Cardiac antiarrhythmic drugs

Amiodarone

This iodinated antiarrhythmic drug causes photosensitivity in around 40% of patients [1–13]. Symptoms develop within 2 h of sun exposure as a burning sensation followed by erythema; the action spectrum is UVA, extending to a degree into visible light wavebands above 400 nm [4]. Light sensitivity may persist for up to 4 months after the drug is stopped [1,2]. Blue or grey pigmentation of the face and other sun-exposed areas, resembling that in argyria, is a much less common late effect, occurring in 2–5% of cases; areas not exposed to the sun may also be involved [3,6–12]. It is induced by a phototoxic reaction involving both UVB and UVA [3,6], and is related to both duration and dosage of the drug [11]. However, although cutaneous side effects are more likely with increasing duration of treatment and cumulative dosage, neither the serum amiodarone level nor the serum metabolite level have any predictive power [13]. Amiodarone-pigmented skin contains the drug and its metabolities in higher concentrations than non-pigmented skin [3]. Iodine-rich amiodarone and its metabolites have been detected bound to lipofuscin within secondary lysosomes in perivascular dermal macrophages [7–10]. Electron-dense granules and myelin-like bodies are also found in peripheral blood leukocytes [12]. The cutaneous pigmentation slowly fades after discontinuation of therapy, but may persist for months to years [8].

Iododerma has occurred with long-term therapy. Vasculitis [14] and linear IgA disease [15] have been recorded. A fatal case of TEN has been reported [16]. The most severe adverse effect seen with amiodarone is pulmonary fibrosis, which occurs in 5–10% of exposed patients and which has a 10% mortality rate. Other problems have been cardiac dysrhythmias, thyroid dysfunction, peripheral neuropathy and reversible corneal deposits [17].

Digoxin

Allergic reactions are very rare [1], but exanthematic erythema, urticaria, bullous eruptions and thrombocytopenic purpura are documented. In one patient, a psoriasiform rash occurred, confirmed by later re-exposure [2].

Procainamide

This drug is well known for precipitating an LE-like syndrome [1–6], perhaps partly as a result of binding of the hydroxylamine metabolite of procainamide to complement component C4, with resultant impaired complement-mediated clearance of immune complexes [5,6]. A lichenoid eruption followed the occurrence of drug-induced LE in one case [7]. Urticarial vasculitis has been reported [8].

Quinidine

An eczematous photosensitivity is well described [1–5]; fever is common. Thrombocytopenic purpura may be induced, resulting from antibodies to drug–platelet conjugates [6,7]. Urticarial, scarlatiniform and morbilliform eruptions occur; the latter may proceed to generalized exfoliative dermatitis if the drug is continued. Fixed and lichenoid eruptions [8–14], often induced by light, are recorded, as well as an acneiform rash [15]. Livedo reticularis has been documented; the mechanism is unknown, although recent exposure to sunlight was a feature common to all cases [16–18]. Drug-induced LE [19–21] and Henoch–Schönlein vasculitis [22,23] have been seen. Psoriasis may be exacerbated [24,25]. Localized blue-grey pigmentation of the shins, hard palate, nails, nose, ears and forearms has been recorded [26].

β-Adrenoceptor-blocking agents

This group of drugs shares certain potential side effects in common [1,2]. Peripheral ischaemia may be aggravated, and cold extremities and Raynaud's phenomenon [3] may present as new symptoms. Peripheral gangrene and peripheral skin necrosis have been reported [4,5]. An LE-like syndrome [6,7], and eczematous or lichenoid eruptions [1,2] may be induced rarely. Psoriasis vulgaris is occasionally aggravated or precipitated by a number of β-blockers including atenolol, oxprenolol and propranolol [8–14]. Cross-sensitivity is not usual [15], but cross-reactivity between atenolol, oxprenolol and propranolol has been reported [16]. Peyronie's disease (induratio penis plastica) has been attributed to labetalol, metoprolol and propranolol [17,18]. Aphthous ulcers have been linked to β-blockers [19], and vasculitis occurred with sotalol [20]. β-Blockers may enhance anaphylactic reactions caused by other allergens, and may make resuscitation more difficult [21–23]. Vitiligo may be exacerbated [24]. Topical ophthalmic β-blockers, especially timolol, have been implicated in pruritus [25], alopecia [26], chronic erythroderma [27] and LE [28].

Acebutolol

Rashes with mixed lichenoid and LE-like features have been reported [1]. The LE syndrome may have pleuropulmonary features [2].

Atenolol

Conjunctivitis and a periocular dermatitis [3], as well as a psoriasiform rash [4], pseudolymphomatous reaction [5] and vasculitis [6], are recorded.

Cetamolol

A psoriasiform eruption has been documented [7].

Labetalol

Mixed eruptions with psoriasiform and pityriasis rubra pilaris-like changes [8], a bullous lichenoid eruption [9] and an SLE-like syndrome [10] are documented.

Metoprolol

Various psoriasiform or eczematous rashes may follow long-term therapy [11,12]. Conjunctivitis and periocular dermatitis have occurred [3]. Peyronie's disease appears to be a rare but confirmed side effect and may be reversible. Telogen effluvium has been noted [13].

Oxprenolol

This drug, like practolol, has caused an oculocutaneous syndrome [14]. An eruption combining well-defined, eroded or scaly red rings with a lichenoid histology [15,16] is recognized. Acute psoriasis with arthropathy has been described [17]. Peripheral skin necrosis associated with Raynaud's phenomenon, an LE syndrome, various patterns of dermatitis [3] and generalized pigmentation [18] are all documented.

Practolol

This drug has been withdrawn, but is discussed in view of its important side-effect profile. It caused an oculocutaneous syndrome comprising dry eyes and scarring, fibrosis and metaplasia of the conjunctiva; a psoriasiform, lichenoid or mixed eruption with a characteristic histology; pleural and pericardial reactions; fibrinous peritonitis; and serous otitis media [19,20]. Subsequent treatment with another β-blocker did not elicit cross-sensitivity reactivation of the syndrome [21]. Ocular cicatricial pemphigoid was seen [22], and exacerbation of psoriasis was recorded [23].

Pindolol

Psoriasiform [24] and lichenoid rashes with pemphigus-like antibodies demonstrated by immunofluorescence have been seen, as well as an SLE syndrome [25].

Propranolol

This is probably the most widely used β-blocker, and many adverse cutaneous reactions have been reported [26–29]. Rashes may be lichenoid [30], psoriasiform [29] or generalized and exfoliative. Other miscellaneous reported reactions include alopecia [31], erythema multiforme [32] and a cheilostomatitis with ulceration of the lips. Peyronie's disease has developed. Generalized pustular psoriasis [33] and pemphigus [34] have occurred.

ACE inhibitors

In addition to dermatological problems, these drugs may be nephrotoxic, cause cough and electrolyte disturbances, and are teratogenic [1,2]. The overall incidence of adverse effects from ACE inhibitors is estimated at 28%, of which about 50% occur in the skin. Cutaneous reactions comprise life-threatening angio-oedema, pruritus, bullous eruptions, urticaria, other generalized rashes, photosensitivity and hair loss [3]. Angio-oedema has been reported with captopril, enalapril maleate and lisinopril [4–11]. The cumulative incidence of angio-oedema, almost always on the head and neck, has been estimated at 0.1–0.7% of cases treated; it usually occurs in the first week of treatment [5,9], although onset more than 6 weeks after starting treatment occurs in 20% of patients [6]. In addition, increased frequency, intensity and duration of bouts of angio-oedema have been recorded during long-term use of ACE inhibitors [7–9]. There may be cross-reactivity between drugs; angio-oedema has developed after substituting lisinopril for captopril [10]. Fatal angio-oedema occurred in a patient on captopril for 2 years [11]. Anaphylactoid reactions have been reported during haemodialysis with AN69 membranes in patients receiving ACE inhibitors; the role of bacterial contamination of dialysate is controversial [12–14]. Anaphylactoid reactions have also occurred with LDL apheresis with dextran sulphate [15].

ACE inhibitors have been implicated in both the exacerbation and induction of psoriasis [16–19]. ACE inhibitors most commonly produce a dose-related pruritic maculopapular eruption on the upper trunk and arms, especially with captopril (2.4–7%) and less with enalapril (1.5%), which is often transitory and rarely requires discontinuation of the drug. Urticaria, a pemphigoid-like reaction, a pityriasis rosea-like reaction, a lichenoid eruption, erythroderma, alopecia and Stevens–Johnson syndrome have been reported [20]. Captopril and enalapril may produce eruptions with histological similarities to mycosis fungoides [21]. An interstitial granulomatous drug reaction characterized by violaceous plaques with a predilection for skinfold areas and by histology resembling the diffuse interstitial phase of granuloma annulare without complete collagen necrobiosis has been documented with ACE inhibitors [22].

Captopril. Dermatological complications occur in 4% [1] to 12% [2] of patients treated with captopril, and less commonly with other ACE inhibitors; side effects are more likely with renal impairment. Loss of sense of taste, or a metallic taste (augesia), ulceration of the tongue and aphthous stomatitis [3] are reported. Early changes within the first months [4–6] include pruritus, urticaria [7] and angio-oedema, which occurs in about 1 in 1000 patients and may occasionally be fatal [8], and pityriasis rosea-like [9] and morbilliform rashes. These are dose dependent and have a good prognosis. Late changes [4–6] consist of pemphigus-like [10–12] and lichenoid [13–17] eruptions. SLE-like eruptions have been recorded [18,19]. Antinuclear antibodies may develop [20,21]. Oral changes may be due to a leukocytoclastic vasculitis [22], and a serum sickness-like syndrome has been induced [23]. Psoriasis has been reported to be exacerbated or triggered [24,25].

Severe reactions [26,27] have included exfoliative dermatitis [28–30], and marrow depression with neutropenia or agranulocytosis [31]. Lymphadenopathy may be induced [32]. Alopecia [33] and an acquired IgA deficiency [34] have been reported. The merits of skin testing in the prediction of captopril reactions have been discussed [35]. It has been postulated that some toxic effects are related to the presence of a sulphydryl group, as enalapril (another ACE inhibitor lacking this group) has been safely substituted in certain cases of captopril hypersensitivity [36].

Cilazapril. Cilazapril had more neurological (mainly headache) but fewer skin reactions than the other ACE inhibitors, lisinopril, enalapril and captopril [37].

Enalapril. Enalapril produces rashes in approximately 1.4% of patients, requiring discontinuation in about 0.4% [38]. Toxic pustuloderma is recorded [38]. A single report of pemphigus foliaceus has appeared; part of the structure of this drug is identical to that of captopril, although it does not contain a sulphydryl group [39]. Bullous eruptions [40] and lichenoid eruptions [41] occur.

Lisinopril [42]. Vasculitis has been recorded [43], as has pallor, flushing and oedema [44].

Angiotensin II receptor antagonists

Sartans, angiotensin II receptor antagonists, have been implicated in the induction of psoriasis [1] and of Henoch–Schönlein purpura [2].

Calcium channel blockers

Cutaneous reactions are rare and have been reported in six per million prescriptions of nifedipine, 17 per million prescriptions of verapamil, and six per million prescriptions of diltiazem [1,2]. In one study, reactions to the dihydropyridine drugs (including nicardipine, nifedipine and nisoldipine), verapamil and diltiazem occurred after an average of 95 days (range 7 days to 10 years) [3]. Pruritus, maculopapular rashes, and urticaria/angio-oedema, alopecia and a hypersensitivity syndrome have been described with all these drugs, as have Stevens–Johnson syndrome and erythema multiforme; TEN has occurred with diltiazem. There is a suggestion that the more severe reactions are commoner with diltiazem. Peripheral oedema as a side effect is common to the dihydropyridine calcium antagonists, including nifedipine, nicardipine, isradipine and amlodipine; it occurs in 7–30% of patients depending on the specific drug, but is usually mild [4]. Psoriasiform eruptions are described [3], as are photosensitivity and erythromelalgia. Amlodipine has caused pruritus [5], a lichenoid eruption [6] and photosensitivity presenting as telangiectasia [7]. Felodipine has also been associated with photodistributed telangiectasia [8].

Diltiazem. Cutaneous reactions to diltiazem have been reviewed [1–3]. They include pruritic macular exanthem, toxic erythema with fever and occasionally facial angio-oedema [4–6], generalized cutaneous reactions [7], erythema multiforme [8], subcorneal pustular dermatosis, a generalized pustular dermatitis [9,10], a lichenoid photodistributed eruption with pigmentary incontinence [11], a photosensitive erythroderma [12], psoriasiform eruptions [2], exfoliative dermatitis in a patient with psoriasis [13], a subacute cutaneous LE-like syndrome [14], vasculitis [15] and vasculitic leg ulcers [16], recurrent nail dystrophy, hyperplastic gingivitis [17], and proptosis and periorbital oedema [18]. Generalized lymphadenopathy has occurred [19]. Patch tests may be positive in diltiazem reactions

[5,6,10]. Dermatological cross-sensitivity between diltiazem and amlodipine is reported [20].

Nicardipine. Erythromelalgia is recorded [1].

Nicorandil. Oral ulceration is documented [2,3].

Nifedipine. Headache, tachycardia and flushing are common side effects. Gingival hyperplasia is well recognized [4]. Burning sensations, erythema, painful oedema and erythromelalgia have been described [5–8]. There have been isolated reports of a truncal morbilliform rash [9], fixed drug eruption [10], a generalized bullous eruption, vasculitis [11], purpura, photosensitivity [12] in one case confirmed by rechallenge [13], gynaecomastia [14], erysipelas-like lesions on the shins with erythematous plaques on the trunk [15], exfoliative dermatitis [16,17] and pemphigoid nodularis [18].

Verapamil. Erythema multiforme has been reported [19], as have gingival hyperplasia, gynaecomastia [20], alopecia, maculopapular eruptions, ecchymosis, vasculitis, urticaria and hyperkeratosis.

Centrally acting antihypertensive drugs

Clonidine. Hypersensitivity rashes occur in up to 5% of patients. A pityriasis rosea-like and LE-like syndrome, exacerbation of psoriasis [1] and an isolated instance of anogenital cicatricial pemphigoid [2] have been documented. Transdermally administered clonidine has caused allergic contact dermatitis, but also erythema, scaling, vesiculation, excoriation, induration and dyspigmentation [3].

Methyldopa. An eczematous eruption of discoid or seborrhoeic pattern is characteristic, is more likely to occur in previously eczematous subjects and persists until the drug is stopped [1]. Eczema of the palms and soles has also been described and may become widespread. The reaction is probably allergic as it may be dose related. Purpuric, erythematous and lichenoid rashes occur, sometimes in association with fever and other allergic symptoms [2,3]. Lichenoid eruptions may be ulcerated [4,5] and persistent ulceration of the tongue has been described. Fixed eruptions are very rare. An LE-like syndrome is documented [6,7] and an autoimmune haemolytic anaemia is well known [5]. Psoriasis may be precipitated. An extensive erythematous skin eruption, fever, lymphadenopathy and eosinophilia due to methyldopa, recurrent on re-exposure, has been recorded [8].

Adrenergic neurone-blocking agents

Guanethidine. Hypersensitivity eruptions are very rare but polyarteritis nodosa has been attributed to this drug [1].

REFERENCE

1 Dewar HA, Peaston MJT. Three cases resembling polyarteritis nodosa arising during treatment with guanethidine. *BMJ* 1964; **ii**: 609–11.

Vasodilator antihypertensive drugs

Diazoxide. Transient flushing is common. During long-term treatment, up to half the patients develop hypertrichosis without other signs of virilization [1]. A clinical picture resembling hypertrichosis lanuginosa may develop [2,3]. Oedema occurs in at least 10% of patients; photosensitivity is very uncommon but well recognized. Lichenoid [3,4] and other rashes occur rarely.

Hydralazine. The LE-like syndrome due to this drug is well known [1–7]. Hydralazine binds to complement component C4 and inhibits its function; this may impair clearance of immune complexes, and predispose to development of an LE syndrome [6,7].

Orogenital ulceration may be part of the picture [8], and the syndrome has presented as a leg ulcer [9]. Cutaneous vasculitis may be severe and necrotizing [10,11]. An association between hydralazine-induced LE syndrome and the development of Sweet's syndrome has been noted rarely [12]. Fixed drug eruption has been reported [13]. Characteristic lung changes are attributed to the drug [14].

Minoxidil. This arterial vasodilator causes hypertrichosis, especially of the arms and face, which may be unacceptable to women [1,2]; the hair disappears slowly after the drug is withdrawn. Fluid retention may require diuretic therapy to control it. Thrombocytopenia [3], bullous eruptions [4], erythema multiforme or Stevens–Johnson syndrome [5] and pseudoacromegaly [6] have been described.

Nitrate vasodilators

Glyceryl and pentaerythritol tetranitrate. Reactions to nitrate vasodilators are rare, but erythroderma with cross-reactivity to glyceryl trinitrate has been caused by this drug [1].

REFERENCE

1 Ryan FP. Erythroderma due to peritrate and glyceryl trinitrate. *Br J Dermatol* 1972; **87**: 498–500.

Diuretics

Carbonic anhydrase inhibitor

Acetazolamide. This drug has caused hirsutism in a child [1]. Hypersensitivity reactions are rare.

REFERENCE

1 Weiss IS. Hirsutism after chronic administration of acetazolamide. *Am J Ophthalmol* 1974; **78**: 327–8.

Loop diuretics

Bumetanide. Occasional hypersensitivity rashes occur. Pseudoporphyria has been reported wih this sulphonamide-derived drug [1].

Etacrynic acid (ethacrynic acid). A Henoch–Schönlein type of vasculitis has been documented.

Furosemide (frusemide). Reactions are rare: only two patients of 3830 receiving this medication in one study developed cutaneous complications [2]. Phototoxic blistering has followed very high dosage (2.0 g/day) in chronic renal failure [3] but erythema multiforme [4,5], bullous pemphigoid [6,7], other bullous haemorrhagic eruptions [8] and an acquired blistering disorder with skin fragility [9] have apparently been precipitated by conventional dosage. The skin changes may mimic those of porphyria. Several cases of generalized exfoliative dermatitis have been documented. Anaphylaxis [10], a necrotizing vasculitis [11] and an eruption resembling Sweet's syndrome [12] have been reported. Cross-reactivity between furosemide, hydrochlorothiazide and sulphonamides is recorded, but the use of one of these drugs in a patient known to have allergy to another involves only low risk [13].

Potassium-sparing diuretics

Spironolactone. This drug, which is also used for the treatment of acne vulgaris and hirsutism [1], may cause gynaecomastia [2–4], gastrointestinal upset, hyperkalaemia and rarely agranulocytosis [1]. Spironolactone has an anti-androgenic effect [4] and may result in loss of libido and impotence or menstrual irregularities. A maculopapular eruption [5], LE-like syndrome [6], annular LE [7], erythema annulare centrifugum [8] and a lichenoid eruption [9] have been seen.

Thiazides and related diuretics

Photosensitivity is uncommon, occurring in 1 in 1000 to 1 in 100 000 prescriptions [1–7]. Hydrochlorothiazide causes considerably more reactions than bendroflumethiazide (bendrofluazide). The mechanism is unknown, and both phototoxic [1,4,7] and photoallergic [2,3] mechanisms have been proposed. The commonest reaction is lichenoid [8], but petechial and erythematous eruptions may occur in exposed skin. Xerostomia has been reported, as has a vasculitis [9]. An eruption resembling subacute cutaneous LE has been described in patients taking a combination of hydrochlorothiazide and triamterene [10,11] and with hydrochlorothiazide alone [12]. Other side effects include hypokalaemia, short-term elevation of LDL cholesterol, impotence, a diabetogenic effect and exacerbation of gout [13].

Chlortalidone (chlorthalidone). Pseudoporphyria has been documented with this thiazide-related diuretic [14]. Psoriasis has been triggered in a patient also receiving captopril [15].

Miscellaneous cardiovascular drugs

Dobutamine

Two patients with local dermal hypersensitivity at the site of dobutamine hydrochloride injection, consisting of erythema, pruritus and phlebitis with or without bullae, have been described [1]. Dermal cellulitis has also been reported [2].

Dopamine

This positive inotropic agent has caused local skin necrosis, due to extravasation at the site of an intravenous cannula [3], and acral gangrene secondary to distal vasoconstriction [4,5]. Localized piloerection and vasoconstriction proximal to the site of infusion have been documented [6]. Allergic reactions may occur [7].

7 Merola B, Sarnacchiaro F, Colao A *et al*. Allergy to ergot-derived dopamine agonists. *Lancet* 1992; **339**: 620.

Vasopressin

This drug, when used intravenously for control of bleeding oesophageal varices or as a local vasoconstrictor agent, has caused cutaneous necrosis at sites of extravasation, and occasionally at distant sites, with a bullous eruption [1]. Mottling, cyanosis, ecchymoses, bullae, ulcers and gangrene are often preceded by coolness and paraesthesiae [2].

Rutosides (Paroven)

This mixture of oxerutins, used for relief of symptoms of oedema related to chronic venous insufficiency and for reduction of lymphoedema, has been associated with transient urticaria [1].

REFERENCE

1 Anonymous. Paroven: not much effect in trials. *Drug Ther Bull* 1992; **30**: 7–8.

Drugs acting on the respiratory system

β-Agonists

Albuterol

Patchy erythema of the hands developed in a pregnant patient following infusion [1].

Salbutamol

LE-like acral erythema developed after infusion in three pregnant patients with premature labour [2].

Salmeterol

An urticarial reaction that recurred on challenge was attributed to this drug administered from a metered dose inhaler [3].

REFERENCES

1 Morin Leport LRM, Loisel JC, Feuilly C. Hand erythema due to infusion of sympathomimetics. *Br J Dermatol* 1990; **122**: 116–7.

Aminophylline

This drug is a mixture of theophylline and ethylenediamine. Urticaria, generalized erythema and exfoliative dermatitis have followed systemic administration, probably as a result of reactions to the ethylenediamine component rather than to theophylline itself [1]. Cross-reactions may occur with ethylenediamine in antihistamines and topical preparations [1,2]. Patch tests may or may not be positive [3].

Metals and metal antagonists

Metals

Arsenic

Features of acute [1] and chronic [2] arsenic poisoning have been reviewed. Bullous eruptions, photosensitivity, exfoliative dermatitis, erythroderma with pustulation, and alopecia may be acute manifestations of arsenic toxicity. Occupational exposure may occur, especially in agriculture. Inorganic arsenic is sometimes present in Chinese proprietary medicines [2]. Fowler's solution (containing 1% potassium arsenite) and sodium arsenate were used in the past for psoriasis; as little as 0.19 g has been carcinogenic and the interval between exposure and tumour induction may be as long as 47 years [3]. Subjects with an abnormally high retention of ingested arsenic may be at particular risk [4]. The cutaneous manifestations of arsenic exposure, including macular pigmentation, palmoplantar punctate keratoses and intraepidermal (Bowen's disease), basal cell or squamous carcinomas of the skin, are well known [2–11]. Keratoses and tumours may be present without pigmentation. In one series of patients, there was a dose-related development of palmar and plantar keratoses in 40%, and carcinomas of the skin in 8%, of patients who received arsenic in the form of Fowler's solution for 6–26 years; the minimum latent period before development of keratoses was 2.5 years, and the average was 6 years [5]. In another series, Bowen's disease occurred within 10 years and invasive carcinomas within 20 years [9]. The lag times for development of keratoses, Bowen's disease and squamous cell cancer were, respectively, 28, 39 and 41 years in another series [2]. Arsenic contamination of well water in Taiwan resulted in numerous affected individuals with arsenical keratoses and cutaneous carcinomas [7]. Carcinomas may arise in the arsenical keratoses [7]. Groundwater contamination leads to an endemic problem [12,13]. Cutaneous electron microscopic changes are said to be characteristic [10]. The diagnostic significance of the skin arsenic content is disputed. A 42-year-old man who took arsenic for 35 years for psoriasis developed melanoderma, keratoses, muscular dystrophies, hyperlipidaemia, testicular atrophy, gynaecomastia, skin tumours and an obliterating angiitis of leg vessels, which led to amputation [6]. The role of arsenic in causing internal malignancy is the subject of controversy [9,14,15].

Gold

The use of gold in rheumatoid arthritis is associated with a 23–30% incidence of reactions [1–3]; most of these are minor, but about 15% may be severe or even fatal [4]. Possession of the HLA-DR3 and HLA-B8 phenotypes reportedly predisposes to thrombocytopenia, leukopenia and nephrotoxicity, HLA-DR4 is linked to leukopenia, and

HLA-B7 is associated with cutaneous adverse reactions [2]. In another study, HLA-DR5 was significantly associated with mucocutaneous lesions, whereas HLA-B8 and HLA-DR3 antigens were associated with proteinuria in rheumatoid arthritis patients after gold therapy; HLA-DR7 was negatively associated with reactions and may confer protection, and HLA-B27 was associated with chrysiasis due to gold therapy [5]. A further study showed that gold dermatitis in patients with rheumatoid arthritis was associated with HLA-B35 and disease duration [6]. Antibodies to the Ro 52-kDa antigen are associated with skin eruptions in rheumatoid arthritis patients treated with gold [7].

Rashes and mouth ulcers are common [1,2,8–13], representing about 50% of all complications with parenteral gold and 35% of those with oral gold. Localized or generalized pruritus is an important warning sign of potential toxicity. Gold reactions may simulate exanthematic eruptions [14], erythema annulare centrifugum [15], seborrhoeic dermatitis or lichen planus [16,17]; a mixture of these patterns, sometimes with discoid eczematoid lesions, is characteristic. Lichen planus is often of the hypertrophic variety especially on the scalp, and severe and irreversible alopecia may follow [18]. There may be striking and persistent post-inflammatory hyperpigmentation. Permanent nail dystrophy has followed onycholysis [19]. Yellow nails have been described [20].

In one study, eczematous or lichenoid rashes persisted up to 11 months after cessation of therapy [21]. Histology was characterized by a sparse dermal perivascular infiltrate, predominantly of $CD4^+$ HLA-DR-positive helper T lymphocytes, an increase in the number of dermal Langerhans' cells and epidermal macrophage-like cells, and Langerhans' cell apposition to mononuclear cells. A patient with a lichenoid and seborrhoeic dermatitis-like rash on gold sodium thiomalate therapy had a positive intradermal test to gold thiomalate; patch tests were positive to thiomalate (the thiol carrier of gold thiomalate) but negative to gold itself [22]. Interestingly, the same patient subsequently developed a seborrhoeic dermatitis-like eruption, but not a lichenoid eruption, while on auranofin; this time, patch tests were positive to both auranofin and gold. A previous contact dermatitis from gold jewellery may be reactivated [23].

Other reactions documented include erythema nodosum [24], severe hypersensitivity reactions [25], vasculitis [26], polyarteritis, an SLE-like syndrome, generalized exfoliative dermatitis and TEN. Psoriasis was reported to be exacerbated in a patient with arthritis treated with gold [27].

Prolonged administration of gold may cause a distinct grey, blue or purple pigmentation of exposed skin (chrysiasis), which is a dose-dependent reaction that occurs above a threshold of 20 mg/kg; gold granules are seen within dermal endothelial cells and macrophages [28–32]. Even in the absence of pigmentation, gold can be detected histochemically in the skin up to 20 years after therapy. Localized argyria with chrysiasis has been caused by implanted acupuncture needles [33]. An unusual late cutaneous reaction involved the appearance of widespread keloid-like angiofibromatoid lesions [34].

