defined scaly circinate edge, the spread and the chronicity of *Trichophyton rubrum* infection offer clues to diagnosis, which can be confirmed by microscopy and culture. However, prior treatment with corticosteroids may disguise the appearance. The possibility of fungal infection should therefore be considered in all unusual forms of perianal dermatitis.

Necrotizing infections

A number of overlapping severe gangrenous and necrotizing diseases may affect the anorectal and perineal (and genital) skin and subcutaneous tissues. Although they may often be a complication of surgery or trauma, they are mentioned here because of the crucial importance of their early recognition and treatment (see also Chapter 27). These conditions are described under several names [3]:

1 Clostridial and non-clostridial gangrene [3–5]
2 Streptococcal cellulitis and myositis
3 Synergistic necrotizing cellulitis
4 Necrotizing fasciitis [6–8]
5 Meleney's progressive bacterial synergistic gangrene [9]
6 Synergistic gangrene [10]
7 Fournier's gangrene, etc.

Clinical features. Although middle-aged and elderly subjects are most often affected, the conditions can follow trauma in young adults, and the prognosis in the latter, given vigorous early treatment, is good [3]. They have also been described in children [11], particularly following circumcision or scalds, but sometimes after a bout of severe diarrhoea [12], or even spontaneously [13]. The problem may present as a primary perirectal abscess in the perineum (or on the scrotum or labia). Pain is generally the first symptom, and may be severe. A distinct dusky red to black spot may appear in affected tissue and is of ominous significance. Tenderness and a dusky erythema extend with extreme rapidity to involve wide areas, and all the perirectal and perineal spaces (hence the terms fasciitis and myositis). Crepitus is an important feature, as is the presence of a dark brown, turbid fluid without pus. Many patients are diabetic [3,7] or leukaemic; in these, the mortality is much higher than the overall rate of 12–25% [7]. A perianal distribution, old age and delay in treatment also greatly reduce the survival rate.

Bacteriology. Swabs should be taken from the margin of the lesion [10]. An immediate Gram stain will distinguish clostridial infections by the finding of large Gram-positive rods. *Clostridium perfringens* was the most common organism in one series [3], but other clostridia, aerobic and anaerobic streptococci, and *Pseudomonas* species [11] have all been isolated. Anaerobes may easily be missed. A wide variety of secondary organisms are commonly cultured.

Treatment. Early recognition and immediate and aggressive treatment are essential in this devastating condition. Electrolyte and fluid balance must be established, and high-dosage antibiotic therapy started without waiting for the result of culture. This will normally consist of intravenous penicillin (24–30 million units/day [3]) together with a broad-spectrum antibiotic, usually an aminoglycoside or a cephalosporin; this regimen can be modified later.

The most important single therapeutic manoeuvre is rapid and extensive débridement of all affected tissue. Other surgical procedures, such as colostomy, may also be necessary. The value of hyperbaric oxygen [14] is disputed.

Dermatological aspects of sexually transmitted disease

Gonorrhoea can result in anal inflammation and discharge, or an oedematous perianal dermatitis with multiple fissures and erosions.

Chancroid can cause extremely painful anal lesions instead of the classic multiple soft chancres. The initial rapidly ulcerating papule of granuloma inguinale (see Chapter 27) may occur in the perianal region in homosexual males. It is soft, painless and bleeds easily on trauma. It may be hypertrophic, sclerotic or phagedenic. There is normally no regional adenopathy, but a 'pseudobubo' may be present. In the anal canal, the lesion never extends beyond the stratified epithelium and strictures do not occur, but anal stenosis or, rarely, epitheliomatous change can supervene. If undiagnosed, lymphogranuloma venereum causes widespread vegetating and scarring lesions of the genitoperineal area. The Frei and complement fixation tests distinguish it from hidradenitis suppurativa.

Syphilis (see Chapter 30) [1] is becoming more common in homosexual men. It should never be forgotten as a possible cause of anal ulceration. Anal chancres are often mistaken for fissures; at the anal margin their significance may not be appreciated. Pain on defaecation or at night may be severe if there is secondary infection of the chancre, but is often absent. The posterior midline is the site of election. Bilateral lymphadenopathy is extremely rare with other perianal ulcers. Dark-ground examination may not be diagnostic if lubricants or ointments have been used. Discharge and bleeding, fissures (especially laterally) and fistulae should also arouse suspicion of anorectal primary syphilis. Painful syphilitic proctitis in the absence of anal lesions can occur [2,3]. Moist flat condylomata lata (Fig. 68.44) can affect all anogenital intertriginous sites and the differential diagnosis includes intertrigo as well as warts, lichen planus and bowenoid papulosis. The granulomatous gumma may affect the anal area as an ulcer, a white plaque or as an atrophic scar.

Perianal viral warts (condylomata acuminata) (Fig. 68.45) occasionally occur in infants and young children, but they are normally seen in young adults, and are not always sexually transmitted. They may be extraordinarily profuse, extending into the anal canal, especially in homosexuals or in immunodeficient (congenital or acquired) subjects in whom there is also a higher risk of progression to dysplasia and frank malignancy [4]. For example, anogenital warts are common in HIV-positive males, nearly half of whom show histological signs of intraepithelial neoplasia. The clinical diagnosis of HPV is usually certain but condylomata lata (secondary syphilis), LP, molluscum contagiosum and BP enter the differential diagnosis. Solitary lesions have a wider differential diagnosis, including giant condyloma and squamous carcinoma. Biopsy should be performed if there is diagnostic doubt or if dysplasia or worse is suspected. Morphology and histology cannot distinguish virus-associated from non-virus-associated lesions; molecular techniques may be preferable but are not yet routinely available [5].

Table 68.34 Causes of anal ulceration in HIV infection.

Idiopathic
Haemorrhoids
Fissures
Sepsis
Syphilis (chancre)
Herpes simplex
Cytomegalovirus
Kaposi's sarcoma
Non-Hodgkin's lymphoma
Squamous carcinoma

Patients with anogenital warts, and their partners, may require full STD and sometimes colorecral assessment. Anogenital HPV can be very difficult to treat.

A phenomenon of chronic erosive and verrucous herpes simplex as part of immunoreconstitution disease has been described in HIV infection [6].

Human immunodeficiency virus infection

Anal ulceration may be a feature of HIV infection; Table 68.34 lists the main causes. Biopsy with special stains and culture is mandatory.

Other problems in HIV infection, including psoriasis, warts, intraepithelial neoplasia, squamous carcinoma and KS are discussed elsewhere.

CMV has been recorded in persistent perineal ulcers in immunosuppressed patients [7]. EBV DNA has been found in epithelial cells from the anal canals of asymptomatic HIV-positive male homosexuals, indicating possible sexual transmissibility [8]. Herpes simplex, gonorrhoea and anal condylomas were commonly associated in a US study on early HIV positivity [9]. Similar findings relate to a central African group with more advanced disease [10]. The importance of primary rectal syphilis has been emphasized [2]. Amoebiasis [11] may be overlooked. Dark-ground examination, and culture and microscopy for ova, should be obligatory [12]. In the absence of organisms, if pus cells are found, a rectal biopsy is indicated. KS of the rectum has been recorded in HIV-positive males [13]. The relationship of KS to anoreceptive anal intercourse and HHV 8 is discussed in Chapter 26 [14,15].

Miscellaneous

Pruritus ani has been attributed to erythrasma [1]. Erythrasma, present also at other sites, was found in 15 of 81 patients examined using Wood's light [1]; all were males. In infants, coxsackie A infections can cause a transient papular or papulovesicular eruption of the perianal area and buttocks. An erythematous desquamating perineal eruption occurring in the first week of the disease may be the first cutaneous feature in up to two-thirds of children with Kawasaki disease [2].

Fournier's gangrene and its differential diagnosis (Table 68.22) is discussed on pp. 68.28–68.29. Anorectal presentation is more serious than urogenital disease because the presentation may be more cryptic and there may be a longer delay in diagnosis [3].

Perianal tuberculosis (see Chapter 28) [4] is still seen where tuberculosis is common, but must always be considered, even in western Europe [5]. A primary lesion is exceptional; the accompanying unilateral lymphadenopathy is an important feature. Indolent, irregular, painful ulcers, fistulae and abscesses may be difficult to distinguish from those accompanying Crohn's disease [6]. Lupus vulgaris and verrucous tuberculosis may spread widely over the buttocks and postanal region, or assume a fungating and vegetating appearance. Tuberculosis cutis orificialis is thought to arise from autoinoculation of organisms contained in swallowed sputum from pulmonary lesions. It may occur in the immunocompromised and has been reported in association with Evans' syndrome (autoimmune haemolytic anaemia and immune

thrombocytopenia) [7]. Perineal scrofuloderma (secondary skin involvement from underlying lymph node disease) may cause diagnostic confusion [8]. Pyoderma gangrenosum, Crohn's disease, hidradenitis, neoplasia, artefact, sexually transmitted diseases, amoebiasis and deep mycoses appear in the differential diagnosis [9].

Daughter yaws (see Chapter 30), initially papules but rapidly becoming ulcerated crusted plaques, have a predilection for periorificial sites on the face and around the perineum.

The giant condyloma of Buschke–Löwenstein (see p. 68.42) is rare. It is probably HPV-related [10].

Non-genital herpes simplex (see Chapter 25) occurs frequently around the pelvic girdle. Vaccinia, usually acquired by indirect transmission [11], is now never seen, but orf still occurs occasionally [12].

Sacral herpes zoster [11] is rare but can be cryptic in presentation; when involving S2–S4 or, less commonly, the ileoinguinal segment of L1–L2, it may cause significant morbidity from acute cystitis or urinary or faecal retention [13–15]. Hospitalization and urological and colorectal assessment are required, and treatment should be with intravenous aciclovir. AIDS has presented as anogenital herpes zoster [16].

Trichosporosis is a common cause of genito-crural and perianal intertrigo in India. Symptoms are itching or burning. Accompanying the intertrigo may be scaly papules. Coexisting dermatophyte, *Candida*, trichomycosis and erythrasma infection may be found. Topical dequalinium chloride is used for treatment in India [17].

Amoebiasis (see Chapter 32) of the perianal skin [18] is usually associated with bowel infections but, where the disease is endemic, direct inoculation of abraded skin or operation wounds can occur. Abscesses and fistulae may at first be indolent and symptomless. Ulcers typically extend slowly, with serpiginous outlines, firm cord-like edges and a whitish slough [19]. Sometimes, however, progression is rapid and remorseless, until a phagedenic ulcer completely destroys the perianal and sacral tissues [20]. A black foul-smelling eschar is surrounded by a violaceous edge, resembling pyoderma gangrenosum. The patient is extremely ill. Vegetating or condyloma-like lesions of intermediate severity occur less frequently. Amoebiasis should be suspected when such a lesion occurs unexpectedly in the course of 'ulcerative colitis' or in a prolonged mild undiagnosed colitis. Cases have been described in infants [21]. Destructive [21] perianal and buttock ulceration may masquerade as squamous carcinoma; however, very rarely, concomitant carcinoma has been reported [22]. The diagnosis is made by finding the *Entamoeba* species in a biopsy specimen from the edge of a lesion (which is always secondarily infected) or by examination, while warm, of a fresh high sigmoidoscopy swab. Treatment with metronidazole may be dramatically effective, but in severe cases surgery may also be required.

Perineal granulomatous lesions are a rare manifestation of schistosomiasis (bilharziasis), which may present as pruritic papules in the genital, umbilical and perineal regions in countries where it is endemic [23,24]. It is usually preceded by rectal or intestinal symptoms. The papules and nodules may be skin-coloured, pink or brown, scattered or grouped, affecting the penis, scrotum and vulva. They can spread onto the perineum and around the anus, and may develop into soft warty vegetating lesions, but remain relatively asymptomatic. Genital lesions simulating warts have been seen in travellers returning from endemic areas [25]. Ulceration is rare and, even more rarely, concomitant carcinoma has been reported [22]. The unusual occurrence of anogenital lesions results from ova shed by worms that have entered the perineal vessels [23]. Viable or calcified ova are found in the dermis.

Larva currens caused by *Strongyloides stercoralis* commonly occurs around the anus and on the buttocks. Likewise, cutaneous larva migrans resulting from the dog hookworm *Ancylostoma brasiliense* may occur around the pelvic girdle.

Perianal histoplasmosis and blastomycosis have also been recorded. Actinomycosis has resulted in multifocal perineal and buttock ulceration in G6PD deficiency [26]. Ulcerating and vegetating lesions, often unrecognized and of long duration, have followed trauma in patients with actinomycosis [27]. Correct diagnosis depends on histological confirmation, but the yellow or red granular pus should arouse suspicion [26].

Classic lesions of scabies commonly involve the buttocks, and nodules are sometimes seen in the perineum.

Benign tumours

The following entities are encountered in the perineal/perianal area: angiomas and angiokeratomas; basal cell papillomas may be mistaken for viral warts or BP, as may melanocytic naevi; inguinogenital epidermoid cysts may become infected; lesions containing molluscum contagiosum have been described; pilar cyst, including giant forms, is much rarer.

Haemorrhoids

Haemorrhoids/piles (Latin *pila*, a ball) are dilatations in the venous system draining the anus, mucosal prolapse or loose tethering of mucosa to the anal wall [1]. Symptoms are rectal bleeding, mucous discharge, pruritus ani and prolapse. The complications of piles are thrombosis, strangulation, ulceration, fibrosis, infection and abscess, which give rise to pain. Patients presenting with these symptoms should be assessed by a proctologist, and by proctoscopy and sigmoidoscopy. Signs depend on the presentation. Perianal skin tags from fibrosed piles are extremely common. The differential diagnosis includes distal bowel cancer, as well as naevi, Crohn's disease, KS and perianal metastases. Treatment is the domain of the colorectal surgeon and gastroenterologist.

Premalignant dermatoses and frank malignancies

The anogenital area is not exposed to solar radiation, the principal cutaneous carcinogen. Treatment of pruritus in the past with radiotherapy or tar preparations, and the use of radiotherapy for gynaecological malignancy, carry theoretical hazards and can occasionally be incriminated in carcinogenesis. However, they do not appear to have influenced greatly the frequency of perineal tumours. Post-granulomatous scarring is an important background to perianal malignancy in some parts of the world, and other chronic inflammatory processes, such as LS, are a potential hazard. There are cases where condylomata acuminata have preceded SCC of the anal or perianal skin [2,3] and HPV has become a major suspect in the precancerous process.

Porokeratosis

Genital porokeratosis of Mibelli is rare but classic lesions have been found on the penis, scrotum and in the natal cleft. Ulceration may occur [4]. Porokeratosis may be confused with psoriasis, Bowen's disease, granuloma annulare or LP. Histopathology of a biopsy confirms the diagnosis [5]. Topical 5-fluorouracil can be used [6].

Anal intraepithelial neoplasia

Anal intraepithelial neoplasia (AIN) describes full-thickness dysplasia of the anus and perianal skin [7]. It can present relatively asymptomatically as red, shiny or scaly patches like Bowen's disease, or as warty lesions like BP. AIN is frequently associated with homosexuality, anal warts, HPV and HIV, although it is not a prominent feature of other conditions involving immunosuppression. Women with anogenital Bowen's disease have an increased risk of intraepithelial neoplasia or invasive malignancy elsewhere in the genital tract [8,9], and a full gynaecological examination is thus obligatory in such cases. In AIDS, the overall risk of progression of AIN associated with HPV to invasive squamous carcinoma is low [10]. Immunoreconstitution with highly active antiretroviral treatment (HAART) may not achieve regression of AIN [11]. Routine screening of the HIV-positive patient with anal cytology is advocated [11]. Treatment options are similar to those for PIN. Relapse is common. Expert proctological advice should be sought.

Carcinoma of the anus

Anogenital squamous carcinoma is sometimes called epidermoid carcinoma. Fifty-six per cent of all anal carcinomas are of the squamous variety [12]. They are slightly more common in women, but seem to be more aggressive in men [13]. In Denmark, the incidence of anal carcinoma has tripled since 1960 to 0.74 cases per 100 000 population [14].

Although associations with smoking, cervical intraepithelial dysplasia and changing sexual habits, including homosexual anal intercourse, have been postulated

[14,15] and coexistent Crohn's disease has been said to be associated with a 10-fold increase in anal carcinoma [16], the aetiology is not clearly understood. HPV is implicated [17,18], especially in verrucous carcinoma (see below) [19]. Anal carcinoma is often associated with a history of anogenital warts. More than 90% of anogenital condylomata contain HPV 6 or 11, although these subtypes are not associated with cancer, and it is rare for condylomata to contain HPV 16, which has a well-documented association with anal carcinoma. Homosexual men have a higher incidence of both perianal warts and anal carcinoma (both *in situ* and invasive), and this may be related to receptive anal intercourse [15], and HPV as well as other sexually transmitted diseases such as gonorrhoea, herpes simplex and *Chlamydia trachomatis* infection [20]. These infections are also risk factors for anal carcinoma in heterosexual men and women, as is cigarette smoking [21]. A role for seminal fluid prostaglandins in homosexual anal cancer has been proposed [22]. Immunosuppression, including by HIV infection, is a risk factor for AIN and anal cancer [23]. A case of Peutz–Jeghers syndrome associated with anal squamous carcinoma has been reported [24].

Diagnosis can present difficulties. Symptoms may include bleeding, pain, presence of a mass and change in bowel habit. Examination will reveal a hard mass that may be flat, raised or polypoid [25]. Squamous carcinoma should be suspected in all nodulo-ulcerative anal and perianal disease, especially in the context of LS, LP, hidradenitis suppurativa, intraepithelial neoplasia and immunocompromise.

Regarding the differential diagnosis [26], it must be appreciated that anal carcinoma often presents with similar symptoms to benign anal lesions such as piles and fissures (pruritus, discomfort or pain, and bleeding). The most common tumours of the anal margin are viral warts, which are distinguished by their multiplicity, their lack of induration and ulceration, and their rapid evolution. Rarely, these may give rise to anal carcinoma [27]. Syphilitic condylomas are also multiple and not indurated. A syphilitic chancre of the anal margin or canal may be more easily mistaken for carcinoma. Amoebiasis and tuberculosis must also be considered. The differential diagnosis includes the manifestations of intraepithelial neoplasia (and the differential diagnosis of these), erosive or ulcerative sexually transmitted disease, basal cell carcinoma, KS, hidradenitis suppurativa, Crohn's disease, pyoderma gangrenosum and artefact. The differential diagnosis also includes ischiorectal or perianal abscess [28–30]. Colorectal assessment should be sought. Proctoscopy and sigmoidoscopy are necessary to exclude anorectal cancer [28–30].

An important consideration in the management of anal carcinoma is the preservation of sphincter function, and this frequently involves combined radiotherapy and chemotherapy [31,32]. Surgical excision of the tumour, and of the inguinal lymph nodes when these are involved, is the treatment of choice. For small well-differentiated tumours, particularly adenocarcinomas, a local excision and repair is ideal. Small squamous carcinomas may respond well to radiotherapy.

Lymphatic or haematogenous dissemination of anogenital cancer dictates individualized multidisciplinary management. The management of ilioinguinal lymphadenopathy is controversial [33–35].

The prognosis for anal carcinoma is variable [32].

Extramammary Paget's disease (see Chapter 36)

Seventy-three per cent of cases of extramammary Paget's disease (EMPD) present as pruritus ani [1]. The association with an underlying malignancy is variable. Two reviews of the literature revealed only a 25% association [2,3]. Despite this, a search for a primary adenocarcinoma of underlying secretory glands should be carried out in perianal EMPD [4]. In some cases, the primary tumour is an anorectal, or even more distant, carcinoma [5,6]. The primary tumour and the Paget's cells in the epidermis are usually mucus secreting. Electron microscopy has shown the Paget's cells to be squamous in character in some patients, but more recent immunohistochemical and enzyme histochemical methods have demonstrated a close relationship between Paget's cells and sweat gland epithelial cells [7]. Anorectal carcinomas may arise from rectal mucosa or from the intramuscular glands. In the latter case, the malignant cells may track to the buttock through the ischiorectal fossa, and the Paget's plaque may begin at a distance from the anal margin, rather like an ischiorectal abscess. Topographical studies have shown that the plaque of Paget's disease is much larger than the visible lesion [8]. Any attempt at removal must be radical and histologically controlled [9].

Extensive surgery in conjunction with photodynamic therapy involving infusion of dihaematoporphyrin and an argon pumped dye laser has been effective in curing a patient with previous postoperative recurrences [10].

The pattern of the intramuscular glands and of the wide range of tumours that arise from them ('cloacogenic' carcinoma) resembles genitourinary rather than intestinal endothelium [11]. The carcinoma may spread, either to involve the anorectal mucosa, or through the perianal tissue to produce a chronic fistula-*in-ano* [12]. It may on occasion mimic a basal cell carcinoma both in clinical and histological appearance [13].

Miscellaneous

Extramucosal anorectal carcinoma presents as an inflammatory rather than a malignant condition and so is not biopsied (or not biopsied deeply) and the diagnosis is missed or delayed; there are many cases in the literature of cancers arising from anal glands adjacent to the anorectal wall and not emergent from the mucosa [1]. Cloacogenic carcinoma constitutes only 2–3% of anorectal cancer, but may behave aggressively [2]. It derives from remnants of the cloacal membrane proximal to the pectinate line where there is an area of transitional mucosa (between keratinized and non-keratinized squamous epithelium) penetrated by the anal glands. Most rectal cancer is adenocarcinoma (columnar epithelium).

Although basal cell carcinoma is the most common type of skin cancer, it is rare in the anogenital area, but over 100 cases have been reported [3,4]. Small basal cell carcinomas may respond well to irradiation.

Anorectal melanoma accounts for only 1% of all tumours of this area [5]; it may occur concomitantly with melanosis of the gastrointestinal tract [6].

Anogenital KS is essentially an HIV-related problem.

Fibrosarcoma, haemangiopericytoma, leiomyosarcoma, malignant fibrous histiocytoma, epithelioid sarcoma, dermatofibrosarcoma protuberans and spindle cell sarcoma may occur, presenting as painful or painless nodules, masses or swellings [7]. Other rarities include Merkel cell carcinoma [8], malignant eccrine poroma [9] and malignant schwannoma [7,10].

Non-Hodgkin's lymphoma of the perianal area has been described in HIV/AIDS [11].

Perianal infiltration, ulceration or abscess occurs in 5% of haematological malignancies [12]. Chronic lymphocytic leukaemia has presented as a painless firm white mass at the anal orifice, associated with weight loss and inguinal lymphadenopathy [13]. Perianal ulceration and suppuration have been reported as the presenting manifestations of primary lymphoma of the anus [14].

Perineal/perianal metastases from transitional cell carcinoma of the distal urethra [15], from rectal carcinoma [16] and from epidermoid anal canal carcinoma [17] have occurred. Carcinoma erysipeloides has been observed in the perineum and on the thigh in carcinoma of the bladder and prostate [18].

A periorificial form of Langerhans' cell histiocytosis/eosinophilic granuloma may cause ulcerating and vegetating lesions within the anal canal and in the perianal skin [19].

Anal manifestations of intestinal disease

These have been well documented [1]. Although they are usually non-specific, the particular skin manifestations of tuberculosis, amoebiasis, schistosomiasis and Crohn's disease may lead to diagnosis of the underlying disease by their typical histology.

Miscellaneous

Effects of topical corticosteroids

The prolonged use of potent topical corticosteroids for inflammatory conditions of the groins or perianal area can produce misleading appearances. Tinea incognito [1] is well recognized, but a persistent, deep, livid erythema of the perianal skin may not be regarded as primarily infective. Striae occur readily on the thighs. Multiple perianal comedones followed the application of a topical corticosteroid for 3 years [2]. 'Infantile gluteal granuloma' [3] (see Chapter 14), usually affecting infants of 4–6 months, may also occur in incontinent elderly patients [4].

Chronic perianal pain and the 'perineal syndrome'

A number of names have been given to sensations of pain localized to the anogenital region in the absence of evident organic cause [5,6]. Proctalgia fugax affects young adult males, and occurs chiefly at night in the form of a sudden cramp-like pain, which resolves in a few minutes. 'Coccygodynia', 'descending perineum syndrome' and 'chronic idiopathic anal pain' chiefly affect females. The pain is described as dull and throbbing. In 35 such patients, it was noted that the pain was precipitated by sitting, and that these three conditions differed from proctalgia fugax [5]. Electrophysiological studies gave variable results. There was a high incidence of previous sciatica and damage to the pelvic floor musculature. Treatment was disappointing. Rarely, sacral cysts and even chordoma can present with this symptomatology.

Such patients will present to surgeons or gynaecologists; however, dermatologists may be confronted by a similar problem in which a patient complains of short-lived episodes of intense burning, which may be accompanied by sweating, limited to the perineum or occasionally the scrotum. Attacks occur without warning, but may be brought about by a full rectum. In one patient, the attacks were severe enough to cause him to stop walking for some minutes. The patients tend to be stressed individuals, as are those with proctalgia fugax [6]. The skin is entirely normal.

The mechanism is unknown. Two patients appeared to have been helped by propantheline, suggesting a cholinergic mechanism [7]. However, the condition may also fall into the group of 'dermatological non-disease' [8],

in which the perineum was affected in eight out of 24 patients. The condition has also been reported in children suffering from intrafamilial stresses [9] (see also pp. 68.48 and 68.82).

Umbilical dermatology

Introduction

The umbilicus is considered here for convenience. Although the umbilicus is not strictly part of the genital apparatus, its evolution and connections link it to the pelvic region.

Structure and function

At birth, the umbilical cord contains two arteries and a vein, the rudimentary arachus (allantois) and the vitelline (omphalomesenteric) duct, enveloped in Wharton's jelly. After separation and retraction of the stump, an umbilicus of variable depth is formed. Persistence of the urachal or vitelline ducts at this 'carrefour embryologique' may cause trouble in early or later life. A deeply retracted umbilicus may be the site of infection or foreign bodies.

Congenital and developmental abnormalities [1]

These are all rare, more common in males, and usually brought about by failure of obliteration of the omphalomesenteric duct or urachus. They present as fistulae, cysts or polypoid tumours.

Patent urachal duct

The umbilical opening is lined by skin or a pouting mucous membrane. Urine may be seen to escape from it, particularly in the elderly, when an obstruction to micturition exists. The condition is rare.

Persistent vitelline duct and polyp

If a connection with the intestine persists, it may become inflamed or cause a faecal umbilical discharge. More commonly, the remains of the duct give rise to a polyp in later life [2]. This may be accompanied by intermittent bleeding or a more persistent mucoid discharge, sometimes profuse. A symptomless sterile umbilical discharge should always arouse suspicion. The histopathological features are those of intestinal mucosa. It may be mistaken for a pyogenic granuloma [3].

Periumbilical 'choristia'

Under this title (meaning dysgenetic translocation of tissue), Bellone *et al*. [4] described extending crusted erythematous periumbilical plaques, in which islands of intestinal mucosal cells were found in the epidermis.

Omphalocele

This form of abdominal hernia appears to be more common in African people. In 5 years in Ibadan, 33 cases were seen [5]. The minor form is caused by herniation of the umbilical cord; a major form is probably because of a fault of embryonic folding of the fetus.

Trauma and artefact

The umbilicus in the newborn

Haemorrhages may occur from slipped ligatures. The cord normally separates within a week of birth, and the raw surface is epithelialized by day 15. During this time, the umbilicus is prone to infection, especially in maternity hospitals and nurseries. Impetigo (pemphigus neonatorum) or, rarely, more severe bacterial infections may occur (see below). The 'absent navel' syndrome has been described as a sign of dystrophic epidermolysis bullosa [1].

Talc granuloma

This lesion, which is probably more frequent than is recognized, occurs in infants and very young children. It is

distinguished histologically from a pyogenic granuloma (on which it may supervene) by the doubly refractile talc crystals [2].

Pyogenic granuloma

This is a dull-red fleshy polypoid lesion, often pedunculated. Bleeding readily takes place from trauma. If it occurs early in life, it may be confused with a capillary haemangioma.

Ileo-umbilical fistula

This may follow laparotomy for Crohn's disease, or may rarely occur spontaneously [3].

Omphalith

In deeply set umbilici, an accumulation of sebum and keratin may lead to the gradual formation of a hard stone-like mass, which may remain unnoticed for many years until discovered accidentally or revealed by secondary infection or ulceration.

'Spontaneous gangrene'

This can occur without catheterization, possibly owing to minor trauma to the umbilicus [4]. Very rarely, the bladder and kidney may also be involved.

Unilateral skin necrosis of the buttock has been reported following indwelling umbilical artery catheterization [4–6], probably caused by thrombosis leading to occlusion of the inferior gluteal artery. A similar case was caused by misdirection of the tip of the arterial catheter [7].

Inflammatory dermatoses

Eczematous conditions and psoriasis

Allergic contact dermatitis is usually brought about by medicaments. Irritant dermatitis from soap and quaternary ammonium compounds also occurs. Psoriasis commonly involves the umbilicus.

Miscellaneous

A pilonidal sinus may occur [1]. Granulomas [2] may present as such, or with an associated discharge, infection, bleeding or profuse sterile purulent exudate. The umbilicus is not infrequently involved in bullous and cicatricial pemphigoid; it may be the site of presentation of the latter (see Chapter 41).

Perforating pseudoxanthoma elasticum occurs in the umbilicus, and was the only site involved in six obese multiparous American black females [3]. It is only rarely associated with systemic problems [4,5].

Pregnancy, Addison's disease and other pigmentary disorders increase the pre-existing pigmentation. Acanthosis nigricans causes acanthotic and papillomatous lesions in the perineum. Periumbilical staining (Cullen's sign) occurs in acute pancreatitis, and occasionally in ruptured ectopic pregnancy or with duodenal ulcer perforation [6].

Umbilical haemorrhage has been described as a complication of cirrhosis following gross ulceration of the umbilical vein [7].

Infections

Infection of the umbilicus in the newborn used to carry a high mortality. It still occurs in some countries. A number of bacterial organisms may be responsible, but staphylococcal, *Pseudomonas* and clostridial species [8] are the most important. Minor forms consist of oozing, crusting and cellulitis, but a spreading oedematous erythema, progressing to necrotizing fasciitis, is of very serious import. Septicaemia and its complications may supervene [9]. At any time in later life, but usually after middle age, the umbilicus may be the seat of intertrigo or candidosis. This is more common in the obese or in those with poor personal hygiene. Genital and perianal warts can occasionally be associated with similar lesions within the umbilicus [10]. Foreign bodies, inserted by children or psychotics, may be overlooked as a cause of purulent infection in a deeply set umbilicus. The periumbilical skin is a common site of schistosomiasis when it affects the skin [11]. Disseminated strongyloidiasis has presented as periumbilical purpura [12].

Tumours and implantations

The umbilicus is a site of implantation of endometriomas [13], which may clinically resemble melanomas. A unique case of postoperative endosalpingosis has also been reported [14]. Colonic mucosa was implanted in an infant, after colostomy for Hirschsprung's disease [15]. A single case of carcinoid of the umbilicus has been noted [16]. Paget's disease has also been recorded [17,18]. Skin metastases from neoplasms of the digestive tract occurred in

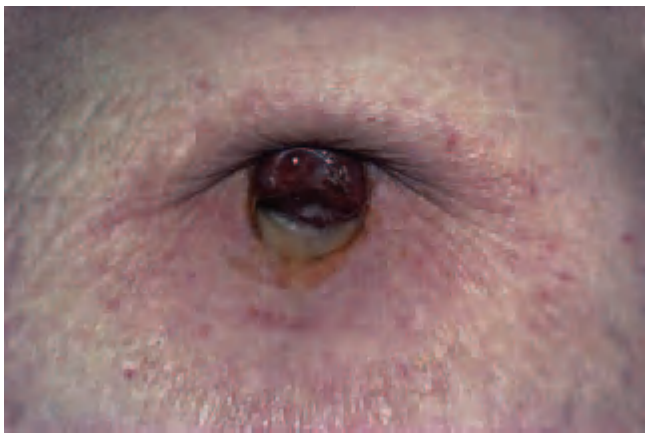

Fig. 68.46 'Sister Joseph's nodule'. (Courtesy of Dr J. Marks, Newcastle-upon-Tyne, UK.)

only 3% of 2187 cases [19], but the umbilicus is a characteristic site, especially for cancer of the stomach (Sister Joseph's nodule) (Fig. 68.46) [20], which was the primary source in 33 out of 40 cases [20]. The ovary, uterus and colon are responsible for most of the others [21–23], although the pancreas has also been a rare primary site [24]. A leiomyosarcoma of the small intestinal wall has presented in this way, as has a malignant peritoneal mesothelioma [25,26]. The lesions usually present as firm irregular nodules, but can occasionally infiltrate diffusely, or ulcerate and produce a fetid discharge. Such metastases were the presenting sign in 18 out of 40 cases, and were a major diagnostic feature in 28 cases [27]. The prognosis is always poor, but not entirely hopeless [28]. Histological identification of the site of the primary tumour may be difficult, and proved possible in only 21 of 85 cases [29,30]. Fine-needle aspiration of the nodule is not particularly helpful in reaching a diagnosis [30]. CT and surgical intervention are obligatory, because it may represent the earliest and only metastasis [23].

Chapter 69

Racial Influences on Skin Disease

D.J. Gawkrodger

Definition and classification of race

The concept of race was first developed in the 18th century as an arbitrary classification to help understand evolution and human variation [1]. The division of our species *Homo sapiens* into 'races' is to some extent artificial, given that the species shows a continuous variability of characteristics and all humans are apparently derived from common ancestors (see Chapter 2). However, there are obviously differences between groups of humans that, in the present context, have an influence on the appearance and susceptibility to disease. The classification into racial groups therefore allows an examination of the genetic and environmental influences on human morphology and on disease.

Definitions

Many definitions are unsatisfactory. A race has been defined as 'a group united by heredity', or 'a major segment of a species' or 'a breeding population' [2]. It can also be regarded as 'one of the divisions of humankind as differentiated by physical characteristics' [1].

Scientifically, race is a matter of genetic variation. A definition that takes this into account is that of Boyd, who defined race as 'a population which differs significantly from other populations in regard to the frequency of one or more of the genes it possesses' [3]. Even this gives considerable latitude to defining quite a small subgroup as a 'race'.

Ethnicity

Another concept to consider is that of ethnicity. This is different from race, but equally difficult to define. Ethnicity can be regarded as a 'people or tribe' and implies shared origins or social background, shared cultural traditions that are maintained between generations and, often, a common language or religion [1,4,5]. One or more of these things leads to a sense of identity as a group.

Racial origins

Little is known about how the races originally differentiated and why they assumed their own characteristics. Conventional theory outlines that a change in gene frequency can occur due to mixture (with other races), mutation, natural selection and genetic drift (i.e. the accidental loss of a gene from the communal pool) [6]. It is assumed that some differences, such as skin pigmentation, are an adaptation to environmental conditions, although often it is still unclear as to exactly what advantage is conferred. Migrations of populations over the last few thousand years have meant that in certain places there has long been

an admixture of genes. For example, many invaders who have swept over Europe in the last 2000 years, including Romans, Celts, Slavs and Moors, have left a genetic legacy behind them. In view of this, it is difficult to accept the concept of a 'pure' race. Isolated groups such as the Australian aborigines, who are thought to have migrated from the South Pacific Islands, may not have had much intermixture of genes from other races until recent times.

No racial group is characterized by a completely distinctive genetic make-up [7]. There is considerable genetic variation within racial groups and sharing of genetic characteristics between them.

Classification of races

In the past, classifications have relied on various physical characteristics such as stature, cephalic index, nasal index, prognathism, capacity of the skull, hair texture, hairiness, skin colour, hair and eye colour, and other special traits such as the epicanthic fold of the eyelid (a Mongoloid feature) or steatopygia (a heavy deposit of fat in the buttocks, seen in Bushmen and Hottentot women) [8]. A satisfactory classification must take most of these factors into account. There are three main divisions—namely, Mongoloid, black African and Caucasoid—which account for over 90% of the world's population [8]. The remaining groups, grouped together by Coon [9] as the Australoid and Capoid races, occupy a doubtful position, as they frequently show some features of the other races. These main races broadly show a geographical grouping. Within each 'geographical' race, it is possible to define 'local' races and so on. A convenient division of the geographical races, albeit with some reservations, is as follows [8–10]:

1 Australoid: Australian aborigines, Melanesians, Papuans and Negritos.
2 Capoid: Bushmen and Hottentots.
3 Caucasoids: Europeans, peoples of the Mediterranean, Middle East and most of the Indian subcontinent, and the Ainu of Japan.
4 Mongoloids: peoples of East Asia, Indonesia and Polynesia, native Americans and Eskimos.
5 Negroids: black people and pygmies of Africa.

Characteristics and variations between racial groups

There is a considerable overlap of features between the racial groups; for example, not all black Africans have tightly curled hair and not all Caucasoids have a lightly pigmented skin. Some characteristics may show considerable variation within a race—for example, head shape for Caucasoids is very variable, but other features are much more constant; for example, straight, black hair is almost universal in Mongoloids.

Australoids. Australian aborigines show some black African features such as black skin, a broad nose and prognathism, but their hirsutism, full beards and wavy hair are more Caucasoid. In addition, they have heavy eyebrow ridges [1–3].

Capoids. Bushmen and Hottentots show mainly black African characteristics, but some of their features are possibly Caucasoid (e.g. thin lips) or Mongoloid (e.g. a type of epicanthic fold) [1,4,5].

Caucasoids. There are at least four Caucasoid subraces extending from Europe, the Mediterranean and North Africa across to the Indian subcontinent. All show wavy hair and abundant facial and body hair. The skin colour is fair to brown and the nose is usually narrow. The Ainu of Japan are classified as Caucasoids, mainly because of their heavy body hair, curly scalp and beard hair and European-like facial features [1,4,5].

Mongoloids. This group extends through the extremes of climatic conditions, from the extreme north (Eskimos) to the equator (Malaysian types) and includes the Chinese and the native Americans in North and South America. Body hair is scanty and scalp hair is straight and black [2,3].

Negroids. Originally confined to Africa. The main characteristics are dark pigmentation, tightly curled hair and a broad nose [4,5].

Jews. Jews, on the whole, are not a race but a cultural community. They usually approximate genetically to the community in which they live [2,5]. However, certain genes are more frequent in certain Jewish communities than in the surrounding population.

The black people of North America are regarded by some as a local race [6]. A study of blood groups in American

blacks has revealed the following admixture of Caucasoid genes: in Oakland (California) 22%, in Detroit 26%, in New York 19%, in Charleston 4% [3]. Some also may have native American genes [4]. Many of the studies on dermatology in 'Negroids' have been done on black Americans and hence may not be strictly applicable for all black Africans.

There is now a tendency in the USA and elsewhere for individuals with any degree of black African descent to adopt the term 'black'. This has come about because of a new consciousness by this group of a shared identity. In some places, the term 'black' has been more widely used and may be implied to include some darkly skinned Caucasoids, such as Mediterranean or Indian people [7]. Quite often, the description 'Afro-Caribbean' is used and, in North America, recently there has been a tendency to use 'African American'. The term 'black African' will therefore often be used to avoid any confusion about which group is being referred to. The terms Australoid, Mongoloid and Caucasoid will also be used to describe racial groups.

Ethnic groups

Some groups of humans do not fit easily into a race, for example pygmies, but ethnicity creates a new category for each group [1,2]. Ethnicity is a social phenomenon with imprecise and fluid boundaries. It is often used, incorrectly, as interchangeable with 'race' [3]. Broad ethnic divisions, for instance into Asian or Afro-Caribbean, may have limited value due to the great diversity of cultural and other variations within the groups. Nonetheless, because of the association with social and cultural factors, ethnicity often has a bearing on disease.

A current recommendation is that, in describing disease or characteristics in a racial or ethnic group, the most precise description possible is given for that group [4]. This will be followed when appropriate, but where it seems desirable to look at racial characteristics more generally, the broad racial groupings will be applied.

Racial variations in the structure and function of the skin

The degree of pigmentation is one of the most obvious and immediate factors in distinguishing the main geographical races. Other differences in the structure and function of the skin are less obvious and not so well studied, but are of some importance [1].

REFERENCE

Pigmentation

Variation

Skin colour depends largely on the content and distribution of melanin in the epidermis. In Caucasoids, the constitutive skin colour (i.e. the amount of melanin pigmentation in the absence of sun exposure) is darkest on the upper thigh and lightest on the lumbar area, whereas in black Africans the abdomen is darkest, although the lumbar area is also the lightest [1]. Males are normally darker than females. In general, the geographical distribution of the intensity of racial pigmentation correlates with the areas of greatest sun exposure, although there are anomalies such as the Tasmanian Australoids, who were dark although they lived in a temperate latitude, and native Americans (Mongoloids), who have a similar pigmentation across the whole continent of North America.

Melanosomes

The density of melanocytes differs between various parts of the body [2] and is similar in most races, although melanocytes may be more numerous in the Australian aborigine [3]. There are differences in the size, distribution and shape of melanosomes. In Caucasoids, the melanosomes are small and aggregated in groups of three or more within a membrane in the keratinocyte [4] and are broken up by lysosomal enzymes before reaching the stratum corneum [5]. In black Africans and Australoids, the melanosomes are larger, distributed singly within keratinocytes, and persist up to the stratum corneum.

Inheritance

Skin colour is continuously variable and its inheritance is

complex. Over the last few years, mutations have been found in redheaded people, in the melanocortin 1 receptor (MCR1), for which the ligand is α-melanocyte-stimulating hormone, that lead to a shift from eumelanin to phaeomelanin production [6]. Between races, there is allelic diversity at the MCR1 and this is greater in pale non-African populations [7]. The exact interpretation of this is still to be resolved.

Physiological effects of skin pigmentation

The minimal erythema dose in black African skin is about 33 times that for Caucasoid [4]. Obviously, a pigmented skin protects against sunlight and particularly against sunburn and skin cancer. However, it seems doubtful that protection against skin cancer conveys an evolutionary advantage, as under 'natural' conditions survival is unlikely to be affected. According to Wasserman [8,9], racial pigmentation is a secondary phenomenon, related to resistance to infection. The disadvantages of a pigmented skin are increased heat absorption and reduced vitamin D synthesis. Black Africans absorb 30% more heat than Caucasoids, although this is partially offset by more efficient sweating [10,11]. Ultraviolet B radiation at low dose enhances natural killer cell activity in black individuals but not in white subjects, suggesting increased immunological resistance to disorders such as photoinduced skin cancer [12].

Hair

Variations in hair depend on a wide range of genetically controlled factors, both between and within races [1]. Hair form is inherited separately from skin colour, and of the two is the more dominant.

Hair forms

Hair form depends on the three-dimensional structure of the hair shaft. There are broadly four hair types—straight, wavy, helical and spiral [2,3]. The helical forms coil with a constant diameter. Spiral forms coil with a decreasing diameter outwards; the extreme of this is 'peppercorn' hair, which is tightly curled and shows multiple kinks [4]. Hair that is elliptical in cross-section is curly, whereas round hair is straight.

Mongoloid hair is usually straight, circular in diameter, and with the largest diameter of all the races. The hair in black Africans and Capoids tends to be short, helical or spiral, flattened or elliptical in cross-section, and midway between the Mongoloid and Caucasoid in thickness. Spiral hair is produced by hair follicles that are curved and upwardly convex towards the epidermis. Black African hair tends to be drier and more brittle than the hair of other races, probably due in part to its intrinsic properties [5]. Hair density in black Africans is less than in Caucasoids (mean ± SD 190 ± 40; 227 ± 55 hairs/cm^2) and hair growth is slower (256 ± 44; 396 ± 55 μm/day) [6]. Telogen counts are higher in black Africans than in Caucasoids, although this contrasts with the lesser degree and later onset of androgenetic hair loss observed [6].

In Caucasoids, the hair is variable and may be straight, wavy, or helical and round or oval in cross-section. It tends to be the thinnest in diameter of all the races. Despite these variations for scalp hair, beard, pubic and eyelash hair is elliptical in all races. The morphology and chemical composition of hair is similar in all races [7].

Hair colour

Mongoloids, black Africans, Capoids and Australoids have hair that is predominantly black, although it may be red in colour. Caucasoid hair is widely variable: in northern Europe it tends to be blond, in southern and eastern Europe it is commonly black [8]. However, blond hair may be found in North Africa and the Middle East, and is even seen in some Australoids. Greying of the hair starts on average in the third decade in Caucasoids, and in the fourth decade in black Africans. Caucasoids show more balding over the vertex than do black Africans [9].

Body hair

Caucasoids have earlier and greater axillary and beard growth than Mongoloids [10] and more extensive male secondary sexual hair. In general, Mongoloids have less body hair than Caucasoids, with black Africans and Capoids occupying an intermediate position.

Selective advantage of hair forms

Any evolutionary advantage conferred by the different hair forms is unclear. Short, curly hair facilitates evaporation of sweat, but thick wavy hair provides a greater degree of physical protection. Hair, especially on the scalp, protects against ultraviolet radiation.

Sweat glands

Eccrine glands

There is little or no difference in the sweating ability of black Africans in comparison with Caucasoids [1]. A study in the Bantu did show a greater number of sweat glands per unit area than in European Caucasoids [2], but such changes are now thought to be due to adaptation to climatic factors [3]. Increased sweating is known to be accompanied by hypertrophy of the sweat glands [4]. Indeed, in Australoids, sweat glands were noted to be larger but not more numerous than in Caucasoids [1].

Keratosis punctata, a hyperkeratosis of the acrosyringeal orifice seen on the palmar creases, is found in 1–2% of black Africans and in less than 0.1% of Latin Americans, but it is not seen in European or Middle Eastern Caucasoids [5].

Apocrine glands

An early paper mentions that apocrine glands are more numerous in black African skin than in Caucasoid skin [6], but the variation in the distribution of apocrine glands between individuals is so great [7] that it is difficult to place much emphasis on this report.

Sebaceous glands

Black African skin showed no consistent difference in sebaceous gland activity as compared with Caucasoid skin [1]. There have been no substantial studies on the comparative number of sebaceous glands in the different races.

REFERENCE

1 Pochi PE, Strauss JS. Sebaceous gland activity in black skin. *Dermatol Clin* 1988; **6**: 349–51.

The epidermis

Comparative studies have been performed on black African and Caucasoid epidermis. The stratum corneum in both has an equal thickness, although in black skin there are more cell layers and it requires more tape strips to remove it than Caucasoid stratum corneum [1]. The stratum corneum in black subjects seems to show greater intracellular cohesion than in Caucasoids. It has a higher lipid content [2] and an increased electrical resistance [3]. There is no difference in corneocyte surface area between Caucasoids, Mongoloids and black Africans, but desquamation was up to 2.5 times greater from black skin, compared with the other two races [4]. Recently, it has been found that quantities of cerumides in the stratum corneum are lower in black Africans than in Caucasoids [5]. The composition of ear wax (cerumen) varies between different races: in black Africans and Caucasoids, it is honey-coloured, wet and sticky; in Mongoloids, it is grey, dry and brittle [6].

Not surprisingly, black African epidermis is more effective at blocking the transmission of ultraviolet radiation, transmitting only 7.4% of UVB as compared to 29.4% for Caucasoid epidermis [7]. Black African skin shows a higher transepidermal water loss than Caucasoid [8]; this is thought to be due to differences in thermoregulation and in the stratum corneum lipids. Some substances do not penetrate black skin as well as Caucasoid, but this is not universally the case [9].

The dermis

Black African skin may be slightly more extensible than Caucasoid [1], although the difference is small. The vasodilatory response after exposure to nicotinate is reduced in black Africans compared with Caucasoids, and hyperaemia after vasoconstrictive stimuli may be different [1,2].

Peripheral vascular responses to cold

Eskimos (Mongoloids) are able to maintain a higher hand blood flow than Caucasoids under identically cold conditions [1]. At –12°C, the finger temperature in black Africans fell more rapidly (and the metabolic rate rose less rapidly) than in Caucasoids under similar conditions [2]. The extent to which these observations represent physiological adaptations, rather than significant interracial differences, is not known.

Common diseases that show racially dependent variations

Many dermatoses manifest themselves similarly in the different races, but not infrequently—due to differences in pigmentation, hair or other factors—the appearance of a disorder varies depending on the racial constitution of the individual. It is not intended here to provide a comprehensive list of every possible racially influenced dermatosis, but rather to select the most important differences, especially for the commonest conditions.

Dermatoses that in white Caucasoid skin appear red or brown appear black, grey or purple in pigmented skin. Furthermore, any pigmentation may mask an erythematous reaction. Inflammation in pigmented skin may provoke reactions of a hyperpigmentary or hypopigmentary nature that persist after the initiating eruption has faded [1]. These pigmentary reactions may be of greater concern to the patient than the eruption itself and are often the reason why medical help is sought. Pigmented skin may have an inherent tendency to show reaction patterns that are different from those seen in white Caucasoid skin. For example, follicular, papular and annular patterns are seen more frequently in Afro-Caribbean skin than in Caucasoid [1].

There are few data on the frequency with which people of different races attend a dermatologist. In an office-based study in the USA, patients classified as 'white' or 'Asian or Pacific Islander' attended a dermatologist proportionally more than 'black' people or 'native Americans or Eskimos', but this may well have been because of economic or social reasons [2].

Some general texts give a useful overview of this topic [3,4].

Acne

The prevalence of acne seems to be similar in both North American black Africans and Caucasoids [1], although it may be more severe in the latter [2]. However, acne is less common in the Mongoloid Japanese [3]. In pigmented skin, acne lesions may become hyperpigmented (Fig. 69.1).

'Pomade' acne is seen in certain Afro-Caribbean groups, due to the custom of anointing the scalp hair with pomades, oils and creams. Up to 70% of long-term users of pomades suffer from this complication [4]. It may be seen in children as well as adults. There is some evidence that black Africans react to comedogenic substances in a different way from Caucasoids. Kaidbey and Kligman studied the comedogenic effects of coal tar in Caucasoids and

Fig. 69.1 Pigmentation associated with acne. (Courtesy of Dr A.G. Messenger, Royal Hallamshire Hospital, Sheffield, UK.)

black Africans and found that whereas Caucasoids produced an inflammatory response with papules and pustules, black Africans did not usually show this but rather developed small comedones [5].

Atopic eczema

The inheritance of atopic eczema is 'polygenic'. It is a disease that is seen worldwide and in all races. Comparative figures are not generally available. There was an impression in the UK that atopic eczema may be more common in Caucasoids from the Indian subcontinent [1], but a subsequent cohort study has not confirmed this [2]. It may be that over-representation of Asian children with atopic eczema in dermatology clinics results from a lower level of familiarity with the disease in this community. In another study, from London, UK, it was suggested that

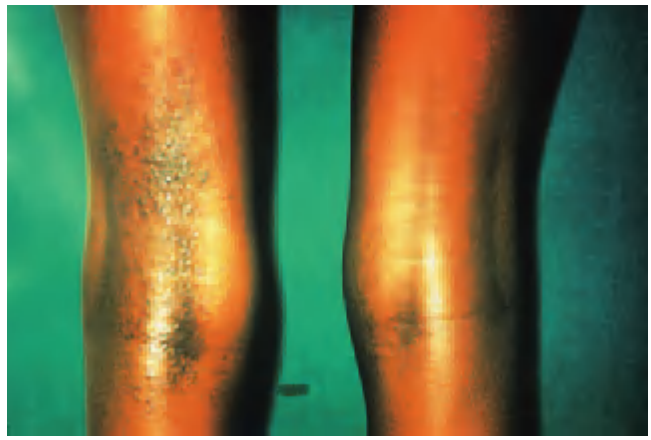

Fig. 69.2 Hyperpigmentation associated with atopic eczema.

atopic eczema is more prevalent in 'black Caribbean' children than in other ethnic groups, including Asians [3]. In India, it is suggested that atopic eczema is not as severe as in Western countries [4].

In black Africans, there is a tendency towards the development of follicular lesions in atopic eczema, and a micropapular follicular form of lichenification resembling lichen nitidus is common [1,5,6]. The follicular eruption may predate the onset of other features of the disease [5,6]. Flexural involvement may be less common than in other races, but the severity of the eczema seems to be no different [3].

Lichenification is seen in all races, but is particularly pronounced in Mongoloids. Postinflammatory hyperpigmentation is a problem in black skin (Fig. 69.2).

Contact dermatitis

Studies using irritants suggest that black African skin is less susceptible to irritants than Caucasoid skin [1], although the difference is not detectable when the stratum corneum has been removed. A comparison of the susceptibility of the skin of Japanese and Caucasoid women revealed that for acute and—to a lesser extent—cumulative irritant exposures, Japanese skin was more easily irritated than was Caucasoid [2].

There is little evidence that there is any racial predisposition for the development of allergic contact dermatitis. A comparative study of Caucasoids and African Americans found similar rates of sensitization to common allergens, the only differences being higher frequency of contact allergy to *para*-phenylenediamine (PPD, e.g. in hair dye) and imidazolidinyl urea (a preservative) in African Americans [3]. The differences are probably due to increased use of hair dyes and hair-care products in African Americans, although racial differences in N-acetylation in the skin may also explain the PPD finding [3]. Others have confirmed few differences between races in contact sensitization [4]. A study from Singapore of contact allergy to topical medicaments showed no differences between Chinese, Malays and Indians [5]. Overall rates for a 'sensitive skin', as judged by telephone interview, did not differ between Afro-American, Asian, Euro-American or Hispanic women, but Afro-Americans had less reactivity to environmental factors, Asians complained more of itch and reacted more to temperature and wind, Euro-Americans had less reactivity to cosmetics but reacted more to wind, whilst Hispanics had lower skin reactivity to alcohol [6].

However, certain patterns of contact dermatitis are recognized in specific groups due to the use of traditional or ethnic preparations. Indian women may develop an allergic contact dermatitis to materials in 'Bindi', a pigment applied as a paste or powder to the central forehead for religious and social reasons [7].

Some reported differences in the prevalence of contact allergy to certain allergens are likely to represent a difference in exposure. The equal sex incidence of nickel allergy in Nigeria [8], distinct from the female preponderance in most Western countries [9], is probably due to the equal popularity of the wearing of jewellery by both men and women in Nigeria. Clinically, contact dermatitis appears different in black skin as compared with Caucasoid. In the latter, acute contact dermatitis produces vesiculation and exudation, whereas in black skin, lichenification and disordered pigmentation are more common. Hyperpigmentation occurs after contact with mild irritants [10], and certain chemicals—for example, phenolic detergents [11]—cause hypopigmentation.

Kaposi's sarcoma

The appearance of the lesions of acquired immune deficiency syndrome (AIDS)-related Kaposi's sarcoma can show variation between the different races. In black Africans, lesions may vary from being slightly hyperpigmented to being a deep purple in colour [1]. The classical form of Kaposi's sarcoma is commonest in mid-European Caucasoids of Jewish lineage, and occurs 10 times more frequently in males than in females [2]. Another, more rapidly progressive form, affects black Africans in central Africa [3].

Keloid formation

Keloids occur in all races, but are more common in black Africans and Mongoloids than in Caucasoids. The exact incidence ratio for black Africans over Caucasoids varies from twice to 19 times, according to the study consulted [1]. In Malaysia, Chinese are more prone to keloids than Indians or Malays [2]. In Hawaii, keloids are five times more common in the Japanese, and three times more frequent in the Chinese, than in Caucasoids [3]. Keloids can occur anywhere on the body, but have a predilection for the shoulders, ears, upper back and anterior chest (Fig. 69.3). They usually follow trauma to the skin, but can arise spontaneously. In black Africans, they may develop in areas of scarification. Treatment options have been reviewed in detail recently [4].

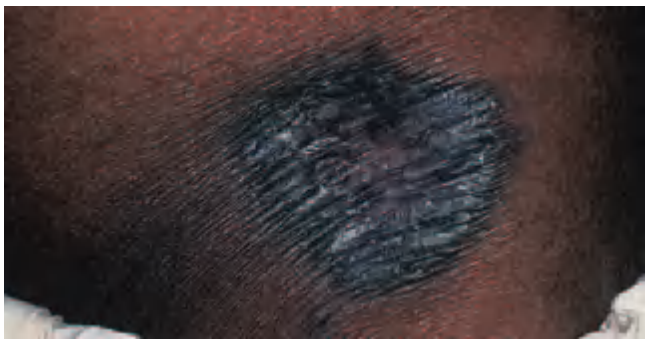

Fig. 69.4 Hyperpigmented lichen planus.

Lichen planus

Lichen planus is a worldwide problem and occurs in all races. In Singapore, lichen planus was proportionally more common in Indians and less common in Chinese and Malays than would be expected, given the composition of the local population [1]. There are no other studies to suggest a racial predisposition, although the appearances may differ between races. In darkly pigmented patients, papules of lichen planus typically are purple in colour (Fig. 69.4). Oral lesions are said to be uncommon in black Africans but frequent in Caucasoids, while the hypertrophic variant, and possibly the erosive type, are more often seen in black Africans [2]. In black Africans,

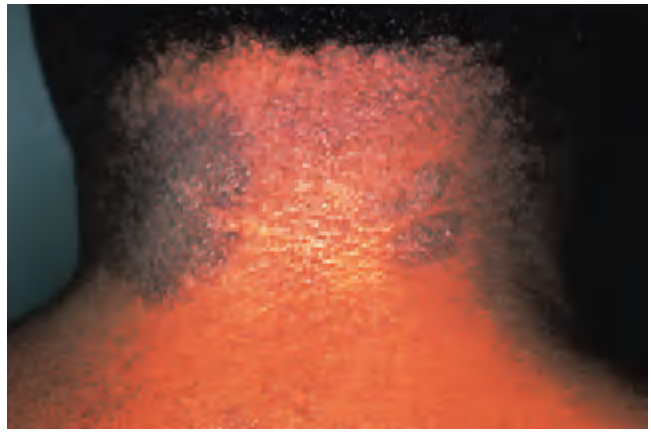

Fig. 69.5 Hyperpigmented lichen simplex chronicus.

postinflammatory hyperpigmentation may be prolonged [3]. In Asian Caucasoids, itching is often not prominent and hyperpigmentation is a more common presentation [4]. Histologically, Asian Caucasoids show less inflammation and basal cell degeneration than black Africans or European Caucasoids [4].

Lichen simplex chronicus

Lichenification is particularly readily induced in Mongoloid and black African skin (Fig. 69.5). Lichen simplex chronicus may affect the neck, forearms and lower legs, and be associated with hyperpigmentation [1]. A common variant is lichen simplex chronicus of the scrotum in elderly black African males.

Lupus erythematosus

It used to be said that lupus erythematosus was uncommon in black Africans, but this is no longer believed to be the case. Indeed, the black populations of North America and North Africa seem to develop severe forms of the disease [1]. In New Zealand, systemic lupus erythematosus was found to be three times as common in Mongoloids as in Caucasoids [2].

Lupus erythematosus is closely associated with certain genetic and human leukocyte antigen (HLA) markers. North American and European Caucasoids with systemic lupus erythematosus show an increased frequency of a C4A, CYP21A gene deletion, often in association with the HLA-B8, -DR3, C4A*Q0 extended haplotype [3]. In African Americans, a large C4A, CYP21A gene deletion, particularly associated with HLA-B44, -DR2 and -DR3 alleles, is a strong genetic risk factor for the development of systemic lupus erythematosus [3]. Complete or partial deficiency of C4A allele has also been identified as a genetic determinant of systemic lupus erythematosus in Chinese and Japanese Mongoloids [4]. West Indian, and to a lesser extent North African, black people have a more severe form of systemic lupus erythematosus than European Caucasoids, mainly due to a higher prevalence of renal disease [1]. The mortality from systemic lupus erythematosus in African Americans is higher than in Caucasoids [5]. Discoid lupus erythematosus also seems to have a nearly similar incidence in all races. In those with a dark skin, the face, scalp and—commonly—the lower lip tend to be affected. Hypopigmentation and gross scarring may result.

Although the difference in prevalence of lupus erythematosus and other autoimmune diseases in Africans in West Africa compared with American Africans may be due to genetic admixture, exposure to malaria has also been proposed as being important [6–9]. Whilst on the one hand scanty congenital *Plasmodium* parasites have been proposed as a cause of autoimmune disease [8], several studies have suggested that malaria may induce a form of tolerance against autoimmune disease; altered macrophage function, tumour necrosis factor levels and nitric oxide production have been suggested to be protective. Antinuclear antibodies and antiphospholipid antibodies occurring in patients with malaria have different specificities compared with those in autoimmune disease [7]. Experimentally, serum from mice infected with *Plasmodium chabaudi* slows development of autoimmune disease when injected into a strain of lupus-prone mice [9].

Melanocytic naevi

Caucasoids have more melanocytic naevi than other races. Black Africans have the fewest naevi, with Mongoloids occupying an intermediate position [1]. Caucasoid children had a median total number of 17 naevi, compared with 2.5 in non-Caucasoids [1]. Young Caucasoid adults had a median of 61 naevi, compared with 16 for non-Caucasoids [1]. A study of schoolchildren in Queensland, Australia, confirmed these findings, but found an even higher prevalence of naevi [2]. Children less than 12 years old had a mean of 28 naevi, with boys having significantly more than girls, and those with a pale skin and light-coloured hair having the highest prevalence [2]. Non-Caucasoid heritage has a protective effect for naevus development, independent of pigmentary characteristics [2].

Palmoplantar keratodermas (Chapter 34)

Some palmoplantar keratodermas are said to be seen more often in black Africans than in other races [1]. One example is keratosis punctata of the palmar creases [2], in which small crateriform pits are visible on the palmar creases (Fig. 69.6). *Focal acral hyperkeratosis* is a type of papular keratoderma, dominantly inherited in familial cases, that occurs almost exclusively in black Africans [3]. It is characterized by oval or polygonal papules, which may show central pigmented pits, situated on the borders of the palms and soles.

Photodermatoses

Racial pigmentation protects from some of the immediate and long-term adverse effects of sunlight. However, even a pigmented skin may be sunburnt, although it may be difficult to see the erythema because of the pigmentation [1]. Conditions such as polymorphic light eruption occur in all races, but some have a particular presentation depending on the race of the individual. In black Africans or Australoids, for example, an actinic cheilitis (or discoid lupus erythematosus) may affect the lower lip, which may not be protected by the same amount of pigment as on other sites of the body.

One photodermatosis that seems to have a racial predilection is actinic prurigo of native Americans [2], although it may be a form of polymorphic light eruption [3] (Chapter 24). It may present as a lower lip cheilitis, but also produces a conjunctivitis, pterygium and eyebrow alopecia [2]. Actinic prurigo has a female : male ratio of 3 : 1 and usually has an onset in the first two decades of life [4]. Those with an early onset tend to have cheilitis and may improve; those with a later onset have a milder disease, which may be more persistent [4].

Pityriasis rosea

In black Africans, this eruption shows several unusual features. It shows an 'inverse' pattern, with lesions on the face, neck, extremities and lower abdomen, rather than on the trunk as is usual [1]. In addition, it may be papular, may affect the palms and soles, and shows a brown-grey or even purple pigmentation [2,3]. The recurrence rate seems to be higher in black Africans than in other races [4] and the hyperpigmentation that may follow can persist for some months.

Postinflammatory pigmentary changes

Pigmented skin shows more of a pigmentary reaction following trauma or inflammation than non-pigmented or lightly pigmented skin. In black Africans, it is also not uncommon to see secondary hypopigmentation after eczema, pityriasis alba, sarcoidosis, leprosy, herpes zoster, pityriasis versicolor or other common eruptions [1,2]. It may also follow cryotherapy and the topical use or intralesional injection of corticosteroids. Table 69.1 lists causes of hypopigmentation in a pigmented skin [1–3]. Sometimes unusual patterns of pigmentation are found; for example, black Africans with systemic sclerosis may develop a

Table 69.1 Causes of hypopigmentation in a pigmented skin.

Division	Disorders
Congenital or genetic	Albinism, piebaldness
Infections	Leprosy, onchocerciasis, pinta, pityriasis versicolor, herpes zoster
Papulosquamous disorders	Pityriasis alba, pityriasis rosea, pityriasis lichenoides chronica, psoriasis, seborrhoeic dermatitis
Physical or chemical agents	Burns, cryotherapy, ammoniated mercury, hydroquinone products, fluorinated corticosteroids
Postinflammatory	Discoid lupus erythematosus, systemic sclerosis, sarcoidosis, some eczematous eruptions
Miscellaneous	Vitiligo, idiopathic guttate hypomelanosis

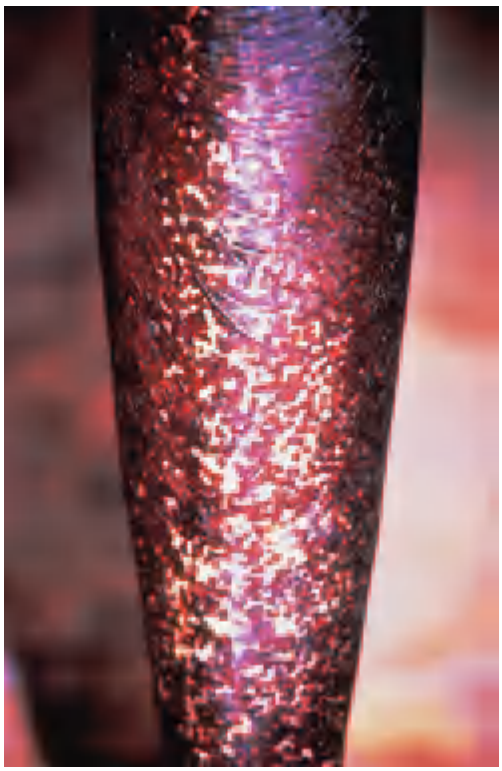

Fig. 69.7 Onchocerciasis showing 'leopard skin' depigmentation. (Courtesy of Dr M.E. Murdoch, Watford District General Hospital, Watford, UK.)

mottled and vitiligo-like hypopigmentation [3] (Chapter 56). Complete or patchy 'leopard skin' depigmentation may be seen with onchocerciasis (Fig. 69.7). On the other hand, some dermatoses result in hyperpigmentation, and it is not unusual to find both hyper- and hypopigmentation coexisting in the same individual.

Hyperpigmentation may occur in black African skin with acne, eczema, sarcoidosis, psoriasis, mycosis fungoides, lichen planus, fixed drug eruption and lupus erythematosus, and frequently is seen when the skin is lichenified, as in chronic eczema [2]. Hyperpigmentation, particularly of the face, may also be acquired due to exposure to a variety of agents. These include exogenous ochronosis from hydroquinone-containing skin-bleaching creams, and mercury deposition from skin-lightening creams containing mercury, and also from exposure to photosensitizing drugs and herbal potions [4].

Psoriasis

The genetic basis for psoriasis is well established, although not well understood. It is relatively common in European Caucasoids (prevalence about 2%), although within the Caucasoid group it is said to vary, being more common in Parsees than in Hindus or Moslems [1]. A high prevalence is reported in East Africans [2] and a low prevalence in West Africans [3–5], which may explain the low prevalence in African Americans. Psoriasis is almost unknown in the Mongoloid native Americans [3] and Eskimos [6], and in Australian aborigines [7]. It is rare in the Japanese (Mongoloid), although the prevalence in the latter is increasing [8]. The prevalence in Mongoloids in Hong Kong, mainland China and Japan was estimated to be 0.3% [9].

In black skin, psoriatic plaques may appear violaceous or bluish black due to pigmentary incontinence. Grey, silvery scales may be seen. Postinflammatory hyperpigmentation may be left after clearing of the lesions [10]. This may be a persistent cosmetic disability.

Sarcoidosis

In the USA, sarcoidosis is 10 times more common in African Americans than in Caucasoids [1]. Skin signs are seen in between one-tenth and one-third of patients with sarcoidosis [2]. Erythema nodosum is the commonest non-specific lesion of sarcoidosis, but is much more frequent in Caucasoids than in black Africans [3,4]. In Africans, the commonest sarcoidal skin lesions are flesh-coloured or slightly hypopigmented papules which tend to occur around the nose, mouth and occiput [2]. Hypopigmented macules, violaceous plaques (often on the face or arms) and subcutaneous nodules are also seen.

Ulceration may occur. Lupus pernio is apparently infrequent in black Africans [2].

In contrast to the American experience, sarcoidosis was said to be uncommon in West Africans, but this may not be the case [5]. It has a very low reported prevalence in the Far East.

Skin cancer

Most forms of skin malignancy and sun-induced degenerative change are more common in North European Caucasoids than in other racial groups. Black Africans have the lowest incidence (1/70 that of Caucasoids) of non-melanoma skin cancer [1], with Mongoloids occupying an intermediate position. Genetic variations that have a racial aspect, e.g. the allelic diversity seen in pale non-Africans for the MC1R locus, will have a bearing on racial susceptibility to skin cancer [2]. In black people, squamous cell carcinoma is the commonest skin tumour [3], as opposed to basal cell carcinoma in Caucasoids. Scarring—for example, from burns or discoid lupus erythematosus—is a predisposing factor in squamous cell carcinoma in Africans [4]. The prognosis in black Africans in the USA is generally worse than in Caucasoids, because of later presentation or more aggressive disease [5]. Basal cell carcinoma is often pigmented in non-Caucasoids.

Malignant melanoma is 10 times more common in North American 'European' Caucasoids than in African Americans, with an incidence in New Mexican Hispanic Caucasoids and Puerto Rico Hispanic Caucasoids of 3.7 and 1.6 times that of African Americans [6]. Puerto Rico Hispanics have more admixture of African genes than Hispanics from New Mexico. In black Africans, malignant melanoma mostly affects the soles or palms [3]. Presentation may be delayed. Malignant melanoma of the sole of the foot, in North America, has a similar incidence in black people as in Caucasoids [7]. Extradermal acrolentiginous tumours with a poor prognosis—e.g. those involving the vulva, cervix, vagina or the anorectal area—made up 44% of new primary malignant melanomas in a study of black American women [8]. In the Mongoloid Japanese, the acral lentiginous type of malignant melanomas makes up a large proportion of cases and the incidence at this site is similar to that for Caucasoids in other sites [9].

Japanese residents in Hawaii had a rate for non-melanoma skin cancer that was 88 times higher than that reported in Japan [10]. This higher rate was attributed to increased sun exposure, and possibly to arsenic exposure. The incidence of basal cell carcinoma in Hong Kong Chinese trebled between 1990 and 1999 (0.32–9.2/100 000/year) and that of squamous cell carcinoma doubled (0.16–0.34) [11].

Syphilis

The primary chancre is similar in Caucasoids and black Africans, but the manifestations of secondary syphilis can be different. In Caucasoids, macular lesions are common, but in black Africans, follicular and papular forms are more frequent and may be hyperpigmented [1]. Annular secondary syphilis is almost unique to Negroids [2]; corymbose forms (a central lesion with surrounding small satellites) are also seen [1]. Palmoplantar lesions in black Africans may be keratotic. The non-venereal treponematoses yaws, pinta and bejel are endemic in certain parts of the world. No racial predilection exists, although the appearances may be modified in different races.

Systemic sclerosis

There are racial differences in the patterns of disease for

Fig. 69.8 Vitiligo. (Courtesy of Dr A.G. Messenger, Royal Hallamshire Hospital, Sheffield, UK.)

people affected by systemic sclerosis (scleroderma). African Americans and Hispanics (who often have inherited some black African genes) are more likely to have diffuse skin involvement, pigmentary change, digital ulceration and pulmonary hypertension than Caucasoids, who exhibit more facial telangiectasia and associated hypothyroidism [1]. The Choctaw Native American Indians (Mongoloids) have a high prevalence of systemic sclerosis that has been identified as being due to a defect in a gene for fibrillin 1 on chromosome 15q, dating from 10 generations ago ('founder effect') [2].

Vitiligo

Vitiligo has the same incidence in all races [1] but its manifestations are much more significant in those with a dark skin than in lightly pigmented individuals (Fig. 69.8). In Afro-Caribbeans, vitiligo may show a 'trichrome' pattern, with hypopigmented as well as depigmented areas.

Hair disorders

Dissecting folliculitis (Chapter 63)
SYN. DISSECTING CELLULITIS; PERIFOLLICULITIS CAPITIS ABSCEDENS ET SUFFODIENS

This is an uncommon, chronic, progressive and suppurative scalp disorder that almost exclusively affects Afro-Caribbean males. Painful, boggy, sterile abscesses form on the scalp (Fig. 69.9) and are connected by sinus tracts [1]. As the disease progresses, scarring and alopecia are seen, and keloids may form [2]. The cause is unknown. Treatment has been difficult in the past as intralesional steroids and systemic antibiotics provide only partial relief, but it is now known that isotretinoin is effective in this condition, although it needs to be continued for 4 months after clinical control is achieved to prevent relapse [3]. Resistant cases may require surgical excision and grafting [4]. Dissecting folliculitis may be associated with acne conglobata and hidradenitis suppurativa, to form the so-called 'follicular occlusion' triad, in which abnormal follicular keratinization and occlusion occur [5].

Folliculitis keloidalis (Chapter 27)

SYN. ACNE KELOIDALIS NUCHAE

This condition is seen almost exclusively in black Africans, with males being mostly affected [1]. Firm, discrete, follicular and perifollicular papules develop, usually on the nape of the neck, but often extending into the occipital scalp or beyond (Fig. 69.10). Complications include pustule formation, hypertrophic scars, keloids and alopecia [2]. The aetiology is unknown, but probably related to the curved shape of the hair follicle. Treatment includes intralesional steroid injection and topical and systemic antibiotics [1].

Hot-comb alopecia (Chapter 63)

Hot combing is a method of straightening curly black hair, although it has to a large extent been replaced by chemical methods [1]. Oil is applied to the hair and acts as a lubricant and heat conductor. A metal comb, heated to 150–260°C, is applied to the hair, re-arranging the hydrogen and disulphide bonds and straightening the hair [2]. The hot comb and oil may break the hair and a traction alopecia may also result. Repeated contact of the hot oil with the scalp can produce a scarring alopecia [3]. Recent evidence suggests that hot combing may not be the reason for the hair loss, which is usually seen in young adult women, and that the histological end-result, follicular degeneration, may have some other cause [4].

Hair-shaft breakage may also be seen with the inappropriate use of chemical relaxers and straighteners [1]. A scarring alopecia may also be seen, again in young women, following the use of hair-straightening chemicals [5].

Pseudofolliculitis barbae (Chapter 22)

This is a disorder common in black African males who shave and is related to the curved hair follicles found in such individuals [1]. Once shaved, the cut hair retracts beneath the skin surface into the curved follicle and grows in a circular direction. The sharpened hair end either penetrates the wall of the follicle, causing a foreign-body reaction, or grows out of the follicle but re-enters the skin and penetrates the dermis, again setting up an inflammatory reaction [1]. Perifollicular papules and pustules develop and scarring may result (Fig. 69.11). The beard area is usually affected, but pseudofolliculitis may involve any site that is shaved, including the pubic area and the scalp [2]. Recommended treatment is to grow a beard, use electric clippers, depilatory creams or a manual razor, sometimes with topical or systemic antibiotics [3].

Fig. 69.12 Traction alopecia. (Courtesy of Dr A.G. Messenger, Royal Hallamshire Hospital, Sheffield, UK.)

Traction alopecia (Chapter 63)

Traction alopecia (Fig. 69.12) is mainly seen in black Africans, because of the practices of plaiting or tightly braiding the hair into multiple braids (corn rowing), although it is not entirely confined to this group [1]. It may also follow the use of tight rollers or 'picking out' the hair with a hard comb to create the 'Afro' hairstyle [2]. Hairs are loosened from their follicles and inflammation and

Fig. 69.13 Futcher's lines. (Courtesy of the late Dr R.R.M. Harman, Bristol Royal Infirmary, Bristol, UK.)

atrophy may result. The distribution depends on the pattern of braiding, but often involves the temporal regions. Treatment consists of persuading the patient to discontinue the offending practice. In long-standing cases, alopecia may be permanent.

Variations of normal pigmentation

Futcher's or Voigt's lines

These are sharply demarcated bilateral lines of pigmentation (Fig. 69.13) that are seen at the anterolateral junction usually of the upper arms, where there is a transition from extensor to flexor surface and from darker to lighter pigmentation [1]. The lines correspond to a dermatome [2]. A second hyperpigmented line may occur on the posteromedial part of the lower aspect of the limbs [3]. The presence of Futcher's lines is proportional to the degree of pigmentation of the individual; they are present in 25% of black Africans [3]. Overall, about 75% of black people have at least one hypo- or hyperpigmented line [3]. These lines may be seen to a lesser extent in other races.

Hyperpigmentation of the palms and soles

Discrete, ill-defined or mottled macular pigmentation is frequently seen on the palms and soles (Fig. 69.14) of African patients, especially those with a darker skin colour [1].

REFERENCE

1 Chapel TA, Taylor RM, Pinkus H. Volar melanotic macules. *Int J Dermatol* 1979; **18**: 222–5.

Midline hypopigmentation

This appears as a line or band of hypopigmentation, or as discrete oval macules, on the anterior chest and midsternal area. Lesions sometimes extend down to the abdomen or up to the neck, where lines of hypopigmentation may radiate out to the clavicles [1,2]. It is commonly seen in black African males, but may occur in other races.

Mongolian spot (Chapter 39)

SYN. CONGENITAL DERMAL MELANOCYTOSIS

Mongolian spot refers to a slatey brown or blue-grey macular pigmentation observed at birth or in the neonatal period (Fig. 69.15). It is present in 100% of Mongoloid babies [1], between 70 and 96% of black Africans, and in up to 10% of Caucasoids [2,3]. The pigmentation is usually faint, round or oval in shape, and ranges in size from a few millimetres to greater than 10 cm in diameter. Mongolian spots are normally located over the sacral area, but the buttocks, flank or shoulders may be involved. Occasionally, multiple or extensive lesions are seen. The pigmentation generally reaches its peak at 2 years and fades by the age of 6 or 7 years.

Nail pigmentation

Longitudinal bands of brown or black pigmentation may be seen (Fig. 69.16); they occur with a higher frequency on the thumb and index fingernails [1,2]. They are present in more than 50% of black Africans, are more common in those with heavy pigmentation, and increase with advancing age.

Oral pigmentation

Oral macular pigmentation is seen in black Africans. It most often affects the gingivae, but may also involve the hard palate, buccal mucosa and tongue [1].

1 Dummett CO, Sakumura JS, Barens G. The relationship of facial skin complexion to oral mucosal pigmentation and tooth color. *J Prosthet Dent* 1980; **4**: 392–6.

Pigmentary disorders

Acanthosis nigricans (Chapter 34)

In some Mongoloid native American tribes, acanthosis nigricans is very common [1]. It may indicate a high risk of diabetes mellitus.

REFERENCE

1 Stuart CA, Smith MM, Gilkison CR *et al.* Acanthosis nigricans among Native Americans: an indicator of high diabetes risk. *Am J Public Health* 1994; **84**: 1839–42.

Dermatosis papulosa nigra (Chapter 36)

This condition is characterized by hyperpigmented, smooth-surfaced, round or filiform papules usually on the face (Fig. 69.17), but sometimes on the neck or upper trunk

Fig. 69.17 Dermatosis papulosa nigra.

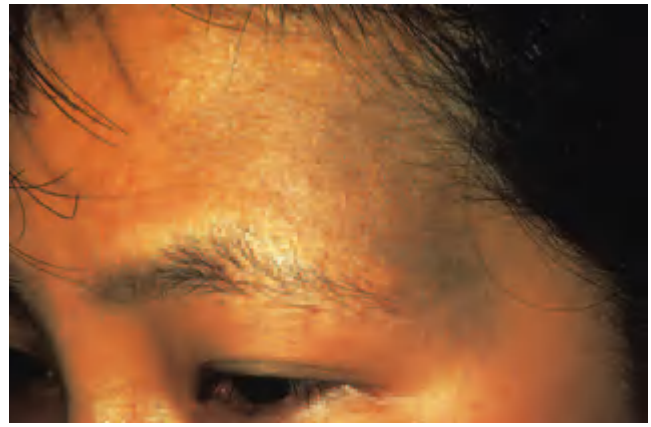

Fig. 69.18 Naevus of Ota.

[1,2]. The papules measure 1–5 mm in diameter. It is most common in black Africans, affecting up to three-quarters of adults (the majority being women), but is occasionally found in Caucasoids and Mongoloids [1]. The cause is unknown.

Naevus of Ota (Chapter 38)

Macular pigmentation, due to dermal melanocytes, is seen adjacent to the eye and also involves the sclera (Fig. 69.18). The pigmentation in naevus of Ota is variable and may be blue, slatey blue or brown. The naevus is usually unilateral and affects the eyelid, maxillary and zygomatic areas—regions that are innervated by the first and second branches of the trigeminal nerve [1]. It is most common in Mongoloids, but may occur in other racial groups. The

prevalence in the Japanese is 0.4–0.8% [2]. Over 80% of cases appear in women. About two-thirds of patients have ocular involvement, commonly of the sclera, but also of the cornea, conjunctiva and retina [1]. Malignant melanoma may develop in the naevus of Ota, more frequently in Caucasoid than Mongoloid patients [3].