A benign vasodilatory 'nitritoid' reaction, consisting of flushing, light-headedness and transient hypotension, may occur immediately after the first injection of gold [2,35]. It occurs in roughly 5% of patients taking gold sodium thiomalate. Non-vasomotor effects, including arthralgia, myalgia and constitutional symptoms within the first 24 h, are recognized. Mucous membrane symptoms include loss of taste, metallic taste, stomatitis, glossitis and diarrhoea. Punctate stomatitis may occur with or without skin lesions. Gold is also deposited in the cornea and may cause a keratitis with ulceration. A polyneuropathy is recorded. In general, auranofin is less toxic than intramuscular gold [2]. Eosinophilia is common and may sometimes herald another complication; serum IgE may be raised [36]. Other immunological reactions are rare, although pulmonary fibrosis is recorded [37]. Blood dyscrasias, especially thrombocytopenic purpura, and occasionally fatal neutropenia or aplastic anaemia occur in a small proportion of cases and usually present within the first 6 months of therapy. Jaundice occurs in about 3% of cases, and may result from idiosyncratic intrahepatic cholestasis [38]. Proteinuria and renal damage are well known.

Mercury

Skin manifestations of mercury exposure have been reviewed [1,2]. Mercury-containing teething powders have long been banned, but occasional occupational or environmental exposure can occur. Mercury amalgam in dental fillings has caused buccal pigmentation. Stomatitis may occur as a toxic reaction. Allergic reactions may be scarlatiniform or morbilliform, and can progress to generalized exfoliative dermatitis. Eczema is recorded [3]. Pink disease or acrodynia, a distinctive pattern of reaction to chronic exposure to mercury in young infants and children, is now very rare [4]. Painful extremities, pinkish acral discoloration, peeling of the palms and soles, gingivitis and various systemic complications may occur. Acrodynia developed in a child following inhalation of mercury-containing vapours from phenyl-mercuric acetate contained in latex paint [5]. A mercury-containing drug given for 3 weeks to a patient with long-standing pustular psoriasis of the palms was associated with development of generalized pustular psoriasis [6]. (See also exogenous ochronosis from topical mercury-containing preparations, p. 73.168.) Cutaneous granulomas are recorded [1], and a nodular reaction occurred after intake of a duck soup that contained metallic mercury for a neck abscess 18 years previously [7].

Silver

Ingestion of silver or topical application of silver preparations to the oral mucosa or upper respiratory tract can produce slate-blue discoloration, especially of exposed skin, including oral and conjunctival mucosae [1–8]. Argyria localized to the left hand occurred in an antique restorer due to polishing silver [9]. Topical application may also cause systemic argyria, in which visceral organs are also discoloured [10]. Localized argyria can result when the backs of earrings become embedded [11]. In some patients, the nail beds of the fingers but not the toes may show bluish discoloration [12]. Silver granules are found free within the dermis; melanin may be increased in the epidermis or within melanophages [13–15].

Metal antagonists

Deferoxamine (desferrioxamine)

Itching, erythema and urticaria are occasionally seen [1]. An indurated erythema with oedema lasting 2 weeks has been reported following infusion of this drug [2].

Penicillamine

There is a fourfold increase in toxicity with this drug in patients with rheumatoid arthritis who have a genetically determined poor capacity to sulphoxidate the structurally related mucolytic agent carbocysteine [1,2]. In addition, penicillamine toxicity is independently associated with HLA phenotype [1–3]. HLA-DR3 and HLA-B8 are associated with renal toxicity, HLA-DR3, HLA-B7 and HLA-DR2 with haematological toxicity, and HLA-A1 and HLA-DR4 with thrombocytopenia. Cutaneous adverse reactions are linked to HLA-DRw6. Anti-Ro(SSA)-positive patients with rheumatoid arthritis more often developed rashes and acute febrile reactions [4].

The cutaneous side effects of this chelating agent comprise three distinct types: (i) acute hypersensitivity reactions occurring early during treatment, (ii) late reactions including disturbances of autoimmune mechanisms leading to pemphigus foliaceus or erythematosus and cicatricial pemphigoid, and (iii) lathyrogenic effects on connective tissue [2,5–9]. Hypersensitivity reactions are common and consist of urticarial or morbilliform rashes appearing within the first few weeks; the eruption clears on drug withdrawal and does not always recur on re-exposure. It is possible to desensitize patients to penicillamine [10].

Autoimmune syndromes caused by penicillamine are well documented. The development of pemphigus during the treatment of both Wilson's disease and rheumatoid arthritis with penicillamine was first noted in the French literature [11,12]. Since then, there have been numerous case reports [13–25]; about 7% of patients receiving penicillamine for more than 6 months develop drug-induced pemphigus [13]. The reader is referred to the section on drug-induced pemphigus (p. 73.40). Findings with direct immunofluorescence mimic the idiopathic disorder, with epidermal intercellular deposition of immunoreactants [16]. Most patients develop pemphigus foliaceus, although there have been isolated reports of pemphigus vulgaris [14] and of pemphigus erythematosus with both epidermal intercellular and subepidermal deposition of IgG [15,17]. In some patients, clinical appearances may resemble dermatitis herpetiformis [21,22]. Oral lesions may be indistinguishable from those seen in idiopathic pemphigus, with cheilosis, glossitis and stomatitis [23]. Painful erosive vulvovaginitis may lead to scarring. Penicillamine-induced pemphigus usually subsides rapidly after cessation of the drug; occasionally it may be more persistent [13] and fatalities have occurred [24,25]. A curious bullous dermatosis without the features of pemphigus has been described recently [26]. Other autoimmune manifestations include a bullous pemphigoid-like reaction [27], cicatricial pemphigoid [28,29], both discoid and systemic LE [30–33], dermatomyositis [34–37], and both morphoea and systemic sclerosis [38,39]. Pre-existing lichen planus [40] may be exacerbated, and lichenoid eruptions develop *de novo* [41,42]. Alopecia, facial dryness and scaling, nail changes and hypertrichosis are recorded. The yellow nail syndrome has been reported frequently in association with penicillamine [43].

Prolonged high-dose therapy for more than a year, as for Wilson's disease, has effects on collagen and elastin [44,45], resulting from inhibition of the condensation of soluble tropocollagen to insoluble collagen. There is anisodiametricity of connective tissue fibres, resulting in the 'lumpy-bumpy' elastic fibre [46–48]. The skin becomes wrinkled and thin, aged looking and abnormally fragile; asymptomatic, violaceous, friable, haemorrhagic macules, papules and plaques develop on pressure sites, and minor trauma causes ecchymoses [49]. There may be light-blue anetoderma-like lesions [50], and small white papules at

Fig. 73.6 Penicillamine dermopathy with milia. (Courtesy of St John's Institute of Dermatology, London, UK.)

venepuncture sites. Lymphangiectasis may develop [49]. Blisters may occur, with a picture resembling epidermolysis bullosa with scarring and milia formation (Fig. 73.6) [51]. Cutis laxa and elastosis perforans serpiginosa [52–58], which may be verruciform [52,53], are described. Lesions resembling pseudoxanthoma elasticum have been documented rarely [59–62].

Penicillamine may induce impaired taste sensation in up to 25% of patients, but other gastrointestinal effects are usually minor. Important non-dermatological complications [2,8] include marrow suppression; various renal problems, such as reversible proteinuria, in up to 30% of patients on therapy for more than 6 months; established nephrotic syndrome; and Goodpasture's syndrome. Thrombocytopenia occurs in up to 3% of patients, and may be either of gradual or precipitous onset. Immunological abnormalities include acquired IgA deficiency [63] and development of myasthenia gravis [64]. The bones may be involved in the connective tissue disorder. A chronic bronchoalveolitis is recognized [65]. Breast enlargement and breast gigantism [66] are documented.

Tiopronin (N-(2-mercaptopropionyl) glycine)

This drug, used in Japan for the treatment of liver disease, mercury intoxication, cataracts and allergic dermatoses, dissociates disulphide bonds, like penicillamine. Morbilliform, urticarial and lichenoid eruptions, bullous in one case, have occurred [1].

Coumarins

There may be cross-sensitivity across the group comprising acenocoumarol (nicoumalone), phenprocoumon and warfarin [1].

Phenprocoumon. A patient on long-term anticoagulation developed repeated episodes of skin and subcutaneous fat necrosis related to episodes of excessive anticoagulation with acquired functional deficiency of protein C, thought to be due to hepatic dysfunction resulting from congestive cardiac failure [2].

Warfarin. Haemorrhage is the commonest adverse reaction. Maculopapular rashes occur [1], and may be seen after a single dose of warfarin [3]. Rarely, an oral loading dose may lead to one or more areas of painful erythema and ecchymosis, which rapidly progress to central blistering and massive cutaneous and subcutaneous necrosis

Fig. 73.7 Warfarin necrosis. (Courtesy of A. Ive, Durham, UK.)

(Fig. 73.7) [4–12]; if extensive, the condition may be fatal [3]. The lesions usually start after 2–14 days of treatment (usually 3–5 days), tend to be symmetrical, and occur over fatty areas, for example the breasts, buttocks, thighs, calves and abdomen. Most patients have been women, but lesions of the penis may occur [6]. Warfarin necrosis has been associated with the heterozygous state for deficiency of protein C, a vitamin K-dependent serine protease [8–10]. Activated protein C is a potent anticoagulant that selectively inactivates co-factors Va and VIIIa and inhibits platelet coagulant activity by inactivation of platelet factor Va. Continued coumarin therapy does not aggravate the condition, but resumption of therapy with loading doses may lead to new lesions [7]. The condition is preventable by vitamin K_1 injections. Other side effects are rare, and include urticaria [13], dermatitis, gastrointestinal upset, purple erythema of the dependent parts (purple toe syndrome) [14–16], acral purpura [17] and alopecia [18].

Oral anticoagulants and quinidine act synergistically to depress vitamin K-sensitive hepatic clotting synthesis [19]. Their combined use can precipitate serious hypoprothrombinaemic haemorrhage. Azapropazone displaces warfarin from protein-binding sites and also alters renal clearance of *R* and *S* isomers of warfarin; this may lead to effective warfarin overdosage [20]. Itraconazole may potentiate the action of warfarin [21].

Indandiones

Hypersensitivity reactions occur in up to 0.3% of patients within 3 months of onset of treatment with phenindione. Scarlatiniform, eczematous, erythema multiforme-like or generalized exfoliative eruptions are seen [1,2]. Alopecia and stomatitis may accompany the rash. Brownish-yellow or orange discoloration of the palmar or finger skin on handling the tablets develops after contact with soap alkali [3]. Cutaneous necrosis occurs rarely.

Heparin: parenteral anticoagulant

The most frequent side effect is haemorrhage [1,2]. Other common side effects include osteoporosis and (temporary) telogen effluvium 6–16 weeks after administration. Hypoaldosteronism may occur. Hypersensitivity reactions including urticaria and anaphylactic shock are well documented but very uncommon [3]. Rapid desensitization was achieved in a patient with heparin urticarial hypersensitivity who required cardiac surgery [4]. Hypereosinophilia is recorded [5]. Vasospastic reactions, including pain, cyanosis and severe itching or burning plantar sensations, are described.

Erythematous infiltrated plaques developing 3–21 days after commencement of heparin therapy [6–14] may

closely mimic contact dermatitis both clinically and histologically, and patch tests may be positive [8,9]. Delayed-type hypersensitivity reactions in patients receiving heparin may occur with both unfractionated and low-molecular-weight heparins. Delayed-type hypersensitivity to heparins is characterized by considerable cross-reactivity between low-molecular-weight heparins, unfractionated heparins and danaparoid [13]. Unfractionated heparins may be tolerated even if low-molecular-weight heparins are not. Subcutaneous provocation testing with a panel of heparins, danaparoid and desirudin (hirudin) is recommended for determining acceptable treatment options for patients allergic to specific heparins. Low-molecular-weight heparin analogues may be satisfactorily substituted in some patients with this reaction [6,15], but are not always tolerated [7,16,17]; a panel of different low-molecular-weight heparin preparations should be checked by subcutaneous provocation tests before reinstitution of heparin therapy. Chlorocresol may be responsible for some reactions attributed to heparin [7,18], including anaphylactoid reactions.

Skin necrosis occurring 6–8 days after onset of subcutaneous heparin is rare, but may occur at injection sites and occasionally at distal sites elsewhere [19–27]. Diabetic women on high-dose antibiotics are predisposed to this complication. A scleroderma-like evolution has been recorded [22]. Clinically, the skin necrosis resembles that of coumarin necrosis [25]. It may occur with use of low-molecular-weight heparin [23,26].

Heparin may cause an allergic thrombocytopenia [28–35]. Thrombocytopenia is usually asymptomatic, but may be associated with arterial or venous thrombosis in about 0.4% of cases [29,33,34]; thromboembolism may occasionally be lethal [30]. Thrombocytopenia usually begins 3–15 days after initiation of therapy, but may occur within hours in previously exposed patients, and is thought to be caused by an IgG–heparin immune complex involving both the Fab and Fc portions of the IgG molecule [29]. Heparin-induced antiendothelial cell antibodies, which recognize heparin-like glycans on the cell surface of platelets and endothelial cells, may lead to platelet aggregation and endothelial cell expression of procoagulant tissue factor, with resultant thrombocytopenia and thrombosis [21]. Thrombocytopenia may occur with both unfractionated and low-molecular-weight heparins [20]. Clinical cross-reactivity between heparin and the polysulphated chondroitin-like substance Arteparon, used in the treatment of degenerative joint disease, has been described [32].

Protamine: heparin antagonist

This low-molecular-weight protein, derived from salmon sperm and/or testes, is used for neutralization of heparin anticoagulation after cardiac surgery. Adverse reactions have been reviewed [1]. Idiosyncratic responses or those related to complement generation of anaphylatoxins are recorded [2]. IgE-dependent anaphylaxis [3], as well as delayed reactions causing skin nodules [4–6], which may be granulomatous [6], may occur in diabetics treated with protamine-containing insulin.

Fibrinolytic drugs

Haemorrhage is the most common untoward effect from use of thrombolysins [1]. Allergic complications are rare, particularly with alteplase or urokinase. These agents should be used electively in all patients previously exposed to streptokinase or anistreplase [2].

Alteplase (tissue-type plasminogen activator)

Painful purpura occurring within hours of administration has been recorded [3].

Aminocaproic acid

A maculopapular eruption occurring 12–72 h after administration of ε-aminocaproic acid, with positive patch tests to the drug, has been described [4]. A transient, non-inflammatory, subepidermal, bullous eruption on the legs, with fibrin thrombi in papillary dermal vessels, has also been recorded [5].

Anistreplase (anisoylated plasminogen streptokinase activator complex)

Anistreplase given for acute myocardial infarction was associated with leukocytoclastic vasculitis [6]. Maculopapular rashes and urticaria are described; patients with maculopapular rashes had significantly higher rises in serum IgM, IgG, IgA and IgE antistreptokinase level [7].

Streptokinase

Allergic reactions have been reported in up to 6% of patients [1–3], ranging from minor rashes to angio-oedema or anaphylaxis (which may be fatal [4–6]), bleeding, strokes and a syndrome resembling adult respiratory distress syndrome [3]. Patients who develop reactions to streptokinase cannot be predicted on the basis of antistreptokinase IgG antibody titres at presentation; minor reactions to streptokinase would not appear to be antibody mediated [7]. However, streptokinase-related thrombolytic agents should be avoided in reinfarction thrombolysis therapy in patients with raised antistreptokinase antibody titres, as hypersensitivity reactions including serum sickness may occur [8–10]. This drug has been reported in association with a hypersensitivity vasculitis [11,12], serum sickness with leukocytoclastic vasculitis [13,14] and a lymphocytic angiitis [15]. Skin necrosis is recorded [16].

Urokinase

Haemorrhagic bullae occurred as a complication of urokinase therapy for haemodialysis catheter thrombosis [17].

Antiplatelet drugs

Clopidogrel

This drug, a novel thienopyridine derivative chemically related to ticlopidine and used in patients at risk of thromboembolic disorders, has caused a photosensitive lichenoid eruption [1].

Ticlopidine

This antiplatelet drug, indicated for coronary artery disease, cerebrovascular disease, peripheral vascular disease and diabetic retinopathy, is also a thienopyridine derivative [2,3]. Gastrointestinal symptoms, thrombocytopenia with minor bleeding including bruising, neutropenia, rashes in 10–15% of patients, and hepatic dysfunction in 4% of cases have been reported. Thrombotic thrombocytopenic purpura has also been documented [4]. Cutaneous reactions, including urticaria, pruritus, maculopapular and fixed drug eruptions, erythromelalgia and erythema multiforme, are recorded in up to 11.8% of patients [5]. Acute generalized exanthematous pustulosis has been documented [6].

Vitamins including retinoids

Vitamin A

Generalized peeling may be a delayed manifestation of acute intoxication [1]. Chronic intoxication produces the following epithelial problems: pruritus, erythema, hyperkeratosis, dryness of mouth, nose and eyes, epistaxis, fissuring, dryness and scaling of the lips, peeling of the palms and soles, and alopecia. A yellow-orange skin discoloration, photosensitivity and nail changes have also been observed [2–5]. Headache, pseudotumour cerebri, anaemia, hepatomegaly and skeletal pain may be present. Cortical hyperostoses and periosteal reaction of tubular bone [6], and more rarely premature epiphyseal closure and change in the contour of long bones [7], are seen.

Retinoids

The cutaneous and systemic side effects of these synthetic vitamin A-related compounds resemble those of hypervitaminosis A, and have been extensively reviewed [1–12].

Acitretin

The side effects of this principal metabolite of etretinate are similar to those of the parent compound [1–6], comprising cheilitis, alopecia, conjunctivitis, peeling of the palms and soles, xerosis, myalgia and pancreatitis; elevated levels of serum triglyceride, cholesterol and liver transaminase are seen. There has been no biopsy-proven hepatotoxicity [7]. Alopecia is particularly frequent [4], and scaling of the palms and soles appears more prominent than with etretinate [5]. There is a higher occurrence of vulvovaginal candidiasis during acitretin exposure [8]. Multiple milia have occurred [9]. Skeletal effects may be significant, but are not an absolute contraindication to therapy [10]. Acitretin does not seem to cause osteoporosis [11].

Persistent levels of etretinate have been detected in plasma following a change to acitretin therapy. Detectable plasma etretinate was present in 45% of current acitretin users and 18% of those who had stoppped acitretin, whereas detectable subcutaneous tissue etretinate was present in 83% of current acitretin users and 86% of those who had discontinued the drug [12]. Inability to detect plasma etretinate is therefore a poor predictor of the absence of etretinate in fat. Acitretin and/or etretinate were detectable in fat and in some cases plasma from women who had ceased acitretin therapy for up to 29 months [12]. It has been proposed that subcutaneous tissue levels of acitretin and etretinate should be monitored when plasma measurements are negative, and that the recommended contraception period of 2 years after cessation of acitretin therapy should be reconsidered to avoid the risk of teratogenicity [13]. It has been suggested that acitretin is only converted to etretinate following alcohol intake [14].

Etretinate

This drug has been largely superseded by acitretin. The dermatological side effects are dose dependent, and resemble those associated with isotretinoin therapy [1–3]. With dosage over 0.5 mg/kg, cheilitis with dryness, scaling and fissuring of the lips is almost universal. There may be pruritus, a dry mouth, dry nose, epistaxis, meatitis, desquamation including the face, hands and feet, and reduced tolerance of sunlight [4] and therapeutic products such as tar or dithranol. Pseudoporphyria has been reported in a renal transplant recipient treated with etretinate to suppress cutaneous neoplasia [5]. A 'retinoid dermatitis' resembling asteatotic eczema may develop in up to 50% of patients [6]. Increased stickiness of the palms and soles, possibly due to increased quantities of carcinoembryonic antigen and other glycoproteins in eccrine sweat [7,8], has been reported. Mucosal erosions, conjunctivitis, paronychia, alopecia [9] and curling, kinking or darkening of hair [10] are all well documented. Intertriginous erosions have also been described [11]. Oedema [12], excess granulation tissue [13] and multiple pyogenic granulomas [14] develop rarely. Erythroderma has been reported [15].

Prolonged therapy may lead to skin fragility [16,17]; blistering, erosions and scarring have been reported in one patient [18]. Softening of the nails is seen [19], and chronic paronychia, onycholysis, onychomadesis, nail shedding, onychoschizia and fragility may occur [20,21]. Parakeratotic digitate keratoses appearing after treatment of disseminated superficial actinic porokeratosis may arise as a result of etretinate-resistant regions in the ring of the cornoid lamella [22]. There has been a single case of generalization of palmoplantar pustulosis following cessation of etretinate therapy [23].

Systemic side effects of etretinate include benign intracranial hypertension [24]. Minor disturbances in tests of liver function are not uncommon, and may not always be reversible; liver changes range from non-specific reactive hepatitis to acute hepatitis, chronic active hepatitis and severe fibrosis or cirrhosis [25–28]. Fatal liver necrosis occurred in a patient with ichthyosiform erythroderma [29], but other factors may have been relevant. However, several studies involving liver biopsies have indicated good tolerance of etretinate without significant hepatotoxic side effects [30–32]; in one study, patients were followed for 3 years [32]. Etretinate, like isotretinoin, can cause increase in triglycerides and cholesterol [33–36] but to a lesser extent [36]. There have been isolated reports of possible etretinate-related thrombocytopenia [37]. Retinal toxicity has been postulated [38], although a recent report has not confirmed this [39]. Erectile dysfunction has been documented occasionally [40].

Skeletal abnormalities, such as periosteal thickening, vertebral hyperostosis, disc degeneration, osteoporosis and calcification of spinal ligaments, occur in a significant number of adults receiving long-term therapy for disorders of keratinization, but the severity of the changes is minor [41,42]. Radiological evidence of thinning of long bones may be seen in children [43], and premature epiphyseal closure has been recorded [44].

Etretinate, like isotretinoin, is grossly teratogenic, and because of its deposition in body fat stores is excreted only very slowly, especially in the obese [45]. Detectable serum levels have been found in some patients more than 2 years after discontinuation of therapy. It is therefore recommended that female patients of child-bearing years should be advised to prevent pregnancy not only during the course of treatment but also for at least 2 years after stopping therapy; if pregnancy is contemplated after this period of time, an estimation of circulating levels of retinoid metabolites should be obtained.

Isotretinoin (13-cis-retinoic acid)

Dermatological complications have been reviewed [1,2]; erythema and scaling of the face, generalized xerosis, skin fragility, pruritus, epistaxis, dry nose and dry mouth may be seen in up to 80% of cystic acne patients. A dose-related cheilitis occurs in over 90% and conjunctivitis in about 40% of patients. Transient exacerbation of acne may occur, especially in the early stages of therapy. Exuberant granulation tissue, or pyogenic granulomas at the site of healing acne lesions, has been reported frequently [3–7].

Rashes, including erythema, and thinning of the hair (in rare cases persistent) occur in fewer than 10% of patients. Both isotretinoin and etretinate may cause curliness or kinking of hair [8]. Nasolabial follicular sebaceous casts have been reported [9]. The following have occurred in approximately 5% of cases: peeling of the palms and soles, skin infections and possible increased susceptibility to sunburn. Phototesting confirmed photosensitivity in some patients in one study [10] but not another [11]. A photoaggravated allergic reaction has been documented in which the patient had positive patch tests to isotretinoin [12]. Reversible melasma is recorded [13], as is facial cellulitis [14]. Scarring, which may be keloidal, may occur after dermabrasion or laser therapy within a year of isotretinoin therapy; such procedures are best postponed during this period [15–17].

Systemic side effects. These include headache, which is not uncommon; anorexia, nausea and vomiting are much more common than with etretinate, as are lethargy, irritability and fatigue [1]. Isotretinoin therapy has been associated with benign intracranial hypertension [2]; in some cases, there was concomitant use of tetracyclines, so this combination should be avoided. A variety of central nervous system reactions have been reported, but may bear no relationship to therapy. The issue of whether isotretinoin may be associated with initiation or exacerbation of depression is a particular matter of controversy [3,4]. Anecdotal reports suggested this possibility; resolution usually, but not always [5], occurs within a few weeks of cessation of therapy. Psychiatric symptoms occurred in seven of 700 patients in one study, with recurrence of depression following rechallenge in some cases [6]. Of 5 million individuals exposed to isotretinoin in the USA between 1982 and 2000, 37 patients committed suicide, 100 were hospitalized for treatment of depression and 284 were managed as outpatients [7]. This incidence of suicide is less than that predicted for a group of comparable age and sex distribution. A large study comparing 7195 patients treated with isotretinoin with 13 700 patients treated with antibiotics, drawn from Canadian and UK databases, concluded that there was no increase in depression or suicide in the isotretinoin-treated group [8]. However, the study has been criticized as flawed with regard to the UK data, because it was provided by general practitioners who were not responsible for prescribing the drug, and there may have been selection bias in the

ascertainment of mental disorders. A recent study of 2821 patients found no evidence to support an association between use of isotretinoin and onset of depression [9]. The field is complicated by the fact that there may be a confounding effect of acne on the development of psychological or psychiatric effects [10,11]. In addition, there is an increased frequency of pretreatment anxiety in patients and their families [7]. Conversely, isotretinoin therapy may lead to an improvement in mental state [10,11].

Patients treated for disorders of keratinization have developed corneal opacities, which improved when the drug was withdrawn [12]. Blepharoconjunctivitis, dry eyes with decreased tolerance of contact lenses and blurred vision due to myopia may occur [13]. Decreased night vision has been documented rarely, as have cataracts and other visual disturbances [13–17]; decreased night vision after isotretinoin therapy may be more permanent than generally suspected [17], and many asymptomatic patients have abnormal electroretinograms [14]. Loss of sense of taste is recorded [18].

Transient chest pain is uncommon. Non-specific urogenital findings and non-specific gastrointestinal symptoms have occurred in approximately 5% of cases. Isotretinoin therapy has been associated with onset of inflammatory bowel disease [19] and with impairment of pulmonary function in patients with systemic sclerosis [20,21].

Approximately 16% of patients develop musculoskeletal symptoms, including arthralgia, of mild to moderate degree; cases of acute knee aseptic arthritis have been documented [22]. High-dose prolonged therapy in a child for epidermolytic hyperkeratosis was associated with premature closure of epiphyses [23]. A high prevalence of skeletal hyperostosis has been noted in patients on prolonged (1 year or more), relatively high-dose (2 mg/kg daily) isotretinoin therapy for disorders of keratinization [24–28]. The syndrome of *d*iffuse *i*diopathic *s*keletal *h*yperostosis (DISH) includes ossification of ligaments and accretion of bone onto vertebral bodies, especially of the cervical spine. Mild osteoporosis has also been seen. X-ray changes have been minimal in prospective studies of patients with cystic acne treated with a single course of isotretinoin at recommended doses [29–31]. Nasal bone osteophytosis has been described with short-term therapy for acne [32].

Mild to moderate elevation of liver enzymes occurs in about 15% of cases; in some patients these return to normal despite continued administration of the drug. A single case of fatty liver developing in a patient (with low to normal levels of α_1-antitrypsin) on low-dose isotretinoin has been reported [33]. Elevated sedimentation rates occur in about 40% of patients. Between 10 and 20% of patients show decreased red blood cell parameters and white blood cell counts, elevated platelet counts and pyuria. Thrombocytopenia may occur [34].