Naevus of Ito (Chapter 38)

This is a variant of the naevus of Ota, and is characterized by macular pigmentation involving the shoulder, supraclavicular area, sides of the neck and upper arm—the areas supplied by the posterior supraclavicular and lateral brachial nerves [1,2]. It is more common in the Japanese and may occur alone or associated with a naevus of Ota.

Other conditions

Ainhum (Chapter 46)

Ainhum is characterized by the development of a constricting band around a digit (often the fifth toe) which may progress to spontaneous amputation of the digit [1]. It is generally found in black inhabitants of tropical countries, but has been described in African Americans [2]. The trauma and infection associated with walking barefoot may stimulate fibrosis. Pseudo-ainhum occurs in all races as a feature of mutilating keratoderma.

Cutaneous amyloidosis (Chapter 57)

Both the lichenoid type and the macular type are more common in Mongoloid subjects, but may be seen in any racial group [1–3]. Lichen amyloidosis consists of discrete, firm papules which often involve the lower leg, extensor aspect of the arms and lower back. The pigmented macular variant commonly affects the scapular region and shows a rippled pattern of pigmentation.

Disseminate and recurrent infundibulofolliculitis (Chapter 27)

This is a type of follicular eczema mainly seen in black Africans [1,2]. Pruritic, follicle-based papules are present on the neck, trunk or limbs. Juxtaclavicular beaded lines are a somewhat similar condition. They consist of asymptomatic parallel rows of skin-coloured papules on the neck and overlying the clavicles [1]. They are also seen in Caucasoids.

Facial Afro-Caribbean childhood eruption

In facial Afro-Caribbean childhood eruption (FACE), monomorphic flesh-coloured or hypopigmented papules are seen on the face, particularly around the mouth (Fig. 69.19), eyelids and ears, in Afro-Caribbean children [1,2]. The eruption persists for several months, but resolves spontaneously without scarring. The cause is unknown.

Fogo selvagem (endemic pemphigus foliaceus) (Chapter 41)

One report suggests this type of pemphigus, seen in clusters in jungle areas of South America, is more common in Native Indians (Mongoloids), who may be genetically predisposed to develop the disorder [1].

REFERENCE

1 Friedman H, Campbell I, Rocha-Alvarez R *et al*. Endemic pemphigus foliaceus (fogo selvagem) in native Americans from Brazil. *J Am Acad Dermatol* 1995; **32**: 949–56.

Hamartoma moniliformis (Chapter 15)

An asymptomatic disorder of small, discrete, flesh-coloured papules seen over the face and neck [1]. Histology reveals an increase in collagen and elastic fibres, capillary endothelial hyperplasia and proliferation of dermal nerves. The condition was first recognized in mentally retarded black children [1], but may occur in Caucasoid children and in mentally normal children.

REFERENCE

Infantile acropustulosis (Chapter 14)

Crops of small, intensely itchy papules appear between 2 and 10 months of age. The papules evolve into pustules and are mostly found on the palms, soles, wrists and ankles [1,2]. Lesions clear within 3 weeks, but recur until the disease resolves spontaneously at the age of about 2 or 3 years. It occurs predominantly in black African infants and the cause is unknown.

Mudi-chood

A papular eruption with a firm adherent scale, known as mudi-chood, is seen on the nape of the neck and upper back in young Dravidian women in Kerala State, south India. It seems to be due to the effects of oils applied to the hair [1,2]. The early lesions are follicular pustules, although later, flat-topped brownish black papules, with a keratinous rim, are seen (Fig. 69.20). Histologically, there is parakeratosis and acanthosis [1]. The Dravidians were the original inhabitants of India. Their racial origin is not quite clear, but they differ from the Caucasoid peoples of central and northern India, e.g. the Punjabis and Rajasthanis (who are descended from invaders from Persia and Central Asia). Dravidians have a darker skin colour and are shorter than their compatriots from north India: they have a prominent premaxilla, black hair and dark irises (P. Sugathan, personal communication). Mudi-chood can be improved by the application of 5% salicylic acid ointment, which removes the scales to leave hyperpigmented macules. Reducing the use of oils or cutting the hair shorter results in cure.

Papular eruption in black males

Described in young African American males, this monomorphic eruption consists of pruritic dermal papules with a predilection for the trunk, upper arms and postauricular area [1]. The condition may be persistent and resistant to treatment. The cause is not known.

REFERENCE

1 Rosen T, Algra RJ. Papular eruption in black men. *Arch Dermatol* 1980; **116**: 416–8.

Papuloerythroderma of Ofuji (Chapter 17)

The unusual eruption, characterized by solid papules coalescing into erythroderma with sparing of the body folds, was first described in elderly Mongoloid Japanese men, but has since also been reported in Caucasoids [1]. The cause is unknown.

REFERENCE

1 Nazzari G, Crovato F, Nigro A. Papuloerythroderma (Ofuji): two additional cases and a review of the literature. *J Am Acad Dermatol* 1992; **26**: 499–501.

Pityriasis rotunda (Chapter 34)

An eruption of asymptomatic discrete, large, scaly, oval or circular plaques on the trunk, mostly reported in Mongoloid or black African individuals [1,2]. It is a type of acquired ichthyosis and in some cases is associated with serious disease such as tuberculosis, leprosy, cirrhosis or underlying malignancy.

Sickle cell disease (Chapter 50)

Sickle cell disease occurs in black African races. The main cutaneous findings are the hand–foot syndrome and leg ulceration. The hand–foot syndrome is the most common and often the initial manifestation of the disease in children and consists of painful, non-pitting oedema of the hands and feet, caused by infarction of the small bones [1]. Ischaemic leg ulcers are, overall, the most frequent skin complication of sickle cell disease, but are rare under the age of 15 years [2].

2 Morgan AG. Proteinuria and leg ulcers in homozygous sickle cell disease. *J Trop Med Hyg* 1982; **85**: 205–8.

Transient neonatal pustular melanosis (Chapter 14)

A transient eruption of sterile vesicles and pustules, with surrounding erythema, which is present at birth. The vesicles rupture easily and leave pigmented macules that fade within the first few weeks of life [1,2]. It affects 4.4% of black Africans and 0.2% of Caucasoid neonates and tends to involve the face, neck, lower back and shins.

Vascular naevi (Chapter 15)

Vascular birthmarks, such as the naevus flammeus usually seen on the neck (the 'stork mark') or sometimes on the forehead or eyelids, or the port-wine stain naevus, are more common in Caucasoids than in black Africans or, to a lesser extent, in Mongoloids [1]. Naevus flammeus is seen in 30% of Caucasoid newborns and in 22% of black newborns [1]. Port-wine stain naevi are found in 1% of Caucasoid infants, but are rarer in other races [1].

Chapter 70

The Ages of Man and their Dermatoses

R.A.C. Graham-Brown

Introduction

Human life is a continuum, but within the continuum there are several identifiable phases, which we (the present and previous authors and editors) have called, after Shakespeare, the 'Ages of Man' [1]. We all begin by passing through a period of development to the point of 'maturity', which is then followed by a process of intrinsic ageing leading inexorably to senescence. During these ages, alterations take place in the structure and function of the skin, and there are important differences in the range, presentation, prognosis and treatment of skin disorders at various points in life. Indeed, some of the physiological events that accompany puberty, pregnancy, the menopause and old age can, of themselves, be sufficient reason for the patient to seek specialist dermatological advice.

This chapter aims to provide an overview of these stages in the life of the skin. The dermatological problems of the neonatal period and infancy have been dealt with elsewhere (see Chapter 14). This chapter deals principally with the skin and skin disorders of puberty, the menstrual cycle, pregnancy, childbirth and the puerperium, the menopause and old age.

Birth to puberty

Somatic growth

Growth, defined as an increase in size, occurs in most tissues, including the reproductive system. In particular, the changes in the skeleton, which can be monitored radiologically, and in the visible teeth, have been used as indices of maturity [1].

Between birth and maturity the skeleton and body keep in step with increases in weight of 20–25-fold, whereas the somatic muscles increase by 30–40-fold, and the nervous system by less than fivefold. The surface area of the skin increases sevenfold. In the first year after birth the body length increases by approximately 50% to around 75 cm, and another 12–13 cm are added in the second year. Subsequently, growth remains steady at 6 cm/year until the spurt associated with puberty. Weight follows a similar pattern.

Postnatal growth is dependent on growth hormone, or somatotrophin, secreted by the anterior pituitary, although other hormonal interactions may also be involved [2,3]. Human growth hormone is a protein with 191 amino acids. It exerts an effect on a number of tissues including the viscera and bone. In particular, it affects stature by stimulating proliferation of cartilage cells at the epiphyseal plates until the point when the epiphyses of the long bones have fused. Growth hormone also antagonizes the

actions of insulin, possibly by reducing the binding of insulin at its target sites, or by interacting with a second-messenger system.

Some of the effects of growth hormone are indirect, in the sense that they are mediated through the production of polypeptide growth factors in the target tissue. The most important of these, which affects the uptake of sulphate into cartilage, is somatomedin C, initially called 'sulphation factor' but now known to be identical with insulin-like growth factor 1 (IGF-1) and closely similar to IGF-2. Somatomedins have also been shown to stimulate incorporation of [^{14}C] leucine into glycosaminoglycans in cartilage and of [^{14}C] proline into collagen.

The secretion of growth hormone from the pituitary is mediated primarily by the interaction between hypothalamic growth hormone-releasing hormone and somatostatin, a 14-amino acid polypeptide that has numerous regulatory and neuromodulatory effects [4]. Negative feedback by both somatomedin C and growth hormone itself may also be involved. The basal concentration of growth hormone in the plasma is below 1 mIU/L, but it can reach peaks of up to 60 times this amount in adolescence. Bursts of secretion occur every 1–2 h during sleep, but can also be produced by physiological and psychological stresses.

Excessive secretion before puberty gives rise to gigantism, but once the epiphyses of the long bones have fused it results in thickening of the bones and enlargement of the hands and feet, known as acromegaly. Acromegalics also have, on average, abnormally high sebum secretion.

Deficiency of growth hormone, either in isolation or as a component of general hypopituitarism, is one cause of short stature.

Sexual development

The period between infancy and puberty that we call childhood is, in relation to sexual development, a hiatus in hormonally controlled events that have already been initiated in the fetus. While the dermatological problems of the neonatal period are so distinctive and of such practical importance as to merit a separate chapter, an understanding of the hormonal status of the fetus and the neonate, and of the cutaneous implications, is an essential starting point for a journey through the 'Ages of Man'.

Males become differentiated from females by their possession of a Y chromosome, which causes the indifferent gonads to become testes [1,2]. The fetal testis secretes a factor known as anti-Müllerian hormone, which induces regression of the Müllerian ducts between the seventh and eighth weeks of gestation, and testosterone, which causes virilization of the Wolffian duct to form most of the male system. Conversion of testosterone to 5α-dihydrotestosterone (see Chapter 4) is necessary for the development of the prostate from the urinogenital sinus, and of the external genitalia. In the latter trimesters of intrauterine life, the testicles descend to their position in the scrotum in response to gonadotrophin from the fetal pituitary, in addition to testosterone.

In females, where testicular secretions are lacking, the Müllerian ducts persist and give rise to the female reproductive tract.

The fetal testis continues to secrete testosterone even after birth [3]. At 50 days of age the level of plasma testosterone (250 ng/100 mL) is more than seven times that in umbilical cord blood (35 ng/100 mL), and is unlikely to be of maternal origin. It falls to the low level of the rest of childhood by about the age of 6 months.

In males, this production of testosterone appears at first sight to be related to the activity of the sebaceous glands, which become functional by 17 weeks of gestation. The glands are large at birth and the skin surface lipid is high, approximately 400 g/cm^2, remaining so for approximately 3 months [4,5]. The level throughout the rest of childhood is maintained at approximately 100 g/cm^2.

Neonatal skin-surface lipid is, however, as high in females as in males, although the hormonal pattern is quite different; the maximum plasma testosterone occurs immediately after birth and falls very rapidly [3]. The pattern of dehydroepiandrosterone, however, very closely follows that of the casual sebum levels in both sexes [6]. For these reasons, it seems possible that the production of sebum in the neonatal period and the occurrence of acne in prepubertal children may be related to adrenal activity.

Sebaceous activity starts to increase again towards the end of childhood, in advance of other signs of approaching puberty [7,8]. Dramatic changes take place between the ages of 8 and 9 years, in both males and females [9], and it seems possible that these are related to an increase in output of adrenal androgens. Comedones start to increase around this period [10].

The skin in childhood

The skin, along with other organ systems, undergoes some degree of maturation during the hiatus of childhood, before the resumption of sexual development at puberty and the transition to adulthood. The skin disorders seen in children in part reflect these physiological changes, but many of the most troublesome cutaneous problems encountered result from intrinsic genetic abnormalities conditioned by environmental influences. Perhaps the best example is atopic dermatitis (see Chapter 18), which has now reached very high levels of prevalence in some societies [1]. The ways in which the environment affects the child changes as he or she becomes more mobile and travels further and further afield.

School years bring exposure to a wide variety of infections and contagions, such as measles, chickenpox, impetigo, warts, molluscum contagiosum, scabies and head lice. There is also a gradual increase in contact with potential irritants: at school during lessons, in sporting activities such as swimming and team games, and in hobbies. The wearing of jewellery and cosmetics, and exposure to sensitizers such as rubber chemicals in footwear and preservatives in medicaments, bring a further range of dermatological problems in the form of allergic contact dermatitis, which is not as rare before puberty as is often suggested [2]. One disorder that seems to have a definite predilection for the prepubertal period in girls is lichen sclerosus et atrophicus [3], which may improve and disappear as puberty approaches, although this is not always the case [4]. In boys, the same pathological changes are frequently found in prepuces removed to relieve phimosis.

There has also been an increasing awareness in recent years that both girls and boys may present to the dermatologist with symptoms and signs that indicate sexual abuse [5]. Vulval or perianal soreness and inflammation for which no other cause can be found should be considered suspicious, as should the presence of anogenital warts [6], although some are undoubtedly acquired innocently. Proof of sexual abuse is always difficult unless there has been disclosure or confession from within the family unit. Furthermore, the social and legal implications of formal investigations for the child and his or her family are enormous. Inquiries must therefore be undertaken with care, although there is a well-established framework in many countries to deal with the problem, generally involving paediatricians, social workers and the police [5]. It is important to note that the changes associated with lichen sclerosus and Crohn's disease in childhood can be mistaken, by non-dermatologists, for evidence of sexual abuse [2], although their presence does not exclude it.

Syndromes of short stature

There is no uniformly agreed definition of short stature, although a reasonable cut-off would seem to be below the third centile for the child's community [7]. There are several disorders in which abnormal or delayed growth and development are accompanied by cutaneous changes. Some lead to short stature (a term preferred to 'dwarfism'), which is a common feature of chromosomal abnormalities. In others, delayed sexual development (infantilism) is also present, and this will be discussed briefly in relation to premature and delayed puberty. It is important to note that due allowance must be made for parental height in assessing possible delayed growth in a child [8].

Some of the more important of the disorders in which skin changes accompany short stature are listed in Table 70.1.

Furthermore, it is well known that severe skin disease of any kind in childhood can have a considerable impact on general physical development. Atopic dermatitis is a good example, short stature being very common in severely affected individuals, at least until puberty [9], although the assessment of this may be complicated by systemic or topical steroid therapy.

Table 70.1 Disorders in which short stature may occur with cutaneous changes.

Often severe	Moderate
Rothmund–Thomson syndrome	Turner's syndrome
Bloom's syndrome	Hypohidrotic ectodermal dysplasia
Cockayne's syndrome	Marinesco–Sjögren syndrome
Bird-headed dwarfism	Xeroderma pigmentosum
Progeria	Trichorhinophalangeal syndrome
Cornelia de Lange syndrome	Focal dermal hypoplasia
Cartilage–hair hypoplasia	Werner's syndrome
Conradi's disease	Darier's disease
Polydysplastic epidermolysis bullosa	Atopic dermatitis
Ataxia–telangiectasia	
Leprechaunism	
GAPO	
Short stature, alopecia and macular degeneration	

GAPO, growth retardation, alopecia, pseudo-anodontia, optic atrophy.

Puberty and adolescence

Hormonal events and cutaneous changes

Puberty is the period over which the secondary sexual characteristics gradually become manifest as the reproductive system develops to full capacity, and there is rapid somatic growth [1–3]. The term adolescence embraces these events, but is also used in a wider sense to include the phase of psychological and social adjustment to the physical changes. Thus, depending on the society, adolescence may be prolonged well beyond the completion of puberty.

The onset of puberty in the male is heralded by an increase in testicular volume resulting from the appearance of a lumen in each seminiferous tubule and an increase in the size and number of the testosterone-producing Leydig cells. Testosterone is responsible for most of the secondary changes such as enlargement of the penis and larynx, growth of pubic, axillary and beard hair, and also for a rise in sebum excretion and increased axillary sweating. Slight growth of pubic hair, probably provoked by adrenal androgens, may precede the rest and be one of the earliest visible signs of impending puberty. Facial hair usually only starts to appear about 2 years later. A full account of the patterns of hair development is given in Chapter 63.

The age at which these changes occurs is highly variable but Tanner's data on white British boys give some guidance [4–6]. In 95%, the genitalia started to enlarge at between 9.5 and 13.5 years (mean 11.6 ± 0.9 years of age), and functional maturity, indicated by ability to ejaculate, was achieved between the ages of 13 and 17 (mean 14.9 ± 1.1) years. The adolescent growth spurt, when the average gain in height reached a peak of 10 cm/year, a velocity of growth similar to that at the age of 2 years, usually occurred between 12.5 and 15 (mean 14.1 ± 0.9) years, approximately 3 years after the first signs of genital enlargement.

In girls, one of the first signs of puberty is the onset of breast development (thelarche), indicated by the elevation of the breast and papilla to form a small mound known as the breast bud [5,7]. The average age in white North American girls is 9.96 ± 1.82 years and 8.87 ± 1.93 years in their African American compatriots [8], but the breasts continue to enlarge for approximately 2 more years. Breast growth is provoked by the secretion of ovarian oestrogens; the further development of the secretory alveoli during pregnancy requires the action of progesterone as well. Pubic hair also starts to develop early (see Chapter 63). The most obvious feature of puberty, namely first menstruation or menarche, occurs at an average age of 13 years, but within an age range of 10–16.5 years. The early menstrual cycles do not usually involve ovulation, so full reproductive function is generally delayed for a further year or two. The growth spurt, with a peak height gain of 8 cm/year occurs between 10.5 and 13 years of age in white British girls [7]. This is approximately 2 years earlier than in boys. It is also noteworthy that rapid somatic growth precedes the major events of sexual maturation in girls but accompanies or succeeds them in boys.

The pubertal growth spurt appears, in both sexes, to be dependent on androgenic steroids as well as on growth hormone. Boys with growth hormone deficiency respond less well to testosterone than do normal subjects, not only in relation to acceleration of growth but also for development of the secondary sexual characteristics [9].

Gonadal function in both sexes is initiated by two gonadotrophic hormones of the pituitary, namely follicle-stimulating hormone (FSH) and luteinizing hormone (LH). In the male, initiation of spermatogenesis requires both hormones, but secretion of testosterone by the Leydig cells needs only LH. It may be noted that when the earliest sign of puberty in the female is the appearance of pubic hair, this probably results from stimulation by androgens from the adrenal cortex, so-called adrenarche, and is thus

dependent on an output of hypophyseal adrenocorticotrophic hormone (ACTH).

Levels of serum FSH and LH rise in both sexes between the ages of 6 and 17 years [10]. As puberty develops, LH is released in pulses, at first only at night but later also during the day [11,12]. The secretion of both gonadotrophins from the pituitary is controlled by a single releasing hormone, gonadotrophin-releasing hormone (GnRH), a decapeptide produced in the hypothalamus. This is influenced by negative feedback of the gonadotrophins, steroid hormones and a peptide called inhibin, which is produced by the gonads [13].

The important question therefore is what initiates the pulsatile release of GnRH to invoke the onset of puberty [14,15]? Animal studies show that the central component of the neuroendocrine mechanism that governs gonadal function is fully mature by birth [14]. Pulsatile GnRH release occurs during infancy, but there is then a hiatus in GnRH release between infancy and puberty [16]. The mechanisms that control this juvenile quiescence and eventual pubertal reawakening remain uncertain.

It has long been assumed that the initiation of puberty depends on the achievement of a particular body size or composition, suggesting the existence of a central growth tracking device or 'somatometer', rather than chronological age [14,17]. It is not understood how the central nervous system detects such changes in somatic development. The metabolites or hormones that are used by the brain as signals of metabolic maturity have yet to be identified. One suggestion is that developing bone produces a peptide that enters the circulation and imposes the prepubertal hiatus. This would explain the congruence of puberty with bone age rather than with chronological age. For example, it is known that in children with constitutional delay of growth and puberty or with isolated growth hormone deficiency, sexual maturity is chronologically delayed but occurs at normal skeletal age [14].

It is also unclear whether season influences the timing of puberty, as it does for the majority of species that live in changing habitats (see [18] for a review). An annual rhythm in human reproductive success exists in most societies, but it has long been controversial whether this is related to biological or sociological factors [19]. Marked seasonal effects on the timing of puberty have been noted in the female rhesus monkey [20], and, in common with most mammals in temperate latitudes, it is the changing photoperiod that is used to time puberty [18]. Studies in sheep and various species of hamster establish unequivocally that the daily pattern of melatonin secretion from the pineal gland provides an endocrine measure of day length, and mediates its effect on reproductive function. Melatonin is secreted during the hours of darkness, and provides an accurate measure of the length of night. Melatonin is not directly pro- or antigonadotrophic; it solely provides a seasonal cue. Humans show a clear daily rhythm of melatonin secretion [21], so the question arises whether it has a role in triggering puberty. Tumours of the pineal gland have been associated with both precocious and delayed puberty [22,23], although there is no experimental evidence that abnormal melatonin secretion causes reproductive malfunction in such cases. The amplitude of the nocturnal rise in melatonin secretion declines over the period of childhood, and has led to a hypothesis that puberty results from a decrease in melatonin secretion [24]. This view is not supported by animal studies. In both the rhesus monkey and sheep, puberty occurs in the autumn, when the periods of melatonin secretion are actually increasing [18,20]. It may be noted that the initial increase in LH secretion in the pubertal human first occurs at night, when melatonin secretion is high, rather than during the day when melatonin secretion is basal [25]. It seems likely that, although the human has retained a melatonin secretory system, the seasonal information that it conveys, at least, has become disregarded in the course of evolution.

Social cues may also play a part in the induction of gonadal activity, as demonstrated in many mammalian species. For example, introduction of a ram can induce an increase in LH pulse frequency and ovulation in both the seasonally anoestrus and prepubertal sheep, and this appears to be effected through a pheromonal mechanism [16,26]. The demonstration that extracts of male axillary secretions can affect the menstrual cycle when applied to the female upper lip [27] suggests that similar cues may have a role in humans.

Dermatoses of puberty and adolescence

Adolescence is a difficult period for most people. It is a time when the whole emphasis of relationships is supposed to change from the herd bond of the 'gang' to the pair bond of courtship and sexual involvement, but this does not happen all at once or completely. Most of us retain a need for the approbation of our peers throughout life, as well as a desire to develop a close one-to-one relationship. The tensions involved in this are at their most acute during adolescence and, for this reason, many skin diseases, which first presented during childhood, only begin to exert their most damaging influences after the onset of puberty. Adolescence is a bad time to have skin disease, especially on the face or on the extremities.

The physiological changes that occur in the skin during puberty and adolescence also have several effects, and may result in sufficient distress to cause the individual to seek medical advice. There are several examples of this: the increase in sebum production often results in unacceptably greasy hair, on which many hours and much money is expended; teenagers often present with secondary sexual hair that they perceive to be abnormal, largely as a result of the pressure exerted by the media; young men become anguished when male-pattern balding begins in the teenage years; members of both sexes become disturbed by the onset of 'body odour'.

Table 70.2 Disorders that present in or cause particular problems during adolescence.

Acne vulgaris
Acne excoriée and neurotic excoriation
Self-mutilation and dermatitis artefacta
Seborrhoeic dermatitis
Pityriasis versicolor
Hyperhidrosis
Axillary bromhidrosis (body odour)
Hidradenitis suppurativa
Fox–Fordyce disease
Polymorphic light eruption
Epidermolysis bullosa simplex (Weber–Cockayne syndrome)
Psoriasis
Atopic dermatitis

It has been pointed out that the pressures of coping with a maturing skin are particularly acute for a girl who is persuaded by advertisers that she should have plenty of hair on her head, but none on her face, under her arms or on her legs. Her skin should be free from grease, spots and wrinkles and, moreover, should be odourless [1]. Puberty makes this ideal image virtually impossible to achieve. Several disorders cause special problems or make their first appearance in adolescence. The classic example is acne vulgaris but there are several others (Table 70.2).

Teenagers may present with a variety of skin disorders in which self-inflicted injury is an important component (Fig. 70.1), varying from mild excoriated acne to severe habitual mutilation. The mental state of these individuals ranges from simple mild anxiety to gross personality disorder, psychotic disturbance and instability. Extreme forms of deliberate self-harm almost invariably begin in adolescence, but most continue for many years [2].

Seborrhoeic dermatitis is generally seen only from adolescence onwards, as is pityriasis versicolor in temperate climates. An explanation for this may lie in the alterations in sebum that appear to occur at puberty [3], especially if it is accepted that yeast organisms have a role in seborrhoeic dermatitis (see Chapter 17). This alteration in sebum is also said to be responsible for the virtual disappearance of scalp ringworm after puberty.

Teenagers may seek help for a number of different axillary problems. Severe eccrine hyperhidrosis can be a very distressing complaint, but usually responds well to treatment (see Chapter 45), as does axillary odour (bromhidrosis). More difficult to deal with are abnormalities of the apocrine glands (hidradenitis and Fox–Fordyce disease).

Polymorphic light eruption often presents for the first time in adolescence, and can ruin summer holidays. So does psoriasis [4]; 25% of 5600 patients with psoriasis

Fig. 70.1 Self-inflicted lesions on the cheek of a teenager.

dated the onset of their disease to between the ages of 10 and 20 years [5]. The impact of the appearance of psoriasis on a teenager should not be underestimated. The patient will be told that psoriasis is probably genetic, that it is likely to continue to be a lifelong problem and that there is no satisfactory cure. All this has to be assimilated during a period of increasing awareness of the importance of being attractive.

Atopic dermatitis can also be a major problem for the teenager and his or her family. It may present for the first time in adolescence, but this is rare. More commonly, children do not grow out of it as they have been led to believe, or atopic dermatitis may disappear during childhood only to reappear in adolescence. In this situation, the skin changes and pruritus are often severe, and usually have already affected the enjoyment of childhood. The adolescent is then quite abruptly faced with the prospect of the skin problem continuing for an apparently indefinite period into adult life. Many, if not all, affected teenagers become increasingly depressed and frustrated, and a sense of hopelessness can descend on the whole family. Many patients completely lose faith in orthodox medicine and seek advice from homeopaths, herbalists, naturopaths and others. A truly sympathetic and holistic approach is therefore required if the dermatologist is to retain the confidence of his or her young patient and their relatives through this difficult period. Good communication needs to be cultivated and maintained. Professional counselling facilities can be very helpful, but are often neglected or not available.

Another troublesome aspect of atopic dermatitis in adolescence is that there is a greater tendency to develop involvement of the hands (and feet) as the years go by. This can lead to difficulties in choosing a suitable occupation (see below). Furthermore, treatment parameters usually differ in adolescents and adults from those in childhood atopic dermatitis [6]. In particular, the information and support needs differ and, in practical therapeutic terms, steroid-sparing strategies may become more important.

Some congenital and genetic diseases, such as tuberous sclerosis and neurofibromatosis, may progress during the teenage years, causing increasing physical and cosmetic disability. Others (e.g. ichthyotic disorders, pigmentary anomalies and port-wine stains), even though largely static, may exert a greater effect because of the social and psychological tensions of adolescence.

However, some disorders improve at puberty. For example, atopic dermatitis clears in many individuals, and autosomal dominant ichthyosis tends to improve.

Skin disease and career

Young people with skin disease are often not aware that they may be at a major disadvantage in pursuing some occupations.

The armed forces medically examine all recruits, and are unlikely to accept anyone with psoriasis, significant atopic dermatitis or bad acne. It is therefore preferable for acne to be eradicated before rather than after application.

Psoriasis and eczema of the hands can be troublesome for those hoping to work in catering. Although they may be accepted by colleges to study, such individuals often find it difficult to obtain subsequent employment.

Hand dermatitis among hairdressers is a far greater problem in those with active atopic dermatitis and in those who have been troubled in the past than in those who are unaffected [7]. A teenager with atopic dermatitis may work in a hair salon for months or even years suffering with hand dermatitis before eventually giving up. The same applies to nursing, where many committed individuals are rejected at the occupational health screen because of eczema. The reasons given include the exposure to irritants that the skin will inevitably have during a nurse's normal duties, and the increased risk of contracting hepatitis and acquired immune deficiency syndrome (AIDS) through broken skin.

Any teenager with a chronic skin disease, especially of the hands, should therefore be made aware of the potential difficulties that he or she may face in the choice of a future occupation. It is better that a change be made early on than after working hard to achieve a set of educational and vocational goals that are unobtainable.

Premature and delayed puberty and hypogonadism

Although it must be acknowledged that the measurement of the onset and progress of puberty remains somewhat controversial [1], the dermatologist will occasionally see patients with what is a clearly abnormally early or delayed puberty, or with various hypogonadal syndromes. The appearance or non-appearance of sexual hair, or the onset of acne lesions in late childhood are the usual reasons for such referrals. Premature and delayed puberty are matters for endocrinological investigations, but the dermatologist should at least be aware of the range of diagnostic possibilities.

Premature puberty

Signs of puberty before the age of 10 years are generally held to be abnormal. This may result from an early onset of complete (or true) puberty, in which the changes are triggered by early activation of the normal hypothalamo–pituitary–gonadal axis. In some instances, early signs of puberty are caused by false (or pseudo-) puberty, in which sex hormone secretion is independent of the normal control mechanisms. Partial or incomplete puberty is also recognized, and there are two forms: thelarche (isolated breast development) and pubarche (isolated development of pubic and axillary hair). The former may be unilateral and be confused with tumours. It is not clear what causes isolated breast enlargement, although tissue hypersensitivity to oestrogen has been suggested (see Chapter 67). Pubarche is often associated with adrenal androgen secretion, and this may be a priming phenomenon in the early phases of normal pubertal development [2]. Indeed, the very early, isolated appearance of sexual hair may presage a true early puberty, and the distinction can be a very fine one. Table 70.3 gives a clinical classification of early puberty.

Table 70.3 Classification of premature puberty. (From Rayner [3].)

Complete (true)	*False (pseudopuberty)*
Constitutional	Adrenal lesions
Sporadic	Congenital adrenal hyperplasia
Familial	Tumours
Cerebral/neurogenic	Cushing's syndrome/hyperplasia
Tumours	Ovarian tumours
Development defects	Testicular tumours
CNS infections	Iatrogenic (sex hormones)
CNS trauma	*Extrapituitary gonadotrophin-secreting tumours*
McCune–Albright syndrome	Teratoma
Neurofibromatosis	Chorionepithelioma
Tuberous sclerosis	Hepatoblastoma
Silver's syndrome	
Hypothyroidism	
Pineal lesions	
Incomplete	
Premature thelarche, pubarche	

CNS, central nervous system.

Most instances of premature, complete puberty are constitutional. Although this may be sporadic, there is often a strong family history. Indeed, it seems likely that many families never present at all, accepting that it is quite normal for them. This is particularly true for girls, in whom approximately 80% of premature puberty is thought to be constitutional [3]. There is no difference in the order of events, but mental and emotional development may lag behind the physical changes. In boys, where the event is rarer, there is more often an underlying pathological condition [4].

The investigation of complete premature puberty is obviously a complex process, especially if a neurogenic origin is suspected, but the dermatologist should always look for other features of the specific syndromes listed in Table 70.3: McCune–Albright syndrome, neurofibromatosis, tuberous sclerosis and Silver's syndrome (short stature, craniofacial disproportion and clinodactyly [4]), as well as hypothyroidism.

Delayed puberty and hypogonadism

Puberty can be considered delayed if there is no sign of sexual development by the age of 15 years in boys and 14 years in girls [1]. There are a number of important causes, listed in Table 70.4. Constitutional delay accounts for at least 50% of male cases, and is much more common than in girls [1].

As with premature puberty, pubertal delay requires endocrinological investigation. However, a dermatologist can make a useful contribution if the patient presents first in the skin clinic. Examination can reveal the obesity, short stature and mental retardation of the Prader–Willi syndrome, the polydactyly of the Laurence–Moon–Biedl syndrome, or the increased height and gynaecomastia of Klinefelter's syndrome.

Table 70.4 Causes of delayed puberty. (From Chaussain [1], Kulin [2] and Santen & Kulin [3].)

Constitutional delay
Hypogonadotrophism
Isolated gonadotrophin deficiency
Hypogonadotrophic eunuchoidism (Kallmann's syndrome)
Multiple hormonal deficiency states
Idiopathic
Tumours
Langerhans' cell histiocytosis
Tuberculosis
Sarcoidosis
Vascular disease
Haemochromatosis
Hyperprolactinaemia
Specific syndromes with hypogonadotrophism
Prader–Willi
Laurence–Moon–Biedl
Multiple lentigines
Rud's
Cerebellar ataxia
Systemic disease
Chronic renal failure
Congenital heart disease
Cystic fibrosis
Thalassaemia major
Diabetes mellitus
Hypothyroidism
Gluten intolerance
Anorexia nervosa
Excessive exercise
Hypergonadotrophic hypogonadism
Klinefelter's syndrome
Ullrich–Turner syndrome
Dystrophia myotonica
Trisomy 21 (Down's syndrome)
17β-Hydroxylase deficiency
Androgen insensitivity (testicular feminization syndrome)
Surgical accidents (e.g. during herniorraphy)
Testicular torsion
Anorchia and bilateral cryptorchidism
Irradiation and cytotoxic drugs
Orchitis (e.g. mumps)
Polycystic ovarian disease

Many extraneous factors can also affect the onset of puberty. Malnutrition and extreme forms of exercise, such as long-distance running and ballet training, may markedly delay onset of puberty, probably by interfering with hypothalamic triggering mechanisms [4,5].

The menstrual cycle

Hormonal influences [1,2]

The menstrual cycle involves changes in the genital tract, which are brought about by two hormones from the ovary. At the start of each cycle, after menstruation is completed, the repair and proliferation of the endometrium, and the synthesis of receptors for progesterone and oestradiol within its cells, are effected by the rising secretion of oestradiol. Following ovulation and the formation of the corpus luteum, the rise in progesterone causes the endometrium to double in thickness and the tubular glands to become tortuous and sacculated. The maintenance of this secretory phase is dependent on both oestradiol and progesterone, and the breakdown of the endometrium that causes menstrual bleeding is a consequence of the withdrawal of these hormones. The cyclic hormonal changes also affect the vaginal epithelium, which can be monitored through desquamated cells in vaginal smears, the consistency and pH of the cervical mucus, and several features of the skin.

Synthesis of oestrogens in the ovary first involves the production of the androgens androstenedione and testosterone, in the theca interna cells of the follicle, and then their conversion to oestrone and oestradiol in the granulosa cells. These processes are stimulated by LH from the pituitary. However, the increased production of oestradiol between the eighth and tenth days of the cycle is also dependent on FSH in the sense that this is responsible for the development of numbers of primary follicles in the early follicular phase, which increases the number of granulosa cells.

Ovulation in the middle of the cycle is associated with surges in both LH and, to a lesser extent, FSH. The surge in LH lasts for approximately 36 h, and is affected by

pulsatile output of GnRH from the hypothalamus. It appears that feedback by oestradiol is responsible: in the early follicular phase, oestradiol acts to inhibit secretion of gonadotrophin but, as the follicle ripens, a threshold is exceeded which switches the feedback from negative to positive.

Cutaneous changes

Many women notice changes in their skin and hair during the course of the monthly cycle. For example, 70% of Scottish women reported a few acne papules during the premenstrual phase of their cycle, and a significant number of others experienced textural variations. Some found the skin and hair greasier (35%), others drier (16%) [1], despite the fact that sebum production has not reliably been shown to alter significantly. Pre-existing skin disorders, other than acne, may also undergo premenstrual exacerbation; examples are psoriasis, rosacea, atopic dermatitis, lupus erythematosus, anogenital pruritus, recurrent aphthae and herpes simplex [2,3].

Some women experience premenstrual flushing identical in quality to that associated with the menopause. In one study of 120 women with classical features of the so-called premenstrual syndrome, 72% were observed to have such flushing episodes [4]. This phenomenon may be related in part to the general increase in cutaneous vascularity during the second half of the menstrual cycle [5], but detailed investigation of one of these women revealed that each flush (recorded using skin resistance and finger temperature) coincided with a measurable pulse of LH. Identical findings are reported in menopausal flushes (see p. 70.20), suggesting a common pathogenesis.

Other cutaneous disturbances described in the 'premenstrual syndrome', include minor non-specific abnormalities and recurrent boils. Premenstrual oedema has also been described, most commonly of the feet and ankles, but occasionally involving the hands and even the face. In rare individuals this may be very marked.

It is not at all clear what causes most of the symptoms associated with the 'premenstrual syndrome', but there have been many suggestions, including hormonal influences, abnormalities of fluid balance, nutritional changes (including essential fatty acid depletion), neurotransmitters and psychological factors. It seems most probable that the syndrome is a complex of interrelated problems, each with a different basic cause or causes [6].

Fig. 70.2 Autoimmune progesterone dermatitis. (Courtesy of Dr J.D. Wilkinson, Amersham Hospital, Amersham, UK.)

Autoimmune progesterone dermatitis (Fig. 70.2)

There are also patients in whom the regular appearance of skin changes in the premenstrual period is associated with evidence of hypersensitivity to progesterone. This has generally been established by skin testing, deliberate challenge with progesterone or the presence of antibodies [7], and the term autoimmune progesterone dermatitis has been coined for this syndrome. The cutaneous lesions that have been described are very variable, resembling eczema, particularly the pompholyx type; urticaria; erythema multiforme [8]; or dermatitis herpetiformis [9]. Many patients develop the eruption after receiving exogenous synthetic progesterone preparations.

Treatment of autoimmune progesterone dermatitis can be difficult. Most patients are unresponsive to topical steroids and antihistamines, but some respond to oestrogen or tamoxifen therapy [7]. One resistant patient required bilateral oophorectomy [9].

Pregnancy, childbirth and the puerperium

Pregnancy, childbirth and the puerperium are associated with profound physiological endocrine upheavals. Many of the consequent cutaneous changes should be considered normal, although not every woman is happy to accept them in this light. The physiological events of pregnancy and its resolution can also modify a number of concomitant dermatoses and tumours, and there are also some pathological skin conditions that are virtually pregnancy-specific.

Endocrine background [1–3]

Pregnancy is characterized by the advent of a new and unique endocrine organ (the placenta). The endocrine changes of pregnancy start soon after the fertilized ovum becomes implanted in the endometrium, when the developing trophoblast begins to secrete chorionic gonadotrophin. This, in turn, stimulates production of oestrogen and progesterone by the corpus luteum. The increase in the concentration of these steroids suppresses the production of FSH by the pituitary and thus prevents further ovulation. At about the ninth week of pregnancy the fetoplacental unit begins to synthesize pregnenolone and progesterone. Pregnenolone crosses to the fetus and is converted to dehydroepiandrosterone by the developing fetal adrenal. This, in turn, returns to the placenta to be aromatized to oestriol. From about the 12th week there are increasing amounts of oestriol and progesterone, and the corpus luteum of pregnancy regresses.

The placenta also produces lactogen (hPL) in quantities as great as 1 g/day by late pregnancy. This hormone has some somatotrophic as well as lactogenic properties. A human chorionic thyrotrophin (hCT), structurally different from pituitary thyroid-stimulating hormone (TSH), has also been isolated.

Placental hormones are partly responsible for the physiological adaptations that occur in pregnancy including, for example, a considerable increase in blood volume. The thyroid enlarges and takes up more iodine. The pituitary also enlarges and increases its output of ACTH, prolactin and gonadotrophins. Circulating cortisol rises, caused mainly by a decrease in its rate of clearance combined with an increase in cortisol-binding globulin.

The breasts enlarge during pregnancy, most noticeably towards term. In the early phases of a first pregnancy there is a rapid growth and branching of the terminal portions of glandular tissue, together with an increase in the vascularity of the breast as a whole. Later, true acini appear for the first time, and alveolar secretion begins during the second trimester. In the last weeks there is considerable parenchymal cell enlargement and the alveoli become distended with colostrum [3].

The state of pregnancy is ended, at least in part, by an alteration in the balance of the antagonistic actions of oestrogen and progesterone. This is probably 'fine-tuned' by the fetal pituitary–adrenal axis and its effect on oestrogen production [1]. Thus, abnormalities of the fetal brain, such as anencephaly, may lead to abnormally early or late onset of parturition. The tendency of labour to be delayed in mothers bearing children with X-linked ichthyosis is caused by a reduction in the processing of hormones by the placental enzyme steroid sulphatase (see Chapter 34).

After birth, the mother's hormonal status changes yet again. Levels of prolactin rise steadily towards the end of pregnancy, and at childbirth the apparently inhibitory effect of the fetoplacental steroid hormones is suddenly lost, leaving prolactin acting unopposed. This initiates lactation [3].

Physiological skin changes related to pregnancy

Pigmentation (see Chapter 39)

Most women notice a generalized increase in skin pigmentation during pregnancy, and the change is more marked in dark-haired than in fair-haired women. Areas that are already pigmented become darker, in particular the nipples, areolae, genital areas and the midline of the abdominal wall. In consequence, the 'linea alba' ('white line') may become brown. The pigmentation usually fades after delivery, but seldom to its previous level. Many women also notice an increase in the size, activity and number of melanocytic naevi.

In approximately 70% of women, especially those of dark complexion, chloasmal pigmentation also develops during the second half of pregnancy. Its intensity is not necessarily proportional to that of the general melanosis. Irregular, sharply marginated areas of pigmentation develop in a roughly symmetrical pattern either on the forehead and temples, or on the central part of the face, or both. It usually fades completely after parturition, but may persist.

Similar changes occur in other species. The pigmentary changes of pregnancy have been induced experimentally in non-pregnant guinea pigs by the injection of small doses of oestrogen and progesterone [1]. The extent to which human pigmentary changes are brought about by

these steroids or by melanocyte-stimulating hormones derived from pro-opiomelanocortin (see Chapter 39) is uncertain [2–4].

Hair and nail changes

Many women maintain that hair growth on the scalp is more vigorous during pregnancy. In the latter part, the proportion of follicles in anagen rises, but a compensatory decrease after parturition associated with shedding of hairs may result in noticeable postpartum alopecia [5,6]. Spontaneous recovery is usual. Mild frontoparietal recession may also occur [7].

Minor degrees of hypertrichosis are not uncommon. Hirsutism, accompanied by acne and, in severe cases, by other evidence of virilization, occurs rarely, usually during the second half of pregnancy. It may result from an androgen-secreting tumour, luteoma, lutein cysts or polycystic ovary disease [8,9]. All cases should be thoroughly investigated. A female fetus may be masculinized. In the absence of a tumour that can be eradicated, the problem tends to recur in subsequent pregnancies. Hirsutism may regress between pregnancies, but this is not always complete.

Pregnant women often report brittleness of the nail plate, and some develop distal onycholysis, similar to that seen occasionally in thyrotoxicosis [7].

Eccrine, apocrine and sebaceous gland activity

Eccrine activity may be noticeably increased during pregnancy [7], although palmar sweating diminishes [10]. This may be responsible for the recognized increased frequency of miliaria. It is often said that apocrine gland activity is reduced during pregnancy, but the evidence is conflicting. Hurley and Shelley [11] were unable to find any increase in apocrine sweating immediately postpartum, but they pointed out that Fox–Fordyce disease usually improves in pregnancy, which suggests that apocrine activity has been reduced.

Although there is considerable individual variation, the rate of sebum excretion tends to increase during pregnancy and return to normal after delivery [12].

The rise in sebum excretion during the last trimester of pregnancy, at a time when oestrogens, which suppress sebum secretion, are being produced in large quantities, suggests that a powerful sebotrophic stimulus is released. The sebum excretion rate in women with twins or triplets is no greater than the rate in women with a single fetus, suggesting that the sebotrophic factor comes from the pituitary rather than the placenta [13]. Sebum excretion does not fall in women who are lactating [14], and suckling presumably promotes secretion of pituitary factors, such as prolactin, which either stimulate sebaceous glands directly or enhance their response to androgens.

Vascular changes

The vascular changes of pregnancy do not differ qualitatively from those in hyperthyroidism or cirrhosis. All are thought to be brought about by the sustained high levels of circulating oestrogen. Vascular 'spiders' are very common in white women but said to be less so in black women [1]. They usually disappear postpartum. Palmar erythema is also common, affecting at least 70% of white women and 30% of black women [2]. In some, it takes the form of a diffuse pink mottling of the whole palm, whereas in others the changes are confined to the thenar and hypothenar eminences [3]. Palmar erythema and vascular spiders commonly occur together.

Less commonly, pregnant women develop small haemangiomas [4,5]. These usually affect the head and neck (Fig. 70.3), and occur in approximately 5% of pregnancies [4].

Varicose veins of the legs and haemorrhoids are frequent complications of pregnancy. A rarer but more serious event is the development of deep-vein thrombosis, which can lead to permanent damage to the leg veins and, occasionally, death from pulmonary embolism. Many pregnant women (possibly 50%) also develop non-pitting oedema of the face, eyelids, feet and hands [6]. The swelling is usually most pronounced in the early morning and disappears during the course of the day. There is no known treatment, but it is important to recognize and differentiate the condition from cardiac, renal or pre-eclamptic oedema.

Fig. 70.3 Pyogenic granuloma in a port-wine stain during pregnancy. This woman had similar lesions in three successive pregnancies.

Gingivitis and pregnancy 'epulis'

Eighty per cent or more of pregnant women develop some gingival oedema and redness [6,7]. This can become painful and ulcerative, especially if oral hygiene is poor. In approximately 2%, the gingival changes are associated with the appearance of a small vascular lesion similar to a pyogenic granuloma, known as a pregnancy epulis or granuloma gravidarum. This may bleed profusely on contact. These phenomena, like palmar erythema and vascular spiders, are probably brought about by the general increase in vascularity associated with high oestrogen levels.

In most women, gum changes resolve after parturition. Vitamin C has been used to try to improve the symptomatology.

Dermatoses modified by pregnancy

Some dermatoses worsen during pregnancy, some improve, and many are unpredictable. Table 70.5 lists those dermatoses and tumours that are commonly modified by pregnancy and the puerperium. The details of most of these are discussed elsewhere in this book; however, some specific points should be noted here.

Infections and immunity in pregnancy

Cell-mediated immunity is depressed during normal pregnancy [1], which probably accounts for the increased frequency and severity of certain infections such as candidiasis. Condylomata acuminata too can be exacerbated, growing very rapidly and occasionally obstructing the birth canal. *Candida*, genital warts and herpes simplex can be transmitted to the baby during childbirth. In babies

Hidradenitis suppurativa
Fox–Fordyce disease

of very low birth weight, candidiasis and herpes simplex can be life-threatening [2]. In view of the known oncogenic potential of some strains, there is a debate about whether mothers infected with human papillomavirus should routinely be offered caesarean section, as generally practised for active herpes simplex infection. However, there is doubt whether this practice prevents neonatal infection [3] either by herpesvirus or by genital warts [4]. Bowenoid papulosis (see Chapter 68), a condition closely linked with wart virus infection, may appear for the first time or deteriorate during pregnancy [5].

Podophyllin should never be used in the treatment of warts during pregnancy because of potential maternal and fetal toxicity; physical treatments are preferable [6].

The immune alterations of pregnancy, childbirth and the puerperium have an adverse effect on leprosy in more than one-third of patients [7]. Leprosy reactional states are more common, and the decline in immune reactivity may also lead to an increase in drug resistance [7]. Furthermore, there are specific problems with some antileprosy drugs: thalidomide cannot be used because of its teratogenicity, and clofazimine has been associated with unexplained fetal deaths [8].

Autoimmune disorders

The outcome of most pregnancies in women with systemic lupus erythematosus is undoubtedly better than was once thought, although a few develop renal damage, and disease exacerbation may be severe enough to cause death [6]. Lupus in the mother may affect the baby (neonatal lupus; see Chapter 14). Cutaneous lupus does not appear to be affected by pregnancy [9].

Most women with systemic sclerosis do not experience major problems, and some appear to improve [10]. Occasionally, however, there is severe progressive deterioration of renal function, with hypertension and pre-eclampsia. This may lead to fetal loss or even maternal death [11].

Dermatomyositis and polymyositis are generally unaffected by pregnancy, but some patients may deteriorate.

Metabolic disease

There is no consensus about the effects of pregnancy on porphyria cutanea tarda. Some women experience few problems, and Marks [12] suggested that endogenous oestrogen might be less harmful than exogenous compounds because of the complete absence of deterioration of the porphyria during one normal pregnancy. However, some cases do show clinical and biochemical deterioration, and on one occasion this was shown to be parallel to the physiological rise in oestrogen [13]. Acrodermatitis enteropathica is said always to deteriorate in pregnancy [14].

Disorders of connective tissue

Women with Ehlers–Danlos syndrome types I and IV often have major problems, including bleeding, wound dehiscence and uterine lacerations (see Chapter 46) [6]. They should probably be counselled to avoid pregnancy altogether. Some patients with pseudoxanthoma elasticum have suffered major gastrointestinal bleeds necessitating blood transfusion [15].

Tumours

The relationship between malignant melanoma and pregnancy (and, indeed, exogenous oestrogens) has been discussed for many years [6]. One large series suggests that melanoma developing during pregnancy carries a slightly worse prognosis, but that pregnancy following excision of a tumour does not affect prognosis [16]. Epidemiological studies from the USA have failed to show significant associations between melanoma and reproductive and other hormonal factors in women [17]. Neurofibromas may grow during pregnancy, or appear for the first time. Rupture of major blood vessels in neurofibromatosis has also been reported [18,19], and hypertension is a common complication. Pregnancy may exacerbate mycosis fungoides [20] and the eosinophilic granuloma form of Langerhans' cell histiocytosis [21].

Miscellaneous dermatoses

Atopic dermatitis often improves in pregnancy, but this is unpredictable; in some patients it is exacerbated. Breastfeeding is often a problem for those suffering from atopic dermatitis because of nipple eczema, and the puerperium may herald a deterioration in hand eczema because of exposure to irritants.

Pregnancy may trigger erythema multiforme, and vaginal stenosis has been described in severe Stevens–Johnson syndrome occurring in pregnancy [22].

Marked deterioration in erythrokeratoderma variabilis occurred during pregnancy in two related women [23].

The effects of pregnancy on psoriasis are variable, although often consistent in the same individual. A rare occurrence is the sudden eruption of acute pustular psoriasis. This used to be considered as a distinct entity called *impetigo herpetiformis*, but this term is probably best discarded.

Acne may improve, but is occasionally exacerbated during pregnancy. This can cause management problems, because a number of antiacne drugs are contraindicated in pregnancy.

Hidradenitis suppurativa and Fox–Fordyce disease often improve considerably, and it is generally presumed that this is a result of a reduction in apocrine gland activity.

AIDS and pregnancy

AIDS is a worldwide problem, and there have now been many pregnancies in women infected by human immunodeficiency virus (HIV). The infection has often only become apparent after birth when the children developed AIDS. Although it appears that pregnancy may subsequently accelerate the development of AIDS symptoms [1,2], there does not seem to be a tendency for HIV disease to progress during pregnancy itself [3]. If opportunistic infections, such as *Pneumocystis* pneumonia or listeriosis, develop in a pregnant woman with AIDS, the outcome is generally fatal [4,5]. This contrasts with the more usual 70% recovery rate in non-pregnant AIDS patients and suggests that the immune suppression of pregnancy may be additive to that of HIV infection. Kaposi's sarcoma has also been reported in AIDS in pregnancy [6]. The effects of maternal HIV infection on the child can be devastating [7].

The dermatoses of pregnancy

Irritation, rashes and other skin changes are common in pregnancy [1]. The possibility that the patient has an unrelated skin condition such as scabies must not be overlooked. However, there are several skin changes that appear to be specifically related to pregnancy and the puerperium, distinct from physiological events, and not caused by exacerbation of a pre-existing condition.

Pruritus gravidarum

Itching in pregnancy is dealt with here because it is uncertain whether it is an extension of the physiological changes or a specific dermatosis [2,3].

As many as one-fifth of pregnant women experience some itching [4]. In most, this can be attributed to some identifiable skin disorder such as scabies, eczema, urticaria, a drug eruption or one of the specific pregnancy-related inflammatory dermatoses discussed below. However, there is also a small group of women who experience intense pruritus without evident primary cutaneous changes, and it is to these patients that the term pruritus gravidarum is applied.

It is generally considered that pruritus gravidarum is a mild variant of recurrent cholestasis of pregnancy, and occurs in 0.02–2.4% of pregnancies [5]. The itching begins in the second or third trimester and is often localized to the abdomen, or the palms and soles, although it may also be very widespread. The patient may be mildly icteric.

Liver function tests are occasionally abnormal, with a raised alkaline phosphatase [2].

The cause is thought to be multifactorial [6], although it is probable that the irritation itself results from abnormal hepatic excretion of bile acids induced by metabolites of both oestrogen and progesterone, both of which have been shown to affect the handling of bile acids [6,7]. The condition also occurs more commonly in mothers of patients with rare inborn cholestatic syndromes [6].

The itching usually subsides rapidly after childbirth, but may persist for some weeks into the puerperium. It may also recur with subsequent pregnancies and the use of oral contraceptive pills. Recurrent attacks increase the liability to cholelithiasis [4]. Treatment with ursodeoxycholic acid is effective in reducing itch and abnormal liver function tests [6].

Striae

Striae distensae (striae gravidarum) are a common and striking feature of most pregnancies. They are dealt with fully in Chapter 46.

Skin tags

SYN. MOLLUSCUM FIBROSUM GRAVIDARUM

Multiple tags often appear in the second half of pregnancy. These are most common on the face, the side of the neck, in the axillae and under the breasts. The histological features are those of ordinary skin tags [8]. They are usually small, but may reach 5 mm in size. They generally regress in the puerperium, and it has been suggested that they are probably a result of hormonal factors [2].

'Cracked' and sore nipples

Many women experience discomfort, irritation and fissuring of the nipples, especially early in the puerperium as they are trying to establish breastfeeding. Anatomical features, such as relatively flat nipples, contribute to the development of this problem. Mastitis and deep abscesses may occur because of penetration of the broken skin by pyogenic bacteria. The problem is, in essence, one of friction and irritation, and can be eased considerably by the judicious use of gentle cleansing and emollients.

Inflammatory dermatoses specific to pregnancy

Classification. The older literature is confusing. Dermatoses considered distinct by some authors are lumped together by others. Holmes and Black [9] have suggested a rationalization of the terminology, and have proposed a classification that seems the most logical for practical use (Table 70.6), even though alternatives are still employed. Ackerman *et al*. [10] argue that there really are only two dermatoses in this category: pruritic urticarial papules and plaques of pregnancy (PUPPP) and pemphigoid gestationis. However, some of the other dermatoses that have been reported as being pregnancy-associated are discussed here, drawing attention to those descriptions that appear to be at least clinically distinct from PUPPP or pemphigoid gestationis, and reviewing whether others are really distinct entities or not.

Table 70.6 Specific dermatoses of pregnancy. (From Shornick [12].)

Pemphigoid (herpes) gestationis
Polymorphic eruption of pregnancy
Prurigo of pregnancy
Pruritic folliculitis of pregnancy

Pemphigoid (herpes) gestationis [11,12]

This rare and highly characteristic disorder affects approximately 1 in 150 000 pregnancies and is considered in detail in Chapter 41. The disease usually appears in the second or third trimester, and presents with an intensely itchy urticarial or vesiculobullous eruption. Immunofluorescence reveals a linear band of immunoglobulin G (IgG) at the basement-membrane zone, identical to that seen in bullous pemphigoid. Recent studies involving tissue typing have supported earlier suggestions of a genetic predisposition [13].

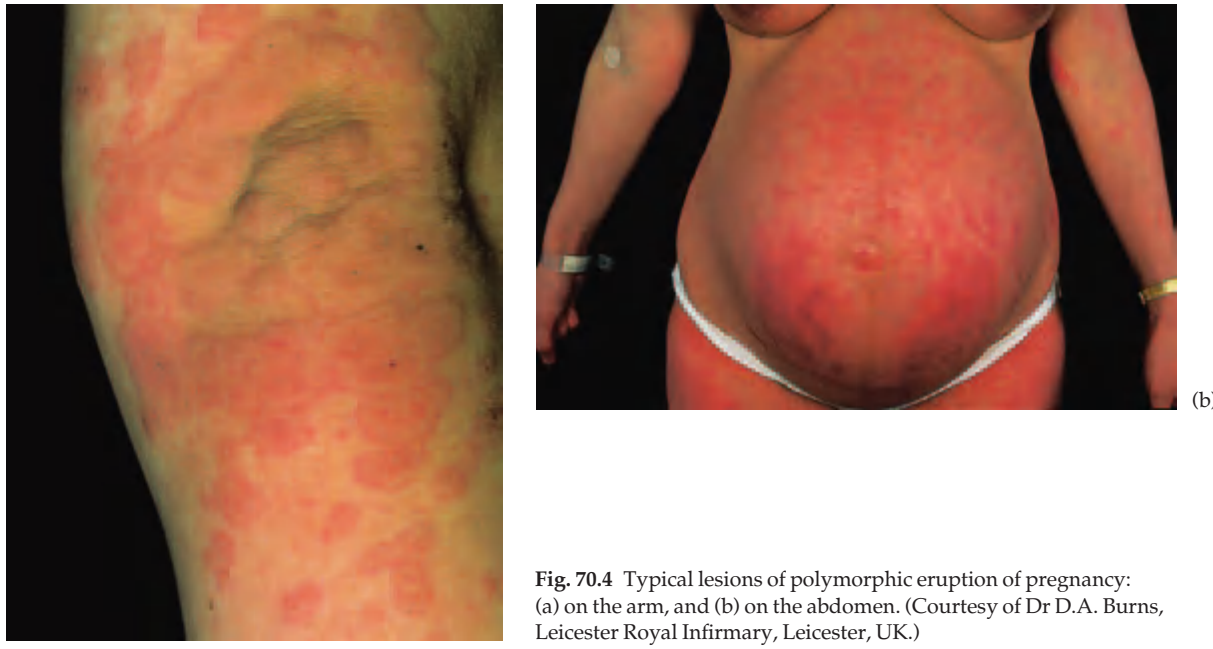
Polymorphic eruption of pregnancy

SYN. PRURITIC URTICARIAL PAPULES AND PLAQUES OF PREGNANCY

In addition to the above designations, these skin changes have been known as toxaemic rash of pregnancy [14], toxic erythema of pregnancy [15] and 'late onset' prurigo of pregnancy [16]. It is probable also that some patients with this condition have been recorded in the literature as prurigo gestationis (see below), erythema multiforme and pemphigoid (herpes) gestationis.

If there is agreement that all these disorders are one and the same, there is still no consensus on which name to use. In the UK, as proposed by Holmes and Black [9,11], the term polymorphic eruption of pregnancy is favoured. Elsewhere, the lengthy descriptive phrase 'pruritic urticarial papules and plaques of pregnancy' or 'PUPPP', as suggested by Lawley *et al*. [17], still finds favour, especially in the USA [18].

Incidence. Polymorphic eruption of pregnancy occurs in approximately 1 in 240 pregnancies [2]. The eruption begins in the third trimester, usually of a first pregnancy, but is occasionally delayed until a few days postpartum. It rarely recurs in subsequent pregnancies [11,17,18], but when it does it is often less severe [2].



(a) (b)

Fig. 70.4 Typical lesions of polymorphic eruption of pregnancy: (a) on the arm, and (b) on the abdomen. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

Aetiology. The cause remains obscure, although the condition has been related to abnormal weight gains in the mother and the newborn, and to twin pregnancy [19]. As the disorder occurs predominantly in primigravidae in the third trimester, it has been postulated that excessive abdominal distension may act as a trigger for the skin changes. The typical distribution (see below) may lend some credence to this view. It has also been shown that serum cortisol levels are low in patients with polymorphic eruption of pregnancy, while human chorionic gonadotrophin (hCG) and oestradiol are normal [20].

Pathology [11,16,17]. The histology of this condition is non-specific, and there are many similarities with the early prebullous phase of pemphigoid gestationis. Most biopsies show epidermal and upper dermal oedema, with a perivascular infiltrate of lymphocytes and histiocytes. There may be a striking number of eosinophils (as there may be in pemphigoid gestationis). Spongiotic vesicles are also seen, and there may be patchy parakeratosis.

Immunofluorescence is uniformly negative, even by immunoelectron microscopy, and this provides the best means of distinguishing this disorder from pemphigoid gestationis, should there be any diagnostic doubt [21].

Clinical features [11,16,17]. The patient usually complains of intense itching. The skin lesions closely resemble the very early stage of pemphigoid gestationis. The eruption consists predominantly of urticated papules and plaques. Less commonly, vesicles, target lesions and polycyclic erythematous areas are seen.

The most striking feature, however, is the distribution of the lesions. They usually begin and predominate on the abdomen, often closely following the lines of the striae, where present (Fig. 70.4). The umbilicus is frequently spared. Lesions often also appear on the upper arms and thighs.

Despite the outdated term toxaemic rash of pregnancy, there is no suggestion that polymorphic eruption has any adverse effect on the outcome of the pregnancy. Indeed, the babies tend to be larger than normal [19].

Treatment. Some patients improve with topical calamine or steroids and systemic sedative antihistamines. Most women are relieved to learn that the condition is not serious, that all should be well with them and their baby, and that the rash will disappear at or soon after childbirth.

Prurigo of pregnancy [16]

SYN. EARLY ONSET PRURIGO OF PREGNANCY; PRURIGO GESTATIONIS OF BESNIER

The main differences between this disorder and polymorphic eruption of pregnancy are that it begins earlier—usually between 25 and 30 weeks' gestation—and that there are no urticated lesions. It occurs in 1 in 300 pregnancies. Clinically, there are multiple excoriated papules over the abdomen and on the extensor surfaces of the limbs. Histology reveals acanthosis and parakeratosis, with perivascular lymphocytic infiltration around upper dermal vessels. Immunofluorescence is negative. The lesions tend to persist throughout pregnancy, and may continue well into the puerperium, although the pruritic element often settles shortly after delivery [2]. As with polymorphic eruption of pregnancy, the mother and fetus are unaffected, but prurigo of pregnancy may recur in successive

pregnancies, which can cause significant distress to the pregnant woman. It has been suggested that cases labelled 'prurigo of pregnancy' may, in fact, have been eczema [20].

Only symptomatic treatment is available, and this is often rather unsatisfactory.

Pruritic folliculitis of pregnancy [22]

This disorder begins in the second or third trimester, and usually resolves within 2 weeks of delivery. The eruption consists of masses of itchy red follicular papules. It strongly resembles steroid-induced acne. Histology reveals a non-specific folliculitis. Immunofluorescence is negative. There is no adverse effect on mother or baby.

Less well-defined dermatoses

Papular dermatitis of pregnancy

Considerable controversy surrounds this entity. It was first described by Spangler *et al*. [23] in 1962, who reported a widespread papular eruption, which they estimated to occur only once in every 2400 pregnancies. In the original description, the rash consisted of widespread, 3–5 mm, intensely itchy papules with a smaller central crust. There were several laboratory abnormalities, including markedly raised urinary chorionic gonadotrophin levels and low urinary oestriol. Of most significance was the observation that there appeared to be a 30% fetal mortality with this eruption. However, there have been no other convincing reports, and a recent review of 85 patients found no evidence of increased fetal loss [24]. The confusion may have arisen because Spangler *et al*. [23] included fetal deaths in pregnancies unaffected by a rash, and spontaneous abortions, without qualifying these by gestational age [2].

It is now generally accepted that the changes reported as papular dermatitis of pregnancy are probably those of pregnancy prurigo, and that the fetal loss in Spangler *et al*.'s series was overestimated.

Autoimmune progesterone dermatitis of pregnancy

There is a single case report of a patient who developed an odd acneiform rash on the extremities and buttocks in two successive pregnancies [25]. There was an associated arthritis and a positive skin test reaction to progesterone. The author used the term autoimmune progesterone dermatitis to describe this phenomenon, thereby leading to confusion with the condition of the same name that is not pregnancy-associated (see above). However, the clinical features of the two disorders are quite distinct.

Prurigo annularis

Two reported cases [7] had annular scaly lesions that persisted for years postpartum. Whether it really had anything to do with the pregnancy must be in doubt.

The menopause

Hormonal and physiological changes

Strictly speaking, the term *menopause* is used to define the fixed single point in a woman's life characterized by her last menstrual period [1–4]. This is established formally after 12 months of amenorrhoea in the middle years of life [5]. The surrounding years, or climacteric, are a time of change and readjustment to the new phase heralded by the menopause and its loss of fertility: literally, *climacteric*

means a step up the ladder. It is a crucial phase for a woman, preparing her for the years to come which, in modern societies at least, may now represent as much as 30 years, or one-third of her life [6,7]. It has been estimated that by 2030, there will be 1.2 billion postmenopausal women worldwide [8].

The age of onset of menopause has been the subject of much study, and some of the data have been criticized because of flaws in their collection and interpretation [5,9]. However, menopause occurs between the ages of 45 and 55 years in 65–70% of women, and the median age in most Western populations is around 50 years. Factors that may influence menopausal age include heredity (age of mother's menopause is highly predictive), smoking, parity, socio-economic factors, exposure to toxins and nutrition [5]. The onset appears to occur a little earlier in developing countries than in Western societies [9].

True premature menopause before the age of 40 years occurs in less than 1% of women [10], but can follow surgery, irradiation, viral infections (especially mumps), accompany various enzymatic and hormonal defects, or be associated with a number of systemic disorders such as Addison's disease, rheumatoid arthritis, diabetes or myasthenia gravis [1].

During the reproductive years, oestrogen is produced mainly by ovarian follicles, but at the menopause there are major changes. There are very few follicles left, the ovaries become atrophic, and the levels of ovary-derived oestrogen fall. The endocrinology of this period of a woman's life results from the interrelationship of reduced ovarian function and resultant changes in gonadotrophins. Although there may be intermittent bursts of oestrogen in the immediate postmenopausal period because of residual follicular activity, the level of plasma oestradiol ultimately falls to less than 20 pg/L and remains there for the rest of the woman's life [9]. The ratio of oestradiol : oestrone changes, with oestrone becoming the more abundant hormone [11], and most oestrogens being derived from the direct peripheral conversion to oestrone of androstenedione, which has been produced by the adrenals. Some oestrone may arise through the alternative pathway via testosterone and oestradiol [6]. The pituitary–gonadal feedback loop is virtually absent, and levels of gonadotrophins are elevated in consequence. In addition, a number of granulosa cell-derived peptide hormones influence FSH levels [12].

These hormonal changes are reflected in a number of physiological alterations [1]. In the breast, glandular tissue decreases and fibrous tissue increases. The body of the uterus becomes smaller and its muscle is partly replaced by fibrous tissue, and the endometrium regresses and becomes atrophic. However, it still retains the capacity to respond to exogenous hormones. The vagina becomes shorter and narrower, and the vaginal epithelium atrophies. The pH of the vagina rises, and infections become more frequent. The external genitalia atrophy, with a loss of vulval subcutaneous fat and thinning of the vulval epithelium. Pubic hair diminishes.

The epithelium of the lower urinary tract also atrophies and this, together with the increased tendency to prolapse, increases the frequency of urinary tract infections. There is a loss of elasticity in the pelvic supporting ligaments, contributing to prolapse and urinary incontinence [13].

There are no structural cutaneous changes that are specifically associated with the menopause, but there are oestrogen receptors in the skin, suggesting that the skin is a target organ for oestrogen and that its withdrawal may be important [14]. It is interesting that there is a far greater concentration of oestrogen receptors in facial skin than in skin on the breasts or thigh. Some of the changes seen after the menopause, such as dryness, epidermal thinning and loss of dermal elasticity, may result, in part, from lower circulating oestrogen levels. Certainly, administration of oestrogen to castrated animals leads to thickening of the dermis and decreased breakdown of collagen. Oestrogen given to postmenopausal women also increases dermal thickness [15], and in preliminary studies has been shown to improve skin elasticity and deformability [16]. The application of topical oestrogens to the face in menopausal women has also been reported to improve various parameters, including reduction in the depth of wrinkles [17]. However, the picture is not as clear-cut with regard to the epidermis. Hormone replacement therapy (HRT) may increase the skin's water-holding capacity [18].

Skin disorders of the menopause

Atrophic vulvovaginitis

It has been known for many years that the atrophic changes in the female external genitalia described above respond, at least partially, to topical oestrogens [1].

Menopausal flushing

The most consistent and distressing complaint associated with the menopause is flushing [2]. This is usually described as a sudden feeling of intense heat in the face, neck and chest, often accompanied by discomfort and sweating. Although the intensity and duration vary, it typically lasts 3–5 min. Visible changes occur in approximately 50% of women, and generally consist of a blotchy erythema on the face, neck, upper chest and breasts. Some women also develop palpitations, throbbing in the head and neck, headaches, waves of nausea and anxiety attacks. Sleep disturbance is not uncommon [3]. It is possible to measure several physiological changes during hot flushes, including increased temperature, pulse rate and respiratory rate [4,5].

Flushes are associated with pulsatile release of LH [6], presumably because of failure of the normal feedback mechanisms. However, flushing can occur after hypophysectomy [7], and so LH itself cannot be responsible for the observed vasomotor instability. One suggested mechanism involves alteration of hypothalamic catecholamine levels, and a failure of normal central thermoregulatory centres through LH-releasing hormone neurones [2]. Flushes similar to those seen in the menopause can be induced by an enkephalin analogue and blocked by naloxone infusions [8], indicating that menopausal hot flushes may also be mediated by an opiate-dependent central mechanism [9].

The consensus is that oestrogen therapy is the most effective treatment for symptomatic hot flushes [2], although not all authorities have always agreed [5]. Alternatives that can be considered when oestrogens are contraindicated include various progestins [10], clonidine [11] and methyldopa [12]. A mixture of ergotamine, belladonna alkaloids and phenobarbital failed to stand up to double-blind trial analysis [13], but may still be worth trying if all else fails.

Keratoderma climactericum

This term has been used to describe the appearance of hard skin on the palms and soles, especially around the heels. Although originally reported as a specific association with the menopause [14], the same changes are seen in men and women at other ages, many of whom are obese. It may therefore be a non-specific effect. There has been a report of a therapeutic response to systemic retinoids [15].

Lichen sclerosus et atrophicus

This disorder is considered in detail in Chapters 56 and 68 but is mentioned here because of its frequent presentation at or around the menopause, and because of the significant symptomatology it may cause.

Complications of HRT

The increasing use of HRT, largely to prevent osteoporosis and cardiovascular disease, has revealed a number of problems associated with this treatment. There is an ongoing debate regarding the relationship between HRT and cancers of the breast and genital tract, but this is beyond the scope of this chapter. However, HRT may be responsible for a number of cutaneous problems, which should at least receive a mention here.

Oestrogen therapy may trigger or exacerbate, amongst others, chloasma (melasma); spider angiomas; darkening of naevi; the skin changes of porphyria cutanea tarda; and acanthosis nigricans [16,17]. Many clinicians also report encountering urticarial or eczematous dermatoses that appear in patients on HRT and subside on cessation of treatment. Allergic reactions have been reported to the transdermal patches frequently used as delivery systems for HRT. These may be to the adhesives or to the oestrogens themselves [18].

Old age

Introduction

Senescence in the skin is a gradual process that ultimately results in the appearances and functional differences that we associate with old age. However, by no means all of these changes are purely intrinsic. The skin is particularly vulnerable to the 'ageing' effects of a number of environmental insults, especially UV radiation, and in women there are additional hormonal changes at the menopause (see p. 70.18). These factors are superimposed on the background changes of intrinsic senescence, and care needs to be exercised in interpreting which are most important in determining any particular aspect of the appearance and function of the skin in an elderly person. However, there have been increasing efforts to disengage the roles of these intertwined and contemporaneous processes.

Biology of ageing

Ageing is the decline in the power of self-maintenance, the increase in susceptibility to disease and the growing probability of death as age advances. Ultimate senescence is as much a biological necessity as initial survival; evolutionary progress has occurred because animals are programmed for both. In the words of Macfarlane Burnet [1], 'The two basic evolutionary needs of all species of higher animal are survival to reproductive age, and death when survival offers no reproductive advantages to the species.'

Modern theories of ageing fall into two categories that, philosophically speaking, start from opposite poles. The first views ageing as an ordered process delicately programmed by the genes [2]; the second suggests that ageing is caused by the progressive retention and amplification of errors in the replication of genetic information in the somatic cells [1]. From the practical viewpoint, both types of theory emphasize the intrinsic inevitability of the process.

If the ageing of most of the bodily organs has, however reluctantly, to be accepted, the ageing of the facial skin appears to be a matter of widespread concern. The reason is that the skin plays a major part in our social and sexual interactions; the concern is not so much to do with physiological functions, which may remain adequate in old age, but about continuing effectiveness, particularly of the facial skin, in communication. To display sexuality or assert social status it is necessary to have skin and hair that look, feel and smell attractive.

The ageing of skin has so far been studied for social and commercial reasons in affluent white populations. Some of these subjects are ill adapted for the environments they now occupy or the lifestyles they endure or enjoy. It must not therefore be assumed that the data obtained will necessarily apply to skin with greater pigmentation, especially that of Mongoloid and Negroid populations.

The most obvious signs of an ageing skin are atrophy, laxity, wrinkling, sagging, dryness, yellowness, a multiplicity of pigmented and other blemishes, and sparse grey hair. Some of these stigmata clearly have genetic components, and some are mimicked by heritable disorders. The abnormal texture of the dermis in cutis laxa makes young children look old; in progeria, on the other hand, the connective tissue remains evenly dense, although the epidermis shows mottled pigmentation [3].

Intrinsic changes of ageing fall into two categories: those that appear to be engendered within the tissues themselves, and those that are the result of alterations, including hormonal, caused by senile changes in other organs. An example of the former is the greying of hair, and of the latter, the lowering of sebaceous gland activity consequent upon reduction of androgen secretion.

Into a third category must be put changes that are mainly the result of environmental factors. These may be overriding; for example, it has been stated that on exposed skin more than 90% of age-associated cosmetic problems are caused by UV radiation [4].

The ageing skin

Dermis

It cannot be doubted that wrinkling of senescent skin is almost entirely the result of changes in the dermis. The debatable questions concern the nature of these changes

and the extent to which they are intrinsic or environmentally caused [1,2].

The dermis diminishes in bulk, and in absolute terms the collagen per unit area of unexposed skin decreases with age [3]. There also appears to be a steady decrease in the number and size of mast cells and fibroblasts [2]. Although it is often assumed that the lax skin of the aged results from lack of water, there is evidence that, on the contrary, water content increases between the fourth and ninth decades [4].

Gross morphological changes, especially in the collagen and elastin fibres, have been revealed by electron and light microscopy. Their relationship to molecular changes as determined by physical and chemical methods requires interpretation. Moreover, it has long been clear that such changes are largely the result of exposure to solar radiation (photoageing) [5].

Accumulating evidence indicates that intrinsically aged skin shares a number of features with photoaged (environmentally aged) skin. Commercial interests have dictated a more detailed interrogation of the mechanisms underlying photoageing. However, the same research techniques are now being applied to intrinsically aged skin. There is an age-related loss of fibroblast frequency and size, coupled with a decrease in their synthetic ability [6]. Over the age of 70 years, there is loss of collagens I and III in the papillary dermis with an associated increase in matrix metalloproteinases [7]. Reactive oxygen species and free radicals are key drivers of degeneration so characteristic of aged skin. This oxidative damage is produced in part by the action of mitogen-activated protein (MAP) kinases. In aged skin, stress-activated MAP kinase activity is elevated [8].

In the dermis of young adults, the collagen bundles are well organized. They form a rhomboid network with the individual bundles lying at angles to one another. Intertwined among the collagen bundles lie single branching elastic fibres, apparently aligned haphazardly, in planes parallel with the surface at all levels beneath the dermal–epidermal junction. The network of collagen bundles, although composed of inextensible fibres, is itself extensible as the bundles rotate relative to one another to form parallel alignments. It seems likely that the return of the network to its unstretched state is brought about by the interwoven elastic fibres [9]. Thus, in cutis laxa, an uncommon disorder in which the skin hangs in folds, the elastic fibres appear to be reduced in number and degenerate (see Chapter 46).

The various descriptions of changes in ageing based on histological staining techniques are often confusing. In general, it appears that the collagen bundles become fragmented and disorientated, and elastin fibres become progressively reduced [10]. However, in senile skin from exposed areas there may, paradoxically, be a striking increase in fibres that take up elastin stains in actinic elastosis (see Chapter 46).

Elastic fibres gradually disintegrate with age, even in protected skin, and after the age of 70 years most fibres appear abnormal [11–13]. These changes are most likely a combination of reduced synthesis and elastolysis. Similar changes can be produced in protected buttock skin within hours by incubating it with pancreatic elastase and bovine chymotrypsin [11].

Epidermis

Many differences between a senile and young epidermis have been described, but a consistent interpretation of the ageing process has proved difficult. In part, this is because the epidermis varies from site to site. Young skin from the back [14], like that from the scalp and axilla [15], has deep and complex rete ridges, whereas that of the face [15] has a fairly flat dermal–epidermal junction. It is widely agreed that in areas where the junction is corrugated in youth, it becomes flattened in the aged [15–20].

Similarly, there are differences in epidermal thickness, even in young skin. On the face or on the dorsum of the hand, for example, it is considerably greater than on the arms, legs or trunk [15]. In many areas, the whole epidermis becomes thinner with age, and the cells become less evenly aligned on the basement membrane and less regular in size, shape and staining properties [15,19–22].

The question of whether these changes result from alterations in the rate of cell replication has also engendered controversy, largely because of differing methods of study [23]. However, there is now some consensus that the cell turnover rate is halved between the third and seventh decades of life [21,24,25], notwithstanding an earlier finding that the frequency of mitoses in abdominal skin increases from childhood until the fifth decade and then levels out [26]. The evidence that the rate of epidermal repair and wound healing declines with age [27] is consonant with the view that epidermopoiesis is decreased.

The permeability of the skin also changes with age, although some of the data are contradictory [28]. According to Christophers and Kligman [16], the capacity of the isolated horny layer *in vitro* to restrict water loss does not differ between young adults and persons over 70 years of age, but the aged skin is decidedly more permeable to chemical substances. However, *in vivo*, they found that the percutaneous absorption of testosterone appeared to be reduced in old age. A possible explanation is that, although substances enter aged skin more easily than young skin, they are removed more slowly into the circulation because of changes in the dermal matrix and reduction in the vasculature [4]. The response to blistering agents, such as 50% ammonium hydroxide, is initially quicker in elderly than in young subjects, but the formation of the full blister takes longer [29].

These physiological differences must be largely related to changes in the stratum corneum, yet neither its thickness nor the number of cell layers seem to vary with age, at

least on the back [16]. However, Marks [30] showed that the surface area of individual corneocytes from unexposed areas of the arms, thighs and lower abdomen increases with age, and suggested that this might reflect an increased transit time [31].

A change in the nature of the corneocytes is also indicated by the tendency of the senescent epidermal surface, especially that of the lower legs, to become dry, flaky and sometimes itchy. Apart from reduced function of the skin glands, the water-binding capacity of the stratum corneum appears to be reduced [32], coupled with an increase in renewal time if damaged [33].

Pigmentation

The most obvious senile change in white skin is irregularity of pigmentation. Yellow or brown macules, known as 'liver spots' or 'age spots', develop on the backs of the hands and exposed parts of the face in more than 50% of persons over 45 years of age. Very rarely, such *senile lentigines* develop into *lentigo maligna*, which is a precancerous condition, although it progresses very slowly [33].

The senile lentigo consists of a localized proliferation of melanocytes at the dermal–epidermal junction [34]. In general, however, the number of dopa-positive melanocytes in both exposed and unexposed skin decreases in old age, although their size increases. The reduction is in the order of 8–20% per decade compared with young adult skin [35]. Their reaction to dopa becomes variable, and some no longer donate pigment [33,36,37].

Even heavily pigmented skin darkens. A study of 578 adult natives of New Guinea revealed that pigmentation increased with age in skin exposed to the sun, but not in axillary skin, and that males darkened more than females [38].

Greying of hair

Greying usually becomes evident around the age of 50 years, by which time about half the population has approximately 50% grey or white body hairs and an even greater proportion has some depigmented scalp hair [39].