Isotretinoin induces reversible changes in serum lipids in a significant number of treated subjects [35–40]. A dose-related increase in triglycerides occurs in about 25% of individuals according to the Roche data sheet; five of 135 cystic acne patients, and 32 of 298 patients treated for all diagnoses, showed triglyceride levels above 500 mg/dL. In another study, 17% of patients taking isotretinoin for 20 weeks exhibited hypertriglyceridaemia, but in 15% this was of only mild to moderate degree [38]. About 15% showed a mild to moderate decrease in serum high-density lipoprotein levels, and 7% experienced minimal elevations of serum cholesterol during therapy; some patients had increases in LDL cholesterol [38]. Lipid abnormalities peaked within 4 weeks in men, but not until 12 weeks in women. If sustained over a long period, these alterations in lipoproteins might be risk factors for coronary artery disease. Patients with an increased tendency to develop hypertriglyceridaemia include those with diabetes mellitus, obesity, increased alcohol intake or a familial history. Some patients have been able to reverse triglyceride elevation by reduction in weight, restriction of dietary fat and alcohol, and reduction in dose while continuing the drug. An obese male patient with Darier's disease developed elevated triglycerides and subsequent eruptive xanthomas [41].

Major human fetal abnormalities related to isotretinoin therapy during pregnancy have been documented [42–45]. The most frequently reported abnormalities involve the central nervous system (microcephaly or hydrocephalus and cerebellar malformation) and cardiovascular system (anomalies of the great vessels). Microtia or absence of external ears, microphthalmia, facial dysmorphia and thymus gland abnormalities have also been reported. There is an increased risk of spontaneous abortion. Women of child-bearing potential should sign a consent form and be instructed that they should not be pregnant when isotretinoin therapy is started (preferably on the second or third day of the next normal menstrual period) and should use effective contraception during, and for 1 month after stopping, therapy. Isotretinoin has a much shorter half-life than etretinate, so that pregnancy is permissible 1 month after stopping therapy. Analysis of data voluntarily reported to Hoffmann La Roche Inc. in the USA enabled prospective study of 88 patients who had completed or discontinued isotretinoin therapy prior to becoming pregnant; 90% of all pregnancies occurred within 2 months after cessation of therapy, and 64% within 1 month [46]. There were no significant increases in the rates of spontaneous abortion or of congenital malformations among the live births. There appears to be no adverse effect of isotretinoin on male reproductive function [47,48].

Tazarotene

Pyogenic granuloma-like lesions have been associated with the use of this topical retinoid in the treatment of psoriasis [1,2].

Tretinoin

Oral tretinoin administered as differentiation therapy of acute promyelocytic leukaemia was associated with mild rashes, the nature of which was unspecified [3]. An acute neutrophilic dermatosis with a myeloblastic infiltrate occurred in a leukaemic patient receiving all-*trans*-retinoic acid therapy [4].

Vitamin B

Vitamin B_1

Anaphylaxis following intravenous administration has occurred [1].

Vitamin B_6 (pyridoxine)

Vasculitis is recorded [2], as is a pseudoporphyria syndrome with megadosage [3]. A photosensitive eruption [4] and rosacea fulminans are documented [5].

Nicotinic acid

Flushing is common; other transient rashes, urticaria, pruritus, scaling, hyperpigmentation and an acanthosis nigricans-like eruption [6,7] are all documented. Persistent rashes and hair loss have rarely occurred.

Vitamin C (ascorbic acid)

Patients with cutaneous and respiratory allergy have been described.

Vitamin E (α-tocopherol)

White hair developed at injection sites in infants given intramuscular vitamin E for epidermolysis bullosa, probably due to quinones formed during vitamin E degradation [1].

REFERENCE

Vitamin K

Skin reactions with vitamin K have been reviewed [1–11]. Three distinct types of cutaneous reaction are seen: (i) localized eczematous at the injection site (onset 4–16 days, dose range 10–410 mg); (ii) localized morphoea-form (average onset 8.5 months, range 5 weeks to 1.5 years, dose range 30–2080 mg); and (iii) very rarely, a diffuse maculopapular eruption [10,11]. The pruritic, erythematous, macular lesions or plaques may last for up to 6 months, whereas the prognosis for resolution of the morphoea-form changes is very poor. Patch and intradermal skin tests may be positive, suggesting an immunological basis. Most, but not all [3,6,8], cases have occurred in patients with liver disease. In addition, a proportion of these reactions progress to produce scleroderma-like changes [9,12–16]. An annular erythema has been documented [17].

Hormones and related compounds

ACTH and systemic corticosteroids

The side effects of these agents have been reviewed [1–13].

Well-known side effects include acne, cutaneous thinning and atrophy, telangiectasia, striae distensae, purpura and ecchymoses, hypertrichosis, impaired wound healing, pigmentary changes, cushingoid (moon) facies, truncal adiposity [14] and buffalo hump of the upper back. Acne occurred in one of 51 patients treated with intravenous corticosteroids in one study [15]. Other systemic side effects include fluid and electrolyte abnormalities, weight gain, oedema, hypertension, cardiac failure, peptic ulcer disease, pancreatitis, diabetes, muscular weakness, myopathy, tendon rupture, glaucoma, posterior subcapsular cataracts, mental changes including psychosis, osteoporosis, vertebral collapse, necrosis of the femoral head, growth suppression in children, opportunistic infection, masking of infection or reactivation of a dormant infection (e.g. tuberculosis), polycythaemia and suppression of the hypothalamic–pituitary axis. Pulse steroid therapy with systemic methylprednisolone has resulted in sudden death due to anaphylaxis, arrhythmia or ischaemic heart disease, but not particularly in dermatological patients [16].

Adrenocorticotrophic hormone

Allergic reactions to ACTH are recorded but are uncommon. Urticaria and dizziness, nausea and weakness are the most frequent, but severe anaphylactic shock has occurred. Synthetic ACTH is usually tolerated by patients sensitive to animal ACTH [17]. Depot preparations containing tetracosactide (tetracosactrin) adsorbed on a zinc phosphate complex have produced reactions [18] and may induce melanoderma [19].

Systemic corticosteroids

In addition to those listed above, the cutaneous side effects of systemic corticosteroids include allergic and immediate reactions [1,2]. In one study, seven of 25 patients with cutaneous delayed-type hypersensitivity to hydrocortisone had an immediate reaction following intradermal injection of hydrocortisone sodium succinate, and had significantly increased levels of IgG antibodies to hydrocortisone. These patients are at risk of developing type III and possibly type I reactions following systemic hydrocortisone [3].

Protein binding of hydrocortisone or a degradation product may be important in the development of corticosteroid allergy [4]. Urticarial reactions have followed the intra-arterial injection of prednisone, prednisolone, hydrocortisone [5] or methylprednisolone [6], but are rare. Anaphylaxis occurred after intradermal injection of triamcinolone for alopecia areata [7]. Anaphylactoid reactions have been reported to topical and parenteral hydrocortisone, but may represent pseudoallergic reactions rather than IgE-mediated immediate hypersensitivity [8,9].

Generalized skin reactions, including urticaria and maculopapular eruptions, developed in patients after therapy with oral triamcinolone acetonide [10], prednisone [11], or dexamethasone and betamethasone [12]; the patients were subsequently shown to be patch-test positive to these corticosteroids. In another study, five patients reacted with diffuse erythema principally on the trunk or on the face, appearing within a few hours to 24 h and fading in 1–3 days, on treatment with systemic or intralesional hydrocortisone, methylprednisolone, prednisolone or betamethasone [2]. On patch testing, one patient reacted to prednisolone and methylprednisolone and two patients were positive to pivalone. Patients sensitive to hydrocortisone or methylprednisolone reacted to these corticosteroids in intradermal tests. A combination of intradermal and patch tests is recommended when allergy to systemic or intralesional corticosteroids is suspected [2].

Other cases of generalized delayed systemic corticosteroid reactions, including eczematous or exanthematous eruptions and erythroderma, with or without bullae or

purpura, often with positive patch or intradermal testing, have been recorded [13–18]. Systemic administration of hydrocortisone, and provocation of endogenous cortisol secretion by injection of the ACTH analogue tetracosactide, provoked dose-dependent allergic skin reactions at sites of previous allergic reactions to topical steroids in two patients with proven topical corticosteroid sensitivity (i.e. systemic allergic contact-type dermatitis); in one case, this was at a positive patch-test site to hydrocortisone 17-butyrate [19]. Thus, it has been postulated that high stress levels, which cause increased secretion of endogenous adrenocortical hormones, could be implicated in exacerbations of eczema in corticosteroid-sensitive patients, and a persistent autoimmune skin reaction to cortisol might occur following topical sensitization to topical hydrocortisone [19]. The fact that, in steroid-sensitive patients, systemic provocation testing with hydrocortisone results in a reaction confined to the skin may be partly explained by the observation *in vitro* that only enriched Langerhans' cells, and not peripheral blood mononuclear antigen-presenting cells, are capable of presenting corticosteroid to T cells of corticosteroid-sensitive subjects [20].

Perioral dermatitis has been recorded in renal transplant recipients on corticosteroids and immunosuppressive therapy [21]. Panniculitis following short-term high-dose steroid therapy in children manifests as subcutaneous nodules on the cheeks, arms and trunk [22]. Reversible panniculitis occurred in a child treated with steroids for hepatic encephalopathy [23]. Juxta-articular adiposis dolorosa developed in a patient treated with high doses of prednisone for the L-tryptophan-induced eosinophilia myalgia syndrome [24]. Acanthosis nigricans may occur with corticosteroid therapy [25]. Immunosuppression with corticosteroids has been associated with the development of Kaposi's sarcoma during the treatment of temporal arteritis [26].

Inhaled corticosteroids have been associated with purpura and dermal thinning [27] as well as acne [28,29], perioral dermatitis and tongue hypertrophy [30], allergic reactions [31], an eczematous dermatitis [32] and adrenal suppression [29]. Nasal corticosteroids may cause nasal congestion, pruritus, burning and perforation of the septum, urticaria and eczema of the face [33]. Intralesional corticosteroid injection may also lead to allergic reactions [34], including a disseminated morbilliform and persistent urticarial dermatitis following intra-articular triamcinolone acetonide [35], erythroderma following intradermal budesonide [36] and erythema multiforme after intradural injection of prednisolone acetate [37]. Facial flushing and/or generalized erythema has followed epidural steroid injection [38]. Anaphylactic shock has been recorded after intra-articular injections of corticosteroids containing carboxymethylcellulose, benzylic acid, polysorbate 80 and merthiolate; skin tests to carboxymethylcellulose were positive [39].

Topical corticosteroids

The dermatological complications of topical corticosteroids have been reviewed [1–4]. Concerns have been expressed about the illegal availability of potent topical steroids in the UK, and their consequent unregulated use [5]. Many of the adverse reactions are related to the potency of the preparation; thus, in general, fluorinated steroids are associated with more significant side effects. Topical steroids cause decreased epidermal kinetic activity [6], decreased synthesis of dermal collagen types I and III and ground substance, and thinning of the dermis and epidermis [7–11]. Initial vasoconstriction of the superficial small vessels is followed by rebound vasodilatation, which becomes permanent in later stages. There are resultant striae, easy bruising, purpura, hypertrichosis and telangiectasia; stellate pseudoscars or ulcerated areas may be seen. Reversible hypopigmentation may develop. Local injection of a potent steroid may result in atrophy with telangiectasia, and localized lipoatrophy may occur. Perilymphatic atrophy is recorded following intradermal steroid injection. Long-term daily use of a potent steroid, especially under plastic occlusion as for fingertip eczema, may result in acroatrophy of terminal phalanges of the fingers [12,13].

Topical steroids may exacerbate acne, or lead to acne rosacea, with papules, pustules and telangiectasia, or perioral dermatitis, characterized by erythema, papules and pustules at the perioral area [14–16]. They decrease the number and antigen-presenting capacity of epidermal Langerhans' cells [17], and mask or potentiate skin infections, including fungal (tinea incognito) and bacterial infections and verruca vulgaris. Their withdrawal may provoke conversion of plaque- to pustular-type psoriasis [18]. Topical steroid therapy around the eye has been associated with development of glaucoma.

Topical corticosteroids may induce allergic contact dermatitis [19–25]. The prevalence of positive patch tests to corticosteroids in contact dermatitis clinics ranges from 2 to 5% [19,20]. The allergen may be the steroid itself, or a preservative or stabilizer such as ethylenediamine. There may be cross-reactivity between different steroids [21–23]. Cross-reactivity is more likely between steroids with similar substitutions at C-6 and C-9 positions. Intradermal tests may be a more sensitive means of detecting corticosteroid hypersensitivity than patch testing [24].

Systemic side effects of topical corticosteroids occur particularly from the use of large amounts of high-potency topical corticosteroids, especially under plastic occlusion [26,27]. Oedema due to sodium retention occurs more frequently with halogenated corticosteroids [27]. Hypothalamic–pituitary axis suppression may occur [28,29]; a single application of 25 g of 0.05% clobetasol propionate ointment suppressed plasma cortisol for 96 h [30]. Cushing's syndrome [31,32] may result, and growth retardation in children is a hazard [33]. Glycosuria and hyperglycaemia may rarely occur [34].

Sex hormones

Gonadotrophins

These drugs may cause allergic reactions [1]. Menotrophin (Pergonal) has been associated with localized keratosis follicularis (Darier's disease) [2]. Intracutaneous administration of two human menopausal gonadotrophin preparations (Organon and Pergonal) caused local induration and erythema [3].

Gonadorelin analogues

Buserelin. A pigmented roseola-like eruption has been documented [1].

Leuprorelin. This drug, given for precocious puberty, has caused anaphylaxis [2], rashes [3] and local reactions [4].

Oestrogens and related compounds

Oestrogens. Spider naevi and melanocytic naevi may develop under oestrogen therapy, as may chloasma. Severe premenstrual exacerbation of papulovesicular eruptions, urticaria, eczema or generalized pruritus occurred in seven women; several had a positive delayed tuberculin-type skin test to oestrogen [1]. Patients with generalized chronic urticaria had an urticarial reaction to intradermal oestrogens. Elimination of oral oestrogen therapy or anti-oestrogen therapy with tamoxifen proved effective. In another patient, a premenstrual urticarial reaction was exacerbated by oestrogen; oophorectomy cured the eruption [2]. A bullous autoimmune oestrogen dermatitis has been delineated [3].

Diethylstilbestrol therapy of pregnant women has been associated with female and male genital tract abnormalities in the offspring. Diethylstilbestrol is a transplacental carcinogen and has caused adenocarcinoma of the vagina 20 years later in young women whose mothers took the drug in the first 18 weeks of pregnancy [4–6]. Acanthosis nigricans has resulted from use of diethylstilbestrol [7]. Hyperkeratosis of the nipples developed in a man treated for adenocarcinoma of the prostate with diethylstilbestrol [8]. Porphyria cutanea tarda may also be precipitated [9,10].

Oral contraceptives. Cutaneous complications of oral contraceptives have been reviewed [1–4]. These drugs combine an oestrogen with a progestogen. Candidiasis is common; the sexual partner may suffer penile irritation after coitus without physical signs or frank candidal balanoposthitis. Genital warts may increase. Facial hyperpigmentation (chloasma) is well recognized [5,6], as are hirsutism and acne. Gingival epithelial melanosis has been recorded [7]. Alopecia related to contraceptive therapy may be of either androgenic or postpartum telogen pattern following withdrawal of the drug. Erythema nodosum is a well-recognized but rare complication [8,9].

The relapse of herpes gestationis is well documented [10]. Rare lichenoid, eczematous and fixed eruptions have been described, as have a lymphocytic cutaneous vasculitis and an eruption resembling Sweet's syndrome [11]. Oral contraceptives have been implicated in both the provocation [12] and induction of remission of pityriasis lichenoides. An SLE-like reaction has also been reported [13]. An oral contraceptive-induced LE-like eruption, with erythematous lesions on the palms and feet in association with a weakly positive antinuclear factor and C1q deposition at the dermal–epidermal junction on direct immunofluorescence, developed in a patient. It resolved on cessation of medication [14].

The jaundice rarely induced by these drugs resembles cholestatic jaundice of pregnancy. The hepatotoxic effects may result in provocation of variegate porphyria, porphyria cutanea tarda [15,16] and hereditary coproporphyria [17]; onycholysis may occur [16]. Photosensitivity unrelated to porphyrin disturbances has also been reported [18,19]. Benign hepatomas may also be a hazard [20].

Other hormonal contraceptives. Keloid formation has followed levonorgestrel implantion [21]. Vaginal erythematous areas were associated with use of a levonorgestrel-releasing contraceptive ring in 48 of 139 subjects [22]. Rosacea has been associated with a progesterone-releasing intrauterine contraceptive device [23].

Hormone replacement therapy. Melasma of the arms is recorded [24–26].

Anti-oestrogens

Clomifene (clomiphene). Hot flushes [1] and recurrent petechiae and palpable purpura of the legs with neutrophilic infiltration in a woman treated for infertility with multiple courses of clomifene [2] have been reported.

REFERENCES

Progesterone and progestogens

Autoimmune progesterone dermatitis. A number of eruptions, including urticaria, eczema, pompholyx, erythema annulare centrifugum and erythema multiforme, have been reported to recur cyclically in the second (luteal) phase of the menstrual cycle, with the period immediately before menstruation peaking in severity [1–8]. Oral and perineal lesions may occur. It has been proposed that they result from sensitization to endogenous progesterone. There is frequently, but not always, a history of prior exposure to synthetic progesterones [1,3]. Confirmation is with a positive intradermal test with progesterone, preferably in an aqueous or aqueous alcohol solution, and/or existence of circulating antibody to progesterone, and by suppression of symptoms with agents that inhibit ovulation and result in decreased serum progesterone [7]. Two patients with recurrent premenstrual erythema multiforme and autoreactivity to 17α-hydroxyprogesterone have been described [5,6]; in one case, the eruption spread in pregnancy, cleared after abortion and was associated with a high-affinity binding factor to 17α-hydroxyprogesterone in the serum [6]. In another case with recurrent erythema multiforme, cured by oophorectomy, progesterone sensitivity was confirmed by challenge with medroxyprogesterone acetate [9].

Medroxyprogesterone acetate. A pigmented purpura [10] and skin necrosis following intramuscular Depo-Provera [11] are recorded.

Megestrol. A generalized morbilliform rash developed in a cachectic man treated with this synthetic orally active progesterone derivative to stimulate appetite and weight gain; skin testing with progesterone acetate was positive [12].

Androgens

Anabolic steroids. Exacerbation of acne vulgaris with development of acne conglobata has been reported [1]. Both the size of sebaceous glands and the rate of sebum secretion are increased [2,3]. A lichenoid eruption was reported in a patient with aplastic anaemia treated with nandrolone furylpropionate (Cemelon) [4].

Danazol. This 17-ethinyltestosterone derivative, which is an inhibitor of pituitary gonadotrophin, is a very weak androgen. Of 530 recipients of danazol, 29% reported at least one adverse event within 45 days after receiving the drug, but there were no known long-term sequelae [5]. Acne, hirsutism, seborrhoea, rash and generalized alopecia are documented [6–8]. Exacerbation of LE-like eruptions has been reported in patients receiving this drug for non-C1-esterase inhibitor-dependent angio-oedema [9] or for hereditary angio-oedema [10].

Gestrinone. This derivative of 19-nortestosterone, like danazol, may cause weight gain, hirsutism, acne, voice change or irregular menstrual bleeding [11].

Testosterone. Severe acne or acne fulminans has followed therapy with testosterone, with [2,12] or without [13] anabolic steroids.

Yohimbine. Yohimbine is an indole alkaloid obtained from the yohimbe tree in West Africa and is used in the treatment of male impotence. A case of generalized erythrodermic skin eruption, progressive renal failure and LE-like syndrome is recorded [14].

Insulin

Adverse reactions to insulin [1–5] used to be relatively common, with bovine insulin having the most potential for production of allergic reactions, followed by porcine and human insulin. Insulin allergy and other local cutaneous reactions are rarely seen with highly purified and biosynthetic preparations [3,4], although local symptoms still occur in approximately 5% of patients [3]. Lipoatrophy, which was reported in 10–55% of patients treated with non-purified bovine/porcine insulin preparations, has almost disappeared since the advent of exclusive human insulin treatment. Allergic symptoms to human insulin are found in less than 1% of *de novo*-treated patients, but still occur when human insulin is used in the insulin-allergic patient [3]. Anaphylaxis may occur with recombinant human insulin [6]. Local allergic reactions are often of immediate hypersensitivity type; they are more common in the first few months, and usually subside with continued therapy. Generalized pruritus and urticaria occur rarely. Typically, more severe anaphylactoid reactions follow reintroduction of insulin in patients who have previously received long-term therapy. Delayed reactions may also occur, and take the form of pruritic erythema and induration, sometimes with papulation, within 24 h of injection [7]. Biphasic responses may be seen in the same individual, with initial immediate urticaria and a delayed reaction after 4–6 h. Allergy may develop to the insulin itself (i.e. bovine or porcine protein), to preservatives such as parabens and zinc [8,9] or to protamine (Surfen) present in depot preparations [10–13]. Sterile furunculoid lesions at injection sites, which heal with scars and which have a granulomatous histology, may result. Lipoatrophy at injection sites, or more rarely distally, occurred especially with longer-acting preparations; affected patients had lesional immunoglobulin deposits and circulating anti-insulin antibodies [14]. Exceptionally, hypertrophic lipodystrophy [15], or hyperkeratotic verrucous plaques at the site of repeated injections [16], may develop.

Thyroxine

Chronic urticaria and angio-oedema was reported in a patient, associated with exogenous thyrotoxicosis, related to thyroid replacement therapy [1].

REFERENCE

1 Pandya AG, Beaudoing DL. Chronic urticaria associated with exogenous thyroid use. *Arch Dermatol* 1990; **126**: 1238–9.

Antithyroid drugs

Thiouracils

Hypersensitivity reactions include drug fever, pruritus,

urticaria, angio-oedema, exanthems, acneiform rashes, depigmentation of hair and LE-like syndromes. Propylthiouracil has caused allergic vasculitis [1–3], and methylthiouracil has resulted in erythema multiforme. Thiouracils may cause excessive hair loss. These drugs may cause marrow failure [4].

Chemotherapeutic (cytotoxic) agents

General side effects

There have been a number of excellent reviews of the dermatological complications of these compounds [1–10], including histopathological reactions [11,12]. Bone marrow depression, with aplastic anaemia, agranulocytosis or thrombocytopenia, and gastrointestinal intolerance may occur with any of these drugs. Mucocutaneous surfaces are especially vulnerable to the toxic effects of this group of drugs on rapidly dividing cells. Common side effects therefore include alopecia (see p. 73.46) and stomatitis [13]. Cytotoxic drugs may cause alopecia by either anagen or telogen effluvium. Severe alopecia of anagen type within 2 weeks of administration of the drug is frequently seen with cyclophosphamide, doxorubicin and the nitrosoureas; it is usually reversible with cessation of therapy. Other chemotherapeutic agents implicated in the production of alopecia include amsacrine, bleomycin, cyclophosphamide, cytarabine, dactinomycin, daunorubicin, etoposide, fluorouracil and methotrexate. Stomatitis occurs most frequently with acridinyl anisidide, dactinomycin, daunorubicin, doxorubicin, fluorouracil and methotrexate; it may respond to reduced dosage. Similarly, a number of drugs may cause pigmentation of the buccal mucosa [14] or of the nails [15–17]. Onycholysis may be induced [18].

Hypersensitivity or allergic reactions such as urticaria and angio-oedema [19,20] occur with all cancer chemotherapeutic agents except altretamine, the nitrosoureas and dactinomycin. With L-asparaginase and mitomycin (administered intravesically) they occur in about 10% of patients, and are relatively frequent with cisplatin; they are very rare with methotrexate. Type I reactions are commonest, but all four types of reactions are represented.

Many of these agents have distinctive cutaneous side effects, ranging from localized or diffuse hyperpigmentation to less usual ones, including radiation enhancement and recall phenomena, photosensitivity and hypersensitivity reactions, and phlebitis or chemical cellulitis. Confluent erythematous and hyperpigmented patches, with focal basal layer vacuolar degeneration, occurred within flexural areas during the first month after autologous peripheral stem cell transplantation [21]. Photosensitivity reactions occur with dacarbazine, fluorouracil, mitomycin and vinblastine. Radiation recall effects involve reactivation of an inflammatory response in areas irradiated months or years previously. Clinically, these range from erythema to vesiculation, with erosions and subsequent hyperpigmentation. They have most often been reported in association with dactinomycin and doxorubicin therapy [22] but also with edatrexate [23] and gemcitabine [24]; melphalan, etoposide, vinblastine, bleomycin, fluorouracil, hydroxyurea and methotrexate may also cause radiation enhancement. UV recall is recorded with mitomycin and the combination of etoposide and cyclophosphamide [25]. Rare complications such as diffuse sclerosis of the hands and feet, Raynaud's phenomenon [26], sterile folliculitis and flushing reactions may also occur. Multiple drug regimens may pose special problems in trying to elucidate the cause of a specific reaction, such as white-banded nails [27] or multiple Beau's lines [28]. A pityriasis lichenoides-like eruption occurred during therapy for myelogenous leukaemia with vincristine and mercaptopurine, antibiotics and aciclovir [29]. Fingertip necrosis occurred during chemotherapy with bleomycin, vincristine and methotrexate for HIV-related Kaposi's sarcoma [30].

Most cytotoxic drugs are teratogenic and are contraindicated during pregnancy, especially during the first trimester. Alkylating drugs usually cause sterility in males, and may shorten reproductive life in women.

Extravasation

Extravasation, leading to skin necrosis with ulceration, occurs with several agents [1–5]. Phlebitis and chemical cellulitis have been recorded with most antimitotic agents. Residual drug should be aspirated and the limb elevated; plastic surgical advice should be sought as soon as possible. High dermal concentrations of doxorubicin have been documented as late as 28 days after accidental extravasation [6]. Histological examination of doxorubicin-related extravasation lesions demonstrated exaggerated interface-type dermatitis with thrombosis of venous tributaries [7].

Acral erythema

Several cytotoxic drugs (especially cytosine arabinoside, fluorouracil, docetaxel and doxorubicin, and rarely cyclophosphamide, hydroxyurea, mercaptopurine, methotrexate and mitotane) can cause dose-dependent acral erythema, often preceded by paraesthesiae, either alone or in combination [1–17]. Bulla formation, desquamation and subsequent re-epithelialization may occur. Reactions may occur sooner (from 24 h to 3 weeks) and more severely with bolus or short-term chemotherapy than with low-dose continuous infusion, and are usually reproducible on challenge. Intravenous ciclosporin, given in bone marrow transplant patients, reportedly worsens the pain of acral erythema [12]. The condition should be distinguished from graft-versus-host disease in patients who receive chemotherapy followed by bone marrow transplantation, and from chemotherapy-induced Raynaud's phenomenon. This may not be easy, as histological changes may suggest graft-versus-host disease [18].

Neutrophilic eccrine hidradenitis

Neutrophilic eccrine hidradenitis may represent a reaction pattern to a variety of chemotherapeutic agents [1–8], but particularly cytarabine and bleomycin. It has been induced by granulocyte–macrophage colony stimulating factor [9]. Clinically, erythematous papules or plaques or nodules are most frequent, although hyperpigmented plaques, pustules, purpura and urticaria have been described. Lesions resolve spontaneously over several days. The histology is characterized by infiltration of eccrine coils with neutrophils and necrosis of the secretory epithelium. The condition has also been described in a patient receiving haemodialysis without chemotherapy [10] and in a patient without a malignancy who was taking paracetamol [11].

Syringosquamous metaplasia

A related but distinct entity termed 'syringosquamous metaplasia', which may be confused with well-differentiated squamous cell carcinoma histologically, has been described in patients receiving chemotherapy for leukaemia and other cancers [1–3]. Clinically, this may appear as an erythematous, blanching, papular crusted eruption, or as erythematous oedematous plaques or confluent erythematous macular areas, in the axillae or groins, with painful erythema and oedema on the palms and soles [4].

Side effects related to immunosuppression

The cutaneous manifestations of immunosuppression have been reviewed [1–4]. Immunosuppressive therapy, such as azathioprine and prednisone for renal transplant patients, may encourage skin infections of various types, for example warts, herpes simplex and herpes zoster [5], pityriasis versicolor and fungal infections [6]. Development of disseminated superficial actinic porokeratosis [7–9], porokeratosis of Mibelli [10–13] and increased numbers of benign [14,15] or eruptive dysplastic [16] melanocytic naevi may be promoted. Eruptive keratoacanthomas occurred in a patient with SLE on prednisolone and cyclophosphamide [17].

Internal malignancy

The frequency of internal cancers common in the general population is not increased in transplant patients. However, that of a variety of otherwise uncommon malignancies is increased [1–3], including non-Hodgkin's lymphoma (mostly B-cell, with 14% of T-cell, and less than 1% of null-cell, origin), which accounts for 21% of cancers in transplant recipients; Kaposi's sarcoma; other sarcomas; carcinoma of the vulva and perineum; carcinoma of the kidney; and hepatobiliary tumours. Non-Hodgkin's lymphoma appears commoner and develops earlier where potent immunosuppressive agents such as ciclosporin and/or the monoclonal antibody OKT3 have been used; however, although cancer develops in 6% of all transplant recipients, only 1% of patients die from this complication [3]. Leukaemia may develop following chemotherapy [4], and bladder cancer has been associated with cyclophosphamide therapy [5].

Skin cancers

Actinic keratoses, squamous cell and basal cell cancer of the lip and skin [6–12], and malignant melanoma [13] have been reported to be more common, especially in immunosuppressed renal transplant patients. The majority of these patients have received azathioprine and corticosteroids. Interestingly, the immunosuppressed renal transplant recipients have been reported to be at high risk for skin cancer unless they express the HLA class I allele A11 [14]. Furthermore, patients with long-standing renal grafts mismatched for HLA-B have a significantly higher incidence of squamous cell cancers than other mismatches, and patients who are homozygous for HLA-DR are at increased risk for actinic keratoses and skin cancer [15]. These findings imply that MHC gene products participate in the pathogenesis of skin cancer in immunosuppressed patients, probably via influences on T-cell recognition of neoantigens [16]. There was no difference from control levels in the number of $CD1^+$ $HLA\text{-}DR^+$ antigen-presenting Langerhans' cells in the epidermis of immunosuppressed renal transplant recipients treated with either azathioprine/prednisone or ciclosporin/prednisone [17].

Alkylating agents

These drugs interfere with cell replication by damaging DNA. Gametogenesis is often severely affected, and their use is associated with a marked increase in non-lymphocytic leukaemia, especially when used in conjunction with radiotherapy.

Alkyl sulphonates

Busulfan. Reactions are rare, but have included urticaria, bullous erythema multiforme [1], Addisonian-like pigmentation [2,3] due to increased epidermal and dermal melanin, and drug-induced porphyria cutanea tarda [4]. Vasculitis has been reported. Keratinocyte nuclear abnormalities with abundant pale cytoplasm have been described [5]. Progressive pulmonary fibrosis may occur.

Nitrogen mustard derivatives

Chlorambucil. Morbilliform rashes occur; urticarial plaques and periorbital oedema have been described rarely [1–4]. A delayed allergic reaction on the third cycle of chemotherapy, with generalized erythroderma with exfoliation and oedema of the face and arms, as well as immune haemolytic anaemia and TEN, have been described [5]. Alopecia is uncommon. Sterility with azoospermia and amenorrhoea is documented.

Cyclophosphamide and mesna. Alopecia is common and occurs in 5–30% of cases [1]. Pigmentation, which may be widespread or localized to the palms, soles or nails, is well documented and usually reversible [2,3]. Nail dystrophy may be seen. Allergic exanthems are rare, but anaphylactic and urticarial reactions less so [4–7]. Type I hypersensitivity with a markedly delayed onset (from 8 to 16 h up to 10 days), associated with immediate skin-test results to cyclophosphamide metabolites but not the parent drug, has been documented [7]. There may be cross-sensitivity to other alkylating agents, especially mechlorethamine and chlorambucil [8]. Sterility may supervene.

Haemorrhagic cystitis, the result of toxicity of the metabolite acrolein, is a complication in up to 40% of cases if cyclophosphamide is used alone. Introduction of the thiol compound mesna (2-mercaptoethane sulphonate) has virtually eliminated this complication. There have been recent reports of urticaria, angio-oedema, allergic maculopapular pruritic rashes, generalized fixed drug eruption, and occasional more severe reactions with flushing, widespread erythema and ulceration or blistering of mucous membranes related to mesna; patch tests may be positive [9–13].

Lomustine. Flushing has been reported.

Mechlorethamine. Angio-oedema and pruritus have been recorded [1]; however, in view of the large number of patients receiving this drug as part of the MOPP (mechlorethamine, Oncovin (vincristine), procarbazine, prednisone) regimen for lymphoma, these side effects must be exceedingly rare. Topical mechlorethamine [2] used to treat psoriasis or mycosis fungoides may cause hyperpigmentation of involved and uninvolved skin [3], contact sensitization [4,5] and rarely immediate-type hypersensitivity with urticaria or anaphylactoid reactions [6].

Melphalan. Trivial morbilliform rashes are relatively common [1]. Severe anaphylactic reactions may occur after intravenous use, especially in patients with IgA κ myeloma

[2]. Urticaria or angio-oedema after oral use is very rare [3]. Vasculitis has been documented, and melanonychia striata has been recorded [4]. Scleroderma has supervened after isolated limb perfusion [5]. Radiation recall is uncommon [6]. Sterility with azoospermia and amenorrhoea are recorded.

Ethylenemine derivatives

Thiotepa (triethylenethiophosphoramide)

Intravesical installation caused pruritus, urticaria or angio-oedema in five of 164 patients with bladder carcinoma [1]. Intravenous administration resulted in patterned hyperpigmentation confined to skin occluded by adhesive bandages or electrocardiograph pads, probably due to secretion of the drug in sweat [2]. In contrast, topical thiotepa has produced periorbital leukoderma [3].

Nitrosoureas

Carmustine

Topical carmustine (BCNU) used for the treatment of cutaneous T-cell lymphoma may result in erythema, skin tenderness and telangiectasia. Contact sensitization may develop [1]. Mild bone marrow suppression has been recorded.

REFERENCE

1 Zackheim HS, Epstein EH Jr, Crain WR. Topical carmustine (BCNU) for cutaneous T cell lymphoma: a 15-year experience in 143 patients. *J Am Acad Dermatol* 1990; **22**: 802–10.

Dacarbazine (DTIC)

Photosensitivity [1,2] and a fixed eruption-like rash [3] have been reported. A patient with malignant melanoma treated with DTIC developed sudden hepatic vein thrombosis (Budd–Chiari syndrome) following intravenous administration [4]. Increasing blood eosinophilia appears to be a sign of the imminent development of this complication. Chemical cellulitis occurs following extravasation.

Procarbazine

Type I reactions are rare; recurrent angio-oedema, urticaria and arthralgia with decreased serum complement have been reported [1,2]. Hypersensitivity to procarbazine in patients treated with mechlorethamine, vincristine and procarbazine (MOP) for high-grade glioma manifested as a maculopapular rash, fever, reversible abnormal liver function and interstitial pneumonitis [3].

Cytotoxic antibiotics

Bleomycin

The principal problem of systemic therapy is progressive pulmonary fibrosis. Alopecia, glossitis and buccal ulceration occur, and drug fever is common, usually 1–4 h after injection. Distinctive, localized, erythematous, tender macules, nodules or infiltrated plaques on the hands, elbows, knees and buttocks have been documented [1–3]. Their causation is uncertain, and the rash may resolve despite continued therapy [4]. Raynaud's phenomenon with or without ischaemic ulcerations, and systemic sclerosis-like changes in men, have been described [5–7]. Capillary microscopy has been advocated for the invest-

Fig. 73.8 Flagellate pigmentation caused by bleomycin. (Courtesy of Dr A. Ilchyshyn, Coventry and Warwickshire Hospital, Coventry, UK.)

igation of bleomycin acral vascular toxicity [8]. In normal human skin, intradermal bleomycin induced a localized time- and dose-dependent inflammatory reaction and persistent post-inflammatory hyperpigmentation; histology showed neutrophilic eccrine hidradenitis, with keratinocyte necrosis, HLA-DR and ICAM-1 expression, and endothelial cell ICAM-1 up-regulation and E-selectin induction [9]. Intralesional bleomycin therapy for warts induced keratinocyte apoptosis and complete epidermal necrosis with diffuse neutrophil accumulation and microabscess formation at the granular layer [10]. Clinically, intralesional therapy may cause persistent Raynaud's phenomenon [11,12] and loss of nails [13].

Cutaneous erythema or hyperpigmentation, which may be diffuse [14], patchy or linear, and prominent over pressure areas, especially the elbows or in striae distensae [15], is seen in approximately 30% of patients [16]. 'Flagellate' streaked erythema or pigmentation [17–24] on the trunk and proximal extremities is common (Fig. 73.8); it recurs in previously involved sites, and develops in new sites, within 24 h of rechallenge [21]. It has been proposed that trauma from scratching induces localized vasodilatation, with increased concentration of cutaneous bleomycin; hyperpigmentation has been documented in a patient treated with bleomycin where a heating pad had been applied [25]. There may be darkening of the nail cuticle and palmar creases.

Dactinomycin (actinomycin D)

A papulopustular acneiform sterile folliculitis, spreading from the face to the trunk and buttocks, and which may mimic septic cutaneous emboli, is common [1]. Dactinomycin-related lesions with the histology of an

interface dermatitis with syringometaplasia developed in the axillae, groins and central line exit site of two children [2]. Radiation recall occurs [3]. Persistent serpentine supravenous hyperpigmentation was recorded in combination dactinomycin and vincristine therapy [4].

Doxorubicin (Adriamycin)

Short-lived localized erythema or urticaria with pruritus along the vein proximal to the injection site may occur in up to 3% of patients [1]. Angio-oedema, generalized urticaria with or without anaphylaxis and chronic urticaria have been reported rarely [2]. Cutaneous and nail pigmentation are well recognized [3,4]. Erythema and desquamation of palmar and plantar skin, with or without onycholysis, occurs frequently in patients receiving doxorubicin [5–7]. Liposomal doxorubicin is associated with a dose-limiting hand–foot syndrome and stomatitis [8,9] and with psoriasiform pustular reactions [10]. Allergic cross-reaction occurs with daunorubicin. Toxic epidermal injury after intra-arterial injection [11], phlebitis and chemical cellulitis with extensive tissue necrosis and ulceration following extravasation [12] are well documented.

Mitomycin

Urticaria and dermatitis [1–3], particularly on the face, palms and soles, or genitals and sometimes more generalized, have been reported after intravesical therapy. Sunlight-induced recall of ulceration following extravasation has been recorded [4].

Antimetabolites

Aminoglutethimide

This inhibitor of adrenal steroid synthesis has been reported to induce SLE [1].

REFERENCE

1 McCraken M, Benson EA, Hickling P. Systemic lupus erythematosus induced by aminoglutethimide. *BMJ* 1980; **281**: 1254.

Azathioprine

The dermatological aspects of this derivative of the antimetabolite mercaptopurine have been reviewed [1–3]. Bone marrow suppression is the main problem; blood counts should be performed weekly for the first month, then

monthly thereafter. Homozygotes for the low-activity allele for thiopurine methyltransferase are at risk of myelosuppression [4–7]. It is therefore recommended that thiopurine methyltransferase levels should be measured before commencing patients on azathioprine [6]. Gastrointestinal upset is common and may necessitate discontinuation of therapy. Hypersensitivity reactions [8–10], including fever [11], maculopapular rashes, urticaria, vasculitis, erythema multiforme or erythema nodosum, cholestatic jaundice, hepatitis, liver necrosis, interstitial pneumonitis, polyneuropathy, pancreatitis, shock [12] with hypotension, nephritis and oliguria are well recognized.

An acneiform exanthem has been described, confirmed on challenge [13]. An eruption comprising tiny superficial blisters and peeling in the flexures is described [14]. Multiple large resistant warts are common on the hands of renal transplant recipients maintained on long-term azathioprine and prednisolone therapy; herpes simplex and herpes zoster infection may occur [15], and Norwegian scabies may be promoted [16]. Disseminated superficial actinic porokeratosis [17] and porokeratosis of Mibelli [18] have been documented. Keratoacanthomas and squamous cell carcinomas may develop [19]. Long-term therapy may predispose to the development of malignancy, especially non-Hodgkin's lymphoma [20]. Azathioprine crosses the placenta, although there is little evidence that azathioprine is teratogenic in humans, and detailed analysis of successful pregnancies notified to the European Dialysis and Transplant Association did not suggest an excessive rate of congenital abnormality [21]. However, depressed fetal haemopoiesis and resultant neonatal thrombocytopenia and leukopenia have been documented [22]. Pregnancy may be best avoided in patients receiving this drug [23]. Allopurinol may potentiate the effect of azathioprine by inhibiting its metabolism; the dose of azathioprine should therefore be reduced to one-quarter of the regular dose.

Cytarabine (cytosine arabinoside)

This drug interferes with pyrimidine synthesis. A self-limited palmoplantar erythema, occasionally with bullae, may occur [1–4]. Neutrophilic eccrine hidradenitis has been reported [5]. A syndrome with fever, malaise, arthralgia, conjunctivitis and diffuse erythematous maculopapular rash is documented [6]. The overall incidence of cutaneous reactions, including morbilliform eruptions, acral erythema, swelling and generalized urticaria, was almost 53% in one series [7].

Fluorouracil

Anaphylaxis is rare; alopecia and recall phenomena [1] may be seen. Erythema followed by hyperpigmentation of sun-exposed areas occurs in up to 5% of patients [2]. Photosensitivity is recorded; pellagra may be caused by direct inhibition of the transformation of tryptophan into nicotinamide. Rarely, hyperpigmented streaks (serpentine supravenous hyperpigmentation) develop over arm veins used for injection [2–5]. Continuous infusion may be followed by the development of erythema, oedema and desquamation of the hands [6–10]. Pyridoxine may decrease the intensity and pain of fluorouracil-induced acral erythema [8]. Oral administration resulted in painful erythema multiforme-like erosions and blisters on the soles and arms in one case [9]. Systemic fluorouracil may result in marked inflammation of metastatic skin lesions [11] and of solar keratoses [12]. Topical application may lead to hyperpigmentation with or without a preceding irritant or allergic contact dermatitis [13].

Capecitabine

Capecitabine is a fluoropyrimidine carbamate that is metabolized to fluorouracil, and has been recorded as causing hand–foot syndrome in 50% of patients, and rarely leopard-like vitiligo, onycholysis and periungual pyogenic granulomas [14].

Gemcitabine

This drug has caused radiation recall [15].

Methotrexate

Dermatological aspects. These have been reviewed [1–3]. Methotrexate is a folic acid analogue and antagonist that inactivates dihydrofolate reductase. There is marked individual variation in absorption from the gastrointestinal tract, and hence in expression of toxic effects. Alopecia occurs in 6% of patients receiving low-dose therapy for psoriasis and in 8% of patients on high-dose regimens for malignancy, and is usually the result of telogen effluvium. Intermittent high dosage has resulted in horizontal pigmented banding of hair (the 'flag sign' of chemotherapy) [4]. Urticaria develops in about 4% of patients on low-dose oral or parenteral therapy for psoriasis [5]. Exacerbation of urticarial vasculitis has been documented [6]. Photosensitivity occurs in up to 5% of cases. Methotrexate use has been associated with severe reactivation of sunburn [7,8]; in one case, there was sparing of chronically sun-exposed skin [8]. Chronic viral wart and molluscum infections may result from immunosuppression. Cutaneous toxicity with local epidermal necrosis may occasionally occur [9,10]. A macular erythema occurring in 15% of patients, and biopsy-proven capillaritis, have been reported with high-dose therapy [3]. An eruption of erythematous indurated papules on the proximal parts of the limbs has been documented in patients with collagen vascular disease [11]. Anaphylactic reactions [12] and pain, burning, erythema and desquamation of the palms and soles [13–15] are seen with high-dose intravenous methotrexate, but are extremely rare. Vasculitis has been very rarely documented with both intermediate dosage therapy for leukaemia [16] and high-dose therapy [17]. TEN is recorded [18,19], and occurred after a single injection of 25 mg for pustular psoriasis [19].

Systemic complications. Because folic acid is an essential co-factor for DNA synthesis and cell division, bone marrow suppression may occur even on low-dose therapy [1–4]. Thrombocytopenia may develop after a single test dose [5]. Severe bone marrow suppression [6] with the dosage used in the therapy of psoriasis is fortunately not common. Stomatitis may be a warning sign of overdosage. The risk of myelosuppression is much greater in the presence of renal impairment. Gastrointestinal upset is common. Abnormalities of taste sensation occur rarely [7].

The main hazard is hepatotoxicity with long-term use [8]. The risk of developing severe hepatotoxicity is related to the daily dose, the dose frequency and the cumulative dose [9]. Alcohol consumption, underlying liver disease and obesity, especially in the presence of diabetes, are aggravating factors. Recommendations have included obtaining baseline haematological, renal and hepatic function tests and a liver biopsy before or within 4 months of starting therapy, and repeating after every 1.5 g [10]. Liver function tests may be unreliable indicators of fibrosis or cirrhosis. These guidelines appear prudent but have never been rigorously tested, and are variously applied in clinical practice [10,11]. There seems to be a discrepancy between the degree of hepatotoxicity in rheumatoid arthritis and that in psoriasis, and many rheumatologists do not routinely carry out liver biopsy [11]. The requirement for liver biopsies in psoriasis patients on long-term, low-dose, once-weekly oral methotrexate has been questioned [12]. Radionuclide liver scans are thought to be of little value in the detection of methotrexate-induced liver disease, but liver ultrasound may be of some assistance [13]. Abnormal liver biopsy may improve after cessation of therapy [14]. Assay of serum levels of the aminopropeptide of type III procollagen is being used in some centres to screen for patients in whom liver biopsy is mandatory [15–17].

Acute renal failure may follow high-dose methotrexate therapy, although renal damage is rare in patients treated for psoriasis. Pulmonary complications, such as pneumonitis or fibrosis, are rare [18,19]. There do not appear to be adverse effects on humoral or cellular immunity from low weekly doses as given for rheumatoid arthritis or psoriasis [20].

Methotrexate is a known teratogen, and may cause oligospermia [21,22]. It is recommended that patients avoid pregnancy or impregnation during, and for 12 weeks after cessation of, methotrexate therapy [23].

Care must be taken with regard to potential drug interactions with methotrexate [24,25]. Drugs that also interfere with folate metabolism, such as trimethoprim–sulfamethoxazole [26–28], may cause pancytopenia; both trimethoprim and sulfamethoxazole bind to dihydrofolate reductase. Drugs that displace methotrexate from plasma protein-binding sites, such as salicylates, sulphonamides and diphenylhydantoin, as well as drugs that impair the renal clearance of methotrexate, such as NSAIDs and sulphonamides, may also cause pancytopenia. A toxic reaction occurred in a patient treated with penicillin and furosemide [29].

Vinca alkaloids and etoposide

These drugs cause metaphase arrest by interfering with microtubule assembly.

Etoposide (VP-16)

This semi-synthetic podophyllotoxin derivative causes bone marrow suppression, alopecia and gastrointestinal symptoms. It has caused Stevens–Johnson syndrome and radiation recall. Four cases of a diffuse, erythematous, maculopapular rash occurring 5–9 days after initiation of therapy, with spontaneous resolution within 3 weeks, have been reported [1]. On histology, scattered, markedly enlarged individual keratinocytes with a 'starburst' nuclear chromatin pattern were seen. Hypersensitivity reactions are generally held to be rare [2–4], but 51% of patients with newly diagnosed Hodgkin's disease had one or more acute hypersensitivity reactions to etoposide administration, including flushing, respiratory problems, changes in blood pressure and abdominal pain [5].

Vincristine

Peripheral neuropathy is well recognized with long-term therapy [6].

Vinblastine

Photosensitivity is common [7]. Acute alopecia and radiation recall are documented. Erythema multiforme-like reactions are described following intravenous injection [8].

Enzymes

L-Asparaginase (crisantaspase)

Dose-dependent IgE-mediated hypersensitivity reactions, including urticaria and anaphylaxis, are frequent, especially when the drug is used alone [1]. Allergic reactions to intramuscular L-asparaginase include local painful erythema, and urticaria or a general exanthem; continuous infusion is better tolerated [2].

Miscellaneous chemotherapeutic agents

Acridinyl anisidide (AMSA)

Skin reactions are rare but widespread erythema has been reported [1].

REFERENCE

Bromodeoxyuridine

A distinctive eruption comprising linear supravenous papules and erythroderma has been described with bromodeoxyuridine given in combination with radiotherapy for central nervous system tumours [1]. Ipsilateral facial dermatitis with epilation of eyebrows and eyelashes, ocular irritation, bilateral nail dystrophy, oral ulceration, exanthem or erythema multiforme have also been described [2].

Carboplatin

Hypersensitivity reactions occur in 1–30% of patients [1–5]; acute allergic reactions include urticaria, bronchospasm, hypotension, facial erythema and facial swelling. Desensitization can be successful [5]. A pruritic maculopapular rash occurred in 10 of 40 patients treated with carboplatin, etoposide and ifosfamide plus mesna followed by autologous stem cell reinfusion; the rash was distributed at the extremities or was confluent on the trunk and face, with facial oedema and painful swelling of hands and feet, and resolved spontaneously with hyperpigmentation in all patients [6].

Cisplatin

Periungual hyperpigmentation [1] and acral erythema [2] or digital necrosis [3] have been documented. Severe hypersensitivity reactions, including flushing, erythema, maculopapular eruptions, urticaria and anaphylaxis, occur in about 5% of cases when this drug is used as a single agent, and in up to 20% when given with other chemotherapeutic agents [4,5]. Cross-reactivity with carboplatin may occur [5]. Atopic subjects are especially at risk. Local reactions follow extravasation [6]. Severe allergic exfoliative dermatitis with ischaemia and necrosis of the hands developed in a patient who had received multiple doses of cisplatin [7].

Hydroxycarbamide (hydroxyurea)

Dermatological aspects of this drug have been reviewed [1–6]. Impaired renal function has been reported in some, but not all, studies [3]. A modest fall in haemoglobin and development of macrocytosis is almost constant.

Stomatitis occurs especially with high-dose therapy and has been accompanied by soreness, violet erythema, and oedema of the palms and soles with subsequent intense universal hyperpigmentation [7], but alopecia is rare. Morbilliform erythema occurs, and hyperpigmentation, generalized or localized to pressure areas, was recorded in up to 5% of cases [2]. A more recent survey reported mucocutaneous adverse reactions after a mean duration of 6.4 weeks of treatment in up to 65% of patients, with pigmentation of nails, skin or mucosa seen in 58.6% [6]. Other less common findings were xerosis, diffuse alopecia, oedema of the legs, oral ulcers and actinic psoriasis; scleral pigmentation and acquired ichthyosis were also noted. Nail pigmentation changes [8], such as multiple pigmented nail bands [9], or onycholysis with nail dystrophy occurs. Fixed drug eruption has been reported [3], as has baboon syndrome [10]. Dermatomyositis-like acral erythema, scaling, and atrophy especially on the dorsum of the hands, with lesser involvement of the feet [1,4,11–14], and palmar and plantar keratoderma have been rarely described with long-term therapy for chronic myeloid leukaemia. Photosensitivity is documented, and LE [15] and vasculitis have been reported. An ulcerative lichen planus-like dermatitis has been recorded [16]. Lichenoid eruptions similar to graft-versus-host disease are documented [17,18]. Several reports have recorded an association with leg ulcers [12,13,19–23]. Accelerated development of skin malignancies occurs, and eruptive squamous and basal cell cancers on light-exposed areas may be seen [24]. Radiation recall occurs [25].

Imatinib

This protein tyrosine kinase inhibitor, used in the therapy of chronic myeloid leukaemia, has caused oedema, pruritus, and exanthematous, psoriasiform and exfoliative dermatoses [1].

REFERENCE

Suramin

Suramin sodium, a polysulphonated naphthylurea used in the treatment of metastatic prostatic and other cancers, has caused generalized, erythematous, maculopapular eruptions within the first 24 h of therapy (which were self-limited despite continued drug infusion), keratoacanthoma and disseminated superficial actinic porokeratosis [1–3]. Distinctive findings include scaling erythematous papules (suramin keratoses) and a predilection for previously sun-exposed areas (UV recall). Severe cutaneous reactions occur in 10% of cases [3]. Histopathological findings have included hyperkeratosis, parakeratosis, spongiosis, acanthosis, exocytosis, apoptosis, a perivascular

lymphohistiocytic infiltrate, upper dermal oedema and increased dermal mucin [3]. Erythema multiforme [4] and TEN [5,6] are recorded.

Taxanes

Docetaxel. Docetaxel, a semi-synthetic analogue of paclitaxel from the needles of the European yew *Taxus baccata* and used in the treatment of advanced and/or metastatic cancer, caused neutropenia, skin reactions (81%) and nail changes (41%), neurosensory toxicity (59%), fluid retention with oedema and hypersensitivity reactions (16–55%) [1–3]. The commonest skin reaction is characterized by discrete erythematous to violaceous patches or oedematous plaques similar to acral erythema [4]. Nail changes recorded [5,6] include horizontal banding [7], dyschromia [8] and subungual abscess [9]. Squamous syringometaplasia [10] and supravenous discoloration of the skin are documented [11].

Paclitaxel. Paclitaxel, a diterpenoid taxane derivative found in the bark and needles of the western yew *Taxus brevifolia*, interrupts mitosis by promoting and stabilizing microtubule formation, and shows substantial activity against advanced refractory cancer. Neutropenia is the major dose-limiting toxic effect; other adverse effects include severe hypersensitivity reactions including anaphylaxis, cardiac toxicity, neurotoxicity, arthralgia or myalgia, mucositis, nausea and vomiting, and alopecia [1–6]. Local necrosis has followed accidental subcutaneous extravasation of paclitaxel [7], and administration via a central vein has produced a recall reaction at a site of prior extravasation [8]. Bullous fixed drug eruption is recorded [9], as is a scleroderma-like reaction [10,11]. Desensitization is possible [12].

Drugs affecting the immune response

Ciclosporin

Ciclosporin is a ligand for the immunophilin, cyclophilin A, and is thought to block early events in T-cell gene activation by interfering with the intracellular translocation of a substance known as nuclear factor of activated T cells [1,2]. It selectively inhibits antigen-induced activation of, and IL-2 production by, $CD4^+$ helper T lymphocytes, thereby blocking T-cell proliferation [3,4]. It inhibits transcription of genes encoding for IL-2 and IFN-γ [5], and blocks expression of IL-2 receptors. Ciclosporin also inhibits Langerhans' cell antigen-presenting function [6–8] and suppresses ICAM-1 expression by papillary endothelium in inflamed skin, thus reducing T-cell recruitment [9]. Much of the information on side effects was derived from patients who underwent organ transplants, and in diseases such as rheumatoid arthritis [10]. The drug is now used by dermatologists [11–18] especially in the management of difficult psoriasis [13–16], refractory atopic eczema [17] and a number of other conditions [16].