The bulbs of grey or white hairs show various abnormalities, but it is uncertain which are critical. In general, the bulbs appear to lack or be deficient in tyrosinase, the enzyme necessary for the first stages of melanin synthesis [40]. Structurally, the follicles of grey hairs still have melanocytes placed normally over the dermal papilla, but the cytoplasm may contain large vacuoles and the melanosomes may be only lightly melanized [33]. The follicles of fully white hairs may completely lack melanocytes. However, among grey or white hairs, there may be a few normal bulbs producing dark hairs.

An unexplained fact is that at all ages from their appearance on the chest in males, and probably elsewhere, grey hairs tend to be thicker and longer than pigmented ones [38].

Premature greying of hair, even before the age of 20 years, is a feature of several hereditary syndromes, and is also associated with a number of disorders induced by organ-specific antibodies. A survey of the age prevalence of normal greying of hair in men [41] showed that it fitted a simple mathematical model of ageing consonant with the view that the condition is 'autoaggressive' or 'autoimmune' in character and arises from somatic gene mutations.

Hair follicles [42]

Changes in the hair follicles vary greatly between sites. For example, it can be widely observed that hair becomes sparse on the vertex while it is still luxuriant on the occiput, and that greying usually starts at the temples.

In the scalp, the density of hair follicles steadily decreases with age, more rapidly in bald than in non-bald persons [43]. The overall capacity of the follicles to produce long hairs is progressively reduced, at least on the vertex, and especially in males. This cannot be accounted for by any diminution in the rate of growth, which remains substantially unchanged [44]. It must therefore result from a shortening of the duration of anagen. This is reflected by the gradual rise in the proportion of follicles in telogen, both in non-bald subjects [45] and in persons with pattern alopecia, where it becomes evident in advance of visible baldness [46].

Scalp hair also becomes finer, especially in persons with visible alopecia. In a group of 58 white women with diffuse alopecia, 13 of whom were clinically hypothyroid, there was a gradual reduction in mean diameter which appeared to be an exaggeration of a trend also found in normal subjects [47]. The diameters showed a wide range, with a single peak around 0.08 mm in normal persons, but two peaks at 0.04 and 0.06 mm, respectively, in patients with alopecia, suggesting that not all the follicles behave identically.

The weight of beard grown per day reaches a peak in the fourth decade, and starts to decrease slightly in the seventh decade [48]. As the density of the hairs remains constant, the decrease in weight must be accounted for by a reduction in the rate of growth, in diameter, or in both. Evidence that the linear growth of beard hair is correlated solely with levels of 5α-dihydrotestosterone (DHT) in the plasma, not with testosterone, whereas hair density is significantly correlated solely with testosterone, not with DHT [49], suggests that the age changes may result not so much from reduced production of testosterone as by lessened peripheral metabolism.

Chest hairs, which are also androgen-dependent, reach a maximum in number, breadth and length around the fifth decade, and then start to diminish markedly [39].

Axillary hair reaches a peak in mass and in rate of production towards the end of the third decade in males and females alike, and this is followed by a rapid decline,

somewhat more severe in females [48,50]. Pubic hair appears to follow a similar pattern.

If most of the changes with ageing involve reductions in the amount of hair, this is not true of all sites. In the male, the eyebrows may become more bushy, and visible hairs develop around the external auditory meati. In the female, hirsutism may occur as a result of endocrine changes associated with the menopause (see p. 70.18).

Sebaceous and apocrine glands

Sebum production is at its greatest in early adulthood, and lessens in old age. A view that it remains unchanged until past the age of 70 years in men, but falls after the menopause in women, has not been entirely sustained [51,52].

Measurements of the sustainable rate of wax ester secretion after depletion of the sebum reservoir by absorption with bentonite clay suggest that sebum secretion declines steadily through each decade by approximately 23% in men and 32% in women [53]. The fatty acid composition also changes [54].

The predominant belief is that, in spite of their decreased output, the sebaceous glands increase in size because turnover of cells is slower in senility [55,56]. However, in one study in 14 women the glands appeared to become smaller and the sebocytes flatter with age [57].

The axillary apocrine glands also regress with age and produce less odour [15].

Eccrine glands

Spontaneous sweating on the fingertips declines in old age, as a result of a combination of a reduction in the number of glands [58] and of the output per gland [59]. On the forearm, the response to epinephrine has been shown to be reduced by ageing equally in men and women, suggesting an intrinsic deterioration of the glands, an interpretation supported by histological evidence. In contrast, the effect of age on the response to acetylcholine is much greater in the male than in the female, suggesting that ageing affects cholinergic sweating indirectly through the hormonal balance in the blood [59]. Such a hypothesis is borne out by the evidence that the maximum rate of cholinergic sweating is much greater in adult males than in females or in juveniles, and is thus probably androgen-dependent [60].

Nail growth

The rate of linear nail growth increases until well into the third decade. From about the age of 25 years it starts to decrease. Until the age of 70 years, nail growth is greater in men than in women, but thereafter the situation appears to be reversed [61]. Nails are more brittle in the elderly and are characterized by beaded ridging—sometimes called 'sausage links'. Brittleness may be caused by a reduction in the nail content of lipophilic sterols and free fatty acids [62].

Nerves and sensation

Age often decreases sensory perception and increases the threshold for pain [29,63]. There is evidence for progressive disorganization or loss of some sense organs; for example, the density of Meissner corpuscles in the little finger falls from over 30/mm^2 in young adults to approximately 12/mm^2 by the age of 70 years [64].

Langerhans' cells and immune functions

Langerhans' cells become considerably reduced in number in elderly people, even in light-protected areas [65,66]. Recent work has confirmed the reduction in number of epidermal Langerhans' cells with age, coupled with a reduced ability to migrate from the epidermis in response to tumour necrosis factor-α [67]. T cells, similarly, are reduced in percentage and absolute number, and lose their responsiveness to specific antigens [4,68]. The number of B cells does not seem to be affected by age, but their dysfunction is reflected by increased autoantibody formation and serum levels of IgA and IgG [68–71]. Elderly skin appears to have a much reduced capacity to produce cytokines such as interleukin-2 (IL-2) [72]. However, the production of some cytokines (e.g. IL-4) increases with age [72]. The decreased intensity of delayed hypersensitivity reactions [73], the increased risk of photocarcinogenesis and the greater susceptibility to chronic skin infections are some consequences of the ageing of the immune system [24].

Skin disease in old age

The demography of most nations is changing. Higher standards of housing, hygiene and nutrition, together with improvements in health care services have meant that the average lifespan has increased considerably over the last century. Added to this, many couples are now limiting their families to two or three children at most. Virtually every Western society is therefore experiencing an increase in the average age of its population. The provision of health care for elderly people is consequently becoming more and more important, and disease of the skin is no exception to this [1]. Elderly patients present in dermatology clinics and consulting rooms with a wide variety of skin problems; a few are more or less specific to old age, but most are familiar skin disorders whose clinical expression, physical and emotional consequences, and management may be altered by the age of the patient and the problems that increasing age bring with it.

The reasons an individual seeks advice for skin changes in old age may be as much influenced by personality and social conditioning as by the absolute severity of the problem. Although some societies are still said to view the outward signs of age, such as wrinkles and grey hair, as marks of distinction, it is clear that in much of the world, 'Westernization' is resulting in an increasing degree of social stigmatization associated with looking old. Furthermore, it has long been recognized that, contrary to the popular belief of the young, elderly people are often anxious to look attractive [2].

Thus, particularly in rich and highly developed societies, there is an increasing reluctance to accept the physiological consequences of old age and the effects of environmental exposure. A myth has begun to develop that these ageing changes are abnormal, and many older people with plentiful spare time and financial resources have become obsessed with the pursuit of an eternally youthful appearance (Fig. 70.5). One reason for this is that the pharmaceutical and cosmetic industries have invested heavily in the promotion of the concept that 'young is beautiful'. A great deal of money is being and will continue to be devoted to the study of compounds that may arrest or reverse the visible effects of ageing. Some are claiming success, most notably with retinoic acid for wrinkles. Such research is also increasingly gaining credence in mainstream medical circles, and dermatologists are becoming more and more involved in this area of practice.

However, most people accept (albeit increasingly reluctantly) that ageing is a natural process, and only seek medical advice when skin changes are particularly troublesome or severe, or develop earlier than might otherwise have been expected.

Skin changes of sufficient severity to warrant medical attention in elderly patients may result from the interplay of several factors:

1 Alterations in structure and function of the ageing skin
2 Cumulative effects of exposure to a variety of environmental insults, especially UV radiation
3 Cutaneous consequences of ageing or age-related disease in other organ systems
4 Changes in the environment—decreasing occupational exposure, increasing leisure exposure to potential irritants and sensitizers
5 Social circumstances, with poor nutrition, home care and mobility often contributing to the expression, perpetuation and failure to resolve of skin problems
6 Physiological problems, such as dementia, increasing rigidity of attitude and refusal to accept advice
7 Increasing physical frailty, resulting in a relative incapacity to carry out tasks correctly.

Of particular practical importance are the latter three problems, which are frequently ignored. An elderly patient may be too proud to point out that physical incapacity prevents the twice daily application of a cream, or may deliberately refuse or forget to relate relevant facts about the home situation. The onus is very much on the dermatologist to consider these factors when dealing with skin disease in the elderly patient.

Incidence of skin problems in old age

It is hard to estimate the true frequency of skin disease in the population as a whole, let alone specifically in older age groups. One problem is that the line between that which is physiological and the 'truly' pathological becomes increasingly difficult to draw with advancing years. Another is that studies of skin problems in the elderly have used different types of population and diagnostic groupings which are not directly comparable (Table 70.7). It is probably better therefore to think of skin problems rather than just skin disease in this age group.

However, it is clear that skin problems are common in elderly people. The general scale of this can be gauged from the findings of a large US study, in which dermatological examination of 20 000 non-institutionalized US citizens revealed that 40% of those aged between 65 and 74 years had some significant dermatological problem [3]. 'Significant', in this context, was defined as requiring, in the view of the examining doctor, a dermatological

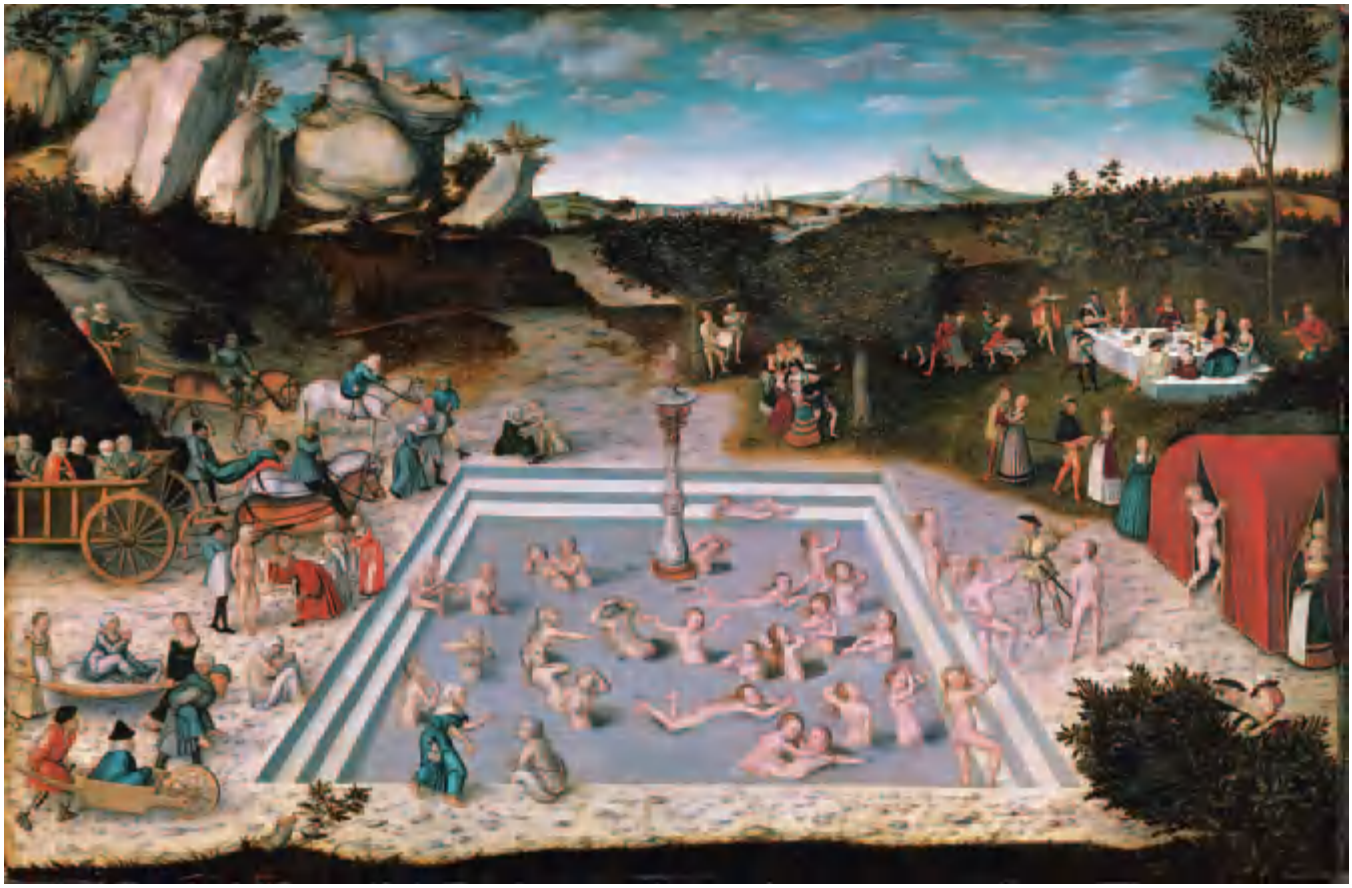

Fig. 70.5 *Der Jungbrunnen*. Lucas Cranach the Elder painted this picture of the Fountain of Youth in 1546, when he was 72 years of age. On the left, a succession of aged and decrepit women are brought to the fountain by an interesting variety of primitive transport. As they move through the basin they are transformed into lovely young maidens. The eternal desire for and, indeed, the possible advantages of rejuvenation are wonderfully expressed. (Courtesy of Staatliche Museen zu Berlin, Gemäldegalerie, Berlin, Germany.)

opinion. Smaller studies on elderly individuals selected randomly and not from skin clinics give much the same impression [4–7]. For example, of 68 volunteers aged between 50 and 91 years, living in Boston, USA, two-thirds of the entire group and 83% of those aged over 80 years complained of skin problems of some kind [4]. In a European study, 77.4% of a population of 584 elderly residents of a municipal old peoples' home in Denmark were found to have a skin problem [7].

Many of the skin problems that are found most commonly on random examination of elderly people are not those for which elderly patients necessarily seek attention from specialist or non-specialist doctors. Although eczemas, pruritus, easy bruising and dryness (under various headings) are certainly seen in skin clinics, tumours, both benign and malignant, tend to figure more prominently than inflammatory problems [8–12].

Table 70.7 Studies on the incidence of skin disease in elderly people.

Reference	No. of patients	Population studied
Droller [5]	476	Random; at home
Young [8]	330	Ambulatory outpatients from skin clinic; chosen 'at random'
Epstein [9]	687	US private practice
Tindall & Smith [6]	163	Volunteers; at home; black and white people
Verbov [12]	170	Mainly outpatients; some in-patients
Weisman *et al*. [7]	584	Residents of old peoples' homes
Beauregard & Gilchrest [4]	68	Volunteers: housing projects, geriatric home visits, medical centre employees
McFadden & Hande [10]	257	Dermatology outpatients

Specific skin problems in old age

Most of the skin disorders that are particularly troublesome in the elderly patient are described elsewhere in this book. However, one or two points should be emphasized about certain specific disorders.

Wrinkles and elastosis

These changes, together with greying of the hair, are most readily associated with an aged appearance. The different clinical forms of wrinkles, and the clinical syndromes associated with elastosis, are described in Chapter 46, and the histological changes of the ageing dermis are discussed above. Plastic surgeons and dermatologists are becoming increasingly involved in their management. Chemical peels, collagen implants and facelift operations are in widespread use, and topical retinoids are employed in the treatment and prevention of wrinkling [1–3].

Pruritus

Itching in old age can be so severe that it ruins quality of life completely [4]. The itch may be localized or generalized, and may or may not be accompanied by skin changes. It is crucial to examine an itchy elderly person carefully for primary cutaneous disease. In one study, 142 of 162 elderly patients had an identifiable cause for their itching (including xerosis), leaving only 20 to whom the term senile pruritus was applicable [5]. Diagnoses that are particularly easy to miss are scabies (often caused by the inadequate examination facilities in residential homes for the elderly) and bullous pemphigoid, which often begins with a non-specific or even no rash [6]. Non-specific skin changes in anogenital itch may also conceal important diagnoses: candidiasis in undiagnosed diabetes; lichen sclerosus et atrophicus, the classical signs of which may easily be obscured by secondary excoriation and inflammation.

If a primary skin disorder has been ruled out, it is important to investigate any elderly patient with generalized itching for systemic causes: renal disease, cholestasis (especially chronic liver disease), thyroid disease, anaemia or cancer. The relationship between carcinomas and pruritus in the elderly patient is controversial, but there is no doubt that lymphomas, leukaemias and other myelodysplastic disorders may present in this way [7]. The frequency with which a systemic cause is found varies, but is high enough to justify a routine search [4], and a useful algorithm for this has been provided by Champion [8].

When all these causes have been excluded, there remains a small core of elderly patients with intractable pruritus. In some, the itching is accompanied by xeroderma, but in others the skin feels relatively normal to the touch. The management of such patients is extremely difficult, and is often totally unsatisfactory for all concerned. The topical use of emollients, soothing preparations such as menthol in calamine, and potent topical steroids may be helpful. However, many of those with the worst pruritus are quite unable to manage topical therapy by themselves, and it is necessary to resort to relatively sedative systemic drugs, such as phenothiazine-type antihistamines. These, too, have their drawbacks, not the least of which is the development of confusion and disorientation.

Senile xerosis and asteatotic eczema

SYN. ECZÉMA CRAQUELÉ

The ageing skin often feels 'dry' to the touch, although the reason for this is not clear. Water loss is not increased in aged skin [9], but the water content of the epidermis appears to be somewhat reduced [10]. It has been suggested that xerosis reflects minor abnormalities in epidermal maturation [7].

The dryness is often worse in the winter, a fact that has given rise to many of the alternative names used for these changes: winter eczema, prurigo or pruritus hiemalis. The changes are often most pronounced on the legs. In some patients, the surface texture of the skin assumes a cracked appearance resembling crazy paving. This is known as asteatotic eczema or eczéma craquelé (Fig. 70.6). Frequent washing is certainly a causative factor in susceptible individuals [11], and central heating may also play a part by reducing atmospheric humidity. Perhaps it is not surprising that this problem is commonly seen in geriatric in-patients.

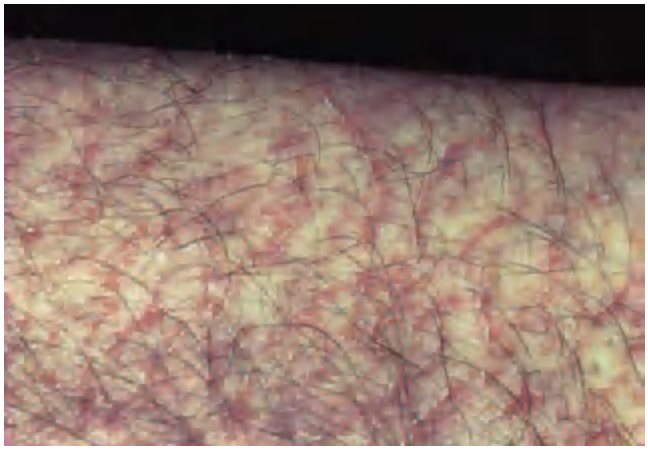

Fig. 70.6 Eczéma craquelé.

The use of emollients to reduce requirements for soaps and detergents will improve xerosis in most patients and, because high water temperature appears to increase the tendency to irritant reactions [12], so will reducing the bath temperature. Moisturizing preparations in the bath are generally held to be effective [4], but bath oils can make the bath very slippery, which has its risks in the elderly and frail patient.

Eczema

The aged may suffer from any of the clinical types of eczema. Atopic dermatitis, for example, occasionally continues into old age or even appears for the first time. However, certain patterns such as asteatotic eczema are more common and more troublesome in elderly subjects.

Seborrhoeic dermatitis may be more common in the elderly infirm and in those confined to bed [13]. In the aged patient, especially the obese, a flexural pattern is often encountered, which may mimic intertrigo and flexural psoriasis.

Some elderly patients present for the first time with a discoid or nummular eczema, and most patients with Sulzberger–Garbe disease (generally considered to be a variant of discoid eczema) are elderly.

Gravitational eczema is much more common in the elderly patient (see Chapter 17), and may be complicated by contact sensitivity.

Contact dermatitis of irritant or allergic origin is generally considered to be less common in elderly people, partly because of decreased occupational exposure [14]. This may also reflect the decline in immune reactivity that occurs with age [15] and the fact that irritant responses to some substances are reduced in intensity [16]. However, patch-test positivity remains quite common, presumably from exposure earlier in life. Allergic contact dermatitis remains a significant problem in elderly people, especially resulting from local medicaments, such as aminoglycosides, lanolin, parabens, antihistamines and anaesthetics. Other sensitizers that continue to cause trouble in old age include rubber in gloves and shoes, plastics in hearing aids and spectacle frames, plants and hair dyes [14].

Marked secondary lichenification and chronic lichen simplex are also often seen in older patients.

Bullous disorders

Pemphigoid (see Chapter 41) is much more frequent in the elderly than in other age groups. Old age modifies the management of all blistering diseases because of unwanted effects of drugs, or because of physical and social circumstances. Steroids precipitate glucose intolerance more often in the elderly, and sulfapyridine or sulfamethoxypyridazine may be better first-line drugs than dapsone for dermatitis herpetiformis because of the tendency for dapsone to cause haemolysis [17]. Drug regimens should be kept simple, and written down where necessary.

Psoriasis

There is a distinct peak of onset of psoriasis in later life that is not as clearly associated with a family history as in patients whose disease begins earlier. This is reflected in different human leukocyte antigen (HLA) associations [18].

Psoriasis causes increased problems in the elderly patient. Disease of lesser extent and severity may be relatively more disabling in old age than in youth, and the systemic effects of widespread or acute pustular psoriasis are less well tolerated than in younger individuals. Flexural psoriasis is a particular problem in the elderly patient [19], but other patterns are also seen. Eruptive guttate disease, however, is rare in old age.

Treatment can be difficult. The patient may be unable to apply topical therapies, and there may be problems in travelling to and from the hospital for outpatient dithranol, or in standing for psoralen and UVA (PUVA) therapy. One solution is the use of systemic therapy, especially methotrexate. There is less reason for concern over long-term toxicity in the elderly patient, relatively small doses may keep the patient comfortable (perhaps because of diminished renal clearance) and the drug is generally well tolerated.

Leg ulcers (see Chapter 50)

Leg ulcers are a major problem. Most are caused by venous hypertension, but arterial disease becomes increasingly important with advancing years. Poor wound healing in elderly people [20], perhaps associated with other illnesses and poor nutrition, may also have a role in the perpetuation of some ulcers.

In managing chronic leg ulcers in the elderly patient it is important to take an overview of the whole situation. Strenuous efforts to heal a stable ulcer in someone who is coping independently at home may be inappropriate in some cases if long-stay in-patient treatment will be required.

Decubitus ulcers [21]

See Chapter 22.

Herpes zoster and post-herpetic neuralgia [22]

Shingles is much more common in old age, the relative incidence rising from 4 in 1000/year at age 55 years to 10 in 1000/year at age 90 years. It has been estimated that 25% of people over the age of 65 years develop shingles at some time, and that all who have had chickenpox would do so were they to live to 100 years old. Post-herpetic neuralgia is also much more common in elderly people. Approximately 50% of patients over the age of 60 years experience pain, and the incidence rises to as many as 75% of the over-70s.

Skin tumours

Most skin tumours are more common in elderly people: benign, such as seborrhoeic keratoses, senile lentigines and skin tags; dysplastic, such as actinic keratoses; and cancers, especially basal and squamous cell carcinomas. Lentigo maligna is seen predominantly in the elderly, and the highest age-specific incidence rates for invasive malignant melanoma are also in those over 60 years [23]. There is also an association between increasing age and decreasing 5-year survival in malignant melanoma [24]. It is not clear why this should be, but elderly patients seem to present with thicker lesions [24,25], and recent evidence suggests that the proportion of nodular melanomas may rise with increasing age [25]. The tendency to wait longer before presenting for treatment also extends to other tumours, and lesions such as that shown in Fig. 70.7 are essentially restricted to elderly people.

Infections with ectoparasites

Outbreaks of scabies in residential homes for the elderly are not uncommon, and are usually attributable to one individual with a heavy infection, verging on Norwegian or crusted scabies. Clothing lice (see Chapter 33) are, in the UK, almost exclusively seen in elderly vagrants.

Fig. 70.7 A large neglected basal cell carcinoma on the back of an elderly lady.

Chapter 71

General Aspects of Treatment

J.A. Cotterill & A.Y. Finlay

General principles

The general principles for the treatment of skin diseases are essentially the same as for other branches of medicine. There are, however, important aspects and details peculiar to dermatology that readily escape the non-specialist, attention to which may make so much difference to the success or otherwise of therapy. In particular, topical therapy in many situations may be in danger of being relegated to an unimportant role. Patients may decry local applications. During history taking, many patients say they have had no treatment, 'only a few ointments'. They may also be unaware of the potential harm that can be done by topical therapy, whether self-administered or iatrogenic. Careful nursing and instruction of the patient on how to use any remedy can be much more important than in other branches of medicine.

Although dermatologists have available to them many more agents of proven beneficial pharmacological activity than were available to their predecessors, they still have to persuade, console and counsel and must convince many patients that no specific treatment is available for their particular problem.

Thus, the central aspect of dermatological management is the consultation, which often demands great skill in communication techniques. Improving doctor–patient communication is not an option but a necessity [1].

The dermatological consultation

The various manoeuvres employed by patients and doctors in the consultation 'gamesmanship' have been described [2].

The individual dermatologist will, however, develop his or her own preferred technique of consultation as he or she matures in the specialty over the years. Thus, there are those dermatologists who like to see their patients completely naked so that they can be sure they are missing no other dermatological pathology. However, seeing a patient initially entirely naked may lead to a considerable loss of valuable data. The patient's dress provides psychosocial information, and the gait of the patient as he or she walks into the consulting room can give some useful information. In particular, the depressed patient often has a characteristic 'droop', whilst the anxious patient is moving in all directions at the same time, typically sitting on the edge of the chair. The depressed patient may be slow in all his or her responses to questions. An anxious person may continuously twirl a ring on a finger, and the quivering lips or the moistening of an eye in response to a question may indicate important stress-provoking factors. The language employed by the patient in describing the symptoms is also important. Whilst photosensitivity eruptions such as porphyria may produce a burning sensation in the skin, very few other skin conditions do this, and symptoms described emotively in this way may indicate that functional factors are important in pathogenesis. The patient who brings in an enormous bag of medicaments, all of which have done 'nothing at all' to help, may also indicate a psychological or psychiatric aspect to the case. A 'hollow' history and the '*belle indifference*' of the classical patient with dermatitis artefacta can be appreciated only by taking a good history. Little matchboxes and plastic bags containing detritus are very characteristic of patients with delusions of parasitosis.

What do patients want? [3–8]

Patients consult dermatologists because they want help with their skin problems. Patients require not only information and medical treatment, but also explanation, understanding and emotional support [3,4]. Whilst patients may hold elaborate, and sometimes sophisticated, theories about their own skin problems, most patients need to know the answers to three basic questions: 'Why me?', 'Why now?' and 'Why this particular illness?' [3]. Sadly patients may receive no diagnosis, few explanations, inadequate advice and leave the consultation feeling the doctor is uninterested and believes all symptoms are unimportant [5]. Above all, the patient values a doctor who listens, although not all doctors may yet have learned to hear what their patients are saying [6]. The doctor must recognize that the patient is now a key medical decision maker in reaching an optimal management choice tailored to the particular needs and views of an individual patient [7]. A paternalistic consultation style is of historical interest only, and care should be patient rather than disease centred.

Eye contact is vital if meaningful data are to be gathered from the patient [8]. Doctors with a mechanistic interrogative style who offer no eye contact usually turn off any meaningful verbal communication from the patient.

Body image, self-esteem and the leper complex

An individual's body image is largely cutaneous, so skin disease affecting any part of the body surface may produce considerable depression in body image, self-esteem, confidence and secondary depression [9]. This is particularly true where skin disease affects areas such as the scalp, hair, face, hands and genital area. The stigma of skin disease can readily produce a 'leper complex' in the individual patient, which compels the patient to withdraw from society and physical contact with other human beings [10,11]. It is vital therefore that the dermatologist provides reassurance by touching the patient at some stage during the consultation.

Timing

A dermatosis is rarely a static event. The effect of the patient's actions and attitudes, the frequent development of anxiety or depression and the daily variations in the internal and external milieu require frequent reappraisal and adjustment of treatment. Topical corticosteroids should be reduced in strength as the disease recedes.

The timing of a return to work often involves a difficult decision; even the return of a patient from hospital to his or her environment may be misjudged. In either case, a relapse may cause the patient to lose confidence. In all dermatological therapy, Napoleon's dictum may be remembered with advantage: 'la puissance ne consiste pas à frapper fort ou à frapper souvent, mais à frapper juste'.

Failure to appreciate the natural history of disease has been responsible for much unnecessary therapy, and for a wrong assessment of therapeutic needs. For instance, in alopecia areata, specific therapy is lacking, and the average duration is unaffected by empirical measures. Infantile eczema tends to improve with time and nummular eczema 'burns itself out' in months or years. In these diseases, the patient is ill-served by measures that can only alter the immediate situation without an additional planned campaign to sustain him or her over this prolonged period. A diminishing concentration of topical corticosteroids, measures designed to distract attention from the disease and manoeuvres designed to help morale are necessary parts of the whole treatment. In diseases with a short-lived but hectic course, such as erythema multiforme exudativum, oral steroids, if given at all, should be 'tailed off' once the expected peak of the disease is past. In chronic diseases, such as psoriasis, systemic sclerosis, lichen sclerosus of the vulva, ichthyosiform erythroderma or dermatitis herpetiformis, therapy should be on the lines of a siege operation or, sometimes, as a deliberately planned retreat in which the disease is contained and held in check. Whenever possible, it is a wise precaution to hold a therapeutic reserve for periods of exceptional activity of the disease process.

Compliance

Hippocrates warned that '(the physician) should be aware . . . that patients often lie when they state they have taken their medicine'. Dermatology patients may not deliberately lie, but there may be many reasons why patients are not able to carry out a therapy regimen. It is essential that the clinician understands these potential difficulties and

takes steps within the consultation to plan therapy which is practical and with which the patient agrees. The term 'concordance' or 'adherence' is now preferred over 'compliance', as the concept of compliance with treatment implies a patient passive in the treatment decision process —a situation likely to ensure inadequate or inappropriate use of therapy. Although concordance issues are of relevance to every dermatology consultation [1], there is relatively little published on the subject; there have however, been two workshops at international meetings [2,3].

Influences on adherence include the degree of motivation of patients, the extent to which their quality of life is impaired by their disease and the attitude of the patient towards their disease and their relationship with their doctor [4]. A longitudinal study [5] has shown that dissatisfaction with care and psychiatric morbidity are significantly and independently associated with poor medication adherence: the physician's interpersonal skills play a major influence in medication adherence. The strongest predictor of adherence to skin-care treatment in childhood atopic dermatitis is a good doctor–patient (mother) relationship [6]. Other factors that are likely to improve adherence with therapy include patient education about how to apply topical preparations, the use of as few different preparations as possible and the use of preparations that are cosmetically acceptable. Realistic and simple regimens with preferably once daily applications are much better than regimens with frequent applications, but a simple manoeuvre such as using a cream in the morning and an ointment at night may improve adherence [7].

The use of therapy that gives early improvement is preferable but where this is not possible the patient must understand the reality of the likelihood of speed of improvement. The patient must have the opportunity to express concerns about treatment so that unfounded fears can be allayed. For patients with psoriasis, even more important than the speed of action of a topical treatment is the opportunity to be involved in the decision taking [8]. Joint discussion and decisions between doctor and patient should be taken. Patients need information about possible side effects and how to handle them: for example if a patient is warned that there may be transient stinging, the patient may continue to use a drug instead of being alarmed and stopping it. The cost and affordability of therapy is an obvious factor in many health care settings.

When systemic drugs are used in an outpatient setting in cardiology and internal medicine clinics, there are widespread discrepancies in drug usage with 76% of patients not taking the planned medication correctly [9]. There are similar problems with patients using topical preparations [10]. The likelihood of a patient taking oral medication as planned is inversely proportional to the number of times per day that the drug should be taken [11]. Even in a controlled research setting, when a patient is asked to record the therapy used for skin disease there is poor correlation between reported treatment use and weighed ointment usage [12]: the use of electronic monitoring may be helpful in the future to monitor medication adherence [13].

There are particular cultural and age-related issues in trying to maximize the likelihood of adolescents taking medication effectively. This is of particular relevance to acne therapy [14]: the use of topical therapy that has a more rapid onset of action is likely to be an advantage in increasing usage.

When topical corticosteroids were introduced into clinical practice in the 1950s their great benefit to patients with inflammatory disease was immediately apparent. It is unlikely that the phobia surrounding their use, especially in children, would have been predicted. The phobia comes from a lack of understanding about the different potencies of corticosteroids available and a concern over side effects, the risk of which is minimal if they are used correctly. The phobia may lead to inappropriate under use and consequent poor control, especially of atopic dermatitis [15]. Surprisingly, however, the mother's anxiety about using topical steroids did not influence reported use of topical steroids in a Japanese study [6]. It is important that clinicians are aware of this issue and address it in discussions about advising their use. An approach to improving treatment compliance in occupational dermatitis has been the concept of a specialist nurse-led 'eczema school' to contribute to the education of patients and carers [16].

Only 33% of patients with psoriasis who were asked to apply an ointment twice daily actually did so [10]. Patients with psoriasis who report that they have not complied with treatment are more likely to believe that both psoriasis and their treatment interfered with their quality of life [17]. Self-reported non-adherer patients with psoriasis demonstrate more negative views towards all aspects of health care [18]. In both psoriasis [19] and in acne [20] adherence with therapy is poorer the greater the severity of the disease. It is possible that having severe skin disease leads to poor life quality, which in turn leads to a degree of depression and a sense of 'giving up'. This may result in poor concordance with therapy and in turn further deterioration in the disease. Strategies are needed to break this negative feedback loop. It is likely that treatment failure is much more often due to non-adherence than has been previously recognized.

There is a major challenge for dermatologists to identify those factors that contribute to non-adherence and to develop strategies that make it more likely that a patient will use medication appropriately and in their best interests.

Side effects

Worldwide more and more people, especially the elderly, are taking not only prescription but also over-the-counter drugs, including herbal remedies. Moreover the pharmaceutical industry is constantly introducing new drugs. The individual doctor is faced with a massive task in keeping up to date with all these drugs, including side effects and cross-reactions. Whilst information technology may help this is no substitute but can complement the practice of a well-informed and competent medical practitioner. The consultation is all-important in warning the patient about possible side effects [1], but skill and care are necessary. The doctor may be guilty of negligence if major side effects are not explained, but, on the other hand, if too much emphasis is placed on side effects the doctor may invite non-compliance. Particular care must be taken during pregnancy [2–4] and lactation [3,4]. Children pose special problems and neonates are at special risk of side effects because of immature renal and liver function [5]. Poor renal function leads to the accumulation of drug and metabolite(s) in the body increasing the risk of side effects [6,7]. In liver disease the reduction in first-pass metabolism may lead to toxic drug levels whilst reduced protein binding may lead to increased bioavailability and side effects [8].

Therapy

General management

Explanation

Like all doctors, but perhaps more than most, dermatologists must achieve rapid rapport with their patients and be seen either to assuage the symptoms and signs of visible disease or to bring the patient—and the relatives or parents—to accept chronicity or irreversible changes. Dermatology has been called an 'applied intuitive art': if so, an easy understanding must be achieved between the artist and sitter. Allowance must be made for symptoms of anxiety—aggression, lack of faith, mistrust. If necessary, the dermatologist must gradually overcome these to become therapeutic in the clinical situation.

Patients nowadays demand and deserve a far fuller explanation of their disease than was formerly either possible or even considered desirable. No longer is it appropriate to give a learned diagnosis, a prescription and little else.

Patients may be well-informed or misinformed, but they are informed. Recourse to the Book of Proverbs or Job is not received with the understanding it used to command. It is never easy to explain autoimmune diseases or the aetiology of atopic dermatitis in easily comprehensible terms. The intelligence of the patient must be gauged; a suitable metaphor or simile is often apt. In any case, the

patient's questions must be answered. In seeking clues to the causation of conditions such as contact dermatitis or chronic urticaria, one should always listen attentively to the patient's explanation. He or she may well be wrong, but occasionally the patient is right, however, unexpected the answer.

Nevertheless, his or her account of the onset and course of the disease may have become distorted by time or for medicolegal reasons, and can never be believed in cases of dermatitis artefacta. The patient's memory (or suppression of memory) of drug or topical medicaments given is usually defective, especially if self-administered.

Avoidance of aggravating factors

General advice that might be considered common sense to the dermatologist may be quite unfamiliar to some patients. Such advice includes care with environmental temperature and, at times, humidity. Advice should be given on appropriate clothing, which should not be too constricting, too hot or too harsh. Irritants and sensitizers should be avoided where possible. Many patients retain the belief that skin disease is a manifestation of dirt or germs to be expunged with vigour and exorcized with soap and water or worse. Care should indeed be taken with soap, but it is seldom necessary to proscribe bathing. It is surprising how often patients will be applying inappropriate household germicides, and in totally inappropriate concentrations. Advice to stop scratching usually causes more frustration and alienation unless something is done to help the sensation of itching.

Regimen

Rest and relaxation can play a major part in treating many dermatoses. With others there are positive benefits in remaining at work or at school. Decisions, including economic ones, are often neatly balanced, but the patient will often require positive guidance on how much activity is to be encouraged.

The arguments for and against admission to hospital clearly depend on so many variables other than the purely medical ones. The last 30 years have seen a great reduction in beds for dermatology patients in many countries. The reasons include better treatments, which remove the need for admission, improved facilities for home nursing, and better transport to outpatient facilities. The dramatic rises in cost of maintaining patients in hospital, whether at the expense of themselves or of their health services, also militate against admission.

No firm guidelines can be laid down about which particular diseases need to be treated on an inpatient basis. These will vary from culture to culture and even from town to town. No doubt many diseases might benefit from time in hospital but this may not be feasible. Sometimes, a short stay before complete remission has been achieved will allow the acute crisis to be averted, allow patients to be taught how to manage themselves, and also build up a better relationship between patient, doctors and nurses.

Recent years have seen the emergence of dermatological intensive care units for the management of such acute, life-threatening emergencies as toxic epidermal necrolysis, pemphigus and erythroderma. These have been pioneered at Creteil, France [1,2] and have pointed the way forward to improving what can be a poor prognosis.

Quite often, the need for hospitalization is avoided if the patient is given precise instructions on how to do at home almost everything that might have been done in hospital.

Systemic drug therapy

Drug therapy may be specific, empirical or placebo in its effect. Dermatology has suffered more than most specialties from an abundance of empirics and placebos. It has not been shown that dermatological patients respond more to placebos than others, but the presence of an obvious and visible disease and the anxiety that this engenders endow all forms of treatment with an aura of suggestibility that often confuses the judgement of the patient and physician alike. The past records of dermatological therapy give abundant evidence of the 'wish to believe'. The results of 'double-blind' trials have destroyed the edifice of this belief. Drugs should not be despised if they help the patient, but they should never be regarded as pharmacologically active without unequivocal evidence of their effectiveness. There must be no confusion in the dermatologist's mind. At his or her command there are a few specific remedies, a number of empirical ones and many placebos. The first are accepted because their action is known. The second are effective in 'double-blind' trials, although their mode of action remains unknown. The third are effective in a manner that bears no relation to the pharmacology of the drug or the pathogenesis of the disease; often, the physician endows them with his or her personality. It is important to be acquainted with the concept of the doctor as a drug and that problems may arise, as with any drug, with overdose, underdose or idiosyncratic reactions [1,2].

The placebo [2–5]

Potentially any treatment may have a dual effect related to the intrinsic property of the active drug and also to the perception that treatment is being received [3]. This latter

is known as the placebo effect [4]. Distinction must be made between placebo and placebo effect [2] as any sort of therapy can act as a placebo but the response of the individual patient determines whether there is a placebo effect. Despite claims to the contrary, no consistent placebo-reactor profile has been demonstrated [2,3] but the effects of placebos can be very specific depending on patient information, i.e. patient expectations. Thus, placebos can induce opposite effects on blood pressure or heart rate depending on whether they are administered as perceived tranquillizers or stimulants and this makes a precise definition of the placebo effect difficult [3]. Moreover, variations in the placebo response to tablets of different colours—green is best for anxiety—has been demonstrated [5].

Recent evidence suggests that the placebo effect is mediated by dopaminergic reward mechanisms in the human brain and related also to the expectation of clinical benefit [3].

The placebo response in dermatology

The less effective any existing treatment, the more likely are any favourable effects to be of placebo type. Lichen planus, alopecia areata and chronic urticaria have been 'cured' in the past with many different preparations, which have not been shown to be pharmacologically effective in these diseases. But the patient has been sustained through the natural course by receiving a potion or a lotion that at least sustains the faith and the hope and, at most, is free from potential toxicity. The placebo effect is also apparent in the control of insomnia and pruritus, and extends to physical methods of treatment, notably acupuncture.

Preparations. Placebos must be harmless. Many drugs that are *not* harmless are really only being given as placebos. Lactose tablets are commonly given but even this substance is not totally harmless. Aspirin should be avoided. Carefully worded instructions may reinforce a placebo effect [3], as may an unusual size or shape of tablet.

No official placebo is included in the British National Formulary, but many manufacturers will supply inert preparations matched to their own products.

In general, physicians should be aware that the effect of a drug they are prescribing may be a placebo effect. On the other hand, it has been cogently argued that a placebo works better if the physician also believes in it!

Ethics. Most but not all physicians would agree that the administration of a placebo as a therapeutic measure is justifiable if no known effective treatment exists. In any case, it is less likely to harm the patient than a poorly tested or a powerful 'new' drug of uncertain value. In some cases, the deliberate use of a placebo initially may be valuable in ensuring rapport with a patient who claims to be prone to all the side effects known for all drugs taken; and to assess the placebo response reactions. It also gains time for the anxious patient to accept a prolonged or incurable condition while a situation of rapport is being built up. This presupposes, of course, that no widely accepted active agent is available that is likely to be more beneficial.

In all cases, particularly in drug trials, the overriding consideration must always be the benefit to the patient. The doctor is always in a particularly authoritative position and must not abuse this authority. The patient's fully informed consent (with a witness) must always be obtained if a 'controlled' trial is embarked on. It is doubtful whether the use of 'dummy' preparations is ever justified in children, even with the parents' consent.

It is very important that none of us loses sight of the fact that we should not do harm to the patient, especially in an experimental situation. The so-called experiment where a mother aged 80 years was injected with malignant melanoma cells from her 50-year-old daughter, which led to the mother's most unpleasant death from metastatic malignant melanoma, must never be repeated [6]. It is essential that any proposed research is vetted by a well-qualified ethical committee before any projects are undertaken.

Antihistamines

These are discussed in Chapter 72. In the hands of many non-dermatologists, the sight of a rash evokes a reflex desire to prescribe antihistamines. These drugs are, of course, no panacea. If they are to be prescribed, there should be some thought whether they are being used for their ability to antagonize other mediators such as acetylcholine (usually considered as a side effect), or for a central effect. Otherwise, their use must be considered as placebo, albeit usually a harmless placebo. The advent of new 'non-sedating' antihistamines, said not to cross the blood–brain barrier, makes it important not to thoughtlessly prescribe the newest antihistamine for the management of all types of pruritus (Chapters 16 & 72). Every general practitioner should have a working knowledge of short-acting, long-acting, sedative and non-sedative types of antihistamine.

Psychopharmacological agents

In recent years, there has been a marked trend, in the UK at least, away from reliance on psychopharmacological agents or willingness to take them on the part of the patient. Even the conservative dermatologist, who may feel on occasions that the short-term administration of sedatives or hypnotics would be of help in reducing itching or restoring normal sleep patterns, may encounter unexpected resistance by the patient. Unfortunately, reasonable alternatives—discussion, the encouragement of the development of relaxation or autosuggestive techniques—are time-consuming and seldom carried out by busy practitioners. Thus, anxiety may intensify until the acute 'emergency' situation, so well known to dermatologists, develops. In such cases, rest, adequate sleep and some form of sedation become imperative and may be obtained only by removal of the patient from his or her environment to hospital.

Two situations in which the rational use of psychopharmacological agents may be necessary are anxiety and depression. Many agents are available for the treatment of these conditions, and national and individual differences in prescribing are widespread. One drug often replaces another for reasons of improved efficacy. The dermatologist is best advised to choose two or three, preferably having short- or medium-term and more prolonged effects, and to use them appropriately.

Anxiety

Environmental sources of anxiety and tension have increased in modern industrialized life. Anxiety, not always recognized or acknowledged by the patient, may be an essential driving force in some individuals ('trait' anxiety) [1]; only when this increases, as a result of extra stresses or the presence of disease, may it become marked ('state' anxiety). Then, the symptoms themselves, for example the intensity of pruritus, may become part of a general stress response characterized by emotional overarousal [2]. It is recognized that pathological anxiety is more common in patients with a chronic medical problem than in those without [3]. So detecting and treating anxiety is an integral part of dermatological management. Successful treatment has several benefits including better quality of life, less disability and less use of resources. Rather than prescribe an anxiolytic initial management should include effective communication, information giving and reassurance. Whilst behavioural therapy is one of the most effective treatments for anxiety [4] most dermatologists are not skilled in this technique. Developing an effective liaison with an interested clinical psychologist or psychiatrist, or even in a dermatological liaison clinic, is the optimal way of delivering this type of care to anxious dermatological patients.

Whilst the benzodiazepines [2–4] are the safest and most effective anxiolytics, there is concern about habituation and addiction to these drugs [5,6] so these drugs should only be used in the short term and for emergencies [3]. Their use in adequate dosage in the short term to prevent nocturnal pruritus and to give the very itchy patient a good night's sleep can be justified. However, conventional doses of sedative antihistamines such as hydroxyzine may be equally effective and not accompanied by the risk of addiction or habituation. A large number are available: the main difference lies in their different plasma half-lives [2]. They are equally effective for treating both anxiety and insomnia, although the causes of the latter should be examined before recourse to drug therapy [7]. They are widely used, especially by older females in the lower socio-economic groups [8]. Diazepam and chlordiazepoxide are the best known. Nitrazepam, used as a hypnotic, has a half-life of about 30 h and may thus accumulate on repeated use. A single dose of diazepam is frequently given to allay apprehension in young children before minor operative procedures [9,10]. When appropriate, a suitable analgesic should be given before the diazepam [11]. The intravenous use of benzodiazepines carries a risk of thrombosis or ischaemia [12,13]. This drug should be diluted with blood and given slowly [12] and resuscitation facilities should be to hand. The benzodiazepines have no antidepressive effect and may, in fact, enhance depression. The side effects are those of any drug affecting the central nervous system, including oversedation [14]. Effects of alcohol are potentiated [15].

Depressive states

Depression is common in dermatological patients and may present in many different guises. It is unusual for the patient to say 'I am depressed'. However, the condition is so common in dermatological patients that the attending dermatologist should always ask him- or herself 'is this particular patient depressed or not?' Dermatologists therefore should become adept at recognizing depression in their patients. Whilst criteria for major depression [16] (Table 71.1) are recognized, it has been claimed that simply asking two questions may be as effective in detecting depression as longer screening instruments [17] (Table 71.2).

Depression with suicidal ideation is common, both in patients with psoriasis [18] and Darier's disease [19], and any extensive skin disease, particularly if it affects important body image areas such as the face, may produce a very severe reactive depression. It is known that patients with chronic urticaria and generalized pruritus are more likely to be depressed than controls [20], and acne scarring, particularly in males, may produce severe reactive depression and even suicide [21]. Dermatological patients may become significantly depressed when they are treated

Table 71.1 Symptoms of depression.*

Depressed mood
Substantial weight loss or gain
Insomnia or hypersomnia
Feelings of guilt or worthlessness
Suicide ideation or suicide attempt
Decreased interest or pleasure*
Psychomotor agitation or retardation
Fatigue or loss of energy
Diminished ability to think or concentrate

* One of these symptoms must be present. Two or more of the above should be present within the same 21-week period.

Table 71.2 Two simple questions to detect depression [17].

1 Over the past 2 weeks have you ever felt down, depressed or hopeless?
2 Have you ever felt little interest or pleasure in doing things?

Table 71.3 Main classes of antidepressants.

Tricyclics
Selective serotonin inhibitors
Monoamine oxidase inhibitors
Norepinephrine (noradrenaline) reuptake inhibitors
Others

with corticosteroids orally or parenterally, and depressed dermatological patients are twice as likely to be admitted to hospital, and to remain as inpatients twice as long as non-depressed dermatological patients [22]. The commonest psychiatric disease present in patients with dermatological delusional disease and with body dysmorphic disorder (dermatological non-disease), in particular, is depression [23]. Depression is a well-recognized risk factor for non-compliance with medical treatment so depressed patients are three times more likely to be non-compliant than non-depressed patients [24].

Finally, dermatological patients who go to litigation are more likely to be depressed than their non-litiginous peers [25]. The treatment of depression therefore is of vital importance in dermatological practice.

The main classes of antidepressants available are shown in Table 71.3.

Rather than continuously experimenting with a wide range of available antidepressants the clinician is best advised to become familiar with one drug from each class [16]. The response to treatment may be slow and there may be little clinical benefit during the first month of therapy. Moreover, side effects are usually worse at this time, especially during the first 2 weeks of treatment [16]. Many patients with significant depression are treated with inadequate doses of antidepressants for an inadequate time. 4–6 months of treatment are necessary to avoid relapse and continuous maintenance therapy is necessary if the patient has had two or more episodes of depression within the previous 5 years [16].

The generally lower side effect profile of selective serotonin reuptake inhibitors compared to, for example, the tricyclic group of antidepressants, and, in particular, lower cardiotoxicity, make these drugs the first-line treatment of depression [26]. It may be difficult to make a clear clinical distinction between anxiety and depression and the depression may become more apparent when a patient fails to respond to anxiolytics. Whilst tricyclic antidepressants such as amitriptyline in adequate dosage are effective in anxious, depressed patients, they also have some sedative properties and are not particularly helpful in patients with pure primary anxiety [2].

Doxepin is both a potent antidepressant and has very marked antihistamine activity. This antidepressant is useful in the itchy, depressed, elderly patient and in some patients with neurodermatitis [26].

Other drugs in use

Butyrophenone derivations such as haloperidol are also used for anxiety, depression and alcohol withdrawal symptoms. Chloral hydrate (0.3–2.0 g) should not be despised as a hypnotic, particularly in children. The unpleasant taste of paraldehyde has limited its oral use, but it is an effective and quick-acting hypnotic, especially for hypomanic states, given by intramuscular injection (5–10 mL). Beta-adrenoceptor antagonists ('β-blockers') have not found much place in dermatology, although symptoms mediated by the β-division of the sympathetic nervous system have been helped by propranolol [27]. A number of side effects have been reported [28]. Pimozide has a special place in the management of patients with delusions of parasitosis [29,30].

Topical therapy

The dictum 'primum non nocere' has a special significance in relation to the vulnerability of damaged skin, often with an impaired barrier function, to develop either sensitivity or irritant reactions to local applications that the same patient might find harmless at other times. There is a particular temptation to be overzealous in treatment when faced with a disease that fails to react to initial therapy. Visual evidence of failure is particularly hard to accept with equanimity. Full details of topical therapy are given in Chapter 75.

EMLA cream (a eutectic mixture of 5% lidocaine (lignocaine) and prilocaine) is particularly useful as a local anaesthetic cream in children to try and ensure pain-free venepuncture, and may also be used to try and minimize distress during curettage of lesions of molluscum contagiosum or in removing genital warts. Its use may ensure that the injection of keloids in children causes minimal

distress, and it has a place in anaesthetizing the skin in children with port-wine stains during laser therapy. The cream is best applied under occlusion 1–4 h before the planned procedure [31]. An amethocaine-containing gel has been claimed to be more effective than the EMLA local anaesthetic in patients with port-wine stains [32].

Cosmetic camouflage

Cosmetic camouflage is very useful in the management of a wide range of dermatological problems ranging from scarring to vitiligo, and vascular anomalies such as port-wine stains. In the UK, the Red Cross offers a voluntary service and in some hospitals the occupational therapists are trained to do this work. Cosmetic camouflage has been shown to improve quality of life [33].

Physical measures

Physiotherapy

The role of physiotherapists has assumed increased importance in recent years. Their duties have extended far from massage and simple forms of heat and light therapy of the past. They have become valuable members of a team devoted to a wide range of physiotherapeutic manoeuvres and to rehabilitation in the widest context.

In dermatology, the physiotherapist is probably not sufficiently invited to participate in the overall management of the patient with chronic or disabling diseases. Rehabilitation is discussed below, but techniques of relaxation are of benefit to many tense patients with irritable or vasolabile skin disease. Muscular relaxation is a key that opens the door to emotional relaxation, but it requires some experience and training to use the key effectively. Relaxation techniques [1] are a valuable adjunct to drug therapy and may even supplant it. Massage and re-education in limb movement are of great practical value in patients with constricting scars and deforming linear scleroderma, for which we have so little to offer. The influence of communal participation of physiotherapeutic activities, in which warmth, touch and encouragement combine to create an ambience conducive to relaxation and to a feeling of positive activity, should not be underestimated.

Massage [2] is valuable in the treatment of lymphoedema (Chapter 51) and rosacea.

Some physiotherapists have expertise in the management of venous leg ulceration and can participate in treatment from an early stage through the period of healing and rehabilitation.

Tap water iontophoresis is performed by many physiotherapy departments and is particularly useful in patients

with hyperhidrosis of the hands, feet and axillae [3]. The need for this therapeutic approach has probably lessened following the introduction of botulinum toxin for the management of not only hyperhidrosis of the axillae and, to a lesser extent, the palms [4,5] but also dyshidrotic hand eczema [6].

Other modes of physical medicine, such as short-wave diathermy, play a small part in dermatological management.

Ultrasound has found a secure place in the treatment of soft-tissue disease and injury [7,8] and may occasionally be of adjuvant value in conditions such as scleroderma [9], panniculitis and other dermatological conditions affecting deeper tissues.

Phototherapy, often performed by physiotherapists, is discussed in Chapter 35.

Acupuncture

The empirical basis on which this technique rested for so long has been dramatically changed by the discovery of the endorphins, and that the response to acupuncture can be mediated centrally by endorphins and enkephalins [10]. It has been shown that acupuncture can reduce the effect of histamine-induced itch and flare in healthy subjects [11]. The acupuncture points described in ancient Chinese medical literature correspond to some of the so-called trigger points described in Western medicine, and are said to represent areas of low electrical resistance.

Low-dose helium neon laser light and other types of lasers directed at acupuncture points have been claimed to be effective in a wide variety of conditions, but no valid double-blind clinical trials have been carried out. Anecdotally, post-herpetic neuralgia and atopic dermatitis seem to be helped in some patients by acupuncture, but it is difficult to assess the results of treatment. However, there are few risks as long as the needles are properly sterilized [12].

Biofeedback techniques

These involve the induction of a learned response aimed at controlling or modifying vascular responses [13] or inappropriate bodily responses to various centrally mediated stimuli. They may reduce emotional intensification of erythema and have been used to control flushing, for patients with dyshidrosis whose disease flared with stress [14] and in patients with atopic dermatitis [15]. Thirty-three patients with eczema were trained to decrease or increase electrical conductivity of the skin. Those who were trained to decrease skin conductance showed clinical improvement, while the controls who were trained in the opposite direction did not. The positive response was accompanied by a significant decrease in measured conductance and anxiety [16]. Eleven of 14 patients with chronic hyperhidrosis improved following biofeedback training. The most important aspect of the treatment was thought to be relaxation [17]. However, there is considerable individual variability in responses [1], and the main value may lie in anxiety reduction [18] and in the active involvement of the patient in self-help. It has been suggested that the techniques may be the 'ultimate placebo' [19] and their place in dermatology may remain limited by the time and patience required. Nevertheless, further developments in these methods may prove rewarding in specific dermatological situations, given a highly motivated and suitable subject.

Behaviour therapy

The use of behaviour therapy in dermatology was well summarized by Bar and Kuypers, who described four main therapeutic approaches [20].

Systemic desensitization is employed mainly in neurotic disorders where anxiety is the main clinical feature. An attempt is made to induce inhibition of anxiety following repeated exposures to weak anxiety-raising stimuli, after which progressively stronger stimuli are introduced. This type of behaviour therapy has limited application in dermatological practice.

In aversion therapy, patients with persistent behaviour disorders such as compulsive scratching or pathological hair pulling can be treated. The patient is given an unpleasant stimulus, for example a mild electric shock, whenever the unadaptive habit is demonstrated or displayed.

Operant techniques can be used to modify compulsive habits, and awards are given to reinforce good behaviour and bad behaviour is either punished or ignored. In children, a token may be given after a period of good (non-scratching) behaviour as part of a so-called token economy system.

Assertiveness training is employed in patients who are afraid of expressing their emotions and also experience extreme social fear. This technique is said to be most useful in patients with facial erythema or erythrophobia and also has a place in the treatment of patients with hyperhidrosis.

An operant technique was used successfully to modify the scratching behaviour in a patient with long-standing severe dermatitis, which had defied all traditional therapy [21]. As soon as the patient was observed scratching he was asked to fold his arms and think of something pleasant. Normal social attention was then withheld as a mild punishment. This man improved. The technique of habit reversal has an important place in the management of both adults and children with atopic eczema [22,23]. The patients were taught situation awareness so that they could recognize situations that made them itch. The patients were also instructed either to grasp an object or to keep the hands firmly on the itching area and pinch it if

necessary but not scratch it. A strong correlation was demonstrated between a reduction in scratching and an improvement in skin status [22,23].

Hypothermia and hyperthermia

Cooling of the scalp to 25°C with ice turban packs or chemical coolants has been used to prevent or reduce hair loss during the critical period after administration of chemotherapeutic drugs [1]. Cooling of port-wine stains prior to treatment with the argon laser has also been tried to improve the efficacy of laser therapy and also to minimize scarring [2]. Some controversy still surrounds the use of skin cooling in laser dermatological surgery [3].

Resulting from the demonstration of the potential of hyperthermia as an antitumour agent [4,5], there have been occasional reports of its value in treating deep mycoses [6], leishmaniasis and myobacterial infections. Some similarity between the kinetics of tumour cells and psoriasis cells has prompted its use in the form of ultrasound in this disease [7]. Chemically generated heat in exothermic bags was used in 22 psoriatics in comparison with Goeckerman's regime [8], with apparent success and without side effects. This convenient and simple form of treatment may have a place in difficult therapeutic situations and merits further study [9].

Homeopathy [1–3]

Homeopathy is a system of therapy originated by Samuel Hahnemann in the latter part of the 18th century. Central to the theory of homeopathy is the thesis that those agents that produce symptoms of any given disease will, in a much smaller dosage, cure that disease. Others have described homeopathy as a harnessing of an energy unknown to orthodox science.

Proponents of homeopathy state that there are three essential processes in the preparation of remedies, namely dilution, succussion and trituration. By diluting the drug, the toxicity of the original product disappears and during succussion and trituration some supposed mechanical energy is imparted to the remedy, imprinting the pharmacological message of the original drug upon the molecules in the diluent. From the practical point of view there seems no doubt that many patients are happy to consult with homeopathic practitioners, and most of these consultations do no harm unless a patient is advised to stop their oral or topical steroids suddenly. There is no doubt that homeopathic practitioners spend a great deal of time with the patient and some patients undoubtedly benefit from this enhanced level of communication which they are unlikely to find in a busy National Health Service clinic.

Despite two centuries of work, there are very few controlled clinical trials that allow homeopathy to be assessed [1].

In a study of alternative medicine, utilized by patients with atopic dermatitis and psoriasis, it was found that over 50% of patients with atopic eczema and over 40% of patients with psoriasis reported previous or current use of one or more forms of alternative medicine, and homeopathy, health-food preparations and herbal remedies were used the most. The use was related to disease duration and disease severity and inefficiency of therapy prescribed by physicians as judged by the patients. The author concluded that the use of alternative medicine is commonplace and should be of concern to dermatologists [4]. This work was confirmed by a later study [5].

Occupational therapy and rehabilitation

A person conditioned to an active life does not take kindly to bed rest. Patients with skin diseases should be encouraged to become mobile as soon as their state allows it. Those with venous leg ulcers should not be kept in bed for long periods (although periodic elevation of the leg is important), but should have active and passive leg exercises to reduce the risk of thrombosis, foot drop and atrophy of the leg muscles. They should be encouraged to walk for increasing periods, rather than sitting, in order to re-educate their leg movements. The elderly patient with exfoliative dermatitis or pemphigus should be stimulated to pass his or her time without boredom, which passes imperceptibly in the aged into depression and despondency. In the alien milieu of a hospital ward, the elderly patient quickly deteriorates mentally and physically. Subsequent discharge or rehabilitation may then be extremely difficult. Occupational therapy should not only engage manual skill but also satisfy the emotional and intellectual needs of the patient of any age.

Patient self-help groups [1]

Increasingly, patients want to know more about their skin disease and its treatment. It is not always possible to meet all the patient's needs in an outpatient appointment, and, moreover, there is a limit to how much a patient can take in at one outpatient visit. This is where the self-help groups are increasingly important. The concept of self-help is that patients 'own' their disease find out more about their disease for themselves and are not just passively reliant on doctors and nurses for information and help. Such groups generate information, emotional support and advice. Patients can meet others with similar skin diseases and so realize that they are not alone. Patient self-help groups usually raise funds to support their activities, which will include research grants. They also lobby Members of Parliament to ensure that the needs of skin patients are heard and met. Pressure is often put on the purchasing health authority and the provider units to improve their service and to increase the amount of money spent on dermatology. Lastly, such groups attempt to diminish the stigma of skin disease that still exists in the community. The role of the patients' self-help group in dermatology is increasingly important to patients with skin disease and their general practitioners, dermatologists and nurses alike.

Quality of life impairment by skin disease

What does quality of life mean?

Being able to assess the impact of skin disease on patients is essential in order to understand and meet what dermatology patients really need [1]. There is however, considerable controversy about the definition of quality of life and whether it can be meaningfully assessed [2,3]. There have been several attempts to define quality of life and the closely associated concept of health-related quality of life (HRQoL) [4]. The need for all outcome measures used in dermatology, including quality of life measures, to be properly validated has been emphasized [5]. There is however, very little information in the literature about the absolute meaning of different overall quality of life measurement scores or the interpretation of degrees of change in scores [6]. Concepts relating to life quality in dermatology are well reviewed in a book by Rajagopalan *et al*. [7].

Why measure quality of life?

All clinical dermatologists are aware of the impact that skin disease may have on their patients. However it is only over the last two decades [8] that there have been attempts to develop methodology to measure the adverse

impact of skin disease on quality of life. There are several reasons why measurement may be helpful.

Clinical therapeutic research. When new drugs are assessed, the outcome measures used are usually clinical measures such as the degree of scaling or the area of skin affected. Pharmaceutical companies and regulatory authorities are realizing that although these measures of disease activity are of course important, it is necessary to have in addition a patient-orientated outcome. There may be a 50% improvement in a psoriasis area severity index (PASI), but if the handicap experienced by the patient is only slightly improved because visible skin remains abnormal, the intervention may not have been very successful from the patient's point of view. It has been argued that a quality of life standard is better than a body-surface-area measurement for identifying patients with severe psoriasis [9]. The addition of (not the replacement by) a HRQoL measure may be essential to make a proper assessment. The introduction of several new therapies in dermatology over the last 10 years has been supported by such information [10,11].

Health service research and audit. Within many health care systems it is becoming mandatory to produce evidence of the effectiveness of care given, and to have systems in place to monitor effectiveness and assess improvement against agreed criteria. An essential part of this process has to involve having patient-orientated measures and simple but well-validated HRQoL questionnaires are well suited for this need [12–15]. The use of these measures can give additional insight into the acceptability of new methods of providing dermatology advice, such as teledermatology [16]. Sound epidemiological data are essential for the planning of health services: HRQoL data can measure the extent of problems caused by skin disorders in a community [17] and be used to compare the HRQoL of people with specific skin diseases, such as psoriasis, to the general population [18].

Research into psychological aspects of dermatology and patient behaviour. Quality of life measures can be used to gain insight into patient attitudes: stress resulting from the anticipation of other people's reactions to their psoriasis contributed more to the variance in patients' disability than any other variable [19]. It is important that the problems relating to compliance with treatment, often not recognized by dermatologists, are better understood. Quality of life indices have been used to provide patient-orientated measures in studies of compliance in psoriasis and acne.

Political/resource allocation. Patients with skin diseases are rarely given any priority for resource allocation in any health care systems. Conditions that result in death are much more likely to find political support for service development. It is the responsibility of dermatologists to argue for appropriate resource allocation and appropriate funding of dermatology services and of the education of doctors about skin problems. One way in which the arguments for this can be strengthened is by using HRQoL data that demonstrate the devastating effects of skin disease on patients' lives. If general HRQoL measures are used it is possible to quantify the effects of skin disease compared to other system disease [20,21]. It may be necessary to demonstrate to managers or politicians and defend the value of dermatology clinical services that is self-evident to clinicians, e.g. in-patient dermatology beds [22–24], patch testing [25], cosmetic camouflage advice [26] and outpatient clinical services [12]. Dermatology-specific measures can also be used to demonstrate the value from the patients' point of view of expensive or unusual therapy such as climate therapy [27].

Informing clinical decisions. Most dermatologists probably consider that they have a reasonably accurate insight into the impact of skin disease on individual patients. The assumptions made about this influence clinical decisions; for example, whether or not to start a patient on a systemic therapy which has risks of side effects. Unfortunately, dermatologists may not have as much insight as they think they have into the degree of their patients' problems [28–30]. The use of a standard HRQoL measure may therefore potentially inform a clinician more accurately about their patient and allow better judgement concerning risk/benefit of therapy change. This will only become relevant on a routine basis if the absolute meaning of HRQoL scores can be more clearly defined than at present [6].

How do quality of life measures relate to other clinical indices?

It is self evident there is likely to be a relationship between the clinical severity of skin disease and the impact that the disease has on life quality. This has been demonstrated in atopic dermatitis in children where the Children's Dermatology Life Quality Index (CDLQI) was shown to be significantly correlated with the Severity Scoring of Atopic Dermatitis (SCORAD) [31]. However there are many influences on the disability experienced and individual patients show a wide variation in their responses to similar degrees of disease [8]. Particular body site affected is an important factor with visible sites such as the face having much greater significance to a patient. The psychological attitudes of patients to their disease vary widely and these attitudes have a major influence on the degree of disability experienced. Clinical scoring systems may reflect sign changes which are not of relevance to a patient's life. For example, in psoriasis, the successful reduction of scaling and thickness may result in a large percentage reduction in PASI, but if the redness persists the quality of

life improvement may be much less [32]. Quality of life measures therefore should not be used instead of clinical measures, as they are designed to assess a completely different, though interrelated, aspect of skin disease.

Methods of measuring quality of life in dermatology

There are several different approaches to the measurement of HRQoL. One depends on the use of fixed repeatable questionnaires that are scored. A second approach uses questionnaires that allow a variable response from the patient, taking into account the particular values of the patient. Another method is to assess the value that a patient or society places on the presence or absence of particular disease states—the utility approach. Decisions concerning which measures are appropriate to use can be confusing: general guidance is given in a review article [1]. Comparisons of assessment of quality of life in cutaneous disease [2] and in psoriasis [3] have been reviewed, and advice has been given [4] concerning understanding research about quality of life.

Some techniques are designed to be used across all disease states, some for use across a range of diseases of the same organ system and some for use in patients with specific diseases. Most published questionnaires are for use in adults, but there have been techniques described for measuring HRQoL in children with skin disease, infants with atopic dermatitis and the secondary impact of having a child with dermatitis on the family.

HRQoL measures are usually designed to assess the impact of skin disease at a particular time (e.g. 'today') or over a fixed period of time (e.g. 'over the last week'). Measures are usually designed in this way so that they can be used for example to compare data before and after intervention. However it should be noted that the long-term 'importance' or impact on a patient's life may therefore not be captured by these indices. Patients with basal cell carcinomas at the time of presentation to dermatologists generally have little or no reduction in their current quality of life [5], but of course if the disease was not treated there could be major problems in the future. It is therefore important that if HRQoL measures are used to inform priorities for resources in a health care organization, these measures should not be used in isolation.

Examples of quality of life measures

General health measures

General health measures are designed to be used across a wide range of disease states. Their use is essential if comparisons are to be drawn between the impact of skin diseases, the impact of diseases of other systems and the general population. Examples of tools available include the 36-Item Short-Form Health Survey (SF-36) [6], the Sickness Impact Profile (SIP) [7], the Nottingham Health Profile (NHP) [8] and the EuroQol and EuroQol Five Dimensions (EQ-5D) [9]. The General Health Questionnaire (GHQ) [10] is designed to detect psychiatric disorder.

Many of these general health measures have been used in dermatology. The UK SIP has been used in psoriasis [11] and atopic dermatitis [12]. The SF-36 has been used in psoriasis [13–15] and acne [16]. The twelve-question version of the GHQ (GHQ-12) has been shown to be of value in assessing psychological distress in patients with skin disease [17], and specifically in vitiligo [18]. In many investigations both a generic measure and a dermatology-specific measure have been used together [14] and the advantages of this have been emphasized in a study using the EuroQol and EG-5D in acne [16].

Dermatology-specific measures

Dermatology-specific measures are useful when comparisons need to be made between the impact of different skin diseases and where there is a need to measure change before or after intervention in any skin disease. Having a single simple measure that can be used across all skin disease is of great practical advantage, especially in a busy clinical setting.

The two dermatology-specific measures that have been most widely used are the Dermatology Life Quality Index (DLQI) [19] and Skindex [20]. Other measures that have been described include the Dermatology Quality of Life Scales [21], the Dermatology-specific Quality of Life instrument [22] and a German instrument, the Deutsches Instrument zur Erfassung der Lebensqualität bei Hauterkrankungen (DIELH) [23].

The DLQI consists of 10 questions covering a wide range of ways in which patients' lives are affected by skin disease (Fig. 71.1). They are answered by a simple tickbox method and each scored 0–3. The DLQI takes on average only 2 min to complete [24]. There are over 170 references describing the use of the DLQI in a wide range of skin conditions and in many languages worldwide [25]. Validation studies have been carried out in the UK in secondary care [19] and primary care [26], and in Spain [27,28], Germany [29], Denmark [30], the USA [31] and Norway [32]. Its use has also been described from France, The Netherlands, Belgium, Sweden, Switzerland, Russia, Yugoslavia, Canada, India, Australia, Malaysia, Hong Kong, South Africa, Tanzania, the Canary Islands and Guyana. When illustrations are added next to the text of the DLQI, the questionnaire tends to be completed more rapidly but there is an influence on the way the questionnaire is answered [24].

Skindex has been developed and thoroughly validated in three versions with 61 [20], 29 [33] or 16 [34] questions. Further validation studies have been carried out in Spain [35], Italy [36] and Japan [37]. The appropriateness of using Skindex-29 in psoriasis along with the generic SF-36 has been emphasized [3].

The aim of this questionnaire is to measure how much your skin problem has affected your life OVER THE LAST WEEK. Please tick one box for each question.

1 Over the last week, how **itchy, sore, painful** or **stinging** has your skin been?
2 Over the last week, how **embarrassed** or **self conscious** have you been because of your skin?
3 Over the last week, how much has your skin interfered with you going **shopping** or looking after your **home** or **garden**?
4 Over the last week, how much has your skin influenced the **clothes** you wear?
5 Over the last week, how much has your skin affected any **social** or **leisure** activities?
6 Over the last week, how much has your skin made it difficult for you to do any **sport**?
7 Over the last week, has your skin prevented you from **working** or **studying**?
If 'no', over the last week how much has your skin been a problem at **work** or **studying**?
8 Over the last week, how much has your skin created problems with your **partner** or any of your **close friends** or **relatives**?
9 Over the last week, how much has your skin caused any **sexual difficulties**?
10 Over the last week, how much of a problem has the **treatment** for your skin been, for example by making your home messy, or by taking up time?

Please check you have answered every question. Thank you.

Each question is answered either 'Very much' (score 3), 'A lot' (score 2), 'A little' (score 1) or 'Not at all' (score 0). Questions 3–10 also have the option 'Not relevant' (score 0). The first part of question 7 has the choices 'Yes' (score 3), 'No' or 'Not relevant'. The second part of question 7 has the choices 'A lot', 'A little' or 'Not at all'. The maximum score (indicating highest possible impairment of quality of life) is 30 and the minimum 0. Further information: www.ukdermatology.co.uk.

Disease-specific measures

Because the questions in disease-specific measures reflect as closely as possible the problems encountered by patients with that disease, disease-specific measures have the potential of being the most sensitive to change. They are therefore particularly suitable for comparative purposes within a cohort of same-disease patients. In many skin diseases however, for example in the widespread inflammatory skin diseases, patients lives are broadly affected in similar ways, and so dermatology-specific measures can also be used. There is therefore no need for every skin disease to have its own disease-specific measure.

Psoriasis. A landmark study of quality of life issues in over 17 000 patients with psoriasis [1], using a study-specific questionnaire, demonstrated the major impact that psoriasis can have on patients' lives and revealed that many patients with psoriasis do not feel that their physicians are aggressive enough with their therapy.

The Psoriasis Disability Index (PDI), originally described in 1987 [2] and revised in 1995 [3] has been extensively used in international studies [4], and is available in several languages.

The stigmatizing effects of psoriasis can be recorded using a 33-item questionnaire [5]. Another technique for measuring this effect has been described [6] and used to demonstrate the high stigmatization experienced by patients with psoriasis compared to patients with other skin diseases [7]. The stress that can be caused by the

impact of psoriasis on quality of life can be measured by the Psoriasis Life Stress Inventory, in its 41- [8] or 15-item versions [9].

A new construct for psoriasis which allows separate recording of signs (disease activity), psychosocial disability and history of interventions has been proposed [10]. The Salford Psoriasis Index (SPI) consists of three independent scores describing each of these aspects. This approach may be of great value in the recording and monitoring of this chronic disease.

Atopic dermatitis. The CDLQI and the DLQI have been used extensively in the monitoring of patients with atopic dermatitis. In a large managed care organization in the USA, patient-assessed severity of atopic dermatitis demonstrated a stronger correlation with the DLQI and CDLQI than did provider-assessed severity, emphasizing the importance of directly assessing the patients' attitudes [11]. The disease-specific measures for use in infants (Infant's Dermatitis Quality of Life Index, IDQOLI) and in families (Dermatitis Family Impact questionnaire, DFI) are described below. Assessment of quality of life in atopic dermatitis has been reviewed [12].

Acne. An initial attempt to produce an Acne Disability Index (ADI) [13] has been largely superseded by the more compact five-question Cardiff Acne Disability Index (CADI) [14], which was derived from it. This simple instrument has demonstrated good reliability and validity [15]. The 'Assessments of the Psychological and Social Effects of Acne' (APSEA) questionnaire [16] has 15 questions some of which relate to the overall impact and some to the recent past. A nine-item Acne Quality of Life Scale [17] has been proposed for use in acne: the questions relate specifically to the social impact of acne. The Acne-specific Quality of Life questionnaire (Acne-QoL) [18] is a 19-question tool which has been validated but not yet widely used.

Other disease-specific measures. Other disease-specific measures have been described for ulcers [19], urticaria [20], excessive axillary sweating [21], scalp dermatitis [22] and for women with androgenetic alopecia [23].

Patient-specific and utility measures

HRQoL measures are, or should be, derived from information gathered from patients' experiences and not from health care professionals' concepts of what they suppose to be the impact of disease. Despite this all fixed questionnaires suffer from the disadvantage that for an individual patient, the weighting given to different aspects of life quality impairment may be different from that assigned in the questionnaire, or the specific issues may be missed. The Patient Generated Index [1] overcomes these problems by being structured in a different way: patients are asked to identify the five ways in which their life is most affected and then assign them comparative values. This technique is effective for identifying individual's specific problems as in atopic dermatitis [2] but it is difficult to incorporate in large scale before and after studies.

Utility measures are methods to assess the hypothetical value placed by people on their health. There are a variety

of different approaches described. Standard gamble, time trade-off and vertical rating scales have been proposed [3] as a method to inform decisions relating to methotrexate therapy for psoriasis. A simple 'financial value' method is to ask patients how much they would be prepared to pay for a cure of their disease if such a cure existed. This has been used in acne [4], psoriasis [5] and atopic dermatitis [6].

Another approach is to ask patients to consider how much time they would be prepared to give up for the sake of a cure. These 'trade off' questions can be related to years of shortening of life, as in the Quality Adjusted Life Year (QALY), or be related to hours trade off. The hours trade off method has been described in psoriasis [5] and in atopic dermatitis [6], whereas the QALY method has been described in acne [7]. In contrast to the concept of hypothetical time that a patient would be prepared to give up, there is no correlation between the measurement of actual time spent on treatment and quality of life scores [8].

Children, infants and family impact

Children. The assessment of quality of life impairment in children is more difficult than in adults because of issues relating to communication, rapid change in lifestyle at different ages and differing rates of maturing. The different general measures and disease-specific measures have been reviewed [1].

The Children's Dermatology Life Quality Index (CDLQI) [2] is designed to be used by children aged 4–15 years old. It can be completed unaided by older children but parents can help younger children as necessary. An illustrated cartoon version, using the same text, has been validated [3]. Overall, children preferred the cartoon version and completed it more rapidly than the text only version. The CDLQI has been used in the assessment on children's lives of the effects of atopic dermatitis, the impact of admission for treatment, the impact of a nurse consultant, and the effect of new topical and systemic anti-inflammatory agents. There are several different validated language translations of the CDLQI. Another measure that has been used in paediatric dermatology is the Pediatric Symptom Checklist [4], which consists of 35 questions answered by the parent. It has been used for psychosocial screening in paediatric dermatology clinics.

The lives of infants with atopic dermatitis may be severely disrupted, even though the affected children may not be able to explain their distress, or have the insight to know that what they are experiencing is abnormal. The Infant's Dermatitis Quality of Life Index (IDQOL) [5] has been proposed to encapsulate and attempt to measure the impact of atopic dermatitis on infants.

Family impact. When a patient is affected by a skin disease, those closest to the person are usually also affected. Having a child with atopic dermatitis can have a major impact on the functioning of a family. Two methods [6,7] have been proposed to measure this secondary impact. The Dermatitis Family Impact (DFI) questionnaire [6] has been used to demonstrate the relationship of dermatitis severity to family life quality [8].

Declaration of interest. The author (AYF) is joint copyright holder of the following questionnaires described above: DLQI, CDLQI, PDI, IDQOL, CADI, ADI and DFI.

Some specific groups for whom problems of readjustment and rehabilitation may be important are outlined below.

Infants with atopic eczema. The main need is for dialogue with the parents and sustained contact to help relieve the inevitable tensions and emotional stresses that the condition imposes on them. Special problems arise in children where hospital admission is required. This is best dealt with in children's units. Joint management with nursing staff trained for the special requirements of sick children

and expertise in basic dermatological therapy is invaluable. The parents should be encouraged to participate in the ward activity and will gain confidence in helping in the management of the problem.

The young adult atopic eczema patient. The problems here are often those of personality and environmental stresses rather than of working conditions. Apparent resolution in the protected environment of a hospital ward does not always survive exposure to the harsher emotional stresses of outside life. However, a temporary withdrawal from an adverse environment is usually helpful. It is important that the dermatologist discusses with both the patient and his or her family possible future employment. For instance, the youngster with severe hand eczema is unlikely to be able to nurse or become a hairdresser, or be able to follow a successful career in catering or engineering involving the continued exposure to coolant oils. Early counselling about future work prospects can prevent a lot of misery later on.

The older child. Children with disabling or disfiguring diseases demand special attention towards adjustment to the various epochs of their life relationships with other children, the first school, and passage through puberty. Play and companionship in the early years mark the transition from maternal social relationships. Disfigurement or disease is always a source of childish cruelty and integration into the social group requires much skilled help from nursing staff and mother figures. The transition to school and pressure of examinations call for guidance and careful management. The difficulties of a spastic, deaf or mute child are evident enough to arouse sympathy. The emotionally volatile, scratching atopic or the obviously disfigured child receives less sympathy and attention, although his or her needs are as great.