Dermatological complications. Hypertrichosis develops in a high proportion of patients; it affects especially the face and eyebrows, the upper back along the spinal column and the lateral upper arms [18–23]. The hypertrichosis is reversible, and children and adolescents seem to be at greater risk of developing this complication [23]. Other cutaneous complications include gingival hyperplasia [21,24], angio-oedema [25] and hyperplastic pseudofolliculitis barbae [26]. Acne keloidalis is recorded [27]. Anaphylaxis may occur in response to intravenous ciclosporin [11], probably due to the solvent. A mild capillary leak syndrome has resulted in purpuric lesions in the flexures and at pressure points [28], and cutaneous vasculitis is recorded [29].

There have been isolated reports of the development of benign lymphocytic infiltrates in patients with psoriasis or alopecia areata [30,31], of pseudolymphoma after therapy of actinic reticuloid [32] and of an aggressive T-cell lymphoma after ciclosporin therapy for Sézary syndrome [33]. Squamous cell skin cancer may develop [34,35] and could potentially be predisposed to by previous PUVA [36]. A study showed no difference in the incidence of cutaneous malignancy in renal allograft recipients treated with either ciclosporin or azathioprine [34]. Kaposi's sarcoma may occur; a renal transplant patient treated with ciclosporin and methylprednisolone developed a Kaposi's sarcoma, which completely regressed on reducing the dosage of both drugs [37]. There have been isolated reports of development of malignant melanoma in ciclosporin-treated patients, but the incidence of this complication does not seem to be increased above the risk in the general population [38,39].

Systemic side effects. Headache and rarely seizures [40], gastrointestinal and musculoskeletal symptoms are well recognized. There is an increased risk of nephrotoxicity [41,42], which appears to be caused by arteriolar vasoconstriction due to local thromboxane A_2 release [43], and consequent hypertension [44]. Impaired renal function may develop after short- as well as long-term treatment for psoriasis [45]. Both renal dysfunction and hypertension are reversible, and lymphoma development unlikely, in patients on short-term low-dose (less than 5 mg/kg) therapy. Adverse effects on renal function and systolic blood pressure appear greater in psoriasis patients receiving higher doses [15]. Some degree of renal impairment is inevitable with longer term therapy [46]. Rarely, a serious capillary leak syndrome occurs, with marked fluid retention and periorbital oedema, and may be fatal; there may be associated gastrointestinal bleeding, pneumonitis, uraemia and urinary sodium loss followed by hypertension and convulsions [21].

Hepatotoxicity is a complication [47] and hypercholesterolaemia is recorded [48]. Ciclosporin may be associated with myopathy without rhabdomyolysis or with rhabdomyolysis; the latter occurs in the setting of concomitant lovastatin or colchicine therapy [49]. Lymphoma and other cancers have developed on high dosage as used for organ grafting [19,50]. Transplant patients treated with ciclosporin have not been shown to have a higher incidence of neoplasms than those receiving other immunosuppressive agents.

Successful pregnancies have occurred in patients receiving ciclosporin for psoriasis [51,52]. There is no evidence of a teratogenic effect in humans, based on the experience of 107 transplant recipients [53].

Interactions of ciclosporin and other drugs have been reviewed [54]. Ciclosporin blood levels may be increased by concomitant therapy with erythromycin or ketoconazole, as a result of inhibition of the hepatic microsomal cytochrome P-450 enzyme system [55], as well as with danazol, oral contraceptives and calcium channel antagonists. Decreased blood levels may be caused by drugs that induce hepatic enzymes, including phenytoin, phenobar-

bital and tuberculostatic therapy with rifampicin and isoniazid. Aminoglycoside antibiotics, melphalan, amphotericin and trimethoprim (alone or in combination with sulfamethoxazole) interact with ciclosporin by altering renal function. Patients should avoid grapefruit juice taken within 1 h of oral ciclosporin as it contains a psoralen that inhibits the CYP 3A subfamily of cytochrome P-450 and reduces metabolism of ciclosporin [56].

PUVA therapy

See Chapter 35.

Immunotherapy

Sera

Animal immune sera can produce any type of early or late hypersensitivity reactions, from urticaria, asthma or fatal anaphylaxis to serum sickness. Clinical manifestations of serum sickness include fever, arthritis, nephritis, neuritis, myocarditis, uveitis, oedema and an urticarial or papular rash. A characteristic serpiginous, erythematous and purpuric eruption developed on the hands and feet, at the borders of palmar and plantar skin, in patients treated with equine antithymocyte globulin [1,2]. Low serum C4 and C3 levels, elevated plasma C3a anaphylatoxin levels, and circulating immune complexes were found. Immunoreactants, including IgM, C3, IgE and IgA, were deposited in the walls of dermal blood vessels on direct immunofluorescence [1,2]. Patients with autoimmune disease may have a particular liability to react to antilymphocyte globulin.

Intravenous immunoglobulin

Angio-oedema-like hypersensitivity eruptions and eczematous, purpuric, petechial/purpuric, lichenoid and vasculitic reactions are recorded [3].

Vaccines

Overall the incidence of significant side effects is very low. Egg, gelatin, antibiotics and preservatives in vaccines may cause reactions [1]. Needle gauge and length may affect the incidence of local reactions [2]. In Canada during 1990, from more than 12 million doses of vaccines there were 2832 reports of adverse events associated with immunizing agents received by the Childhood Immunization Division of the Laboratory Centre for Disease Control [3]. Only 39 of 43 618 Alaskan natives who received 101 360 doses of hepatitis B plasma-derived vaccine developed side effects, including myalgia/arthralgia lasting longer than 3 days, rashes (eight patients) and dizziness [4]. Influenza vaccination in the elderly is, however, reported to cause no more systemic side effects than placebo [5]. In contrast, another study found local reactions in 17.5% of patients, including swelling, itching and pain [6]. Leukocytoclastic vasculitis has been reported with influenza vaccination [7]. Measles and measles–mumps–rubella vaccine, hepatitis B vaccine, and diphtheria and tetanus toxoids have been statistically associated with anaphylaxis [8], and measles–mumps–rubella vaccine with thrombocytopenia and purpura [8,9] and Gianotti–Crosti syndrome [10]. A variety of reactions have been documented following hepatitis B vaccination [11], including urticaria/angio-oedema [12], erythema multiforme [13], erythema nodosum [14], polyarteritis nodosa and pityriasis rosea [15], and lichenoid eruptions [16,17].

Local reactions include erythema, swelling and tenderness, which may result from an Arthus reaction [18–20]. Keloid scarring may develop. Local inflammatory reactions, fever, lymphadenopathy, urticaria and lichenoid rashes have been observed following vaccination in patients sensitive to the preservative merthiolate; patch testing and intradermal testing may be positive [21,22]. Inflammatory nodular reactions may occur as a result of aluminium sensitization, as with hepatitis B, diphtheria and tetanus vaccination [23,24]; patch testing to aluminium may be positive [23]. Itching, eczema and circumscribed hypertrichosis developed over nodules following immunization with vaccines adsorbed on aluminium hydroxide in three children [24]. Transient subcutaneous nodule formation at the injection site, and increased regional adenopathy, have been rarely noted in patients with HIV infection treated with gpl60 vaccination [25].

Urticaria, angio-oedema or anaphylaxis may occur in patients allergic to egg protein who are vaccinated with live measles vaccine. However, in a series of children with egg allergy and a positive skin-prick test to egg white, 0.98% developed a mild reaction not requiring therapy

following immunization with a full dose of vaccine [26]. Of 98 patients with a history of previous inoculations with human diploid cell rabies vaccine, 3% developed generalized urticaria or wheezing within 1 day, and a further 3% developed urticaria 6–14 days, after booster vaccination [27]. Urticaria and systemic symptoms including malaise and fever, or Stevens–Johnson syndrome may follow tetanus toxoid vaccination [28,29]. Vaccination may result in development of an autoimmune state; dermatomyositis has been provoked. Fatalities have rarely occurred following vaccination as a result of anaphylaxis [30,31]. Vaccination against Japanese encephalitis caused serious adverse reactions, including urticaria, angio-oedema, hypotension and collapse [32]. An association with vaccination for influenza and with tetanus toxoid and induction of bullous pemphigoid has been noted rarely [33–35].

Hyposensitization immunotherapy

Hyposensitization immunotherapy is a standard treatment for recalcitrant hay fever and bee or wasp stings in many countries in the world, including the USA, Scandinavia and the continent of Europe [1]. However, in the UK, allergen-injection immunotherapy for IgE-mediated diseases has been largely discontinued, following the recommendations of the Committee on Safety of Medicines in 1986 [2], because of concern about deaths related to bronchospasm and anaphylaxis. The Committee recommended that immunotherapy be given only where full facilities for cardiopulmonary resuscitation are available and that patients be kept under medical observation for at least 2 h. The necessity for the latter recommendation has been questioned, as serious reactions occur within minutes [1]. The British Society for Allergy and Clinical Immunology Working Party concluded that specific allergen immunotherapy for summer hay fever uncontrolled by conventional medication and for wasp and bee venom hypersensitivity has an acceptible risk/benefit ratio, provided that treatment is given by experienced practitioners in a clinic where full resuscitative facilities are immediately available; a symptom-free observation period of 60 min after injection is sufficient [3,4]. Patients with asthma should be excluded, however, in view of an increased frequency of reactions [4,5]. Fatalities from allergen immunotherapy are extremely rare [6]. In one series, β-blocker drugs did not increase the frequency of systemic reactions in patients receiving

allergen immunotherapy, but patients developed more severe systemic reactions that were more refractory to therapy [7].

In contrast, local urticarial reactions are common [1]. Desensitization injections for hay fever have resulted in occasional tender nodules lasting for several months or years [8,9]; these are thought to develop as a result of allergy to aluminium, as it is present in the lesions and patch tests may be positive [9,10]. Inflammatory nodules at injection sites, first developing several years later, have also been described [11]. Injections of mixtures of grass pollens, cereal pollens and dust-mite allergens have resulted in multiple cutaneous B-cell pseudolymphomas [12]. Polyarteritis nodosa [13], vasculitis [14,15] and serum sickness [16,17] have been described following hyposensitization therapy for allergy to pollen, house-dust mite and wasp venom. Cold urticaria developed during the course of hyposensitization to wasp venom [18].

BCG vaccination

Vaccination with BCG causes a benign self-limiting lesion consisting of a small papule, pustule or ulcer, which heals to leave a small scar within weeks. Axillary lymphadenitis and abscesses occurred after vaccination of rural Haitian children [1], and disseminated BCG infection in children born to HIV-1-infected women [2]. Occasionally, local abscess formation may follow vaccination of strongly tuberculin-positive individuals, administration of too much vaccine, or injection of vaccine too deeply [3–5]. BCG abscesses may also rarely arise following needlestick injury in health-care professionals [6]. In Austria, where the Ministry of Health's recommendation is for all neonates to be vaccinated, the normal complication rate is 0.3–0.6%, with suppurative lymphadenitis, generalized lymphadenopathy and osteitis [7]. Following a change to a more virulent vaccine strain, this rate temporarily increased substantially, with 5% of 659 children vaccinated at the University Hospital, Innsbruck requiring surgical excision of suppurating lymph nodes [7]. Anaphylactoid reactions to BCG vaccine, probably as a result of immune complex reactions mediated by antibodies to dextran in the vaccine, have been reported [8]. A papulonecrotic type of vasculitis has been documented [9]. Dermatomyositis may occasionally be a complication [10].

BCG immunotherapy for malignant melanoma [11] has been associated with local ulceration [11,12], local recurrent erysipelas, keloid formation, influenza-like symptoms, lymphadenopathy, urticaria and angio-oedema, granulomatous hepatitis, arthritis [13] and reactivation of pulmonary tuberculosis. Widespread miliary granulomas were present in a patient with fatal disseminated infection following intralesional immunotherapy of cutaneous malignant melanoma [14].

Cytokines

Cytokines are being increasingly used in the management of neoplastic and haematological disorders and AIDS, and in addition are starting to be used for the therapy of specific dermatological disorders; side effects have been reviewed [1]. Reactions range from minor injection-site reactions, pruritus and flushing to life-threatening autoimmune disorders, severe erythroderma or bullous skin reactions [2].

Colony-stimulating factors

Recombinant haematopoietic colony-stimulating factors used in the treatment of haematological disorders are usually well tolerated, but may induce itching and erythema or lichenoid reactions [1] at the site of injection, thrombophlebitis with intravenous infusion, facial flushing and a transient maculopapular eruption, fever, chills, myalgias, arthralgia and bone pain, transient leukopenia, decreased appetite, nausea and mild elevation of transaminase levels [2]. Neutrophilic dermatoses have been recorded in children [3]. Two types of recombinant human granulocyte colony-stimulating factor are in use for neutropenia: one is a glycosylated natural product from mammalian cells, and the other a non-glycosylated form from *Escherichia coli*. A drug eruption may occur with either type without detectable antibodies; intradermal tests may be useful and there may not be cross-reactivity [4]. Both local reactions at the site of injection and diffuse maculopapular eruptions may be seen [4–7]. Local pustular reactions [8] or subcorneal pustular dermatosis [9] are documented. Intravenous recombinant granulocyte–macrophage colony-stimulating factor (GM-CSF) therapy for leukaemia resulted in a widespread confluent maculopapular eruption in three patients, associated with a dermal lymphocyte, macrophage and granulocyte infiltration, exocytosis, and keratinocyte ICAM-1 expression [10]. Of 23 patients with advanced malignancy treated with GM-CSF, nine had a cutaneous eruption characterized by local erythema and pruritus at the injection site, recall erythema at previous injection sites or a generalized maculopapular rash [11]. Other studies have reported widespread rashes [12,13], in one series manifested as annular erythematous papules and plaques on the extremities, becoming generalized and clearing with fine desquamation [13]. Recurrent exacerbation of acne [14], widespread folliculitis [15], toxic folliculitis [16] and a Sweet's syndrome-like rash [17–19] have been recorded. A capillary leak syndrome with pleural and pericardial effusions, ascites and large-vessel thrombosis has been noted only with high-dose GM-CSF therapy [20]. Necrotizing vasculitis developed at GM-CSF injection sites in one patient with white cell aplasia, but not in over 150 other neutropenic patients who received the drug [21]. However, vasculitis was reported in a large series [22]. Thrombotic and necrotizing panniculitis has been documented [23]. Psoriasis [24], and arthritis in Felty's syndrome with rheumatoid arthritis [25], have been reported to deteriorate.

Interferon

Cutaneous reactions to recombinant IFN [1–12] given to patients with chronic hepatitis C, cancer or AIDS are frequent (5–10%) but usually of moderate degree. No adverse cutaneous side effects resulted from intralesional injection of IFN-γ in 10 patients treated for keloid scarring [13]. Most patients experience influenza-like symptoms following systemic therapy; reversible leukopenia and thrombocytopenia are recorded with higher dosage. Local reactions consist of erythema, eczema, epilation, or induration at injection sites or urticaria. More serious reactions include vesiculobullous reactions, vasculitis, necrosis, ulceration, alopecia and exacerbation of psoriasis. Skin ulceration or necrosis may be a serious problem with both IFN-α and IFN-β [7–12]. Raynaud's phenomenon and digital necrosis induced by IFN-α is recorded [14].

Of 63 patients treated with IFN-γ for prophylaxis of infection in chronic granulomatous disease, one had a severe cutaneous reaction (unspecified), and rashes or injection-site erythema or tenderness occurred in 17% and 14% of cases respectively [1]. Diffuse inflammatory lesions have occurred with IFN-α and ribavirin therapy for hepatitis C [15]. Transient, localized or disseminated oedematous, erythematous and/or papular changes, vesicles or petechiae were seen in six patients during intravenous IFN-α for chronic active hepatitis C, 5–14 days after starting therapy [2]. Eruptions disappeared in 10–14 days despite continuation of IFN-α; histology revealed upper dermal perivascular $CD4^+$ lymphoid infiltration and oedema, with endothelial cell but not keratinocyte ICAM-1 and E-selectin expression, suggesting a non-allergic mechanism.

Capillaritis is recorded with IFN-α [16], as is lichen planus [3,17]. Reactivation of oral herpes simplex and enhanced radiation toxicity have been recorded. IFN-α-2a for the treatment of cutaneous T-cell lymphoma has induced temporary alopecia [18]. In contrast, IFN-α therapy has caused increased eyelash and eyebrow growth [19], as well as straight hair [20]. Severe urticaria has been documented with IFN-α-1a [21] and mucinoses with IFN-α-1b [22]. Both IFN-α and IFN-α-1b have been associated with granulomatous or sarcoidal reactions [23–25]. IFN-α has caused hypertriglyceridaemia [26] and IFN-β has been related to squamous cell cancer following ulceration [27].

IFN-α used in the treatment of disseminated carcinoma [28,29] or intralesionally for viral warts [30], and IFN-β therapy for multiple sclerosis [11,31], have been reported to exacerbate or trigger onset of psoriasis; psoriatic arthritis has also been triggered by IFN-α [32] and IFN-γ [33], and Reiter's syndrome by IFN-α [34]. Psoriasis appeared at the site of subcutaneous injection of recombinant IFN-γ in patients with psoriatic arthritis [35], and at the site of intralesional injection in a patient receiving recombinant IFN-β for a basal cell carcinoma [36]. Exacerbation of underlying autoimmune disease is documented with IFN-α [37]. Neutralizing antibodies to recombinant IFN-α may be produced [38]. Systemic sclerosis has been associated with IFN-α [39]. Systemic LE has been recorded following IFN therapy of myelogenous leukaemia [40], and pemphigus vulgaris after IFN-β and IL-2 therapy for lymphoma [41].

Interleukins

IL-1. Mucositis and an erythematous eruption with erosions in intertriginous areas and under occlusive tape have been documented [1].

IL-2. Immunotherapy with IL-2, either alone or in conjunction with lymphokine-activated killer cells, is used in the treatment of metastatic cancer; mild influenza-like symptoms are common. Cutaneous complications [2–8] include mucositis, macular erythema (principally restricted to the head, neck and upper chest), burning and pruritus (which resolves with mild desquamation), erythroderma and petechiae. Transient urticaria, necrotic lesions and blisters may be seen [8]. Type I hypersensitivity reactions, ranging from pruritus, erythema and oedema to hypotension, within hours of chemotherapy in patients previously treated with high-dose IL-2 have occurred [9]. A generalized capillary leak syndrome, with non-pitting oedema and diffuse pulmonary infiltrate on chest X-ray, is recorded [6] and is also documented with denileukin difitox, formed from the fusion of human IL-2 with diphtheria toxin [10]. Exacerbation of psoriasis (including erythroderma) has been described [2–6]. IL-2 treatment predisposes to acute hypersensitivity reactions to iodine-containing contrast media [6]. Glossitis, telogen effluvium, punctate superficial ulcers and erosions in scars may be seen. Erythema nodosum has been documented [11]. Local inflammatory painful nodules with a central multiloculated vesicle have occurred at the site of subcutaneous injections of IL-2 and IFN-α [12]. Linear IgA bullous dermatosis has been associated with IL-2 therapy [13]. TEN is a rare complication [14]. It is of interest that lymphocytes activated by IL-2 can non-specifically destroy keratinocytes *in vitro* [15].

Other side effects include hypothyroidism (antithyroid antibodies are present in 50% of patients), neurological and psychiatric disturbances, musculoskeletal disorders, impaired renal function, cardiovascular injuries, cholestasis, pancreatitis, anaemia, thrombocytopenia, lymphocytopenia and eosinophilia [6].

IL-3. Erythema and purpura at the site of injection, and urticaria [16] may be induced.

IL-4. Transient acantholytic dermatosis is recorded [17].

IL-6. Coalescent, erythematous, scaling macules and papules occurred [18].

Stem cell factor

Human recombinant stem cell factor, a cytokine that acts on haematopoietic progenitor cells and which is used for human anaemic disorders and for speeding haematological recovery after chemotherapy, causes reversible hyperpigmentation at sites of injection; there are increases in melanocyte numbers, dendrite extension and melanin [1].

REFERENCE

Tumour necrosis factor

Subcutaneous or intramuscular administration of TNF for advanced malignancy is limited by local pain, erythema and swelling or frank ulceration, and intravenous infusion may cause hypotension [1].

REFERENCE

Inhibitors of tumour necrosis factor

Etanercept. This fusion protein, comprising the extracellular ligand-binding domain of the 75-kDa receptor for TNF-α and the constant domain of human IgG1, has been associated with injection-site reactions [1–3], follicular hyperkeratosis at distant sites and necrotic and purpuric reactions [3], urticaria [4], autoimmune rashes [5], leukocytoclastic vasculitis [6] and onset of cutaneous squamous cell cancer [7].

Infliximab. Various dermatological complications are recorded, including an atopic dermatitis-like rash [8], eczematid-like purpura [9], erythema multiforme and lichenoid reactions [10], and necrotizing fasciitis and sepsis [11].

Monoclonal antibodies

Basiliximab. This IL-2 receptor monoclonal antibody has caused myalgia [1].

Cetuximab. Paronychia and aphthous ulcers [2,3], follicular papulopustules [4], and a facial acneiform follicular eruption [3] are recorded with this chimeric antiepidermal growth factor receptor antibody.

OKT3. Orthoclone OKT3, a murine monoclonal antibody directed against the CD3 subset of T lymphocytes, has been used as an immunosuppressive agent in renal transplant recipients, and has been anecdotally associated with anaphylaxis [5].

Rituximab. This murine–human chimeric antibody (IDEC-C2B8) has caused vasculitis and serum sickness [6,7].

Miscellaneous drugs affecting the immune response

Diphencyprone

Diphencyprone [1] used for alopecia areata has resulted in urticaria [2,3] and erythema multiforme [4], and has been linked to the development of vitiligo [5–7]. Severe contact dermatitis reactions may be induced.

REFERENCES

Erythropoietin

This drug has caused a generalized eczematous reaction [1].

REFERENCE

1 Hardwick N, King CM. Generalized eczematous reaction to erythropoietin. *Contact Dermatitis* 1993; **28**: 123.

Roquinimex

The incidence of graft-versus-host reactions is enhanced in patients treated with the cytokine inducer carboxamide–quinoline immunotherapeutic agent roquinimex (Linomide), used for post-transplantation immunotherapy in autologous bone marrow transplantation for acute and chronic myelogenous leukaemia [1,2]. Cutaneous graft-versus-host reactions were associated with eccrine sweat gland necrosis.

Antihistamines

H_1 antihistamines

All traditional H_1 antagonists cause side effects [1–4], especially sedation, most marked with the aminoalkylether and phenothiazine groups. Dizziness, poor coordination, blurred vision and diplopia, as well as nervousness, insomnia and tremor may occur. In addition, atropine-like anticholinergic effects including dryness of mucous membranes, urinary retention, palpitations, agitation, increased intraocular pressure and gastrointestinal upset are seen. Phenothiazine-derived drugs may cause photosensitivity or cholestatic jaundice. The effects of nervous system depressants, such as alcohol, hypnotics, sedatives, analgesics and anxiolytics, may be potentiated. Decreased efficacy of drugs metabolized by the liver microsomal enzyme system, including oral anticoagulants, phenytoin and griseofulvin, may occur as a result of liver-enzyme induction by antihistamines. The newer antihistamines (e.g. terfenadine, astemizole, loratadine, cetirizine) are much less likely to cause sedation [1–4].

Terfenadine and astemizole rarely cause QT interval prolongation and torsade de pointes. Arrhythmias occur when metabolism of terfenadine is impaired, as with inhibition of the cytochrome P-450 isoform CYP 3A4 by ketoconazole, itraconazole and related imidazole antifungals, erythromycin, clarithromycin and related macrolide antibiotics, grapefruit juice, or liver disease [5–7]. Patients on terfenadine or astemizole should be instructed accordingly. The UK Committee on Safety of Medicines

withdrew terfenadine from over-the-counter sale, as did the US FDA. However, no increased risk of life-threatening ventricular arrhythmic events or cardiac arrest with terfenadine compared with over-the-counter antihistamines, ibuprofen or clemastine was found in one study [8].

True hypersensitivity reactions are rare. Fixed eruptions have been caused by thonzylamine and cyclizine [9], cetirizine [10], hydroxyzine [11] and loratadine [12]. Skin eruptions have been documented with terfenadine [13,14], including possible exacerbation of psoriasis [15]; alopecia has been reported rarely [16]. Cetirizine has been linked to maculopapular eruptions and precipitation of urticaria [17–20]. Lichenoid and subacute LE-like dermatoses are recorded with antihistamine therapy [21]. Hydroxyzine caused a systemic contact dermatitis in one case [22]. A pityriasis lichenoides et varioliformis acuta-like drug exanthem was reportedly caused by astemizole, with a positive challenge test [23]. Antihistamines are associated with atypical lymphoid hyperplasia, presenting as solitary or multiple nodules and plaques, or multiple papules, in some patients [24].

H_2 antihistamines

Severe adverse reactions are rare with cimetidine, ranitidine, nizatidine and famotidine [1]. Gastrointestinal upset, headache, drowsiness, fatigue or muscular pain occur in fewer than 3% of patients. Confusion, dizziness, somnolence, gynaecomastia or galactorrhoea with increased prolactin levels (cimetidine and ranitidine only), impotence and loss of libido (with cimetidine), bone marrow depression, hepatitis, abnormal renal function or nephritis, arthralgia, myalgia, cardiac abnormalities, and minor or severe skin reactions occur in fewer than 1% of patients.

Cimetidine. Mucocutaneous reactions are rare in relation to the enormous worldwide use of this drug. Reported reactions include a seborrhoeic dermatitis-like rash [2] and asteatotic dermatitis [3], erythema annulare centrifugum [4], erythrosis [5], giant urticaria [6], transitory alopecia [7], erythema multiforme [8] and exfoliative dermatitis [9]. Other effects have included thrombocytopenia [10] and leukocytoclastic vasculitis [11]. Exacerbation of cutaneous LE [12] and SLE with granulocytopenia [13] are documented. Cimetidine binds to androgen receptors, thereby blocking the binding of dihydrotestosterone, and gynaecomastia and hypogonadism are now well-known side effects [14]. The drug augments cell-mediated immunity *in vitro* by blockade of H_2 receptors on T lymphocytes [15].

Ranitidine. Urticaria [1] and anaphylaxis [2] are recorded, as are allergic dermatitis and allergic contact dermatitis [3,4]. Immune complex-mediated rashes [5], lichenoid eruptions [6] and photosensitivity with UVA sensitivity on monochromator light testing [7] have been documented, as has cholestatic hepatitis [8]. This drug has a less marked effect on androgen receptors than cimetidine, but gynaecomastia has occurred [9].

Injections, infusions and procedures

Radiographic contrast media and radiopharmaceuticals

Radiographic contrast media

Reactions to radiographic contrast media were previously reported to occur in about 4–8% of cases; severe reactions occurred in 1 in 1000 administrations, and occasionally fatal anaphylactoid reactions developed (1 in 3000 for intravenous cholangiograms and between 1 in 10 000 and 1 in 100 000 for intravenous urography) [1–3]. Although IgE-mediated mechanisms may be involved [4], the vast majority of contrast reactions are not due to iodine allergy but rather to non-immunological release of mast cell mediators or to direct complement activation [5,6]. The risk of severe reactions is increased in atopics, asthmatics, those taking β-blockers, and with higher doses of contrast media; up to 40% of patients with a previous reaction may develop a recurrence [7,8].

Newer low-osmolality radiocontrast media are associated with fewer reactions [8–14], for example administration of iohexol in 50 660 patients undergoing excretory urography resulted in a frequency of adverse reactions of any type of 2.1% [9]. In another series, there was a 7.0% incidence of mild adverse reactions to low-osmolar iodine contrast medium in 4550 radiological procedures including computed tomography (CT), intravenous urography, arteriography, venography and myelography [12]. There were only two cases of severe anaphylactoid reactions during 783 consecutive cases undergoing voiding cystourethrography or retrograde pyelography [14]. The incidence of contrast media complications in the catheterization laboratory is 0.23%, with one death per 55 000 [15].

Low-osmolality radiocontrast media (e.g. iohexol or iopamidol) should be the contrast media of choice for patients with a prior immediate generalized reaction to conventional contrast media; in addition, patients should receive H_1 antihistamines and corticosteroid prophylaxis therapy [8,13,15]. However, although in one study the relative risk for all adverse drug reactions was three to

six times higher for ionic vs. non-ionic contrast media [16], in another study mortality was not lower with the newer low-osmolar media than with the older high-osmolar media [17]. In this latter large study, the overall mortality was 13 per million intravenous injections of radiocontrast media, rising to 35 per million in those over 65 years of age [17]. A further study in the USA found that in a clinical trial comparing the safety of low- vs. high-osmolality radiologic contrast media in patients who underwent either cardiac angiography or contrast-enhanced body CT, 19% of 1004 patients had at least one adverse reaction [18]. The mean cost per patient of treating adverse reactions was $459 (range $0–39 057).

In addition to immediate reactions, widespread erythema and oedema at 6 h, reaching a maximum at 9–12 h, followed intravenous injection of a CT contrast medium (iotrolan) [19]. Fixed drug eruptions have been recorded with iopamidol and iomeprol [20,21]. Mild to moderate delayed allergy-like reactions to contrast media of the maculopapular exanthematous and urticarial/angio-oedematous types have been reported in 0.5–2% of recipients [22]. Isolated cases of reticulate purpura [23], bullous lichen planus [24], iododerma [25], vasculitis [26] and erythrodermic psoriasis [27] have been documented. There has been a single case report of fatal TEN following second exposure to diatrizoate solution for excretory pyelography [28].

Radiopharmaceuticals

The reported incidence of reactions to agents used in nuclear medicine is low; these usually take the form of immediate urticaria or angio-oedema [1–3]. Urticarial or anaphylactic reactions to technetium (^{99m}Tc) sulphur colloid and ^{99m}Tc human albumin microspheres together accounted for 50% of reported reactions [2]. The bone-scanning agent ^{99m}Tc methylene diphosphonate produces a delayed-onset erythematous pruritic eruption within 4–24 h [4].

Halides

Bromides

Bromides have a long half-life and are excreted slowly by the kidney; bromism may develop in patients with impaired renal function, and eruptions may not develop until as much as 2 months after the drug has been discontinued. Acneiform and vegetating lesions occur more often, and bullae less frequently, than with iodism [1,2]. Vegetating bromoderma presents as single or multiple papillomatous nodules or plaques, studded with small pustules, on the face or limbs. Bromoderma tuberosum has been caused by anticonvulsive treatment with potassium bromide [3]. Bromism is also characterized by weakness, restlessness, headache, ataxia and personality changes [2].

Iodides

Serious and even fatal reactions of anaphylactic type have been caused by radiograpic contrast media containing organic iodine [4]. Iodism, nasal congestion and conjunctivitis, often accompanied by an exanthematic eruption, may be associated with a wide variety of systemic symptoms [5,6]. Prolonged administration of small doses of iodide, as in many cough mixtures, may provoke eruptions with or without mucosal or systemic symptoms. Lesions may first develop some days after the drug is discontinued. The following may occur: urticaria, an acneiform rash, papulopustular lesions, nodules, anthracoid or carbuncular lesions, or clear or haemorrhagic bullae on the face, forearms, neck and flexures or on the buccal mucosa [6]. If the iodine is continued, the bullae may be replaced by vegetating masses, which simulate pemphigus vegetans or a granulomatous infection [7]. Iododerma has developed after administration of oral [8] and intravenous [9,10] radiographic contrast media, and during thyroid protection treatment [11]. Iododerma seems more frequent in patients with renal failure, and may be accompanied by leukocytoclastic vasculitis [2]. The eruption recurs within days of readministration in a sensitized individual [12]. Cell-mediated [5] and 'hyperinflammatory' [13] mechanisms have been postulated. Vegetating iododerma may be an idiosyncratic response that is commoner in patients with polyarteritis nodosa or paraproteinaemia [14]. Fixed eruptions occur rarely [15]. Generalized pustular psoriasis has been reportedly provoked by potassium iodide [16].

Histology of bromoderma and iododerma

In bromoderma, verrucous pseudoepitheliomatous hyperplasia is associated with abscesses containing neutrophils and eosinophils in the epidermis, and with a dense dermal infiltrate initially consisting mainly of neutrophils and eosinophils and later containing many lymphocytes, plasma cells and histiocytes. The abundant dilated blood vessels may show endothelial proliferation. In iododermas, ulceration is more marked, but there is usually less epithelial hyperplasia. Both conditions must be differentiated from blastomycosis and coccidioidomycosis, and from pemphigus vegetans [17].

Agents used in general anaesthesia

Neuromuscular blocking agents, skeletal muscle relaxants and general anaesthetics

The incidence of life-threatening anaphylactic or anaphylactoid reactions during anaesthesia has been variously reported to occur in 1 in 1000 to 1 in 20 000, and minor reactions probably occur in more than 1% of cases; neuromuscular blocking agents are the triggering agents in 50–69% of these reactions, with latex being less frequently incriminated (about 12%) [1–10]. The mortality rate in anaphylactic reactions to drugs used in general anaesthesia is between 4 and 6% [8]. Reactions were most likely with suxamethonium and gallamine, then D-tubocurarine and alcuronium, and least likely with pancuronium and vecuronium [3,6,9]; in another study, succinylcholine and rocuronium were most frequently incriminated [10]. Mucocutaneous manifestations including erythema, urticaria

and angio-oedema are reported in up to 80% of reactions, but may only be recognized after the acute phase has passed. Reactions are more frequent in women and in atopic patients. Proposed mechanisms for anaphylactic reactions include type I (IgE antibody-mediated) hypersensitivity [9,11–13], with antibodies persisting for up to 29 years [12], and direct histamine release. Only one reaction in three is likely to be IgE-mediated (type I) anaphylaxis, but non-immune reactions are no less hazardous than type I reactions [9]. Cross-reactivity is widespread with most of the drugs but is least with pancuronium. It has been suggested that pancuronium should be used where muscle relaxation during anaesthesia is essential but sensitivity to another relaxant exists [3], although others have questioned the safety of this procedure [7]. IgE-dependent sensitivity to thiopental may result in anaphylactic reactions [5].

Local anaesthetic agents

Local anaesthetics may cause both immediate anaphylactic reactions and contact dermatitis [1–10]. True allergic reactions caused by local anaesthetics are extremely rare [9,11]; more often, the allergic response is caused by a metabolite, preservative or unrelated substance. Acute anaphylactic reactions are uncommon, but are probably less likely to occur when amide linkage agents are used [4,5]. Necrosis of the fingertip has followed local injection for nail extraction [12]. Dizziness and confusion due to systemic absorption followed repeated application of topical lidocaine (lignocaine) [13]. Severe lidocaine intoxication with progressive neurological and psychiatric abnormalities and cardiorespiratory arrest occurred following topical application to painful ulcerated areas in a patient with cutaneous T-cell lymphoma [14].

Tetracaine (amethocaine). Tetracaine in the form of a self-adhesive patch caused slight or moderate erythema at the site of application in 26% of patients, and slight oedema in 5% [15].

EMLA cream (proprietary name). A eutectic mixture of prilocaine and lidocaine in a cream base (EMLA cream) has been associated with methaemoglobinaemia [16–18]; two metabolites of prilocaine, namely 4-hydroxy-2-methylaniline and 2-methylaniline (*o*-toluidine), have been incriminated. A 3-month-old infant became cyanosed after application of 5 g, but concomitant sulphonamide therapy may have made a contribution [16]. Small but significant increases in methaemoglobin levels have been reported in children aged 1–6 years following routine administration of 5 g before surgery, and these may persist for at least 24 h [17], so it is recommended that the minimum effective dose be used in children requiring daily application. Blanching following application of EMLA cream is common [19]. Hyperpigmentation is recorded [20]. Contact dermatitis can arise to both lidocaine and prilocaine [21–23].

Bupivacaine. A delayed hypersensitivity rash may occur after injection of arthroscopy portals with bupivacaine [24].

Infusions and injections

Intravenous infusion

Pain, oedema, induration and thrombophlebitis are well-recognized complications [1–4]. Localized bullous eruptions following infusion of commonly used non-vesicant fluids, such as saline, have been described [5]. Extravasation was reported to occur in 11% of 16 380 administrations to children monitored over a 6-month period [6]. Skin necrosis following intravenous infusion of chemotherapeutic agents occurs in up to 6% of patients [1,3,5–9].

Blood transfusion

Urticaria occurs in about 1% of transfusions [1], and may be the result of allergy to soluble proteins in donor plasma. Post-transfusion purpura may rarely occur as a result of profound thrombocytopenia about 1 week after transfusion, and is associated with antiplatelet alloantibodies. Other potential side effects include transmission of infectious diseases, including syphilis, hepatitis B and HIV-related syndromes (AIDS).

Graft-versus-host disease may develop following transfusion of unirradiated blood in immunosuppressed patients [2–8], including those with malignancies [2], and infants with severe congenital immunodeficiency [3]. Isolated reports of fatal transfusion-associated graft-versus-host disease in presumed immunocompetent hosts receiving fresh unirradiated blood have been reported [9–11]. This paradoxical situation may be partly explained by situations in which recipients heterozygous for a given MHC haplotype receive a transfusion from a donor homozygous for this haplotype, as the recipient would not react to the donor haplotype but the donor lymphocytes would react to the non-identical recipient haplotype [8]. Thus, some recipients of non-irradiated blood from their offspring may be at risk of developing graft-versus-host disease. An acute fatal illness, characterized by fever, diffuse erythematous rash and progressive leukopenia, has been described in Japanese patients 10 days after surgical operation and has been termed 'postoperative erythroderma' [12]. Histologically, scattered single cell epidermal cell eosinophilic necrosis, satellite cell necrosis, basal cell liquefaction degeneration and a scanty dermal infiltrate may be seen; the reaction is compatible with an acute graft-versus-host reaction following blood transfusion [12].

Hydroxyethyl starch

Hydroxyethyl starch (hetastarch) is used as a plasma expander for hypovolaemia, to prime cardiopulmonary bypass machines, as a sedimenting agent to increase the yield of granulocytes during leukapheresis, and to improve microcirculation as in the treatment of sudden deafness. It has been implicated in the development of lichen planus [1], and severe generalized pruritus in up to 32% of recipients, beginning 2 weeks after exposure and taking up to 2 years to settle [2–6].

Renal dialysis

Dermatological complications of renal dialysis have been reviewed [1,2]. These include marked premature ageing, hyperpigmentation, xeroderma, decreased sebaceous and sweat gland secretion, Raynaud's syndrome, generalized pruritus and carpal tunnel syndrome due to amyloid β deposition [1]. Extravasation, phlebitis and bacterial infection of the cannula, with resulting septicaemia, may occur and are related to the site of insertion of the cannula into the arteriovenous fistula. A bullous dermatosis of haemodialysis has been described [2,3]. This resembles porphyria clinically and histologically, and porphyrins may be elevated [3], although cases with pseudoporphyria in which there are no abnormalities of porphyrin metabolism have also been documented [2]. Two-thirds of patients with dialysis-associated anaphylaxis have IgE antibodies to ethylene oxide/human serum albumin [4]. Allergic contact dermatitis due to rubber chemicals in the haemodialysis equipment may be seen around the arteriovenous shunt [5]. Porokeratosis localized to the access region for haemodialysis has also been reported [6].

Necrosis from intramuscular injections

Severe painful local necrosis at the site of an injected medicament (embolia cutis medicamentosa, also known as Nicolau's syndrome) may follow intramuscular therapeutic injections and was originally described with bismuth. It occurs particularly with preparations containing corticosteroids, local anaesthetics, antirheumatic drugs and antihistamines; more rarely, chlorpromazine, penicillin, phenobarbital and sulphonamides have been implicated [1,2]. The condition has also followed sclerotherapy [3]. Clinically, stellate erythema and infiltration are followed by central deep necrosis that heals with scarring.

Polidocanol

The sclerosing solution polidocanol is said to cause allergic reactions in up to 0.06% of cases; systemic allergic reactions may be more common than previously recognized [1].

Drugs affecting metabolism or gastrointestinal function

Hypoglycaemic drugs

Dermatological aspects of the oral hypoglycaemic drugs have been reviewed [1–4].

Biguanides

Rashes are much less frequent with metformin and phenformin than with sulphonylureas. Transient erythemas, pruritus and urticaria have been noted.

Sulphonylureas

Chlorpropamide and tolbutamide are most often prescribed, and both can give rise to toxic or allergic reactions. Angio-oedema with glibornuride, urticaria with glibenclamide and a bullous dermatitis with carbutamide have been described [5]; there was no cross-reactivity between first- and second-generation sulphonylureas.

Chlorpropamide. Eruptions occur in 2–3% of patients on chlorpropamide [2]. These include maculopapular rashes, photosensitivity [6], erythema annulare, Stevens–Johnson syndrome [7], erythema nodosum [1], lichenoid eruptions [8,9], purpura and exfoliative dermatitis [10]. Porphyria has been provoked [11]. A disulfiram-like effect, with flushing of the face, headache and palpitations after taking alcohol, occurs in up to 30% of patients [12,13]. The fact that the flush is blocked by naloxone suggests that opioids may be involved in the response.

Glibenclamide. Bullae and cholestasis have occurred together [14].

Glipizide. Pigmented purpuric eruption is documented [15].

Lipid-lowering drugs

Acipimox

This nicotinic acid analogue causes less prostaglandin-mediated flushing and itching than nicotinic acid [1].

Clofibrate

Erythema multiforme and a variety of other erythematous rashes have been described [2].

Gemfibrozil

This lipid-lowering drug, which mainly lowers triglycerides, has been associated with exacerbation of psoriasis [3,4].

Statins

The lipid-lowering drugs lovastatin, simvastatin and pravastatin can cause eczema [4,5]; these drugs block an early step in cholesterol biosynthesis by inhibiting the activity of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase. Simvastatin has caused a lichenoid eruption with skin and mucosal involvement [6,7], and chronic actinic dermatitis [8]. Pravastatin has also been associated with a lichenoid rash [9]. Atorvastatin has caused linear IgA bullous dermatosis [10] and TEN [11].

Triparanol and diazacholesterol

These drugs inhibit a late step in cholesterol biosynthesis (Δ^{24} sterol reductase) and can induce ichthyosis or palmoplantar hyperkeratosis [4].

Drugs for gastrointestinal ulceration

Omeprazole

This proton pump inhibitor, a substituted benzimidazole, has gained widespread use in the treatment of gastric and duodenal ulceration and reflux oesophagitis. Adverse events with the drug are rare and involve mainly the gastrointestinal and central nervous systems, with diarrhoea, headache and dizziness, and confusion in the elderly, moderate elevation of aminotransferases and possible leukopenia [1–3]. The prevalence of cutaneous reactions to omeprazole is approximately 0.5–1.5% [1–4]. A variety of eruptions are recorded, including angio-oedema and urticaria [4,5], anaphylaxis [6], maculopapular rashes, lichen planus [7,8], pityriasiform eruption [9], erythema multiforme and erythroderma [10], exfoliative dermatitis [11], bullous eruption [12] and photosensitivity. Gynaecomastia is recorded [13].

Tripotassium dicitratobismuthate (De-Nol)

The Netherlands Centre for Monitoring of Adverse Reactions to Drugs has received several reports of skin reactions, on average 2 days after starting treatment, including maculopapular exanthema, angio-oedema and erythema [14].

Bismuth subsalicylate (PeptoBismol)

Black granules at follicular orifices have been reported [15]. Blue linear pigmentation of the soft palate, oral mucosa and vagina, ulcerative stomatitis, generalized pigmentation, dermatitis and erythroderma are recorded.

Laxatives

Side effects of laxatives have been reviewed [1].

Dantron (danthron)

A highly characteristic irritant erythema of the buttocks and thighs has been observed in patients who are partially incontinent. The erythema results from skin soiling by faecal matter containing an anthralin (dithranol)-like breakdown product [2].

Phenolphthalein

Fixed eruptions are well known [3–5]. Bullous erythema multiforme and an LE-like reaction are documented.

Miscellaneous drugs

Food and drug additives

Dermatological complications of food and drug additives

have been reviewed [1–14]. These substances have been implicated in the causation of urticaria [4–7], anaphylaxis, purpura and vasculitis [8–12]. However, one study suggested that common food additives are seldom if ever of significance in urticaria [11]. In another study, only 0.63% of food additive provocation tests resulted in exacerbation in 1110 patients with urticaria; tests were again not positive on re-provocation [13]. The prevalence of adverse reactions to food additives is estimated to be 0.03–0.23% [15]. The necessity for double-blind, placebo-controlled testing to substantiate alleged food additive allergy has been emphasized [16]. Information about excipients ('inert ingredients') has been reported in a study that examined the sweeteners, flavourings, dyes and preservatives present in chewable and liquid preparations of 102 over-the-counter and prescription brands of antidiarrhoeal, cough and cold, antihistamine/decongestant, analgesic/antipyretic and liquid theophylline medications [17]. An average preparation contained two sweeteners, primarily saccharin and sucrose, followed by sorbitol, glucose, fructose and others. The type of flavouring was not specified in 36 of the 102 preparations; cherry was the most common flavouring, followed by vanilla and lemon. Twenty-one different dyes and colouring agents were used; red dye no. 40 was the most common, followed by yellow no. 6. Sodium benzoate and methylparabens were the commonest of eight preservatives used. Mandatory labelling of excipients in all pharmaceutical preparations is the only way that physicians and patients can be fully informed [17]. It is important to appreciate that peanut oil, to which patients may be strongly allergic, is found in certain medications [18]. Caffeine in coffee and cola beverages caused urticaria in a 10-year-old child, confirmed by prick test and oral challenge test with caffeine [19].

Colouring agents

Colourings in food and medications (including some antihistamines), such as tartrazine, sunset yellow and other azo dyes, have been reported to cause adverse reactions [1,2], including urticaria [3,4] or vasculitis [5,6].

Flavouring agents

Aspartame. Aspartame, a synthetic dipeptide composed of aspartic acid and the methyl ester of phenylalanine and used under the trade name of NutraSweet (G.D. Searle & Co., Skokie, Illinois, USA) as a low-calorie artificial sweetener, has been associated with relatively few adverse side effects despite its widespread use [1]. Cutaneous side effects reported include urticaria, angio-oedema and other nondescript 'rashes' [2], granulomatous septal panniculitis [3] and lobular panniculitis [4]. However, in a recent study of patients with a history of aspartame sensitivity, it was not possible to identify any subject with a clearly reproducible adverse reaction [5]. Similarly, a multicentre, placebo-controlled, challenge study showed that aspartame and its conversion products are no more likely than placebo to cause urticaria and/or angio-oedema reactions in subjects with a history consistent with hypersensitivity to aspartame [6].

Cyclamates. Cyclamates, used as sweeteners in soft drinks, have caused photosensitivity [7].

Quinine. Quinine in tonic water and other bitter drinks may cause fixed eruptions [8].

Preservatives

The antioxidant food preservatives butylated hydroxyanisole (BHA) and butylated hydroxytoluene (BHT) have been reported to exacerbate chronic urticaria [1]. Sodium benzoate has been associated with urticaria, angio-oedema, asthma and rarely anaphylaxis [2]. Parabens used as preservatives may also cause urticaria [3].

Sulphiting agents are commonly used in parenteral emergency drugs, including epinephrine (adrenaline), dexamethasone, dobutamine, dopamine, norepinephrine (noradrenaline), phenylephrine, procainamide and physostigmine [4]. Published anaphylactic or asthmatic reactions have been associated with sulphited local anaesthetics, gentamicin, metoclopramide, doxycycline and vitamin B complex. The reactions have a rapid onset and do not always coincide with a positive oral challenge, although patients with a history of positive oral challenge to 5–10 mg of sulphite may be at increased risk of developing a reaction to parenteral sulphites. Sulphites added as antioxidant preservatives may provoke urticaria, asthma, anaphylaxis and shock [4–10], as well as urticarial vasculitis [11]. Intolerance due to metabisulphite as an antioxidant in a dental anaesthetic has led to angio-oedema; patch tests were positive [12]. Basophil activation induced by sulphites may be IgE dependent [13]. It has been claimed that there is a high specificity of patch testing in the diagnosis of patients with sulphite sensitivity [14].

Miscellaneous food additives

Agricultural or veterinary chemicals may leave residues in animals and plants used as human food, for example penicillin in milk or meat, with resultant urticaria [1,2]. The exposure of a rural Turkish population to flour contaminated with hexachlorobenzene induced an outbreak of cutaneous porphyria [3]. Contaminated rapeseed cooking oil containing acetanilide resulted in the Spanish 'toxic oil syndrome'; the central feature of the illness was a toxic pneumonitis, but fixed rashes and scleroderma-like changes in survivors were seen [4–6]. Outbreaks of atypical erythema multiforme and other exanthems in the Netherlands were attributed to an additive in margarine [7,8]. The high arsenic content of a rural water supply in Taiwan caused arsenicism [9]. Chemicals added to tobacco, for example menthol in cigarettes, have caused urticaria [10]. *N*-Nitroso compounds, which are known to be carcinogenic in animals, occur in food products and certain alcoholic drinks, but there is no direct proof as yet of a causal role in human disease [11].

Herbal remedies, homeopathy and naturopathy (alternative therapy)

Adverse cutaneous effects of herbal drugs have been reviewed [1–4]. Virtually all herbal remedies may cause allergic reactions, and several cause photosensitization. Some herbal medicines, particularly Ayurvedic remedies, contain arsenic or mercury that may produce typical skin lesions. Other popular remedies that can cause dermatological side effects include St John's wort, kava, aloe vera, eucalyptus, camphor, henna and yohimbine. In addition, some herbal treatments used specifically for dermatological conditions, for example Chinese oral herbal remedies for atopic eczema, have been reported to cause systemic adverse effects. There is concern that some agents, notably Chinese herbal creams, have been shown repeatedly to be adulterated with corticosteroids [5,6].

Chinese herbal medicine

Adverse effects of Chinese herbal medicines, including life-threatening 'dazao'-induced angio-oedema and liquorice-induced hypokalaemic periodic paralysis, accounted for 0.2% of medical admissions to a hospital in Hong Kong over an 8-month period [1]. Herbal poisoning in Hong Kong, Taipei and Kuala Lumpur has occurred as a result of addition of adulterants (*Podophyllum emodi*) or erroneous substitutes (*Datura metel*) [2]. A fatality due to total liver necrosis associated with ingestion of Chinese herbal medicines is believed to have occurred because the patient prepared a decoction from a herbal mixture containing *Eurysolen gracilis* Prain (Labiatae), a herb not used in Chinese medicine [3]. A multisystem illness developed in a patient after ingestion of Chinese herbal medicines containing the potentially toxic compounds benzaldehyde, cinnamoyl alcohol and ephedrine [4]. Some Chinese patent medicines contain mercurial ingredients, cinnabar (red mercuric sulphide) and calomel (mercurous chloride) [5]. Alopecia and sensory polyneuropathy from thallium in a Chinese herbal medication has been reported [6]. Cutaneous aspects of thallium poisoning include palmar and plantar scaling, acneiform lesions on the face and diffuse alopecia, accompanied by acute nervous system and gastrointestinal symptoms [7]. Chinese herbal medicine may contain camouflaged prescription anti-inflammatory drugs, corticosteroids and lead [8], and some practitioners of Chinese medicine supply 'herbal creams' that actually contain potent topical steroid ointments [9,10]. Fixed drug eruption has been documented with use of a Chinese traditional herbal medicine containing mainly pseudoephedrine and ephedrine [11].

There are major concerns about hepatotoxicity [12–16] and nephrotoxicity [17–23] with Chinese herbal medicine. In one case, hepatotoxicity was associated with ingestion of the Chinese herbal product jin bu huan anodyne tablets (*Lycopodium serratum*) [14]. A rapidly progressive fibrosing interstitial nephritis developed in young women who followed the same slimming regimen containing two Chinese herbs (*Stephania tetrandra* and *Magnolia officinalis*) [17–19]. The known carcinogen, aristolochic acid, has been suspected in some cases of nephropathy [19,20]. Urothelial malignancy has supervened [22]. Acquired Fanconi's syndrome was induced by a mixture of Chinese crude drugs [23].

The need for correct identification of herbs in herbal poisoning [24], and for monitoring of the safety of herbal medicines [25], has been emphasized. Greater awareness of their toxicity is required [26,27]. Special licensing of herbal remedies exists in Germany, France and Australia and has been advocated in the UK [28].

Analgesic and anti-inflammatory Chinese medicinal materials, especially those containing fragrance, may cause contact sensitization and can cause systemic contact dermatitis [29,30]. Erythema multiforme [30], exanthem [31] and erythroderma [32] are described. Fever with oedematous erythema was caused by a decoction of the crude drug Boi of Kampo (Sino-Japanese traditional) medicine for the alleviation of arthralgia; oral ingestion tests incriminated the constituent sinomenine [33].

A 'tea' prepared from a decoction of herbs has been reported to be of benefit in eczema [34,35]. The decoction contains paenol (2'-hydroxy-4'-methoxyacetophenone), which is known to have platelet antiaggregatory, analgesic and antipyretic properties [36]. Hepatotoxicity was described in a 9-year-old girl who consumed a Chinese herbal tea for 6 months [37] and was reported in a further patient [38]. Reversible abnormal liver function tests have been reported in two children receiving Chinese herbal therapy (Zemaphyte) [39]. Toxicology screening in a

group of adults on Zemaphyte for 1 year revealed no abnormalities in haematological or biochemical parameters; transient nausea and abdominal distension, with a mild laxative effect, was noted in about one-third of patients [40]. Dilated cardiomyopathy followed therapy of atopic eczema with Chinese herbal medicine [41].

Kava dermopathy

The kava plant, a member of the black-pepper family, is used ceremonially by many traditional societies of the southern Pacific in the form of an intoxicant beverage prepared from roots to induce relaxation and sociability and promote sleep. Herbal drugs containing kava have been used for insomnia, nervousness and depression. A reversible ichthyosiform kava dermopathy resulted from excessive use of kava [1,2]. Systemic contact-type dermatitis occurred after oral administration of kava extract [2].

Homeopathic drugs

Cases of erythroderma, confluent urticaria and anaphylaxis have been reported following homeopathic medication [1]. Treatment of a diaper dermatitis and mild respiratory and enteral infections with the homeopathic mercurial medicine Mercurius 6a (cinnabar dilute $1 \times 10(6)$) was followed by dissemination of the dermatitis, irritability and albuminuria [2]. Baboon syndrome was associated with use of a homeopathic medicine containing mercury [3].