The young manual worker. There will be much anxiety about the manual worker's future working capacity. After all relevant investigations have been carried out, the work possibilities should be assessed. With the patient's consent, contact with his or her firm's medical officer and general practitioner should be routine, and the results of patch tests, etc. should be conveyed with an interpretation that is relevant to the occupation. To a worker, persistent hand eczema may mean the difference between a livelihood or disablement. Anxieties may not be readily revealed and may require patience to uncover. Re-education in working procedure, an explanation of irritant (or allergic) dermatitis and attention to the causes of persistence and relapse should be part of the normal procedure of treatment. After suffering a severe attack of dermatitis, a patient is likely to be suspicious of any agent to be handled on return to work, but he or she should be encouraged to persist at work during the first critical weeks in which non-specific factors may temporarily exacerbate the condition. The patient should be seen at intervals for at least 3 months after return to work. The employers should be willing to grant time to attend hospital for this purpose.

Medicolegal aspects of dermatology [1]

A survey among members of the British Association of Dermatologists indicated that a significant proportion of dermatologists in the UK were concerned about the possibility of being sued, and an even greater percentage had altered their practice because of this concern [2].

The problem is not confined to the UK, with major concerns about potential litigation amongst dermatologists in the USA, Irish Republic and, more recently, in several other European countries.

There are several measures that minimize the possibility of litigation, and good and effective communication between the dermatologist and the patient is the most important. Moreover, continuing effective communication is necessary after the patient has been seen, especially if there has been dermatological surgery, so that if there are any problems these can be dealt with rapidly and effectively. There is nothing more frustrating for the patient than to find the dermatologist elusive, and resulting patient anger can initiate speedy legal retribution. It is important that not only the dermatologist but also all associated staff adopt an open and easy policy as far as communication with patients is concerned.

A second necessary line of defence against possible litigation involves making adequate and comprehensive case notes. This is particularly important as far as pigmented lesions are concerned, where it is prudent to record the variability or otherwise of the shape, the size and degree of pigmentation of the lesion. There has been a recent increase in litigation involving patients with malignant melanoma, not only over allegations about failure to make an accurate diagnosis, but also in regard to possible delay in seeing the patient after referral by the general practitioner. It is good practice for the dermatologist to see all the referral letters from the primary care physician so an informed assessment of urgency can be made. Even so, the vast numbers of anxious patients referred on account of recent change in pigmented lesions, the majority of which turn out to be absolutely benign, makes running an effective dermatological service very difficult. Particular difficulties arise when the general practitioner does not label the referral letter 'Urgent' and the patient subsequently turns out to have a malignant melanoma. In this instance, the information given by the general practitioner in the referral letter may or may not be sufficient to allocate an urgent appointment.

Dissatisfaction with scars after lesion removal is another potential area of litigation. It is good practice to explain that spread scars are the almost universal accompaniment

of excision of lesions on the back and legs and the development of not only hypertrophic scarring but also keloid scarring should be emphasized, particularly in keloid-prone areas such as presternal skin and over the deltoid area. Comprehensive notes recording that a full discussion has taken place about the future cosmetic appearance of the scar, including possible diagrams of how a lesion will be excised, are both very helpful in rebutting potential litigation.

Consultant dermatologists have a responsibility to train others, and faulty technique using liquid nitrogen is a relatively common cause of litigation against general practitioners. Skin necrosis, and even peripheral neuropathy, are the commonest causes for litigation following inappropriate liquid nitrogen treatment.

Skin and subcutaneous atrophy following injections of triamcinolone in inappropriate sites, such as the arm, or too superficially, or at the same site in the buttock are also relatively common causes of cosmetic litigation as far as the general practitioner dermatologist is concerned.

It is very important that colleagues refrain from making disparaging remarks about other colleagues in front of patients. It is also important not to use emotive words, such as 'dermatitis' to, for example, an engineering worker, who may equate this diagnosis immediately with a diagnosis of industrial dermatitis, and therefore financial compensation.

One other potential pitfall for the dermatologist is the side effects from the use, not only of oral, but also of topical, steroids. Skin atrophy, striae, depression of the pituitary–adrenal axis and avascular necrosis of the femoral neck are particular examples. Avascular necrosis of the femoral neck is more common in alcoholic individuals and special care should be exercised, not only using oral steroids, but also topical steroids, in such patients [3]. It should be remembered, however, that avascular necrosis of the femoral neck has also been described in patients receiving physiological corticosteroid replacement therapy [4]. Patients on long-term oral steroid therapy should be advised about prophylaxis for osteoporosis [5].

The possibility of inducing not only cataracts but also glaucoma, especially if there is a family history of glaucoma, following the long-term use of tropical corticosteroids on the face and around the eyes in particular, should be remembered in patients, for instance, with long-standing eczema of the face [6].

Particular care needs to be exercised to avoid prescribing drugs that have previously caused an allergic reaction in a particular patient [1]. Although the resulting medical problem may not be severe, there is always a chance of a much more severe allergic reaction leading to the development of potentially fatal toxic epidermal necrolysis.

Avoidance of drug interactions is also important, particularly where potent drugs, such as methotrexate, ciclosporin, warfarin and corticosteroids are concerned. A recent study of 790 claims against general practitioners has shown that the largest proportion (25%) were related to errors in prescribing, monitoring or administering medicine [7].

Careful systems of work are vital to prevent burning of normal skin during the use of various forms of ultraviolet (UV) light, including psoralen and long-wave UV radiation (PUVA) therapy and topical dithranol (anthralin) treatment. Management changes in the British National Health Service, attempting to achieve a skill mix, have led to relatively inexperienced nurses being given the task of administering dithranol or UV therapy. Hospital managers should be told about the possible disastrous consequences of such a policy in dermatological patients, where nursing treatment expertise, built up over many years, is vital to ensure best results. Care also needs to be exercised in the topical treatment of ulcers, where the prescription of topical agents containing neomycin have led to the development of deafness [8].

Why do patients go to litigation? [9]

There are four main reasons why people sue their doctors, and the decision to take legal action is not only determined by the original 'injury' but also by insensitive handling and poor communication after the original incident. The patient seeks explanations when things go wrong and these explanations are often considered inadequate by patients who sue their doctors. The four main reasons that emerged from a recent analysis of 227 patients and relatives were, firstly, a concern with standards of care. Both patients and relatives wanted to prevent similar incidents in future. Secondly, there is a need for an explanation to know how the injury happened and why. Thirdly, there was a belief that the doctor or hospital involved should have to account and apologize for their actions. Lastly, financial compensation for pain and suffering was a significant factor. Moreover, the patients and their relatives all expressed a desire for greater honesty and assurances that lessons had been learned from their experiences [9].

Litigation and patients with psychiatric problems

Whilst patients may quite correctly seek financial compensation for errors made by their dermatologist, it is possible that some patients are more likely to go to litigation than others.

In a recent study involving nearly 100 patients, suing either their doctors or their employers and seen for medicolegal purposes, a very significant past or present history of psychiatric disturbance was found in almost 70% of the litigants. The commonest psychiatric disease present was depression, but anxiety, alcoholism and personality disorder were all represented. The medicolegal patient may also be trying to deceive both the dermatologist and the

court. In this series there were two patients with artefact dermatitis and one with dermatitis simulata.

It is easy to miss a diagnosis of depression in dermatological patients, and it is thought that perhaps 50% of depressed patients in medical practice go unrecognized [10]. The depressed patient with dysmorphophobia is particularly likely to be angry, and this anger can be directed at the dermatologist or general practitioner, but, more commonly, internally, resulting ultimately in suicide [11].

Dysmorphophobic patients tend to haunt dermatologists, particularly those who are undertaking cosmetic procedures, such as laser treatment and skin resurfacing. Even though the results of treatment are good, the patient may remain dissatisfied and litigious. Before any cosmetic procedures are undertaken in a depressed patient, it is very important to make sure that communication between the patient and the doctor is optimum. Photography before and after any procedure is also important, so that there is some objective measure of the outcome. Preoperative assessment by a psychiatrist may be indicated in patients with long-standing or gross psychopathology.

Preparing a medicolegal report [1]

The data necessary to prepare a medical report on a patient seen with possible occupational dermatosis are described in Chapter 21.

Dermatologists may be asked by solicitors to prepare medicolegal reports. The commonest request is to prepare a report about alleged industrial dermatitis. Less often, a report on the dermatological consequences of an accident, either on the road, in the factory or, for instance, following a badly performed perm, may be sought. Thirdly, there may be a request to prepare a report about alleged medical negligence.

Until recently in the UK it was normal practice to appoint one expert witness to prepare a report for a claimant and a second expert witness to carry out a similar role for the defence. The present position is that normally one joint expert only is appointed by the court under Civil Proceedings Rules Part 35:3. Such a joint expert owes a duty to the court and will be expected to make a detailed declaration at the end of the expert report (Table 71.4).

It should be noted that the report has to be based on a complete and detailed enquiry of the relevant events, and a conventional medical history is not sufficient [1].

It should be remembered that the medical report may eventually go before a judge in court and it is humiliating for an expert witness to be questioned by a barrister about numerous spelling and grammatical errors. It is important that the dermatologist does not become biased on one side or the other. The expert witness has a duty to the court, and the medical report should be formulated to help the court. Solicitors may try and manipulate individual reports, asking the dermatologist to omit certain sentences and add others. As a generalization, this type of pressure should be resisted. Although the solicitor may wish you to amend the report for a tactical reason, the best guideline to follow is that the report should not be changed to such an extent that the writer can no longer agree with the content [12].

In a civil case involving, for instance, a claim for compensation for industrial dermatitis, the test of whether there is a causal relationship between exposure to coolant oil and the development of subsequent dermatitis depends on balance of probabilities. If, on balance of probabilities, there is more than a 50% chance that an individual's skin problem was caused, for instance, by coolant oil, that is sufficient for the claimant to establish the case. In contrast, in a criminal matter, the burden of proof has to be beyond all reasonable doubt, i.e. 99% or above certainty. In a medical negligence case, the solicitor may seek a report dealing mainly with diagnosis, causation and prognosis and seek a separate report dealing with liability and negligence.

The essence of negligence is that there has been a breach of a duty of care resulting in damage, and in medical cases this occurs in a context of diagnosis and/or treatment. There are four essential components, and all four must be present and proven before the patient can succeed in the action against the doctor [13].

Table 71.4 Expert's declaration.

1 I understand that my overriding duty is to the court, both in preparing reports and in giving oral evidence
2 I have set out in my report what I understand from those instructing me to be the questions in respect of which my opinion as an expert is required
3 I have done my best, in preparing this report, to be accurate and complete. I have mentioned all matters which I regard as relevant to the opinions I have expressed. All of the matters on which I have expressed an opinion lie within my field of expertise
4 I have drawn to the attention of the court all matters, of which I am aware, which might adversely effect my opinion
5 Where I have no personal knowledge, I have indicated the source of factual information
6 I have not included anything in this report which has been suggested to me by anyone, including the lawyers instructing me, without forming my own independent view of the matter
7 Where, in my view, there is a range of reasonable opinion, I have indicated the extent of that range in the report
8 At the time of signing the report I consider it to be complete and accurate. I will notify those instructing me if, for any reason, I subsequently consider that the report requires any correction or qualification
9 I understand that this report will be the evidence that I will give under oath, subject to any correction or qualification I may make before swearing to its veracity
10 I have attached to this report a summary of my instructions
11 I confirm that in so far as the facts stated in my report are within my own knowledge I have made clear which they are and I believe them to be true and that the opinions I have expressed represent my true and complete professional opinion

1 The doctor must have had a duty of care to the plaintiff.
2 There must have been a breach of that duty.
3 The plaintiff must have suffered damage.
4 The damage must be a consequence of a breach of duty of care.

The Bolam test is often used to determine whether there has been a breach of duty of care. In this particular case the judge stated that 'a doctor is not guilty of negligence if he has acted in accordance with the practice accepted as proper by a responsible body of medical men skilled in that particular art'. This Bolam principle remains vital and central to how a doctor's professional behaviour is to be judged by other doctors, and not by lawyers, politicians or administrators. The Bolam test has been modified in the last decade so that a court in the UK can now reject medical opinion if it is not reasonable or responsible [14].

It should be noted that in exercising reasonable care, there may be an act of either commission or omission and each of these categories could lay the dermatologist open to litigation if harm has occurred. Moreover, a distinction must be made between an error of clinical judgement and negligence.

It is reassuring that the medical defence organizations in the UK still regard dermatology as a low-risk specialty, with few and relatively low-cost claims. On the other hand, plastic and reconstructive surgery involves a higher risk, as does cosmetic practice, especially when not carried out by consultant dermatologists or plastic surgeons.

It is important to remember that if something has gone wrong with patient care, a full and frank explanation with as little delay as possible will do much to diffuse the anger, upset and resentment that the patient feels and ultimately may reduce the risk that the patient will go to litigation [9]. There is a need for an explanation of how the injury has happened and why [9]. The doctor adopting this open type of approach could find him- or herself in direct conflict with the 'never admit anything' insurance type of mentality and it is important that Trust managers in the UK National Health Service, for instance, do not put pressure on their medical practitioners to adopt this approach. A prompt explanation is vital, as any delay would be seen as an attempt at cover up.

Consent [15]

Any treatment that entails the physical touching of a competent adult patient without consent constitutes the tort of battery. Consent provides a defence that makes the touching lawful. From the legal profession's point of view it is important to establish whether a competent adult patient consented to treatment or not and a requirement to obtain consent is imposed by law. In English law, once a patient has been informed in broad terms of the nature of the intended procedure and gives consent, the consent is valid, although there may be difficulties in deciding what constitutes the nature of the treatment or procedure and information in broad terms. It is very important to continue to review the information given to patients before obtaining consent. The use of information leaflets and documentation for the patient to read about treatment or surgical procedures is very helpful in this regard [16] but some doctors are still not providing enough information [14]. Medicolegally, times are changing so courts of law in the UK are putting more emphasis on the needs of patients and this can be seen as part of a wider social movement to give greater respect for individual rights.

The court appearance

Fortunately, less than 1% of cases where a medical report has been requested ever threatens to reach court, and in the majority of these cases a settlement is often reached out of court before the scheduled hearing. Should your appearance be necessary as an expert witness in court, it is important to follow several rules, but usually the expert witness drifts into this type of work without any training. Good preparation before the scheduled hearing is important and the original clinical notes, taken when preparing the medical report, can also be very useful. It is important to take the attitude that you are there to help the court, rather than to take one side or the other. Speak clearly and slowly enough to allow the judge to make notes. Do not fidget and do keep your evidence simple [17]. Take your time, when you need to, before answering the barrister's questions. When you are unclear as to what the barrister is asking, you may politely ask if the question might be rephrased. Emotionally, it may be difficult to switch from the role of a caring medical practitioner to an adversarial court system. Do not try and cross swords with an aggressive barrister, and address your comments at the judge, or jury if present. Remember, you are perfectly at liberty to ask for a short break if you have been in the witness box for some time and are getting tired.

Chapter 72

Systemic Therapy

S.M. Breathnach, C.E.M. Griffiths, R.J.G. Chalmers & R.J. Hay

Introduction

Topical therapy is generally preferable for skin diseases, because it minimizes the risk of systemic toxicity. However, there are quite a number of drugs that are only effective when administered systemically. This chapter gives a brief survey of some of the more important systemic agents used by dermatologists. The reader is also directed to additional information on drug therapy for specific conditions dispersed amongst other chapters in these volumes.

The important subject of drug reactions and interactions is referred to in Chapter 73. The particular problems of prescribing for special groups, such as children, pregnant and lactating women and elderly people are dealt with in some detail in the *British National Formulary* [1] (and other national formularies), as are the difficulties in prescribing for patients with liver failure, renal failure and diseases affecting other organs. Where there is any doubt, the advice of a clinical pharmacologist, a pharmacist or the drug manufacturer should be sought, or information obtained from such reference works as *Martindale* [2] and Goodman and Gilman [3]. The *ABPI Data Sheet Compendium* [4] is also valuable. The dosage for children is often calculated roughly on the basis of age, but should more accurately be based on body weight or, even better, body surface area [1].

Systemic corticosteroid therapy

Corticosteroids were first introduced into dermatology by Marion Sulzberger [1]. Most of their effects are mediated by the intracellular glucocorticoid receptor via activation or repression of gene expression [2,3]. Activation requires DNA binding of the receptor, while repression is mediated by protein–protein interactions with other transcription factors. The immunosuppressive and anti-inflammatory effects are exerted mainly by an interaction of the glucocorticoid receptor with the activating protein 1 (AP-1) and nuclear factor κB (NF-κB) families of transcription factors without DNA binding. Cytokines such as tumour necrosis factor-α (TNF-α) and interleukin 1 (IL-1) activate the hypothalamus–pituitary–adrenal (HPA) axis; glucocorticoids inhibit IL-1 and TNF-α forming a cytokine–HPA axis feedback circuit. In addition, glucocorticoids induce apoptosis of inflammatory cells

of the haematopoietic system, such as monocytes, macrophages and T lymphocytes, while protecting resident tissue cells [4]. Corticosteroids, by evoking formation of a cell-membrane protein termed lipocortin, also inhibit phospholipase A_2 (PLA_2), a membrane enzyme that generates a variety of pro-inflammatory lipids from membrane phospholipids, including the prostaglandins, the leukotrienes and platelet-activating factor [5]. Other proposed mechanisms of corticosteroids include a cytostatic action, a 'stabilizing' action on lysosomal membranes, and suppression of cytokine expression. Glucocorticoid effects on bone result from inhibition of bone formation because of a decrease in the number and function of osteoblasts, and increased bone resorption resulting from osteoclastogenesis (with increased expression of RANK ligand and decreased expression of its decoy receptor, osteoprotegerin), as well as stimulated expression of collagenase 3 [6].

Indications

Systemic corticosteroid treatment, rather than topical corticosteroid therapy, is indicated in special circumstances only. These include the following.

1 Acute self-limited steroid-sensitive disorders (e.g. acute contact allergic dermatitis), where the offending allergen is evident. In these circumstances a 1-week course of oral prednisone in reducing dosage may be sufficient.

2 Acute anaphylactic reactions (e.g. following a bee or wasp sting or a drug to which the patient is sensitized). Hydrocortisone should be given intravenously in a dose of 100 mg, after prior administration of epinephrine (adrenaline) 0.5 mg intramuscularly, and chlorphenamine (chlorpheniramine) 4 mg intramuscularly (adult doses).

3 Acute autoimmune connective tissue diseases and generalized immunological vascular disorders (e.g. systemic lupus erythematosus, dermatomyositis, polyarteritis nodosa, giant cell arteritis, Wegener's granulomatosis).

4 Chronic disabling immunological bullous diseases (e.g. pemphigus vulgaris, pemphigoid).

5 Acute generalized exfoliative dermatitis (e.g. resulting from a severe drug reaction).

6 A number of miscellaneous disorders including severe lichen planus, pyoderma gangrenosum and sarcoidosis, in which there is evidence of cardiac, renal, ocular or extensive pulmonary or cutaneous involvement.

7 Although systemic steroids are often used, the value of such treatment is unproven in erythema multiforme, Stevens–Johnson syndrome, toxic epidermal necrolysis, chronic urticaria and cutaneous T-cell lymphoma.

Pharmacological considerations

Corticosteroids are anti-inflammatory, immunosuppressive, antiproliferative and vasoconstrictive.

Prednisone and prednisolone

Like cortisone and hydrocortisone, prednisone and prednisolone differ chemically only in the presence of a hydroxy group instead of a keto group at C11. The biological properties are similar, but prednisone has to be metabolically transformed in the liver to the 11β-hydroxy derivative to acquire biological potency, and hence prednisone should not be given to patients with liver disease. Both drugs possess four times the glucocorticoid potency and relatively less mineralocorticoid (salt-retaining) activity than hydrocortisone and cortisone.

Route of administration

Intramuscular

The intramuscular route, especially for triamcinolone, is popular in the USA for systemic steroid administration for short-term (less than 4 weeks) treatment. Triamcinolone does not differ significantly from prednisolone in its actions on a short-term basis, although in the long term it possesses greater mineralocorticoid activity. In the longer term, intramuscular steroids, especially in depot formulation, can cause marked HPA suppression and severe local atrophic changes, although the latter partially remit after a year or more. In the event of untoward steroid-induced complications, the drugs cannot be withdrawn promptly.

Intravenous

The intravenous route is useful in emergency treatment of acute anaphylaxis and in the pre- and postoperative cover of patients who have previously been receiving systemic steroid treatment for 4 weeks or more. A suitable regimen is 25 mg hydrocortisone preoperatively at the time of induction of anaesthesia, 100 mg during the operation and 100 mg on the first postoperative day—all doses being intravenous.

Thereafter the patient can be maintained on oral therapy as required. In fact, hypotensive crises attributable to adrenal insufficiency are extremely rare in patients withdrawn from glucocorticoid therapy and subsequently undergoing surgery without supplemental corticosteroid cover.

Pulsed steroid therapy

This is usually administered as doses of 1 g of methylprednisolone given intravenously over several hours using an intravenous line. The dose can be repeated daily for up to 5 days. It may be indicated in patients with severe bullous dermatoses, especially pemphigus vulgaris. It is a potentially hazardous procedure, and thromboembolism,

cardiac arrest and steroid psychosis are occasional complications [7].

Oral steroids

Route of administration and dosage. Oral steroids may be taken in a single daily dose or using an alternate-day regimen.

Single daily dose. Short-term systemic steroid therapy is best given as a single daily dose. Prednisone and prednisolone have minimal mineralocorticoid activity and have a sufficiently prolonged action to ensure the sustained effectiveness of a single daily dose. The single dose should be given first thing in the morning. This is because the maximum rate of adrenocortical cortisol secretion occurs early in the morning and therefore less pituitary–adrenal suppression occurs at this time, while therapeutic efficacy is maintained [8].

Alternate-day dosage. Prolonged therapy may be instituted using an alternate-day regimen (twice the daily dose on alternate days with no steroid treatment on the other days) [9]. Conversion from a daily to an alternate-day regimen should be carried out gradually rather than abruptly (e.g. by progressive diminution of the dose on even-numbered days while building up the dose on odd-numbered days). In order to prevent alternate-day relapses, it may be necessary to maintain a small dose on the even-numbered day. Institution of an alternate-day systemic steroid regimen reduces but does not prevent steroid toxicity. Posterior subcapsular cataracts and osteoporosis may remain problems [10,11]. Alternate-day systemic steroid therapy is not always as effective as daily treatment when given in equivalent dosage.

Systemic steroid toxicity

A comprehensive account of the range of unwanted side effects consequent upon systemic steroid therapy is beyond the scope of this text, and is addressed in Chapter 73 [12–15]. Betamethasone and deflazacort may be used in emergencies in patients with adverse immunoglobulin E (IgE)-mediated allergic reactions to hydrocortisone and methylprednisolone [16].

The approximate physiological daily cortisol secretion by the adrenal cortex is 20 mg/day for an average adult (prednisone equivalent 5 mg/day). Short courses of prednisolone (e.g. up to 30 mg/day for less than 2 weeks), although suppressing pituitary–adrenal function, do not require tapering because recovery is rapid. However, for patients with a longer history of oral steroid treatment, gradual reduction of dosage prior to discontinuation is important, because abrupt reduction may lead to the 'steroid-withdrawal' syndrome, which resembles the clinical features of adrenocortical insufficiency. Random plasma-cortisol determination may be within normal limits and stimulation tests of pituitary and adrenal function may also be normal [17].

One of the major problems with prolonged systemic corticosteroid therapy is osteoporosis. Patients receiving the equivalent of prednisolone 7.5 mg/day or more for over 3 months should receive prophylactic therapy to prevent bone resorption, such as calcium, bisphosphonates (alendronate, etidronate or risedronate), calcitriol or gonadal steroids (hormone replacement therapy in women, testosterone in men) [18,19].

Tests of pituitary–adrenal function

Baseline plasma-cortisol levels and study of diurnal variation of plasma cortisol are crude estimates of HPA integrity. The adrenocorticotrophic hormone (ACTH) stimulation test measures adrenal but not hypothalamo-pituitary integrity. The metyrapone test is based upon inhibition of an enzyme involved in synthesis of a cortisol precursor (2-deoxycortisol) resulting in reduction in cortisol levels and a consequent increase in ACTH. The cortisol precursors are measured in the urine and the resultant values give an indication of HPA integrity. Stress tests including insulin-induced hypoglycaemia measure the integrity of the whole HPA system, and are best carried out with the assistance of a specialized unit.

Systemic corticosteroids and pregnancy

There is little concrete evidence that systemic corticosteroids are harmful in pregnancy. Although the literature contains sporadic reports of stillbirth, spontaneous abortion and cleft palate associated with systemic corticosteroids [20], a recent review concluded that they are not teratogenic. Very little corticosteroid ingested by a mother enters her breast milk [21].

Systemic corticosteroids and cataracts

Posterior subcapsular cataracts are a recognized complication of systemic corticosteroid therapy. Screening by slit-lamp examination for patients in whom prolonged treatment with systemic corticosteroids is contemplated may help to obviate medicolegal consequences [10].

ACTH and tetracosactide

Although these agents are not corticosteroids, they provoke increased secretion of endogenous adrenal corticoids. There is little or no evidence to support the use of ACTH or tetracosactide (tetracosactrin) in place of systemic steroids. Their anti-inflammatory actions depend entirely upon increased hydrocortisone production by the adrenal

cortex. They also suffer from the disadvantage that they stimulate adrenal androgen as well as hydrocortisone production, and therefore cause more salt and water retention than prednisolone [22]. Maximum response of adult adrenals is no more than 100 mg/day cortisol. ACTH and tetracosactide have to be given by injection and can cause severe anaphylactic reactions. There is no sound evidence for the often asserted view that these drugs are associated with less growth retardation in children than with oral corticosteroids. The only arguable advantage of ACTH or tetracosactide therapy is a reduced likelihood of pituitary–adrenal suppression, and this view has been challenged [22]. Certainly, overall, and dose for dose, manifestations of steroid toxicity are at least as frequent as in oral corticosteroid treatment.

Sex hormones and related compounds

Androgens

Testosterone is the most potent androgen and is currently only used for replacement therapy. Although many derivatives of testosterone have been developed with a pronounced anabolic action (the 'anabolic steroids'), they nevertheless retain significant and often troublesome virilizing activity.

Anabolic steroids

Danazol (100–600 mg/day). Danazol is a synthetic steroid derived from ethisterone. It has a high affinity for androgen receptors, and although itself a weak androgen, it has marked antiandrogenic activity. It also inhibits gonadal steroid production and reduces secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) by the pituitary. It increases the hepatic synthesis of a number of proteins including complement C1-esterase inhibitor and antitrypsin [1,2], and is of great value in hereditary angio-oedema because of C1-esterase inhibitor deficiency [3]. It causes enhanced production by the liver of functional C1-esterase inhibitor, but its beneficial effect is probably a result of more complex actions [4]. It can also be used to treat more severely affected patients with cholinergic urticaria who are unresponsive to antihistamines [5], probably because of its ability to enhance hepatic synthesis of antitrypsin, and can be used to inhibit ovulation in autoimmune progesterone dermatitis. Apart from its troublesome virilizing actions, it may cause hepatotoxicity; liver function tests should be carried out before and at monthly intervals during treatment.

Stanozolol (2.5–10 mg/day). Stanozolol is also a potent anabolic steroid with mild virilizing activity. It is just as effective as danazol in hereditary angio-oedema and with similar side effects, but considerably cheaper. Additionally, it has marked fibrinolytic properties, and has been advocated in the management of lipodermatosclerosis [6]. Its side effects are similar to those of danazol.

Anti-androgens [7–9]

Pregnancy must be avoided during therapy with anti-androgens because of the possible risk of abnormal development of a male fetus.

Cyproterone acetate. Cyproterone is a potent anti-androgen that competes with androgens at receptor sites and inhibits gonadotrophin secretion. In low doses (2 mg/day), usually in combination with ethinylestradiol in a reverse sequential regimen, it can be used for treatment of acne in females. It can also be used to treat hirsutism and other

signs of virilization in females (at 12.5–50 mg/day in a reverse sequential regimen). Liver toxicity is an occasional problem and the drug is contraindicated in pregnancy.

Spironolactone [10]. Spironolactone blocks androgen receptors, but at low dosage it is less effective than other anti-androgens; high dosage (200 mg/day) is very effective at the cost of several adverse effects (particularly dysfunctional uterine bleeding). The concomitant use of a combined oral contraceptive may prevent these.

Flutamide. This also blocks androgen receptors, and at 250–500 mg/day for 6 months may be effective at treating hirsutism. Dry skin is very frequent, and hepatotoxicity is possible with high dosage.

Finasteride. Finasteride, a 5α-reductase type 2 inhibitor that blocks conversion of testosterone to dihydrotestosterone in the skin, is the least effective anti-androgen, but a dosage of 5 mg/day may decrease hirsutism without adverse effects. At a dosage of 1 mg/day, the drug produced clinical improvement in up to 66% of men with androgenetic alopecia treated for 2 years [11,12].

Oestrogens

Oestrogens prevent skin ageing [13], and may be useful in the management of autoimmune progesterone dermatitis [14].

Ethinylestradiol (10–35 μg/day). Ethinylestradiol (ethinyl oestradiol) is valuable replacement therapy in the treatment of postmenopausal symptoms including hot flushes, vaginitis and vaginal atrophy [15]. Plasma levels of FSH and LH, which are elevated in postmenopausal females, are useful guides to dosage. Ethinylestradiol should be avoided in patients with a history of breast cancer, liver or thromboembolic disease.

Anti-oestrogens

Tamoxifen (20 mg/day). Tamoxifen is an anti-oestrogenic drug that acts at receptor sites to block oestrogen binding. It therefore inhibits ovulation in fertile women. It may be useful in the treatment of progesterone-induced dermatitis or erythema multiforme [16]. Side effects are those associated with the menopause, together with abnormal vaginal bleeding. Bone density may be affected in the course of long-term treatment.

Antihistamines

Historical note

The first effective and safe antihistamine, neoantergan, was based upon a molecule '2786 RP' discovered by Parisian investigators, Bovet and Walthert, in 1944 [1]. This antihistamine, known as anthisan or mepyramine maleate, was one of a series of diamethylamino-*N*-propyl phenothiazine compounds. Soon afterwards in the USA, diphenhydramine (Benadryl®) was launched and found to be effective by O'Leary and Faber [2] in chronic urticaria. In the UK, definition of the actions and potential role of the first-generation antihistamines was pioneered by Bain *et al.* [3,4] in urticaria.

It had long been recognized that not all of the actions of histamine, notably that of stimulation of gastric acid secretion, could be blocked by antihistamines. This puzzle was unravelled by Black *et al.* [5] who described a subset of histamine receptors designated H_2, which led to the development of the first clinically useful H_2 antihistamine, cimetidine, subsequently to be found effective in the management of chronic urticaria [6]. The later discovery of a third subset of histamine autoreceptors, H_3 [7], has as yet not generated any clinically useful applications in dermatology. However, the new class of H_1 antihistamines, in which troublesome sedative side effects of the classical

Table 72.1 Histamine receptors.

Receptors	Main action relevant to skin	Expression in skin	Antagonist
H_1	Vasodilatation Vasopermeability Itch	Yes	Chlorphenamine Terfenadine
H_2	Vasodilatation Vasopermeability	Yes	Cimetidine Ranitidine
H_3	Regulation of histamine Neurotransmitter release	?	Thioperamide*

DPPE, *N*,*N*-diethyl-2-[4-(phenyl methyl) phenoxy] ethanamine HCl.
* Experimental antagonists.

antihistamines are minimalized by substitutions on the basic imidazole ring, thus preventing the drug from crossing the blood–brain barrier, has been the biggest recent milestone in the long history of antihistamines [8–12]. In 2002, 17 different oral H_1 antihistamines were available in the UK for treating allergic disorders [13].

Histamine receptors

Four classes of histamine receptor are presently recognized (Table 72.1). The discovery of H_2 receptors [5], alluded to above, was followed by demonstration of expression of H_1 and H_2 receptors in human skin. Histamine-induced vasodilatation and wealing are mediated by both classes of receptor, whereas itching is only served by H_1 receptors [14–16]. H_3 receptors are responsible for the ability of histamine in some tissues to regulate, by inhibitory feedback, its own biosynthesis and release. H_3 receptors, which also regulate transmitter release at autonomic nerve terminals, have not been convincingly shown to be represented in skin. On the other hand, the recently described intracellular (H_{ic}) histamine receptors that are responsible for the ability of histamine to promote cell and tissue growth (e.g. in embryonic tissue and wound healing) [17] are probably expressed in skin, although this has not yet been specifically demonstrated.

Other actions of antihistamines

Most H_1 antihistamines also express anticholinergic activity, resulting in the well-known side effects of the earlier 'classic' antihistamines, which include dryness of the mouth, blurring of vision and constipation. Drowsiness is also a feature of many early antihistamines. Available evidence suggests that histamine plays a part in the maintenance of the waking state, which may go some way towards explaining the sedative actions of some H_1 antihistamines. Many H_1 antagonists also prevent release of mediators from activated mast cells, although in most cases only in a higher concentration than that achieved clinically. This response does not involve H_1 receptors [18]. Two H_1 antagonists, ketotifen and cetirizine, deserve mention as they have been claimed to be potent inhibitors of release of mast cell products [19–21]. However, no evidence of reduced urinary excretion of histamine or its metabolites was detected in patients with mastocytosis treated by the H_1 antihistamine, ketotifen [20]. Cetirizine has also been claimed to possess selective inhibitory activity against eosinophil-rich dermatoses [21,22] but the clinical relevance of this action is unclear.

Table 72.2 Pharmacokinetic and pharmacodynamic activity of representative first- and second-generation antihistamines [8,23].

H_1 antagonist	T_{max} (h)	Half-life (h)	Weal suppression duration (h)
Chlorphenamine	2.8	27.9	24
Hydroxyzine	2.1	20.0	24
Diphenhydramine	1.7	9.2	12–24
Terfenadine	1.0	17	12–24
Astemizole	3.0	9.5 days	Variable
Loratadine	1.0	7.8–11.0	12–24
Cetirizine	0.9	7.4	24

T_{max}, time of maximum plasma concentration.

H_1 antihistamines (Table 72.2 [8,23])

These are conveniently classified as first- and second-generation H_1 antihistamines. The first-generation drugs, although potent, are accompanied by troublesome atropine-like side effects, and also cause drowsiness [24], which may be useful or disadvantageous depending upon the clinical context.

First-generation H_1 antihistamines

These are exemplified by chlorphenamine (an alkylamine), diphenhydramine (an aminoalkyl ether) and hydroxyzine (a piperazine). Plasma half-lives of these drugs are variable (chlorphenamine approximately 24 h; hydroxyzine

20 h; diphenhydramine 9 h), although peak plasma concentrations are reached in approximately 2 h. Protein binding is almost total, and metabolism occurs via the hepatic microsomal cytochrome P-450 system. Thus, the half-life of certain H_1 antihistamines may be prolonged in patients receiving microsomal oxygenase inhibitors such as ketoconazole, erythromycin, doxepin or cimetidine.

The principal actions of H_1 antihistamines are on vasodilatation and increased vascular permeability, thus reducing the redness, weal and axon reflex flare reactions in acute urticaria, and suppressing the associated itching. The clinical effects of these H_1 antihistamines usually persist longer than measurable plasma levels would suggest, because of persistence of tissue levels or because of active metabolites. Once-daily administration is therefore adequate. In urticaria, first-generation H_1 antagonists reduce the size, duration and frequency of weals and greatly alleviate the itching. Although more often a nuisance, the sedative effects of first-generation H_1 antihistamines have been claimed to be highly beneficial in suppressing itching in some patients with atopic eczema [25]. Their effect is enhanced by other sedative drugs, especially alcohol. Other side effects of these antihistamines include tachycardia, with prolongation of the Q–T interval on the electrocardiogram and other arrythmias, as well as psychological disturbances.

Second-generation H_1 antihistamines [8]

These are exemplified by terfenadine, astemizole, loratadine and cetirizine, none of which produces sedation significantly greater than that caused by an otherwise identical placebo, provided recommended dosage is used. The absorption and metabolism of second-generation H_1 antihistamines resembles that of the first generation described above. The plasma half-lives of terfenadine, astemizole and cetirizine are listed in Table 72.2. These drugs in recommended regimens do not significantly cross the blood–brain barrier, thus accounting for their minimally sedating characteristics. Terfenadine is almost completely devoid of histamine H_2 or cholinergic receptor blockade and is effective in the treatment of chronic urticaria [26]. Agents including grapefruit juice and certain drugs (ketoconazole, itraconazole, erythromycin, other macrolide antibiotics, cimetidine and doxepin), which inhibit hepatic metabolism via the cytochrome P-450 system, should not be given concurrently with terfenadine, because they may promote adverse effects including cardiac arrhythmias, Q–T interval prolongation and torsades de pointes (ventricular tachycardia) [27–29]. Terfenadine is also contraindicated in patients with liver or heart disease. Terfenadine may cause rashes, which occasionally (and paradoxically) include urticaria [30,31]. The UK Committee on Safety of Medicines withdrew terfenadine from over-the-counter sale, as did the US Food and Drug Administration, because of the cardiac complications. Recently, fexofenadine, the major active metabolite of terfenadine, has been introduced as an alternative to terfenadine [32].

Astemizole also undergoes first-pass metabolism via the liver cytochrome P-450 system but its half-life together with its active metabolite dimethylastemizole is prolonged at 9.5 days [8]. It binds with greater avidity to H_1-receptor sites than any other H_1 antihistamine, evidence of histamine weal suppression being evident 4 weeks or more after discontinuation [33], but it has not been shown to be teratogenic. Like terfenadine, it must not be co-administered with macrolide antibiotics, imidazole antifungals or doxepin, because of the risk of cardiac arrhythmia [34]. Patients with a pre-existing Q–T interval prolongation are especially at risk. Other side effects of astemizole include increase in appetite and excessive weight gain [8].

Loratadine is a potent minimal-sedation antihistamine that is also substantially free of anticholinergic side effects. Loratadine is not metabolized through the liver cytochrome P-450 enzyme system to any great extent and is therefore believed free of cardiac arrhythmic complications. It inhibits evoked release of leukotrienes from human lung *in vitro* but is less active in suppressing histamine release [35]. How relevant these 'antiallergic' properties are to its therapeutic action is unclear. Desloratadine has now replaced loratadine in the UK.

Like loratadine, cetirizine, which is an active metabolite of hydroxyzine, is only minimally metabolized via the liver and therefore can be administered safely with macrolide antibiotics, imidazole antifungals and doxepin. In recommended dosage it has minimal sedative and anticholinergic actions. Cetirizine is claimed to be effective in diseases involving heavy eosinophil infiltration [21,22]. It has been proposed, on this basis, that cetirizine is especially valuable in patients with the common physical urticaria, delayed pressure urticaria [36], although adequate confirmation of this claim is lacking. Levocetirizine is also available.

H_1-antihistamine therapy in childhood

The second-generation low-sedation antihistamines are probably safer in children than the older 'classic' antihistamines; liquid formulations of astemizole, cetirizine and loratadine are available in the UK. Overdose of the first-generation antihistamines may cause severe toxicity including hyperpyrexia and convulsions in children.

H_1-antihistamine therapy in pregnancy

No antihistamines administered systemically should be deemed safe in the first trimester of pregnancy. However, of the available H_1 antihistamines, chlorphenamine [37]

and tripelennamine [38] have shown little or no evidence of teratogenicity experimentally and are probably the least risky to use.

Development of tolerance during H_1-antihistamine therapy

Although tolerance of the first-generation H_1 antihistamines was reported soon after their introduction into medical practice [39], little or no information is available on the molecular basis of this phenomenon [40]. Suppression of wealing because of mast cell activation and histamine progressively dwindled in response to single doses of 75 mg hydroxyzine given daily for 3 weeks; no tolerance was demonstrated in response to chlorphenamine 16 mg/day in the same study [41]. Interestingly, this study showed that hydroxyzine, but not chlorphenamine, caused tolerance not only to itself but to several other first-generation antihistamines.

H_2 antihistamines

Cimetidine and ranitidine

The presence of H_2 receptors expressed on human skin blood vessels [14,15] prompted exploration of the value of H_2 antihistamines, co-administered with H_1 antihistamines, in the treatment of chronic urticaria. The object was to achieve an H_1-antihistamine-sparing effect, thus mitigating unwanted first-generation H_1 antihistamine side effects including drowsiness and atropine-like side effects. This strategy proved modestly successful [6,12,42–44]. However, the subsequent availability of the second-generation low-sedation antihistamines has undermined the need for an H_1-antihistamine-sparing regimen. Because ranitidine, unlike cimetidine, is not metabolized via the liver cytochrome P-450 system, it should probably be used in preference to cimetidine if H_2 antihistamine therapy is instituted.

Other antiallergic drugs

Sodium cromoglycate. Although ineffective in suppressing mast cell activation in the skin [1], it inhibits release of histamine and other mast cell-derived mediators from mast cells of lung, conjunctiva, nose and gastrointestinal tracts. It therefore has no proven role in the skin; however, it does ameliorate the diarrhoea associated with mastocytosis [2].

Leukotriene receptor antagonists. Montelukast and zafirlukast may be useful in chronic urticaria [3].

Systemic non-steroidal anti-inflammatory therapy

Non-steroidal anti-inflammatory drugs (NSAIDs) are defined as substituted phenolic or benzene-ring compounds that owe their pharmacological actions mainly to inhibition of the enzyme cyclo-oxygenase (COX) (prostaglandin synthetase). This enzyme complex was shown by Vane [1] in 1971 to transform arachidonic acid into prostaglandins. However, NSAIDs undoubtedly influence other pro-inflammatory molecular pathways. NSAIDs have been advocated in a large number of common and uncommon dermatoses, including acne, psoriasis, sunburn, erythema nodosum, cryoglobulinaemia, Sweet's syndrome and systemic mastocytosis, as well as in urticarial, livedoid and nodular vasculitis [2].

Transformation of arachidonic acid and the mode of action of NSAIDs

There are two forms of COX: a constitutive enzyme (COX-1) and an induced enzyme (COX-2) (Fig. 72.1). NSAIDs act mainly by inhibition of COX-2 [3]. In contrast, inhibition of COX-1 by NSAIDs probably accounts for some of their unwanted side effects including gastric ulceration.

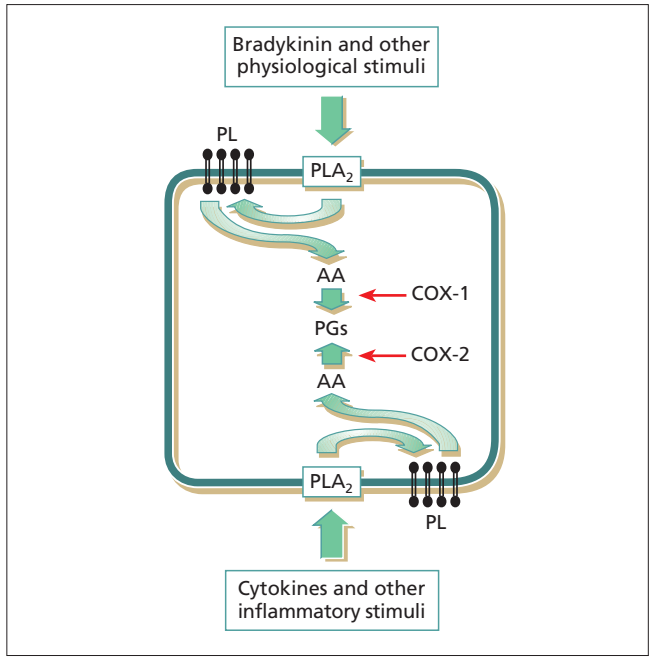

Fig. 72.1 Transformation of arachidonic acid (AA) to prostaglandins (PGs) by cyclo-oxygenases (COX) 1 and 2. PLA_2, phospholipase (PL) A_2.

Arachidonic acid is also transformed via the lipoxygenase pathways (5-lipoxygenase; 12-lipoxygenase) to form a group of strongly pro-inflammatory hydroxy fatty acids of which the best known is leukotriene B_4 (LTB_4) (Fig. 72.2) [4]. Because of the proposed role of the leukotrienes and other hydroxy fatty acid products of arachidonic acid in the pathogenesis of psoriasis [5] and other inflammatory dermatoses [6], several generally unsuccessful attempts have been made to develop selective lipoxygenase-inhibiting NSAIDs for clinical dermatological use [7]. These compounds have generally proved ineffective, toxic or both.

Acetylsalicylic acid (aspirin) is the archetypal NSAID and has been shown to owe its anti-inflammatory action to inhibition of COX-2 [1]. Its role in the management of skin diseases is limited. Administration of aspirin has been shown to suppress ultraviolet erythema in humans [8]. Furthermore, Roberts *et al.* [9] have proposed that aspirin be co-administered with H_1 and H_2 antihistamines in the management of the diarrhoea of systemic mastocytosis, which is believed to be mainly caused by overproduction of prostaglandin D_2 by the increased population of mast cells in the involved tissues. Although originally proposed to be antipruritic, aspirin administration probably does not allay the itching of atopic eczema [10].

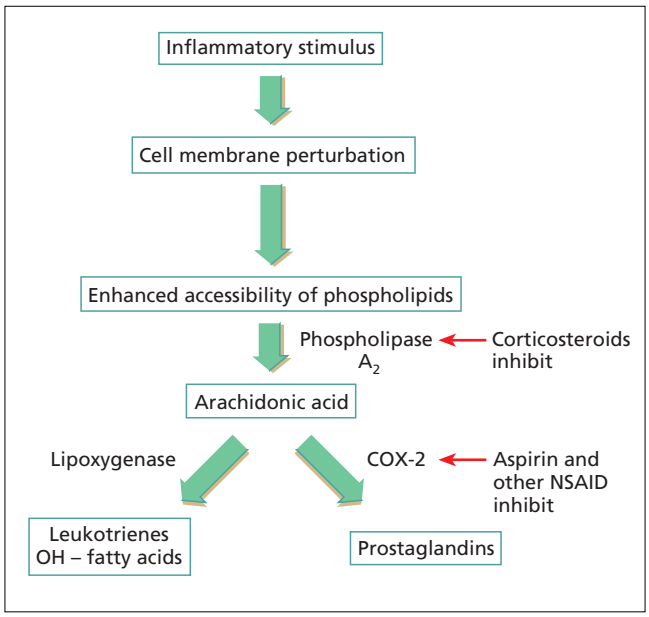

Fig. 72.2 Generation of eicosanoids from cell membrane lipids in the inflammatory response. Arachidonic acid, released from cell membrane phospholipid by the action of phospholipase A_2, is further transformed by cyclo-oxygenase 2 (COX-2) to prostaglandin, and by lipoxygenase to leukotrienes and related fatty acids. NSAID, non-steroidal anti-inflammatory drugs.

The early phase of UVB-induced erythema is caused, at least in part, by release of vasoactive prostaglandins [11]. Oral administration of indometacin (indomethacin) has been demonstrated to reduce the erythema and concurrently to suppress the increased tissue levels of COX products in UVB-irradiated skin [12]. Proposed clinical indications for oral indometacin include cutaneous vasculitis [13] and erythema nodosum [14], although these indications have not yet been confirmed by placebo-controlled double-blind trials. The value of oral indometacin in the management of psoriatic arthritis is well established; reports that oral indometacin may exacerbate the skin lesions of psoriasis have not been substantiated (see Chapter 73).

Adverse reactions to systemic NSAIDs, including urticaria and angio-oedema, are unfortunately commonplace (see Chapter 73) [15]. Reactions occur most frequently in response to piroxicam, sulindac, meclofenamate, tolmetin and phenylbutazone [16]. The best known and probably the most severe include Stevens–Johnson syndrome and toxic epidermal necrolysis. Photosensitivity is very common, especially with piroxicam, but the underlying mechanisms, which involve phototoxicity in many instances, are unknown [17].

Cytokines

Cytokines are small polypeptides, molecular mass less than 60 kDa, which act as intercellular messengers; they have a pivotal role in cutaneous inflammation. They can be either pro-inflammatory or anti-inflammatory; however, a single cytokine may have several different functions and may act on many cellular targets. DNA technology has facilitated the large-scale manufacture of recombinant human cytokines, several of which have been used to treat skin disease.

Interferons

Interferons are naturally occurring endogenous glycoproteins, which are now available for therapeutic use through recombinant DNA technology. This group of compounds exhibits antiviral, cytostatic and immunomodulatory properties and has therefore found application in both malignant and inflammatory dermatoses. Three types of interferon are available: interferon-α (IFN-α), IFN-β and IFN-γ. Unfortunately, side effects are common, including influenza-like symptoms with fever, hepatotoxicity and leukopenia; this has limited clinical usage.

Kaposi's sarcoma

Because of its antiviral, antiangiogenic and tumoristatic properties, interferon ought to be an ideal treatment for acquired immune deficiency syndrome (AIDS)-related Kaposi's sarcoma, which is probably caused by human herpesvirus 8. There have been numerous reports of remissions induced by IFN-α, invariably at the cost of troublesome side effects. In earlier studies [1], high doses did induce remissions, especially in patients without associated opportunistic infections [2]. Subsequent studies suggested that better results were obtained in the presence of sustained CD4 T-lymphocyte counts [3]. There is some evidence of synergism between IFN-α and zidovudine [4,5]. Patients who respond to treatment with IFN-α appear to have fewer opportunistic infections [6]. Co-administration of granulocyte–macrophage colony-stimulating factor (GM-CSF) with IFN-α has been shown to limit the bone marrow-suppressant side effects of the latter [7]. Both IFN-α and IFN-β inhibit neoangiogenesis—a further explanation for their effectiveness in Kaposi's sarcoma [8]. IFN-γ is ineffective in Kaposi's sarcoma.

Melanoma

There has been considerable interest in the use of IFN-α to treat metastatic melanoma. Approximately 5% of treated patients may achieve total remission. The optimal drug regimens of IFN-α are not known but up to 20% of patients may respond [9]. This response rate can be significantly increased by combination therapy with cisplatin and other antimetabolites [10]. Despite the mixed results, IFN-α is approved in the USA and Europe for high-risk melanoma patients [11]. IFN-α has been administered subsequent to melanoma lysate vaccine, leading to a response rate higher than that produced by either IFN-α or vaccine alone [12].

Cutaneous T-cell lymphoma

Cutaneous T-cell lymphoma (CTCL) is a Th2 cytokine disease in that peripheral blood mononuclear cells secrete increased amounts of IL-4 and IL-5. IFN-α, which suppresses IL-4 and IL-5 production, is effective in up to 50% of patients—particularly those with Sézary syndrome [13]. Remission rates as high as 70% have been reported when subcutaneously administered IFN-α-2a is used in combination with psoralen with UVA treatment (PUVA) or extracorporeal photopheresis [14].

Atopic dermatitis

Recombinant IFN-γ has been administered on a double-blind placebo-controlled basis to patients with atopic dermatitis with demonstrably superior effect compared with placebo control [15]. The rationale for IFN-γ treatment is based upon the findings of high-serum IgE levels and predominant Th2 cells producing IL-4 and IL-5, coupled with low production of IFN-γ by Th1 cells in atopic subjects. Administration of IFN-γ, according to this scheme, results in isotype switching away from IgE production, because of inhibition of growth of IL-4- and IL-5-producing Th2 cells [16]. Approximately one-half of the IFN-γ treated patients, but only one-quarter of the placebo-treated patients, experienced significant clinical improvement [15]. There was no reduction in serum IgE in the IFN-γ-treated group but the blood eosinophil count fell in these patients. Side effects including leukopenia were frequent in the actively treated patients. Long-term studies have demonstrated efficacy and safety for up to 2 years if IFN-γ is delivered subcutaneously at 50 μg/m^2 three times weekly. The most commonly reported side effects are influenza-like symptoms [17,18].

Interleukins

Interleukins are an expanding group of endogenous soluble mediators in use for therapy of inflammatory dermatoses, malignancy and infection.

Melanoma

IL-2 is the most widely used of the interleukins for therapy of melanoma in a variety of regimens ranging from IL-2 monotherapy to combinations with lymphokine-activated killer cells or polychemotherapy. Following a trial that demonstrated that high-dose IL-2 could induce complete remission in 6% of patients with metastatic melanoma, this approach has been approved for the indication in the USA [1]. Combining IL-2 with chemotherapy or IFN-α does not appear to improve efficacy [2].

GM-CSF as adjuvant therapy appears to prolong overall and disease-free survival in patients with stage III or IV melanoma [3].

Psoriasis

Psoriasis is a Th1-mediated disease—with a predominance of Th1 cytokines in plaques. Systemic administration of Th2 cytokines, such as IL-4, IL-10 or IL-11, is a logical cytokine-modulating approach to restore the cytokine balance in psoriasis. Recombinant human IL-4 administered five times weekly over 6 weeks in an open study produced a highly significant reduction in psoriasis severity [4]. IL-10 inhibits antigen presentation and production of pro-inflammatory cytokines such as TNF-α. Several studies [5–7] have confirmed the effectiveness of subcutaneously administered IL-10 (8 μg/kg/day or 20 μg/kg three times weekly). An open study of recombinant IL-11 (approved for treatment of chemotherapy-induced thrombocytopenia) indicated significant reduction in psoriasis severity [8].

Cytokine blocking agents

DNA technology has allowed large-scale production of neutralizing or inhibitory antibodies to pro-inflammatory cytokines. This approach to the therapy of inflammatory disease has been pioneered in the fields of rheumatoid arthritis and Crohn's disease. In dermatology, the anticytokine agents have been most extensively trialled in psoriasis with very little controlled trial evidence from other dermatoses.

TNF-α, as a key pro-inflammatory cytokine, is perhaps the most attractive target for anticytokine approaches for the treatment of inflammatory skin disease. The two agents used currently to neutralize activity of TNF-α are infliximab and etanercept.

Infliximab is a chimeric (human–mouse) monoclonal antibody against TNF-α composed of a human constant and a murine variable region of the IgG antibody [1]. Infliximab was developed initially for treatment of rheumatoid arthritis and Crohn's disease. It is now licensed, with different regimens, for treatment of both conditions. In rheumatoid arthritis the preferred regimen is combination with methotrexate, infliximab being given as 3–5 mg/kg infusions at baseline and at weeks 2 and 6 followed by regular infusions every 8 weeks, irrespective of disease activity. For Crohn's disease, a single 5 mg/kg infusion is given and repeated at 2 and 6 weeks if fistulae are present.

Following anecdotal reports [2] of effectiveness of infliximab for concurrent psoriasis in patients receiving it for Crohn's disease, a double-blind placebo-controlled trial [3] was performed in severe plaque psoriasis. Infliximab infusions of 5 or 10 mg/kg were compared with placebo delivered as monotherapy at baseline and at weeks 2 and 6. Eighty-two per cent and 91% of patients treated with 5 and 10 mg/kg infusions, respectively, achieved a highly significant reduction in clinical severity of psoriasis. Subsequent studies have borne out this remarkable and rapid response [4]. Combination with methotrexate [5] is also effective. It is probable that if licensed for psoriasis, the preferred regimen for use will be 5 mg/kg infusions according to the above loading

dose, with infusions repeated at 8-week intervals. Side effects include risk of infections, reactivation of pulmonary tuberculosis [6], infusion reactions and development of antibodies against double-stranded DNA [3].

Case reports attest to the efficacy of infliximab in Behçet's disease [7], pyoderma gangrenosum [8], graft-versus-host disease [9], subcorneal pustular dermatosis [10], toxic epidermal necrolysis [11] and hidradenitis suppurativa [12].

Etanercept is a recombinant fusion protein comprising two extracellular ligand-binding proteins of the p75 TNF receptor linked to the Fc portion of human IgG [13]. The drug is administered subcutaneously twice weekly. In the USA, etanercept is approved for the treatment of rheumatoid arthritis and psoriatic arthritis; in the UK for rheumatoid arthritis only. Most trials of etanercept have been for the treatment of psoriasis—some as a secondary end point in studies on psoriatic arthritis [14]. Etanercept significantly reduces clinical severity of psoriasis in approximately 26% of patients over the course of 12 weeks [14]. Side effects include respiratory tract infections, headaches, rhinitis and, rarely, demyelination [15]. Etanercept is also reported anecdotally to show some efficacy in the treatment of scleroderma [16] and cicatricial pemphigoid [17].

There is little doubt that cytokine blockers will become commonplace in the treatment of psoriasis and perhaps other inflammatory skin diseases. Their utility will be improved by the development of oral agents that block TNF-α indirectly by approaches that include inhibition of mitogen-activated protein (MAP) kinases.

Receptor targeted therapies

Monoclonal antibodies can either be humanized, consisting of a human Fc fragment and a mixed human–mouse Fab (antigen binding) portion; or chimeric, in which the Fc fragment is human and the Fab portion is murine. Fusion proteins link a human or murine Fab domain to a human molecule, usually an immunoglobulin. These biotechnological approaches have been intensively trialled for the treatment of psoriasis but to date only one compound has been approved for use in treatment of skin disease. These agents are delivered parentally by intravenous, intramuscular or subcutaneous injection; overall they are well tolerated with low immunogenicity.

Monoclonal antibodies directed at the CD4 molecule on T cells have been used for the therapy of psoriasis. The first in 1991—a murine IgG1 antibody—produced significant improvement in three patients with severe psoriasis [1]. The only formal placebo-controlled trial [2] was for the use of a humanized anti-CD4 IgG4 monoclonal antibody in severe psoriasis. Patients only responded after a second course of treatment, with a reduction of 66% in clinical severity at 3 months.

Most new biological therapies under development for treatment of psoriasis are targeted at the co-stimulatory or accessory molecule ligand pairs binding T cells to antigen-presenting cells. Alefacept, a recombinant human LFA-3–IgG1 fusion protein, blocks the binding between CD2 on T cells and LFA-3 on antigen-presenting cells thereby inhibiting T-cell activation. Furthermore, this approach selectively targets the disease-causing $CD45RO^+$ memory-effector T cells and produces apoptosis of circulating T cells. Once weekly intravenous or intramuscular administration over a 12-week cycle produces significant clinical improvement in approximately one-third of patients, some of whom achieve prolonged remission [3]. Alefacept appears safe in the short to medium term, although there are significant decreases in circulating peripheral blood T

cells [4]. In 2003, alefacept became the first biological agent to be licensed for the treatment of severe psoriasis. At the time of writing this approval is limited to the USA.

Other agents targeting co-stimulatory molecules and under development for psoriasis include efalizumab, a monoclonal antibody against CD11a (LFA-1), which blocks CD11a–ICAM-1 binding and may inhibit lymphocyte binding to endothelium via the same mechanism. Efalizumab is delivered subcutaneously once weekly and produces significant clinical improvement in approximately one-quarter of patients treated over a 12-week cycle [5]. A primatized antibody to CD80 (IDEC-114) blocks binding of CD80 to CD28; intravenous administration results in modest improvement in psoriasis [6].

Cytotoxic T-lymphocyte-associated antigen 4 (CTLA4) is expressed on T cells and binds CD80 and CD86 on antigen-presenting cells. CTLA4-Ig is a chimeric protein that binds CD80 and CD86 thereby inhibiting co-stimulation. An open study of intravenous administration demonstrated efficacy in psoriasis [7].

CD25 is the high-affinity IL-2 receptor expressed on T cells. Two monoclonal antibodies against CD25—basiliximab and daclizumab—are licensed for treatment of allograft rejection. Both agents are effective in psoriasis—daclizumab as monotherapy [8] and basiliximab in combination with ciclosporin [9,10]. It appears that the anti-CD25 approach is only effective if used in patients with rapidly progressive and/or generalized pustular psoriasis rather than in stable but extensive disease. Basiliximab has also been reported effective, in a case report, in atopic dermatitis [11] but ineffective for graft-versus-host disease [12].

Essential fatty acids

Essential fatty acids are simply defined as those that cannot be synthesized by humans. The major essential fatty acids found in humans are the ω-6 fatty acids linoleic acid and its products, γ-linolenic acid and arachidonic acid, precursors of important mediators of inflammation, the eicosanoids. Arachidonic acid is synthesized from linoleic acid in the liver. Although vertebrates cannot synthesize linoleic acid *de novo*, plants can synthesize both linoleic and γ-linolenic acids, important constituents of evening primrose oil. Skin, unlike liver, is devoid of δ-5 desaturase and cannot convert γ-linolenic acid to arachidonic acid directly. Thus, arachidonic acid found in skin is not directly dietary in origin.

Linoleic acid and γ-linoleic acid in atopic dermatitis

Current interest in essential fatty acids in atopic dermatitis originates in an observation by Hansen [1] that patients with this disorder had elevated serum levels of linoleic acid but reduced levels of its δ-6-desaturase products, γ-linoleic acid and dihomo-γ-linolenic acid. A number of reports suggested that oral replacement therapy using oil from the seed of evening primrose caused clinical improvement in the skin of patients with atopic dermatitis [2]. The evidence base from controlled trials of evening primrose oil indicated that there is no good evidence to support a useful therapeutic effect in atopic dermatitis [3].

Eicosapentaenoic acid and related fatty acids

These polyunsaturated fatty acids possess a longer chain length than linoleic acid and more double bonds, and are found in large quantities in fish oils, in which eicosapentaenoic acid (EPA) and docosahexaenoic acid predominate. Attempts have been made to modify the severity of psoriasis by long-term administration of diet supplemented by fish oil [4]. Subsequent experience [5] suggests that EPA dietary supplementation, which by itself causes only marginal improvement of psoriasis, may enhance the efficacy of co-administered conventional psoriatic therapy such as phototherapy [6]. The most frequently prescribed dietary source of fish oil is Maxepa®, a concentrated fish oil product. The daily intake is 60–75 g flavoured with fruit juice and containing 180 mg EPA and 120 mg docosahexaenoic acid per gram of oil.

Retinoids

This class of compounds covers both the synthetic and the natural forms of vitamin A (the term vitamin A includes the preformed vitamin A alcohol, retinol; its aldehyde, retinal; and its acid, *trans*-retinoic acid, as well as the provitamin, β-carotene). Chemical manipulation of retinol has led to numerous new compounds that are less toxic than the parent molecule.

The mode of action of the retinoids has not been completely elucidated but they have profound effects on differentiation, cell growth and immune response. They are used especially in dermatology but also have a role or a potential role in cancer prevention and perhaps cancer therapy.

Effect on differentiation

It has been known for many years that vitamin A deficiency results in epithelial squamous metaplasia and that vitamin supplements reverse this effect. Retinoids have now been shown to induce differentiation in a number of cell types (e.g. mouse teratocarcinoma and human myeloid leukaemia cells), and to cause regression of bronchial metaplasia in heavy smokers [1]. Epidermis undergoes profound changes and shows hypergranulosis and hyperplasia with decreased numbers of tonofilaments and desmosomes and widening of intercellular spaces [2]. The effect on desmosomes appears to contribute to the keratolytic effect of retinoids in hyperkeratotic disorders.

Effect on carcinogenesis [2,3]

In models of carcinogenesis, induction of the enzyme ornithine decarboxylase occurs during transformation [4]. The enzyme induction is inhibited by retinoids and this inhibition has been used to test the anticarcinogenic effect of new retinoids.

Tumour growth [3]

The growth of a number of human tumour cell lines (e.g. melanoma) seems to be inhibited by retinoids but the response may be variable. Retinoids have not yet established themselves as of major importance in cancer treatment. High concentrations of retinoids cause cytotoxicity through membrane labilization, although at lower doses membrane stabilization may occur.

Receptors

There are specific retinol and retinoic acid receptors. The activity of retinoids is mediated through these in a similar manner to steroid hormones. There are at least six retinoic acid and retinoid X receptors, all of which belong to the family of steroid–thyroid–vitamin D receptors. The receptors have a more significant effect on differentiation [5] than on the inhibition of tumour growth.

Cell surface effects

Retinoids affect transformed cell surfaces and lead to loss of anchorage-independent growth, cell adhesiveness and density-dependent growth [6]. It is not clear whether these effects are exerted directly by the retinoid involvement in glycosyl transfer reactions or through changes in gene expression.

Immunostimulation

In animal models, retinoids may act as an adjuvant and stimulate antibody formation to antigens that were previously not immunogenic [7,8]. In addition, retinoids may stimulate cell-mediated cytotoxicity.

Neutrophil migration

The migration of neutrophils is reduced by retinoids, both in experimental models of inflammation [9] and in patients with acne [10]. The mode of action is unknown.

Skin flora

Retinoids do not seem to have an appreciable direct action on the skin flora.

Ageing

The effects of retinoids on the ageing process, particularly ageing skin, are complex. The emphasis is currently on topical therapy.

Isotretinoin (13-*cis*-retinoic acid)

Oral isotretinoin has been shown to be very effective in the treatment of severe recalcitrant cystic acne unresponsive to antibacterial agents and to be superior to etretinate.

Dose ranges have varied considerably from 0.1 to 2.0 mg/kg/day, but the most widely used regimen at present is 1.0 mg/kg/day as a 16-week course. This produces prolonged remission in the majority of patients (see Chapter 43). Topical isotretinoin also appears to suppress acne [11].

In a long-term study of up to 10 years (mean 9 years), post-isotretinoin, 85% clinical improvement has resulted from a 4-month course and 69% of patients were still free of acne. Twenty-three per cent required a second course, the relapse occurring within 3 years in 96% of patients [12]. The need for a second course of isotretinoin is more likely if low-dose regimens are used (0.1 and 0.5 mg/kg). The most effective dose commensurate with side effects is 1 mg/kg/day for 4 months [13]. In addition to acne, isotretinoin has been used in the treatment of Gram-negative folliculitis, rosacea and, rather less successfully, in hidradenitis suppurativa and steatocystoma multiplex.

In acne, the major therapeutic effect seems to be a profound reduction in sebaceous gland size and activity. There are reductions in bacterial flora, but it is likely that these changes are secondary to the reduction in sebum secretion. The anti-inflammatory and desquamating effects of retinoids may also have a beneficial role.

A wide range of disorders of keratinization have been found to be responsive to isotretinoin. In Europe, this group of disorders is now usually treated with acitretin.

Etretinate

This retinoid has now been superceded by acitretin, which is the hydrolysis product and active metabolite of etretinate [14]. The major disadvantage of etretinate is its binding to body fat for up to 2 years after a course has been completed, during which it is advised that female patients should not become pregnant. Etretinate is 50 times more lipophilic than acitretin [15]. The elimination half-life of etretinate is over 100 days, whereas for acitretin it is 2 days [16,17].

Acitretin

In most respects, this drug resembles the parent compound. It is less bound to fat than etretinate, and it had been hoped that the advisable time interval in which female patients should avoid pregnancy after stopping the drug might be shortened. However, it has been shown in some patients that there is reverse metabolism to etretinate (particularly in the presence of alcohol) and therefore the same restriction of 2 years is advised between the end of a course and pregnancy [18]. The efficacy of acitretin is very similar to etretinate and in general is used in slightly lower doses. Acitretin is effective in various forms of psoriasis, although in plaque psoriasis the results are often disappointing [19,20]. The efficacy can be improved by adding UVA, photochemotherapy (PUVA) or UVB phototherapy (see Chapter 35) [19].

Acitretin is effective in pustular psoriasis, both palmoplantar or generalized (von Zumbusch) [21,22], also in erythrodermic psoriasis.

In many skin conditions, reports have been confined to etretinate prior to the development of acitretin. Most clinicians would agree that the effects are similar with slightly lower doses of acitretin being required. The following disorders of keratinization are often responsive to retinoids: epidermolytic hyperkeratosis, keratoderma, X-linked ichthyosis, ichthyosis vulgaris, erythrokeratoderma variabilis, pityriasis rubra pilaris, discoid lupus erythematosus and lichen planus, Darier's disease, lamellar ichthyosis and non-bullous ichthyosiform erythroderma. Long-term treatment is required as worthwhile remissions following cessation of treatment have not been reported. Toxicity therefore may prove to be a problem in these patients.

A range of skin tumours may sometimes clear with retinoids. These include solar keratoses, keratoacanthoma, epidermodysplasia verruciformis, basal cell epithelioma and leukoplakia. However, these preparations may be of particular value in the prevention of tumours in those patients with high-risk disorders such as xeroderma pigmentosum, porokeratosis of Mibelli, familial self-healing squamous epithelioma of the skin and in those transplantation patients with extensive sunlight-damaged skin.

A number of side effects are common to all the retinoids. These appear to be dose-related and are largely cutaneous. They include cheilitis, conjunctivitis, dryness of mucous membranes and epistaxis, desquamation of hands and feet, pruritus, myalgia, arthralgia, lethargy and alopecia [23–25]. Intracranial hypertension may occur and is a reason not to combine isotretinoin with tetracyclines. Likewise, it is better to avoid supplementary therapy with vitamin A in patients on synthetic retinoids. Retinoids also appear to increase the hepatotoxicity of methotrexate. There are reports [26] of depression and suicidal intention in patients taking isotretinoin, but a causal relationship has not been demonstrated [27,28].

Patients may develop abnormal liver enzyme levels during therapy with retinoids; not all values have returned to normal on cessation of the drug [29].

Increase in very-low-density lipoprotein (VLDL) cholesterol and reduction in high-density lipoprotein (HDL) cholesterol have been reported with retinoid therapy. Many patients receiving isotretinoin have been reported with elevated serum VLDL triglyceride in the absence of a preceding hyperlipoproteinaemia. These levels have returned to normal on cessation of treatment, but all patients should be screened for hyperlipoproteinaemia prior to treatment with any retinoid.

An ossification disorder resembling idiopathic skeletal hyperostosis has been reported in patients receiving long-

term retinoids. These drugs should only be given to younger children when there are good indications [30–32].

Teratogenicity

Retinoids are known to be teratogenic. Maternal ingestion of retinoids early in pregnancy can lead to fetal abnormalities [33] and the infants seem to have a characteristic appearance [34,35].

It is important that women are not pregnant prior to starting treatment. Effective contraception is mandatory during and after a course of treatment. Isotretinoin has a short half-life and therefore contraceptive measures need to be taken for only 1 month after cessation of treatment, but etretinate has a long half-life. The manufacturers recommend that conception should not occur for 2 years after cessation of acitretin therapy. It is preferable to check blood levels at that time to confirm that no drug is detectable, even though it is recognized that only a minority of patients back-metabolize acitretin to etretinate. Males can safely father children even when they are taking the drug.

Bexarotene

Synthetic third-generation oral retinoids are under development. Bexarotene is a retinoid X receptor (RXR)-selective retinoid 'rexinoid' approved for the treatment of cutaneous T-cell lymphoma [36]. A 45% response rate for monotherapy is reported in regimens of 300 mg/m^2/day; the main side effects are hypertriglyceridaemia (79%) and central hypothyroidism. Combination therapy with either PUVA, interferon-α or extracorporeal photopheresis is reported to enhance the response [37].

Immunosuppressive and cytotoxic drugs

These drugs, which have been primarily developed for use in oncology, must be approached with great caution when they become part of a dermatologist's armamentarium; it is essential that the treatment is not more disabling than the disease. An understanding of the clinical

pharmacology of these drugs and their possible side effects is required for the proper management of patients [1]. Brief details are given below of those drugs that may be of value in dermatological practice. A more complete review can be found in Friedmann [2].

Alkylating agents

The effect of these drugs is dependent on proliferation and is expressed only when cells enter the S phase. Alkylation of DNA by these drugs leads to impaired replication.

Cyclophosphamide [3]

Dose: 1–3 mg/kg body weight daily in two or three divided doses. Cyclophosphamide is inactive *in vitro* but is metabolized to an active antimitotic agent that also has profound immunosuppressive activity. It has been successfully used together with corticosteroids in the treatment of pemphigus and pemphigoid, Wegener's granulomatosis, systemic lupus erythematosus, polymyositis, mycosis fungoides and histiocytosis X.

Chlorambucil

Dose: 0.1–0.2 mg/kg/day in one or two doses. Chlorambucil is slow acting and rather less toxic than cyclophosphamide. It has been successfully used in the treatment of mycosis fungoides, Behçet's disease, lupus erythematosus, Wegener's granulomatosis, steroid-resistant sarcoidosis and in combination with prednisone for Sézary syndrome. Benefit has been reported in lichen myxoedematosus [4], granuloma annulare [5] and as a steroid-sparing agent for patients with recalcitrant dermatomyositis [6].

Dacarbazine

Dose: 2–4.5 mg/kg/day intravenously for 10 days. This is an imidazole derivative whose mode of action is unknown. It is used particularly for the treatment of metastatic malignant melanoma (see Chapter 38).

Antimetabolites

Methotrexate

Methotrexate has been used for the treatment of severe psoriasis and psoriatic arthritis since the 1950s [1–6]. It is a structural analogue of folic acid and is a potent competitive inhibitor of dihydrofolate reductase, which converts dietary folic acid via dihydrofolate to tetrahydrofolate. These steps are essential in the generation of 1-carbon fragments needed for the synthesis of nucleic acids. Methotrexate is converted to methotrexate polyglutamates, which have prolonged intracellular storage. They block not only dihydrofolate reductase but also other essential enzymes involved in nucleotide synthesis including thymidylate synthase and AICAR (5-aminoimidazole-4-carboxamide ribonucleotide) transformylase [7,8]. The latter is involved in purine biosynthesis and indirectly inhibits the metabolism of intracellular adenosine, which is known to be toxic to T lymphocytes and is potently anti-inflammatory. Indirect evidence of adenosine accumulation has been shown in psoriasis patients, whose adenosine excretion was found to be double that of controls following each methotrexate dose; greater increases were seen in those showing clinical improvement than in those without [9]. Although originally hypothesized that the effects of methotrexate in psoriasis were brought about by a direct interference in epidermal cell division [10,11], it is now recognized that it significantly inhibits proliferating lymphoid cells but has little effect on epidermal cells at therapeutic doses [12]. Inhibition of epidermal proliferation, on the other hand, is probably relevant in the context of acute methotrexate toxicity.

Therapeutic indications and efficacy

Psoriasis and psoriatic arthritis. Methotrexate is of particular value in the management of acute generalized pustular psoriasis and psoriatic erythroderma [1–3], but has been most widely employed for inducing and then maintaining control of psoriasis in patients with extensive chronic plaque disease, especially in those who also have psoriatic arthritis [4]. Published studies suggest that methotrexate can produce a reduction in disease severity of at least 50% in more than three-quarters of patients treated [5–10]. Its efficacy in a controlled trial was slightly less than that of ciclosporin [11].

Cutaneous sarcoidosis. Small open studies have demonstrated improvement in skin lesions of various morphologies [12,13]. However, methotrexate was less effective in pulmonary sarcoidosis where improvement in lung function was seen in only one-third of patients [13], and it is important to be aware that improvement in skin lesions is often slow. The side effect profile appears to be similar to that seen in psoriasis patients, although the significance of liver biopsy abnormalities may be more difficult to assess because many patients with sarcoidosis will show granulomatous infiltration in the liver [13].

Dermatomyositis. Methotrexate is increasingly advocated for cutaneous lesions. Eight of 13 patients given weekly low-dose oral methotrexate (2.5–30 mg) for skin disease inadequately controlled either by topical and systemic corticosteroids or by antimalarials, were considered to have had a good or excellent response and in all 13 it was possible to reduce or discontinue corticosteroid therapy [14]. Early introduction of methotrexate in children with juvenile dermatomyositis has been claimed to hasten recovery and allow a more rapid reduction in corticosteroid dosage [15,16].

Cutaneous lupus erythematosus (LE). Small studies suggest benefit from methotrexate for cutaneous lesions of LE [17–20]. In a larger prospective randomized controlled trial of patients with mild systemic LE only three of 18 patients receiving low-dose methotrexate (15–20 mg/week) had residual cutaneous disease after 6 months of therapy compared to 16 of 19 patients given placebo [21]. Although there is less evidence in chronic discoid LE [22], there is thus reasonable evidence to suggest that methotrexate may enable corticosteroid dosage to be reduced in patients with systemic lupus and that it is worth considering for patients with cutaneous LE unresponsive to more standard therapies.

Systemic sclerosis and morphoea. In one randomized double-blind study of 29 patients with active systemic sclerosis allocated to weekly injections of either methotrexate 15 mg or placebo for 24 weeks, a predefined favourable response was seen in a significantly greater proportion of patients in the methotrexate group (8 of 17; 47%) than in the placebo group (1 of 12; 8%) [23]. However, a larger double-blind controlled trial of 71 patients with early diffuse systemic sclerosis randomized to the same interventions failed to demonstrate significant benefit after 12 months' treatment [24], although even this study was insufficiently powered. However, both studies showed improvement in skin scores. In a small open study, nine of 10 children with active localized morphoea responded to a combination of pulsed intravenous methylprednisolone and weekly low-dose methotrexate within a median of 3 months [25]. Methotrexate has been advocated for arresting progression of linear morphoea en coup de sabre and facial hemiatrophy in children [26]. A small uncontrolled study of methotrexate 15 mg/week for 24 weeks claimed some benefit in nine patients with widespread morphoea but these claims must be treated with caution in a disease where spontaneous improvement is not uncommon [27].

Atopic dermatitis. There are no good case series let alone randomized controlled trials of the use of methotrexate for atopic dermatitis. Recently, however, it has been claimed that, whereas the weekly regimen used in psoriasis appears not be effective, methotrexate taken as 2.5 mg on four consecutive days each week can help to control selected patients with widespread moderately severe atopic dermatitis [28]. However, there must be concerns that long-term use of such a regimen may increase the risks of liver toxicity and further data are required before this approach can be generally recommended.

Other dermatoses. Benefit from weekly low-dose methotrexate has been claimed in individual case reports or small series for polyarteritis nodosa [29], Behçet's disease [30], cutaneous small vessel vasculitis [31], antiphospholipid syndrome [32], pyoderma gangrenosum [33], pityriasis lichenoides [34–36], bullous pemphigoid [37], pemphigus [38], multicentric reticulohistiocytosis [39], scleromyxoedema [40] and Langerhans' cell histiocytosis [41].

Safety precautions and side effects

Haematological or renal abnormality. Myelosuppression is the most important cause of methotrexate-associated death. Methotrexate should be avoided in patients with significant haematological abnormalities or renal impairment. Because methotrexate is eliminated largely via the kidneys, toxic levels may build up rapidly in patients with renal impairment, and even low doses of the drug may then produce acute myelosuppression [1]. This is particularly liable to occur in the elderly when concomitant drug administration or illness such as fever or diarrhoea may result in sudden deterioration of renal function; elderly patients especially should be warned to omit methotrexate doses whenever they are at risk of acute dehydration.

Drug interactions. Certain drugs may increase toxicity of methotrexate by increased antifolate effect (e.g. sulphonamides, trimethoprim, phenytoin) or by decreasing renal elimination (e.g. aspirin and NSAIDs, probenecid, ciclosporin) [2]. As life-threatening myelosuppression may result from interactions between methotrexate and such drugs, patients and all their medical attendants should be made aware of these risks.

Liver disease, alcohol and diabetes. Methotrexate should not be administered to patients with significant current or previous liver disease, especially if caused by viral hepatitis or to alcohol. Any patient suspected of alcohol abuse is unsuitable for methotrexate, although many dermatologists allow patients receiving methotrexate to continue taking small amounts of alcohol (e.g. 4–6 units of alcohol weekly). Obese diabetic patients are also at increased risk of liver damage from methotrexate [3].

Fertility. Because methotrexate is both arbortifacient and teratogenic [4–7], it is strictly contraindicated in pregnancy. Adequate contraceptive measures must be taken by women of child-bearing potential during methotrexate therapy and for at least one menstrual cycle after stopping the drug [8]. It should also be avoided during lactation. Although low-dose methotrexate has not been found to be mutagenic in sperm [9] and normal children have been born where the father was taking methotrexate at the time of conception [10], the drug may depress spermatogenesis [11]. It is customary to advise men to avoid fathering children during therapy and for at least 3 months thereafter [8].

Miscellaneous precautions. Other important contraindications to the use of low-dose methotrexate include active peptic ulceration, hepatitis virus infection, active infectious disease such as tuberculosis, immunodeficiency states and unreliability of the patient.

Management of the patient

The risks and benefits of therapy should be clearly explained to the patient both verbally and in writing. Adequate contraceptive measures must be commenced where appropriate and baseline blood tests obtained.

Methotrexate is usually given orally and is given as a single weekly dose as it is well-established that the toxicity for a given total dose is considerably increased when it is administered daily [12]. Unambiguous instructions including which day of the week the tablets are to be taken should be given to the patient and specified on the prescription. Deaths have occurred where prescribers, dispensers or patients have confused 10 mg for 2.5-mg tablets. It is thus good practice always to specify 2.5-mg tablets for inflammatory diseases. The rationale proposed for giving methotrexate in three divided doses once weekly [13] is now thought unlikely to be valid [14] and may have higher risk of hepatic fibrosis [15].