Naturopathy

Bizarre and unpredictable cutaneous reactions may follow topical application or ingestion of naturally occurring substances. A curious gyrate erythematous eruption was seen in a patient following local application of onion rings as a home remedy for arthralgia [1]. Substantial amounts of psoralen may be absorbed from vegetables; a patient who consumed a large quantity of celery root (*Apium graveolens*) 1 h before a visit to a suntan parlour developed a severe generalized phototoxic reaction [2]. A bullous phototoxic reaction developed after exposure to aerosolized bergamot aromatherapy oil in a sauna and subsequent UVA radiation in a tanning salon [3]. Phytophotodermatitis followed application of *Citrus hystrix* as a mosquito repellent [4]. Phototoxicity has been reported from herbal remedies for vitiligo incorporating powdered seeds of *Psoralea corylifolia*, which contains psoralen, isopsoralen and psoralidin [5].

Contact sensitization has been caused by alternative topical medicaments containing plant extracts [6–9], including tea-tree oil [7,8], which has also caused systemic contact dermatitis [7]; allergic airborne contact dermatitis has been caused by benzaldehyde, eucalyptus oil, laurel oil, pomerance flower oil, lavender oil, rosewood oil and jasmine oil used for aromatherapy [9]. Application of henna as a decoration may cause allergic contact eczema [10]. A diffuse morbilliform eruption occurred with a *Gingko biloba* supplement [11], recurrent erythema nodosum with *Echinacea* therapy [12], erythroderma with intake of St John's wort (*Hypericum perforatum*) [13], and tea-tree oil dermatitis has been associated with linear IgA disease [14].

Miscellaneous

Canthaxanthin, a synthetic non-provitamin A carotenoid deposited in epidermis and subcutaneous fat, caused fatal aplastic anaemia when ingested to promote tanning [1].

REFERENCE

Industrial and other exposure to chemicals

For a discussion of sclerodermatous reactions to environmental agents, see p. 73.44. A form of fluoride toxicity occurred due to industrial poisoning in the Italian town of Chizzolo, resulting in pinkish brown, round or oval macules seen in hundreds of the local population [1]. Similar small outbreaks have occurred in North America [2]. Exfoliative dermatitis has been recorded with trichloroethylene [3]. Occupational exposure to trichloroethylene has also caused Stevens–Johnson syndrome [4].

Patients exposed to dioxin after an industrial accident at Seveso, Italy developed early irritative lesions, comprising erythema and oedema of exposed areas, vesicobullous and necrotic lesions of the palms and fingertips, and papulonodular lesions; later lesions were those of chloracne [5]. Contamination of rice-bran cooking oil with polychlorinated biphenyls in Taiwan resulted in chloracne, and congenital abnormalities in offspring [6].

Pruritus, urticaria, and discoid and diffuse eczema may occur following the use of brominated disinfectant compounds such as 1-bromo-3-chlor-5,5-dimethylhydantoin (Di-halo, Aquabrome) in public swimming pools [7]. Accidental occupational exposure to high concentrations of methyl bromide during a fumigation procedure resulted in erythema with multiple vesicles and large bullae, with predilection for moist flexures and pressure areas [8]. Idiopathic thrombocytopenic purpura has been associated with industrial exposure to wood preservatives [9], turpentine [10], and to insecticides such as chlordane and

heptachlor [11]. Reversible alopecia occurred with occupational exposure to borax-containing solutions [12].

Local and systemic effects of topical applications

Many topical therapeutic agents may cause serious or even dangerous systemic side effects if absorbed in sufficient quantity; such absorption may be facilitated through diseased skin, and with use of newer vehicles or occlusive polythene dressings. The risk of serious systemic effects is greatest in infancy and in the old and frail. The quantity absorbed in relation to body weight is greatest in infancy, when the surface area is relatively greater; moreover, neonatal skin is more permeable. Most dangerous or fatal reactions have occurred because either the physician was unaware of the potential hazard or the patient continued self-treatment without medical supervision.

Topical therapy

Anthralin (dithranol)

Topical anthralin, used in the therapy of stable plaque psoriasis, is well known for causing erythema, irritation and a sensation of burning in normal skin; it stains the skin and clothing [1]. Application of 10% triethanolamine following short-contact anthralin treatment has been reported to inhibit anthralin-induced inflammation without preventing the therapeutic effect [2]. Allergic contact dermatitis to anthralin is very rare. The natural and synthetic anthranols have toxic effects on liver, intestines and the central nervous system, but systemic toxicity in humans under therapeutic conditions has not been established [3].

Boric acid

Poisoning has usually occurred in infants treated for napkin eruptions. Almost all cases have been caused by the use of boric ointments or lotions. However, use of borated talc proved fatal in one infant [1]. Wet boric dressings caused the death of an adult woman [2].

Calcipotriol

This vitamin D_3 analogue has been reported to cause transient local irritation, and facial or perioral dermatitis [1]. Contact allergy is recorded [2]. Topical application of calcipotriol for 5 weeks to a mean of 16% of the body surface of psoriatic patients did not result in detectable systemic alteration of calcium metabolism [3]. The manufacturer's data sheet (Leo Laboratories) states that increased serum calcium may occur with application in daily doses of 50–100 g of the 50 μg/g ointment. Severe symptomatic hypercalcaemia developed after application of about 200 g of the ointment over 1 week to exfoliative psoriasis covering 40% of the body surface [4]. It is recommended that treatment be confined to stable mild to moderate psoriasis, and that the recommended dose of 100 g/week should not be exceeded. Hyperpigmentation occurred at the site of topical calcipotriol application in two patients receiving photochemotherapy [5].

Formaldehyde

Industrial exposure is recognized to be a health hazard, and a threshold limit of 2 ppm is allowed in the UK and the USA [1]. Irritant or allergic dermatitis is common in exposed workers [2]. Systemic symptoms including breathlessness, headache and drowsiness have been attributed to prolonged exposure to very low levels in the home [3].

Lindane (g-benzene hexachloride)

Lindane therapy for scabies has potential toxicity, which includes neurotoxicity with convulsions, especially in children [1–7]. Most reports have occurred with overexposure or misuse, although side effects have followed single applications, particularly when the epidermal barrier has been compromised. Whether this constitutes a significant problem in normal individuals is doubtful [6]. Nevertheless, it has been suggested that permethrin may be a safer and less toxic alternative [8].

Hexachlorophene (hexachlorophane)

This substance has potential neurotoxicity. Exposure of babies to a talc containing 6.3% hexachlorophene due to a manufacturing error resulted in deaths, with ulceration, skin lesions and a characteristic demyelinating encephalopathy [1]. A 3% emulsion has produced milder neurological changes but a 0.33% concentration in talc is apparently safe. Encephalopathy has occurred in burns patients [2].

Hydroquinone

Depigmenting creams containing 6–8% hydroquinone, used especially by black South African women, have caused rebound hyperpigmentation and coarsening of the skin, with ochronotic changes in the dermis, colloid degeneration and colloid milium [1–6]. Collagen degeneration may be seen histologically [2]. Similar changes have been seen in black women in the USA [3] and in a Mexican American woman [4]. Interestingly, ochronosis does not develop in areas of vitiligo [7]. The Q-switched ruby laser may be helpful in treating exogenous ochronosis [8]. The nails may be pigmented [9].

Lead lotions

The continued use of wet dressings of lead subacetate in the treatment of exfoliative dermatitis caused lead poisoning, with punctate basophilia and an elevated urinary lead level [1].

REFERENCE

1 Kennedy CC, Lynas HA. Lead poisoning by cutaneous absorption from lead dressings. *Lancet* 1949; **i**: 650–2.

Mercury

Poisoning is now fortunately rare, but was seen from continued application of large amounts of a topical application, as for psoriasis [1,2]. Idiosyncratic poisoning after much smaller doses is also recognized [3]. Intoxication has followed the use of a mercury dusting powder [4] and poisoning of a suckling infant has followed the use of perchloride of mercury lotion for cracked nipples [5]. Fever, a generalized morbilliform rash and oedema of the extremities have been the usual clinical features. Exfoliative dermatitis and encephalopathy have developed; permanent damage to the renal tubules is manifest as persistent albuminuria or frank nephrotic syndrome [6]. Rarely, gross symptoms, such as loose teeth [7], swollen bleeding gums and weight loss, may be observed.

Application of a mercury-containing cream to the face over many years can produce slate-grey pigmentation, especially on the eyelids, nasolabial folds and neck folds (exogenous ochronosis) [8–10]; mercury granules lie free in the dermis or within macrophages [11]. Mercury is a moderate sensitizer and leads to contact sensitivity.

Minoxidil

Topical minoxidil, as used for androgenetic alopecia, is associated with cutaneous problems in up to 10% of patients, with allergic contact dermatitis occurring in 4% of individuals [1]. The contact allergen is often propylene glycol [2]. Diffuse hypertrichosis occurred during treatment with 5% topical minoxidil in female patients [3]. Acute non-allergic eruptions of the scalp resulted from combined use of minoxidil and retinoic acid [4].

Phenol

Severe systemic reactions, such as abdominal pain, dizziness, haemoglobinuria, cyanosis and sometimes fatal coma, have followed the application of phenol to extensive wounds. Accidental application of pure phenol to a small area of skin in an infant has proved fatal. The prolonged use of phenol as a dressing for a large ulcer may give rise to exogenous ochronosis, with darkening of the cornea and of the skin of face and hands.

Podophyllin

Excessive application may lead to severe local irritation or ulceration [1]. There have been occasional reports of confusional states, coma, peripheral neuropathy, vomiting and even death following the application of this resin to large areas of genital warts, especially in pregnancy [2,3]. However, careful review of the reports suggests that in the majority the effects could not be attributed with certainty to podophyllin [2]. Animal experiments suggest teratogenicity; although teratogenicity is controversial in humans, the drug is best avoided in pregnancy.

3 Sundharam JA, Bargman H. Is podophyllin safe for use in pregnancy? *Arch Dermatol* 1989; **125**: 1000–1.

Resorcinol

Acute resorcinol poisoning is very rare but an ointment

containing 12.5% resorcinol applied to the napkin area produced dusky cyanosis, a maculopapular eruption, haemolytic anaemia and haemoglobinuria in an infant [1]. The continued application to large leg ulcers of ointments containing resorcinol has caused myxoedema and widespread blue-grey pigmentation mimicking ochronosis [2]. Application for warts caused generalized urticaria with angio-oedema, pompholyx of palms and soles, or papulovesicular eczema with pompholyx [3].

Salicylic acid and salicylates

The frequent application of salicylic acid ointments to extensive lesions will produce symptoms of salicylism even in adults [1–7]. Most cases of poisoning have occurred in children with psoriasis or ichthyosis [1,2]; fatal cases have been recorded [4]. Drowsiness and delusions are followed by acidosis, coma and death from respiratory failure.

Tretinoin

Topical tretinoin, used for the management of photo-aged skin, may cause erythema, peeling, burning and itching of the skin within days [1,2]. Pink discoloration without other signs may also develop, as may inflammation in solar keratoses.

Transdermal drug-delivery systems

Transdermal delivery systems are available for clonidine, estradiol (oestradiol), glyceryl trinitrate, scopolamine and nicotine, and systems for other drugs are being developed. Erythema, irritancy, scaling, vesiculation, excoriation, induration, pigmentary changes and contact sensitization are not uncommon; the occlusive element may lead to miliaria rubra [1–13]. Systemic reactions may occur. Allergic skin reactions occur in up to 50% of patients with clonidine, but with glyceryl trinitrate, scopolamine, estradiol and testosterone they are much less frequent [2]. Reactivation of an area of contact dermatitis may develop via oral medication rarely [2]. Transdermal compared with oral metoprolol had comparable efficacy, and systemic side effects were comparable; 69% of patients had local side effects at the patch site (erythema, papular exanthem, pruritus, localized urticarial exanthem) [4]. Allergic contact dermatitis is recorded with nicotine

[8–11], glyceryl trinitrate and estradiol [12]. Use of transdermal oestrogen patches resulted in systemic sensitization to ethanol [14]. Transdermal fentanyl patches have been associated with a diffuse rash [15].

Management of drug reactions

Diagnosis

Drug reactions, apart from fixed drug eruption, have non-specific clinical features, and it is often impossible to identify the offending chemical with certainty, especially when a patient with a suspected reaction is receiving many drugs simultaneously. Drug reactions may be mistaken for naturally occurring conditions and may therefore be overlooked. By the same token, it may on occasion be very difficult to state that a given eruption is drug induced. Experience with the type of reaction most commonly caused by particular drugs may enable the range of suspects to be narrowed, but familiar drugs may occasionally produce unfamiliar reactions and new drugs may mimic the reactions of the familiar. The assessment of a potential adverse drug reaction always necessitates taking a careful history, and may involve a trial of drug elimination, skin tests, *in vitro* tests and challenge by re-exposure [1].

A drug reaction may first become evident after the offending medication has been stopped, and depot injections may have delayed effects. Interpretation of elimination tests should be tempered by the knowledge that drug reactions may take weeks to settle. *In vivo* and *in vitro* tests are only applicable to truly allergic reactions. Skin tests, including prick and intradermal testing and patch testing, are for the most part unreliable, even when apparently appropriate antigens are used; they may be hazardous [2–4]. *In vitro* tests are not widely available and are essentially research tools.

All too frequently therefore the diagnosis is no more than an assessment of probability. The fact that major disagreements occurred between clinical pharmacologists asked to assess the likelihood of adverse drug reaction in two series confirms that identification of a responsible drug is often a subjective judgement [5,6]. An algorithm has been reported that provides detailed criteria for ranking the probability of whether a given drug is responsible for a reaction, based on (i) previous experience, (ii) the alternative aetiological candidates, (iii) timing of events, (iv) drug level and (v) the results of drug withdrawal and rechallenge [7,8]. A number of other algorithms have been developed to assist in the diagnosis of which, if any, drug is the cause of a given eruption [9–12]. The difficulties inherent in the diagnosis of drug reactions have been reviewed [1,13,14].

Drug history

Patients should be specifically questioned about laxatives, oral contraceptives, vaccines, homeopathic medicines, etc. as these may not be volunteered as medications. They should be asked when they last took a tablet for any reason. The history should include information on when each drug was first taken relative to the onset of the reaction, whether the same or a related drug has been administered previously, and whether there is a prior history of drug sensitivity or contact dermatitis. Allergic drug reactions do not usually develop for at least 4 days, more commonly 7–10 days, after initial drug administration in a previously unsensitized individual. However, this time relationship cannot be relied on to differentiate between allergic and non-allergic reactions, as a previous sensitizing exposure may not have produced a clinically evident reaction.

Drug elimination

Resolution of a reaction on withdrawal of a drug is supportive incriminatory evidence but not diagnostic. Failure of a rash to subside on drug withdrawal does not necessarily exonerate it, as traces of the drug may persist for long periods and some reactions, once initiated, continue for many days without re-exposure to the drug. The unwitting substitution of a drug that is chemically closely related may perpetuate a reaction, as when an antihistamine of phenothiazine structure is prescribed to alleviate the symptoms of a reaction caused by another phenothiazine. Elimination diets have been advocated for diagnosis of food additive intolerance leading to urticaria [1,2].

Skin testing

Skin testing has been reviewed [1–7]. Drug skin tests are of three types: patch tests for delayed cellular hypersensitivity, prick tests for immediate hypersensitivity, and intradermal tests for both immediate or delayed hypersensitivity [5]. The quick patch test (application under a Finn chamber for 30 min) can be used in patients with severe hypersensitivity [8]. Prick tests and intradermal tests performed with sequential dilutions may be useful in the identification of patients who present with immediate IgE-related hypersensitivity reactions, and are sensitive to one of a number of drugs, including penicillin and other β-lactam antibiotics, agents used in general anaesthesia, tetanus toxoid, streptokinase, chymopapain, heterologous sera or insulin, and may thus aid in the prevention of anaphylaxis [1]. Vasculitis related to circulating immune complexes cannot be reproduced by skin tests. Delayed cellular hypersensitivity is involved in inducing maculopapular rashes, baboon syndrome, localized or generalized eczema or acute generalized exanthematous pustulosis. In such reactions, drug patch tests or delayed positive reactions on intradermal tests occur in more than 50% of patients [5]. Significantly higher numbers of positive patch tests are seen in maculopapular than in urticarial reactions [4]. Diluted drug patch tests can be positive in the drug hypersensitivity syndrome (drug rash with eosinophilia and systemic symptoms). Drug skin tests are not of great value in investigating Stevens–Johnson syndrome or TEN; relevant positive patch tests were seen in only 9% of 22 patients with Stevens–Johnson syndrome/TEN compared with 50% of 14 patients with acute generalized exanthematous pustulosis [9].

The results of skin-test reactions, including intradermal testing and patch testing, were evaluated in 242 patients with delayed-type (non-immediate) drug eruptions [6]. Intradermal testing was positive in 89.7% of patients, and patch tests were positive in 31.5% of cases; overall, 62% of patients had either a positive intradermal or patch test. Intradermal testing was more frequently positive in maculopapular rashes, erythema multiforme and erythrodermic rashes than in eczematous reactions, whereas positive patch tests were comparatively frequent in erythroderma, eczematous reactions and anticonvulsant-induced reactions. It was concluded that a combination of patch testing and intradermal testing is useful in the demonstration of causative agents in delayed-type drug eruptions [6]. Unfortunately, the usefulness of this approach is limited, because the significant antigenic determinants are unknown for most drugs [1]. Moreover, intradermal testing is not always safe. False-negative skin testing may occur because of poor absorption through the skin, because a metabolite rather than the substance administered in the test is the sensitizing antigen, or because testing is performed either too soon after a reaction, in a refractory period, or too late, so that the patient no longer demonstrates skin-test reactivity.

Drug skin tests should be performed 6 weeks to 6 months after complete resolution of the reaction [3]. For patch tests, the commercial form of the drug should be tested diluted at 30% in petrolatum and/or water; the pure drug should be tested diluted at 10%. Lower concentrations are used in severe drug reactions. Sodium lauryl sulphate in the commercial form of some drugs can induce irritation when they are patch tested as such, and positive patch tests to drugs can be related to an excipient rather than the drug itself [4]. It is useful to carry out the test on the site most affected in the initial reaction [10].

Re-elicitation of an exfoliative dermatitis has followed patch testing [9].

Drug prick tests are performed on the volar forearm skin with the commercialized form of the drug, but with sequential dilutions in cases of urticaria. Intradermal tests are performed with sequential dilutions (10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}) of 0.04 mL of a pure sterile or injectable form of the drug. Prick tests and intradermal tests should be read at 20 min and at day 1, and patch tests at day 2 and day 4; these tests also need to be read at 1 week.

The success of skin testing varies with the drug tested, with a high percentage of positive results on patch testing with β-lactam antibiotics, pristinamycin, carbamazepine and tetrazepam, or with β-lactam antibiotics and heparins on delayed readings of intradermal tests. The results of drug skin tests also depend on the clinical features of the adverse drug reaction. Appropriate controls are necessary to avoid false-positive results.

Patch testing

Patch testing in drug eruptions may be helpful in identifying the drug responsible, especially in systemic contact-type dermatitis medicamentosa, photosensitivity (photopatch testing) or fixed drug reactions [1–7]. Positive patch tests have been found overall in about 15% of patients with drug eruptions [1,2] and 25% of patients with penicillin allergy [1–3]. Patch testing in a previously involved site, but not in normal skin, yielded a positive response in a proportion of cases of fixed drug eruption, especially with phenazone (pyrazolone) derivatives (e.g. phenylbutazone), but also with a sulphonamide, doxycycline, trimethoprim, chlormezanone, a barbiturate and carbamazepine [5]. In a series of 30 patients [6], positive reactions were always seen with phenazone salicylate (16 patients) and carbamazepine (three patients), and in one case with chlormezanone. Both positive and negative reactions were seen with trimethoprim (three and two, respectively), doxycycline (two and one) and sulfadiazine (one and one). The vehicle used as a diluent for the drug may be important in determining whether a reaction is seen; use of dimethylsulfoxide as the vehicle may increase the number of positive patch tests [5,8,9]. Topical provocation of fixed drug eruption has also been reported with sulfamethoxazole [10], dimenhydrinate [11] and metronidazole [12]. However, other reports in the literature do not suggest that patch testing is helpful in fixed drug eruption [13].

Patch testing has supported a diagnosis of allergy, in the absence of topical sensitization, to diazepam, meprobamate and practolol [14], anticonvulsants including hydantoin derivatives and carbamazepine [15–17] (but only in patients with exfoliative dermatitis and maculopapular exanthem and not with fixed drug eruption, erythema multiforme or urticaria [16]), tartrazine dyes [18], chloramphenicol [19], diclofenac-induced maculopapular eruption [20], and in TEN induced by ampicillin [21]. Antibiotics (especially penicillin, ampicillin and other β-lactam antibiotics [22,23] and aminoglycosides), NSAIDs (pyrazolone derivatives and occasionally aspirin), neuroleptics (phenothiazines, barbiturates, meprobamate, benzodiazepines), β-blockers, gold salts, carbimazole, amantadine, corticosteroids, mitomycin, heparin and amide anaesthetics have all been associated with positive patch tests in allergic subjects. Positive patch tests to the following drugs have been found in patients with acute generalized exanthematous pustulosis: diltiazem [24,25], metronidazole [26], nystatin [27] and terbinafine [28].

However, care must be exercised, because anaphylactoid responses may occur even in response to the small amounts of drug absorbed from a patch test. Moreover, patch testing has produced exfoliative dermatitis in a patient sensitized to carbamazepine [29] and relapse of a generalized drug eruption in the case of clobazam [30]. A patch test with a solution of the drug will sometimes induce a generalized petechial reaction in patients with purpura caused by drug sensitivity, for example in carbromal or apronalide (Sedormid) purpura.

Penicillin

It is clearly important to exclude from treatment with penicillin those patients truly at risk of developing hypotensive episodes or fatal anaphylaxis. The role of skin testing in this situation has been reviewed [1–12]. Skin tests should be carried out using major-determinant antigens (benzylpenicilloyl polylysine, PPL) and minor-determinant mixture (benzylpenicillin, benzylpenicilloate and benzylpenilloate) antigens [13]. Procedures have been published, and the reader is referred to the original articles for details about methodology [13–15]. Epicutaneous testing should precede intradermal testing, and positive (histamine or opiate) and negative (diluent) controls should be included. False-negative results may be found after a systemic allergic reaction, as a result of a refractory period or temporary desensitization, so that skin testing should be postponed for at least 4–6 weeks [13].

There is a high incidence of wrongly diagnosed penicillin allergy on the basis of history, and a considerable proportion of patients who have had proven allergic reactions to penicillins eventually stop producing the IgE antibody responsible. In a large study, only 1% of 566 patients with a history of penicillin allergy, and negative skin tests to major determinant (PPL) and minor-determinant mixture and its components (potassium benzylpenicillin, benzylpenicilloate and benzylpenicilloyl-*N*-propylamine), had possibly IgE-mediated reactions [4]. In another study [7], 7.1% of 776 individuals with a previous history of penicillin allergy and 1.7% of 4287 subjects negative by history had positive skin tests to major determinant (PPL) and/or a minor-determinant mixture. Positive skin tests were seen in 17% and 12% of patients with a history of anaphylaxis or urticaria, respectively, but in only 4% with a history of an exanthem. Mild adverse reactions to skin tests occurred in 1% of patients positive by history and 9% of those with positive skin tests. In patients with negative skin tests who received benzylpenicillin or ampicillin, mild acute allergic reactions occurred in 0.5% of subjects negative by history and 2.9% of subjects positive by history. Thus, routine penicillin skin testing can facilitate the safe use of penicillin in 90% of individuals with a previous history of allergy [7]. Positive skin tests, an average of 5 years later, to major and minor determinants of benzylpenicillin and/or minor-determinant mixtures of ampicillin, amoxicillin or cloxacillin were found in 19% of 112 patients with a history of urticaria and angio-oedema or exanthem to penicillins and other semi-synthetic penicillins (most frequently ampicillin and amoxicillin) [8]. Skin-test reactivity was limited in about half to the semi-synthetic penicillin reagents derived from ampicillin, amoxicillin or cloxacillin. The existence of isolated skin-test positivity to reagents specific for ampicillin or amoxicillin, with good tolerance of major and minor penicillin determinants, has been confirmed in other reports [9,16,17], emphasizing the necessity for using reagents specific for the side-chains of these aminopenicillin drugs to exclude possible immediate hypersensitivity in patients who reacted to these antibiotics clinically [8–11,16,17]. Thus 7% of 288 patients with a history of penicillin allergy reacted only to skin testing with amoxicillin and not to

benzylpenicillin or phenoxymethylpenicillin diagnostic reagent determinants [16]; these would have been missed if the latter agents had been used alone.

Patients treated with penicillin after a negative skin test to PPL and to minor-determinant mixture develop IgE-mediated reactions only very rarely, and these are almost always mild and self-limited [1,4,7]. Thus, when adequately performed, negative skin tests indicate that the risk of a life-threatening reaction is almost negligible, and that any β-lactam antibiotic may be safely given. In contrast, the risk of an acute allergic reaction, including respiratory obstruction or hypotension, with a positive history and positive skin test is 50–70%; the risk in a patient with a negative history but a positive skin test is about 10% [1,13,18].

Intradermal skin testing is generally safe, with few reactions, and although skin testing may rarely cause sensitization [19], it does not usually do so [13]. However, there is a risk, albeit very small, of fatality from skin testing [20]. A more major problem with skin testing is that use of the major determinant (PPL) alone misses about 10–25% of all positive subjects, and that even addition of benzylpenicillin G as the sole minor-determinant antigen misses 5–10% of positive subjects [21,22]. This is significant because patients with reactivity to minor antigenic determinants are thought to be at a higher risk for anaphylaxis [13,23]. In addition, as detailed above, reagents for detecting sensitivity to aminopenicillins (ampicillin and amoxicillin) should be used [15]. Comprehensive skin testing is therefore only practicable in specialized centres. Skin tests can give both false-positive and false-negative reactions [18]. Thus, it has been argued that a positive or negative result in an individual patient cannot be used to entirely reliably predict outcome [24].

Further difficulties are that skin tests have no predictive value in non-IgE-mediated reactions such as serum sickness, haemolytic anaemia, drug fever, interstitial nephritis, contact dermatitis, maculopapular exanthems or exfoliative dermatitis. Accelerated or late IgE-mediated reactions may occur despite a negative pretreatment skin test [1,13]. Positive intradermal skin-test reactions occurred in only 87% of patients with a history of delayed-type rashes induced by penicillins and cephalosporins and who had positive oral provocation tests [25]. Oral challenge was positive in 18 of 33 patients with positive delayed skin testing and patch testing to ampicillin or amoxicillin, but also in 16 of 27 patients with negative allergy tests [26]. Skin testing is contraindicated where there is a history of exfoliative dermatitis, Stevens–Johnson syndrome or TEN.

There is clearly individual variation in the approach to the diagnosis and management of β-lactam allergy [12], based on a survey of 3500 physician members and fellows of the American Academy of Allergy and Immunology and of allergy training programme directors in the USA. PPL and fresh penicillin G were used for skin testing by more than 86% of both respondent groups, whereas minor-determinant mixtures were used by only 40%. Epicutaneous followed by intradermal injection was the skin-test technique used by 86% of these allergists.