Most serious problems and the rare deaths associated with low-dose methotrexate arise because of an absolute or relative overdosage. A small test dose, usually 5 mg, should be given in order to detect those patients who may be unduly sensitive to the drug [16]. If the full blood count is stable at 7 days then subsequent doses may be gradually increased (usually in 2.5–5 mg steps) according to clinical response and any accompanying toxicity. The aim of therapy should not be to induce complete clearance of psoriasis but to achieve sufficient control that it may readily be managed with topical therapy. Most patients are adequately controlled on doses of 7.5–15 mg weekly and few patients require more than 20 mg. Even lower doses may suffice, particularly in the elderly.

Folic acid supplementation. There is little evidence that folate supplementation diminishes methotrexate efficacy [17,18], although methotrexate toxicity is enhanced by folate depletion. Recent studies in both rheumatoid arthritis and psoriasis patients have shown that low-dose methotrexate increases circulating concentrations of homocysteine and that this rise can be reversed by folic acid administration [19,20]; elevated homocysteine levels are associated with increased risk of cardiovascular disease. Given the fact that folic acid also has protective effects on the bone marrow, it seems appropriate to recommend that all patients treated with methotrexate should receive supplemental folic acid. There is as yet insufficient information to determine the most appropriate dosage but 1–5 mg/day appears to be adequate to correct these problems without affecting clinical response to therapy [17,18].

Monitoring schedule. Initially, patients should be assessed weekly by clinical examination and laboratory measurement of full blood count, plasma urea, electrolytes and creatinine, and liver enzyme tests. Once therapy has been stabilized, assessments should be performed every 2–3 months. Results should be carefully monitored; recording of results such as haemoglobin or platelets in a table or graph makes it easier to detect abnormal trends. In any individual, the dosage of methotrexate required to maintain adequate control of psoriasis will vary from time to time and should be adjusted accordingly.

As alcohol abuse greatly increases the risks of liver damage in patients receiving methotrexate, they should be reminded regularly of the need to restrict alcohol intake. Liver damage cannot be reliably detected by standard liver enzyme tests or imaging techniques and regular liver biopsy for all patients receiving low-dose methotrexate for psoriasis is still advocated by several authorities [8,21]. However, several studies suggest that the risk of serious liver damage in carefully monitored patients receiving once weekly low-dose methotrexate is small [22–24] and that the cost and morbidity of repeated biopsy may be difficult to justify when compared with the low yield of significant liver pathology. If there are concerns about pre-existing liver damage then it may be appropriate to obtain a liver biopsy as a baseline soon after successful methotrexate therapy has been established.

It can reasonably be argued that liver biopsy need no longer be performed routinely in all patients receiving long-term methotrexate but, to provide greater reassurance that significant damage is not overlooked, several investigators have recommended the use of a serological marker of fibrosis, the aminoterminal peptide of type III procollagen (PIIINP). They have concluded that patients whose PIIINP levels are consistently normal are very unlikely to have significant liver damage [25–27]. If PIIINP assay is available it should be performed 3 monthly and liver biopsy may be restricted to the small minority in whom PIIINP levels are repeatedly elevated.

Management of problems

Inadequate response. A small minority of patients are unable to absorb methotrexate adequately but may respond satisfactorily if it is given intramuscularly or intravenously. Patients with psoriasis who relapse while receiving methotrexate may frequently be brought satisfactorily under control by a course of intensive topical therapy and/or UVB phototherapy [28]; in contrast to the combination of methotrexate and PUVA, which should be avoided, a major increased risk of skin cancer from combining UVB with methotrexate has not been demonstrated [29]. Combination of methotrexate with other systemic agents is discussed further in Chapter 35.

Nausea. This occurs in 25%, usually appears within 12 h of methotrexate ingestion, and may last up to 3 days. It is usually mild but may limit therapy [30]. Folic acid 5 mg/day has been found to be more helpful than antiemetics, taking methotrexate with the evening meal or dividing the dose, although any of these manoeuvres may help some patients. Ondansetron 8 mg orally 2 h before and, if necessary, 12 and 24 h after the weekly methotrexate dose, can be dramatically effective [31].

Liver inflammation and fibrosis. An acute rise in liver enzymes to greater than three times the upper limit of normal is usually an indication to discontinue methotrexate. If PIIINP levels are repeatedly abnormal over a 12-month period then liver biopsy should be considered. The decision to discontinue methotrexate depends not only on the results of liver biopsy but also on the ease with which an individual patient's psoriasis may be managed by other means. In general, severe fibrosis and cirrhosis are considered contraindications to further methotrexate therapy. Nevertheless, some dermatologists have continued treatment in patients with documented cirrhosis without encountering significant deterioration of liver disease [32]. In patients with hepatic inflammation or mild to moderate fibrosis without cirrhosis, continuation of methotrexate therapy is probably still safe so long as alcohol is strictly avoided and patients are closely monitored. If PIIINP remains elevated then a further liver biopsy should be considered after 12 months to 2 years of continued therapy.

Respiratory disease. Methotrexate-induced pneumonitis is rare in psoriasis. It is characterized by acute onset with fever, cough and dyspnoea. Chest X-ray shows pulmonary infiltration. It resolves rapidly with withdrawal of methotrexate and systemic corticosteroids [29]. Pulmonary fibrosis is a rare complication.

Haematological abnormalities. A rise in mean corpuscular volume (MCV) is common in patients receiving long-term methotrexate and usually indicates relative folate deficiency although it is important to exclude other causes of macrocytosis. If MCV rises above 106 fl despite folate replacement then further methotrexate therapy is probably contraindicated [33]. Falls in haemoglobin, white cell or platelet counts should prompt a reduction in dose or, if severe, withdrawal of methotrexate.

Acute toxicity and overdosage. Absolute or relative overdosage of methotrexate can result in acute toxicity, manifested clinically by myelosuppression, mucosal ulceration and, rarely, cutaneous necrolysis. Early treatment may be life-saving. The metabolic effects of methotrexate can be bypassed by administration of folinic acid. As soon as overdose is suspected, serum should be collected for measurement of methotrexate levels and folinic acid should be administered intravenously. The dose of folinic acid should be at least as high as the total dose of methotrexate thought to be responsible for the overdose and should in any event not be less than 20 mg. Subsequent doses (which may be taken orally if no more than 20 mg) should be given at 6-hourly intervals until the serum methotrexate is less than 0.01 μmol/L. The dose of folinic acid required will vary according to the serum methotrexate concentration. A dose of 20 mg suffices where the methotrexate concentration is 0.5 μmol/L or less, but at higher concentrations the dose can be calculated at 100 mg for every 1 μmol/L of measured serum methotrexate concentration [34].

Azathioprine

Azathioprine is one of many immunosuppressive drugs used in dermatology following original use in transplant surgery. It is converted in the body to 6-mercaptopurine (6-MP), an inhibitor of purine synthesis and an immunosuppressive agent; this in turn is metabolized to purine thioanalogues by hypoxanthine guanine phosphoribosyl transferase (HGPRT). Additionally, an imidazole metabolite appears to have powerful anti-inflammatory properties. It is now known that thiopurine methyltransferase (TPMT) is a major enzyme involved in the metabolism of azathioprine. TPMT activity is determined by an allelic polymorphism for either high or low enzymic activity. Homozygotes for the low activity allele (0.5% of the population) are known to be at high risk for myelosuppression [1,2]. It is recommended that patients starting azathioprine should have blood TPMT levels measured beforehand and the dose titrated accordingly [3].

Indications

The licensed indications for azathioprine are dermatomyositis [4], systemic lupus erythematosus (also useful in severe cutaneous disease [5]) and pemphigus vulgaris [6,7]. Other dermatological conditions in which it may be useful include bullous pemphigoid [8,9], intractable atopic dermatitis [3,10], chronic actinic dermatitis [11], Behçet's disease [12], Wegener's granulomatosis [13] and other vasculitides [5], pyoderma gangrenosum [14], psoriasis [15] and perhaps pityriasis rubra pilaris in adults [16]. It appears to be inferior to methotrexate in the treatment of psoriasis but may be useful for psoriatic arthritis.

Management of the patient

The usual azathioprine regimen is 1–3 mg/kg/day. Baseline TMPT assay is recommended, with dose adjustment if necessary. Doses at the lower end of this range are generally recommended in the elderly. Azathioprine is usually used as a steroid-sparing agent, but has been used as monotherapy (e.g. in atopic dermatitis or psoriasis). It takes a few weeks to reach a steady state; dose titration may be required. Weekly blood monitoring is required initially (probably for 4 weeks), gradually extending to every 3 months.

Contraindications include low TPMT activity, pregnancy, hypersensitivity, concurrent malignancy and concurrent allopurinol therapy (because of risk of marrow toxicity). Other drugs that may interact with azathioprine include sulfsalazine, warfarin, angiotensin-converting enzyme inhibitors and any drug that suppresses bone marrow function.

Complications of treatment

Myelosuppression is a relatively common side effect of azathioprine and can develop very quickly, certainly between regular blood monitoring, and can be severe. It is more common at the start of treatment, especially in those with TPMT deficiency, but may also occur in those with normal TPMT activity.

Hypersensitivity may be manifest by rash or hepatitis, often with eosinophilia. Pancreatitis may occur [17]. Azathioprine-induced shock in dermatology patients has only been reported rarely but can be life-threatening [18].

Bleomycin

This is a polypeptide antibiotic given parenterally. It has no immunosuppressive action and its toxicity is confined to the skin (pigmentation, inflammatory lesions especially on the palms and fingers) and the lungs. It is effective against squamous cell carcinoma of the skin and elsewhere, and in inducing remission in mycosis fungoides and other lymphomas. It has been used intralesionally for the treatment of intractable virus warts [1,2] but vasospasm, sometimes severe, is a potential side effect.

Hydroxyurea

Dose: 500 mg two or three times daily. Hydroxyurea blocks pyrimidine synthesis. It causes much more short-term marrow suppression than methotrexate, necessitating frequent blood counts. However, it is less effective than methotrexate and has little effect on psoriatic arthropathy. A combination of hydroxyurea with retinoids has been reported to be particularly effective [3]. Hydroxyurea is easy to administer, relatively inexpensive and has few contraindications or side effects. Leukopenia can develop and regular blood monitoring is needed. Hydroxyurea does have a place for those patients who cannot take other drugs because of systemic disorders such as hyperlipidaemia, mild renal impairment, cardiopulmonary disease and mild liver disease [4]. It may occasionally cause a dermatomyositis-like rash or leg ulceration.

Mycophenolate mofetil

Dose: 0.5–1 g twice daily. Mycophenolate mofetil (MMF) is the ester of mycophenolic acid (MPA), but provides advantages over MPA in that it has increased bioavailability. After ingestion, MMF is hydrolysed to MPA—the active acid form. MPA inhibits the enzyme inosine monophosphate dehydrogenase (IMPDH), a key enzyme in *de novo* purine synthesis. Thus, MPA blocks the production of guanosine nucleotides needed for RNA and DNA synthesis. MPA is particularly effective in blocking the type II isoform of IMPDH expressed mainly in T and B cells, thereby inhibiting T- and B-cell activation and proliferation. Monotherapy with MMF for psoriasis is not as effective as ciclosporin [5]; indeed MMF is probably best used in psoriasis as combination therapy as a ciclosporin-sparing agent [6]. Efficacy in atopic dermatitis is uncertain, with efficacy at 1 g twice daily reported with long-term remission for up to 20 weeks [7] but other studies not being able to discern benefit [8]. MMF is understandably beneficial for therapy of autoimmune bullous diseases, particularly bullous pemphigoid and pemphigus, and may be used as a steroid-sparing agent [9,10]. Beneficial use of MMF has been reported in a variety of skin diseases including pyoderma gangrenosum [11], bowel-associated dermatitis–arthritis syndrome [12], systemic lupus erythematosus [13], chronic actinic dermatitis [14] and extensive lichen planus [15].

Adverse effects include mild to moderate leukopenia and anaemia [16], immunosuppression and gastrointestinal symptoms. There is no significant toxic effect on renal or hepatic function.

Melphalan

This is used mainly in the treatment of myelomatosis and polycythaemia. Other indications include scleromyxoedema (see Chapter 57) [17].

Ciclosporin [1]

This drug was isolated and purified in 1972 from a soil fungus found in Norway. Its main use until recently has been as an immunosuppressant in patients following kidney, liver, heart, bone marrow or other transplants. It has increasing uses in dermatology, but its use demands careful monitoring. Ciclosporin is a cyclic polypeptide made up of 11 amino acids. The main mode of action is on helper T cells whose cell cycle is blocked in G0 or early G1 and whose production of various lymphokines, notably IL-2, is inhibited. It may also have some direct effect on DNA synthesis and on proliferation of keratinocytes [2]. Apart from its use in transplant patients, ciclosporin has been used to treat a wide range of general medical diseases in which T cells contribute—rheumatoid arthritis, systemic lupus erythematosus, polymyositis and dermatomyositis, uveitis, thyrotoxicosis, diabetes, biliary cirrhosis, various nephropathies, colitis, Crohn's disease and others. Dermatological uses [3–5] include notably psoriasis [6], pustular psoriasis [7] and psoriatic arthritis. Ciclosporin is particularly effective in widespread plaque psoriasis. Treatment at low dosage (3–5 mg/kg/day) for 1–3 months will produce substantial improvement in over 60% of patients [8]. The preferred treatment regimen for psoriasis is short-course intermittent therapy—using ciclosporin for no more than 3 months at a time but reinstituting therapy on relapse [9]. Using this regimen, most patients require four or fewer courses of ciclosporin (average dosage 3.4 mg/kg/day) over 2 years [10]. Most patients relapse once ciclosporin is discontinued.

The other main use of ciclosporin in skin diseases is atopic dermatitis. It is a very effective treatment [11], but relapse occurs within a few weeks of discontinuing the drug, although at 1 year later and still off the drug, the disease was only approximately 50% of the severity before ciclosporin treatment was started [12]. Ciclosporin has also been reported to benefit patients with chronic hand dermatitis [13].

Ciclosporin is also used for pemphigus and pemphigoid. There are reports of benefit of ciclosporin in dermatomyositis [14], pyoderma gangrenosum [15] and chronic idiopathic urticaria [16].

Absorption of the drug from the gut is variable, often approximately 30%, although a microemulsion formulation of ciclosporin that has better absorption has replaced the original product. Excretion is mainly via the liver but again the rate is variable. For practical purposes, assessment of blood levels of ciclosporin is unnecessary when using 'dermatological doses' in otherwise well patients, and monitoring renal function (by serum creatinine estimations) and blood pressure suffice.

Ciclosporin has little toxicity on the bone marrow or liver but does have a considerable and largely reversible toxicity on the kidney [17]. Short-term (mean 2.4 months) ciclosporin at a dosage of 5 mg/kg/day was associated with a significant but small and reversible increase in blood pressure, but only a transient mild reduction in glomerular filtration rate (GFR), which did not reach significance [18]. Renal function and biopsy findings have been studied in patients who have taken ciclosporin continuously for 5 years (average 3.3 mg/kg/day). Six of eight patients who had renal biopsies showed tubular atrophy and arteriolar hyalinosis, four had increase in interstitium and two showed increased instance of glomerular obsolescence. Renal function was assessed by GFR and serum creatinine. Both a fall in the GFR and a rise in serum creatinine correlated with the severity of the ciclosporin nephrotoxicity seen on biopsy [19]. Other side effects include nausea and vomiting, hypertension, hypertrichosis, tremor and hyperkalaemia.

Long-term toxicity may include an increased tendency for lymphomas. Although a recent epidemiological study of 1252 patients over 5 years did not demonstrate an increased incidence of lymphoma, it did reveal a sixfold increase in skin cancer, particularly in those patients who had received prior PUVA [20]. There are notable interactions with ketoconazole, erythromycin and other drugs that increase blood levels; with rifampicin and hydantoinates, which decrease blood levels; and with

NSAIDs, which seem to increase the nephrotoxicity without changing the blood levels.

New oral calcineurin inhibitors, structurally dissimilar to ciclosporin but with similar mechanisms of action, have been developed, such as pimecrolimus (a derivative of ascomycin). Oral pimecrolimus appears effective in the treatment of moderate to severe psoriasis but apparently without risk of nephrotoxicity or hypertension [21].

Fumaric acid esters (fumarates)

For more than 20 years fumarates have been used extensively in northern Europe, particularly German-speaking countries, for the treatment of moderate to severe psoriasis [1,2]. The commercially available preparation of fumarates, Fumaderm®, comprises a mixture of dimethylfumarate and the calcium, magnesium and zinc salts of monoethylfumaric acid. After ingestion, dimethylfumarate is hydrolysed to momomethylfumarate—the main active metabolite. Clinical trials [3–5] attest to the efficacy of fumarates. The drug is introduced gradually, starting at 30 mg/day, building up over several weeks to a maximum dose of 240 mg three times daily. It is estimated that, if they tolerate the drug, approximately 57% of patients will achieve a 70% reduction in severity of psoriasis. Two-thirds of treated patients develop gastrointestinal symptoms such as dyspepsia and diarrhoea; one-third of patients develop flushing. In most patients these side effects settle down over time. Lymphocyte counts fall in nearly all treated patients, sometimes by 50% [3–5]. Renal function and liver function should be monitored but impairment is unusual. The mechanism of action of fumarates appears to be an ability to promote the secretion of Th2 cytokines [6], such as IL-10, which are beneficial in psoriasis.

PUVA [1]

Photochemotherapy with 8-methoxypsoralen followed by UVA radiation for psoriasis is considered in detail in Chapter 35. If necessary, 5-methoxypsoralen can be substituted, or 8-methoxypsoralen bath PUVA used, especially if a patient is nauseated by 8-methoxypsoralen.

PUVA is also of value in mycosis fungoides (MF) (see Chapter 54) [2]. Seventy-three patients with MF were treated with PUVA, which produced clinical and histological clearance in a very high proportion of patients with pretumour-stage MF. The response of patients with tumours was less satisfactory, such patients requiring, in addition, radiotherapy.

PUVA may be used in selected children with severe atopic dermatitis [3]. Fifty-three children (mean age 11.2 years) had twice-weekly PUVA; 39 (74%) of them achieved

a clear or nearly clear skin. The mean duration of treatment to remission was 37 weeks, with mean cumulative UVA dose of 1118 J/cm. This relatively high UVA exposure is of concern. However, 22 children remained in remission 1 year after discontinuing PUVA.

PUVA has been described to be of benefit in a whole range of dermatological conditions. Some of the reports involve large numbers of patients and others only single-case reports. For an excellent review of the uses of PUVA in conditions other than psoriasis, including hand eczema, nodular prurigo, vitiligo, the various photodermatoses, granuloma annulare, lichen planus, lyphomatoid papulosis, urticaria, aquagenic pruritus, urticaria pigmentosa, idiopathic pruritus and many other conditions, refer to [4].

It is undisputed that solar UV radiation is a major aetiological factor in squamous and basal cell carcinoma and malignant melanoma in humans. Tumours have been induced in the skin of hairless albino mice by PUVA exposure using both 8-MOP and 5-MOP [5]. An early report suggested that PUVA therapy accelerated the development of skin tumours in patients with xeroderma pigmentosum [6], and it appeared to have an obvious promoter effect in a patient previously exposed to X-irradiation, arsenic and several cytotoxic drugs, who developed 25 basal or squamous cell carcinomas, the first within 21 months of onset of PUVA therapy [7].

There is now substantial literature dealing with the incidence of skin tumours in groups of PUVA-treated patients. Although certain studies have failed to show a clear relationship between PUVA and tumour development [8–10], long-term follow-up of a large US cohort has provided conclusive evidence for the carcinogenicity of PUVA [11]. In this study, an initial cohort of 1380 PUVA patients was followed up for a mean of 13.2 years. Squamous cell carcinoma (SCC) developed in one-quarter of patients exposed to high doses of PUVA, giving a relative risk of SCC of 5.9-fold by comparison with patients receiving low-dose PUVA. High-dose PUVA was regarded as a total of over 299 treatments; low-dose less than 160 [11]. Precise UVA doses were not given, but taking an average dose of 11 J/cm^2 after clearing, the high-dose group can be estimated to have had more than approximately 3200 J and the low-dose group less than 1760 J. The latter figure may therefore be taken as a cumulative dose, which should ideally not be exceeded. However, a study in Northern Ireland, where there is a high population of sun-sensitive Celtic subjects, indicated increased risk for non-melanoma skin cancer (including particularly basal cell carcinoma) with cumulative UVA doses above only 250 J/cm^2 [12]. Therefore, far more conservative UVA limits may be needed with certain populations, and safety limits may be better expressed as numbers of treatments rather than cumulative UVA doses. In the Northern Ireland study, a cumulative UVA dosage of 250 J/cm^2 equated with approximately 100 treatments. The US study showed that fair-skinned persons had an approximately twofold higher risk of SCC than those with skin types III or IV. Overall, there was no substantial increase in the risk of basal cell carcinoma with high-dose PUVA in the US study [11]. Metastatic SCC was seen in seven patients, but two of these were elderly and had had little PUVA. Four were younger (41–57 years) and had had moderate- to high-dose PUVA, although methotrexate or ionizing radiation may have played an additional part [11].

The substantially increased risk of SCC with high-dose PUVA therapy has been supported by a large Swedish study [13]. The male genitalia appear to be particularly at risk [14–16]. In a prospective cohort study [11,16] of 892 men first exposed to PUVA in 1975–76, 24 (2.7%) had developed a total of 51 genital neoplasms. It appears that increased risk is associated with high-dose PUVA in association with UVB and coal tar. Shielding of the genitalia during PUVA therapy reduces the risk.

PUVA lentigines may exhibit cytologically atypical melanocytes [17]. There is an increased risk (incidence rate ratio 8.4) in patients who have received PUVA—the 1380 patient cohort study of patients who first received PUVA in 1975–76 calculated that high-dose PUVA (more than 250 treatments) and passage of time were contributing factors. PUVA is best avoided in those predisposed to malignant melanoma (e.g. those with numerous melanocytic naevi or atypical moles, and a family history of melanoma) [18,19].

There is no evidence of any internal carcinoma hazard, but acute leukaemia [20,21] and a preleukaemic state [22] have been reported. In addition, a patient transformed from myelodysplasia to acute fatal myeloid leukaemia after 4 months of PUVA [23].

These findings have led to a recommendation that PUVA patients should not receive more than 1000 J/cm or more than 150 treatments in a lifetime unless there are strong indications otherwise [24]. The male genitalia should be protected while receiving PUVA treatment.

Photopheresis

The use of extracorporeal photoimmunochemotherapy (ECP; photopheresis) was pioneered in the early 1980s. Primarily developed for the treatment of cutaneous T-cell lymphoma (CTCL), ECP has been used to treat a variety of dermatological diseases. Derived from PUVA treatment, ECP involves the extracorporeal exposure of peripheral blood mononuclear cells (PBMC) to 8-methoxypsoralen and UVA irradiation before being returned to the patient. The machine used for this process provides the leukopheresis step prior to UVA exposure. 8-Methoxypsoralen is delivered directly to the collected buffy coat containing the PBMCs (for a detailed review of the procedure refer to Knobler and Jantschitsch [1]). Various protocols are under development for ECP but the one used most widely is photopheresis on two successive days, repeated at 2–4-week intervals. It is estimated that during one treatment session 5–10% of the circulating T-cell pool is treated. The exact mechanism of action is not fully understood but it is believed that the patient's immune system is stimulated to destroy the altered and/or damaged malignant T cells.

CTCL was the first disease for which ECP was evaluated and as a consequence most evidence of efficacy comes from treatment of this disease. Indeed, ECP is approved in the USA for palliative treatment of Sézary syndrome. The original study by Edelson *et al*. [2] demonstrated partial or complete remission in 27 out of 37 CTCL patients. Subsequent studies [3,4] confirmed this observation and it is accepted that complete remission may occur in 25% of patients with no response in a further 25%. A good therapeutic response is dictated by short disease duration, normal numbers of CD8 cells and a normal CD4 : CD8 ratio [5]. An advantage of ECP is the low side effect profile [3]. Some patients with Sézary syndrome are less responsive to ECP, and combination therapy with IFN-α, methotrexate, PUVA, bexarotene or superficial electron beam therapy may be required [6–8]. It should be noted that although the Sézary syndrome form of CTCL is responsive to ECP, some workers have questioned this high rate of response, mainly disputing the definition of Sézary syndrome—if a strict definition of clonal disease is instituted, only 16% of patients have a complete response [9]. Long-term survival is good with survival rates of 100 months from time of diagnosis [7]. Unsurprisingly, ECP has been used to treat a variety of inflammatory disease where autoreactive T cells are believed to be an important contributor to the disease process. ECP may be an important therapy for graft-versus-host disease after allogeneic bone marrow transplantation [10], and perhaps in the treatment of acute or chronic rejection of organ transplants [11]. Systemic sclerosis [12], systemic lupus erythematosus [13], atopic dermatitis [14], pemphigus vulgaris [15] and psoriatic arthritis [16] have all been reported to respond to ECP.

Plasmapheresis

Plasmapheresis (plasma exchange) has been used for many years in patients with severe systemic lupus erythematosus in whom high-dose corticosteroids and immunosuppressants were not controlling their disease [1,2]. However, the evidence that it is effective when added to immunosuppressive treatment with prednisolone and ciclosporin in severe lupus nephritis is lacking [3]. It can also be life-saving in Goodpasture's syndrome [4]. It is used in myaesthenia gravis, Waldenström's macroglobulinaemia, cryoglobulinaemia, thrombotic thrombocytopenic purpura and Guillain–Barré syndrome. Plasmapheresis is occasionally used in acute polymyositis or dermatomyositis, but in a controlled trial involving 39 patients, it was shown to be no more effective than sham apheresis [5].

Plasmapheresis is an effective treatment for pemphigus vulgaris and bullous pemphigoid unresponsive to conventional therapy—it is particularly useful for rapid control of severe active disease and as a means of reducing the dosage of corticosteroid and other immunosuppressive therapy. Between seven and 14 therapeutic plasma exchanges are required [6]. Side effects of plasmapheresis may include hypertension.

Plasmapheresis was effective in a series of eight patients with pemphigus vulgaris, in whom the treatment was added to their glucocorticoid and immunosuppressive therapy, which had not been controlling their disease [7]. Bullous pemphigoid seems to be less successfully treated by plasmapheresis. In a study involving 100 patients, it was found that neither azathioprine nor plasmapheresis was effective as an adjuvant to corticosteroid [8]. Solar urticaria has been reported to respond to plasmapheresis when added to photochemotherapy (PUVA) that had not been effective on its own [9].

Intravenous immunoglobulin [1]

High-dose intravenous immunoglobulin (IVIg) is produced from pooled human plasma. There are at least seven licensed IVIg preparations available, but differences between these preparations may affect outcome. IVIg has been used to treat a variety of autoimmune bullous and inflammatory dermatoses. Most reports are anecdotal with few randomized controlled trials. Treatment with IVIg is best performed in an inpatient setting but if patients are low risk, then infusions can be performed in an ambulatory setting. High doses (1–2 g/kg) are recommended, usually delivered as a 5 consecutive day cycle of 0.4 mg/kg/day, although a 3-day cycle may be used. Each infusion is given over 4–4$^1/_2$ h. Initially, cycles are repeated every 3–4 weeks until there is effective control of disease—once this has been achieved the time intervals between cycles can be gradually increased. A proposed end point is two infusions 16 weeks apart. Adverse effects are usually mild and self-limiting—common side effects include headache, chills, flushing and vomiting. More serious adverse events have included aseptic meningitis, thrombosis and anaphylaxis, particularly in IgA-deficient patients who have anti-IgA antibodies. There is a potential risk of transference of infectious agents but batches are screened for human immunodeficiency virus (HIV), syphilis and hepatitis [1].

IVIg is believed to work as an immunomodulatory agent—reducing levels of IL-1 in serum [2], it may also down-regulate expression of Fas and Fas ligand on keratinocytes, thereby preventing apoptosis [3].

Most use of IVIg in dermatology is for therapy of autoimmune mucocutaneous blistering diseases [1]. Small case series of pemphigus vulgaris [4–6] indicate that 2 g/kg IVIg produces prolonged clinical remission sustained after cessation of therapy. IVIg also has a corticosteroid-sparing

effect in pemphigus vulgaris [5]. Pemphigus foliaceus is responsive to IVIg and prolonged remission has been achieved [7]. In 27 of 32 cases of bullous pemphigoid non-responsive to conventional therapy reported in the literature as having received IVIg therapy, there was significant and long-lasting clinical improvement [1]. Mucous membrane pemphigoid appears, on the basis of case reports and small uncontrolled series, to respond to IVIg to the extent that disease progression (particularly eye disease) is halted [8]. Cases of epidermolysis bullosa acquisita [9], pyoderma gangrenosum [10], dermatomyositis [11], atopic dermatitis [12] and psoriasis [13], amongst a large list of dermatoses [14], have all been treated successfully with IVIg. The use of IVIg for the treatment of toxic epidermal necrolysis is perhaps the most contentious—a rationale for its use is the ability to prevent keratinocyte apoptosis. No randomized controlled trial has been performed, but some groups [3,15] advocate it as the treatment of choice while others believe it has no benefit [16].

Gold (sodium aurothiomalate)

Dose: 10 mg intramuscularly as a test dose, followed by 50 mg at weekly intervals. Although this regimen was devised for treatment of rheumatoid arthritis it has been successfully used in the treatment of pemphigus [1]. If there has been no improvement by the time the total dose reaches 1 g, treatment should be stopped. If improvement does occur, the frequency of the injections is reduced to every 2–3 weeks. Renal, hepatic and marrow damage must be looked for and rashes are common.

Auranofin is an oral preparation of gold, rather less effective than the parenteral preparation. Its main advantage is that its tissue half-life is much less than with injectible gold. Dose: 3–6 mg/day, increasing to 9 mg/day after 3–6 months. It has also been used in discoid lupus erythematosus.

Chelating agents

Chelating agents are available that form complexes with a number of heavy metals. They are only occasionally of use in dermatology.

d-Penicillamine [1]

This is a degradation product of penicillin and chelates copper, mercury, zinc and lead. It is used for Wilson's disease, lead poisoning, cystinuria and rheumatoid arthritis [1,2]. Its dermatological interest lies in its ability to cause a variety of diseases, including systemic lupus erythematosus-like syndrome, pemphigus-like bullous eruptions, lichenoid and other eruptions and elastosis perforans serpiginosa (see Chapter 73). Earlier reports of possible benefit in scleroderma have not been substantiated [3–5].

Desferrioxamine

This is used in the treatment of various iron-storage diseases. In general, acute iron overload seems to respond much more satisfactorily. However, it is logical to use it in porphyria cutanea tarda as long as iron overload is present, although its value has yet to be proved (see Chapter 57).

Antibiotics and antibacterial agents

Antibiotics were originally substances synthesized by microorganisms that were toxic to other microorganisms at high dilution. The term is now more widely applied to any drug with therapeutic activity against living organisms, particularly bacteria. Antifungals and antivirals are drugs with activity against fungi and viruses, respectively.

Most modern antibiotics are synthetic or semi-synthetic. They are usually divided into bacteriostatic and bactericidal groups, although the distinction is not complete; erythromycin, for example, may be either bactericidal or bacteriostatic depending on the nature of the infecting organism and the drug concentration achieved.

In clinical use, antibiotics are divided into those with a narrow spectrum of activity and those broad-spectrum drugs that act against Gram-positive and Gram-negative organisms. In the laboratory, antibiotics can be further divided into five main groups:

1 Antibiotics that interfere with bacterial cell wall synthesis (e.g. the penicillins, cephalosporins and glycopeptide antimicrobials such as vancomycin and teicoplanin)
2 Antibiotics affecting bacterial cell-membrane permeability (e.g. the polymyxins)
3 Antibiotics that inhibit bacterial protein biosynthesis (e.g. the tetracyclines, aminoglycosides, macrolides, lincosamides and chloramphenicol)
4 Antibiotics that affect bacterial nucleic acid metabolism (e.g. the rifamycins and quinolones)
5 *Para*-aminobenzoic acid (PABA) antagonists (e.g. the sulphonamides).

Drug resistance

Bacterial resistance can emerge in three ways. When all sensitive bacteria have been eradicated, any remaining inherently resistant bacteria are free to multiply; this is the most common form of resistance. Less frequently, bacteria may acquire resistance, by mutation, to a drug to which they were initially sensitive. The third form, which is cause for concern, is transferable drug resistance. Here, extrachromosomal genetic information affecting the expression of resistance contained in a plasmid or a transposable section of chromosomal DNA can be transferred from one bacterium, which may be non-pathogenic, to another previously susceptible bacterium. This often takes place in the bowel or skin and may involve a variety of different organisms. Information on multiple drug resistance can be transferred with a single plasmid.

The mechanisms of drug resistance are variable and include changes in permeability of the cell membrane or antibiotic efflux, alterations in ribosomes, altered cell-wall precursors or target enzymes and the emergence of auxotrophs that have different growth substrates.

Sulphonamides

These antibacterial drugs were introduced into clinical practice in the 1930s, but the frequency of resistance combined with adverse events have limited their use. The combination of a sulphonamide (sulfamethoxazole) with trimethoprim, known as co-trimoxazole, however, is still used in dermatology although less frequently than previously. Resistance is widespread.

Sulphonamides are derivatives of *para*-amino-benzenesulphonamide. They act by inhibiting the bacterial enzyme dihydrofolic acid synthetase, which converts PABA to dihydrofolic acid. Mammalian cells and resistant bacteria do not synthesize folic acid and are unaffected.

Sulphonamides are bacteriostatic and most are well absorbed orally. They are distributed through all body tissues, metabolized in the liver and excreted mainly by the kidneys.

Adverse effects. Although the frequency of serious adverse events is low, sulphonamides can cause a number of serious problems. Besides crystalluria, a risk if there is inadequate fluid intake, they may rarely cause blood dyscrasias such as acute haemolytic anaemia (particularly in patients with glucose-6-phosphate dehydrogenase deficiency), fever, serum sickness and a large variety of skin reactions including erythema nodosum and erythema multiforme. Potentially fatal cases of the severe form of erythema multiforme have followed the use of long-acting sulphonamides [1]. Because of the relatively high incidence of this reaction, the long-acting sulphonamides are little used.

Uses. There are now very few situations where they are drugs of first choice. They are of value in lymphogranuloma venereum, chancroid, nocardiosis and toxoplasmosis (combined with pyrimethamine). Sulfapyridine is now used only as an alternative to dapsone in dermatitis herpetiformis and allied conditions.

Sulfapyridine

Dose: 0.5–1.5 g/day as an alternative to dapsone in dermatitis herpetiformis.

Silver sulfadiazine

This has a role as a topical non-absorbable antimicrobial with a broad spectrum.

REFERENCE

1 Baker H. Drug reactions. IV. Erythema multiforme gravis and long-acting sulphonamides. *Br J Dermatol* 1968; **80**: 844–6.

Trimethoprim [1]

Trimethoprim is a synthetic antimicrobial agent in its own right. It is a potent inhibitor of bacterial dihydrofolic acid reductase, which converts dihydrofolic acid to tetrahydrofolic acid, but has many thousand times less effect on the comparable mammalian enzyme. Trimethoprim is very well absorbed orally, distributed widely through most body tissues and is excreted almost completely by the kidney. Although available as a separate drug, it has been used mainly in combination with sulfamethoxazole in the proportions 1 to 5 as co-trimoxazole. This is a logical mix as these drugs inhibit successive stages in bacterial folate metabolism and it is not surprising that their combined effect is synergistic. Both drugs used singly are bacteriostatic but co-trimoxazole appears to be bactericidal.

Co-trimoxazole tablets BP

There are two strengths containing sulfamethoxazole 400 or 800 mg and trimethoprim 80 or 160 mg, respectively. The dose is two tablets twice daily. The combination is effective against a wide range of Gram-positive and Gram-negative bacteria as well as *Nocardia* and actinomycetoma agents and is in general well tolerated. However, it is best avoided in pregnancy and in infants under 6 weeks and therefore in lactating mothers feeding young babies. Adverse reactions are similar to those seen with sulphonamides. Typical skin reactions may occur in up to 8% of patients and this has limited its use for relatively benign conditions such as acne. Impairment of red cell folate utilization may occur, particularly in the elderly, and supplements of folinic acid may be necessary [1]. Rarer side effects include renal impairment and hepatic reactions.

Co-trimoxazole may be used for urinary tract and respiratory infections but, in infections affecting the skin, is of value in chancroid, atypical mycobacterial infections [2] and mycetoma. Co-trimoxazole has potential value in the treatment of *Pneumocystis* infections, particularly in AIDS patients in whom, unfortunately, there is a high frequency of adverse reactions.

Penicillins

The basic structure of a penicillin consists of a thiazolidine ring, a β-lactam ring and a variable side-chain. The starting point for the semi-synthetic penicillins, of which there are now many, is 6-aminopenicillamic acid. It is convenient to divide the penicillins into five main groups according to their antibacterial properties and consequent clinical usage [1]:

1 Penicillinase-sensitive penicillins (natural penicillins) (e.g. benzyl penicillin (penicillin G), and phenoxymethyl penicillin (penicillin V))

2 Penicillinase-resistant penicillins (e.g. methicillin, flucloxacillin)

3 Amino penicillins, which are broad-spectrum penicillins (vulnerable to penicillinase) (e.g. ampicillin, amoxicillin). By combining clavulanic acid, a potent β-lactamase inhibitor, with amoxicillin (Augmentin®), the spectrum of activity has been broadened to cover penicillin-resistant staphylococci

4 Carboxy penicillins (e.g. carbenicillin)

5 Other penicillins, which include extended-spectrum penicillins (e.g. piperacillin), aminopenicillins and penicillins that are stable against Gram-negative lactamases (e.g. temocillin).

Toxicity. The main problems with their use are hypersensitivity reactions, which are not uncommon. An incidence between 1 and 10% is usually accepted [2], and it appears that administration of these drugs by the oral route is associated with a lower frequency of adverse reactions than the intravenous route [3]. These reactions range from urticaria and vasculitis to anaphylaxis. Cross-reactivity in this allergy is usual. Rare side effects include interstitial nephritis, haemolytic anaemia and pancytopenia.

Penicillinase-sensitive penicillins (penicillin)

Penicillin is the drug of choice against *Streptococcus pyogenes* group A, *Treponema pallidum* and meningococcal septicaemia as well as in yaws, actinomycosis and diphtheria. Because of the emergence of resistant strains of the organism, its use in the treatment of gonorrhoea has largely been superceded. In most serious infections, penicillin is given by injection as benzyl penicillin but treatment may be continued with oral penicillin V and this drug also has a role in prophylaxis against streptococcal cellulitis in patients with lymphoedema.

Benzyl penicillin injection BP (penicillin G). Dose: 300 mg (0.5 mega-units) four times daily up to 1.8 g (3 mega-units) daily. Long-acting injectable preparations are available.

Phenoxymethyl penicillin (penicillin V). Dose: 250–500 mg orally every 6 h.

Penicillinase-resistant penicillins

For practical purposes this means cloxacillin or flucloxacillin, which are resistant to staphylococcal β-lactamase and are drugs of choice against penicillin-resistant staphylococci [4]. Flucloxacillin is somewhat less effective against other Gram-positive infections. Adequate levels are achieved by the oral route but parenteral administration is preferred in serious infections.

Flucloxacillin. Dose: 250–500 mg every 6 h and at least 30 min before food.

Amino penicillins

Ampicillin is commonly used, having a spectrum of activity against Gram-positive and Gram-negative bacteria. It is acid stable and therefore absorbed orally, but is not resistant to penicillinase. It is little used in dermatology but is important as a cause of drug rashes. These occur in about 5–10% of all patients treated but in a majority of those with infectious mononucleosis, cytomegalovirus infections or lymphatic leukaemia [2]. The typical morbilliform rash is thought to be toxic in nature and unrelated to true penicillin hypersensitivity. Amoxicillin is almost identical, is twice as well absorbed as ampicillin but is more expensive. It should probably only replace ampicillin in the patient known to be susceptible to antibiotic-induced diarrhoea [5]. Where an even broader spectrum is needed, perhaps in the treatment of heavily infected leg ulcers with surrounding cellulitis, amoxicillin with clavulanic acid (Augmentin) is worth consideration [6,7]. However, its role in dermatology is a limited one.

Ampicillin. Dose: 250 mg to 1 g every 6 h and at least 30 min before a meal.

Amoxicillin capsules. Dose: 250–500 mg every 8 h.

Amoxicillin 250 mg and clavulanic acid (Augmentin) tablets. Dose: 1–2 tablets every 8 h.

Other penicillins

Carbenicillin, piperacillin, ticarcillin and azlocillin must all be given by injection or infusion and have little place in dermatology.

Imipenem

Imipenem is a carbapenem, a bi-cyclic β-lactam compound with a broad spectrum [8]. It shows considerable activity against many Gram-positive bacteria as well as *Neisseria* spp. It is also used in *Nocardia* infections. It is seldom used in dermatology and is given intravenously.

Cephalosporins [1,2]

The cephalosporins are derivatives of 7-amino-cephalosporamic acid and are similar in structure and properties to the penicillins. They are bactericidal, acting on peptidoglycans in bacterial cell walls, and have wide spectra of activity encompassing Gram-negative organisms and staphylococci—penicillin-resistant staphylococci are generally susceptible but the degree of effectiveness varies between cephalosporins. Many are given parenterally but some orally effective ones are available (e.g. cefalexin, cefaclor). They are excreted by the kidney but unlike penicillin may cause tubular damage. Their main role is perhaps as alternative therapy in penicillin hypersensitivity, but this is not without risk as some 8–10% of all penicillin-allergic patients react to cephalosporins. Apart from this they have little dermatological use.

Quinolones [1]

The chief quinolone antibiotics are more correctly classified as fluoroquinolones or 4-quinolones. Their mode of action is via inhibition of DNA synthesis. Their spectrum of activity is broad and generally includes both Gram-positive and Gram-negative bacteria. The principal quinolone in wide use is ciprofloxacin; others include norfloxacin and ofloxacin. This can be given orally in doses of 750 mg twice daily for soft-tissue infections [2]. Ciprofloxacin is active *in vitro* against a wide range of bacteria from *Escherichia coli* to *Bacillus anthracis* and *Yersinia enterocolitica*. It is also active against staphylococci and streptococci as well as *Mycobacterium tuberculosis*, although atypical mycobacteria are generally less sensitive. In dermatology, ciprofloxacin is best reserved for

severe infections such as those occurring in the immunocompromised patient, but other indications include Gram-negative folliculitis, rhinoscleroma and cutaneous anthrax. It is an alternative treatment for chancroid and genital chlamydial infections.

Tetracyclines

These are orally effective broad-spectrum antibiotics with relatively low toxicity. The original three tetracyclines were chlortetracycline, oxytetracycline and tetracycline. Later derivatives include demethylchlortetracycline, methacycline, doxycycline and minocycline (the last three being synthetic). They act by inhibition of protein synthesis through ribosomal binding. With the exception of minocycline they all have similar spectra of activity; differing, however, in their absorption, distribution and excretion.

Both streptococci and staphylococci may be resistant to tetracyclines, although the incidence of staphylococcal resistance is less than previously and such strains are sensitive to minocycline [1]. However, as much more effective agents are available for these organisms, the tetracyclines are generally not used in these infections.

The tetracyclines are bacteriostatic against many Gram-positive and Gram-negative bacteria and are also active against rickettsiae, *Mycoplasma*, *Chlamydia*, which cause lymphogranuloma venerum, psittacosis and trachoma, as well as amoebae.

Absorption of some tetracyclines is impaired by simultaneously taking milk, aluminium, calcium or magnesium salts or iron preparations, because of chelation. However, food does not interfere with the absorption of doxycycline or minocycline. All tetracyclines are concentrated in the liver and excreted into the bile, whence they enter an enterohepatic circulation. Urinary excretion is significant and renal failure may be exacerbated by all except doxycycline [2].

Side effects [3–5]. A variety of rashes has been described (see Chapter 77), including phototoxicity, especially shown by demethylchlortetracycline [6]. Glossitis, cheilitis and persistent pruritus ani may occur. Gastrointestinal disturbances are dose dependent [7] and are much more common with doses of 2 g/day or more, which are rarely used in dermatology. Nausea and vomiting are direct irritant effects; diarrhoea may be the result of superinfection, resistant staphylococci being especially dangerous. Minocycline can cause vertigo and hyperpigmentation. The latter is usually slate grey and can affect the skin, nails and sclerae [8]. Tetracyclines are deposited in growing teeth and bones [9] and their use should be avoided in pregnancy, during lactation and in childhood. Rarely, there may be diffuse fatty degeneration of the liver. An uncommon dermatological problem is the development of Gram-negative folliculitis after tetracycline therapy of acne [10,11].

Dermatological uses. Apart from the infections mentioned above, tetracyclines are rarely drugs of first choice. The exception, of course, is the treatment of acne vulgaris (see Chapter 42) [12,13] and rosacea (see Chapter 46).

Tetracycline, chlortetracycline, oxytetracycline

Dose: daily doses range from 500 mg (for acne) up to 3 g.

Doxycycline, minocycline

Dose: 100–200 mg/day. Doxycycline is the ordinary tetracycline of choice in patients with renal impairment. Minocycline is usually effective against staphylococci resistant to other tetracyclines and is used increasingly as a first-line treatment of acne (50 mg twice daily).

Preparations are also available as syrups, and injections for intramuscular, intravenous or intralesional use. Tetracycline resistance has been reported in *Propionibacterium acnes* and caution should be exercised over the use of repeated courses of these antibiotics. Resistance may also be passed to other bacteria [13].

Macrolides

The main macrolide antibiotics are erythromycin and its derivatives azithromycin and clarithromycin. They work by binding to ribosomes and inhibiting protein synthesis.

Erythromycin [1]

Dose: 1–2 g/day in divided doses. This is the most widely used member of the macrolide group of antibiotics. It is active mainly against Gram-positive organisms such as staphylococci and streptococci. Staphylococci may rapidly develop resistance, especially in hospital, where in some studies as many as 50% of strains may be resistant; streptococci are also occasionally resistant.

Side effects include an allergic cholestatic hepatitis that occurs only with erythromycin estolate. Otherwise gastrointestinal problems such as dyspepsia and diarrhoea are not uncommon. Erythromycin is an extremely useful drug for the outpatient treatment of staphylococcal or streptococcal pyodermas, especially in the penicillin-allergic patient. It may also be used for atypical mycobacterial infections. Particular dermatological uses are for erythrasma and acne; it may safely be given in renal failure as less than 5% is excreted in the urine.

Azithromycin and clarithromycin [2]

These are newer macrolide agents with a somewhat different spectrum of activity than erythromycin and longer half-life. At present they are little used in dermatology, although they show promise as treatment for atypical mycobacterial infections, particularly those caused by the *Mycobacterium avium* complex, but *M. marinum* is also responsive [3].

Aminoglycosides

This group includes streptomycin (see below), neomycin, gentamicin, amikacin and tobramycin. They are little used in dermatological practice, their chief use being against Gram-negative infections. They inhibit protein synthesis; bacteria may rapidly become resistant, and cross-resistance occurs within the group. Normally there is almost no absorption by mouth. They are ototoxic and, to a lesser degree, nephrotoxic.

Dermatological uses. These are few. Streptomycin is still used in some countries for tuberculosis, is effective in tularaemia and some forms of actinomycetoma and can be used as an alternative to tetracyclines in granuloma venereum. The topical use of neomycin is discussed in Chapter 78.

Gentamicin [1] *and amikacin* [2]

Amikacin is now more widely used than gentamicin [2]. Its use is mainly restricted to the treatment of serious Gram-negative infections, especially those caused by *Pseudomonas aeruginosa* [3,4] and to *Nocardia* infections [5]. Gentamicin has a synergistic effect with carbenicillin against *Pseudomonas* and other Gram-negative organisms and is used in combination with penicillin for some forms of endocarditis. Aminoglycosides should not be used in pregnancy and should be controlled by measurements of plasma concentration.

Spectinomycin

This is an aminocyclitol antibiotic derived from a streptomycete species and is related to the aminoglycosides. Its use in dermatology is limited but it is very effective in the management of gonorrhoea as a single intramuscular injection [1].

REFERENCE

1 Holloway WJ. Spectinomycin. *Med Clin North Am* 1982; **66**: 169–84.

Lincosamides

Lincomycin and its derivative clindamycin (which ought to be used in preference to lincomycin) act against Gram-positive cocci including some penicillin-resistant staphylococci. They are highly active against *Bacteroides* infections and penetrate well into bone.

Side effects. Diarrhoea may occur in up to 20% of cases; pseudomembranous colitis may supervene and may last

for weeks after the drug has been withdrawn [1,2]. There have been a number of deaths from this complication; one severe case has been reported in a patient treated for acne.

Clindamycin

This is an effective alternative drug for the treatment of acne [3]; however, in view of its known toxicity, it is now rarely used systemically for this condition. It is useful in a 1% formulation for the topical treatment of mild to moderate acne.

Chloramphenicol

This would be a useful drug for a number of infections were it not for bone marrow aplasia, which occurs in 1 in 40 000 courses of treatment [1]. This has been known for 25 years, and yet a survey of 576 cases of blood dyscrasia caused by chloramphenicol concluded that in most cases there had been no indication to justify its use. Nevertheless, it remains an alternative treatment for typhoid fever and *Haemophilus influenzae* meningitis.

Rifamycins

See p. 72.37.

Polymyxins

Polymyxin B and polymyxin E (colistin) are relatively toxic drugs that are not absorbed from the gastrointestinal tract. Their use for Gram-negative infections has been largely superceded by gentamicin and ciprofloxacin. Polymyxin B is used topically.

Glycopeptide antibiotics

The two main examples of this group are vancomycin and teicoplanin. They act by inhibition of peptidoglycan polymer formation in bacterial cell walls. Vancomycin is chiefly used for the treatment of serious staphylococcal infections such as septicaemia as well as other life-threatening conditions such as pseudomembranous colitis. It has no obvious use in skin disease [1].

REFERENCE

1 Wise RI, Kory M, eds. Reassessments of vancomycin: a potentially useful antibiotic. *Rev Infect Dis* 1981; **3** (Suppl.): 199–300.

Fusidic acid [1]

This is produced by a strain of *Fusidium coccineum* and has the basic structure of a steroid, although it shows little in the way of metabolic effects. It is a very safe drug, primarily used for staphylococcal infections, although it is also active against other Gram-positive bacteria and the Gram-negative cocci. Nearly all strains of staphylococci are outstandingly sensitive to fusidic acid [2] but there have been increasing reports of resistant mutants, which can multiply rapidly. However, concomitant administration of penicillin can be used to kill any resistant mutants as they emerge. It is available for oral use, as an injection and for topical application. It is a useful drug for staphylococcal osteomyelitis in particular, and its indiscriminate prescription for minor infections should be discouraged for fear of encouraging resistant strains that are now emerging.

Metronidazole [1,2]

Metronidazole is a synthetic agent active against protozoa and anaerobic bacteria. It is particularly useful in trichomoniasis, bacterial vaginosis [2], amoebiasis and giardiasis, and has proved extremely valuable against *Bacteroides* and *Helicobacter* species [3]. For the dermatologist it has a limited role in the treatment of tetracycline-failed rosacea [4]. Metronidazole is well absorbed by the oral or rectal route and it may be applied topically. It may also be given intravenously. It is available as 200 and 400 mg tablets, the usual adult oral dosage being 200 mg twice daily for rosacea, 200 mg every 8 h for *Trichomonas* infections, 400 mg every 8 h for anaerobic bacterial infections and 800 mg every 8 h for amoebiasis. The suppositories contain 500 mg, and in anaerobic infections are prescribed in the adult dosage of 1 g every 8 h at first, dropping to 1 g every 12 h. Topical formulations are available for the treatment of rosacea.

The fate and mode of excretion of metronidazole are not fully understood [5]; it is generally regarded as safe in hepatic and renal disease. There is no evidence that it is a human teratogen, and it may be given to lactating mothers, although it causes darkening of milk and may give it a bitter taste. In normal doses and for short periods it is generally a remarkably safe drug but minor gastrointestinal side effects such as nausea and an unpleasant taste in the mouth are not uncommon. Vomiting, abdominal pain and diarrhoea may follow. Darkening of urine, headache and drowsiness also occur, and leukopenia may be noted. Much less common adverse reactions are peripheral neuropathy, particularly associated with prolonged treatment, and central nervous system effects (dizziness, ataxia and fits) from high dosage. The only important interaction is with alcohol, which produces a disulfiram-like reaction in some patients.

Antituberculous drugs (see Chapter 28)

The important first-line drugs for the treatment of *Mycobacterium tuberculosis* infections are isoniazid, rifampicin, ethambutol and, in some cases, streptomycin [1,2]. In the initial period of treatment, usually 60 days or until sensitivities are available, three of these drugs are used concurrently. For the continuation phase of therapy, two drugs to which the organism is sensitive are sufficient for cure without the occurrence of resistant strains (for details see Chapter 28).

Second-line drugs such as pyrazinamide, ethionamide, cycloserine, PABA or thiacetazone may be required where drug resistance or adverse reactions preclude the use of more than one of the four first-line agents.

The emergence of multidrug-resistant strains of *Mycobacterium tuberculosis* (MDR-TB) is a major potential threat [3], particularly as they may affect AIDS patients who expectorate large numbers of bacilli.

Isoniazid

This is a synthetic, orally absorbed bactericidal agent usually given in a dosage of 300 mg/day to adults (5–10 mg/kg every 24 h). It is excreted mainly by the kidney after acetylation and further metabolism. It can be used in pregnancy [4] but during lactation should be supplemented with pyridoxine because of the theoretical risk of toxic side effects (see below). In severe renal failure, the adult dosage should be reduced to 200 mg/day. Adverse reactions may be divided into toxic and allergic. Toxic reactions are more common in slow acetylators and include most commonly peripheral neuropathy but also convulsions, mental disturbances and a pellagra-like rash [5]. They are usually reversible on cessation of therapy. Pyridoxine 10 mg/day given prophylactically will reduce the incidence of these problems where high doses are used. The main allergic reactions are rashes, agranulocytosis and hepatitis, this last being apparently more common in patients with pre-existing liver disease [6].

Rifampicin

This is a synthetically modified antibiotic of the rifamycin group. It is bactericidal and very effective against *M. tuberculosis*, many atypical myobacteria and Gram-positive cocci. It is also useful in leprosy. To counter the emergence of resistant strains, it is always used in combination with other antimicrobials.

Rifampicin is well absorbed orally and is available as 150 mg capsules and a 100 mg/5 mL mixture. In adults it is usual to prescribe 450–600 mg/day as a single dose before breakfast (10 mg/kg/day). Excretion is predominantly in the bile and so hepatic impairment is an indication for avoidance or at least lower dosage. In pregnancy, rifampicin is best avoided but where it has been used the incidence of abnormalities noted at birth has not been excessively high—4.3% compared with 1.8% in tuberculous controls [7]. If used in late pregnancy it may cause haemorrhagic problems in neonates. Rifampicin is generally regarded as a relatively non-toxic antituberculous drug but many different adverse reactions have been described: mild gastrointestinal disturbances and rashes —particularly flushing [8,9]. Transient impairment of liver function as revealed by elevation of transaminase levels is common but need not usually interrupt therapy. Orange-red discoloration of urine, saliva and sweat may be noticed. Thrombocytopenia, however, is an uncommon side effect that must not be ignored. Three other serious adverse reactions are a flu-like illness, a syndrome of dyspnoea, wheezing and hypotension, and the occurrence of renal failure, all of which are characteristically associated with intermittent or irregular medication [10]. Drug interactions occur with warfarin (diminished anticoagulant effect), oral contraceptives (possibly) and corticosteroids (diminished steroid effect).

Other rifamycins. Rifabutin has particular activity against *M. avium–intracellulare* in addition to *M. tuberculosis*. It is used, for instance, as prophylaxis in patients with low CD4 counts. It may also be useful where there is a high risk of rifampicin resistance.

Streptomycin

This is an aminoglycoside antibiotic used mainly in the treatment of tuberculosis. It must be administered parenterally and is commonly given in a dosage of 500–1000 mg/day by intramuscular injection. Lower dosage is preferred in patients over 40 years [11]. Excretion is by the kidney so that dosage should be reduced in renal impairment. Dosage reduction is also important in the premature infant. Of the important side effects, the most common is vertigo, which is especially troublesome in elderly people. Deafness may also develop and both these eighth-nerve effects are dose related [12]. These two adverse reactions provide a strong contraindication to the use of streptomycin in pregnancy and lactation as the infant may be affected, and in patients with pre-existing vestibular or auditory impairment. Allergic reactions include skin eruptions from the trivial to exfoliative dermatitis, eosinophilia and drug fever. Contact sensitization to streptomycin is a well-recognized hazard among nurses, justifying precautions to avoid skin contamination (e.g. by wearing gloves). Because streptomycin is a neuromuscular-blocking agent, it may increase the effects of suxamethonium and other similar drugs, and should be used only with extreme caution in myasthenia gravis.

Ethambutol

This is a synthetic agent effective only against *M. tuberculosis* and some atypical mycobacteria. It is orally absorbed and is available on its own as 100 and 400 mg tablets and in combination with isoniazid in a variety of strengths. The usual initial dosage is 15 mg/kg/day in adults and 25 mg/kg/day in children, reducing later in that age group to 15 mg/kg/day. It may also be used as intermittent treatment in a dosage of 45–50 mg/kg twice weekly. Excretion is mainly via the kidney, necessitating reduction of dosage in renal impairment. Optic (retrobulbar) neuritis with diminished visual acuity and red-green colour blindness, slowly reversible on cessation of therapy, was a relatively common side effect of higher dosage regimens but should be rare with currently recommended levels [13,14]. It seems to be more effective to train patients to check their own vision regularly when on this drug than to rely on periodic ophthalmic examinations. Ethambutol may also, although rarely, cause peripheral neuropathy and renal damage, and may precipitate attacks of gout. It appears not to be a teratogen in humans and is not contraindicated during lactation.

Para-aminosalicylic acid

This drug is much less active than the above drugs, but has a role in preventing the emergence of resistant strains of *M. tuberculosis*. It is given in the high dosage of 10–20 g/day and unfortunately is associated with a high incidence of minor but unpleasant side effects [15]—gastrointestinal symptoms occur in nearly all patients. Allergic reactions with rashes and fever are common and there seems to be either cross-hypersensitivity with streptomycin or potentiation of streptomycin allergy. Although once a valued drug in triple therapy, its use is now largely restricted to poorer countries where its low cost is a major consideration.

Other antituberculous drugs [2]

A number of other antituberculous drugs are available and may be required if resistance or hypersensitivity reactions preclude the use of standard treatment. They include pyrazinamide, capreomycin, ethionamide and cycloserine. Pyrazinamide is bactericidal and low-priced [16].

Antileprosy agents

Sulphones

The sulphones were the first effective compounds used for the treatment of leprosy. The principal agent is 4,4-diaminodiphenyl sulphone (dapsone). The sulphones are related to the sulphonamides, and probably act in the same way. *Mycobacterium leprae* is usually extremely sensitive [1] but may become resistant. The sulphones are bacteriostatic, not bactericidal.

Dapsone. This drug is orally absorbed and is available in the form of 50 and 100 mg tablets. The usual adult dosage in leprosy is 50–100 mg/day. It is excreted mainly in the urine [2]. Some degree of haemolysis is an extremely common adverse reaction [3,4]. In pregnancy and lactation there is clearly a risk of haemolysis and methaemoglobinaemia in the baby, but the presence of dapsone in breast milk may have prophylactic value against leprosy [5]. Resistance to dapsone is known to occur in approximately 20% of patients who receive the drug for the treatment of leprosy as a single agent. With the use of multiple-drug regimens, this complication is thought to be much rarer. Leprosy apart, dapsone is a well-established means of suppressing the cutaneous lesions of dermatitis herpetiformis [6] and several other diseases. Most dermatologists are more familiar with the use of the drug in this way and further details are described in Chapter 41.

Clofazimine (Lamprene®) [7,8]

This oral synthetic drug is a phenazine dye. The usual dosage is 100 mg three times a week or 100 mg/day in combination with rifampicin if sulphone resistance has occurred [9]. It has an anti-inflammatory effect that may prevent erythema nodosum from developing. For lepra reactions, 300 mg/day is recommended. Clofazimine has a very long half-life: 70 days or more. It accumulates in the tissues and is slowly excreted in urine, sweat, sebum and milk.

The main side effect is the emergence of red-brown to black discoloration of skin and conjunctivae, but urine and sputum become red too and breast milk may be discolored. Mild gastrointestinal reactions may occur and ichthyosiform rashes [10]. In general, clofazimine is a well-tolerated drug that may be prescribed in pregnancy and during lactation. In renal and hepatic impairment, biochemical tests of function are recommended from time to time but the drug may be used. Clofazimine may be valuable in treating pyoderma gangrenosum [11] and perhaps also in discoid lupus erythematosus.

Rifampicin

This drug has been discussed previously (under Antituberculosis drugs). It seems to be bactericidal for *M. leprae* in very low dosage and acts much more rapidly than dapsone, rendering the patient non-contagious in a few days or weeks [12]. It does not shorten the total duration of treatment, which should be continued with dapsone.

Thiambutosine

This is a diphenylthiourea, useful as a second-line drug when dapsone cannot be used. Resistance may develop, especially after 1 year of treatment.

Antifungal drugs [1–3]

The drugs available for systemic use against fungal diseases are few in number. There are three main families of antifungals: the polyenes (amphotericin B); the azoles, which include the imidazoles (e.g. ketoconazole, miconazole) and the triazoles (fluconazole and itraconazole); and the allylamines. There is also a miscellaneous group of drugs such as griseofulvin, tolnaftate and flucytosine. Most antifungals work through damage to or inhibition of the fungal cell membrane. The main exceptions are the pyrimidine analogue, flucytosine, which affects RNA and DNA synthesis, and potassium iodide which probably affects phagocytic function.

Polyenes [4]

Nystatin [4]

Nystatin was the first polyene antibiotic discovered and is still valuable today as a topical anti-*Candida* agent. It is not absorbed from the gut in significant amounts.

Amphotericin B [1,4]

This is a polyene antibiotic derived from *Streptomyces nodosus*. It has a very wide range of activity against *Candida* spp. and almost all deep fungal pathogens. Resistance is rare. Absorption from the gut is negligible and so, as with nystatin, tablets and lozenges are for practical purposes topical therapy for the mouth or prophylaxis. For systemic use, amphotericin B must be given by slow intravenous infusion in 5% dextrose. This solution is unstable; it should

be used promptly and other drugs should not be added, except heparin or hydrocortisone. The definitive adult dosage range is normally in the range of 0.4–1 mg/kg/day but toxicity is minimized if there is a build-up from a very low dose (1 mg) on the first day, to full dosage by days 3–5. In the seriously ill patient, a more rapid build-up to full dosage over 24–48 h is necessary.

The fate of amphotericin in the body is not fully understood [5]. Only small amounts appear in urine; much is probably bound to sterol-containing membranes. Adverse reactions are common: initially, fever, rigors, hypotension, nausea, vomiting, tinnitus and bronchospasm. Phlebitis at the site of infusion is also frequent. Hypokalaemia and hypochromic anaemia may occur and, rarely, liver function abnormalities. Nephrotoxicity is of great importance; renal clearance may be decreased and tubular damage may develop. These are particularly problems of extended treatment but are potentially reversible. If renal impairment is severe, therapy must be interrupted and should be restarted at a lower dosage.

Amphotericin B is used principally for systemic mycoses such as candidosis, aspergillosis, mucormycosis and cryptococcosis as well as the endemic respiratory infections such as histoplasmosis.

Lipid-associated amphotericins

Three formulations of lipid-associated amphotericin B have been developed: a liposomal formulation (AmBisome), a colloidal dispersion (Amphocil®) and a lipid complex (Abelcet®). They can be used at much higher dosage (usually 3 mg/day) without nephrotoxicity [6].

Flucytosine [7]

This is a synthetic cytosine analogue that is converted to 5-fluorouracil in the body. It is effective against yeasts, including *Candida* spp., *Cryptococcus neoformans* and many of the fungi involved in chromoblastomycosis. It is orally absorbed but may be given intravenously too. The tablets contain 500 mg, the usual adult dosage being 150 mg/kg/day. Lower doses are necessary in renal failure. It is important to monitor serum levels, aiming to achieve 40–60 mg/L and to avoid toxic levels—above 120 mg/L. Because resistance, both primary and secondary, is well recognized, sensitivity testing initially and at intervals is strongly recommended. It is rarely used on its own. In cryptococcal meningitis in the non-AIDS patient, flucytosine and amphotericin B are given in combination. They appear to be more effective as a combination than amphotericin B on its own and the daily dosage of the latter can be reduced to 0.4–0.6 mg/kg.

The main side effects are nausea, vomiting, diarrhoea and rashes, but thrombocytopenia and neutropenia may also occur.

Azoles

Miconazole

This is a commonly used topical imidazole, poorly absorbed by the oral route. It may be administered intravenously by slow infusion three times in 24 h, the usual adult dosage being 1.8–3 g/day. Side effects are not particularly common. They include pruritus, rashes, fever, faintness and venous thrombosis at the infusion site. Anorexia, nausea, vomiting and diarrhoea occur and anaphylaxis is a rare but genuine problem. It is seldom used now except in infections caused by *Scedosporium apiospermum* [8].

Ketoconazole [9,10]

Ketoconazole is a broad-spectrum imidazole, which is available in different topical formulations from cream to shampoo or as an oral agent. The drug is well absorbed after oral administration, although lower levels are seen in patients who are neutropenic. It is effective in chronic mucocutaneous candidosis and widespread dermatophytosis. It can also be used topically for pityriasis versicolor. It also appears to be effective in mycetoma infections caused by *Madurella mycetomatis* but not in sporotrichosis. Certain systemic mycoses such as paracoccidioidomycosis and those with soft-tissue lesions are the most sensitive [10].

Adverse events are not common but include headache, vomiting and giddiness as well as nausea. It also leads to blockade of androgen biosynthesis by interference with cytochrome P-450 at high dosage [11]. This results in symptoms such as gynaecomastia in men and menstrual irregularities in women. In addition, it causes asymptomatic changes in liver function and overt hepatitis on occasions [12]. The true frequency of the latter is estimated to be about 1 in 10 000 but it may be more common in patients receiving treatment for nail disease. It is more common also in those with a prior history of liver disease. While this is a comparatively uncommon complaint, it is sufficient to limit the use of the drug in superficial fungal disease. Also, much of its function has been assumed by the development of itraconazole and fluconazole (see below). Drug resistance is also seen rarely [13].

Itraconazole [14]

Itraconazole is a triazole antifungal drug that is avidly bound in tissue, including skin. Its serum levels are generally low after a 100–200-mg dose. It is given orally and has a broad spectrum of action against the main fungal pathogens. It is effective in dermatophytosis, candidosis and *Malassezia* infections. Originally used in a dosage of 100 mg/day, it is now often given at 200 or 400 mg. At

higher doses it is possible to use shorter courses such as 400 mg/day for 1 week in tinea corporis. Because it is retained for very long periods in the nail, it is used in pulses of 400 mg/day for 1 week per month for 3–4 months [15].

In vaginal candidosis it is given as a single treatment of 600 mg/day and it produces responses in oropharyngeal candidiasis in doses of 100–200 mg/day. For recalcitrant pityriasis versicolor, a total dose of 1000 mg is necessary. Other infections responding to itraconazole include sporotrichosis, chromomycosis, paracoccidioidomycosis and histoplasmosis [14]. It has also been reported to be effective in cryptococcal meningitis, particularly as a long-term suppressive therapy of HIV-positive patients. Itraconazole is unusual amongst azoles in producing responses against aspergillosis.

Although itraconazole may occasionally cause nausea and headache, more serious adverse reactions, such as hepatic reactions and anaphylaxis, are extremely rare.

A new formulation of itraconazole in cyclodextrin, as well as an intravenous form, are also available. This oral solution is much better absorbed in AIDS patients than the conventional formulation.

Fluconazole [16]

Fluconazole is a triazole antifungal that is well absorbed after oral administration. It may also be given intravenously. Unusually for an azole, it is mainly excreted via the kidney. It is active against a range of fungal pathogens.

The principal uses of fluconazole in dermatology are in the treatment of oropharyngeal and vaginal candidosis [17]. In the latter disease, it is effective in a single dose of 150 mg; with oropharyngeal infections, treatment responses are rapid, often within 3 days of starting therapy with 50–100 mg/day [18]. For dermatophytosis, it has been found that weekly doses of 150 mg may be effective after 2–3 weeks and a similar weekly pulse has been used for onychomycosis. In systemic mycoses it is used in the management of cryptococcosis, either as primary therapy or long-term suppression, and in systemic candidosis [19].

Few adverse effects apart from nausea and dyspepsia have been attributed to fluconazole. The dosage of the drug has to be reduced in patients with renal impairment.

Certain fungi such as *Candida krusei*, *C. glabrata* and some strains of *C. albicans* may be primarily resistant to fluconazole and secondary resistance may develop in immunocompromised patients [16].

Other azoles

Two new orally active triazoles in development, voriconazole and posaconazole, have not been evaluated in superficial fungal disease. They show promise in the management of a range of systemic infections.

Allylamines

Terbinafine [20]

Terbinafine is a fungicidal allylamine antifungal, similar to naftifine. It works by the inhibition of squalene epoxidation in the synthesis of the ergosterol in the fungal cell membrane [21]. The accumulation of squalene in the cell is thought to contribute to its *in vitro* fungicidal activity. It may be given orally or topically in a dosage of 125 mg twice daily. Its chief use is in dermatophytosis, where it is highly effective even in patients with chronic infections of the hands and feet. In onychomycosis it is given in a regimen of 250 mg/day for 6 weeks for fingernails and 12 weeks for toenails [22]. It is less active when given orally in superficial candidosis and pityriasis versicolor. In dermatophytosis there is a particularly low relapse rate with this drug. Recently, it has been shown to be active in a range of other deep fungal infections, from sporotrichosis to chromoblastomycosis.

There are few side effects apart from the occasional episode of gastrointestinal discomfort. Loss of taste may occur but is reversible. Skin rashes have also been reported. Hepatic reactions are extremely rare.

Griseofulvin [23]

Griseofulvin is derived from a number of *Penicillium* species. It is a fungistatic drug whose principal activity is directed against dermatophytes. Its mode of action is via the inhibition of the formation of intracellular microtubules.

The usual human dosage is 10 mg/kg/day in tablet or, in children, solution form. Treatment duration varies between 2 and 4 weeks for tinea corporis to over 1 year for onychomycosis. The success rate even after 1 year of treatment for toenail infections is less than 30–40%.

Drug interaction with phenobarbital and coumarin anticoagulants occur. Side effects include headaches and nausea, but serious reactions are extremely rare. There are a few reports of apparent precipitation or exacerbation of systemic lupus erythematosus and porphyrias by griseofulvin.

Potassium iodide [2]

In the form of a saturated aqueous solution (100 g in 100 mL water), this is the preferred treatment for lymphocutaneous sporotrichosis and subcutaneous zygomycosis (basidiobolomycosis). It is administered orally, starting with 0.6 mL three times daily and gradually increasing until a level of four or five times the dose is attained in an adult. The mode of action is obscure. Progress must be expected to be slow and treatment should be continued until 4 weeks after apparent cure. Iodides are best avoided in pregnancy because of the risk of goitre and

hypothyroidism in the infant. Adverse reactions include iododerma, salivary and lacrimal gland swelling and hypersecretion, and gastrointestinal disturbances, as well as anxiety, depression and hypothyroidism.

Cell wall antagonists

A number of new antifungals are in development that have a different site of action, the inhibition of the cell wall. Caspofungin is an echinocandin that blocks glucan synthase [24]. It is available as an intravenous drug for use in the treatment of aspergillosis or candidosis, particularly caused by resistant *Candida* species.

Antiviral drugs

With the spread of HIV infection, considerable efforts have now been expended in searching for new antiviral drugs. Despite this there are still few effective antiviral agents [1]. Because there are fewer steps involved in the assembly of viruses, and these are inextricably associated with human metabolic and other cellular functions, the ratio between antiviral activity and host toxicity is often a narrow one. Many agents employed in the treatment of viral infections of the skin have one of three viral targets: inhibition of viral polymerase (e.g. aciclovir), inhibition of reverse transcriptase (e.g. zidovudine) or protease inhibition (e.g. indinavir). The two latter groups are mainly used for the treatment of retroviral infections.

Other approaches to treatment have involved the use of interferons, which have proved to be of limited value in most viral infections apart from some genital papillomavirus infections, and many of the available preparations are associated with dose-limiting side effects when given intravenously.

Drug resistance will occur with antivirals but often it involves a modification of the viral genome that may, in turn, affect viral pathogenetic mechanisms. This alteration in viruses may affect their capacity to cause disease except in severely immunocompromised patients such as those with AIDS.

Vidarabine (adenosine arabinoside, ARA-A)

This purine nucleoside acts by inhibiting viral DNA synthesis. It has effects mainly against the herpes group of viruses and appears to be effective in early cases of herpes simplex encephalitis and in varicella-zoster infections of immunocompromised subjects. However, its use has largely been superceded by aciclovir. At a dosage of 10 mg/kg/day intravenously it causes mainly mild gastrointestinal side effects, and rashes in 5% of subjects. CNS and haematological side effects have also been reported [2]. A 3% ointment has an established place in the topical treatment of herpes simplex keratoconjunctivitis.

Idoxuridine

This synthetic nucleoside is effective against DNA viruses, particularly the herpes group. Its use is now restricted to topical application because of severe bone marrow and hepatic toxicity when given intravenously. It has been used in 5–40% concentration in dimethyl sulfoxide (DMSO) to shorten the duration of clinical symptoms in herpes zoster infections. It can also be used in herpes keratitis but is less effective in genital herpes simplex infections [3].

Aciclovir [4–7]

This antiviral agent works by inhibition of DNA synthesis. Its mode of action involves activation by thymidine

kinase and subsequent inhibition of viral polymerase. Resistance to aciclovir has been recorded sometimes, following alterations to or deficiency of thymidine kinase. This has been associated with lack of response to therapy [8,9].

Aciclovir is very active against herpesviruses. In serious infections it has been used intravenously but it is also available as 200-mg tablets, as an ophthalmic ointment and as a cream [5]. Unfortunately, it has no effect on the latent phase of either herpes simplex or zoster and is apparently ineffective in clinical practice against other viruses. The intravenous dosage for serious systemic herpes simplex infections is 5 mg/kg every 8 h by slow infusion (over 1 h). In herpes zoster, 10 mg/kg every 8 h is advised. Orally, 200 mg every 4 h (five times daily) is effective and a remarkably safe treatment for severe vulvovaginal herpes simplex [10], for example.

Studies with aciclovir have shown that it is possible to suppress recurrences of herpes simplex by intermittent administration over a long period. This has given rise to concerns over the risk of drug resistance and this approach is really only indicated in a few patients with incapacitating recurrent attacks of infection [11].

Aciclovir is less effective against herpes zoster unless given in higher dosage (e.g. 10 mg/kg intravenously 8 hourly [12]. It is therefore mainly used for treatment of varicella-zoster infection in immunocompromised patients.

The main route of excretion is renal [13]. Side effects include elevation of blood urea and creatinine, which may rarely progress to acute renal failure. In patients with established renal impairment, lower doses are indicated. Although animal and human evidence shows no teratogenic activity, aciclovir is best avoided in pregnancy. Levels are reported to be higher in human milk than in serum when given during lactation.

Newer drugs related to aciclovir

These include famciclovir, penciclovir, ganciclovir and valaciclovir [14].

Famciclovir. This is well absorbed after oral administration. It is used at a dosage of 250–500 mg up to three times daily. At these dosages it appears to be as effective as the higher dose regimen of intravenous aciclovir and is well tolerated. There is also a lower frequency of post-herpetic neuralgia after its use.

Penciclovir. This is a promising treatment for severe herpes simplex infections and, because of its pharmacokinetic properties, is given less frequently than aciclovir.

Ganciclovir [15]. This is another deoxyguanosine analogue, which can be used in the treatment or prophylaxis of cytomegalovirus (CMV) infections. It is also active against other herpesviruses. Its use is generally reserved for CMV infections in severely immunocompromised patients when it is given in a starting dosage of 5 mg/kg/12 h intravenously. It can also be used as long-term suppressive therapy to prevent relapse. However, there is a high frequency of nephrotoxicity as well as metabolic disturbances such as hypokalaemia or hypocalcaemia.

Valaciclovir. This has a similar antiviral spectrum to aciclovir. It is mainly used for the treatment of herpes zoster infections (1000 mg for 7–14 days). It is also used for shorter periods (5 days) for herpes simplex infections [16].

Zidovudine (AZT, Retrovir®) [17]

AZT has been developed for the treatment of human retrovirus infections. Its principal site of action is the inhibition of virus-RNA-dependent DNA polymerase (reverse transcriptase) [18]. AZT is given by the oral route and the normal dosage is 250–500 mg/day; variations to this regimen and drug combinations are under assessment. The use of AZT in patients with AIDS or symptomatic HIV infections has been found to result in higher levels of circulating CD4 lymphocytes and, in some studies, a decrease in mortality over the short term. Treated patients are still infectious and the therapy does not cure the infection. It is currently used to treat HIV patients with CD4 counts lower than 500/mm^3 [19]. It has been suggested that AZT may benefit some skin complications of AIDS such as psoriasis. Administration of AZT to infected women in the second and third trimesters of pregnancy significantly reduces the risk of neonatal infection [20].

The main toxic side effects of zidovudine are neutropenia and anaemia, which occur in the majority of patients, particularly at higher doses. This is a particular problem in advanced disease. Other side effects include headache, myalgia and nausea. Progressive nail pigmentation has been described in black patients [21]. Resistance to AZT occurs regularly with long-term use.

Other antiretroviral agents

These include zalcitabine (DDC), a dideoxynucleotide analogue, and stavudine, which is a thymidine analogue. Both have been used for the treatment of patients with very low CD4 counts or where there is AZT resistance. Zalcitabine causes a painful neuropathy. Pancreatitis, rashes, ulceration and hepatitis have been described. Stavudine also causes a painful neuropathy.

Protease inhibitors

In order to circumvent the rising problem of drug resistance with antiretrovirals, a new family of drugs whose main focus of action is on the inhibition of aspartic proteases

encoded by retroviruses has been developed. These cleave the Gag and Gag-Pol proteins into smaller moieties needed for maturation. The main compounds are saquinavir, indinavir, ritonavir and nelfinavir but there are others in development. Most work by mimicking the transitional state that occurs during peptide bond cleavage by aspartic proteases. Generally, they are used in combination, usually with AZT or other reverse transcriptase inhibitors and/or further protease inhibitors to prevent viral replication and increase CD4 counts. These compounds differ in structure and in the specific sites inhibited [22–24]. At present, treatment using combinations of these drugs is known as highly active antiretroviral therapy (HAART), and successful maintenance therapy can be given for HIV-infected individuals. However, it is likely that resistance will ultimately develop.

Foscarnet phosphonoformate [25]

Foscarnet is a pyrophosphate analogue that inhibits herpesvirus polymerase. It is active against most herpesviruses including CMV. It also inhibits reverse transcriptase and has activity *in vitro* against HIV, particularly in combination with AZT. It is given intravenously in severe herpes simplex and CMV infections, or topically. It is an alternative drug for severe aciclovir-resistant herpes simplex infections and for this indication the usual initial treatment is 40 mg/kg every 8 h. Adverse effects include renal tubular damage, malaise, nausea and headache. Tremor and hallucination may occur at high dosage.

Antiparasitic agents

Drugs that are used to treat parasitic infections which affect the skin include antibacterial agents such as metronidazole and co-trimoxazole as well as those with specific activity against parasites. This section is largely concerned with the latter group.

Drugs used to treat roundworms

The benzimidazoles. Mebendazole and albendazole are the best known of these compounds. Mebendazole (methyl 5-benzoylbenzimidazole-2 carbamate) is a synthetic drug that is active against diverse species such as *Ascaris*, *Enterobius* and *Trichuris* [1]. It is also active against the adult forms of *Trichinella spiralis* and some filariae such as *Loa loa*. It works through blocking the assembly of microtubules. It is poorly absorbed from the gastrointestinal tract. Adverse events are not common and are mainly seen at high dosage. The more common but trivial side effects are abdominal pain and diarrhoea.

Albendazole (methyl 5-*N*-propoxythio-2-benzimidazole carbamate) has broad-spectrum activity for parasites from *Ascaris* to *Trichuris* [2,3]. Albendazole is absorbed after oral administration but this is enhanced in the presence of a fatty meal. Once again it is well tolerated and abdominal pain and diarrhoea are the main side effects. Liver and bone marrow toxicity occur only at high dosage.

Tiabendazole is less used than previously. It is well absorbed and is active against a range of nematodes as well as some fungi. However, side effects such as nausea and vomiting are common.

Diethylcarbamazine

Diethylcarbamazine (DEC) is discussed in Chapter 32. It is a piperazine derivative used in the treatment of microfilariae [4]. It rapidly kills these microorganisms, an event that leads to considerable inflammation, which can cause damage in the eye and skin. It acts by affecting microfilarial muscle activity and affects their membranes, leading to increased host killing capacity. In onchocerciasis it can cause severe itching, oedema, erythema and hypotension—the DEC reaction. The dosage is usually built up from an initial 50-mg dose, depending on the infection.

Ivermectin

This is a macrocyclic lactone derived from avermectin B1, which is used for intestinal parasites in animals and for the management of onchocerciasis and other nematode infections [5–7]. It blocks the transmission of signals from interneurones to excitatory motor neurones. It is also effective against *Sarcoptes scabiei*. Its advantage in onchocerciasis is that it is microfilaricidal but does not lead to severe inflammatory responses. Ivermectin is well absorbed after oral administration. Side effects are not common but include fever, itching and headache. A mild DEC-like reaction may occur in some patients. Its usual dose is 150 µg/kg orally, repeated when necessary every 6–12 months.

Pentavalent antimony

The main variants used for the treatment of leishmaniasis are sodium stibogluconate and meglumine antimoniate. Neither is orally active and both have to be given parenterally (intramuscularly or intravenously) [8]. There is a slow elimination phase, which may give rise to toxicity at high dosage. Common adverse events include abdominal pain, nausea and headache [9]. Other effects are renal impairment, pancreatitis and alterations in electrocardiogram (ECG) and cardiac arrhythmias. In particular the Q–T interval may be prolonged.

Drugs to improve the peripheral circulation

Raynaud's phenomenon and perniosis are the principal dermatological indications for systemic vasodilator therapy. Raynaud's phenomenon occurs in a primary, usually mild, form unassociated with systemic disease, or secondary to various underlying causes. The most common of these is connective tissue diseases; others include hyperviscosity disorders, cervical rib, drugs with a vasoconstrictor action and, rarely, occupational causes (see Chapter 23). The management of Raynaud's phenomenon has been extensively reviewed [1–4], and includes the use of calcium-channel blockers, angiotensin II receptor antagonists, prostacyclin analogues, serotonin antagonists, calcitonin gene-related peptides and newer agents such as endothelin-1 receptor antagonists and nitric oxide donors.

Calcium-channel blocking agents are of moderate benefit, and of these nifedipine is the treatment of choice [5,6]. It acts by inhibiting contraction of smooth muscle cells by reducing the cellular uptake of calcium, a process fundamental to vasospasm; it also reduces platelet aggregability. Modified release nifedipine 20–60 mg/day is usually effective. Diltiazem is also useful, but verapamil less so. Side effects include flushing, headaches and peripheral oedema. The response of primary Raynaud's phenomenon is usually more impressive than that secondary to connective tissue disease. Use of calcium-channel antagonists can occasionally precipitate erythromelalgia [7]. The angiotensin II receptor type 1 losartan has been recorded as useful in Raynaud's phenomenon [8].

Severe Raynaud's phenomenon (see Chapter 23), especially that secondary to systemic sclerosis and other connective tissue diseases, is more difficult to treat and may be poorly responsive to nifedipine. For these patients, intravenous prostacyclin or one of its stable analogues such as iloprost may be necessary [9–14]. Prostacyclin inhibits platelet adhesion and aggregation, and vascular smooth muscle proliferation, increases red cell deformability, and decreases blood viscosity. For reasons that are poorly understood, it causes sustained clinical benefit, a single low-dose infusion (0.5 ng/kg/min) often causing clinical remission for several weeks. Side effects include flushing, headaches and hypotension.

The serotonin antagonist ketanserin is not clinically beneficial [15], but fluoxetine, a selective serotonin-reuptake inhibitor, has been reported to be effective [16], as have dazoxiben, a thromboxane synthetase inhibitor

[17], and prazosin [18]. α-Adrenergic-blocking agents (e.g. thymoxamine, a non-selective α-adrenoceptor blocker) 40 mg three times daily, or prazosin, a selective α-adrenergic-blocking agent, 0.5–1.0 mg three times daily, may suffice in mild cases. The use of intravenous calcitonin gene-related peptide (CGRP) has been recommended for severe Raynaud's phenomenon [19]. CGRP, which was given in a dosage of 0.6 μg/min for 3 h/day on 5 consecutive days, causes flushing, diarrhoea, headache and hypotension.

Perniosis also responds well to calcium-channel antagonists. A double-blind cross-over placebo-controlled study of nifedipine in 10 patients [20] showed a convincing response in the nifedipine phase of the trial. Other drugs reported anecdotally to improve the peripheral circulation include oxpentifylline (pentoxifylline), fibrinolytic agents including stanozolol, and low-molecular-weight dextran infusion.

Miscellaneous drugs used in special ways in dermatology

Antimalarials

A variety of drugs have been used in the treatment of malaria. However, for over 35 years it has been well known that several of these drugs may have other useful properties in the management of skin diseases [1,2]. There are several diseases where there is an undoubted beneficial effect: discoid and systemic lupus erythematosus, polymorphic light eruption and solar urticaria (see Chapters 56 and 24). They are of some value in rheumatology, where there is a resurgence of their use, as well as their more obvious application in diseases caused by some protozoa. Their use in porphyria cutanea tarda and sarcoidosis is discussed elsewhere (see Chapters 57 and 58).

The mode of action of antimalarials is complex and their usage is largely on empirical grounds. They can interfere with many biological processes. They bind to DNA, stabilize membranes, inhibit hydrolytic enzymes, interfere with prostaglandin synthesis and block chemotaxis [1,2].

The major problem with chloroquine is retinopathy and potential blindness [3,4]. There are considerable problems in defining the criteria for the diagnosis of retinopathy and the estimate that 3–5% of patients who receive the drug may develop this complication is almost certainly too high. A number of questions remain unanswered. It is generally agreed that the risk to the retina of giving chloroquine sulphate 250 mg/day for 3 months is virtually negligible, although the drug is cumulative to some extent from one year to another. It has long been thought that it is the total cumulative dose that determines the retinal toxicity. It has been suggested that it is the daily dose that counts and that 4 mg/kg/day chloroquine is likely to be safe [5].

Because of the potential retinopathy with chloroquine, hydroxychloroquine or mepacrine are the two antimalarial drugs now used. Hydroxychloroquine is more effective than mepacrine but is said to have some ocular toxicity, albeit less than with chloroquine. It is likely that in the dosage used by dermatologists (up to 400 mg/day) the risk of ocular toxicity is negligible. In many hospitals, the ophthalmologists will not agree to screen or monitor patients as they think the risk is so small, but if hydroxy-

chloroquine is continued for more than a few months it would seem prudent to obtain ophthalmological screening, which should also be sought before starting treatment. Mepacrine lacks ocular toxicity, and is often an effective drug, especially in discoid lupus erythematosus and Hutchinson's chilblain lupus. In effective dosage (200 mg/day), it usually causes the skin to turn yellow and occasionally produces lichenoid reactions. Ocular toxicity of antimalarials as used in dermatology is well reviewed by Cox and Paterson [6].

Dapsone and sulfapyridine [1–5]

Dapsone (DDS) has been the mainstay in the treatment of leprosy for many years (see Chapter 29). It also has some action against malaria and other parasites, and has also proved a very valuable drug in the management of a wide range of mainly uncommon dermatoses. Its mode of action is not fully understood. Although many of the diseases found empirically to respond to this drug have in common the involvement of either polymorphs or immune complexes, the metabolic action of dapsone cannot be explained simply in these terms. The diseases for which dapsone is particularly effective are dermatitis herpetiformis and erythema elevatum diutinum. Other diseases also favourably but not invariably influenced include other bullous diseases (pemphigoid, mucous membrane pemphigoid, linear IgA disease, chronic bullous disease of childhood, bullous eruption of systemic lupus erythematosus, subcorneal pustular dermatosis), pyoderma gangrenosum, rheumatoid arthritis and collagen diseases, relapsing polychondritis, acne conglobata, leukocytoclastic vasculitis and granuloma faciale.

Toxicity is a considerable problem with dapsone but overall the drug has probably fewer long-term side effects than do corticosteroids or sulfapyridine. The main toxic side effect is haemolysis, which is not usually dependent on glucose-6-phosphate dehydrogenase deficiency, although that enzyme defect may compound the problem. Some haemolysis is almost invariably found on therapeutic dosage. Methaemoglobinaemia is also common and is responsible for the bluish lips commonly seen in patients on this drug. A level of 3% methaemoglobinaemia is often unnoticed, 12% may be acceptable, but 20% is usually not. Regular blood checks of haemoglobin and reticulocytes but also including white cells and platelets should therefore be undertaken in all patients for the first few months after starting dapsone. Dapsone has several other but less common side effects, including agranulocytosis, peripheral neuropathy, drug rashes, renal damage, hypoalbuminaemia, cholestasis, psychoses and reversible male infertility. A dosage of 100 mg/day is often used as a starting dose. Many patients with dermatitis herpetiformis can be controlled on very much less. Some diseases can only be controlled by larger doses, but the incidence of side effects then rises very sharply and most dermatologists prefer not to exceed a dosage of 100–150 mg/day. It is possible to reduce dapsone-dependent methaemoglobinaemia by the concomitant administration of cimetidine (400 mg three times daily) [6].

Other drugs that share some of the useful assets of dapsone include sulfapyridine and, to a lesser extent, sulfamethoxypyridazine. Sulfapyridine is in general less effective than dapsone and, in doses that are effective, tends to cause more side effects, especially marrow suppression, although not haemolysis. The usual dose is 0.5 g twice or three times daily.

Clofazimine

This antileprotic drug has also been used especially in pyoderma gangrenosum and in lupus erythematosus and Sweet's disease.

Sulfasalazine

This drug is best known for its activity in inflammatory bowel disease and rheumatoid arthritis with their associated skin problems. The mode of action is uncertain [1,2]. It is not very well absorbed from the gut and does have side effects. Among other activities it may be a 5-lipoxygenase inhibitor. It has been found to be of some value in pustular psoriasis, arthropathic psoriasis and psoriasis vulgaris [1–5]. Its use in other conditions such as dermatitis herpetiformis, scleroderma and acne [6] has been recommended but is less well established. Sulfasalazine

has been reported to be useful in metastatic cutaneous Crohn's disease [7,8]. A recent report suggested benefit in a minority of patients with alopecia areata [9].

Thalidomide

Thalidomide is an interesting drug but it is linked with the causation of severe birth defects, so that its use is very restricted, and it must never be given to pregnant women. It also has other toxic side effects, notably peripheral neuropathy [1–3]. It can be helpful in severe leprosy reactions (see Chapter 29). It may also be beneficial in some but by no means all patients with nodular prurigo [4], lupus erythematosus [5–7], actinic prurigo and other light-sensitive dermatoses, aphthosis [8], Behçet's disease, Weber–Christian disease, pyoderma gangrenosum, sarcoidosis, graft-versus-host disease, adult Langerhans' cell histiocytosis [9] and certain dermatological conditions associated with HIV infection [10]. It is a drug the use of which must always be kept under the strictest control and it must be used only by patients who are able to understand the problems. It is important to check regularly for peripheral neuropathy. Guidelines for the clinical use and dispensing of thalidomide have been drawn up [11–13].

Colchicine [1–3]

Colchicine has been used in the treatment of gout for many centuries and is still a valuable remedy. It is also of use in familial Mediterranean fever. It has an antimitotic action (for which it is sometimes used topically) but its useful anti-inflammatory effects in skin diseases probably depend more on its suppression of various aspects of polymorph activity, notably chemotaxis. It may also inhibit histamine release from mast cells. Its use is somewhat restricted by its side effects, especially those on the gastrointestinal tract, but the bone marrow and kidney may also be affected. It should be avoided in pregnancy. It is not therefore a first-line drug but can prove of value in Behçet's disease [4], chronic bullous dermatosis of childhood (linear IgA disease) [5], pustular psoriasis [6], relapsing polychondritis [7], leukocytoclastic vasculitis, urticarial vasculitis [8], epidermolysis bullosa acquisita [9] and Sweet's syndrome—all diseases in which polymorphs are presumed to have a role. A common regimen is 0.5–1 mg/day orally, although larger doses are used by rheumatologists.

Traditional Chinese herbal medicine

The treatment involves taking a 'tea' prepared from a decoction of plant materials. Usually 10 or so plant materials are included. Trials have also been performed using a tablet form of treatment (Zemaphyte®) and showed a beneficial response in children [1] and adults [2] with atopic eczema. Even when treatment is effective and continued, the benefit often wears off after 6–12 months. Relapses occur once treatment is stopped. Of concern are the reports of hepatotoxicity [3–6] and renal toxicity [7] potentially associated with Chinese herbal remedies. While Chinese herbs cannot yet be recommended for the routine treatment of children with atopic eczema, they did help approximately half of the children who took part in the Great Ormond Street Hospital Trial [8]. Further adequate randomized controlled trials are necessary [9]. Chinese herbs have also been advocated for psoriasis [10].

Transdermal delivery systems

The blood is the target for penetration in transdermal delivery systems. There are two major routes for drug penetration through skin: the stratum corneum, and shunts via hair follicles and eccrine sweat gland ducts [1].

With drugs metabolized in the liver, achievement of therapeutic blood levels is enhanced by transdermal delivery because the 'first pass' effect inherent in oral administration is avoided. Thus, transdermally delivered drugs show reduced differences in 'peak' and 'trough' blood levels, and a different profile of metabolites [2]. Efficiency of transdermal delivery is greater with lipid-soluble drugs. Additional advantages include ability to use short half-life drugs, better patient compliance, reduced dosage frequency, avoidance of unpredictable intestinal absorption and gastric irritation, and fewer complications.

Recent examples of drugs marketed in a transdermal form include scopolamine, clonidine, nitroglycerine, estradiol, nicotine and prostaglandin E1 ethyl ester for the treatment of trophic acral skin lesions in systemic scleroderma [3]. Within the transdermal 'patch', the drug, which may be formulated in a liquid, solid, ointment or cream form, behaves as a reservoir. The blood levels are proportional to the active surface area of the 'patch', and drug delivery occurs over a period of 1–7 days. Skin irritation and sensitization are significant difficulties with transdermal delivery systems, which contain several sources of problems besides the drug itself, including the adhesive, vehicle penetration enhancers and polymers. More advanced transdermal delivery systems are now available that should enable continuous or pulsed delivery of new drugs including genetically engineered products [3].

Chapter 73

Drug Reactions

S.M. Breathnach

Introduction [1–4]

A drug may be defined as a chemical substance, or combination of substances, administered for the investigation, prevention or treatment of diseases or symptoms, real or imagined. The distinction between drugs and 'other chemicals' is not always easily made, as chemicals of very diverse structure are increasingly added to foods and beverages as dyes, flavours or preservatives. Such chemicals may cause harmful side effects. Moreover, chemicals used in agriculture or in veterinary medicine may contaminate human food. In addition, with the advent of therapeutic agents that may be useful for improving the appearance, as with minoxidil for androgenetic alopecia and tretinoin for photo-aged skin, the distinction between drugs and cosmetics has become blurred [5].

An adverse drug reaction (ADR) may be defined as an undesirable clinical manifestation resulting from administration of a particular drug; this includes reactions due to overdose, predictable side effects and unanticipated adverse manifestations. Another definition is that of 'an appreciably harmful or unpleasant reaction, resulting from an intervention related to the use of a medicinal product, which predicts hazard from future administration and warrants prevention or specific treatment, or alteration of the dosage regimen, or withdrawal of the product' [6]. It has been proposed that therapeutic ineffectiveness should also be regarded as an ADR [7]. ADRs may be said to be

the inevitable price we pay for the benefits of modern drug therapy [8]. They are costly both in terms of the human illness caused and in economic terms, and can undermine the doctor–patient relationship.

Sometimes, ADRs result from human error [9]. In one study, 0.9% of 530 medication errors resulted in ADRs [10]; these usually involved errors at the ordering stage, but also occurred at the administration stage [11]. In hospitals, medication errors occur at a rate of about one per patient per day; dispensing errors made by pharmacy staff range from 0.87 to 2.9% [12]. ADRs are under-reported and are an underestimated cause of morbidity and mortality; it has been estimated that ADRs represent the fourth to the sixth leading cause of death [13]. The actual frequency of fatal adverse drug events is unknown; estimates in the USA are as high as 140 000/year, although this number is heavily disputed [14]. In one study, 68% of fatal ADRs were judged to have been preventable; of these, a pharmacist could have prevented 57% [15]. Approximately 1 in 2000 of all deaths for which there were records of coroner's inquests in one district were related to drugs; of these, 20% were due to errors [16]. During 1995, 206 deaths were attributed to ADRs on death certificates in the USA, but the spontaneous post-marketing surveillance system (MedWatch) of the Food and Drug Administration (FDA) tabulated 6894 fatalities. The numbers of deaths in these datasets varied 34-fold and were up to several 100-fold less than values based on extrapolations of surveillance programmes [17]. Confusion may occur between drugs with similar spelling of their brand names [18,19]. It has been proposed that licensing authorities should exercise more control over the naming of new proprietary formulations, that non-proprietary and new proprietary names should be internationalized, and that doctors should issue printed prescriptions if possible [20].

The average extra length of stay for patients with an adverse drug event in one study in the USA was 1.9 days, and the average extra cost of hospitalization was $1939 [21]. In another study, at a university-affiliated hospital, the mean cost of an ADR or medication error varied from $95 for additional laboratory tests to $2640 for intensive care; the estimated total cost for the medication-related problems reported in 1994 was almost $1.5 million [22]. In a European study, ADRs occurred at 10.1 per 1000 patient-days, and the cost of ADRs leading to hospitalization was estimated at €11 357 per hospital bed per year [23]. Another estimate of the cost of an ADR during hospitalization or leading to hospitalization was approximately €2800 [24]. Litigation was reported for 14% of fatal ADR cases at one centre; judgements and settlements averaged $1.1 million [15]. Drug reactions, principally to corticosteroids and methotrexate, accounted for 32% of claims and 26% of dollar losses in dermatology malpractice suits in the USA from 1963 to 1973 inclusive [25]. Medication side effects, most frequently to corticosteroids, antibiotics and chemotherapeutic agents, represented 26% of lawsuits in a study of dermatology residency programmes in the USA between 1964 and 1988 [26]. If legal consequences are to be avoided, consistent care is needed at every stage from drug manufacture to administration [27].

It is in everyone's interests to minimize the chances of their occurrence, and to this end government regulatory bodies and the pharmaceutical industry collaborate to ensure adequate screening of new products. In addition to extensive *in vitro* and animal testing, prolonged and strictly controlled clinical trials are essential. Even so, hazards cannot be completely eliminated, for a serious reaction of low incidence may not be suspected until a very large number of patients have been treated with a new drug. Premarketing clinical trials conducted before a new drug is licensed will not identify adverse reactions occurring in less than 0.1–1% of patients, or those occurring only after prolonged administration, or with a long latency period, or only in susceptible patients, or when the drug is combined with some other factor, such as another drug [28,29].

Another problem is that only a very small fraction of all adverse reactions are ever reported to monitoring agencies, and first warning is still often given by anecdotal reports published in medical journals [30,31]. Many of these reports are subsequently validated but a substantial proportion of poorly documented reports are not [31,32]. In an analysis of 5737 articles from 80 countries between 1972 and 1979, only half the reports contained enough information for the calculation of the frequency of a particular reaction [32]. The usefulness of anecdotal case reports has again been called into question [33]. As incorrect reports may have serious legal and other consequences, a heavy responsibility rests with medical editors; a chance association or coincidental reaction should not be allowed to enter the literature. Criteria for assessment of potential drug reactions have been promulgated and include recurrence on challenge; existence of a pharmacological basis for the reactions; the occurrence of immediate acute or local reactions at the time of administration, of previously known reactions with a new route of administration, or of repeated rare reactions; and the presence of immunological abnormalities [31,34]. In the assessment of an unrecorded new reaction, the existence of similar but unpublished reports to the manufacturer or to the Committee on Safety of Medicines is of particular importance.

Incidence of drug reactions [1,2]

Data collection

It is difficult to obtain reliable information on the incidence of drug reactions, despite attempts at monitoring by government and the pharmaceutical industry. One problem is the lack of standardized coding for drug reactions [3]. Moreover, the information that is available must be interpreted with considerable care, because data will be biased, depending on the method of collection [1,2]. Thus, data on medical in-patients, especially from acute care facilities, may indicate a relatively high incidence, because these patients are generally sicker and receive more intensive drug treatment. In contrast, spontaneous reporting may underestimate the true incidence [4]. National schemes for collating reported ADRs exist in many countries, and the World Health Organization's Adverse Reaction Collaborating Centre, in Uppsala, provides a very large database [2], as does the Adverse Event Reporting System of the US FDA [5,6]. The UK's 'yellow card' reporting scheme solicits ADR reports from doctors, dentists, coroners, and drug manufacturers; the wide availability of reporting forms is important in encouraging reporting [2]. The scheme has recently encouraged reporting by nursing staff, midwives and health visitors [7]. Yellow reporting cards may be obtained electronically on http://www.mca.gov.uk/yellowcard. Pharmacists also play an important role in reporting ADRs [8]. The advisability of direct reporting of ADRs by patients is becoming an increasingly important topic for discussion in the world of pharmacovigilance [9]. 'Pharmacovigilence' in France, which involves reporting to regional centres, along with most other national schemes, also relies entirely on spontaneous reporting [10,11]. Institution of an ADR reporting project in Rhode Island in the USA increased the rate of reporting of such reactions more than 17-fold over a 2-year period [12]. The quality of ADR reporting to the FDA improved following introduction of the MedWatch scheme [13]. Specialty-based systems for spontaneous reporting of ADRs (e.g. the Adverse Drug Reaction Reporting System of the American Academy of Dermatology [14] and the Gruppo Italiano Studi Epidemiologici in Dermatologia [15]) have been introduced. In the UK, in contrast, the speciality-based Cutaneous Reactions Database established at the Institute of Dermatology in 1988 was unfortunately closed in 1990 because of a meagre response [16].

Reporting of ADRs in clinical trials is neglected, compared with efficacy outcomes; of 192 randomized trials analysed, only 46% specified reasons for withdrawals due to toxicity, and only 39% of clinical adverse effects and 29% of laboratory-determined toxicity were adequately documented [17]. Inherent difficulties with spontaneous reporting are that reactions associated with newly marketed drugs, those of unusual morphology, and reactions starting soon after initiation of therapy are more likely to be notified; at best only a crude estimate of true incidence is provided [18–20]. Thus, drugs with a high potential for eliciting clinically significant ADRs are usually detected and either withdrawn from the market or placed on

restricted use within the first year or two of marketing [21]. In contrast, spontaneous reports do not reliably detect ADRs widely separated in time from the original use of the drug, or that occur more commonly in populations not usually exposed to the drug [22]. They are an unreliable measure of risk, and may simply provide evidence of the relative awareness among physicians of specific toxic effects [23].

All national spontaneous reporting systems are compromised by under-reporting [2,4]; in the UK, surveys suggest that only around 10% of serious reactions are notified to the Committee on Safety of Medicines [24,25]. A survey of 44 000 patients receiving one or other of seven new drugs suggested that under-reporting by the spontaneous system may be as high as 98% when compared with information collected by the more objective 'event monitoring' system [10]. Heavy prescribing by a minority of doctors immediately following licensing may place patients at unnecessary risk, and affects safety monitoring of new drugs; the 10% of doctors who prescribed most heavily accounted for 42% of total prescribing in a survey of 28 402 general practitioners asked to supply post-marketing data on 27 new drugs dispensed in England between September 1984 and June 1991, but returned proportionately far fewer questionnaires [26]. Reasons for under-reporting include lack of time, lack of report forms and the misconception that absolute confidence in the diagnosis of an adverse reaction was important [27]; workload may affect reporting [28]. Another factor is the perceived deterrent to reporting ADRs caused by fear of involvement in litigation [29]; reporting of errors should be free of recrimination [30]. The offer of a small fee increased the rate of reporting in one hospital study almost 50-fold [31].

Pharmacoepidemiology, the epidemiological assessment of adverse drug effects, and pharmacovigilance, the process of identifying and responding to safety issues about marketed drugs, necessitate making use of information from clinical trials, spontaneous reporting systems, specialty-based reporting systems, case reports, prescription monitoring, case series, cohort studies, case–control studies, population-based registries using computerized material, and special surveillance programmes (e.g. Boston Collaborative Drug Surveillance Program in the USA) [32–34]. Crude inspection of lists of spontaneously reported drug-event combinations can be supplemented by quantitative and automated numerator-based methods such as Bayesian data mining; pharmacovigilance specialists should not be intimidated by the mathematics [35]. Computerized detection of adverse events may soon be practical on a widespread basis [36]. This is just as well, as it has been estimated that the top 20 drug companies will each need to launch four to six times the number of drugs they currently produce merely to maintain shareholder returns, with more trials, and more safety reports for evaluation [37].

General incidence of adverse drug reactions

The incidence of ADRs varies from 6% [1] to 30% [2], with at least 90 million courses of drug treatment given yearly in the USA [3]. The reported percentage of patients who develop an ADR during hospitalization varies markedly in different studies from 1.4 to 44%, although in most studies the incidence is about 10–20% [4–6], of which about one-third are allergic or pseudoallergic [6]. In one study, 0.23% of a total of 90 910 admissions had drug allergy; antimicrobials and antiepileptic drugs comprised 75% of the drug allergies reported [7]. The incidence of drug allergy in hospitalized patients was 4.2 per 1000; drug allergy developed during in-patient treatment in 2.07 per 1000 hospitalizations [7]. About 3–8% of hospital admissions are a consequence of ADRs [8–10]. A survey of 30 195 randomly selected hospital records in 51 hospitals in the state of New York found that 19% of adverse events caused by medical treatment were the result of drug complications; the most frequently implicated classes of drugs were antibiotics, antitumour agents and anticoagulants [11]. Negligence accounted for 18% of ADRs, while allergic/cutaneous complications constituted 14% of all drug-related complications.

Less information is available about the incidence among outpatients. It has been estimated that about 1 in 40 consultations in general practice is the result of ADRs [12], and eventually 41% of patients develop a reaction [13]. In one multicentre general practice study in the UK, the percentage of consultations involving an ADR increased from 0.6% for patients aged 0–20 years to 2.7% for patients aged over 50 years [14]; in another study, 2.5% of consultations were the result of iatrogenic illness [15].

Fatal reactions to drugs are more common than is generally realized. It was previously estimated that penicillin caused 300 deaths each year in the USA alone [16]. Anaphylactic reactions to penicillin were reported in 1968 to occur in about 0.015%, and fatal reactions in up to 0.002% (i.e. 1 per 50 000), of treatment courses [17]. These figures may be somewhat less today, with use of newer β-lactam antibiotics. The risk of fatal aplastic anaemia with chloramphenicol therapy was reported as at least 1 in 60 000 [18], and the risk of a fatal outcome from treatment with monoamine oxidase inhibitors may be of the same order. It has been estimated that the incidence of fatality as a result of a drug reaction among in-patients is between 0.1 and 0.3% [5,19,20]; fatality due to allergy occurs at a rate of 0.09 per 1000 cases [7].

Risk of adverse drug reactions among different patient groups

Certain patient groups are at increased risk of developing an ADR. Women are more likely than men to develop ADRs [1]. The incidence of such reactions increases with the number of drugs taken in both hospital in-patients [2–4] and outpatients [5,6]. Although data are somewhat conflicting [7], the burden of evidence suggests that the incidence of adverse reactions increases with patient age [1,8,9]. Although those over 65 years of age comprise only 12% of the population in the USA, 33% of all drugs are prescribed for this age group, and the elderly have a significantly higher incidence of ADRs, related to decreased organ reserve capacity, altered pharmacokinetics and pharmacodynamics, and polypharmacy [10]. Similarly, in

the UK the elderly are dispensed twice as many prescriptions as the national average [11]. Potential adverse drug interactions are more common in elderly patients because of the higher number of concurrent medications, rather than age-based factors [12].

ADRs contribute to the need for hospitalization in 10–17% of elderly inpatients [13–15]. Inappropriate medication is a major cause of ADRs in elderly patients; 27% of elderly patients on medication admitted to a teaching hospital experienced ADRs, of which almost 50% were due to drugs with absolute contraindications and/or that were unnecessary [16]. ADRs occur in 6–17% of children admitted to specialist paediatric hospitals [17].

Patients with Sjögren's syndrome (SS) have also been reported to have a high frequency of drug allergy. In different series, drug allergy has been reported in 43% of SS patients compared with 9% of patients with systemic lupus erythematosus (SLE) without SS [18], in 62% of SS patients [19], and in 41% of rheumatoid arthritis patients with SS compared with 17% of those without SS [20]. Antibiotic allergy is increased in SLE [21].

Acquired immune deficiency syndrome

Patients with acquired immune deficiency syndrome (AIDS) appear to be at increased risk for ADRs [1–7], up to 100-fold by some estimates [7]. The reasons are likely to be multifactorial, and include changes in drug metabolism, oxidative stress, cytokine profiles and immune hyperactivation. Human immunodeficiency virus (HIV)-positive individuals have been postulated to have a systemic glutathione deficiency, resulting in a decreased capacity to scavenge reactive hydroxylamine derivatives of sulphonamides, although this has been disputed (see pharmacogenetic mechanisms of drug reactions, p. 73.13). In the past, drugs especially implicated included sulphonamides such as co-trimoxazole (trimethoprim–sulfamethoxazole) [8–14], other sulphur congeners, for example dapsone [15], pentamidine, antituberculosis regimens containing thioacetazone (thiacetazone) [16,17] or isoniazid and rifampicin, amoxicillin–clavulanate [18,19], clindamycin, pyrimethamine [20] and thalidomide. Patients with AIDS are more likely to have particularly severe reactions, ranging from erythema multiforme to toxic epidermal necrolysis (TEN) (especially with sulphonamides, clindamycin, phenobarbital (phenobarbitone) and chlormezanone) [21,22], and to demonstrate multiple cutaneous drug reactions [3] (see Chapter 74). Drugs that are implicated in hypersensitivity have changed since the advent of highly active antiretroviral therapy, including abacavir, non-nucleoside reverse transcriptase inhibitors such as nevirapine, and protease inhibitors such as amprenavir [7]. There has been a decrease in the use of antimicrobials such as co-trimoxazole, and in Europe nevirapine has replaced sulphonamides as the leading cause of Stevens–Johnson syndrome and TEN related to AIDS [23] (see also Chapter 74).

Drug reaction frequency in relation to types of medication

The incidence of reactions to a particular drug must obviously be related to the quantity prescribed [1]. Nearly one in every 10 prescriptions in the USA in 1981 contained either hydrochlorothiazide or codeine [2]. One in every five prescriptions was for a diuretic or other cardiovascular drug; analgesics and antiarthritics constituted 13%, anti-infectives 13%, and sedatives and other psychotropics 11% of prescriptions. Of the 10 drugs most frequently reported by the yellow-card system to the UK Committee on Safety of Medicines in the first 6 months of 1986, seven were non-steroidal anti-inflammatory drugs (NSAIDs) (accounting for 74% of serious adverse reactions); the remaining drugs were the angiotensin-converting enzyme (ACE) inhibitors enalapril and captopril (accounting for 19% of serious reactions) and co-trimoxazole (accounting for 7% of serious adverse reactions) [3]. In another study, anti-inflammatory agents were the drugs responsible for almost 50% of the reactions necessitating admission to a general medical ward; most of the drug-related admissions to the hospital as a whole were caused by digoxin, phenytoin, tranquillizers, antihypertensives, cardiac depressants and antineoplastic agents [4]. ADRs accounted for 8% of 1999 consecutive admissions to medical wards in yet another study [5]; the drugs most frequently involved were antirheumatics and analgesics (27%), cardiovascular drugs (23%), psychotropic drugs (14%), antidiabetics (12%), antibiotics (7%) and corticosteroids (5%). Nitrofurantoin and insulin were associated with admission rates of 617 and 182 per million daily doses, compared with 10 for diuretics and seven for benzodiazepines. ADRs were responsible for the admission of 2% of 5227 consecutive patients to the University Hospital Centre in Zagreb [6]; drugs incriminated included acetylsalicylic acid (aspirin) (38%), other NSAIDs (23%), cardiovascular agents (20%) and antimicrobials (3%).

Incidence of drug eruptions (adverse cutaneous drug reactions)

Drug eruptions are probably the most frequent of all manifestations of drug sensitivity, at 24% of all ADRs in one study [1], although their incidence is difficult to determine. Even where the eruption is apparently the only manifestation, death can result from exfoliative dermatitis, erythema multiforme or TEN. For information on the incidence of drug-induced erythema multiforme, Stevens–Johnson syndrome and TEN, the reader is referred to Chapter 74. Epidemiological data suggest that a relatively small number of drugs are responsible most often for the most serious reactions [2]. Cutaneous reactions to common drugs such as digoxin, antacids, paracetamol (acetaminophen in the USA), glyceryl trinitrate, spironolactone, meperidine, aminophylline, propranolol, prednisone, salbutamol and diazepam are very rare.

The baseline rate of rash development, reflecting a variety of different causes, was similar for 36 marketed drugs

in the UK, at around 1 per 1000 patients per month from the second to the sixth month of one study; however, the rate for rash in the first month after prescription varied substantially from 0.9 to 6.4 per 1000 patients per month, and was highest for diltiazem [3]. Most estimates of the incidence of drug eruptions are inaccurate, because many mild and transitory eruptions are not recorded and because skin disorders are sometimes falsely attributed to drugs. There have been several studies of the incidence of drug eruptions [3–13]. The reaction rate has been reported as about 2% [6,9], or 5.5 adverse skin reactions per 100 000 of the population in four Italian regions [10].

A survey [8] of adverse cutaneous drug reactions (ACDRs) among in-patients found that one-third were fixed drug reactions, one-third were exanthematous and 20% were urticaria or angio-oedema; the high frequency of fixed drug reactions in this series reflects the fact that patients under study had been admitted to hospital. Antimicrobial agents were most frequently incriminated (42%), then antipyretic/anti-inflammatory analgesics (27%), with drugs acting on the central nervous system accounting for 10% of reactions. A few drugs gave specific reactions (e.g. phenazone salicylate caused a fixed eruption, and penicillin and salicylates caused urticaria); however, most were capable of causing several types of eruption. Morbilliform exanthematous eruptions, urticaria and generalized pruritus were the commonest reactions in other large series [9,13]. The average patient had received eight different medications, which contributed considerably to the difficulties in identifying the causative drugs [9]. Antibiotics, blood products and inhaled mucolytics together caused 75% of the eruptions; amoxicillin (51 cases/1000 exposed), trimethoprim–sulfamethoxazole (33 cases/1000 exposed) and ampicillin (33 cases/1000 exposed) caused the most reactions. Reaction rates varied in the range of 1–8% for several classes of antibiotic [13]. In a study of ACDRs among children and adolescents in northern India, antibiotics were responsible for most eruptions, followed by antiepileptics; co-trimoxazole was the commonest antibacterial culprit, followed by penicillin and its semi-synthetic derivatives, and then sulphonamides, with antiepileptics being the most frequently incriminated drugs in erythema multiforme, Stevens–Johnson syndrome and TEN [11]. A more recent study from India found that the drugs most often incriminated included antimicrobials (especially sulphonamides), anticonvulsants and NSAIDs [12]. Antimicrobials, NSAIDs, analgesics and radiological contrast media were the most frequent culprits in a study from Italy [10], and the most common drug classes involved in yet another study were cardiovascular agents (36%), contrast media (20%), drugs affecting blood clotting (13%) and anti-infectives (14%) [1].

Desensitizing vaccines, muscle relaxants, intravenous anaesthetics and radiological contrast media were the most frequent causes of anaphylaxis or anaphylactoid reactions reported to the UK Committee on Safety of Medicines in 1986/1987 [14]. The chairman of the Committee accordingly advised in 1986 that desensitizing vaccines only be given where full cardiorespiratory resuscitation facilities are available. Quinidine, cimetidine, phenylbutazone, hydrochlorothiazide (especially in combination with amiloride) and furosemide (frusemide) have also been frequently implicated in drug eruptions [15,16]. In the USA and the UK, antibiotics, hypnotics and tranquillizers are the most frequent offenders; on a reaction per dose basis, penicillin, warfarin and imipramine are the three drugs most frequently incriminated [17]. The prevalence of a history of penicillin allergy in the US population has been estimated to be between 5 and 10% [18]. An international study of 1790 patients from 11 countries documented the frequency of allergic reactions to long-term benzathine benzylpenicillin (benzathine penicillin) prophylaxis for rheumatic fever at 3.2%; anaphylaxis occurred in 0.2% (1.2/10 000 injections) and the fatality rate was 0.05% (0.31/10 000 injections) [19]. Reactions to sulphonamides may affect up to 5% of those treated [20]. Rashes occurred in 7.3% of children given commonly used oral antibiotics [21]. Based on the number of patients treated, the frequency of rash with cefaclor was 12.3%, with penicillins 7.4%, with sulphonamides 8.5%, and with other cephalosporins 2.6%.

Classification and mechanisms of drug reactions [1–11]

Drug reactions may arise as a result of immunological allergy directed against the drug itself, a reactive metabolite or some contaminant of the drug or, more commonly, by non-immunological mechanisms, such as pseudoallergic reactions caused by non-immune-mediated degranulation of mast cells and basophils. Autoimmune reactions, in which the drug elicits an immune reaction to autologous structures, may also occur. Drug reactions may be predictable (type A) or unpredictable (type B) (Table 73.1). About 80% of drug reactions are predictable, usually dose related, are a function of the known pharmacological actions of the drug and occur in otherwise normal individuals. Side effects are unavoidable at the regular prescribed dose. Unpredictable reactions are dose independent, are not related to the pharmacological action of the drug, and may have a basis in pharmacogenetic variation in drug bioactivation and drug or metabolite detoxification or clearance. Intolerance refers to an expected drug reaction occurring at a lower dose, and idiosyncratic and hypersensitivity reactions are qualitatively abnormal unexpected responses. Type C reactions include those associated with prolonged therapy (e.g. analgesic nephropathy), and type D reactions consist of delayed reactions (e.g. carcinogenesis and teratogenicity). The skin has a limited repertoire of morphological reaction patterns in response to a wide variety of stimuli, and it is therefore often impossible to identify an offending drug, or the pathological mechanism involved, on the basis of clinical appearances alone. We therefore remain relatively ignorant about the mechanisms underlying many clinical drug eruptions.

Non-immunological drug reactions

Overdosage

The manifestations are a predictable exaggeration of the desired pharmacological actions of the drug, and are directly related to the total amount of drug in the body. Overdosage may be absolute, as a result of a prescribing or dispensing error or due to deliberate excess intake by the patient. It may also occur despite standard dosage due to varying individual rates of absorption, metabolism or excretion (see below). An inappropriately large dose may be given to an infant or very old person or to one with renal impairment. Drug interaction (see below) may also cause drug overdosage.

Side effects

These include unwanted or toxic effects, which are not separable from the desired pharmacological action of the drug. Examples are the drowsiness induced by antihistamines; the atropine-like anticholinergic properties of some phenothiazines, many antihistamines, and tricyclic antidepressants; and the anagen alopecia caused by cytotoxic drugs.

Cumulative toxicity

Prolonged exposure may lead to cumulative toxicity. Accumulation of drugs in the skin may lead to colour disturbance, as a result of either deposition within phagocytic cells or mucous membranes (e.g. prolonged administration of gold, silver, bismuth or mercury) or binding of the drug or a metabolite to a skin component (e.g. high-dose chlorpromazine therapy).

Delayed toxicity

Examples are the keratoses and skin tumours that appear many years after inorganic arsenic, and the delayed hepatotoxicity associated with methotrexate therapy.

Facultative effects

These include the consequences of drug-induced alterations in skin or mucous membrane flora. Antibiotics that destroy Gram-positive bacteria may allow the multiplication of resistant Gram-negative species. Broad-spectrum antibiotics, corticosteroids and immunosuppressive drugs may promote multiplication of *Candida albicans* and favour its transition from saprophytism to pathogenicity. Corticosteroids promote the spread of tinea and erythrasma. Antibiotics such as clindamycin and tetracycline may be associated with pseudomembranous enterocolitis following bowel superinfection with *Clostridium difficile*.

Drug interactions

Interactions between two or more drugs administered simultaneously may occur before entry into the body (in an intravenous drip), in the intestine, in the blood and/or at tissue receptor sites; interaction may also occur indirectly as a result of acceleration or slowing in the rate of drug metabolism or excretion. It should be remembered that the adverse consequences of drug interactions may occur not only on introduction of a drug but also on removal of a drug that causes acceleration of drug metabolism, as this may result in effective overdosage of the remaining drug. The subject of drug interactions has been extensively reviewed [1,2]. Combinations of drugs with potential adverse interactions continue to be prescribed [3].

Intestinal drug interactions. Examples include inhibition of griseofulvin absorption by phenobarbital [1], inhibition of tetracycline absorption by antacids [4] and decreased absorption of the oral contraceptive by tetracycline [5]. Whether the latter is of real significance is a matter of debate [6].

Displacement from carrier or receptor sites. Most drugs are reversibly bound to carrier proteins in plasma or extracellular fluid; bound drug acts as a reservoir, preventing excessive fluctuation in the level of the active unbound fraction. Displacement from a carrier protein augments drug activity, whereas displacement from a receptor site diminishes it. Many acidic drugs such as salicylates, coumarins, sulphonamides and phenylbutazone are bound to plasma albumin, and compete for binding sites. Thus, a sulphonamide may displace tolbutamide from albumin leading to hypoglycaemia; or aspirin, sulphonamides, clofibrate or phenylbutazone may displace warfarin from albumin, causing bleeding and ecchymoses. Similarly, sulphonamides and aspirin may increase methotrexate toxicity. Ciprofloxacin increases plasma levels of theophylline.

Enzyme stimulation or inhibition [2]. A drug may either stimulate or inhibit metabolic enzymes important to its own degradation or that of another agent, with significant clinical consequences. Thus, some drugs induce synthesis of drug-metabolizing enzymes in liver microsomes. The liver microsomal hydroxylating system (which mediates metabolism of phenytoin and debrisoquine) is based on cytochrome P-450, and appears to be a family of enzymes capable of acting on different substrates including barbiturates, fatty acids and endogenous steroids. The cytochrome P-450-dependent system also catalyses deamination (e.g. amfetamine (amphetamine)), dealkylation (e.g. morphine, azathioprine), sulphoxidation (e.g. chlorpromazine, phenylbutazone), desulphuration (thiopental (thiopentone)) and dehalogenation (e.g. halogenated anaesthetics). This lack of specificity accounts for the ability of an inducing agent to stimulate metabolism of many other drugs, and of one drug to inhibit metabolism of a structurally unrelated drug. Antibiotics, if administered over a period of time (e.g. rifampicin for tuberculosis), can be enzyme inducers. Barbiturates stimulate metabolism of griseofulvin, phenytoin and coumarin anticoagulants, and griseofulvin induces increased metabolism of coumarins. Similarly, rifampicin, phenytoin and carbamazepine increase the metabolism of ciclosporin [7]. Drugs causing enzyme inhibition include chloramphenicol, cimetidine, monoamine oxidase inhibitors, *p*-aminosalicylic acid, pethidine and morphine. Dicoumarol, chloramphenicol and phenylbutazone inhibit metabolic inactivation of tolbutamide. Allopurinol inhibits metabolism of azathioprine and mercaptopurine by xanthine oxidase. Cimetidine inhibits liver enzymes and decreases

hepatic blood flow, thereby potentiating the action of some β-blockers (propranolol) and benzodiazepines, carbamazepine, warfarin, morphine, phenytoin and theophylline. Ketoconazole may potentiate oral anticoagulants [8] and erythromycin may potentiate carbamazepine [9]; both may potentiate ciclosporin. Nifedipine and ciclosporin are both metabolized by the same cytochrome P-450 enzyme, P-450cpn; ciclosporin potentiates the action of nifedipine, phenytoin and to a lesser extent valproate by decreasing P-450cpn availability by competitive inhibition [10].

Altered drug excretion. Examples include the well-known probenecid-induced reduction in the renal excretion of penicillin, and aspirin-induced reduction in renal clearance of methotrexate.

Metabolic changes

Drugs may induce cutaneous changes by their effects on nutritional or metabolic status. Thus, drugs such as phenytoin that interfere with folate absorption or metabolism increase the risk of aphthous stomatitis, and isotretinoin may cause xanthomas by elevation of very low-density lipoproteins [1].

Teratogenicity and other effects on the fetus [1–6]

The advent of isotretinoin has focused the attention of dermatologists considerably on the problem of teratogenicity in general [5]. The fetus is particularly at risk from drug-induced developmental malformations during the period of organogenesis, which lasts from about the third to the tenth week of gestation. Thalidomide, retinoids and cytotoxic drugs are proven teratogens. Heavy alcohol intake (which produces fetal alcohol syndrome), smoking, anticonvulsants (especially phenytoin and trimethadione (troxidone)), warfarin and antiplatelet drugs, inhalational anaesthetics, lithium, quinine, ACE inhibitors, misoprostol, certain antimicrobials (e.g. trimethoprim, aminoglycosides, 4-quinolones and itraconazole) and cocaine are probably teratogenic. High-dose corticosteroids have been linked to cleft palate. A major correlation has been found between the incidence of glucocorticoid-induced cleft palate and the chromosome 8 segment identified by *N*-acetyltransferase in mice [7]. 6-Aminonicotinamide-induced cleft palate and phenytoin-induced cleft lip with or without cleft palate are also influenced by this genetic region but not as strongly. Sex hormones, psychotropic drugs, benzodiazepines, tetracycline, rifampicin, penicillamine and the folate antagonist pyrimethamine are possibly teratogenic and should be avoided in the first trimester of pregnancy. Chlorpheniramine appears safe to use. The potential adverse effects on the fetus and on the breastfed infant of a number of drugs not infrequently used by the dermatologist have been reviewed [4].

Drugs may also cause fetal damage later in pregnancy. Warfarin may cause haemorrhage, and phenytoin near to term produces a coagulation defect in the neonate, which is correctable by vitamin K. Antithyroid drugs and iodides may cause neonatal goitre and hypothyroidism. Fetal adrenal atrophy may follow high-dose maternal corticosteroid therapy. NSAIDs have various ill effects, although aspirin has been advocated in pregnancy for the prevention of fetal growth retardation. Tetracyclines are deposited in developing bones and cause discoloration and enamel hypoplasia of teeth [8]. Aminoglycoside antibiotics are ototoxic, and chloroquine has caused a neonatal chorioretinitis. Androgens and progestogens may virilize the fetus. Diethylstilbestrol (stilboestrol) administered from early pregnancy for several months has been associated with female and male genital tract abnormalities, and carcinoma of the vagina 20 years later in the offspring.

Effects on spermatogenesis

Most chemotherapeutic agents potentially damage sperm; conception should also be avoided after griseofulvin for 3 months. A number of drugs cause oligospermia [1], which may come to light only as a result of infertility investigations; oestrogens, androgens, cyproterone acetate, cytotoxic drugs, including methotrexate given for psoriasis [2], colchicine, most monoamine oxidase inhibitors, ketoconazole and sulfasalazine (sulphasalazine) have all been incriminated. The synthetic retinoids isotretinoin and etretinate do not seem to affect the numbers of sperm [3,4].

Non-immunological activation of effector pathways (anaphylactoid reactions)

Certain drugs, such as opiates, codeine, amfetamine, polymyxin B, D-tubocurarine, atropine, hydralazine, pentamidine, quinine and radiocontrast media, may release mast cell mediators directly to produce urticaria or angio-oedema [1–7]. Some drugs, such as radiocontrast media, may activate complement by an antibody-independent method [8]. Anaphylaxis-like responses to cyclo-oxygenase inhibitors such as aspirin and other NSAIDs may lead to amplified mast cell degranulation and enhanced biosynthesis of lipoxygenase products of arachidonic acid, which cause vasodilatation and oedema [9,10]. ACE inhibitors, which cause or exacerbate angio-oedema, may potentiate bradykinin activity; they have been reported to enhance bradykinin-induced cutaneous weals in normal individuals [11,12].

Exacerbation of disease

Examples of adverse drug effects on pre-existing skin conditions include lithium exacerbation of acne and psoriasis, β-blocker induction of a psoriasiform dermatitis [1] and corticosteroid withdrawal resulting in exacerbation of psoriasis; cimetidine, penicillin or sulphonamide exacerbation of lupus erythematosus (LE); and vasodilator exacerbation of rosacea. Sometimes, a drug may unmask a latent condition, as when barbiturates precipitate symptoms of porphyria.

Intolerance

The characteristic effects of the drug are produced to an exaggerated extent by an abnormally small dose. This may simply represent an extreme within normal biological variation. Alternatively, the intolerance may be contributed to by delayed metabolism or excretion due to impaired hepatic or renal function, or by genetic variation in the rate of drug metabolism (see below).

Idiosyncrasy

This describes an uncharacteristic response, not predictable from animal experiments, and not mediated by an immunological mechanism. The cause is often unknown, but genetic variation in metabolic pathways may be involved. Such genetic abnormalities include glucose-6-phosphate dehydrogenase deficiency, hereditary methaemoglobinaemia, porphyria, glucocorticoid glaucoma and malignant hyperthermia of anaesthesia, all of which

are characterized by unusual pharmacological responses to various drugs.

Pharmacogenetic mechanisms and genetic influences underlying intolerance and idiosyncratic reactions [1–4]

The pharmacokinetics of drugs, including their absorption, plasma protein binding, distribution, metabolism and elimination, may be influenced by genetic factors. Oxidation, hydrolysis and acetylation are the three metabolic pathways most subject to genetic influence. Genetic factors also influence pharmacodynamics, i.e. tissue or organ responsiveness. Thus, genetic variations in all these areas may underlie both intolerance and idiosyncrasy. Variation in the regulation and expression of the human cytochrome P-450 enzyme system may play a key role in both interindividual variation in sensitivity to drug toxicity and tissue-specific damage [5]. Pharmacogenetic variability probably underlies reactions such as TEN. It has been proposed that most patients who have a severe ACDR have an abnormal metabolism of the offending drug [6].

Examples of genetically mediated intolerance include pupil size responses to phenylephrine and parasympatholytics, and the very rare dominantly inherited familial resistance to coumarin anticoagulants, the result of mutation in the receptor for vitamin K and anticoagulants. Low levels of red cell glucose-6-phosphate dehydrogenase, inherited as a sex-linked dominant trait, are common in black people, certain Levantine peoples and Filipinos, and result in a chronic deficit of reduced glutathione sulphydryl (SH) groups. Affected individuals are at risk of acute haemolysis on exposure to antimalarials, sulphonamides, dapsone, nitrofurantoin, phenacetin, aspirin and chloramphenicol, all of which may oxidize the few reduced SH groups in older red cells. Genetic variation in thiopurine methyltransferase activity may be linked to the side effects of azathioprine therapy, as homozygotes for the low-activity allele are at risk of myelosuppression, whereas homozygotes for high activity are inadequately immunosuppressed with conventional doses of azathioprine [7]. Increased susceptibility to aminoglycoside-induced deafness in two Japanese pedigrees was associated with a particular mitochondrial DNA polymorphism [8].

Oxidation. Anticonvulsants, many hypnotics, tricyclic antidepressants, anticoagulants and various anti-inflammatory and anxiolytic agents are eliminated by oxidation. For many drugs, oxidation rates vary as a continuous spectrum within the population. Genetic differences in metabolism of sulphonamides may underlie idiosyncratic toxicity [1–6]. Oxidative metabolism of sulphonamides by cytochrome P-450 enzymes and *N*-acetylation yields a reactive hydroxylamine intermediate [7], which is inactivated by glutathione conjugation. The hydroxylamine metabolite is toxic to lymphocytes, and the lymphocyte toxicity is markedly increased in patients with a history of hypersensitivity or with glutathione synthetase deficiency. HIV-positive individuals have been reported in some studies to have a systemic glutathione deficiency, resulting in a decreased capacity to scavenge hydroxylamine derivatives of sulphonamides, which may partially explain the increased frequency of sulphonamide reactions [8–10]. However, other studies have not been able to confirm intracellular glutathione deficiency in peripheral blood cells of HIV-infected patients [11,12].

Phenytoin, phenobarbital and carbamazepine are oxidized by the cytochrome P-450 enzyme system into potentially reactive arene-oxide intermediates; liver microsomal epoxide hydrolase converts such reactive intermediates to non-toxic dihydrodiols [13–17]. Phenytoin hypersensitivity syndrome appears to be associated with an inherited deficiency of epoxide hydrolase, which is primarily responsible for detoxifying the toxic arene-oxide intermediate [13–16]. Activated phenytoin has been shown to be toxic to lymphocytes from patients with phenytoin reactions and, to a lesser degree, to lymphocytes from their parents [15]. However, in another study a genetic defect altering the structure and function of the microsomal epoxide hydrolase protein was thought unlikely to be responsible for predisposing patients to anticonvulsant adverse reactions [17].

Culprit drug-reactive metabolites, generated by a microsomal oxidation system, had increased toxic effects on lymphoid cells from patients with TEN (13 each with sulphonamide and anticonvulsant reactions) and on those from first-degree relatives, whereas oxygen free radical and/or aldehyde detoxification pathways were normal [18].

Impaired metabolism of phenacetin and phenformin, inherited as a result of genetic polymorphism in liver

microsomal oxidation, may result in adverse reactions [19,20]. The induction of liver enzymes responsible for drug oxidation may itself be under genetic control [21]. There is a fourfold increase in toxicity to penicillamine in patients with rheumatoid arthritis with a genetically determined poor capacity to sulphoxidate the structurally related mucolytic agent, carbocysteine [22].

Hydrolysis. Genetic influence on drug hydrolysis is well illustrated in the case of suxamethonium, which normally results in only very brief neuromuscular blockade due to rapid hydrolysis by plasma pseudocholinesterase. Genetically determined atypical cholinesterases cannot hydrolyse the drug, leading to prolonged apnoea in affected individuals; conversely, dominantly inherited resistance to suxamethonium, mediated by a highly active cholinesterase, has been reported.

Acetylation. Isoniazid, many sulphonamides, hydralazine, dapsone, procainamide, etc. are inactivated by conversion to acetyl conjugates. Acetylation rates vary greatly, with a bimodal frequency distribution, and there is marked ethnic variation. Rapid inactivation is dominantly inherited, and is commonest among Eskimos and Japanese and least common among certain Mediterranean Jews. The LE-like syndrome due to procainamide may occur more in fast acetylators, implying that a conjugate and not the parent compound is responsible [1]. Slow acetylators, in whom higher and more persistent drug levels occur, are more liable to develop adverse reactions to isoniazid (pellagra-like syndrome and peripheral neuritis), dapsone (haemolysis) [2] and hydralazine (LE-like syndrome) [3,4]. A slow acetylation phenotype is a risk factor for hypersensitivity to trimethoprim–sulfamethoxazole in HIV-infected subjects [5,6], and for sulphonamide-induced TEN and Stevens–Johnson syndrome independent of HIV infection [7,8].

Influence of human leukocyte antigen (HLA) types. An association between HLA types and susceptibility to drug eruptions has been reported on several occasions, particularly in relation to gold (HLA-DRw3, HLA-DR5 and HLA-B8) and penicillamine toxicity [1–6]. Penicillamine toxicity is associated with HLA phenotypes as follows [1]: HLA-DR3 and HLA-B8 with renal toxicity; HLA-DR3, HLA-B7 and HLA-DR2 with haematological toxicity; HLA-A1 and HLA-DR4 with thrombocytopenia; and HLA-DRw6 with

cutaneous adverse reactions. DR1/DR4 heterozygosity, or the DR5 subtypes DRB1*1102 or DRB1*1201, have been found in 61% of patients with intolerance to tiopronin given for rheumatoid arthritis [7].

A positive association with HLA-Aw33 and HLA-B17/Bw58 haplotypes, and a negative association with the HLA-A2 haplotype, has been reported in southern Chinese patients with drug eruptions after exposure to allopurinol [8]. Aspirin-sensitive asthma is associated with HLA-DQw2 [9]. HLA-linkage associations with certain bullous disorders have been reported [10,11]. Hydralazine-induced LE is commonest in female patients with the HLA-DRw4 haplotype [12,13]. Fixed drug eruptions to feprazone and trimethoprim–sulfamethoxazole are linked, respectively, to HLA-B22 and HLA-A30 B13 Cw6 [14,15]. The above findings indicate that there may be genetic predisposition to develop certain drug eruptions.

Drug-induced chromosomal damage [1–3]

This may be studied by examining the chromosomes of patients or animals exposed to drugs, or *in vitro* by the addition of drugs to cell cultures; substances capable of inducing chromosomal damage are termed clastogens. Effects may be dose related, but *in vitro* results may not be representative of the *in vivo* situation. Antimitotic and antibiotic agents have been the most studied, although psychotropics, anticonvulsants, hallucinogens, immunosuppressants and oral contraceptives have also been investigated and shown to cause, in varying degree, chromosomal damage. Damage ranges from staining variations through 'gaps' in staining, chromosome breaks, gross aberrations (such as deletions, fragments, translocations and inversions) to polyploidy. Such damage may be stable and retained over a succession of cell divisions, or transient.

Miscellaneous

Jarisch–Herxheimer reaction

This is the focal exacerbation of lesions of infective origin when potent antimicrobial therapy is initiated, and is classically observed in the treatment of early syphilis with penicillin; it may also occur 3 days after starting griseofulvin therapy, during therapy with diethylcarbamazine for onchocerciasis and tiabendazole (thiabendazole) for strongyloidiasis, and with penicillin or minocycline for erythema chronicum migrans due to *Borrelia burgdorferi* infection [1]. The reaction has been attributed to sudden release of pharmacologically and/or immunologically active substances from killed microorganisms or damaged tissues. However, there is little evidence that it is an allergic reaction [2]. Clinically there may be fever, rigors, lymphadenopathy, arthralgia, and transient macular urticarial eruptions; a vesicular eruption has also been described [3].

Infectious mononucleosis–ampicillin reaction

Ampicillin almost always causes a severe morbilliform eruption when given to a patient with infectious

mononucleosis or lymphatic leukaemia (see later). The reaction occurs much less frequently with amoxicillin. The exact mechanism is not known, although a recent report suggests that real sensitization to ampicillin and amoxicillin occurs, and is detectable *in vivo* and *in vitro* by skin tests and the lymphocyte transformation test [1].

Immunological drug reactions

Allergic hypersensitivity reactions are caused by immunological sensitization to a drug, as a result of previous exposure to that drug or to a chemically related cross-reacting substance [1–7]. It has been estimated that only about 6–10% of ADRs are immunologically mediated [8]. Although drugs frequently elicit an immune response, clinically evident hypersensitivity reactions are manifest only in a small proportion of exposed individuals. Thus, using highly sensitive passive haemagglutination assays, IgM class antibodies to the penicilloyl group (the major hapten determinant derived from penicillin) are detectable in almost 100% of normal individuals, even in the absence of a history of penicillin therapy; 40% of patients receiving more than 2 g of penicillin for more than 10 days develop IgG class antibodies [9]. Macromolecular drugs such as protein or peptide hormones, insulin or dextran are antigenic in their own right. In contrast, most drugs are small organic molecules with a molecular mass of less than 1 kDa; conjugation of free drug as a hapten with a macromolecular carrier is then required to initiate an immune response [10]. Fortunately, many drugs have only a limited capacity to form covalent bonds with tissue proteins. Clinical sensitization may also result from allergy to reactive drug metabolites as haptens, or to minor contaminants.

Clinical features distinguishing allergic from non-allergic drug reactions. Prior exposure before sensitization should have been without adverse effect. If there has been no previous exposure, there should be a latent period of several days of uneventful therapy before the reaction supervenes, during which primary sensitization occurs. Thereafter, reactions may develop within minutes (or even seconds) and certainly within 24 h. Allergic reactions do not resemble the pharmacological action of the drug, may follow exposure to doses far below the therapeutic level, and are reproducible on readministration (if judged safe).

Factors concerned in the development of hypersensitivity. The route of administration of a drug may affect its immunogenicity and the nature of any allergy. Topical drug exposure is more likely to result in sensitization than oral administration, and favours development of contact dermatitis; thus, poison ivy is a potent contact sensitizer but oral ingestion may promote tolerance. Anaphylaxis is more likely to be associated with intravenous drug administration. However, anaphylaxis may sometimes occur as quickly after oral penicillin administration [11]. Whether allergy develops may also depend on the antigenic load in terms of degree of drug exposure, and individual genetic variation in drug absorption and metabolism. Thus, as stated above, an LE-like syndrome with antinuclear antibody formation following hydralazine therapy occurs more frequently in slow acetylators of the drug [12]. Hydralazine-related SLE is 10 times more frequent in HLA-DR4-positive patients than in the population at large, and is commoner in females. Allergic drug reactions are less common in childhood and possibly in the aged; in the latter, this may be related to impaired immunological responsiveness. Immunosuppression may increase the risk by inhibiting the regulatory function of suppressor T cells [13]. Environmental factors may also affect susceptibility to drug hypersensitivity, as for example the well-recognized increase in ampicillin-induced morbilliform eruptions associated with infectious mononucleosis, and photoallergic reactions to drugs such as thiazide diuretics or phenothiazines.

Duration of hypersensitivity. The duration of allergic sensitivity is unpredictable. Although there is a general tendency for immunological responses to a drug to fall off with time, provided the patient is not re-exposed to the drug or a related substance, this can never be relied on; where necessary, safe confirmatory procedures (if available) should be carried out.

Drug eruptions may occur as a result of a variety of different immunological mechanisms as described below.

IgE-dependent (type I) drug reactions: urticaria and anaphylaxis [1]

In vivo cross-linkage by polyvalent drug–protein conjugates of two or more specific IgE molecules, fixed to sensitized tissue mast cells or circulating basophil leukocytes, triggers the cell to release a variety of chemical mediators, including histamine, peptides such as eosinophil chemotactic factor of anaphylaxis, lipids such as leukotriene C_4 or prostaglandin D_2, and a variety of pro-inflammatory cytokines [2]. Interleukin-5 (IL-5) and eotaxin play a role in activating and recruiting eosinophils in drug-induced cutaneous eruptions [3]. Such cytokines in turn have effects on a variety of target tissues including skin, respiratory, gastrointestinal and/or cardiovascular systems. Eosinophil degranulation may also result in release of pro-inflammatory mediators [4]. Dilatation and increased permeability of small blood vessels with resultant oedema and hypotension, contraction of bronchiolar smooth muscle and excessive mucus secretion, and chemotaxis of inflammatory cells, including polymorphs and eosinophils, occurs. Clinically, this may produce pruritus, urticaria, bronchospasm and laryngeal oedema, and in severe cases anaphylactic shock with hypotension and possible death. Immediate reactions occur within minutes of drug administration; accelerated reactions may occur within hours or days, and are generally urticarial but may involve laryngeal oedema. Penicillins are the commonest cause of IgE-dependent drug eruptions.

Antibody-mediated (type II) drug reactions

Binding of antibody to cells may lead to cell damage following complement-mediated cytolysis. The classical example of immune complex formation between a drug (as hapten) bound to the surface of a cell (in this case, platelets) and IgG-class antibody, with subsequent complement fixation, was the purpura caused by apronalide (Sedormid). A further example is the thrombocytopenic purpura that may result from antibodies to quinidine–platelet conjugates [1,2]. A number of drugs, including penicillin, quinine and sulphonamides, may rarely produce a haemolytic anaemia via this mechanism. Methyldopa very occasionally induces a haemolytic anaemia mediated by autoantibodies directed against red cell antigens.

Immune complex-dependent (type III) drug reactions

Urticaria and anaphylaxis. Immune complexes may activate the complement cascade, with resultant formation of anaphylatoxins such as the complement protein fragments C3a and C5a, which trigger release of mediators from mast cells and basophils directly, resulting in urticaria or anaphylaxis.

Serum sickness. Serum sickness-like reactions and other immune complex-mediated conditions necessitate a drug antigen to persist in the circulation for long enough for antibody, largely of IgG or IgM class, to be synthesized and to combine with it to form circulating antibody–antigen immune complexes. They therefore develop about 6 days or more after drug administration. Serum sickness occurs when antibody combines with antigen in antigen excess, leading to slow removal of persistent complexes by the mononuclear phagocyte system. It was usually seen in the context of serum therapy with large doses of heterologous antibody, as with horse antiserum for the treatment of diphtheria. It has been reported more recently with antilymphocyte globulin therapy [1]. Clinical manifestations of serum sickness include fever, arthritis, nephritis, neuritis, oedema, and an urticarial or papular rash.

Vasculitis [2–4]. Drug-induced immune complexes play a part in the pathogenesis of cutaneous necrotizing vasculitis. Deposition of immune complexes on vascular endothelium results in activation of the complement cascade, with generation of the anaphylatoxins C3a and C5a, which have chemotactic properties. Vasoactive amines and pro-inflammatory cytokines are released from basophils and mast cells, with resultant increased vascular permeability and attraction of neutrophil polymorphonuclear cells. Immune complex interaction with platelets via their Fc receptors causes platelet aggregation

and microthrombus formation. Release by neutrophils of lysosomal enzymes contributes further to local inflammation. These events lead to the histological appearance of leukocytoclastic vasculitis. Deposition of immunoglobulins and complement in and around blood vessel walls is detectable by direct immunofluorescence staining of skin biopsies. Hydralazine and the hydroxylamine metabolite of procainamide bind to complement component C4 and inhibit its function; this may impair clearance of immune complexes, and predispose to development of an LE syndrome [4].

Arthus reaction. The Arthus reaction is a localized form of immune complex vasculitis. Intradermal or subcutaneous injection of antigen such as a vaccine into a sensitized individual with circulating precipitating antibodies, usually of IgG1 class, leads to local immune complex formation and the cascade of events described above. Clinically, there is erythema and oedema, haemorrhage and occasionally necrosis at the injection site, which reaches a peak at 4–10 h, and then gradually wanes.

Cell-mediated (type IV) reactions

The role of delayed-type cell-mediated immune reactions in contact drug hypersensitivity, as with penicillin [1], is well established, but the importance of such mechanisms involving specific effector lymphocytes in other varieties of cutaneous drug allergy is uncertain. Nevertheless, it is thought that a number of ACDRs, including some morbilliform and bullous ACDRs, fixed drug reactions, lichenoid reactions, LE-like reactions and erythema multiforme, Stevens–Johnson syndrome and TEN, involve T-lymphocyte responses to altered self. An intercurrent infectious disease (especially respiratory tract and urinary tract infections in the case of maculopapular eruptions) was documented in 58.5% of patients with ACDRs, compared with 7.5% of a control group [2]. It has been proposed that viruses may non-specifically stimulate cytotoxicity in general, which spills over to affect target cells altered by drug antigen [3]. Viruses incriminated, especially in the drug hypersensitivity syndrome, include human herpesvirus 6, Epstein–Barr virus, cytomegalovirus and hepatitis C virus [4–10].

The involvement of the skin immune system in cell-mediated drug eruptions, and graft-versus-host disease as a model for cutaneous drug eruptions, have been reviewed [11,12]. There is increasing evidence of a role for T cells and cell-mediated immunity in some drug eruptions. Sulfamethoxazole-reactive lymphocytes can be detected in peripheral blood of patients with drug-induced eruptions, at a frequency of 1/172 000, within the frequency range of urushiol-reactive T cells in patients with urushiol (poison ivy) dermatitis [13]. Patients with acute drug allergy to carbamazepine, phenytoin, sulfamethoxazole, allopurinol or paracetamol had activated drug-specific $CD4^+$ or $CD8^+$ T cells in the circulation [14]. In one study, predominant $CD8^+$ T-cell activation was associated with more severe (bullous) skin lesions or liver involvement, whereas predominant activation of $CD4^+$ cells elicited mainly maculopapular reactions [15]. Drug-specific T-cell clones from drug-induced exanthems contained heterogeneous T-cell subsets with distinct phenotypes ($CD4^+ > CD8^+$, perforin and granzyme B positive) and cell functions (strong IL-5 production, moderate interferon-γ (IFN-γ) production, and cytotoxic potential) [16,17]. Perivascular predominantly $CD4^+$ T cells, with 30% $CD8^+$ cells, basal keratinocyte HLA-DR and intercellular adhesion molecule (ICAM)-1 expression, and E selectin expression by endothelial cells, were seen in maculopapular or exfoliative antibiotic-induced ACDRs [18,19]. However, in other studies $CD8^+$ T cells predominated in the epidermis in drug-induced maculopapular and bullous eruptions and patch-test reactions to β-lactam antibiotics [20,21]. β-lactam-specific peripheral and epidermal T lymphocytes from bullous exanthems were predominantly $CD8^+CD4^-$, displayed a Th1-like cytokine pattern, proliferated in an antigen- and major histocompatibility complex (MHC)-specific manner and were cytotoxic against epidermal keratinocytes in lectin-induced cytotoxicity assays. In contrast, T-cell lines from patients with penicillin-induced urticarial exanthems were predominantly $CD4^+CD8^-$, with a Th2-like cytokine pattern. Drug-specific T-cell clones and cell lines from a phenobarbital-induced eruption were heterogeneous with regard to CD4/CD8 phenotype, T-cell receptor Vβ repertoire, antigen recognition pattern and cytokine production [22]. Epicutaneous test reactions to antibiotics contained a heterogeneous population of drug-specific T cells [23]; it has been proposed that T cells producing IL-5 might contribute to eosinophilia, whereas cytotoxic $CD4^+$ T cells might account for tissue damage [23–25]. Drug-specific T cells also contribute to the neutrophil infiltration in drug-induced acute generalized exanthematous pustulosis, by secreting the chemokine IL-8 [26–28].

Proliferation of $CD8^+$ dermal T cells, from a sulfamethoxazole-induced bullous exanthem, to sulfamethoxazole was significantly increased in the presence of liver microsomes, suggesting that microsomal enzymes, such as the cytochrome P-450 system, generate highly reactive metabolites, which are the nominal antigens for T-cell activation

[29,30]. The expression of ICAM-1 by target keratinocytes plays an important role in the cytotoxicity of epidermal T cells in bullous drug eruptions [31]. Penicilloyl-modified MHC-associated peptides may act as T-cell epitopes; T cells may have specificity for both the backbone and the side-chain of penicillin [32]. Penicillin G may also stimulate T cells directly by binding to MHC molecules on the cell surface. Alternatively, it may bind to soluble proteins like human serum albumin, which require processing for presentation in an immunogenic form. These different modes of presentation, which elicit a variety of immunological reactivities, may explain the heterogeneity of clinical pictures seen in penicillin allergy [33]. Morbilliform drug hypersensitivity reactions in HIV-infected subjects showed spongiosis, hydropic generation of the basal layer, Civatte bodies, an epidermal lymphocytic infiltrate, and perivascular lymphocytes and macrophages [34]. Immunohistochemistry demonstrated $CD8^+$ HLA-DR-positive T lymphocytes, marked depletion of epidermal Langerhans' cells and strong keratinocyte IL-6, tumour necrosis factor-α (TNF-α) and, to a lesser degree, IFN-γ expression.

Erythema multiforme, Stevens–Johnson syndrome and TEN. The reader is referred to Chapter 74.

Lichenoid drug eruptions. The mechanisms underlying lichenoid drug eruptions are essentially unknown, but they may develop as a result of autoreactive cytotoxic T-cell clones directed against a drug–class II MHC antigen complex, such that keratinocytes and Langerhans' cells are viewed by the immune system as 'non-self'. Cloned murine autoreactive T cells produce a lichenoid reaction in recipient animals following injection [1]. The presence of epidermotropic T cells correlates with that of class II MHC (HLA-DR)-expressing keratinocytes and Langerhans' cells in lichenoid eruptions [2].

LE-like syndrome induced by drugs. Drug-induced LE, with production of antihistone antibodies, may result from interaction between the drug and nuclear material to produce a drug–nucleoprotein complex that is immunogenic. Alternatively, drugs may alter immunoregulation in such a way that autoantibody production is favoured; procainamide and hydralazine modulate lymphocyte function directly and induce autoreactivity. Thus, drugs may cause an SLE-like condition by a mechanism analagous to that in immunostimulatory graft-versus-host disease [1]. Hydralazine, isoniazid and the hydroxylamine metabolites of procainamide and practolol may also predispose to the development of an LE-like syndrome by inhibiting binding of C4 and in turn of C3 to immune complexes, thus preventing complement-mediated clearance of immune complexes by solubilization and opsonization [2].

Drug-induced pemphigus. Immunoprecipitation studies have shown that patients with drug-induced pemphigus foliaceus and pemphigus vulgaris often have circulating autoantibodies with the same antigenic specificity at a molecular level as autoantibodies from patients with idiopathic pemphigus [1]. Binding of an active thiol group in a drug to the pemphigus antigen complex might result in autoantibody production, or culprit drugs may result in immune dysregulation. In addition, drugs with thiol groups in their molecule, such as penicillamine, captopril and thiopronine, and piroxicam can cause acantholysis directly *in vitro* in the absence of autoantibody [2].

Fixed drug eruptions. Graft autotransplantation investigations carried out in the 1930s demonstrated cutaneous memory in involved skin in fixed drug eruption [1]. Serum factors from patients with fixed drug eruption have been reported to cause inflammation on injection into a previously involved site, but not when injected into normal skin [2], and to induce lymphocyte blast transformation [3,4]. However, cell-mediated rather than humoral immunity is thought to play the major role in the development of lesions in this condition.

Lesional skin contains increased numbers of both helper and suppressor T lymphocytes [5–8], and T suppressor/cytotoxic T cells may be seen adjacent to necrotic keratinocytes in the epidermis [6]. T cells may persist within lesional skin and contribute to immunological memory [7,9]; $CD8^+$ suppressor/cytotoxic T cells were present in suprabasal epidermis in involved skin 3 weeks after challenge [5]. Intraepidermal $CD8^+$ T cells phenotypically resembling effector memory T cells are greatly enriched in the resting lesions of fixed drug eruption; upon activation, they can rapidly produce large amounts of IFN-γ followed by localized epidermal injury [10].

T cells from lesional epidermis in two patients with fixed drug eruption utilized a very limited range of Vα and Vβ genes compared with peripheral blood T cells, indicating some expansion or preferential migration of T cells recognizing a restricted set of antigens [11]. Keratinocytes in lesional skin express ICAM-1 [12], which is involved in interaction between keratinocytes and lymphocytes, HLA-DR [6] and the chemotactic protein IP-10 [8], findings that suggest a role for cytokines in the evolution of the histological changes [8,13]. ICAM-1 was noted to be induced on endothelium and keratinocytes 1.5 h after drug challenge, and there was increased reactivity in lesional skin *in vitro* to TNF-α and IFN-γ, as well as to the causative drug [13]; drug-induced, TNF-α-dependent keratinocyte ICAM-1 expression in lesional skin may provide a localized initiating stimulus for epidermal T-cell activation. Early release of histamine from mast cells or basophils has been reported in fixed drug eruption, based on suction blister fluid levels [14]. Significantly higher frequencies of HLA-B22 and HLA-Cw1 antigens were found in 36 patients with fixed drug eruption, and familial cases occur, suggesting a genetic predisposition [15].

Histopathology of drug reactions [1]

In most patterns of reaction to drugs, the histological changes are no more distinctive than are the clinical features. For example, urticaria, erythema multiforme, TEN and exfoliative dermatitis provoked by drugs cannot be differentiated from the same reactions resulting from other causes. Graft-versus-host disease-type drug eruptions in the acute phase show a predominance of epidermal $CD8^+$ T cells, reduced epidermal OKT6-positive Langerhans' cells, and increased keratinocyte expression of HLA-DR and ICAM-1 [2]. In contrast, Langerhans' cells from lesional maculopapular drug eruptions reportedly increased in number by 66% and displayed more intense staining and more prominent dendrites in one study [3].

The histological changes in the vegetating iododermas and bromodermas, certain lichenoid eruptions and fixed drug eruptions are not pathognomonic, but are sufficiently characteristic to be of importance in differential diagnosis. The histology of a number of other drug eruptions has been reviewed [4]. Amiodarone-induced hyperpigmentation shows a lymphocytic dermatitis and yellowish-brown granules within several cell types; the drug or a metabolite composes at least a portion of the deposits. Clofazimine-induced hyperpigmentation involves accumulation of a ceroid lipofuscin within lipid-laden macrophages. The cutaneous eruption of lymphocyte recovery after chemotherapeutic agents is a maculopapular eruption with a non-specific superficial perivascular dermatitis. Chemotherapy-induced acral erythema reveals a non-specific interface dermatitis. Specific reactions occur with etoposide (starburst cells) and busulfan (busulphan) (large atypical keratinocytes), and other chemotherapeutic agents may involve sweat glands: neutrophilic eccrine hidradenitis is characterized by neutrophil infiltration and by necrosis; syringosquamous metaplasia involves squamous metaplasia of the sweat duct. Drug-induced generalized pustular toxic erythema is characterized by subcorneal pustules and occasional eosinophils. Cephalosporins may produce a syndrome clinically and histologically like pemphigus, and naproxen produces one like porphyria cutanea tarda. The photosensitive dermatitis associated with quinine and piroxicam is histologically a non-specific spongiotic dermatitis. A lichenoid giant cell dermatitis may be caused by methyldopa or chlorothiazide, and phenytoin and carbamazepine dermatitis histologically imitates mycosis fungoides.

Bromodermas and iododermas

In bromoderma, verrucous pseudoepitheliomatous hyperplasia is associated with abscesses containing neutrophils and eosinophils in the epidermis, and a dense dermal infiltrate initially consisting mainly of neutrophils and eosinophils and later containing many lymphocytes, plasma cells and histiocytes. The abundant dilated blood vessels may show endothelial proliferation. In iododermas, ulceration is more marked, but there is usually less epithelial hyperplasia. Both conditions must be differentiated from blastomycosis and coccidioidomycosis, and from pemphigus vegetans.

Fixed eruptions

In the acute stage, the epidermal changes may be indistinguishable from erythema multiforme, with loss of cell outlines and necrosis of the lower epidermis. In less acute lesions, the epidermis may show little abnormality but the dermis is oedematous and there is a conspicuous perivascular lymphocytic infiltrate. Later, there is increased melanin in the epidermis and within melanophages in the dermis.

Lichenoid eruptions

The changes may be non-specific or may resemble idiopathic lichen planus, although the cellular infiltrate tends to be more pleomorphic and less dense, and the presence of focal parakeratosis, focal interruption of the granular layer, and cytoid bodies in the cornified and granular layers suggest a drug cause [5]. Later, there may be scarring, with destruction of the sweat glands.

Types of clinical reaction [1–13]

The mucocutaneous reactions that may result from ADRs have been the subject of extensive reviews, to which the reader is referred for further information. The following section details a number of different drug-induced reaction patterns; see also the discussion of adverse effects of individual drugs later. It is unfortunate that although certain drugs are commonly associated with a specific reaction, most drugs are capable of causing several different types of eruption.

Exanthematic (maculopapular) reactions

These are the most frequent of all cutaneous reactions to drugs, and can occur after almost any drug at any time up to 3 (but usually 2) weeks after administration; they may be accompanied by fever, pruritus and eosinophilia. It is not possible to identify the offending drug by the nature of the eruption. The clinical features are variable; the lesions may be scarlatiniform, rubelliform or morbilliform, or may consist of a profuse eruption of small papules showing no close resemblance to any infective exanthem (Fig. 73.1). Less common are eruptions with large macules, polycylic and gyrate erythema, reticular eruptions and sheet-like erythema. The distribution is also variable but is generally symmetrical. The trunk and extremities are usually involved, and not uncommonly intertriginous areas may be favoured, but the face may be spared. Palmar and plantar lesions may occur, and sometimes the eruption is generalized. Purpuric lesions, especially on the legs, and erosive stomatitis may develop. There may be relative sparing of pressure areas. If the administration of the drug is continued, an exfoliative dermatitis may develop, although occasionally the eruption subsides despite continuation of the medication.

Fig. 73.1 Maculopapular erythema caused by ampicillin.

Morbilliform drug eruptions usually, but not always, recur on rechallenge. The main differential diagnosis is from viral rashes. In a recent series of atypical exanthems, morphology and laboratory investigations led to an aetiological diagnosis in about 70% of cases [1]. It is useful, in differentiating exanthematic drug eruptions from viral exanthems, to remember that viral rashes may start on the face and progress to involve the trunk, and are more often accompanied by conjunctivitis, lymphadenopathy and fever. Maculopapular drug eruptions usually fade with desquamation, sometimes with post-inflammatory hyperpigmentation. Commoner causes are listed in Table 73.2.

Table 73.2 Drugs causing exanthematic reactions.

Most common	Less common
Ampicillin and penicillin	Cephalosporins
Phenylbutazone and other pyrazolones	Barbiturates
Sulphonamides	Thiazides
Phenytoin	Naproxen
Carbamazepine	Isoniazid
Gold	Phenothiazines
Gentamicin	Quinidine
	Meprobamate
	Atropine

Purpura

A purpuric element to a drug eruption is not uncommon, but primarily purpuric drug-induced rashes also occur. Many drugs may interfere with platelet aggregation [1] but, with the exception of aspirin, this does not usually result in bleeding. A number of drugs have been implicated in the development of drug-induced purpura [2–4]. Several mechanisms may be involved. These include altered coagulation after anticoagulants or some cephalosporins, allergic and non-allergic thrombocytopenia, altered platelet function (as after valproic acid) or vascular causes, including steroid-induced fragility and loss of support. Cytotoxic drug therapy may result in non-allergic purpura due to bone marrow depression, with a platelet count of less than 30 000/mm^3. Bleomycin may induce thrombocytopenia by causing endothelial damage and consequent platelet aggregation [5]. A large number of drugs have been reported to cause allergic thrombocytopenia [2–4]. Heparin may cause purpura with overdosage or due to an allergic thrombocytopenia [6]. The classical example of complement-mediated destruction of platelets, following immune complex formation between a drug (as hapten) bound to the platelet surface and IgG class antibody, was the purpura caused by apronalide (Sedormid). Quinine, quinidine [7,8] and chlorothiazide may also cause allergic purpura. Tissue plasminogen activator (alteplase) has been associated with painful purpura [9]. A purpuric vasculitis-like rash followed secondary spread of a contact dermatitis to balsam of Peru [10].

Capillaritis (pigmented purpuric eruption) may be due to aspirin, carbromal or more rarely to thiamine or meprobamate [11–14], carbamazepine, phenacetin, as well as glipizide, pefloxacin, lorazepam, aspirin, paracetamol, polyvinyl pyrrolidone plasma expander, ciclosporin and griseofulvin [15,16]; it may be due to formation of antibody to a drug–capillary endothelial cell complex [12]. Chronic pigmented purpura is recorded with thiamine propyldisulphide and chlordiazepoxide [13] and aminoglutethimide [17]. NSAIDs, diuretics, meprobamate and ampicillin were the commonest drug cause of pigmented purpuric eruptions in one study [18].

Annular erythema

Erythema annulare centrifugum has been reported in association with chloroquine and hydroxychloroquine [1], oestrogens, cimetidine [2], penicillin, salicylates and piroxicam, as well as with hydrochlorothiazide [3], spironolactone [4], thioacetazone [5], the phenothiazine levomepromazine [6] and etizolam [7]. Annular erythema has occurred with vitamin K [8].

Pityriasis rosea-like reactions

The best-known drug cause of a pityriasiform rash is gold therapy [1], but several other drugs have been implicated, including metronidazole [2], captopril [3], isotretinoin [4] and omeprazole [5] (Table 73.3).

Chlorpromazine	Streptomycin
Cimetidine	Sulphonamides
Diltiazem	Sulphonylureas
Gold	Thioacetazone (thiacetazone)
Griseofulvin	

Exfoliative dermatitis

Exfoliative dermatitis is one of the most dangerous patterns of cutaneous reaction to drugs [1–5]. It may follow exanthematic eruptions or may develop, as in some reactions to arsenicals and the heavy metals, as erythema and exudation in the flexures, rapidly generalizing. The eruption may start several weeks after initiation of the therapy. A dermatitis in patients previously sensitized by contact may also become universal.

The main drugs implicated are listed in Table 73.5. In one large series, sulphonamides, antimalarials and penicillin were most frequently implicated [1]. In another series from India [3], the commonest associated drugs were isoniazid (20%), thioacetazone (15%), topical tar (15%) and a variety of homeopathic medicines (20%), with phenylbutazone, streptomycin and sulfadiazine (sulphadiazine) each accounting for 5% of cases. Phenytoin is a well-recognized cause [6]. Recently incriminated drugs have included captopril, cefoxitin, cimetidine and ampicillin.

Anaphylaxis and anaphylactoid reactions

This systemic reaction, which usually develops within minutes to hours (the vast majority within the first hour), is often severe and may be fatal [1–3]. Fatal drug-induced anaphylactic shock was estimated at 0.3 cases per million

Table 73.6 Drugs causing urticaria or anaphylaxis.

Animal sera	Dextrans
Vaccines containing egg protein	Mannitol
Desensitizing agents including pollen vaccines	Sorbitol complexes
Antibiotics	Enzymes
Penicillins	Trypsin
Cephalosporins	Streptokinase
Aminoglycosides	Chymopapain
Tetracyclines	Steroids
Sulphonamides	Progesterone
Antifungal agents	Hydrocortisone
Fluconazole	Polypeptide hormones
Ketoconazole	Insulin
Blood products	Corticotrophin
Angiotensin-converting enzyme inhibitors	Vasopressin
Radiographic contrast media	Food and drug additives
Non-steroidal anti-inflammatory drugs (NSAIDs)	Benzoates
Salicylates	Sulphites
Other NSAIDs (e.g. phenylbutazone, aminopyrine, propyphenazone, metamizole, tolmetin)	Tartrazine dyes
	Hydantoins
Narcotic analgesics	Hydralazine
Anaesthetic agents: local and general	Quinidine
Muscle relaxants	Anticancer drugs
Suxamethonium	Vitamins
Curare	Protamine

inhabitants per year, based on notifications to the Danish Committee on Adverse Drug Reactions and to the Central Death Register during the period 1968–90 [3]. The most frequent causes were contrast media for X-ray examinations, antibiotics and extracts of allergens. In less severe cases, there may be premonitory dizziness or faintness, skin tingling and reddening of the bulbar conjunctiva, followed by urticaria, angio-oedema, bronchospasm, abdominal pain and vasomotor collapse. It usually develops on second exposure to a drug, but may develop during the first treatment if this lasts sufficiently long for sensitization to occur. Anaphylaxis is unlikely to occur with a drug taken continuously for several months; in contrast, intermittent administration may predispose to anaphylaxis [1]. It is commoner after parenteral than oral drug administration. The β-blockers enhance anaphylactic reactions caused by other allergens, and may make resuscitation more difficult [4].

The principal drug causes are shown in Table 73.6. Antibiotics (especially penicillin) and radiocontrast media are the most common known causes of anaphylactic events [2]; the incidence of such reactions for each is about 1 in 5000 exposures [5,6], of which less than 10% are fatal [2]. The risk for recurrent anaphylactic reactions is 10–20% for penicillins [5] and 20–40% for radiocontrast media [7]. Anaphylaxis to paracetamol-containing tablets has occurred, although it was the additive polyvinyl pyrrolidone that was reponsible [8].

Anaphylactoid reactions are those that clinically resemble an immediate immune response but in which the mechanism is undetermined. Some drugs and agents, such as mannitol and radiographic contrast media, can stimulate mediator release by an as yet unknown direct mechanism independent of IgE or complement. Anaphylactoid reactions may be produced by non-steroidal analgesics and anti-inflammatory agents (NSAIDs) [9,10], including aspirin and other salicylates, indometacin (indomethacin), phenylbutazone, propyphenazone, metamizole and tolmetin [11], as well as by radiographic contrast media, *d*-tubocurarine, benzoic acid preservatives [12], tartrazine dyes, sulphite preservatives [13] and ciprofloxacin [14]. The HLA-DRB1*11 allele showed a positive association with NSAID-induced anaphylactoid systemic reactions but not with purely cutaneous reactions [15].

Urticaria

Urticaria (see Chapter 47) is, after an exanthematous eruption, the second most common type of ACDR [1] (Fig. 73.2). Drug-induced urticaria is seen in 0.16% of medical in-patients and accounts for 9% of chronic urticaria or angio-oedema seen in dermatology outpatient departments [1]. Occurring within 24–36 h of drug ingestion, it is most commonly caused by penicillins, sulphonamides and NSAIDs. Drug-induced urticaria is seen in association with anaphylaxis, angio-oedema and serum sickness. On rechallenge, lesions may develop within minutes. Angio-oedema, involving oedema of the deep dermis or subcutaneous and submucosal areas, is more rarely seen than urticaria as an ACDR, and occurs in less than 1% of patients receiving the particular drug.

The commoner drug causes of urticaria/angio-oedema are listed in Table 73.6. The frequency of urticaria/angio-oedema or anaphylactic responses to aspirin and other NSAIDs is about 1% in an outpatient population and is familial [2]. Aspirin (salicylates) may also aggravate chronic urticaria [3,4]. In addition, an unsuspected agent, for example the yellow dye tartrazine, may really be responsible for an urticaria attributed to aspirin or another drug. The analgesic codeine is also a cause of urticaria [5]. Penicillin is a very well-documented cause of acute urticaria, but the role of this drug in chronic urticaria is controversial [6]. Urticaria develops in about 1% of patients receiving blood transfusions [7]. There have been numerous papers on the potential role of food and drug additives [8–16], including preservatives such as benzoic acid, butylated hydroxyanisole, butylated hydroxytoluene, sulphites and rarely aspartame, as well as tartrazine dyes, in the development of chronic urticaria. However, one study suggested that common food additives are seldom if ever of significance in urticaria [9]. Urticaria may follow alcohol consumption [17], intra-articular methylprednisolone [18] and even cetirizine [19].

Certain drugs, such as opiates, codeine, amfetamine, polymyxin B, *d*-tubocurarine, atropine, hydralazine, pentamidine, quinine and radiocontrast media, may release mast cell mediators directly. Cyclo-oxygenase inhibitors, such as aspirin and indometacin, and ACE inhibitors, such as captopril and enalapril, may cause urticaria or angio-oedema by pharmacological mechanisms. ACE inhibitors may cause increased frequency, intensity and duration of bouts of idiopathic angio-oedema during long-term use [20,21].

Serum sickness

Serum sickness, a type III immune complex-mediated reaction, may occur between 5 days and 3 weeks after initial exposure [1–5], and in its complete form combines fever, urticaria, angio-oedema, joint pain and swelling, lymphadenopathy, and occasionally nephritis or endocarditis, with eosinophilia. In minor forms of serum sickness, fever, urticaria and transitory joint tenderness may be the only manifestations.

Drugs implicated include heterologous serum [1,2], immune globulin (as treatment for Kawasaki disease) [6], aspirin, antibiotics [7,8] such as penicillin [3,7,9], amoxicillin [7], flucloxacillin [7], cefaclor [10–14], cefprozil [15], piperacillin [16], ciprofloxacin [17], cefatrizine [18], cotrimoxazole [7], troleandomycin (triacetyloleandomycin) [7], streptomycin, sulphonamides and sulfasalazine [19], thiouracils, intravenous streptokinase [20,21], *N*-acetylcysteine [22], staphylococcal protein A immunomodulation [23] and amfebutamone (bupropion) [24]. Of 32 women in an *in vitro* fertilization programme, 15% developed serum sickness 8–12 days after oocyte retrieval by echographic puncture, when a medium containing bovine serum was employed for rinsing follicles [25]. Patients had specific IgG antibodies against, and positive intradermal skin testing to, bovine serum albumin. A characteristic serpiginous, erythematous and purpuric eruption developed on the hands and feet at the borders of palmar and plantar skin in a series of patients treated with intravenous infusions of horse antithymocyte globulin for bone marrow failure [1,2]. Circulating immune complexes, low serum C4 and C3 levels, and elevated plasma C3a anaphylatoxin levels were found. Direct immunofluorescence revealed the presence of immunoreactants including IgM, C3, IgE and IgA in the walls of dermal blood vessels.

Erythema multiforme, Stevens–Johnson syndrome and toxic epidermal necrolysis

See Chapter 74.

Drug hypersensitivity syndrome

The drug hypersensitivity syndrome [1–3], also known as *d*rug *r*ash with *e*osinophilia and *s*ystemic *s*ymptoms (DRESS) syndrome [4] or as *d*rug-*i*nduced *d*elayed *m*ulti-*o*rgan *h*ypersensitivity *s*yndrome (DIDMOHS) [2], has been reported with the anticonvulsants phenytoin, carbamazepine, phenobarbital and lamotrigine (see also anticonvulsant hypersensitivity syndrome, p. 73.45), and with trimethoprim–sulfamethoxazole, minocycline, procarbazine, allopurinol, terbinafine and dapsone. Superimposed viral infection may have a role in the aetiology [5] (see also mechanisms of drug reactions, cell-mediated immune reactions, p. 73.18). The syndrome comprises fever, facial oedema with infiltrated papules, generalized papulopustular or exanthematous rash which may extend to exfoliative dermatitis, lymphadenopathy, haematological abnormalities (hypereosinophilia in 90% of cases, atypical lymphocytes/mononucleosis in 40% of

cases), and organ involvement such as hepatitis, possible nephritis, pneumonitis, myocarditis and hypothyroidism, occurring after 3–6 weeks of drug therapy. The cutaneous histological pattern shows a lymphocytic infiltrate, sometimes mimicking a cutaneous lymphoma. The mortality is of the order of 10%; the syndrome may proceed to Stevens–Johnson syndrome or TEN (see Chapter 74). Management is usually with oral corticosteroids. This syndrome should be distinguished from drug-induced pseudolymphoma syndrome, which has a more insidious beginning with nodules and infiltrated plaques appearing several weeks after starting the drug, without constitutional symptoms (see below).

Fixed eruptions [1–9]

A fixed drug eruption characteristically recurs in the same site or sites each time the drug is administered; with each exposure, however, the number of involved sites may increase. Usually, just one drug is involved, although independent lesions from more than one drug have been described [10]. Cross-sensitivity to related drugs may occur, such as between phenylbutazone and oxyphenbutazone, between tetracycline-type drugs, and between anticonvulsants [11]. There may be a refractory period after the occurrence of a fixed eruption.

Acute lesions usually develop 30 min to 8 h after drug administration as sharply marginated, round or oval itchy plaques of erythema and oedema becoming dusky violaceous or brown, and sometimes vesicular or bullous (Fig. 73.3). The eruption may initially be morbilliform, scarlatiniform or erythema multiforme-like; urticarial, nodular or eczematous lesions are less common. Lesions are sometimes solitary at first, but with repeated attacks new lesions usually appear and existing lesions may increase in size. A multifocal bullous fixed drug eruption due to mefenamic acid resembled erythema multiforme [12]. Occasionally, involvement is so extensive as to mimic TEN [13,14].

Lesions are commoner on the limbs than on the trunk; the hands and feet, genitalia and perianal areas are

Fig. 73.3 Bullous fixed drug eruption with hyperpigmentation. (Courtesy of St John's Institute of Dermatology, London, UK.)

favoured sites. Perioral and periorbital lesions may occur. Genital [15] and oral mucous membranes [16] may be involved in association with skin lesions, or alone. In the case of isolated male genital fixed drug eruption (often affecting only the glans penis), the drugs most commonly implicated in one series were co-trimoxazole (trimethoprim–sulfamethoxazole), tetracycline and ampicillin [15]. With oral fixed drug eruption, co-trimoxazole, oxyphenbutazone and tetracycline were the most common causative drugs [16]. Pigmentation of the tongue may occur as a form of fixed drug eruption in heroin addicts [17]. As healing occurs, crusting and scaling are followed by pigmentation, which may be very persistent and occasionally extensive, especially in pigmented individuals; pigmentation may be all that is visible between attacks. Non-pigmenting fixed reactions have been reported in association with the sympathomimetic agents pseudoephedrine [18,19] and tetryzoline (tetrahydrozoline) hydrochloride, diflunisal, thiopental (thiopentone), piroxicam, the radiopaque contrast medium iothalamate, arsphenamine [20], paracetamol [21], intra-articular triamcinolone acetonide [22] and eperisone hydrochloride [23].

The number of drugs capable of producing fixed drug eruption is very large. However, most fixed drug eruptions are due to one or other of the substances listed in Table 73.7. Earlier series incriminated particularly analgesics, sulphonamides and tetracyclines. In a report from Finland, phenazones caused most eruptions, with barbiturates, sulphonamides, tetracyclines and carbamazepine causing fewer reactions [24]. A series from India reported that acetylsalicylic acid was the drug most commonly

Table 73.7 Drugs causing fixed eruptions.

Antibacterial substances
Sulphonamides (co-trimoxazole)
Tetracyclines
Penicillin
Ampicillin
Amoxicillin
Erythromycin
Trimethoprim
Nystatin
Griseofulvin
Dapsone
Arsenicals
Mercury salts
p-Aminosalicylic acid
Thioacetazone (thiacetazone)
Quinine
Metronidazole
Clioquinol

Barbiturates and other tranquillizers
Barbiturate derivatives
Opium alkaloids
Chloral hydrate
Benzodiazepines: chlordiazepoxide
Anticonvulsants
Dextromethorphan

Non-steroidal anti-inflammatory drugs
Aspirin (acetylsalicylic acid)
Oxyphenbutazone
Phenazone (antipyrine)
Metamizole
Paracetamol (acetaminophen)
Ibuprofen
Various non-proprietary analgesic combinations

Phenolphthalein and related compounds

Miscellaneous
Codeine
Hydralazine
Oleoresins
Sympathomimetics
Sympatholytics
Parasympatholytics: hyoscine butylbromide
Magnesium hydroxide
Magnesium trisilicate
Anthralin
Chlorthiazone
Chlorphenesin carbamate
Food substitutes and flavours

implicated in children [25]; a more recent study found that co-trimoxazole was the usual culprit in children [26]. Co-trimoxazole has been implicated as the most frequent cause in many studies [6,8,27]. A fixed drug eruption apparently caused by co-trimoxazole was reported in a man following intercourse with his wife, who was taking the drug [28]. Trimethoprim has caused a linear fixed drug eruption [29]. A report in 1991 showed that co-trimoxazole caused the maximum incidence (36.3%), followed by tetracycline (15.9%), pyrazolones (14.2%), sulfadiazine (12.4%), dipyrine (9.3%), paracetamol (7.9%), aspirin (1.7%), thioacetazone (0.88%) and levamisole (0.88%) [27]. Co-trimoxazole was also the most common cause of fixed drug eruption (75%), followed by naproxen sodium (12.5%), dipyrone (9.5%), dimenhydrinate (1.5%) and paracetamol (1.5%) in a study in 2000 [8]. However, a survey of current causes of fixed drug eruption in the UK listed NSAIDs including aspirin, paracetamol, antibacterial agents, systemic antifungal agents, psychotropic drugs, proton pump inhibitors, calcium channel blockers, ACE inhibitors and hormonal preparations [9], reflecting the decreased use of co-trimoxazole.

A drug-specific clinical pattern in fixed drug eruptions based on a study of 113 patients has been reported [8,27]. Sulphonamides, including co-trimoxazole, induced lesions on the lips, trunk and limbs, with only minimal involvement of mucosae. Naproxen predominantly affected the lips and face. Tetracycline and co-trimoxazole caused lesions mainly on the glans penis. Pyrazolones affected mainly the lips and mucosae, with a few lesions of the trunk and limbs. Dipyrine, aspirin and paracetamol caused lesions of the trunk and limbs, sparing the lips, genitalia and mucosae. Levamisole caused associated constitutional disturbances with extensive skin lesions, as did thioacetazone [27]. Paracetamol is a rare cause of fixed drug eruption [30–33]; other drugs implicated have included codeine [34], naproxen [35], rofecoxib [36], ciprofloxacin [37], clarithromycin [38], rifampicin [39], metronidazole [40], terbinafine [41], fluconazole [42], lamotrigine [43], dimenhydrinate [44], cetirizine [45], loratadine [46], ticlopidine [47], phenylpropanolamine hydrochloride [48], and lactulose in an injected botulinum toxin preparation [49]. Familial fixed drug eruption has occurred occasionally [50,51].

Lichenoid eruptions

Lichenoid drug eruptions and lichen planus are discussed in Chapter 42. Some of the drugs that induce this pattern of reaction are listed in Table 73.8 [2]. Photodistributed lichenoid lesions may occur with a number of drugs, including thiazide diuretics (Fig. 73.4).

Photosensitivity

Drug–light reactions, which cause eruptions on exposed areas, with sparing of upper eyelids, submental and retroauricular areas, may be phototoxic or photoallergic; these cannot always be distinguished clinically, and some drugs may produce cutaneous involvement by both mechanisms [1–5]. The main drugs implicated in photosensitivity reactions are listed in Table 73.9.

Phototoxic reactions

Phototoxic reactions are commoner than photoallergic reactions, and can be produced in almost all individuals given a high enough dose of drug and sufficient light irradiation. They occur within 5–20 h of the first exposure, and resemble exaggerated sunburn. Erythema, oedema, blistering, weeping, desquamation and residual hyperpig-

mentation occur on exposed areas; there may be photo-onycholysis. The following are well-recognized causes of phototoxicity:

- tetracyclines [1–4], especially demeclocycline, less frequently doxycycline, oxytetracycline and tetracycline, and rarely minocycline and methacycline;
- other antibacterials including sulphonamides and fluoroquinolones [4];
- phenothiazines, especially chlorpromazine, promethazine and less commonly thioridazine;
- furosemide [5] and nalidixic acid [4,6], both of which produce a pseudoporphyria syndrome, with blistering of the exposed areas;
- NSAIDs, including ibuprofen [7], piroxicam [8–11], carprofen and tiaprofenic acid [12];
- psoralens;
- amiodarone (which causes photosensitivity in over 50% of cases) [13];
- certain anticancer drugs [14], including dacarbazine [14,15], 5-fluorouracil, mitomycin and vinblastine;
- coal tar and its derivatives;
- fibric acid derivatives, including bezafibrate and fenofibrate [16,17];
- the non-steroid antiandrogen flutamide given for prostatic carcinoma [18,19].

Table 73.9 Drugs causing photosensitivity.

Frequent
Amiodarone
Phenothiazines
  Chlorpromazine
  Promethazine
Psoralens
Sulphonamides: co-trimoxazole
Tetracyclines: demeclocycline
Thiazides
Non-steroidal anti-inflammatory drugs
  Azapropazone
  Piroxicam
  Carprofen
  Tiaprofenic acid
  Benoxaprofen (withdrawn)
Nalidixic acid
Coal tar

Less frequent: topical
Antihistamines
Local anaesthetics
Benzydamine
Hydrocortisone
Sunscreens
  p-Aminobenzoic acid
  Benzophenone
Halogenated salicylanilides

Less frequent: systemic
Ampicillin
Antidepressants (tricyclic)
  Imipramine
  Protriptyline
Antidepressants (monoamine oxidase inhibitors): phenelzine
Antifungal agents
  Griseofulvin
  Ketoconazole
β-Blockers
Carbamazepine
Cimetidine
Cytotoxic agents
  Dacarbazine
  Fluorouracil
  Mitomycin
  Vinblastine
Diazepam
Furosemide (frusemide)
Methyldopa
Oral contraceptives
Quinine
Quinidine
Sulphonylureas
  Chlorpropamide
  Tolbutamide
Retinoids
  Isotretinoin
  Etretinate
Triamterene

Photoallergic reactions

Photoallergic reactions require a latent period during which sensitization occurs, and usually appear within 24 h of re-exposure to drug and light in a sensitized individual; unlike phototoxic reactions, they may spread beyond irradiated areas. Most systemic drugs causing photoallergy also cause phototoxicity. There may be cross-reactivity with chemically related substances.

Photoallergic reactions may occur as a result of local photocontact dermatitis to a topical photoallergen. Photocontact dermatitis is a relatively common cause of photosensitivity, accounting for 9% of cases in a multicentre study [1]. Topical photoallergens include antihistamines, chlorpromazine, local anaesthetics, benzydamine, hydrocortisone, desoximetasone (desoxymethasone) and sunscreens containing *p*-aminobenzoic acid (PABA) and its derivatives. Contact allergy and photoallergy to benzophenones in PABA-free sunscreens may be commoner than is realized [2]. Halogenated salicylanilides, previously used as a disinfectant in soaps, and related compounds also cause photocontact dermatitis.

Photoallergic reactions may also occur as a result of systemically administered drugs [3], such as phenothiazines (chlorpromazine, promethazine), sulphonamides, aromatic sulphonamides such as thiazide diuretics

[4,5] and oral hypoglycaemic agents (chlorpropamide and tolbutamide), griseofulvin [6] and quinidine [7,8]. Quinidine-induced photo-eruptions may be either eczematous or lichenoid; a persistent livedo reticularis-like eruption may be seen in severe cases of quinidine photosensitivity. Enalapril has caused a photosensitive lichenoid eruption [9]. Tricyclic antidepressants may cause allergy as well as photosensitivity [10]. NSAIDs, disinfectants, sunscreens, phenothiazines and fragrances caused photoallergic reactions most often in a 5-year survey by the German, Austrian and Swiss photopatch test group [11].

Porphyria and pseudoporphyria

A number of drugs may precipitate porphyria cutanea tarda with resultant photosensitivity, or cause a pseudoporphyria syndrome with bulla formation. The reader is referred to Chapter 57.

Photorecall reactions

A curious photorecall-like eruption, restricted to an area of sunburn sustained 1 month previously, occurred in a patient treated with cefazolin (cephazolin) and gentamicin [1]. An ultraviolet recall-like eruption has been reported with piperacillin, tobramycin and ciprofloxacin [2]. A recurrent cutaneous reaction localized to the site of pelvic radiotherapy for adenocarcinoma of the prostate followed sun exposure in one patient [3]. Methotrexate is associated with severe reactivation of sunburn [4,5].

Photo-onycholysis

Photo-onycholysis may be caused by tetracycline, psoralens and UVA (PUVA) therapy, and the fluoroquinolone antibiotics pefloxacin and ofloxacin.

Pigmentation reactions

Hyperpigmentation (Table 73.10)

Drug-induced alteration in skin colour [1–3] may result from increased (or more rarely decreased) melanin synthesis, increased lipofuscin synthesis, cutaneous deposition of drug-related material, or most commonly as a result of post-inflammatory hyperpigmentation (e.g. fixed drug eruption). Oral contraceptives may induce chloasma [4]. Other drugs implicated in cutaneous hyperpigmentation include minocycline [5,6], antimalarials [7,8], chlorpromazine [9,10], imipramine (photodistributed) [11–13] and desimipramine [14], amiodarone [15], carotene and heavy metals. Long-term (more than 4 months) antimalarial therapy may result in brownish or blue-black pigmentation, especially on the shin, face and hard palate or subungually. Yellowish discoloration may occur with mepacrine (quinacrine) or amodiaquine. Long-term high-dose phenothiazine (especially chlorpromazine) therapy results in a blue-grey or brownish pigmentation of sun-exposed areas, the result of a phototoxic reaction, with

Table 73.10 Drugs causing pigmentation.

Oral contraceptives	Chemotherapeutic agents
Minocycline	Miscellaneous
Antimalarials	Amiodarone
Chloroquine	Carotene
Hydroxychloroquine	Clofazimine
Mepacrine	Pefloxacin
Antidepressants	Sulfasalazine (sulphasalazine)
Chlorpromazine	
Imipramine	
Heavy metals	
Gold	
Lead	
Silver	

pigment deposits in the lens and cornea [10]. The cancer chemotherapeutic agents may be associated with pigmentation as follows [16]. Skin pigmentation may be caused by bleomycin, busulfan, topical carmustine, cyclophosphamide, daunorubicin, fluorouracil, hydroxyurea, topical mechlorethamine, methotrexate, mithramycin, mitomycin and thiotepa. Busulfan and doxorubicin cause mucous membrane pigmentation. Nail pigmentation may result from bleomycin, cyclophosphamide, daunorubicin, doxorubicin and fluorouracil. Methotrexate may induce pigmentation of the hair, and cyclophosphamide of teeth. Sulfasalazine has caused reversible hyperpigmentation [17], and pefloxacin blue-black pigmentation of the legs [18].

Gold may cause blue-grey pigmentation in light-exposed areas (*chrysiasis*) [19,20] and silver may cause a similar discoloration (*argyria*) [21]. Lead poisoning can cause a blue-black line at the gingival margin and grey discoloration of the skin. Clofazimine produces red-brown discoloration of exposed skin and the conjunctivae, together with red sweat, urine and faeces [22]. Slate-grey to blue-black pigmentation may occur after long-term topical application of hydroquinone, causing ochronosis [23].

Hypopigmentation

Topical thiotepa has produced periorbital leukoderma [1]. Hypopigmentation has occurred as a result of occupational exposure to monobenzyl ether of hydroquinone, *p*-tertiary-butylcatechol, *p*-tertiary-butylphenol, *p*-tertiary-amylphenol, monomethyl ether of hydroquinone and hydroquinone [2]. In addition, hypopigmentation may result from phenolic detergent germicides [3], and following use of diphencyprone for alopecia areata [4,5]. Depigmentation of the skin and hair occurred after a phenobarbital-induced eruption [6]. Photoleukomelanodermatitis occurred due to afloqualone for cervical spondylosis; photopatch and oral challenge tests were positive [7]. Generalized cutaneous depigmentation followed a sulphamide-induced ADR [8].

Acneiform and pustular eruptions

The term 'acneiform' is applied to eruptions that resemble acne vulgaris [1,2] (see Chapter 43). Lesions are papulopustular but comedones are usually absent. Adrenocorticotrophic hormone (ACTH), corticosteroids

[3], dexamethasone in neurosurgical patients, anabolic steroids for body-building [4], androgens (in females), oral contraceptives, iodides and bromides may produce acneiform eruptions. Isoniazid may induce acne, especially in slow inactivators of the drug [5]. Other drugs implicated in the production of acneiform rashes include dantrolene [6], danazol [7], quinidine [8], lithium [9,10] and azathioprine [11]. Acne rosacea was temporally associated with daily high-dose vitamin B supplement therapy in one patient [12], and eosinophilic pustular folliculitis (Ofuji's disease) developed in association with use of the cerebral activator indeloxazine hydrochloride [13].

Acute generalized exanthematous pustulosis (toxic pustuloderma)

Pustular reactions (toxic pustuloderma, acute generalized exanthematous pustulosis) have been reported in association with a number of drugs [1]. The main differential diagnosis of a generalized pustular drug eruption is pustular psoriasis [2]. Two histological patterns may be seen: (i) a toxic pustuloderma with spongiform intraepidermal pustules, papillary oedema and a mixed upper dermal perivascular inflammatory infiltrate; or (ii) a leukocytoclastic vasculitis with neutrophil collections both below and within the epidermis, suggesting passive neutrophil elimination via the overlying epidermis [3,4]. The presence of eosinophils in the inflammatory infiltrate is a helpful pointer to a drug cause [2]. A responsible drug was found in 87% of a series of 63 patients with acute generalized exanthematous pustulosis; antibiotics were implicated as the causative agent in 80% of individuals [4]. The latter included particularly ampicillin, amoxicillin, spiramycin, erythromycin and cyclins. Hypersensitivity to mercury was also recorded as a precipitating cause. Pustulosis developed within 24 h of drug administration. It often started on the face or in flexural areas, rapidly became disseminated, with fever, and settled spontaneously with desquamation. Facial oedema, purpura, vesicles, blisters and erythema multiforme-like lesions were also seen; transient renal failure was noted in 32% of cases. Occasionally, TEN may be mimicked [5].

Acute generalized exanthematic pustulosis is usually due to penicillins or macrolides [6,7]. There have been individual reports of pustular drug reactions with ampicillin (which may be localized [8]), amoxicillin (with or without clavulanic acid) [9], propicillin [10], imipenem [11], the cephalosporins cefalexin (cephalexin) and cefradine (cephradine) [12,13], co-trimoxazole [14], doxycycline [15], chloramphenicol [16], norfloxacin [17], ofloxacin [18], teicoplanin [19], streptomycin [20], isoniazid, metronidazole [21], terbinafine [22–24], fluconazole [25], itraconazole [26], nystatin [27], salazosulfapyridine/salazopyrine [28], mesalazine [29], diltiazem [30], captopril [31] and enalapril [32], furosemide [33], hydrochlorothiazide [34], cytarabine [35], high-dose chemotherapy [36], sertraline [37], chlorpromazine [38], nitrazepam, acetylsalicylic acid [39], naproxen [40], allopurinol [41], hydroxychloroquine [42], pyrimethamine, piperazine ethionamate, the mucolytic agent eprazinone [43], dextropropoxyphene [44], icodextrin [45] and mexiletine [46]. Cases of generalized pustulation in association with the anticonvulsant hypersensitivity syndrome caused by phenytoin [47] and carbamazepine [48] have been recorded. Patch testing with the culprit drug may be positive in patients with acute generalized exanthematous pustulosis [49].

Eczematous eruptions

Allergic contact dermatitis is discussed in Chapter 20. This section concerns the entity termed 'systemic contact-type dermatitis medicamentosa' [1–5] (Table 73.11). A patient initially sensitized to a drug by way of allergic contact dermatitis may develop an eczematous reaction when the same, or a chemically related, substance is subsequently administered systemically. The eruption tends to be symmetrical, and may involve first, or most severely, the site(s) of the original dermatitis, before becoming generalized. Patients with a contact allergy to ethylenediamine may develop urticaria or systemic eczema following injection of aminophylline preparations containing ethylenediamine as a solubilizer for theophylline [6,7]. Patients with contact allergy to parabens may develop systemic eczema on medication with a drug containing parabens as a preservative [8]. Similarly, sensitized patients may develop eczema following oral ingestion of neomycin or hydroxyquinolines [9]. Diabetic patients sensitized by topical preparations containing *p*-amino compounds, such as *p*-phenylenediamine hair dyes, PABA sunscreens and certain local anaesthetic agents (e.g. benzocaine), may develop a systemic contact dermatitis with the hypoglycaemic agents tolbutamide or chlorpropamide. Sulphonylureas may also induce eczematous eruptions in sulphanilamide-sensitive patients as a result of cross-reactivity. Phenothiazines can produce allergic contact dermatitis, photoallergic reactions and eczematous contact-type dermatitis, and may cross-react with certain antihistamines. Tetraethylthiuram disulphide (disulfiram, Antabuse) for the management of alcoholism can cause eczematous reactions in patients sensitized to thiurams via rubber gloves. 'Systemic contact-type dermatitis' reactions have also been described with [4] acetylsalicylic acid, codeine [10], phenobarbital, pseudoephedrine hydrochloride and norephedrine hydrochloride [11], ephedrine [12], erythromycin [13], isoniazid [14], dimethylsulfoxide, hydroxyquinone, nystatin, subcutaneous hydromorphone

Table 73.11 Systemic drugs that can reactivate allergic contact eczema to chemically related topical medicaments. (From Fisher [1].)

Systemic drug	Topical medicament
Ethylenediamine antihistamines Aminophylline Piperazine	Aminophylline suppositories and ethylenediamine hydrochloride
Organic and inorganic mercury compounds	Ammoniated mercury
Tincture of benzoin inhalation	Balsam of Peru
Procaine Acetohexamide *p*-Aminosalicylic acid Azo dyes in foods and drugs Chlorothiazide Chlorpropamide Tolbutamide	Benzocaine (*p*-amino compound) and glyceryl *p*-aminobenzoic acid sunscreens
Chloral hydrate	Chlorobutanol
Iodochlorhydroxyquinoline	Halogenated hydroxyquinoline creams (Vioform)
Iodides, iodinated organic compounds, radiographic contrast media	Iodine
Streptomycin, kanamycin, paromycin, gentamicin	Neomycin sulphate
Glyceryl trinitrate tablets	Glyceryl trinitrate ointment
Disulfiram (Antabuse)	Thiuram (rubber chemical)

given for cancer pain [15], amlexanox [16], enoxolone [17], vitamin B_1, vitamin C, parabens, butylated hydroxyanisole, hydroxytoluene and tea-tree oil [18]. Allergic eczematous reactions to endogenous or exogenous systemic corticosteroids, including hydrocortisone and methylprednisolone, have been documented in patients who are patch-test positive to topical corticosteroids [19,20].

The term 'baboon syndrome' denotes a characteristic pattern of systemic allergic contact dermatitis [21–23], in which there is diffuse erythema of the buttocks, upper inner thighs and axillae, provoked by penicillin [24], ampicillin, amoxicillin [25], nickel, heparin, mercury (including that found in a homeopathic medicine [26]), terbinafine [27] and hydroxyurea [28]. Patch tests are commonly positive and usually vesicular, although histology of the eruption itself may show leukocytoclastic vasculitis; oral challenge with the suspected antigen may be required to substantiate the diagnosis. Disulfiram therapy of a nickel-sensitive alcoholic patient may induce this syndrome, as the drug leads to an initial acute increase in blood nickel concentration [21]. Cases have been described from Japan under the name 'mercury exanthem' following inhalation of mercury vapour from crushed thermometers in patients with a history of mercury allergy.

The term 'endogenic contact eczema' [29] refers to the occurrence of an eczematous contact drug reaction following primary sensitization by oral therapy, as in the case of a patient with a drug-related exanthem who later develops localized dermatitis due to topical therapy. Thus, eczematous eruptions may develop following therapy with penicillin [30], methyldopa, allopurinol, indometacin, sulphonamides, gold, quinine, chloramphenicol, clonidine or bleomycin [31]. The alkylating agent mitomycin C administered intravesically for carcinoma of the bladder has been associated with an eczematous eruption, particularly on the face, palms and soles in some patients; these may have positive patch tests to the drug [32,33].

Some of the more important causes of eczematous drug reactions are listed in Table 73.11. Sensitivity to the suspected drug may be confirmed by subsequent patch testing, when the skin reaction has settled.

Bullous eruptions

Bullous drug eruptions encompass many different clinical reactions and pathomechanisms [1,2]. Isolated blisters, often located preferentially on the extremities, may be caused by a wide variety of chemically distinct drugs. Fixed drug eruptions and drug-induced vasculitis may have a bullous component; these are reviewed elsewhere in this chapter. Erythema multiforme, Stevens–Johnson syndrome and drug-induced TEN are discussed in Chapter 74. The specific drug-induced entities of porphyria and pseudoporphyria, bullous pemphigoid, pemphigus and linear IgA disease are discussed here.

Fig. 73.5 Bullous eruption in barbiturate overdose. (Courtesy of Charing Cross Hospital, London, UK.)

Bullous eruption in drug overdosage

Bullae, often at pressure areas, may be seen in patients comatose after overdosage with barbiturates (Fig. 73.5), methadone, meprobamate, imipramine, nitrazepam or glutethimide [1–5].

Drug-induced porphyria

Porphyria is discussed in Chapter 57. Drugs reported to exacerbate the acute hepatic porphyrias are listed in Table 73.12; these either cause excess destruction of haem or inhibit haem synthesis [1–3].

Pseudoporphyria

Pseudoporphyria, in which porphyria-like blistering of exposed areas on the extremities occurs in the absence of abnormal porphyrin metabolism, may be caused by high-dose furosemide [4], naproxen [5,6] and other NSAIDs [7–9], combined carisoprodol and aspirin [10], nalidixic acid [11], tetracyclines [12] and sulphonylureas. Phototoxic mechanisms have been implicated in some cases. A similar syndrome has been reported in a patient taking very large doses of pyridoxine (vitamin B_6) [13].

Table 73.12 Drugs that are unsafe to use in patients with acute intermittent porphyria, porphyria cutanea tarda or variegate porphyria.

Aminoglutethimide	Meprobamate
Barbiturates	Novobiocin
Carbamazepine	Oestrogens
Carbromal	Primidone
Chlorpropamide	Progestogens
Danazol	Pyrazolone derivatives
Diclofenac	Rifampicin
Diphenylhydantoin (phenytoin)	Sulphonamides
Ergot preparations	Tolbutamide
Glutethimide	Trimethadione
Griseofulvin	Valproic acid

Drug-induced bullous pemphigoid

Idiopathic bullous pemphigoid is discussed in Chapter 41. In drug-induced bullous pemphigoid, patients tend to be younger; tissue-bound and circulating anti-basement-membrane zone IgG antibodies may be absent, or additional antibodies such as intercellular or antiepidermal cytoplasmic antibodies may be detected. Some cases of drug-induced bullous pemphigoid are short-lived, whereas others become chronic. Drug-induced bullous or cicatricial pemphigoid have been reported with a number of medications [1–5], especially furosemide [6,7] but also bumetanide [8], spironolactone [9,10], penicillamine [11,12], the penicillamine analogue tiobutarit [13], penicillin [14] and its derivatives [15], ciprofloxacin [16], sulfasalazine, salicylazosulfapyridine, phenacetin [17], enalapril [18], fluoxetine [19], novoscabin, topical fluorouracil, and PUVA therapy [20]. In the case of enalapril-induced bullous pemphigoid, the IgG antibody was directed against the 230-kDa bullous pemphigoid antigen [18]. Cicatricial pemphigoid has been described in association with penicillamine [12] and clonidine [21]. An association with vaccination for influenza and with tetanus toxoid and induction of bullous pemphigoid has been noted rarely [22–25].

Progesterone
Propranolol
Interferon-β and interleukin-2
Heroin

Drug-induced pemphigus

The variants of idiopathic pemphigus are discussed in Chapter 41. A number of drugs have been implicated in drug-induced pemphigus (Table 73.13) [1,2], usually of foliaceus type, although the erythematosus, herpetiformis and urticaria-like forms also occur; drug-induced pemphigus vulgaris is rare. Most patients with drug-induced pemphigus have tissue-bound and/or low-titre circulating autoantibodies with the same antigenic specificity at a molecular level as autoantibodies from patients with the corresponding subtype of idiopathic pemphigus [3,4]; however, in the case of penicillamine-induced pemphigus, 10% do not have tissue-bound, and more than 30% do not have circulating, autoantibodies. About 80% of cases are caused by drugs associated with a thiol group in the molecule, especially penicillamine [5–11], but also the structurally related ACE inhibitors captopril [3,12–14] and ramipril [15], gold sodium thiomalate, drugs with disulphide bonds such as pyritinol [16], *S*-thiopyridoxine, tiopronin (mercaptopropionylglycine; which is chemically related to penicillamine and used as an alternative therapy in penicillamine intolerance) [4,17,18], and bucillamine [19], as well as those with a sulphur-containing ring that may undergo metabolic change to the thiol form, such as piroxicam [20]. Penicillin [21,22], and its derivatives ampicillin [22], procaine penicillin and amoxicillin, may also cause pemphigus. Other drugs that cause pemphigus may contain an active amide group [23].

Rifampicin [24], cefalexin [25], cefadroxil, ceftazidime [26], pyrazolone derivatives [27] including dipyrone [28], propranolol, propranolol–meprobamate [29], optalidon, pentachlorophenol, phenobarbital [30], nifedipine [31], phosphamide, hydantoin, combinations of indometacin and aspirin [32], glibenclamide [33], as well as heroin [34], have all been established as rare causes of a pemphigus-like reaction. Fatal pemphigus vulgaris has been recorded after IFN-β and IL-2 therapy for lymphoma [35]. Fludarabine has been implicated in the development of paraneoplastic pemphigus [36,37].

Linear IgA disease

Idiopathic linear IgA disease is discussed in Chapter 41. The drugs implicated as a cause of this condition have been reviewed [1–3], and include vancomycin especially [1–9], but also amiodarone, ampicillin, atorvastatin [10], captopril [11], carbamazepine [12], cefamandole (cephamandole), diclofenac, furosemide [13], glibenclamide, IFN-γ, iodine, lithium, penicillin [14,15], phenytoin [16] and somatostatin, as well as tea-tree oil [17]. Most patients lack circulating antibodies to the basement membrane; resolution of the rash follows discontinuation of medication.

Vasculitis

Drug-induced cutaneous necrotizing vasculitis [1–3] may also involve internal organs, including the heart, liver and kidneys, with fatal results. The patterns of polyarteritis nodosa, Henoch–Schönlein vasculitis and hypocomplementaemic vasculitis are not seen commonly with drugs. Drugs that have been implicated are listed in Table 73.14. These include ampicillin, sulphonamides, furosemide [4], thiazide diuretics, phenylbutazone and other NSAIDs, quinidine, amiodarone [5], hydralazine [6], enalapril [7], propylthiouracil [8,9], mefloquine [10], cimetidine [11], coumadin [12,13], anticonvulsants including phenytoin and in isolated cases carbamazepine and trimethadione [14,15], zidovudine (azidothymidine) [16], indinavir [17], fluoxetine [18], didanosine [19], piperazine [20], centrally acting appetite suppressants [21], hyposensitization therapy [22,23], bacille Calmette–Guérin (BCG) vaccination (which may cause a papulonecrotic type of vasculitis) [24], radiographic contrast media [25], food and drug additives including dye excipients such as tartrazine (FD&C yellow no. 5), ponceau, sodium benzoate, 4-hydroxybenzoic acid [26,27], vitamin B_6 [28] and the use of a nicotine patch [29].

Table 73.14 Drugs recorded as inducing vasculitis.

Additives	Levamisole
Allopurinol	Maprotiline
Aminosalicylic acid	Mefloquine
Amiodarone	Methotrexate
Amfetamine (amphetamine)	Penicillin
Ampicillin	Phenacetin
Aspirin	Phenothiazines
Arsenic	Phenylbutazone
Captopril	Phenytoin
Carbamazepine	Piperazine
Cimetidine	Procainamide
Coumadin	Propylthiouracil
Didanosine	Quinidine
Enalapril	Radiocontrast media
Erythromycin	Streptomycin
Etacrynic acid (ethacrynic acid)	Sulphonamides
Fluoroquinolone antibiotics	Trazodone
Fluoxetine	Tetracycline
Furosemide (frusemide)	Thiazides
Griseofulvin	Trimethadione
Guanethidine	Vaccines
Hydralazine	Zidovudine
Iodides	

Leukocytoclastic vasculitis and necrotizing angiitis have also been documented in drug abusers [30–32].

Lupus erythematosus-like syndrome

A reaction resembling idiopathic LE has been reported in association with a large variety of drugs [1–9], although only about 5% of cases of SLE are drug induced. Cutaneous manifestations are in general rare: 18% and 26%, respectively, of patients with procainamide- and hydralazine-induced LE had skin changes in one series [6]. Photosensitivity may be prominent; some patients develop discoid LE lesions; urticarial or erythema multiforme-like lesions may also be seen. Constitutional symptoms may be present, and there may be evidence of Raynaud's disease, arthritis or polyserositis. Renal involvement is rare, as is central nervous system involvement. The condition usually, but not always, resolves after discontinuation of the drug. Abnormal laboratory findings include the presence of LE cells, and of antinuclear antibodies directed against ribonucleoprotein, single-stranded DNA and especially histones [10,11]. Antibodies against native double-stranded DNA are rarely found in drug-induced LE, and complement levels are normal; deposition of immunoreactants in uninvolved skin is rare. Patients with drug-induced LE may have the lupus anticoagulant [12,13].

A partial list of drugs reported to induce an SLE-like syndrome or exacerbate idiopathic LE is given in Table 73.15. Drugs most commonly implicated in inducing LE include especially hydralazine [14,15] and procainamide [16,17], and less commonly β-blockers, methyldopa [18,19], isoniazid, most anticonvulsants in clinical use

Table 73.15 Drugs inducing lupus erythematosus-like syndromes.

Angiotensin-converting enzyme inhibitors (captopril)	Lithium
Anticonvulsants	Methyldopa
Carbamazepine	Methysergide
Hydantoins	Nitrofurantoin
Primidone	Oral contraceptives
Trimethadione	Penicillin
Valproate	Penicillamine
Allopurinol	Phenothiazines (chlorpromazine)
Aminoglutethimide	Phenylbutazone
p-Aminosalicylic acid	Procainamide
β-Blockers	Quinidine
Calcium channel blockers	Streptomycin
Clonidine	Sulfasalazine (sulphasalazine)
Co-trimoxazole	Sulphonamides
Ethosuximide	Terbinafine
Gold salts	Tetracycline
Griseofulvin	Thiazide diuretics
Hydralazine	Thionamide
Ibuprofen	Thiouracils
Isoniazid	

including phenytoin, carbamazepine, ethosuximide, trimethadione, primidone and valproate (but not phenobarbital or benzodiazepines) [20], and quinidine [21,22]. LE following penicillamine therapy [23,24], 2-mercaptopropionylglycine [25], rifampicin [26], etanercept [27] and the tetracycline derivative COL-3 used in antiangiogenesis [28] has also been documented. Minocycline may induce an autoimmune syndrome of which LE may form part [29–31].

Subacute LE with positive Ro/SSA antibodies has been reported in association with a number of drugs [9], including phenytoin [32], thiazide diuretics such as hydrochlorothiazide [33–36], ACE inhibitors [37,38], calcium channel blockers [39], terbinafine [40–42], griseofulvin [43], piroxicam, oxprenolol, interferons and statins. The oral contraceptive induced LE lesions on the palms and feet of a patient [44]. In addition, a number of drugs may exacerbate pre-existing SLE, such as griseofulvin, β-blockers, sulphonamides [45], testosterone and oestrogens.

Dermatomyositis reactions

Dermatomyositis has been reported to be precipitated by a variety of drugs, including penicillamine [1–3], NSAIDs (niflumic acid and diclofenac) [4], carbamazepine [5] and vaccination, as with BCG [6]. Acral skin lesions simulating chronic dermatomyositis have been reported during long-term hydroxyurea therapy [7]. Allergy to benzalkonium chloride has caused a dermatomyositis-like reaction [8].

Scleroderma-like reactions

Penicillamine [1,2], bleomycin [3,4], bromocriptine [5], vitamin K (phytomenadione) [6,7], sodium valproate [8] and 5-hydroxytryptophan combined with carbidopa [9,10] (see also the eosinophilia–myalgia syndrome below) have all been implicated in either localized or generalized morphoea-like, or systemic sclerosis-like, reactions. Eosinophilic fasciitis has been associated with tryptophan ingestion in some cases [11], as well as with phenytoin [12].

Chemical and industrial causes of scleroderma-like reactions [1]

Scleroderma-like changes formed part of the clinical spectrum of the Spanish toxic oil syndrome, which resulted from contamination of rapeseed cooking oil with acetanilide [2]. Scleroderma-like changes have been induced by industrial exposure to vinyl chloride [3], epoxy resins [1,4], organic solvents [5] including perchlorethylene [6], trichlorethylene and trichlorethane [7], and in coalminers due to silica exposure [8,9].

Eosinophilia–myalgia syndrome

Ingestion of tryptophan, taken as a mild antidepressant, a 'natural hypnotic', or by athletes to increase pain

tolerance, was associated with eosinophilia–myalgia syndrome [1–4], characterized by eosinophilia, myalgia, arthralgia, limb swelling, fever, weakness and fatigue, respiratory complaints, pulmonary hypertension, arrhythmias, ascending polyneuropathy and a variety of cutaneous manifestations. The latter included diffuse morbilliform erythema, urticaria, angio-oedema, dermatographism, livedo reticularis, alopecia and papular mucinosis. Some patients developed chronic muscle weakness, with diffuse scleroderma-like or fasciitis-like skin changes. The eosinophilia–myalgia syndrome is now thought to have been caused by a contaminant of L-tryptophan following a change in the manufacturing process between October 1988 and June 1989 [5,6].

Erythema nodosum [1]

Sulphonamides, other antibiotics [2], a variety of analgesics, antipyretics and anti-infectious agents, as well as the contraceptive pill [2–5], oestrogen replacement therapy [6], treatment of haematological disorders with granulocyte colony-stimulating factor [7], all-*trans*-retinoic acid [8] and *Echinacea* herbal therapy [9] have all been implicated in the aetiology of erythema nodosum. Erythema nodosum leprosum was induced by prolonged treatment with recombinant IFN-γ (in 60% of patients within 7 months) [10] and by co-trimoxazole [11].

Pseudolymphomatous syndrome: anticonvulsant hypersensitivity syndrome

This syndrome should be differentiated from the drug hypersensitivity syndrome, which has a more acute onset (see above). A number of drugs may produce a reaction pattern that simulates a lymphoma [1–6]. Skin involvement may consist of erythematous plaques, multiple infiltrative papules or solitary nodules; there may be facial oedema. Pseudolymphomatous syndrome develops between 2 weeks and 5 years after starting drug therapy, but usually within 7 weeks. Histopathologically, there is epidermotropism of atypical lymphocytes, often with Pautrier's microabscess-like structures; pseudolymphomatous syndrome differs from mycosis fungoides in that there may be moderate to marked spongiosis, necrotic keratinocytes, epidermal eosinophils, papillary dermal oedema and extravasated erythrocytes, and a mixed dermal inflammatory infiltrate including neutrophils. Misdiagnosis of pseudolymphomatous syndrome as malignant lymphoma may lead to patients being treated unnecessarily with chemotherapy.

Phenytoin especially, but also phenobarbital and carbamazepine, mephenytoin, trimethadione and sodium valproate have been implicated [7–12]. Cutaneous lesions in patients with reactions to phenytoin or carbamazepine may show histological features of mycosis fungoides; cutaneous lesions resembling those of mycosis fungoides in the absence of fever have been reported with phenytoin and carbamazepine. Phenobarbital has produced a hypersensitivity syndrome resembling Langerhans' cell histiocytosis [13].

Other drugs have been associated with mycosis fungoides-like drug eruptions, including allopurinol, antidepressants (e.g. fluoxetine [14,15] and amitriptyline [15]), phenothiazines [16], thioridazine, benzodiazepines, antihistamines [4], β-blockers (e.g. atenolol [17]), ACE inhibitors [18], calcium channel blockers, salazosulfapyridine [19], lipid-lowering agents, mexiletine, ciclosporin [20], penicillamine, amiloride hydrochloride with hydrochlorothiazide, bromocriptine [21] and gemcitabine [22]. A generalized cutaneous B-cell pseudolymphoma was induced by neuroleptics [23]. Cutaneous T-cell lymphoma

and Sézary syndrome have been reported in association with silicone breast implants [24,25].

Pseudolymphomatous syndrome usually responds to drug withdrawal, although not for many months in some cases [5]. Occasionally, a true lymphoma may develop.

Acanthosis nigricans-like and ichthyosiform eruptions

See Chapter 34.

Erythromelalgia [1]

Drugs implicated include iodide contrast media, vaccines (influenza and hepatitis), nifedipine, felodipine, nicardipine, bromocriptine, norephedrine, pergolide and ticlopidine.

Hair changes (see also Chapter 63)

Drug-induced alopecia

A considerable number of drugs have been reported to cause hair loss [1–5]; the most important causes are listed in Table 73.16. Cytotoxic drugs may cause alopecia by either anagen or telogen effluvium. Chemotherapeutic agents implicated in the production of alopecia include amsacrine, bleomycin, cyclophosphamide, cytarabine, dactinomycin, daunorubicin, doxorubicin, etoposide, fluorouracil, methotrexate and the nitrosoureas [2]. Telogen alopecia has been caused by anticoagulants (heparins and coumarins), antithyroid drugs (carbimazole and thiouracils), levodopa, propranolol, albendazole and oral contraceptives. Retinoids cause alopecia by disrupting

Table 73.16 Drugs causing alopecia.

Anticoagulants	Retinoids
Coumarins	Acitretin
Dextran	Etretinate
Heparin	Isotretinoin
Heparinoids	Miscellaneous
Anticonvulsants	Albendazole
Carbamazepine	Allopurinol
Valproic acid	Amfetamine (amphetamine)
Cytotoxic agents	Antithyroid drugs
Drugs acting on the central nervous system	Bromocriptine
	Captopril
Amitriptyline	Cholestyramine
Doxepin	Cimetidine
Haloperidol	Dixyrazine
Lithium	Gentamicin
Hypocholesterolaemic agents	Gold
Clofibrate	Ibuprofen
Nicotinic acid	Levodopa
Triparanol	Metoprolol
Antithyroid drugs	Oral contraceptives
Carbimazole	Propranolol
Thiouracils	Trimethadione

Table 73.17 Drugs causing hypertrichosis.

Androgens	Penicillamine
Corticosteroids	Phenytoin
Ciclosporin	Psoralens
Diazoxide	Streptomycin
Minoxidil	

keratinization. Hydantoins may cause scalp alopecia and hypertrichosis elsewhere, and clofibrate may cause alopecia by interfering with keratinization. Temporary hair loss has been described after 5-aminosalicylic acid enemas [6] and bromocriptine [7], and danazol has induced generalized alopecia [8]. Certain β-blockers have caused increased hair loss [9–11] as have dixyrazine [12] and ibuprofen [13].

Drug-induced hirsutism and hypertrichosis

The hirsutism induced in women by corticosteroids, androgens and certain progestogens is well recognized. Other drugs that may cause hypertrichosis are listed in Table 73.17 [3,4]. Up to 50% of children treated with diazoxide, and up to 40% of patients on ciclosporin, develop hypertrichosis. Zidovudine has caused excessive growth of eyelashes [14].

Drug-induced hair discoloration (see Chapter 63)

Drug-induced change in hair colour, usually occurring 3–12 months after the onset of treatment, is a rare but well-recognized phenomenon [1,2]. Darkening of hair has occurred during treatment with verapamil [3], tamoxifen [4], carbidopa [5] and PABA. Etretinate has caused darkening as well as lightening, curling and kinking of hair [6]. Greying of hair has been reported with chloroquine and mephenesin [7]. Chloroquine depigmentation is reversible and occurs only in red- or blonde-haired individuals; both IFN-α [8] and chloroquine are capable of arresting phaeomelanin synthesis.

Nail changes

Drug-induced nail abnormalities have been the subject of several reviews [1–7] (see Chapter 62). Heavy metals may induce the following changes: arsenic causes transverse, broad, white lines (Mee's lines); silver causes blue discoloration of the lunulae; gold results in thin and brittle nails with longitudinal streaking, yellow-brown discoloration and onycholysis; and lead produces partial leukonychia. Penicillamine therapy is associated with the yellow nail syndrome and nail dystrophy. Cytotoxic agents may produce transverse or longitudinal pigmentation, splinter haemorrhages, Beau's lines, leukonychia, Mee's lines, onycholysis, shortening of lunulae, pallor, atrophy, nail shedding and slow growth; acute paronychia has occurred with methotrexate. The β-blockers may induce a psoriasiform nail dystrophy, with onycholysis and subungual hyperkeratosis. Thiazide diuretics may result in onycholysis. Discoloration or pigmentation occurs with antimalarials (blue-brown discoloration), lithium (golden discoloration), phenolphthalein (dark-blue discoloration), phenothiazines (blue-black or purple pigmentation), phenytoin (pigmentation), psoralens and tetracyclines (yellow pigmentation). Oral contraceptives may induce photo-onycholysis and onycholysis, and are associated with an increased growth rate and reduced splitting and fragility. In contrast, heparin reduces nail growth and causes transverse banding and subungual haematomas. Retinoids cause thinning and increased fragility, onychoschizia, onycholysis, temporary nail shedding, onychomadesis, ingrowing nails, periungual granulation tissue and paronychia.

Table 73.18 Drugs causing onycholysis.

Antibiotics	*Miscellaneous*
Cefaloridine (cephaloridine)	Acridine
Cloxacillin	Captopril
Chloramphenicol	Norethindrone and mestranol
Chlortetracycline	Practolol (discontinued)
Demethylchlortetracycline	Psoralens
Doxycycline	Phenothiazines
Fluoroquinolones	Retinoids
Minocycline	Sulpha-related drugs
Tetracycline hydrochloride	Thiazides
Chemotherapeutic agents	*Photo-onycholysis*
Adriamycin	Oral contraceptives
Bleomycin	Psoralens
5-Fluorouracil	Fluoroquinolones
Mitoxantrone	Tetracyclines

Onycholysis

Drugs causing onycholysis [6,7] and photo-onycholysis are listed in Table 73.18.

Oral conditions (see also Chapter 66)

ADRs affecting the mouth have been extensively reviewed [1–4]. Disturbance of taste has been reported with a wide variety of drugs [5,6], including captopril, griseofulvin, metronidazole and protease inhibitor antiretrovirals. Orofacial effects of antiretroviral therapies have been reviewed [6]. These include mouth ulcers due to bone marrow suppression, erythema multiforme (e.g. with didanosine), lichenoid reactions with zidovudine, xerostomia (seen in up to one-third of patients taking didanosine), oral and perioral paraesthesiae (especially with ritonavir), and cheilitis with indinavir.

Xerostomia

Dryness of the mouth (xerostomia) may result from anticholinergic side effects of drugs. Xerostomia has been recorded in association with antidepressants, tranquillizers, antiparkinsonian drugs, antihypertensives and gastrointestinal antispasmodics (Table 73.19). Parotitis with salivary sialadenitis has been reported in up to 15% of patients taking phenylbutazone, and may be associated with fever and a rash [7]. A similar syndrome may occur with repeated administration of iodinated contrast media [8] and with nitrofurantoin [9].

Table 73.19 Drugs associated with xerostomia.

Antidepressants (tricyclic)	Minor tranquillizers
Amitriptyline	Diazepam
Doxepin	Chordiazepoxide
Imipramine	Hydroxyzine
Antidepressants (monoamine oxidase inhibitors)	Antiparkinsonian drugs
Isocarboxazid	Antihypertensives (ganglion blockers)
Phenelzine	Gastrointestinal antispasmodics
Psychotropic agents	Atropine
Chlorpromazine	Propantheline bromide
Thioridazine	Phenobarbital (phenobarbitone)
Haloperidol	
Prochlorperazine

Stomatitis

Type I immediate hypersensitivity and type IV delayed hypersensitivity reactions may be involved in allergic stomatitis [1]. The allergic stomatitides may present with clinical appearances that mimic classic oral vesiculobullous and ulcerative lesions. Stomatitis may form a part of drug-induced lichenoid reactions, fixed drug reactions or erythema multiforme, but may also arise separately from these conditions as a side effect of a number of drugs (Table 73.20). Chemotherapeutic agents causing stomatitis or buccal ulceration include [2] actinomycin D, adriamycin, amsacrine, bleomycin, busulfan, chlorambucil, cyclophosphamide, dactinomycin, daunorubicin, doxorubicin, fluorouracil, IL-2, mercaptopurine, methotrexate, mithramycin, mitomycin, nitrosoureas, procar-

Table 73.20 Drugs causing stomatitis or buccal ulceration.

Chemotherapeutic agents	Antihypertensive agents
Antirheumatic drugs	Captopril
Gold	Hydralazine
Naproxen	Methyldopa (rare)

Zomepirac	Valproic acid
Antidepressants	
Amitriptyline	
Doxepin	
Imipramine	

bazine and vincristine. Penicillamine may induce stomatitis or ulceration as part of drug-induced pemphigus [3] or a lichenoid drug eruption. Gold therapy is another well-recognized cause of stomatitis [4–6]. Allergic reactions to dental materials and therapy may cause stomatitis. Positive patch tests to mercuric chloride were seen in 42%, and to copper sulphate in 16%, of patients with oral mucosal lesions associated with amalgam restorations, compared with 9% of controls, in one series [7]. It has been postulated that mercury released from dental amalgams can cause hypersensitivity/toxic reactions resulting in lichen planus lesions, and may play a major role in the pathogenesis of gingivitis, periodontitis and periodontal disease [8]. Mercuric chloride caused statistically significant increased IFN-γ release, but not proliferation, in lymphocyte cultures from patients with hypersensitivity to amalgam restorations [9]. β-Blockers have been implicated in aphthous ulcers [10].

Hyperpigmentation

Hyperpigmentation of the buccal mucosa may occur with chemotherapeutic agents [1]. Oestrogen is associated with gingival hypermelanosis [2]. Amalgam tattoos with localized hyperpigmentation of the buccal mucosa result from implantation of amalgam in soft tissues, especially of the gingival or alveolar mucosa [3].

Reactions caused by antibacterial, antifungal and immunosuppressive therapy

Systemic antibiotics or immunosuppressive medication [4], and corticosteroids administered by aerosol [5], may lead to the development of candidiasis of the buccal mucosa. Black hairy tongue may be associated with broad-spectrum antibiotic therapy and with griseofulvin treatment.

Gingival hyperplasia

Gingival hyperplasia may be caused by phenytoin [6], nifedipine [7], diltiazem [8], felodipine, verapamil and ciclosporin [9].

Important or widely prescribed drugs

Antibacterial agents

β-Lactam antibiotics

Inaccurate histories of allergy to antibiotics are frequently documented in medical records by hospital doctors [1]. Reactions to β-lactam antibiotics may be immediate, accelerated or delayed [2–5]. Non-immediate reactions to penicillins are a reproducible phenomenon, suggesting that a specific mechanism is responsible [6]. In one study, 39% of 74 subjects with a cutaneous reaction to a penicillin derivative had a non-immediate reaction, in 93% to an aminopenicillin (10.3% ampicillin, 82.7% amoxicillin).

There was a positive delayed direct challenge and a delayed skin-test response in 65% of cases, and a lymphomonocytic infiltrate on skin biopsy [6]. Cross-reactivity exists between several members of this group of antibiotics, but restricted sensitivity to a single penicillin derivative also occurs [7]. As a group, penicillins had a higher frequency of allergic reactions than cephalosporins in a study of patients with cystic fibrosis treated with parenteral β-lactam antibiotics [8]. Serum sickness reactions occur [9]. (See also acute generalized exanthematous pustulosis, p. 73.35.)

Penicillin

Toxic reactions to penicillin are extremely rare and usually only follow massive doses, but can occur with normal doses in patients with renal impairment; encephalopathy with epilepsy may result from binding of the β-lactam ring to γ-aminobutyric acid receptors [1]. In contrast, immunological reactions are common [2–4]; allergy to penicillin has been reported in up to 10% of patients treated [5]. All forms of penicillin, including the semisynthetic penicillins, are potentially cross-allergenic; in general, allergic reactions to semi-synthetic compounds are commoner than to natural penicillins. All four types of immunological reaction may occur: urticaria and anaphylactic shock (type I), haemolytic anaemia or agranulocytosis (type II), allergic vasculitis or serum sickness-like reaction (type III) and allergic contact dermatitis [6] (type IV). Immediate reactions occur within 1 h, and take the form of urticaria, laryngeal oedema, bronchospasm and/or anaphylactic shock. So-called accelerated reactions with the same clinical features develop 1–72 h later. Reactions occurring more than 72 h after exposure are termed late reactions; these include maculopapular rashes with scarlatiniform and morbilliform exanthems, urticaria, serum sickness, erythema multiforme, haemolytic anaemia, thrombocytopenia and neutropenia. Fever is the commonest reaction.

The antigenic structures responsible for penicillin allergy include a 'major determinant', the penicilloyl group formed by spontaneous hydrolysis of penicillin (penicilloyl polylysine is used for skin testing), and additional antigenic compounds to which benzylpenicillin is metabolized, termed 'minor determinants' [3]. Most immediate-type anaphylactic hypersensitivity reactions are mediated by IgE antibodies to minor antigenic determinants, whereas accelerated reactions are usually the result of IgE antibodies directed against the major antigenic determinant [3,7]. For information on skin testing for penicillin, see the diagnosis section at the end of the chapter (p. 73.174).

Anaphylactic reactions to penicillin reportedly occur in about 0.015% of treatment courses; fatal reactions occur in 0.0015–0.002% (i.e. 1 in 50 000 to 1 in 100 000) of treatment courses [8]. Young and middle-aged adults aged 20–49 years are at most risk [9]. Atopy does not augment the risk of a reaction to β-lactam antibiotics, but may increase the risk of any reaction being severe [3]. Anaphylaxis is commoner after parenteral administration, and is very rare, but has been recorded, after oral ingestion [9]. Maculopapular reactions occur in about 2% of treatment courses [3]; where there is a history of a prior penicillin reaction, the risk of a subsequent reaction increases to about 10% [10]. A fair proportion (33% in one study) of children may lose their skin-test reactivity within a year [11]. In practice, when penicillin is given to children said to be allergic to penicillin, very few experience an adverse reaction [7]. In adults, the rate of disappearance of penicillin-specific IgE is highly variable, from 10 days to indefinite persistence [3]. For a group of penicillin-allergic patients, the time lapsed since a previous reaction is inversely related to the risk of a further IgE-mediated reaction [10]. In one study, 80–90% of patients were skin-test positive 2 months after an acute allergic reaction, but less than 20% were skin-test positive 10 years later [12]. Nevertheless, patients with a prior history of an IgE-dependent reaction remain at risk of recurrence, even though IgE antibodies become undetectable by skin testing [13]. Most serious and fatal allergic reactions to β-lactam antibiotics occur in individuals who have never had a prior allergic reaction; a negative history should therefore not induce a false sense of security [3]. Continuous prophylactic treatment is associated with a very low incidence of reactions [14].

Activation of allergy in a sensitized individual may require only minute amounts of the drug, as from contaminated syringes, dental root-canal fillings, viral vaccines, contaminated milk or meat products, and contamination of transfused blood [15]. Urticaria and wheezing occurred in the penicillin-sensitive spouse of a man receiving

parenteral mezlocillin, and was postulated to have arisen as a result of seminal fluid transmission of penicillin [16]. Hypersensitivity reactions have occurred after intrauterine placement, in penicillin-sensitive patients, of spermatozoa or embryos exposed to penicillin *in vitro* [17].

Penicillin has been reported to cause erythema multiforme [18], vesicular and bullous eruptions, exfoliative dermatitis [19], vascular purpura or fixed eruptions, post-inflammatory elastolysis (cutis laxa), which was generalized and eventually fatal in one case [20], and a very few cases of pemphigus vulgaris [21,22], pemphigoid [23] and pustular psoriasis [24]. It has been proposed that penicillin may have a role in chronic 'idiopathic' urticaria [25].

Cloxacillin and flucloxacillin

Cloxacillins cross-react with penicillins, but unlike ampicillin do not produce distinctive eruptions. Flucloxacillin rarely elicits primary penicillin hypersensitivity. In one case report, parenteral cloxacillin was tolerated but oral administration caused progressive generalized erythema with pruritus, facial angio-oedema and tachycardia [27]. Flucloxacillin has been implicated as a cause of cholestatic jaundice; this complication is rare, and the risk is greater in elderly patients and those receiving therapy for more than 2 weeks [27].

Ampicillin

A morbilliform rash, with onset on the extremities and becoming generalized, occurs in 5–10% of patients treated with ampicillin, and usually develops 7–12 days after onset of therapy. This time interval suggests an allergic mechanism, although the rash disappears spontaneously even if ampicillin is continued, and may not develop on re-exposure [1]. Skin tests are generally negative. An urticarial reaction, present in about 1.5% of patients, indicates the presence of type I IgE-mediated general penicillin allergy [2,3]. Administration of ampicillin when a patient has infectious mononucleosis leads to florid morbilliform and sometimes purpuric eruptions in up to 100% of patients [4–6]. Cutaneous reactions to ampicillin are increased in cytomegalovirus infection [7], chronic lymphatic leukaemia [8], renal insufficiency or when allopurinol is administered concomitantly [9]. Ampicillin has been reported to cause a fixed drug eruption [10], erythema multiforme and Stevens–Johnson syndrome [11,12], TEN [13], Henoch–Schönlein purpura [14], serum sickness [15] and pemphigus vulgaris [16] in individual cases. Administration of ampicillin to a patient with a history of psoriasis resulted in erythroderma on two separate occasions [17]. A recurrent, localized, pustular skin eruption developed on the cheeks with ampicillin in one case [18].

Delayed intradermal skin tests and patch tests, indicating delayed hypersensitivity, were positive in about half of 60 subjects with maculopapular reactions to the aminopenicillins ampicillin and amoxicillin [19]; in another study, hypersensitivity to an antigenic determinant in the side-chain structure was suggested, as intradermal and patch tests were positive to ampicillin but there was good tolerance to benzylpenicillin [20]. Re-exposure of patients to ampicillins and other penicillins is contraindicated after urticarial reactions; anaphylactic reactions to ampicillin

have been recorded. The risk is far less after morbilliform rashes but is not negligible.

Amoxicillin

Cutaneous eruptions including urticaria or morbilliform or maculopapular rashes occur in 1–2% of treatment courses with amoxicillin [1–3]. Immediate allergy (anaphylaxis or urticaria/angio-oedema) to amoxicillin has occurred in patients with good tolerance of benzylpenicillin, aztreonam and ceftazidime [4,5]. However, amoxicillin has been reported to cross-react with penicillin on first exposure [6]. Amoxicillin caused an unusual intertriginous eruption in two patients [7]. Serum sickness has been reported with amoxicillin in children [8]. Amoxicillin has caused a fixed eruption [9], and a curious, recurrent, localized, pustular eruption [10]. This drug has also been implicated in the development of an acute generalized exanthematous pustulosis [11]. There may be an increased frequency of rash with amoxicillin and clavulanate therapy in HIV-positive patients [12]. Amoxicillin, like clavulanic acid and flucloxacillin, may cause a cholestatic hepatitis [13]. This occurs at a frequency of 1 in 6000 adults when the drug is combined with clavulanic acid (co-amoxiclav) [14]. Amoxicillin has also been implicated in the baboon syndrome [15], palmar exfoliative exanthem [16] and localized peri-buccal pustulosis [17].

Methicillin

Methicillin caused reappearance of a recently faded ampicillin rash in a patient with glandular fever [18].

Cephalosporins [1]

In general, cephalosporins are fairly well tolerated [1–3], adverse reactions ranging from 1 to 10% [1]; parenteral administration may cause minor adverse reactions, including thrombophlebitis and pain. The most common adverse effects are allergic reactions, occurring in 1–3% of patients [2]; haematological toxicity occurs in less than 1% of patients. Anaphylaxis is rare (less than 0.02%) [1]. Other reactions include localized gastrointestinal disturbances, hepatotoxicity, nephrotoxicity and mild central nervous

system effects. Cephalosporin reactions are minimally, if at all, increased in patients with histories of penicillin allergy [1]. Post-marketing studies of second- and third-generation cephalosporins showed no increase in allergic reactions in patients with a history of penicillin allergy. Cephalosporin antibiotics are safe in penicillin-allergic patients and penicillin skin tests do not identify potential reactors [1]. Isolated independent hypersensitivity to individual cephalosporins, such as cefazolin [4,5], cefonicid [6] and cefuroxime [7], with good tolerance to other β-lactam antibiotics, has been described.

Hypersensitivity reactions include various exanthems and contact urticaria [8]; cases of anaphylaxis to cefaclor [9] and of fatal anaphylactic shock related to cefalotin (cephalothin) [10] have been reported. Vulvovaginitis and pruritus ani are not uncommon. Delayed reactions have been reported with cefonicid [6] and cefuroxime [11]. Serum sickness reactions occur [12–15], especially with cefaclor; the latter drug may also cause urticaria and erythema multiforme [15]. Exfoliative dermatitis has been attributed to cefoxitin [16]. Disulfiram-like reactions to alcohol have been described with newer members of this group. Pustular reactions have been documented with cefradine, cefalexin and cefazolin [17–19]. Ceftazidime has been implicated in the development of erythema multiforme [20]. Cephalosporins [21] including cefalexin [22] have been reported to cause TEN, and cefalexin has precipitated pemphigus vulgaris [23]. Cefazolin has caused an unusual fixed drug eruption [24]. A curious photo-recall-like phenomenon followed the use of cefazolin and gentamicin sulphate, in that the eruption was restricted to an area of sunburn sustained 1 month previously [25]. Cefotaxime has caused a photodistributed phototoxic telangiectasia [26].

Monobactams

Monobactams (e.g. aztreonam) show weak and rare cross-reactivity with IgE antibodies to penicillin [1–3], although immediate hypersensitivity on first exposure to aztreonam in penicillin-allergic patients has been recorded [4,5]. In general, aztreonam is well tolerated in high-risk patients allergic to other β-lactam antibiotics, but there is a 20% sensitization rate following exposure [6]. However, aztreonam and the monobactams can be safely given to penicillin-allergic patients [7]. Generalized urticaria to aztreonam but good tolerance of the other β-lactams has been recorded [8].

Carbapenems

Cross-reactivity and allergic reactions to imipenem occur in patients known to be allergic to penicillin [9]. Carbapenems should be avoided in patients with penicillin allergy [7]. Imipenem combined with cilastatin, a non-antibiotic enzyme inhibitor that prevents breakdown of imipenem to nephrotoxic metabolites, may cause phlebitis or pain at the site of infusion [10]. Imipenem has been associated with a pustular eruption [11], and imipenem–cilastatin with palmoplantar pruritus during infusion in a child with AIDS [12].

Tetracyclines

Many of the side effects are common to all drugs within the group, and cross-sensitivity occurs [1]. Nausea, vomiting and diarrhoea are well-recognized dose-related effects. Oral or vaginal candidiasis may occur as a result of overgrowth of commensals. Resumption of therapy does not necessarily lead to recurrence of the vaginitis [2].

Photosensitivity

All tetracyclines, but especially demethylchlortetracycline, may cause phototosensitive eruptions [1,3–6], which clinically resemble exaggerated sunburn, sometimes with blistering. Phototoxicity is thought to be involved, in that high serum levels predispose to its occurrence. Reactions to both UVA and UVB have been reported. High concentrations of tetracycline are found in sun-damaged skin [3]. Symptoms may persist for months [1]. Photo-onycholysis may develop in fingernails and (if exposed) toenails; the thumb (normally less exposed) may be spared [7,8]. Tetracycline therapy is best avoided if there is a prospect of considerable sun exposure. Porphyria cutanea tarda-like changes may develop after chronic sun exposure [6,9]. A photosensitive lichenoid rash has been attributed to demethylchlortetracycline [10].

Pigmentation

Methacycline is a rare cause [1]. Long-term minocycline therapy for acne may result in pigmentation. Although this is generally held to be a rare event, it may occur in about 1.4% of patients [2–5]. The average time for the development of pigmentary changes was 5 months, and onset of this complication did not seem to be related to cumulative dosage of the drug [3]. Facial hyperpigmentation was reported in two sisters on long-term minocycline therapy, who were also being treated with Dianette (cyproterone acetate and ethinylestradiol); it was suggested that pigmentation occurred either as a result of a genetic alteration in the metabolic handling of the drug or because of accentuation by the concomitant therapy [6]. Other drugs, including amitriptyline [2], phenothiazines and 13-*cis*-retinoic acid, have been implicated in the accentuation of minocycline-related hyperpigmentation.

Three types of pigmentation are described with minocycline and may occur in combination or isolation [3]. A focal type with well-demarcated blue-black macules is seen in areas of previous inflammation or scarring, especially in relation to acne scars. Minocycline has been associated with post-inflammatory hyperpigmentation in women who have undergone sclerotherapy [7]. Macular or more diffuse hyperpigmentation may appear distant from acne sites, especially on the extensor surface of the lower legs and forearms and on sun-exposed areas. These two types resolve on cessation of therapy, with a mean time to resolution of 12 months [3]. A more persistent diffuse brown-grey change may develop, especially in sun-exposed areas [5]. Minocycline pigmentation may respond well to laser therapy [8–11].

The oral cavity and lips may be involved [12,13]. Conjunctival pigmentation may occur with tetracyclines [14,15] and scleral pigmentation with minocycline [16,17]. Minocycline can cause nail pigmentation and longitudinal melanonychia [5,18,19], and tetracycline may produce yellow discoloration of the nail [20]. Cutaneous osteomas presenting as blue skin nodules that fluoresce yellow under UV light may rarely develop in patients being treated with tetracycline [21] or minocycline [22] for acne.

Black galactorrhoea occurred in a patient taking both minocycline and phenothiazines [23].

Pigmentation may also involve bones, teeth, thyroid, aorta and endocardium [19,24]. Histological and electron microscopic studies have demonstrated increased melanin, haemosiderin and either minocycline or a metabolite in the skin [25–27]; pigment may be seen in dermal histiocytes and eccrine myoepithelial cells [26]. Minocycline is metabolized to form a brown-black degradation product [28].

Other cutaneous side effects

Allergic reactions are far less common than with penicillin. Morbilliform, urticarial, erythema multiforme-like and bullous eruptions [1,2], exfoliative dermatitis and erythema nodosum [3] have been reported, as well as a recurrent follicular acneiform eruption in one patient [4]. Minocycline has caused eosinophilic cellulitis and pustular folliculitis with eosinophilia [5]. Gram-negative folliculitis of the face is uncommon but well recognized; *Proteus* may be responsible, and the condition responds to ampicillin [6]. Tetracyclines are a well-known cause of fixed drug eruptions [7–9], and minocycline [10] and doxycycline [11] have caused Stevens–Johnson syndrome. TEN has been recorded [12]. It has been suggested that tetracyclines may exacerbate psoriasis [13,14]. An eruption resembling Sweet's syndrome has occurred with minocycline, tetracycline and doxycycline [15–17]. Pruritus at the site of active acne has been recorded within 2–6 weeks of starting oral tetracyclines (oxytetracycline, doxycycline or minocycline) [18].

Gastrointestinal absorption and drug interactions

Absorption of tetracyclines is reduced when taken with meals, especially those containing calcium or iron such as milk, or with drugs such as iron or antacids [1]. The decrease in serum levels following a test meal has been reported as follows: oxytetracycline 50% [1], minocycline 13% [1] and doxycycline 20% [2]. Oxytetracycline may have a hypoglycaemic effect in insulin-dependent diabetics [3]. Tetracyclines can potentiate the action of warfarin by depressing prothrombin activity, and elevate serum levels of lithium given simultaneously [4].

Systemic side effects of tetracyclines

Long-term use of tetracycline for acne may rarely result in benign intracranial hypertension [1,2]. As retinoids may potentiate this effect, it is safest not to use them in combination with tetracycline therapy for acne. Oesophageal ulceration has been described in a number of patients [3]. With the exception of doxycycline and minocycline, tetracyclines may exacerbate renal failure. Combination therapy with tetracyclines and nephrotoxic drugs such as gentamicin or diuretics should be avoided [4]. Deteriorated tetracyclines have caused nephropathy accompanied by an exanthematic eruption. Patients should be warned not to use outdated or poorly stored tetracycline, because degraded tetracycline can cause a Fanconi-type syndrome comprising renal tubular acidosis and proteinuria [5,6] and lactic acidosis [7]. Dose-related vestibular disturbance has been reported with minocycline [8]. Reversible pulmonary infiltration with eosinophilic or neutrophilic alveolitis has been rarely described in association with tetracycline [9] and especially minocycline [10–12] therapy. There have been isolated case reports linking tetracycline with SLE [13].

Minocycline has been reported to cause other serious, albeit rare, adverse events. Serum sickness-like reactions occur at about 15 days [14,15]. A hypersensitivity syndrome may develop at about 23–35 days, with a severe self-limiting eruption, sometimes exfoliative dermatitis, associated with eosinophilia and acute hepatic failure, occasionally fatal [16–20]. A drug-induced autoimmune syndrome with hepatitis or vasculitis and some features of SLE occurs rarely with minocycline, on average 1–2 years after the start of therapy, and is commoner in women [20–25]. Hepatitis, sometimes with the histological features of chronic active hepatitis, may be associated with polyarthralgia and positive antinuclear antibodies but negative or only weakly positive anti-DNA antibodies, and is only rarely fatal; patients usually recover within 3 months of drug cessation. Perinuclear antineutrophilic cytoplasmic antibody (p-ANCA) may be a marker for development of minocycline-induced autoimmunity [26–28]; in one study, all such patients were p-ANCA positive and had the haplotype HLA-DR4 or HLA-DR2, and all had the HLA-DQB1 allele, suggesting genetic susceptibility [28]. Systemic reactions to minocycline are certainly more frequent than those to oxytetracycline or doxycycline [29], and it has therefore been suggested that the use of minocycline in acne should be restricted to patients unresponsive to other tetracyclines [30].

Effects on the fetus and on teeth

There is little evidence that tetracycline is teratogenic [1]. There is an isolated case report of congenital abnormalities in a child whose mother took clomocycline for acne [2]. Yellow discoloration of the teeth due to tetracycline exposure during mineralization of the deciduous or permanent teeth is well known [3–5]. A yellow-brown fluorescent discoloration is formed as a result of a complex with calcium orthophosphate. Tetracyclines should not be given to pregnant women or children under the age of 12 years. Tetracyclines are excreted in breast milk, but chelation with calcium decreases their absorption so that tooth discoloration is probably prevented [1].

Tetracycline may be deposited up to late adolescence in calcifying teeth such as the molars, but as these are not normally visible this is not a problem [5]. Minocycline may rarely stain the teeth of adults [6–8].

Tetracyclines and the contraceptive pill

Tetracyclines have been reported to interfere with the action of the contraceptive pill [1,2], and it is standard practice to inform female patients of this and to suggest use of an additional or alternative method of contraception while on medication. However, there is controversy as to whether there is really a significant risk of interaction [3–6]. It has been argued that there is a baseline pill failure rate of at least 1% per year, and that antibiotics commonly used in dermatology do not increase the risk of pregnancy [6].

Sulphonamides and trimethoprim

Reactions occur in 1–5% of those exposed [1–5]. They are commoner in patients with AIDS [6–8], and slow acetylators are at greater risk [9]. Type I reactions (urticaria and anaphylaxis) are rare but recorded. Phototoxic and photoallergic eruptions occur [10,11]. Morbilliform and rubelliform rashes are seen, and erythema multiforme, Stevens–Johnson syndrome and TEN [12–17], erythema nodosum [1], generalized exfoliative dermatitis [1,18,19] and fixed eruptions [20] are all well known. In addition, an LE-like syndrome and allergic vasculitis [21] are documented. Agranulocytosis or haemolytic anaemia is occasionally precipitated.

Sulfasalazine

Rashes occur in 1–5% of patients, and may be widespread as part of a hypersensitivity syndrome with hepatitis and encephalopathy [1–5], but desensitization is possible [6]. Blood disorders attributable to sulfasalazine occur at a rate of 3 per 1000 users [7]. An autoimmune syndrome has been described [8]. Photosensitivity [9] and a fixed eruption [10] have been documented. TEN, erythroid hypoplasia and agranulocytosis have been reported [11]. Bronchiolitis obliterans and alveolitis are well-recognized complications, and acute hypersensitivity pneumonia is recorded. LE, including cerebral LE, may be induced [12]. Reversible oligospermia may occur [13], and reversible hair loss has been attributed to use of this drug in enemas [14]. Many of the above adverse effects are attributable to the carrier molecule, sulfapyridine, which delivers 5-aminosalicylic acid, the component of sulfasalazine active in ulcerative colitis, to its site of action in the colon; patients who are slow acetylators may be especially prone to side effects [15]. Urticaria, and possibly the renal toxicity, are due to the 5-aminosalicylic acid component [16].

Mesalazine (5-aminosalicylic acid)

Fever, erythematous skin eruption and lung involvement [17], and fever, diarrhoea, exfoliative dermatitis, marked atypical lymphocytosis and severe hepatotoxicity [18] have been described in patients with a previous history of sulfasalazine hypersensitivity. Additional cutaneous hypersensitivity reactions including vasculitis [19], a Kawasaki-like syndrome [20] and an LE-like syndrome [21] have been documented. This drug may cause renal damage, and is associated with blood dyscrasia [22] including fatal bone marrow suppression and thrombocytopenia [23]. A pustular reaction is recorded [24].

Olsalazine

This drug, which consists of a dimer of two molecules of 5-aminosalicylic acid linked by an azo bond, dispenses with the unwanted effects of sulfapyridine. Nonetheless, up to one in five patients experience diarrhoea, rash, nausea and abdominal pain severe enough to stop treatment with the drug [16].

Sulfamethoxypyridazine

Obliterative bronchiolitis and alveolitis have been documented in a patient with linear IgA disease of adults [25].

Sulfadoxine

This sulphonamide is used in malaria prophylaxis in combination with pyrimethamine. The risk of reactions seems to be very low, but drug fever, TEN and photodermatitis have been recorded [1]. Stevens–Johnson syndrome may occur with Fansidar (pyrimethamine and sulfadoxine) for malaria prophylaxis [1–4] or with sulfadoxine alone [5]. TEN has occurred with Fansidar in an AIDS patient [6].

Trimethoprim–sulfamethoxazole (co-trimoxazole)

The general incidence and patterns of reactions to this mixture of sulfamethoxazole and trimethoprim are about the same as for sulphonamides in general; cutaneous reactions are seen in 3.3% of patients [1–3]. Severe cutaneous reactions of all types occur in about 1 per 100 000 users of the drug [2,3]. In view of these severe reactions, the drug is now indicated primarily for *Pneumocystis carinii* pneumonia, and for acute exacerbations of chronic bronchitis and urinary tract infections, and otitis media in children, only where there is good reason to prefer this combination [4]. There is a greatly increased incidence of reactions in patients with AIDS [5–13]. In one study, 18 of 38 patients with AIDS and *P. carinii* pneumonia treated with trimethoprim–sulfamethoxazole developed cutaneous reactions within a median of 11 days. It is sometimes possible to continue treatment through a hypersensitivity reaction, as reported for 67% of cases in the above study [14]. Adjuvant corticosteroids reduce the incidence of adverse cutaneous reactions to co-trimoxazole in patients with AIDS who are treated for hypoxaemic *P. carinii* pneumonia, but the incidence of mucocutaneous herpes simplex virus infection is higher [15]. If it is deemed essential to continue the drug, desensitization can be attempted [16,17].

Fixed eruptions occur [18–22], and may be due to the sulphonamide or trimethoprim components; a widespread fixed eruption mimicking TEN has been documented in one case [23]. Pustular reactions [24] and Sweet's syndrome [25] have been documented. Severe reactions have included erythema multiforme or Stevens–Johnson syndrome [26,27] that has been fatal [27], TEN in AIDS patients [5,11,12], cutaneous vasculitis [28] and fatal agranulocytosis [29]. One patient developed a rapidly progressive subepidermal bullous eruption within hours of intravenous trimethoprim–sulfamethoxazole [30].

Trimethoprim

Used alone, this substance causes less reactions than sulphonamides; fixed eruption has been proven [1–3] and was linear in one case [4]. Two patients experienced life-threatening immediate reactions and one patient developed generalized urticaria following oral trimethoprim–sulfamethoxazole; prick tests and oral challenge tests were positive with trimethoprim but not sulfamethoxazole [5].

Aminoglycosides

Gentamicin, tobramycin, streptomycin and kanamycin cross-react and are all potentially ototoxic and nephrotoxic. Exanthematic eruptions are common with streptomycin, developing in 5% or more of patients. Continued treatment may lead to generalized exfoliative dermatitis with these drugs [1] in a minority, but in a proportion of patients the rash subsides and treatment can be continued. Fever and eosinophilia may be associated with the reactions. Urticaria [2], maculopapular rashes, fever and eosinophilia are well recognized with this group of drugs. Skin necrosis following subcutaneous injection of aminoglycoside antibiotics (gentamicin, sisomicin and netilmicin) has been reported in elderly females with a history of thrombosis being treated with heparin anticoagulant therapy [3–5]. The reaction has also occurred following intramuscular sisomicin in a patient with defective fibrinolysis and abnormal neutrophil function [6]. A toxic erythema with generalized follicular pustulosis has been documented with streptomycin [7]. Deafness has rarely followed topical therapy with neomycin, including administration of aerosol preparations in the treatment of extensive burns. An anaphylactic reaction due to streptomycin occurred during *in vitro* fertilization immediately after embryo transfer [8].

Macrolide antibiotics

Macrolides account for 10–15% of the worldwide oral antibiotic market, with severe adverse reactions being rare [1]. Gastrointestinal reactions occur in 15–20% of patients on erythromycins and in 5% or fewer patients treated with some recently developed macrolide derivat-

ives that seldom or never induce endogenous release of motilin, such as roxithromycin, clarithromycin, dirithromycin, azithromycin and rikamycin. Except for troleandomycin and some erythromycins administered at high dose and for long periods of time, the hepatotoxic potential of macrolides is low. Transient deafness and allergic reactions to macrolide antibacterials are highly unusual and are more common with the erythromycins than with the recently developed 14-, 15- and 16-membered macrolides.

Azithromycin

This drug has caused toxic pustuloderma [2].

Clarithromycin

Fixed drug eruption is recorded [3].

Erythromycin

This is one of the most innocuous antibiotics in current use. Cholestasis caused by the estolate ester is the only potentially serious side effect. Hypersensitivity skin reactions are rare but when they occur skin tests may be positive [4,5]. Erythema multiforme, Stevens–Johnson syndrome, toxic pustuloderma [6], systemic contact dermatitis [7] and vasculitis have all been recorded.

Spiramycin

Rashes, usually transient erythema, may occur in up to 1% of cases. Spiramycin, given for toxoplasmosis in pregnancy, was associated in one case with an erythematous maculopapular pruritic eruption with eosinophilia and raised γ-glutamyl transpeptidase [8]. The drug has caused an allergic vasculitis [9].

Clindamycin and lincomycin

These antibiotics have become particularly associated with a potentially lethal pseudomembranous colitis due to superinfection with *Clostridium difficile* [1–3]. Vancomycin or metronidazole is the treatment of choice for this complication. Hypersensitivity skin reactions are rare with lincomycin but common with clindamycin, occurring in up to 10% of patients [4]. Erythema multiforme and anaphylaxis are very rare [5].

Miscellaneous antibiotics

Chloramphenicol

Although contact dermatitis from topical application is common, hypersensitivity skin reactions to oral therapy are rare. Macular, papular and urticarial eruptions are reported [1], as is acute generalized exanthematous pustulosis [2]. Pruritus may be prominent. Erythema multiforme and TEN [3] occur rarely. There is a risk of aplastic anaemia [4] and death has exceptionally followed the use of eye drops [5].

5 Fraunfelder FT, Bagby GC. Ocular chloramphenicol and aplastic anemia. *N Engl J Med* 1983; **308**: 1536.

Fusidic acid

Topical use can lead to contact dermatitis but hypersensitivity reactions to oral or parenteral use are very rare; jaundice has accompanied intravenous use. Acanthosis nigricans-like lesions have been reported after local application [1].

REFERENCE

1 Teknetzis A, Lefaki I, Joannides D, Minas A. Acanthosis nigricans-like lesions after local application of fusidic acid. *J Am Acad Dermatol* 1993; **28**: 501–2.

Metronidazole and tinidazole

Metronidazole. Pruritus, fixed eruptions and generalized erythema [1–4] are rare. A pityriasis rosea-like eruption has been described [5]. A reversible peripheral neuropathy may complicate prolonged therapy.

Tinidazole. A fixed eruption with cross-reactivity with metronidazole has been reported [6,7].

Nitrofurantoin

Pruritus, morbilliform rashes and urticaria may be seen occasionally. Erythema multiforme, erythema nodosum [1], exfoliative dermatitis and an LE-like syndrome [2] are documented. Acute or chronic pulmonary reactions may accompany these skin manifestations, and may lead to pulmonary fibrosis [3]. Polyneuritis is a dose-dependent toxic reaction. Hepatitis, cholestatic jaundice and marrow suppression may occur rarely. Abnormal immunoelectrophoretic patterns may be induced [4].

Quinolones

These compounds are related to nalidixic acid; central nervous system toxicity, upper gastrointestinal tract reactions and phototoxicity have been recorded [1–7]. Cross-reactivity occurs [8]. Gastrointestinal side effects occur in up to 6% of patients. Hypersensitivity reactions involving the skin have been reported in 0.5–2% of patients, and in up to 2.4% of patients receiving cinoxacin; they most frequently manifest themselves as rash or pruritus. Fever, urticaria, angio-oedema and anaphylactoid reactions are rare. Anaphylactic or anaphylactoid reactions have been documented with cinoxacin [9], ciprofloxacin (1.2 per 100 000 prescriptions) [10,11] and pipemidic acid [12]. Fixed drug eruption due to pipemidic acid is recorded [13]. Norfloxacin [14] and ofloxacin [15] have caused a pustular eruption. Ciprofloxacin [16,17], pefloxacin, fleroxacin [18] and enoxacin [19] have been associated with photosensitivity. Pefloxacin and ofloxacin have caused photo-onycholysis [20], and sparfloxacin has been implicated in photosensitivity and a lichenoid tissue reaction [21]. Hypersensitivity leukocytoclastic vasculitis has been reported with both ofloxacin and ciprofloxacin [22,23] and serum sickness with ciprofloxacin [24]. Intravenous administration of ciprofloxacin through small veins on the dorsa of the hands may be associated with local reactions at the site of infusion [25]. Stevens–Johnson syndrome or TEN has been described with quinolones [26] including ciprofloxacin [27]. Ciprofloxacin has caused bullous pemphigoid [28].

Nalidixic acid. Cutaneous reactions are common, occurring in up to 5% of patients; various hypersensitivity reactions are seen, including exfoliative dermatitis. Phototoxicity is now well recognized [29–33]. A bullous photodermatitis may occur, usually on the hands or feet; chronic scarring and increased skin fragility may mimic porphyria cutanea tarda. Long-wave UV light is responsible [32]. An LE-like syndrome has been reported [34], as well as transient alopecia.

Synergistins

An eczema-like drug eruption is recorded after oral antibiotic synergistins, pristinamycin and virginiamycin, following contact sensitization with topical virginiamycin [1].

REFERENCE

Vancomycin

Allergic skin reactions are not uncommon, occurring in up to 5% of patients. Rapid intravenous infusion of vancomycin can cause a histamine-induced anaphylactoid reaction characterized by flushing, a maculopapular eruption of the neck, face, trunk and extremities (so-called 'red man syndrome'), prolonged hypotension and, in rare cases, cardiac arrest [1–3]. Desensitization has been successfully achieved in patients with vancomycin hypersensitivity [4–6]. TEN has occurred [7]. Vancomycin has been reported to have induced linear IgA bullous dermatosis [8–12], which may mimic TEN [13].

Topical antibiotics

The side effects of topical antibiotics have been reviewed [1]. Allergic contact dermatitis is rare with topical clindamycin, erythromycin and tetracycline, polymyxin B, gentamicin and mupirocin, but is more frequent with neomycin.

Bacitracin

Anaphylaxis due to bacitracin allergy has followed topical application of this antibiotic [2–5]. The patients had had multiple prior exposures and previous local reactions of pruritus, urticaria or possible allergic contact dermatitis. Two patients with anaphylactic reactions to Polyfax ointment, containing polymyxin B and bacitracin, have been

reported; one had previously documented positive patch tests to Polyfax, and the other had clinical intolerance to the preparation [5]. Another patient developed anaphylaxis to a similar proprietary mixture (Polysporin) [6]. Intracutaneous injection of bacitracin in sensitive individuals induces histamine release with large weal-and-flare reactions [7].

Chloramphenicol

Urticaria and angio-oedema have been described with topical use [8]. Fatal aplastic anaemia has followed the use of eye drops containing this antibiotic [9].

Sulphonamides

Erythema multiforme and Stevens–Johnson syndrome have been reported from topical preparations [10,11].

Antituberculous drugs

Severe cutaneous reactions (such as Stevens–Johnson syndrome and TEN) and multiple drug reactions to antituberculous drugs (including thioacetazone, streptomycin and isoniazid) occur more often in HIV-positive patients [1–5]. The World Health Organization has advised against the use of thioacetazone in tuberculosis patients with known, or suspected, HIV infection in view of the severe cutaneous hypersensitivity [3–5]. The following drugs are reported to cause contact dermatitis: isoniazid, rifampicin, ethambutol, *p*-aminosalicylic acid, streptomycin and kanamycin [6]. The incidence of other reactions to individual drugs is difficult to assess because several drugs are usually used in combination.

Cycloserine

A lichenoid drug eruption with positive patch tests and resolution 4 months after withdrawal has been reported [7].

Ethambutol

Hypersensitivity reactions are very rare. Side effects are largely confined to visual disturbances, with loss of acuity, colour blindness and restricted visual fields; these are usually reversible if the drug is stopped promptly. Patients should have ophthalmic assessments prior to and during therapy. Lichenoid reactions occur and may be restricted to light-exposed sites [8,9].

Ethionamide

Eczema chiefly affecting the forehead, acneiform eruptions, butterfly eruptions on the face, stomatitis, alopecia and purpura have been reported.

Isoniazid

Allergic skin reactions occur in fewer than 1% of patients. An acneiform eruption, usually occurring in slow inactivators of the drug, is well recognized [10,11]. Urticaria, purpura and an LE-like syndrome [12,13] have been reported, as have photosensitive lichenoid eruptions [14]. Rarely, a pellagra-like syndrome has been induced in malnourished patients, due to metabolic antagonism of nicotinic acid with resultant pyridoxine deficiency [10,15]. Exfoliative dermatitis [16] and Stevens–Johnson syndrome [2] have been reported.

Pyrazinamide

Hepatitis, arthralgia, flushing, photosensitivity, lichenoid photodermatitis, maculopapular rashes, urticaria and pellagra are recorded [17].

Rifampicin

Cutaneous hypersensitivity reactions are very uncommon. There have been isolated reports of LE [18], erythema nodosum leprosum-like eruption in borderline lepromatous leprosy [19], exacerbation of bullous erythema multiforme, TEN [20] and pemphigus [21,22]; existing pemphigus may also be exacerbated [23]. Altered liver function, usually transient, and thrombocytopenic purpura may occur. Rifampicin has precipitated porphyria cutanea tarda [24]. It induces liver enzymes and may thus reduce the effectiveness of a number of drugs, including oral contraceptives.

Streptomycin

See aminoglycosides section on p. 73.60.

Thioacetazone

Severe cutaneous hypersensitivity reactions have been reported, including maculopapular rashes (which progress to mucosal involvement with constitutional symptoms), Stevens–Johnson syndrome and TEN, especially in HIV-seropositive patients [2,3,5,25,26]. Cutaneous hypersensitivity reactions have been reported in 20% of HIV-seropositive patients compared with 1% of HIV-seronegative patients who receive the drug as part of treatment for tuberculosis [26]. Figurate erythematous eruptions resembling erythema annulare centrifugum may occur [27].

Antileprotic drugs

Clofazimine

This drug regularly causes a reversible, dose-dependent, brown-orange pigmentation of the skin [1–3]. Biopsy specimens from two lepromatous leprosy patients on long-term clofazimine therapy revealed ceroid-lipofuscin pigment as well as clofazimine inside macrophage phagolysosomes [3]. Reddish-blue pigmentation occurred in scarred areas of LE in one patient [4]. Xeroderma, pruritus, phototoxicity, acne and non-specific rashes are described [2]. Gastrointestinal symptoms may occur early due to direct irritation of the gut and are quickly reversible; ulcerative enteritis may occur after 9–14 months of treatment. After prolonged high-dose therapy, persistent diarrhoea, abdominal pain and weight loss, associated with deposition of crystalline clofazimine in the small intestinal submucosa and mesenteric lymph nodes, may occur [5,6]. Splenic infarction has been associated with this syndrome [7,8].

Dapsone

Reactions have been reviewed [1]. Fixed eruptions occur in 3% of West Africans being treated for leprosy. Erythema multiforme [2] and exfoliative dermatitis [3] have been described during leprosy treatment. Another uncommon side effect is a hypersensitivity reaction (dapsone or sulphone syndrome) within the first month or so, with fever, a widespread erythematous eruption studded with pustules, exfoliative dermatitis, hepatitis, lymphadenopathy and anaemia [4–10]. In Vanuatu, 24% of 37 patients treated over 4 years with daily dapsone 100 mg, clofazimine, and monthly rifampicin and clofazimine for leprosy developed the dapsone syndrome, with a fatality rate of 11% [11]. The increase in reactions may have related to a high starting dose of dapsone, possibly enhanced by the combination with clofazimine and rifampicin and by a genetic susceptibility of the Melanesian population.

Red cell life is always shortened, but clinical haemolytic anaemia is uncommon; patients with low red cell glucose-6-phosphate dehydrogenase levels [12] and those who are slow acetylators [13] are at a special risk of developing this complication. Methaemoglobinaemia and Heinz body formation are seen [14]. Agranulocytosis is rare but well recognized and may occur in the first weeks of therapy [15–17]. For patients receiving the drug for dermatitis herpetiformis, this side effect occurred at a median dosage of 100 mg/day and a median duration of therapy of 7 weeks [16]. The total risk was one case per 3000 patient-years of exposure to the drug; however, agranulocytosis was estimated to occur in 1 in 240 to 1 in 425 new patients receiving dapsone for dermatitis herpetiformis [16]. Agranulocytosis occurred in approximately 1 in 10 000 to 1 in 20 000 US soldiers receiving dapsone for malarial prophylaxis [18]. Elderly patients do not tolerate dapsone well, and sulfapyridine or sulfamethoxypyridazine (the latter obtainable on a named-patient basis from Lederle Laboratories) is to be preferred for IgA-related diseases. A fatal haematological reaction developed in a Burmese boy during induction of treatment for lepromatous leprosy [19].

Severe but usually reversible hypoalbuminaemia due to failure of albumin production [20,21] or an atypical nephrotic syndrome may occur. Rarely, dapsone causes a peripheral neuropathy, usually purely motor or mixed sensorimotor and usually recovering within a year [22–25], and optic atrophy [25]. Permanent retinal damage has followed overdosage [26]. Headaches [27], and occasionally a psychosis [28], may be precipitated.

Thalidomide

Teratogenicity (phocomelia), gastric intolerance, drowsiness, neuropsychiatric upset and a sensory peripheral neuropathy developing after several months have been reported [1]. Minor to moderate skin eruptions occur in up to 46% of patients taking thalidomide, including morbilliform, seborrhoeic, maculopapular and non-specific rashes; severe skin reactions such as exfoliative ery-

throderma, erythema multiforme and TEN are rare [2]. A dermatitis associated with eosinophilia develops in a few cases of erythema nodosum leprosum treated with thalidomide over several years [3]. Hypersensitivity reactions characterized by fever, tachycardia and an extensive erythematous macular eruption developed on rechallenge in a number of patients with HIV infection treated with thalidomide for severe aphthous oropharyngeal ulceration [4]. In addition, brittle fingernails, exfoliative erythroderma [5], toxic pustuloderma [6], face or limb oedema, pruritus, red palms and xerostomia have been described [7].

Antifungal drugs

Dermatological aspects of antifungal drugs have been reviewed [1–3]. Rashes occur as follows.

- Itraconazole: in 1.1% of cases, with pruritus in 0.7%; the drug is teratogenic.
- Fluconazole: in 1.8% of cases; exfoliative dermatitis is recorded.
- Terbinafine: in 2.7% of cases, including erythema, urticaria, eczema, pruritus, and isolated Stevens–Johnson syndrome and TEN [3].

Relevant interactions between itraconazole, fluconazole and terbinafine have been discussed [4].

Amphotericin

Skin reactions are rare. The 'grey syndrome', characterized by ashen colour, acral cyanosis and prostration, may occur as an immediate reaction to infusion. Allergic reactions occur to liposomal amphotericin [1,2].

Fluconazole

Angio-oedema has occurred [3], as has fixed drug eruption [4]. An anaphylactic reaction developed in a patient who had previously received ketoconazole and metronidazole, suggesting cross-sensitization [5], and Stevens–Johnson syndrome has been reported in a patient with AIDS [6]. Thrombocytopenia is described [7].

Itraconazole

Serum sickness [8] and acute generalized exanthematous pustulosis [9] are recorded.

Flucytosine

Transitory macular and urticarial rashes have been seen. A toxic erythema occurred in a patient [10]. Anaphylaxis has been reported in a patient with AIDS [11]. Bone marrow depression can occur.

Griseofulvin

Reactions to griseofulvin are uncommon and usually mild; headaches and gastrointestinal disturbances are the most frequent. Morbilliform, erythematous or, rarely, haemorrhagic eruptions are occasionally seen [1,2]. Photodermatitis [3,4] with sensitivity to wavelengths above 320 nm is by no means rare; clinically, the features are mainly eczematous, although pellagra-like changes may be seen [4]. The reaction is thought to be photoallergic and

photopatch tests are positive in some cases; there may be photo cross-reactivity with penicillin [4]. Histology may be non-specific; direct immunofluorescence showed immunoglobulin and complement at the dermal–epidermal junction and around papillary blood vessels in one series [4]. Urticaria and a fixed drug eruption [5,6], cold urticaria [7], severe angio-oedema [8], erythema multiforme [9,10], serum sickness [11], exfoliative dermatitis [12] and TEN [13,14] are recorded. Exacerbation of LE has been reported [15–19], with fatality in one case [18]. Patients with anti-SSA/Ro and SSB/La antibodies may be at increased risk of developing a drug eruption [19,20]. Temporary granulocytopenia has been reported, and proteinuria may occur. Hepatitis and a morbilliform eruption are recorded [21]. Griseofulvin may interfere with the action of anticoagulants and the contraceptive pill [22], and should be avoided in pregnancy as potentially teratogenic; men should avoid conception for 6 months after taking the drug.

Ketoconazole

Pruritus and gastrointestinal upset are the most frequent side effects [1]. Urticaria and angio-oedema are recorded [2]. Severe anaphylaxis has been observed in two patients, one of whom had previously reacted to topical miconazole [3]. Other adverse reactions include exfoliative erythroderma [4]. The drug may block testosterone synthesis, causing dose-dependent lowering of serum testosterone and resultant oligospermia, impotence, decreased libido and gynaecomastia in some men [5–7]. It also blocks the cortisol response to ACTH, and may lead to adrenal insufficiency [7–9]. Hypothyroidism has been documented [10]. The most serious side effect is idiosyncratic hepatitis, which occurs in about 1 in 10 000 patients, and which may lead to fulminant and potentially fatal hepatic necrosis [11–17]. Trichoptilosis has resulted from misuse of ketoconazole 2% shampoo [18].

Nystatin

A fixed drug eruption has been reported [1], as has Stevens–Johnson syndrome in an isolated case [2].

REFERENCES

Terbinafine

This drug is well tolerated with relatively few side effects [1]. Idiosyncratic hepatitis has been reported [2], with serious hepatobiliary dysfunction occurring in 1 in 54 000 [3]. Neutropenia, pancytopenia and thrombocytopenia are recorded [4–8]. Cutaneous adverse effects occur in 3% of patients [3,9]; these include severe urticaria, pityriasiform rashes, erythroderma, erythema multiforme [10,11] and TEN [12], serum sickness-like reactions, acute generalized exanthematous pustulosis [13–17], LE-like rashes [18–20], induction or exacerbation of psoriasis which may be pustular [21–24], baboon syndrome [25], fixed drug eruption [26] and alopecia [27].

Antiviral agents

Aciclovir (acyclovir)

In general, there are very few side effects [1]. Vesicular reactions, palm and sole dermatitis, peripheral oedema, erythema nodosum, exanthems, hyperhidrosis, acne, lichenoid eruption, pruritus, urticaria, vasculitis, alopecia and fixed drug eruption are recorded [2–4]. Intravenous use may cause inflammation and phlebitis. A nephropathy may develop with intravenous use, especially in patients with renal failure, due to renal precipitation of the drug; the dose should be reduced in patients with impaired renal function. An encephalopathy may occur. Peripheral oedema has been reported very rarely [5,6].

Idoxuridine

This drug is used only topically for herpes simplex and herpes zoster, in view of its toxicity on systemic administration. Severe alopecia and loss of nails followed parenteral use [1].

REFERENCE

1 Nolan DC, Carruthers MM, Lerner AM. Herpesvirus hominis encephalitis in Michigan: report of thirteen cases, including six treated with idoxuridine. *N Engl J Med* 1970; **282**: 10–3.

Foscarnet

This drug is used for cytomegalovirus retinitis in AIDS, and for mucocutaneous herpes simplex virus unresponsive to aciclovir in immunocompromised patients. A generalized cutaneous rash has been reported with use of this drug in AIDS [1]. Genital ulceration, both of the penis [2,3] and vulva [4], is documented. In one study [2], 15% of 60 patients treated with intravenous foscarnet developed penile ulceration [2]. Eosinophilic folliculitis has been reported [5].

Ribavirin (tribavirin)

This synthetic guanosine analogue used in the treatment of relapsing chronic hepatitis C infection has been implicated in the development of Grover's disease [1].

REFERENCE

1 Antunes I, Azevedo F, Mesquita-Guimaraes J *et al*. Grover's disease secondary to ribavirin. *Br J Dermatol* 2000; **142**: 1257–8.

Antiretroviral drugs

Cutaneous side effects of antiretroviral agents have been reviewed [1–4]. There are three categories of agent: nucleoside reverse transcriptase inhibitors, non-nucleoside reverse transcriptase inhibitors and protease inhibitors. Nucleoside reverse transcriptase inhibitors have resulted in alterations of the nails, nail and mucocutaneous pigmentation, hair changes, vasculitis and morbilliform eruptions. Drug hypersensitivity is associated with the non-nucleoside reverse transcriptase inhibitors nevirapine, delavirdine and efavirenz, as well as the nucleoside reverse transcriptase inhibitor abacavir and the protease inhibitor amprenavir [2]. Protease inhibitors have been associated with lipodystrophy syndrome, hypersensitivity reactions, urticaria, morbilliform eruptions and a large number of drug interactions.

Nucleoside reverse transcriptase inhibitors

Abacavir. This drug is associated with a hypersensitivity syndrome in 4% of cases [1]. Stevens–Johnson syndrome is recorded [2].

Zidovudine. This drug may cause gastrointestinal upset and marrow suppression (with serious anaemia in 32% and leukopenia in 37%), myalgia, headache and insomnia [3–6]. Such side effects have been reported in healthcare workers treated with zidovudine for attempted prophylaxis of HIV infection following accidental needlestick injury [7,8]. Zidovudine-related thrombocytopenia resulted in ecchymoses around Kaposi's sarcoma lesions in a patient with AIDS, simulating rapid intracutaneous spread of neoplasm [9]. Vaginal tumours have been documented in rodents. Diffuse pigmentation, as well as isolated hyperpigmented spots on the palms, soles and fingers, and pigmentation of the fingernails and toenails (usually starting at 4–8 weeks into therapy but up to 1 year) and buccal mucosa have been described [10–15]. Postural hypotension has been recorded [16]. Hypertrichosis of the eyelids has occurred [17]. A possible link with neutrophilic eccrine hidradenitis has been postulated in HIV-infected patients [18]. Hypersensitivity reactions from rash to anaphylaxis have been documented [19,20]. Other reported cutaneous reactions include acne, pruritus, urticaria and leukocytoclastic vasculitis [21].

Lamivudine. Paronychia is recorded [22].

Dideoxycytidine. A maculopapular reaction with oral ulceration developed in 70% of patients treated with this anti-AIDS agent, but resolved spontaneously in those who continued on therapy [23].

Non-nucleoside reverse transcriptase inhibitors

Delavirdine. Various rashes occur in 18–50% of cases.

Efavirenz. Mild rashes are recorded within the first 2 weeks of therapy [1].

Nevirapine. Severe rashes have been observed in 3% of patients taking nevirapine in clinical trials, 85% of whom were men [2,3]. A hypersensitivity syndrome is well recorded [4,5]. The drug is the leading cause of Stevens–Johnson syndrome and TEN related to AIDS in Europe [6–9].

Protease inhibitors

Saquinivir causes rashes, and indinavir causes taste disturbance and dry skin [1]. Indinavir has been associated with the development of cheilitis in 40% of cases, diffuse cutaneous dryness and pruritus in 12%, asteatotic dermatitis on the trunk, arms and thighs, and scalp hair loss in 12% [2]. Multiple pyogenic granulomas were observed in the toenails in 6% and softening of the nail plate in 5% of subjects. Multiple subcutaneous lipomas are associated with protease inhibitors [3]. Paronychia is a recognized complication [4,5]. Angiolipomas shortly after initiation of therapy [6] and leukocytoclastic vasculitis [7] have been documented with indinavir. A peripheral lipodystrophy syndrome has been linked to therapy with protease inhibitors [8–12] and was noted in 14% of patients on indinavir [2]. It comprises peripheral lipoatrophy, relative central adiposity, sometimes with a 'buffalo hump', insulin resistance and serum lipid abnormalities. The mix of features is variable in individual patients.

Antimalarials [1–4]

Pruritus, lichenoid eruptions, exfoliative dermatitis, pigment changes, bleaching of hair, alopecia, photosensitivity with exacerbation of psoriasis and porphyria cutanea tarda, retinopathy and corneal opacities have all been reported.

Chloroquine and hydroxychloroquine

Adverse cutaneous reactions to hydroxychloroquine are commoner in patients with dermatomyositis than in those with cutaneous LE [1]. Pruritus is common in Africans on acute or prolonged treatment, but rare in Europeans [2–5]. Pigmentary changes develop in about 25% of patients receiving any of the antimalarials for more than 4 months [6–9]; chloroquine binds to melanin [9]. Blackish-purple patches on the shins are often seen, and brown-grey pigmentation may appear in light-exposed skin [8]. The nail beds may be pigmented diffusely or in transverse bands, and the hard palate is diffusely pigmented. In contrast, red-blonde (but not dark) hair may be bleached [10]. Chloroquine has been associated with vitiligo-like depigmentation [11].

Photosensitivity may be seen [12]; in addition, certain types of porphyria may be provoked [13]. Effects on psoriasis are unpredictable, but precipitation of severe psoriasis has long been recognized [14–19], including erythroderma [19]. However, 88% of a series of 50 psoriatics who were treated with standard doses of chloroquine noted no change in their psoriasis [20]. Lichenoid eruptions are uncommon, and erythema annulare centrifugum is rare [21]. TEN with oral involvement has been documented. A pustular eruption with hydroxychloroquine has been reported [22]. Toxic psychosis has been described with hydroxychloroquine [23]. All antimalarials are potentially teratogenic.

Chloroquine and hydroxychloroquine may cause serious ophthalmic side effects [24,25]. Corneal deposits occur in 95% of patients on long-term therapy, but of these 95% are asymptomatic [26]. A potentially irreversible retinopathy leading to blindness may develop in 0.5–2% of cases [27,28]. The retinal changes may progress after the drug is stopped. Use of less than 250 mg (or 4 mg/kg) daily of chloroquine, with pretreatment and 6-monthly ophthalmological assessment using an Amsler grid, is recommended. Malaria prophylaxis with two tablets weekly is said not to carry an appreciable risk. Ocular toxicity with hydroxychloroquine is rare below 6.5 mg/kg; guidelines for screening include baseline renal and liver function tests, assessment of near visual acuity and yearly visual acuity [29].

Mefloquine

Dizziness, nausea, erythema and neurological disturbance are documented. Pruritus occurs in 4–10% and maculopapular rash in up to 30% of cases; urticaria, facial lesions, cutaneous vasculitis, Stevens–Johnson syndrome and TEN [1,2], and exfoliative dermatitis [3] have been recorded.

Mepacrine (atabrine, quinacrine)

This drug constantly causes yellow staining of the skin, which may involve the conjunctiva and may mimic jaundice [1]. Lichenoid eruptions are well known. Large numbers of military personnel given mepacrine for malaria prophylaxis in the Second World War developed a tropical lichenoid dermatitis, which was quickly followed by anhidrosis, cutaneous atrophy, alopecia, nail changes, altered pigmentation and keratoderma [2,3]. A few patients developed localized bluish-black hyperpigmentation confined to the palate, face, pretibial area and nail beds after prolonged administration of more than a year. Years later, lichenoid nodules, scaly red plaques, atrophic lesions on the soles, erosions and leukoplakia of the tongue, and fungating warty growths appeared [3,4]. Progression to squamous cell carcinoma, especially on the palm, has occurred. Ocular toxicity is much less than with chloroquine.

Pyrimethamine

This folate antagonist can cause agranulocytosis even in very low dosage, especially when combined with dapsone [1]. A lichenoid eruption has been reported [2], as has photosensitivity. The reported rate for all serious reactions to pyrimethamine–sulfadoxine (Fansidar) in one study was 1 in 2100 prescriptions and for cutaneous reactions including Stevens–Johnson syndrome 1 in 4900, with a fatality rate of 1 in 11 100 [3]. In another study [4], severe cutaneous adverse reactions to Fansidar, including erythema multiforme, Stevens–Johnson syndrome and TEN, were estimated at 1.1 (0.9–1.3) per million. Similar rates for severe reactions to pyrimethamine–dapsone (Maloprim) were 1 in 9100 prescriptions and for blood dyscrasias 1 in 20 000, with a fatality rate of 1 in 75 000. For developing countries with mainly single-dose use, the risk was estimated at 0.1 per million, compared with mainly prophylactic use in Europe and North America at a risk of 10 and 36 per million respectively. Prophylactic use thus had a 40 times higher risk than single-dose therapeutic use [4]. Reactions to pyrimethamine are more common in patients with HIV infection [5]. Epidermal necrolysis, angioedema, bullous disorders and serious hepatic disorders also occurred. Because few serious reactions have been recorded with chloroquine and proguanil, it has been recommended that use of compound antimalarials should be restricted [3].

Quinine

Purpura due to quinine may or may not be thrombocytopenic [1,2]. Erythematous, urticarial, photoallergic [3–5], bullous and fixed eruptions are recorded. Lichenoid eruptions are rare. If contact allergic sensitivity is already present, eczematous reactions may occur, as in 'systemic contact-type eczema' [6]. Splinter haemorrhages, and a maculopapular and a photosensitive papulonecrotic eruption, due to a lymphocytic vasculitis, have been recorded in one case [7].

Anthelmintics

Amocarzine (CGP 6140)

This macrofilaricidal and microfilaricidal drug used for the therapy of onchocerciasis may be associated with dizziness and pruritus with or without a rash [1].

Benzimidazole compounds

These are used for the therapy of both intestinal helminthiasis and hydatid disease; fever, gastrointestinal upset, reversible neutropenia and transient abnormalities in liver function are reported. Telogen effluvium has been documented with both albendazole [2,3] and mebendazole.

Ivermectin

Fever, rash, pruritus, local swelling and tender regional lymphadenopathy are documented [4]. The incidence of moderate adverse reactions including pruritus, localized rash and fever was 4% in a study of patients with onchocerciasis from Ecuador [5], and increased itching and/or rash occurred in 8% of cases in another study [6]. Patients with reactive onchodermatitis (sowda) may have severe pruritus and limb swelling with ivermectin [7]. A 3-year, placebo-controlled, double-blind trial involving 7148 patients given ivermectin annually for onchocerciasis by mass distribution identified musculosketetal pains, oedema of the face or extremities, itching and papular rash as adverse reactions; bullous skin lesions that did not recur developed in five persons [8].

Levamisole

Prolonged use at high dosage as an immunostimulant is associated with type I reactions, with itching, pruritus and urticaria. Lichenoid [9] and non-specific [10] rashes, leukocytoclastic vasculitis with a reticular livedo pattern due to circulating immune complexes [11] and cutaneous necrotizing vasculitis [12] have been reported. A distinctive purpuric eruption of the ears is recorded [13].

Niridazole

Urticaria and a pellagra-like dermatitis have been described.

Piperazine

Occupational dermatitis has been caused [14]. Previous contact sensitization induced by ethylenediamine has led to severe cross-reactions on subsequent oral administration of piperazine, including generalized exfoliative dermatitis [15].

Tetrachlorethylene

This drug has caused TEN.

Tiabendazole

An unusual body odour is well known after the administration of this drug. Skin reactions, consisting of urticaria or maculopapular rashes, are infrequent and usually mild and transient. Erythema multiforme [16] and TEN [17] have been reported.

Drugs for *Pneumocystis*

Pentamidine

This drug is increasingly being used in the treatment and

prophylaxis of *Pneumocystis carinii* pneumonia in patients with AIDS. Urticaria, including contact urticaria [1], or maculopapular eruption proceeding to erythroderma have been reported with nebulized therapy [2,3]. TEN may occur with systemic therapy [4,5].

Non-steroidal anti-inflammatory drugs

Acetylsalicylic acid and related compounds

Aspirin

Reactions to aspirin [1–4] occur in 0.3% of normal subjects [2,4]. These are usually sporadic, but occasionally more than one family member may be affected, and an HLA linkage has been reported [5]. Urticaria or angio-oedema is the commonest reaction [1]. Two types of specific IgE antibody were found in sera from aspirin-sensitive patients with salicyloyl and *O*-methylsalicyloyl discs using radioallergosorbent tests, favouring an IgE-dependent mechanism [6]. Chronic idiopathic urticaria is often aggravated by aspirin [7,8]; this exacerbation probably has a non-allergic basis. It has been estimated that patients with chronic urticaria or angio-oedema have a risk of up to 30% of developing a flare in the condition following administration of aspirin or an NSAID [3]. The reaction is dose dependent and is greater when the urticaria is in an active phase. Aspirin may render the skin of such patients more reactive to histamine [5]. The syndrome of nasal polyposis, bronchial asthma and aspirin intolerance is well known [4,9]; up to 40% of patients with nasal polyps, and 4% of patients with asthma, may develop bronchoconstriction on exposure to aspirin, but only 2% develop urticaria [4]. Anaphylactoid responses may occur [3]; these may involve abnormalities of platelet function [10]. Cross-sensitivity between aspirin and tartrazine is now thought to be rare [3]. Oral desensitization is feasible if essential, and may be maintained by daily aspirin intake [3].

Other reported reactions include purpura, scarlatiniform erythema, erythema multiforme, fixed eruption and a lichenoid eruption (which recurred on challenge) [11], but all are rare [1]. Neonatal petechiae may result from aspirin therapy of the mother [12]. Aspirin has been reported to provoke generalized pustular psoriasis [13]. Oral ulceration may follow prolonged chewing of aspirin [14], and at the site of an insoluble aspirin tablet placed at the side of an aching tooth.

Nephropathy, marrow depression and gastric haemorrhage are well-recognized hazards. The elderly are at increased risk of developing such complications [15]. The drug may interfere with renal clearance, for example of methotrexate. Aspirin is safe to administer to patients with glucose-6-phosphate dehydrogenase deficiency [16].

Diflunisal

Various cutaneous reactions have been reported in up to 5% of patients, including pruritus, urticaria, exanthems, Stevens–Johnson syndrome, erythroderma [1] and a lichenoid photoreactive rash [2]. A non-pigmenting fixed drug eruption has been documented [3].

Paracetamol (acetaminophen)

This drug is a major metabolite of phenacetin, and has largely replaced it. Allergic reactions are very rare, considering that it has been estimated that more than 1.4 billion tablets are sold per annum in the UK [1,2]. Urticaria [3], anaphylaxis, a widespread maculopapular eruption, a fixed eruption [2,4–8] that may be non-pigmenting [8], exfoliative dermatitis [9], delayed hypersensitivity reactions [10], linear IgA bullous dermatosis [11] and figurate purpura [12] have been seen.

Phenacetin

Capillaritis, vasculitis and a bullous pemphigoid-like eruption [1] have been documented.

Salicylamide

Use of teething jellies containing this substance has resulted in severe urticaria in infants [2].

Other NSAIDs

Dermatological aspects of the NSAIDs have been extensively reviewed [1–13]. All these drugs inhibit the enzyme cyclo-oxygenase, and decrease the production of prostaglandins and thromboxanes [6]. NSAIDs represent about 5% of all prescriptions in the UK [5] and USA [2]; nearly one in seven Americans were treated with an NSAID in 1984, and in 1986 100 million prescriptions for these drugs were written in the USA [14]. NSAIDs accounted for 25% of all suspected ADRs reported to the UK Committee on Safety of Medicines in 1986 [5,15]. Reactions to NSAIDs occur in about 1 in 50 000 administrations; NSAIDs should be avoided in patients known to be intolerant of aspirin [6]. In a large series, allergic or pseudoallergic reactions were observed in 0.2% of patients exposed to minor analgesics (including aspirin and pyrazolones, mainly metamizole, propyphenazone) and in 0.8% of patients exposed to NSAIDs (including the pyrazolone oxyphenbutazone); most reactions were cutaneous, mainly maculopapular exanthems, urticaria and angio-oedema [10]. Piroxicam, meclofenamate sodium, sulindac and zomepirac sodium had the highest reaction rates relative to the number of new prescriptions in the USA [1,2]. In contrast, naproxen, fenoprofen, ibuprofen and indometacin all had low rates of reaction; ibuprofen is available as a non-prescription drug in the USA and the UK. In another study of 2747 patients with rheumatoid arthritis, toxicity index scores computed from symptoms, laboratory abnormalities and hospitalizations attributed to NSAID therapy indicated that indometacin, tolmetin sodium and meclofenamate sodium were the most toxic, and buffered aspirin, salsalate and ibuprofen the least toxic [16].

Cutaneous adverse reactions to NSAIDs were, in order of frequency in one study [11], urticaria/angio-oedema, fixed eruptions, exanthems, erythema multiforme and Stevens–Johnson syndrome. Drug exanthems and urticaria occur in 0.2–9% of patients treated with NSAIDs [2,6]. Drug exanthems develop in 1% of patients on phenylbutazone and 0.3% of patients on indometacin [6]; they are most frequently associated with diflunisal, sulindac, meclofenamate sodium, piroxicam and phenylbutazone. All the NSAIDs, but particularly aspirin and tolmetin, may cause urticaria and anaphylactoid reactions, especially in a patient with a history of aspirin-induced urticaria. Pyrazolone NSAIDs, feprazone, nimesulide, piroxicam and flurbiprofen cause fixed drug eruptions. Although all NSAIDs may precipitate exfoliative erythroderma, this is commonest with phenylbutazone [6]. All the NSAIDs, but particularly phenylbutazone, piroxicam, fenbufen and sulindac, may cause Stevens–Johnson syndrome or TEN [6]. Oral lichenoid lesions have also been recorded with NSAIDs [17]. Psoriasis has been reported anecdotally to be exacerbated by indometacin and meclofenamate sodium, but there is no definitive evidence that NSAIDs consistently exacerbate psoriasis [5]. Contact dermatitis induced by topical NSAIDs is rare but increasing; ketoprofen and bufexamac are major contact allergens [13].

Children on NSAIDs were 2.4 times as likely to have shallow facial scars, as described in drug-induced pseudoporphyria, in one study; this relative risk was increased to 6 with naproxen [18].

Most of the NSAIDs causing photosensitivity are phenylpropionic acid derivatives: carprofen, ketoprofen, tiaprofenic acid, naproxen and nabumetone [19–24]. NSAIDs that cause photosensitivity absorb UV radiation at wavelengths longer than 310 nm, resulting in the generation of singlet oxygen molecules, which damage cell membranes [12]. The cutaneous photosensitivity appears to be elicited by a phototoxic mechanism [19–21,24]. The phototoxic reactions with NSAIDs are immediate, consisting of itching, burning, erythema and at higher fluences wealing; this contrasts with the delayed reactions associated with psoralens and tetracyclines, which produce abnormal delayed erythema or exaggerated sunburn. Propionic acid derivatives may also precipitate photourticaria by mast cell degranulation [23]. Piroxicam, an enolic acid derivative structurally unrelated to phenylpropionic acid, is the most frequently cited non-phenylpropionic acid NSAID to cause photosensitivity [20,21,25]; phototoxicity to the parent drug has not been elicited in volunteers or experimental animals, although a phototoxic metabolite has been identified *in vitro*. Indometacin, sulindac [26], meclofenamate sodium and phenylbutazone have all been associated with photosensitivity [2]. NSAIDs may cause pseudoporphyria changes [27].

Apart from the cutaneous complications, NSAIDs may cause a variety of adverse effects [14,28–30], including gastrointestinal bleeding, intestinal perforations and acute deterioration in renal function with interstitial nephritis [28]; the elderly and patients with impaired renal function or receiving concomitant diuretic therapy are most at risk. NSAIDs may inhibit platelet aggregation and increase bleeding times [29]. Aplastic anaemia is a recognized complication, and has occurred in the same individual with two different NSAIDs (sulindac and fenbufen) [31]. Hepatic syndromes [30], pneumonitis (naproxen, ibuprofen, fenoprofen and sulindac can elicit pulmonary infiltrates with eosinophilia [32]) and neurological problems, such as headache, aseptic meningitis and dizziness, are recorded [14]. Niflumic acid and diclofenac both precipitated a dermatomyositis-like syndrome in a patient [33]. The potential for adverse interactions between NSAIDs and other drugs is considerable [14].

Propionic acid derivatives

Carprofen. This drug causes photosensitivity [1].

Fenbufen. Morbilliform and erythematous rashes, erythema multiforme [2], Stevens–Johnson syndrome and allergic vasculitis have been recorded rarely. Fenbufen has caused exfoliative dermatitis, haemolytic anaemia and hepatitis [3], and was the drug implicated most commonly in adverse reactions reported to the UK Committee on Safety of Medicines in 1986 and 1987. A florid erythematous rash with pulmonary eosinophilia has been described in four cases [4].

Fenoprofen. This drug has caused pruritus, urticaria, vesicobullous eruption, thrombocytopenic purpura and TEN [5].

Ibuprofen. Pruritus is the only common cutaneous reaction. When used in rheumatoid arthritis, rashes are rare, although patients with SLE are liable to develop a generalized rash with fever and abdominal symptoms [6]. Angio-oedema/urticaria [7,8], anaphylaxis [9], fixed eruptions [8], a linear eruption [10], vesicobullous rashes, erythema multiforme, vasculitis [11] and alopecia [12] occur. Psoriasis has been reported to be exacerbated [13]. This drug is available over the counter in the UK.

Ketoprofen. Topical application has caused photoallergic contact dermatitis [14] and systemic ketoprofen has caused pseudoporphyria.

Naproxen. The incidence of side effects is low given the widespread and long-term use of naproxen. Rashes occur in about 5% of patients; pruritus is the commonest symptom. Naproxen is associated with a photosensitivity dermatitis [15] and pseudoporphyria [16–20]; most photo-urticarial reactions are evoked by the UVA band. Urticaria/angio-oedema, anaphylaxis [21], purpura and thrombocytopenia [22], hyperhidrosis, acneiform problems in women [23], vasculitis [24,25], vesicobullous and fixed drug eruptions [26], erythema multiforme, a pustular reaction [27] and lichen planus-like reaction [28] have all been reported, as has recurrent allergic sialadenitis [29].

Tiaprofenic acid. This drug may cause photosensitivity [30].

Phenylacetic acids

Diclofenac. A variety of cutaneous adverse effects [1,2], including pruritus, urticaria, various exanthems, papulovesicular eruptions [3], delayed allergy [4], vasculitis [5], a bullous eruption associated with linear basement membrane deposition of IgA [6] and fatal erythema multiforme [1] have been recorded.

Oxicams

Piroxicam. This drug may cause adverse cutaneous reactions in 2–3% of patients [1,2]. More than two-thirds of affected patients have photosensitivity; lesions may be vesicobullous or eczematous, and occur within 3 days of starting therapy in 50% of cases [3–10]. Photosensitivity may result from phototoxic metabolites [7]. Photocontact dermatitis developed in three patients after the application of a gel containing 0.5% piroxicam. Patch tests were positive to thiomersal and thiosalicylic acid and photopatch tests with piroxicam were positive. Patch tests in patients with systemic photosensitivity to piroxicam were also positive for thiomersal and thiosalicylic acid. Contact allergic sensitivity to the latter is a marker for patients with a high risk of developing photosensitivity reactions to piroxicam [10,11].

Other eruptions include urticaria, maculopapular [12] or lichenoid rashes, alopecia, erythema multiforme [13] and vasculitis [14]. Piroxicam was well tolerated in patients with an urticarial reaction to a single NSAID, but provoked urticaria in 27% of patients with allergy to at least two different NSAIDs, indicating that mechanisms other than interference with prostaglandin synthesis and release of inflammatory mediators participate in allergic reactions to NSAIDs [15]. Classical fixed drug eruption [16,17] and a non-pigmenting fixed drug reaction [18], with cross-sensitivity among piroxicam, tenoxicam and droxicam in one case [19], have also been reported. Contact sensitivity to piroxicam is recorded [20]. Piroxicam was thought to have triggered subacute LE in a patient with Sjögren's syndrome and seronegative arthritis [21]. Isolated case reports of linear IgA bullous dermatosis [22], fatal pemphigus vulgaris [23] and fatal TEN [24] have appeared. The drug has caused peripheral neuropathy and erythroderma [25]. Blood dyscrasias have been reported.

Anthranilic acids

Meclofenamate sodium. Rashes occur in up to 9% of patients. More than two-thirds of reactions have been exanthematous, with prominent pruritus; vasculitic, purpuric or petechial reactions are also noted, as well as occasional urticaria, fixed drug eruption, erythema multiforme [1], exfoliative erythroderma and a vesicobullous reaction. It has been reported to exacerbate psoriasis [2]. Selective adverse reactions to glafenine and meclofenamate occurred in a patient tolerating aspirin and other cyclo-oxygenase inhibitors [3].

Mefenamic acid. Urticaria, a morbilliform eruption, fixed drug eruption [4,5], pseudoporphyria [6] and generalized

exfoliative dermatitis are documented. Acute renal failure, severe thrombocytopenia and jaundice developed after a small dose of mefenamic acid in one patient with drug-dependent antibodies reacting against platelets [7].

Heterocyclic acetic acids

Indometacin (indomethacin). Allergic reactions are very uncommon, but pruritus, urticaria, purpura and morbilliform eruptions are documented. Stomatitis [1] and thrombocytopenia occur rarely, as well as a generalized exfoliative dermatitis and TEN [2]. Vasculitis has been documented [3]. There have been rare reports of exacerbation of psoriasis [4,5]; however, indometacin in a standard dose of 75 mg/day had no significant harmful effect on psoriasis in a series of patients treated with the Ingram regimen of coal-tar bath, suberythemal UVB phototherapy and dithranol in Lassar's paste [6]. Exacerbation of dermatitis herpetiformis has been recorded [7].

Sulindac. Rashes occur in up to 9% of patients. The drug has caused anaphylaxis [1] and anaphylactoid reactions [2], photosensitivity [3], facial and oral erythema, a pernio-like reaction [4] and fixed drug eruption [5]. Stevens–Johnson syndrome [6–8], TEN [6,9], serum sickness and exfoliative erythroderma are documented. Blood dyscrasias, toxic hepatitis, pancreatitis, and aseptic meningitis in patients with SLE are recorded.

Tolmetin. Anaphylactoid reactions are well recognized [10]. TEN has been recorded.

Pyrazolones

Amidopyrine (aminophenazone). This is the most dangerous of all analgesics and has caused hundreds of deaths due to blood dyscrasias. It has been withdrawn from western Europe and North America but is still available in certain parts of the world. TEN, exfoliative dermatitis and erythema multiforme are all well known.

Azapropazone. Photosensitivity is recognized [1]. A multifocal bullous fixed drug eruption resembling erythema multiforme has been reported [2]. A bullous eruption on the face and extremities, with histological features suggestive of pemphigoid but negative immunofluorescence, has been reported [3]. The drug is contraindicated in patients receiving warfarin, as the latter medication is potentiated [4].

Phenylbutazone and oxyphenbutazone. Reactions have been frequent and often fatal [1,2]. Therefore, in the UK oxyphenbutazone has been withdrawn and phenylbutazone is restricted to hospital use for ankylosing spondylitis.

Pruritus, morbilliform eruptions, urticaria and buccal ulceration are most common; erythema multiforme, fixed eruptions (especially with oxyphenbutazone), generalized exfoliative dermatitis and TEN [3] are all well-documented hazards. Drug exanthems or erythroderma may occur in up to 4% of patients treated with phenylbutazone. Occasional reports of exacerbation of psoriasis have occurred [4]. Rarer reactions have included generalized lymphadenopathy, a Sjögren-like syndrome, non-thrombocytopenic purpura, allergic vasculitis [5] and polyarteritis nodosa. Provocation of temporal arteritis has been reported. A haemorrhagic bullous eruption of the hands was observed in three patients [6]. Cutaneous necrosis has been seen after intramuscular injection. Phenylbutazone causes fluid retention, gastrointestinal bleeding and bone marrow depression [2]; the hazards of the latter are greatly increased if the dose exceeds 200 mg/day.

Allopurinol

Dermatological complications occur in up to 10% of cases [1–7]. Acute sensitivity reactions are well known, including scarlatiniform erythema, morbilliform rashes, urticaria or generalized exfoliative dermatitis, which may be associated with fever, eosinophilia, hepatic abnormalities and a nephropathy. Vasculitis (perhaps triggered by oxypurinol, the principal metabolite of allopurinol, which has a long half-life and accumulates in renal failure [5]), erythema multiforme [7], Stevens–Johnson syndrome and TEN [5,8,9] have been reported. Cell-mediated immunity directed towards allopurinol and more importantly to its oxypurinol metabolite is thought to be involved in the pathogenesis of allopurinol-induced hypersensitivity [10]. Hypersensitivity reactions occur on average within 2–6 weeks of starting the drug, although the interval may be much longer. Eruptions are commoner in the setting of impaired renal function [11] and with concomitant thiazide therapy [12], and may first appear up to 3 weeks after the drug has been discontinued [13]. The mortality is about 20% [5]. Other allopurinol-induced cutaneous changes include alopecia and ichthyosis [14]. Allopurinol potentiates the risk of a reaction to ampicillin [15] and increases blood ciclosporin levels [16]. Desensitization may be successful in cases with minor rashes induced by allopurinol [17–19].

Antidepressants

Tricyclics and related compounds

Antidepressants are associated with a range of idiosyncratic reactions affecting the liver, skin, haematological and central nervous systems; reactions are mediated by chemically reactive metabolites formed by the cytochrome P-450 enzyme system either directly or indirectly via an immune mechanism. Individual susceptibility is determined by genetic and environmental factors, which result in inadequate detoxification of the chemically reactive metabolite [1]. Sedative, cardiovascular, anticholinergic and gastrointestinal side effects are well known [2,3]. Agranulocytosis may occur occasionally. Cutaneous reactions are rare [2] but include maculopapular rashes, photosensitivity (protriptyline and imipramine), urticaria, pruritus, hyperhidrosis, vasculitis or acne (maprotiline), and TEN (amoxapine).

Amineptine. Severe acne [4,5] and rosacea [6] have been reported.

Amitriptyline. A bullous reaction in a patient with overdosage of amitriptyline and clorazepate dipotassium has been reported [7]. Alopecia is documented.

Clomipramine. A photoallergic eruption has been documented [8].

Imipramine. This drug has caused urticarial or exanthematic eruptions occasionally [9] and agranulocytosis has occurred. Oedema of the feet is seen in older people. Glossitis and stomatitis are rare, as are transient erythema of the face, photosensitivity and exfoliative dermatitis. Slate-grey pigmentation of exposed skin may develop; golden-yellow granules, which ultrastructurally are electron-dense inclusion bodies in phagocytes, fibroblasts and dendrocytes, are seen in the papillary dermis [10–12]. Q-switched alexandrite and ruby lasers may be helpful in treating the pigmentation [13]. Cutaneous vasculitis is well documented. Atypical cutaneous lymphoid hyperplasia has been documented [14].

Maprotiline. Acne [15] and vasculitis [16] are recorded.

Mianserin. Erythema multiforme has recently been reported [17], as has a severe allergic reaction [18].

Trazodone. This drug has caused leukonychia [19], erythema multiforme [20] and vasculitis [21], and has been implicated in causing a psoriasiform eruption. Skin swelling is recorded [22].

Monoamine oxidase inhibitors

Iproniazid. Vasculitis and peripheral neuritis are documented.

Phenelzine. Hypersensitivity skin reactions are rare.

Selective serotonin reuptake inhibitors

Fluoxetine

This drug has caused urticaria [1], urticarial vasculitis [2] and hypersensitivity [3], and serum sickness [4]; familial cases are documented [5]. Atypical cutaneous lymphoid hyperplasia [6], including pseudomycosis fungoides [6–8], is recorded.

Paroxetine

Cutaneous vasculitis has been reported [9].

Miscellaneous selective serotonin reuptake inhibitors

The 5-HT_3 receptor antagonists granisetron, ondansetron and tropisetron are antiemetic medications used during chemotherapy. Effects include headache and gastrointestinal symptoms, and rarely hypersensitivity reactions [10]. There were no cross-over reactions to citalopram or paroxetine among patients hypersensitive to zimeldine [11].

Lithium

Skin reactions [1–5] are relatively uncommon. Pustular and psoriasiform lesions induced by this drug have received particular attention [6]. The pustular propensities of lithium have been attributed to lysosomal enzyme release and increased neutrophil chemotaxis [2]. Tetracycline should be avoided in treating these pustular eruptions as it may precipitate serious lithium toxicity. The acneiform 'erysipelas' eruption consists of monomorphic pustules on an erythematous base, tends to affect mainly the arms and legs, is not associated with comedones or cystic lesions, and may be very persistent. Various patterns of folliculitis may occur. Lithium can aggravate pre-existing psoriasis, making it more difficult to control [6–10], and may precipitate a palmoplantar pustular reaction [11] or even generalized pustular psoriasis [12]. Psychiatrists should avoid the use of lithium in psoriatics if possible. Darier's disease may also be exacerbated or initiated [13,14].

Additional reactions described include morbilliform rashes, erythema multiforme [15], a dermatitis herpetiformis-like rash [16], linear IgA bullous dermatosis [17] and a generalized exfoliative eruption [18]. An LE-like syndrome [19] with increased prevalence of antinuclear antibodies [20], toenail dystrophy [21] and hair loss [22,23] have been reported. Keratoderma has been documented [24], as has hidradenitis suppurativa [25]. None of these effects is related to excessive blood levels of lithium or other evidence of toxicity.

Hypnotics, sedatives and anxiolytics

Barbiturates

A toxic bullous eruption may appear at pressure points in comatose patients after overdosage [1–4]. In one series, 8% of patients admitted with drug-induced coma had such bullae [3] (see Fig. 73.5). The bullae are few, large and may lead to ulceration [2]. Necrotic lesions are seen in 4% of patients recovering from, and in 40% of fatalities related to, barbiturate-induced coma [4]. Allergic reactions are very uncommon and may be scarlatiniform or morbilliform. Exfoliative dermatitis has proved fatal [5], as has erythema multiforme. Urticaria and serum sickness are very rare, as is purpuric capillaritis. Fixed eruptions are well known [6] and particularly occur on the glans penis. TEN, LE-like syndrome, purpura and photosensitivity are recorded [7]. Phenobarbital is one cause of the anticonvulsant hypersensitivity syndrome (see p. 73.45) [8,9]. In one case, a syndrome resembling Langerhans' cell histiocytosis was produced [10]. Hypopigmentation may follow a severe reaction [11]. Exfoliative dermatitis is recorded [12].

Benzodiazepines

Allergic reactions are very rare [1].

Alprazolam. Photosensitivity has been recorded with this newer benzodiazepine [2].

Chlordiazepoxide. Morbilliform erythema, urticaria [3], fixed eruption [4], photoallergic eczema [5] and exacerbation of porphyria have been recorded. Erythema multiforme and chronic pigmented purpuric eruption occur rarely [6].

Clobazam. A generalized erythematous pruritic eruption [7] and TEN confined to light-exposed areas [8] have been reported. There has been a report of coma-induced bullae and sweat gland necrosis associated with the drug [9].

Diazepam and nitrazepam. Bullae similar to those seen after barbiturates may occur in comatose patients after overdosage [10,11]. Thrombophlebitis may follow intravenous injection of diazepam [12]. Hyperpigmentation in previously dermabraded scars has been attributed to diazepam [13]. Vasculitis is documented [14]. An eruption comprising oedema, moon face and generalized erythema, with erosions of cheeks, axillae and the genitocrural area was attributed to nitrazepam; a provocation test was positive [15].

Lormetazepam. A fixed drug eruption has been reported [16].

Temazepam. An extensive fixed drug eruption has been reported [17]. Extravasation following attempted femoral vein injection of a suspension of the contents of capsules in tap water, by an addict, resulted in extensive necrosis of genital and pubic skin [18].

Miscellaneous hypnotics, sedatives and anxiolytics

Carbromal

This drug, now rarely used, commonly produced a characteristic capillaritis with punctate purpura and haemosiderin giving a golden-brown discoloration of the skin, especially on the legs [1].

Chloral hydrate

Hypersensitivity reactions are very rare. Chloral is now virtually given only in tablet form as dichloralphenazone, in which the phenazone may cause a fixed eruption [2].

Ethchlorvynol

Overdose has caused bullous lesions [3].

Glutethimide

Dermographism with subsequent erythema, and vesicles that lasted several days, were reported in one comatose patient [4] and bullae in another patient [5] following overdosage. Fixed eruptions are recorded [6].

Meprobamate

Anorexia, drowsiness, dizziness, flushing and gastrointestinal symptoms may occur, especially with high doses. Fixed eruptions may occur [7]. The most characteristic cutaneous reaction, preceded by itching, malaise and fever, is an erythema starting in the limb flexures that rapidly gives way to a fierce non-thrombocytopenic purpura [8]. A widespread toxic erythema was associated with an anaphylactoid reaction in a patient in whom patch testing proved useful in diagnosis [9].

Antipsychotics

The most important clinical side effects include those on the central nervous and cardiovascular systems and the ocular effects [1,2]. Drugs with high potency, such as haloperidol and pimozide, tend to have fewer cardiovascular and anticholinergic effects and are less sedating, but have more neurological effects. Long-term use of antipsychotic agents results in tardive dyskinesia.

Phenothiazines

The side effects of this group of drugs have been reviewed [1–4].

Chlorpromazine. This drug is still widely used, although many related compounds are now available. Pigmentation of the skin in light-exposed areas after chronic use may be a problem, especially in women and black people [5–11]. Rarely, a purplish or slate-grey pigmentation develops [6]. There may be brown discoloration of cornea and lens [5], and bulbar conjunctiva [7]. Chlorpromazine has an affinity for melanin *in vitro* [8]. Electron microscopy shows many melanosome complexes within lysosomes of dermal macrophages, and electron-dense 'chlorpromazine bodies' in macrophages, endothelial cells and Schwann

cells [9,10]; energy-dispersive X-ray microanalysis has revealed the abundant presence of sulphur in these granules, which is a constituent of the chlorpromazine molecule [10]. Similar pigmentary deposits are found in internal organs [11] and in blood neutrophils and monocytes.

Chlorpromazine has caused lichenoid eruptions [12], exfoliative dermatitis, erythema multiforme, an LE-like illness [13] with positive antinuclear factor [14] and the lupus anticoagulant [15], and Henoch–Schönlein vasculitis [16]. Phototoxicity is well known [17–19] and phenothiazine-derived antihistamines may cause photosensitivity in atopics and subsequent development of actinic reticuloid [19]. Photocontact urticaria has been documented [20]. A pustular reaction is recorded [21]. Cholestatic jaundice is an important hazard.

Fluspirilene. Subcutaneous nodules may develop at injection sites after long-term high doses of this depot preparation [22].

Thioridazine. Vasculitis is documented [23].

Thiothixene. A sensitivity reaction has been recorded [24].

Trifluoperazine. A fixed eruption has been recorded [25].

Loxapine. Dermatitis, pruritus and seborrhoea have been recorded, and photosensitivity eruptions may occur occasionally [26].

Levomepromazin. An erythema annulare centrifugum-like pseudolymphomatous eruption has been reported [27].

Miscellaneous antipsychotic agents

Clozapine. An acute severe adverse reaction resembling SLE is recorded [1].

Haloperidol. This drug causes reactions at injection sites [2,3].

Olanzapine. A pustular reaction is documented [4].

Anticonvulsants

Allergic rashes to antiepileptic drugs are usually mild, taking the form of urticarial or morbilliform eruptions; the rare occurrence of a severe reaction indicates that the drug should be ceased, and this can be done abruptly with minimal risk of status epilepticus [1,2]. There may be cross-reactivity in terms of clinical reactions to the aromatic anticonvulsants (phenytoin, phenobarbital, carbamazepine, primidone and clonazepam), which may all cause the so-called drug hypersensitivity syndrome (see

p. 73.27), with fever, mucocutaneous eruptions, lymphadenopathy and hepatitis, 1 week to 3 months into therapy; there may be multiorgan involvement with renal and pulmonary lesions [3–10]. The reaction may develop into TEN. Arene oxide metabolites may be involved in the pathogenesis of these eruptions [3]. Sodium valproate may usually be substituted safely. The drug hypersensitivity syndrome reportedly occurs at a rate of 1 in 1000 to 1 in 10 000 exposures; siblings of patients may be at increased risk of developing this syndrome [9]. Generalized pustulation may be a manifestation of anticonvulsant hypersensitivity [11]. A severe form of hypersensitivity vasculitis, with extensive visceral involvement and poor prognosis, is seen very rarely with phenytoin and in isolated cases with carbamazepine and trimethadione [12]. Drug-induced SLE is much more frequent, and has been described with most anticonvulsants in clinical use (phenytoin, carbamazepine, ethosuximide, trimethadione, primidone and valproate) [12]. Of the newer anticonvulsant drugs, vigabatrin is usually well tolerated, but lamotrigine is associated with rashes [13,14]. Anticonvulsants may be associated with pseudolymphoma (see p. 73.45).

Carbamazepine [1]

Eruptions occur in 3% [2–5] to 12% [6–8] of patients and include diffuse erythema, miliary exanthem, maculopapular or speckled morbilliform reddish rash, urticaria, purpuric petechiae or a mucocutaneous syndrome, any of which may occur from day 8 to 60. The drug hypersensitivity syndrome [9–11], erythroderma and exfoliative dermatitis, erythema multiforme and TEN [3,4,12] are well recognized. Eczema and photosensitivity [13], an LE-like syndrome and dermatomyositis [14], as well as a pustular [15–17] and a lichenoid [3,18] reaction, are very rare. Lesions with clinical and histological features suggestive of mycosis fungoides (pseudolymphoma) have been reported [18–21]. Patch testing has been advocated for the diagnosis of carbamazepine eruptions [9,10,22,23], but has resulted in reinduction of exfoliative dermatitis [24]. A psoriasiform eruption has been reported [25], as has thrombocytopenia and leukopenia complicated by Henoch–Schönlein purpura [26]. Cross-reactivity may occur with oxcarbazepine [27,28]. Other adverse effects include nausea, vomiting, ataxia, vertigo and drowsiness. Abnormal liver function [29] and bone marrow suppression with occasional deaths due to aplastic anaemia have been recorded [3]. Development of a rash may act as an early warning of marrow toxicity. Carbamazepine therapy during pregnancy carries a 1% risk of development of spina bifida in the offspring [30].

Oral steroid therapy enabled 16 of 20 patients successfully to continue on carbamazepine after development of a rash shortly after introduction of the drug [31]. Desensitization has been achieved by induction of tolerance in patients in whom there was no suitable alternative therapy [32,33].

Diphenylhydantoin (phenytoin, Dilantin)

Cutaneous manifestations related to phenytoin have been reviewed [1–7]. The various diverse presentations share certain histopathological findings: adhesion of the infiltrated cells to the basal layer of the epidermis, cell infiltration into the epidermis, vacuolation of the basal cells, and dyskeratotic cells in the epidermis and epidermal necrosis, with $CD8^+$ T cells predominant in the epidermis [5].

About 5% of children develop a mild transient maculopapular rash within 3 weeks of starting treatment. This is more likely to occur if high loading doses are given initially [3,4]. In other series, between 8.5% [8] and 19% [9] of patients receiving phenytoin developed exanthematic rashes [10]. A phenytoin-induced hypersensitivity state, with generalized lymphadenopathy, hepatosplenomegaly, fever, arthralgia and eosinophilia, occurs in about 1% of patients, and may be accompanied by hepatitis, nephritis and haematological abnormalities [7,11–13]. Skin involvement may lead to a suspicion of lymphoma, the phenytoin-induced pseudolymphoma syndrome [14–19]. Cutaneous lesions may be restricted to a few erythematous plaques [18], or cutaneous nodules [15], or consist of a generalized erythematous maculopapular rash [14], generalized exfoliative dermatitis [16,20] or TEN [21,22]. Generalized pustulation has been recorded as a manifestation of the anticonvulsant drug hypersensitivity syndrome [23]. Universal depigmentation has resulted from TEN [24]. Cutaneous histopathology in the pseudolymphoma syndrome is often indistinguishable from that of mycosis fungoides, with infiltrating cells having cerebriform nuclei and forming Pautrier microabscesses [17,19]. The rash resolves after cessation of the drug; systemic corticosteroids may aid resolution [25]. However, there is a threefold risk of true lymphoma on long-term therapy [26–28], and T-cell lymphoma has been reported in an adult [29].

Long-term treatment causes fibroblast proliferation, and may result in dose-dependent gingival hyperplasia [30,31] or coarsening of the features [32]; hypertrophic retro-auricular folds were reported in an isolated case [33]. Hypertrichosis may be seen. Other reactions have included fixed eruptions [34], including a widespread fixed drug eruption mimicking TEN [35], erythema multiforme [1,3], TEN with cholestasis [36], cutaneous vasculitis [37], an LE-like syndrome [38,39] and eosinophilic fasciitis [40]. Linear IgA bullous dermatosis has been provoked [41]. Localized reactions to intravenous phenytoin have included delayed bluish discoloration, erythema and oedema, sometimes with bullae, distal to the site of injection; immediate burning pain and swelling, and a delayed erythematous eruption with superficial sloughing, partial epidermal necrosis and frequent multinucleate keratinocytes on histology have also been reported [42,43].

Treatment during pregnancy may lead to a characteristic 'fetal hydantoin syndrome', with general underdevelopment and hypoplasia of phalanges and nails [44]; neonatal acne may be associated [45]. However, recent controlled observations suggest that acne is neither caused nor worsened by hydantoins [46], despite reports to the contrary [47].

Lamotrigine

Dosage-related allergic rashes occur in about 5–10% of patients, usually in the first 8 weeks, leading to a withdrawal rate of 2% of patient exposures [1–4]. In one study, six of eight patients with a prior lamotrigine-related rash had no recurrence on rechallenge, and two other patients had only mild rashes [5]. Rashes leading to hospitalization, including hypersensitivity syndrome [6], Stevens–Johnson syndrome and TEN [7], occurred in 1 in 100 to 1 in 300 individuals in clinical trials, and appeared to be increased with over-rapid titration when starting therapy and with concurrent valproate medication [3,8].

Sodium valproate

Occasional transient rashes and stomatitis are documented. Temporary hair loss may be followed by increasing curliness of the regrowing hair [1]. Alteration in hair colour has been noted [2]. One case of generalized morphoea [3] and two cases of cutaneous leukocytoclastic vasculitis recurring on challenge [4] have been reported. An extrapyramidal syndrome may be induced [5], and the drug may be teratogenic [6].

Trimethadione

Serious hypersensitivity reactions may occur, including erythema multiforme, urticaria and generalized exfoliative dermatitis.

Vigabatrin

An allergic vasculitis developed in one patient 6 months after commencement of this drug [1].

Opioid analgesics and amfetamine (amphetamine)

Cutaneous side effects common to drug abuse, most frequently cocaine, heroin and pentazocine, following parenteral injection include [1,2] infections, abscesses, septic phlebitis, subcutaneous and deep dermal cellulitis, necrosis, tetanus, widespread urticaria, cutaneous manifestations of primary and secondary syphilis, HIV infection and endocarditis. Starch and talc granulomas, lymphangitis and lymphadenitis in draining lymph nodes, pigmentary abnormalities including hyperpigmentation over the injected veins, accidental 'soot' tattoos (caused by needles sterilized over an open flame), scarring, ulceration, necrotizing angiitis and leukocytoclastic vasculitis may supervene. Skin popping refers to injection of drugs beneath the skin without concern for vascular access; this may result in ulcers being delayed for a number of years [3].

Codeine

This drug has been associated with pruritus, urticaria (usually due to non-immunological release of histamine) [1,2], angio-oedema, macular and maculopapular eruptions, scarlatiniform rashes [1,3,4], fixed eruption, bullous eruption, generalized eczema [5], erythema multiforme and erythema nodosum.

Heroin

Use of the dorsal vein of the penis for administration of the drug has produced ulceration [1]. Systemic infections, such as candidiasis, may supervene [2]. Leukocytoclastic vasculitis and necrotizing angiitis have been reported in drug abusers [3–5]. Pigmentation of the tongue may occur as a form of fixed drug eruption in heroin addicts [6]. A possible association with development of pemphigus erythematosus has been suggested [7].

Morphine

Morphine is a potent histamine releaser and may cause pruritus and urticaria [1]. Profuse sweating is a common effect. Morphine provokes facial flushing blocked by naloxone [2]. Local skin irritation during subcutaneous morphine infusion is recorded [3].

Pentazocine

Woody induration of the skin and subcutaneous tissues at injection sites, perhaps with central ulceration and peripheral pigmentation, and a granulomatous histology, is well recognized [1–8]. Pigmentation, ulceration and a chronic panniculitis have supervened after many years of use. Phlebitis, cellulitis, fibrous myopathy [9] and limb contractures can complicate these changes. Generalized eruptions are rare [10]. There is an isolated report of TEN [11].

Methylamfetamine

A link with necrotizing angiitis has been recorded when this drug is used alone or with heroin or D-lysergic acid diethylamide [1].

Antiparkinsonian drugs

Amantadine

Reversible livedo reticularis has occurred in a high percentage of patients receiving amantadine, a tricyclic amine used in the treatment of Parkinson's disease [1,2].

Apomorphine

Panniculitis, ranging from mild pruritic erythema to painful nodules, has been observed [3].

Bromocriptine

Transient livedo reticularis [4], erythromelalgia [5], acrocyanosis with Raynaud's phenomenon [6,7], morphoea [8] and swelling of the legs with a sclerodermatous histology [9] have been reported rarely, as have alopecia [10], pseudolymphoma [11] and psychosis.

Carbidopa

Scleroderma-like reactions have occurred when this drug has been given in conjunction with tryptophan [12,13].

Levodopa

There have been several isolated reports of the occurrence of malignant melanoma [14–16], in certain instances involving multiple primaries, but the association may be by chance alone.

Antivertigo drugs and cerebrovascular dilators

Cinnarizine

This drug [1], and its derivative flunarizine [2], have been implicated in the precipitation of lichenoid eruptions. In the case of cinnarizine, clinical and immunofluorescence features of lichen planus were combined with the presence of a circulating anti-basement-membrane zone IgG antibody [2]. Other side effects include drowsiness, depression and parkinsonism.

Miscellaneous nervous system drugs

Drugs for alcoholism

Cyanamide. This inhibitor of alcohol dehydrogenase, used in the treatment of alcoholism in some countries, has been implicated in the development of a lichen planus-like eruption with oesophageal involvement [1,2], as well as exfoliative dermatitis [2].

Disulfiram. This drug causes vasomotor flushing, morbilliform rash and urticaria, as well as eczema in patients sensitized to rubber; it cross-reacts with rubber [3–5]. A toxic pustular eruption is recorded [6].

Drugs to aid smoking cessation

Amfebutamone. This antidepressant drug, structurally related to the phenylethylamines (amfetamines) and used in aiding smoking cessation, has been implicated in causing liver dysfunction, pruritus and urticaria [1], serum sickness [2,3], and generalized pustular and erythrodermic psoriasis [4].

Appetite suppressants and stimulants

Centrally acting appetite suppressants may induce urticarial vasculitis [1]. Megestrol, a synthetic orally active progesterone derivative used to stimulate appetite and weight gain in cachectic patients, caused a generalized morbilliform rash in a man; skin testing with progesterone acetate was positive [2]. Sibutramine, a centrally acting drug used in weight management, caused an erythema multiforme-like reaction [3].

Pyritinol

This drug, given for cerebral concussion, caused an unusual erythema multiforme-like eruption and severe headache after 10 days' treatment [4].