Agents used in general anaesthesia

Intradermal [1–4] or prick [5,6] testing may be helpful in identifying the causative drug [7], and is essential in confirming lack of sensitivity to pancuronium before use in cases of documented sensitivity to other relaxants [3]. In one series of patients with a history of anaphylaxis during induction of general anaesthesia, skin testing was performed by the prick and intracutaneous methods with dilutions of thiobarbiturates, muscle relaxants or β-lactam antibiotics [8]. No patient experienced a recurrence of anaphylaxis during subsequent general anaesthesia when agents producing positive skin tests were avoided, provided a premedication regimen of prednisone and diphenhydramine was given [8].

Local anaesthetics

Avoidance of local anaesthetics on the basis of a vague or equivocal history of a prior adverse reaction may result in substantial increased pain and risk. True allergic reactions probably constitute no more than 1% of all adverse reactions to these drugs, some but not the majority of which are due to preservatives, especially parabens. Skin testing and/or incremental challenge beginning with diluted drug is a safe and effective method for identifying a drug that a patient with a history of an adverse reaction can tolerate [1–7]. Patients with positive patch tests to local anaesthetics and a negative history of anaphylactoid reactions rarely have positive intradermal skin tests. The risk of anaphylactic reactions with amide local anaesthetics (except butanilicaine) is therefore low in such patients [3]. Conversely, patients with anaphylactic reactions to local anaesthetics are usually patch-test negative [3]. Skin testing may produce systemic adverse reactions, especially with undiluted drug. False-positive reactions occur, but false-negative reactions have not been reported, and most skin-tested patients who tolerate a local anaesthetic are skin-test negative to the drug. The choice of a drug for use in skin testing and incremental challenge may be facilitated by current concepts of non-cross-reacting groups of local anaesthetics. Thus, benzoic acid esters, both those with and without *p*-aminobenzoyl groups, do not cross-react with amide local anaesthetic agents.

Analgesics and NSAIDs

Prick tests were positive in only 13% of 117 patients with a history suggestive of anaphylactoid reactions to a variety of mild analgesics including NSAIDs [1].

Heparin

Provocation testing may be a useful diagnostic measure [1–6]. Low-molecular-weight heparin analogues may be satisfactorily substituted in some patients with this reaction, but are not always tolerated [2]. Subcutaneous testing of a panel of heparins, danaparoid and desirudin (hirudin) is recommended for determining acceptable treatment options for patients allergic to specific heparins [3,6]. In type I reactions, or in the presence of skin necrosis with or without heparin-induced thrombocytopenia, a low-molecular-weight heparin should be replaced by danaparoid sodium or hirudin. In the presence of a negative subcutaneous provocation test, the compound can be used with little risk. If all types of low-molecular-weight heparin and danaparoid sodium show positive skin tests, oral anticoagulants should be used, and intravenous injections of any kind of heparin should be avoided because of the potential for anaphylactic shock.

Skin testing in urticaria

Skin tests have been advocated as useful in the investigation of chronic urticaria [1,2]. Patch testing with a series of penicillins was positive in 6.9% of patients in one study [1], and there were positive intracutaneous tests to cilligen and/or penicillin G in 21.5% of patients. Avoidance of dietary dairy produce, which potentially might have contained penicillin, alleviated the urticaria in 50% of the penicillin-allergic patients. The reported prevalence of positive intracutaneous tests to penicillin was much higher in this study than in other reported series in the literature.

In vitro tests

Tests for IgE antibody

The detection of drug-specific circulating antibodies does not prove an allergy. It is important to record when a blood test is taken in relation to the evolution of a drug reaction, as the antibody response to a drug has a finite duration. For example, antipenicillin IgE antibodies begin to disappear within 10–30 days. Radioallergosorbent tests (RASTs) for drug-specific IgE class antibody are available for penicillin, insulin and ACTH. RAST detects specific IgE antibody to the penicilloyl determinant, and is positive in 60–90% of patients with a positive skin test to PPL [1,2]; however, there is no *in vitro* test for minor-determinant antigens, and therefore in practice this test is of very limited use [2,3]. Investigation of cross-reactivity of antibodies to penicillin in 123 patients with a history of penicillin allergy, using enzyme-linked immunosorbent assay, detected IgE antibodies specific to amoxicillin, ampicillin or flucloxacillin, respectively, in three patients [4]. These antibodies did not cross-react with other penicillin antigens, and would have been missed had testing involved only use of benzylpenicillin. Thus, allergy to semi-synthetic penicillins can occur without allergy to benzylpenicillin, negative tests specific for benzylpenicillin or phenoxymethylpenicillin cannot be generalized to other penicillins, and exclusive reliance on benzylpenicilloyl RAST to detect allergy to semi-synthetic penicillins could lead to serious adverse consequences [5]. IgE antibodies specific for 1-phenyl-2,3-dimethyl-3-pyrazoline-5-one were found in 17 of 19 serum samples from individuals sensitive to pyrazoline drugs with 4-amino-antipyrine discs by RAST [6].

Miscellaneous in vitro tests

The histamine-release test [1], basophil degranulation test [2–4] and passive haemagglutination test [5] are of strictly limited use. A positive basophil degranulation assay, which involves binding of drug to specific IgE on the basophil surface, has been reported with penicillin, erythromycin, sulphonamides and aspirin, but false-negative results are common [3,4]. The leukocyte and macrophage migration inhibition tests [6–9], platelet-activating factor release from white blood cells after antigenic challenge as tested by platelet aggregation [10], and the lymphocyte toxicity assay [11–14] are the subject of investigation but are essentially research tools.

A number of drugs have been reported to induce lymphocyte proliferation, as determined by incorporation of ^{3}H-thymidine, in patients with drug eruptions, including penicillin, carbamazepine, phenytoin, furosemide, sulfamethoxazole and hydrochlorothiazide [15–20]. However, in general only low levels of stimulation are observed, perhaps because the antigen responsible for the reaction is a drug metabolite rather than the parent compound, and the significance of the test is difficult to interpret. Addition

of human liver microsomes containing cytochrome P-450 enzymes to the reaction medium of the lymphocyte transformation test, in order to aid generation of potentially reactive drug metabolites, may increase the sensitivity of *in vitro* detection of T-cell reactivity [21,22].

Challenge tests

A drug suspected of causing a drug eruption may be reliably incriminated by the reaction in response to a test dose administered after recovery. However, fatal reactions have occurred to test doses, for example penicillin and quinine, and provocation tests should only be performed in exceptional circumstances [1–6]. A history of Stevens–Johnson syndrome or TEN constitutes an absolute contraindication to drug challenge, and test dosing in reactions of anaphylactic type, blood dyscrasia or SLE-like reaction is seldom advisable. Challenge tests are open to misinterpretation [6], because a very small challenge dose may fail to elicit a reaction that a therapeutic dose would provoke, because of false positives, and because false negatives may occur as a result of a refractory period following a reaction [7].

Test dosing in patients with drug reactions such as fixed drug eruption, which are not potentially fatal, may be helpful [5]. Topical challenge in the form of patch testing in a previously involved site may yield a positive response in a high proportion of such cases [8]. Oral provocation tests using tartrazine, and other food additives such as sodium benzoate, have been advocated for the investigation of chronic urticaria or food intolerance [9–12]. Protocols for the analysis of adverse reactions to foods and food additives have been published [13].

Treatment

Clearly, prevention is better than cure [1,2]. Drugs implicated in a previous reaction should be avoided; the patient should be asked about allergies, and hypersensitivity records in the notes and on prescription charts should be checked. In the case of suspected penicillin allergy, an alternative antibiotic, preferably with a non-β-lactam structure such as erythromycin, should be substituted;

use of griseofulvin should be avoided as it has a 5–10% cross-reactivity based on non-structural mechanisms [2]. However, lack of a positive history does not eliminate the possibility of an allergic reaction, as in the case of penicillin hypersensitivity [3]. Where it is essential to readminister one of a group of drugs to a patient with a previous history of an adverse reaction to a related medication, as with radiographic contrast media and agents used in general anaesthesia, then if possible preliminary skin testing should be carried out to enable identification of safe alternative therapy. In addition, the procedure should be covered by premedication with oral corticosteroids and antihistamines, with or without epinephrine, in order to obtund the onset of an anaphylactic reaction. In the situation where there is no acceptable alternative for an essential drug, then rapid desensitization therapy should be considered.

The approach to treatment of an established presumed drug eruption obviously depends on the severity of the reaction. For many minor conditions, withdrawal of the suspected drug, and symptomatic therapy with emollients, mild to moderately potent topical corticosteroids and systemic antihistamines where indicated, is all that is necessary. When a patient is receiving multiple drugs, it is wise to withdraw all but the essential medications, and to consider substituting alternative non-cross-reacting drugs for the remainder. Because of the wide variety of patterns of drug reaction, it is only possible to summarize the therapy of individual reactions here. The reader is referred to the discussion of the more serious conditions in this book and elsewhere [1–7].

Anaphylaxis

The management of severe acute urticaria and anaphylaxis is detailed in Table 73.21.

Table 73.21 Management of anaphlyaxis.

Stop drug administration
Give 0.5–1 mL epinephrine (adrenaline) 1 in 1000 i.m. immediately
Check airway and give oxygen
Antihistamines
Chlorpheniramine maleate 10–20 mg i.v. *or*
Hydroxyzine 25–50 mg i.m. and four times daily orally *or*
H_1 and H_2 antagonists *or*
Cimetidine 300 mg i.v. 6 hourly
Corticosteroids
Hydrocortisone 250 mg i.v. and 100 mg 6 hourly
Prednisolone 40 mg/day for 3 days
Give i.v. 0.9% NaCl or 5% glucose
Monitor blood pressure and pulse
For bronchospasm
Aminophylline 250 mg i.v. over 5 min and 250 mg in 500 mL 0.9% NaCl over 6 h *or*
Nebulized terbutaline, salbutamol or metaproterenol

Exfoliative dermatitis/erythroderma

The complications of this potentially serious drug-induced condition include hypothermia, fluid and electrolyte loss, infection, high-output cardiac failure, stress ulceration and gastrointestinal haemorrhage, malabsorption and venous thrombosis. The management [1,2] includes maintenance of body temperature and fluid and electrolyte balance, treatment of cardiac failure by use of digitalization and diuretics (avoiding vasodilator drugs), and administration of intravenous albumin for hypoalbuminaemia. If the patient does not respond rapidly to potent topical corticosteroids, prednisolone 40–60 mg/day should be given. This approach also applies to the anticonvulsant hypersensitivity syndrome; oral corticosteroid therapy has been helpful [3,4].

Toxic epidermal necrolysis

See Chapter 74.

Desensitization

It is possible to induce a state of antigen-specific mast cell unresponsiveness, in patients with type I IgE-mediated reactions, if a drug is essential for a patient's well-being and no alternative is available. Desensitization markedly diminishes the risk of anaphylactic reactions but not of non-IgE-mediated reactions; it should only be carried out in an intensive care setting. Mechanisms proposed to explain the development of tolerance following

desensitization procedures include mediator depletion, tachyphylaxis, production of blocking antibodies, or change in the level of specific IgE antibodies.

Desensitization is most frequently carried out for patients with penicillin allergy, with increasing doses of penicillin being administered over 3–5 h [1–3]. The drug is usually given orally; increasing doses are given, starting with a very weak concentration (e.g. one millionth of the therapeutic dose) and working up to a full dose. There have been no severe allergic reactions recorded in patients who completed oral desensitization to penicillin; about 35% experience minor cutaneous reactions including pruritus or urticaria. Although the protection is usually short-lived, tolerance can be maintained by long-term administration of low doses of oral penicillin. Patients with sensitivity to vancomycin [4], 5-aminosalicylic acid [5] and allopurinol [6] have been successfully desensitized.

Patients with HIV infection with previous cutaneous reactions to sulphonamides [7–11] or antituberculous medication [12] have also been desensitized. A 10-day oral desensitization regimen was described for trimethoprim–sulfamethoxazole in 28 HIV-infected patients [8]; 82% were successfully desensitized, and four of the 28 patients had relatively severe rashes (three maculopapular, one erythroderma) during the desensitization phase. Four patients subsequently had rashes 12–33 weeks after desensitization [8].

Chapter 74

Erythema Multiforme, Stevens–Johnson Syndrome and Toxic Epidermal Necrolysis

S.M. Breathnach

Definition and terminology

Clinically, erythema multiforme involves macular, papular or urticarial lesions, as well as the classical iris or 'target lesions', distributed preferentially on the distal extremities. Lesions may involve the palms or trunk, as well as the oral and genital mucous membranes with erosions. Stevens–Johnson syndrome (SJS), first described in 1922, comprises extensive erythema multiforme of the trunk and mucous membranes, accompanied by fever, malaise, myalgia and arthralgia [1,2]. Toxic epidermal necrolysis (TEN; Lyell's syndrome), first described in 1956 [3], is characterized by extensive sheet-like skin erosions with widespread purpuric macules or flat atypical target lesions, accompanied by severe involvement of conjunctival, corneal, irideal, buccal, labial and genital mucous membranes [4,5]. Historically, the three presentations were considered to form a spectrum from mild to fulminatingly severe cases. More recently, there has been a re-evaluation of this concept and a tendency to consider erythema multiforme minor and major as part of one spectrum, often related to (especially herpesvirus) infections and perhaps on occasion to drug reactions, but to separate off SJS and TEN, both of which are more closely linked to drug sensitivities, and which may be regarded as severe variants of a single disease [6–10].

Erythema multiforme major occurs in younger males, frequently recurs, has less fever and milder mucosal lesions, and lacks association with collagen vascular diseases, human immunodeficiency virus (HIV) infection or cancer; herpes simplex is associated with SJS in up to 10% of cases [10]. SJS, with occasional skin blisters and erosions covering less than 10% of the body's surface area, is differentiated from TEN, in which typically sheet-like erosions involve more than 30% of the body surface. However, there are a number of cases (10–20% in adults, and a higher percentage in children) that even experienced clinicians and histopathologists are unable to classify, as they seem to have features of both groups.

There may be significant differences between countries in the clinical classification of severe cutaneous reactions, indicating the need for precise definitions [11]. Thus, the term 'acute disseminated epidermal necrosis (ADEN)' has been proposed [12], with ADEN type 1 corresponding to SJS, type 2 to transitional SJS/TEN with epidermal detachment between 10 and 29% and type 3 to full-blown TEN, while it has even been advocated by Lyell that the term 'exanthematic necrolysis' should replace TEN [13].

Erythema multiforme

Aetiology

Immunology

The clinical picture would seem to be a reaction pattern to many different triggering factors; it appears to have an immunological basis. Human leukocyte antigen (HLA) studies have shown an association with HLA-B62 (B15), HLA-B35 and HLA-DR53 in recurrent cases [1–3]. Immune complexes have been demonstrated, both in the skin and circulation [4,5], autoantibodies against epithelial cells have been demonstrated [6], and autoantibodies against desmosomal plaque proteins desmoplakin I and II, with suprabasal acantholysis, were found in seven of 10 patients with erythema multiforme major [7]. However, these findings are probably simply epiphenomena. The histology suggests delayed hypersensitivity; $CD4^+$ lymphocytes have been found in the dermis and $CD8^+$ cells in the epidermis. Herpesvirus-infected peripheral blood mononuclear cells induced up-regulation of CD54 and major histocompatibility complex class I molecules in adjacent non-infected human dermal microvascular endothelial cells *in vitro*, and consequent increased endothelial binding of peripheral blood mononuclear cells [8]. Herpes simplex virus (HSV) DNA can be identified in lesions of herpes-induced erythema multiforme [9,10]. It has been proposed that peripheral blood mononuclear cells (macrophages or Langerhans' cells) pick up HSV DNA and transport fragments to distant skin sites, leading to recruitment of HSV-specific $CD4^+$ Th1 cells that produce interferon-γ (IFN-γ) [11]. This initiates an inflammatory cascade that includes expression of IFN-γ induced genes, increased sequestration of circulating leukocytes, monocytes and natural killer (NK) cells, and recruitment of autoreactive T cells. By extrapolation, drug hapten-specific T cells could be involved in the pathogenesis of drug-induced erythema multiforme. Peripheral blood mononuclear cells obtained from a patient with carbamazepine-induced erythema multiforme at the time of disease showed increased binding to intercellular adhesion molecule-1^+ (ICAM-1^+) heterologous keratinocytes, and to autologous keratinocytes *in vitro*, which could be inhibited completely by antibodies to lymphocyte function-associated antigen-1 (LFA-1), the ligand for ICAM-1 [12]. Perforin-positive cells may mediate apoptotic cell death in erythema multiforme and SJS [13]. MCP-1, RANTES, macrophage IFN-γ inducible gene (Mig), and IFN-γ inducible protein 10 (IP 10) were expressed by basal keratinocytes above and mononuclear cells within inflammatory foci. These cytokines contribute to the cell-specific and spatially restricted recruitment of mononuclear cells in the acute inflammation of erythema multiforme [14].

Drug induced

Erythema multiforme has been regarded as a well-recognized pattern of adverse cutaneous drug reaction [1–7], although in a prospective study of cases of erythema multiforme only 10% were drug related [2]. In another study, antecedent medication use, especially cephalosporins, was recorded in 59% of erythema multiforme patients and 68% of SJS patients [4]. Often drugs are blamed on inadequate evidence; confirmation of drug sensitivity necessitates re-exposure to the drug, which may carry an unacceptable risk.

Drugs implicated (Table 74.2), often on anecdotal evidence, include sulphonamides and co-trimoxazole, barbiturates, pyrazolone derivatives (phenylbutazone), phenolphthalein, rifampicin, penicillins, hydantoin derivatives, carbamazepine, phenothiazines, chlorpropamide, thiazide diuretics and sulphones. Recent reports have incriminated phenazone, minoxidil, fenbufen, mianserin, sulindac, methaqualone, ceftazidime [8], trazodone [9], progesterone [10], lithium [11], ampicillin [12], amoxicillin [13], vancomycin [14], ofloxacin [15], danazol [16], intradural prednisolone acetate [17], indapamide and sertraline [18], allopurinol [13,19], suramin [20], terbinafine [21,22], fenoterol [23], antiretroviral agents including didanosine [24], griseofulvin [25], celecoxib and rofecoxib [26,27], sulfaguanidine [28], porfirin sodium as part of photodynamic therapy [29], the H_2-blocker roxatidine [30], granulocyte macrophage stimulating factor [31], thalidomide [32] and amfebutamone [33]. Erythema multiforme may follow vaccination [34,35].

Table 74.2 Drugs reported as causing erythema multiforme or Stevens–Johnson syndrome.

Antibiotics
Sulphonamides
  Co-trimoxazole
  Sulfadoxine–pyrimethamine
Sulphones
Penicillins and ampicillin
Cephalosporins
  Ceftazidime
Quinolones
Rifampicin
Tetracyclines
Erythromycin
Thiacetazone

Antifungal or antiyeast preparations
Terbinafine
Griseofulvin
Nystatin

Antiretroviral drugs
Abacavir
Nevirapine

Non-steroidal anti-inflammatory drugs
Salicylates
Fenbufen
Ibuprofen
Sulindac
Paracetamol (acetaminophen)
Pyrazolone derivatives
  Antipyrine
  Phenylbutazone
  Phenazone

Metals
Arsenic
Bromides
Mercury
Gold
Iodides

Anticonvulsants
Barbiturates
Carbamazepine
Hydantoin derivatives
Lamotrigine
Trimethadione

Antihypertensives
Frusemide (furosemide)
Hydralazine
Minoxidil
Thiazide diuretics

Drugs acting on the central nervous system
Danazol
Lithium
Mianserin
Phenothiazines
Trazodone

Miscellaneous
Allopurinol
Chlorpropamide
Codeine
Cyclophosphamide
Methaqualone
Nitrogen mustard
Pentazocine
Phenolphthalein
Progesterone
Topical agents (see text)
Vaccination

Topical agents and erythema multiforme-like reactions

Topical sensitivities reportedly also provoke erythema multiforme. The substances involved are usually potent sensitizers such as *Primula obconica* [1], poison ivy, a variety of weeds [2], diphenyl cyclopropenone and bromofluorene [3–5]. A large number of topical medications can induce erythema multiforme-like eruptions, including balsam of Peru, chloramphenicol, econazole, ethylenediamine, furazolidone, mafenide acetate cream used to treat burns, the muscle relaxant mephenesin, neomycin, nifuroxime, promethazine, scopolamine, sulphonamides, ophthalmic anticholinergic preparations (scopolamine hydrobromide and tropicamide drops), vitamin E, the antimycotic agent pyrrolnitrin, as well as proflavine, budesonide [6], topical nitrogen mustard [7], sesquiterpene lactones in herbal medicine [8], bufexamac [9] and phenylbutazone [10], nitroglycerin patch [11], tea tree oil [12] and a paint-on henna tattoo [13].

Erythema multiforme has also been associated with use of rubber gloves [14] and with blister beetle dermatitis [15]. In addition, contact with a number of environmental substances may induce erythema multiforme-like reactions [16], including nickel, formaldehyde, trichloroethylene, phenyl sulphone derivative, the insecticide methyl parathion, nitrogen mustard, epoxy compounds, trinitrotoluene, cutting oil [17] and bisphenol A [18].

Pathology [1–4]

The most important changes are in the upper dermis and lower epidermis. Some cases have prominent dermal inflammatory changes, with a lymphohistiocytic infiltrate rich in T lymphocytes around blood vessels, oedema and vasodilatation, but little epidermal change. There may also be vacuolar degeneration of the lower epidermis or individually necrotic epidermal cells (Fig. 74.1). Such changes occur especially in classical erythema multiforme with target lesions. In more severe bullous cases, there is more dramatic necrosis of the whole epidermis. Electron microscopy demonstrates the damaged basement membrane in the floor of the bulla, with a few ragged islands of epidermal cells showing some evidence of regeneration. The histology of the oral lesions is similar to that in the

skin, and there may be very marked degenerative changes in the epithelium [5].

Fig. 74.2 Erythema multiforme. Typical target lesions over knuckles.

Clinical features [1–4]

Erythema multiforme can occur at any age, including neonates [5,6] or young children [7]. In general, the course is that of an eruption developing over a few days and resolving in 2–3 weeks. Repeated attacks associated with recurrent herpes simplex are frequent.

Erythema multiforme minor; papular or simplex form. This accounts for approximately 80% of cases. Clinically, macular, papular or urticarial lesions, as well as the classical iris or 'target lesions' (Fig. 74.2), are distributed preferentially on the distal extremities. Lesions may involve the palms or trunk, as well as the oral (Fig. 74.3) and genital mucous membranes. The lesions are dull red, flat or slightly raised maculopapules, which may remain small or may increase in size to reach a diameter of 1–3 cm in 48 h. Typical cases show at least some target (or iris) lesions. Target lesions are less than 3 cm in diameter, rounded and have three zones: a central area of dusky erythema or purpura, a middle paler zone of oedema and an outer ring of erythema with a well-defined edge. Atypical target lesions have only two of the zones. The lesions appear in successive crops for a few days and fade in 1–2 weeks, sometimes leaving dusky discoloration. There may be a few lesions, or they may be very profuse.

Classically, the backs of the hands, palms, wrists, feet and extensor aspects of the elbows and knees are affected;

Fig. 74.3 Erythema multiforme. Mucosal lesions.

less commonly the face. Often the hands are selectively involved. Thus, the typical distribution is acral. The Koebner phenomenon is not uncommon, and accounts for some bizarre distributions. There may be occasional erythematous lesions, erosions or bullae on the mucous membranes. Photoaggravation of erythema multiforme is well recognized [8].

Localized vesiculobullous form. This form is intermediate in severity. The skin lesions present as erythematous macules or plaques, often with a central bulla and a marginal ring of vesicles (herpes iris of Bateman). Mucous membranes are quite often involved. In this type, the skin lesions tend to occur in the classical acral distribution, but may be few in number.

Erythema multiforme major. This is a severe illness associated with more extensive target lesions and mucous membrane involvement. The onset is usually sudden, although there may be a prodromal systemic illness of 1–13 days before the eruption appears.

Atypical cases. Because the diagnosis of erythema multiforme depends on the clinical and pathological appearance, criteria for the diagnosis of atypical cases are difficult to apply. However, there are cases where the clinical picture is atypical but the histology nevertheless shows the characteristic changes. Erythema multiforme-like lesions have been reported in the setting of acute generalized exanthematous pustulosis [9]. Lesions many centimetres across may remain stationary or slowly enlarge over several weeks or months (persistent erythema multiforme) [10,11]. On rare occasions, cases with otherwise typical morphology and histology may develop lesions almost continuously rather than episodically [10]. Erythema multiforme along Blaschko's lines has been reported [12], as has disseminated granuloma annulare following erythema multiforme minor [13].

Rowell's syndrome. This syndrome comprises lupus erythematosus associated with erythema multiforme-like lesions, and immunological findings of speckled antinuclear antibodies, anti-La antibodies and a positive test for rheumatoid factor [14–19]. However, the existence of the syndrome as a defined entity has been questioned [19].

Differential diagnosis

Drug eruptions and lupus erythematosus must be excluded, along with pemphigoid and toxic erythemas of unknown cause. The distinction between atypical erythema multiforme and urticarial vasculitis can be difficult. Kawasaki disease (see Chapter 27) may resemble erythema multiforme, but the characteristic red lips, strawberry tongue, red and swollen palms and soles, and the lymphadenopathy should permit a clinical diagnosis. Differential diagnosis of mouth lesions is considered in Chapter 66.

Treatment [7,20]

Symptomatic treatment only is necessary in the papular and localized bullous forms. Ocular involvement requires the early help of an ophthalmologist. In the more severe cases, good nursing is of paramount importance; such cases may require the sort of attention used for TEN (see below), in a dermatological intensive care unit or burns unit. The value of systemic corticosteroids is still debated [7,20–22], but relief of systemic symptoms such as fever is achieved. For more severe cases, prednisolone at an initial dosage of 30–60 mg/day, decreasing over a period of 1–4 weeks, may be given.

Antiviral therapy with agents such as aciclovir for erythema multiforme following overt herpes simplex infections tends to be disappointing once the eruption has appeared; this is so for recurrent cases, even when given at the very first sign of recurrent herpes. However, long-term prophylactic use may be quite helpful [23–25]. A dosage of 200 mg three times daily may be appropriate, but smaller or larger doses may be needed. Relapses tend to occur when the drug is omitted. It is of interest that some patients who suffer from recurrent erythema multiforme without overt herpes infection are helped by prophylactic aciclovir, implying that recurrent herpes infection may nevertheless be responsible. Aciclovir prevented recurrent polyarthritis associated with erythema multiforme [26].

Thalidomide has been used in a few cases to prevent relapses of recurrent erythema multiforme [27]. Other drugs used have included dapsone [11,28], azathioprine [11] and mycophenolate mofetil [29].

Stevens–Johnson syndrome and toxic epidermal necrolysis

Incidence of reactions

The incidence of TEN has been estimated at 1.2 cases per million per year in France based on nationwide surveillance between 1981 and 1985 inclusive [1]. Another study, based on the data of the Group Health Cooperative of Puget Sound, Seattle, Washington (which covers about 260 000 individuals), investigated hospitalized patients from 1972 to 1986 inclusive. The incidence of erythema multiforme, SJS and TEN was estimated at 1.8 cases per million person-years for patients aged between 20 and 64 years; the incidence for patients aged less than 20 years, and 65 years or more, increased to 7 and 9 cases per million person-years, respectively [2]. The incidence of TEN was estimated at 0.5 per million per year. Reaction rates per 100 000 exposed individuals were as follows: phenobarbital 20, nitrofurantoin 7, co-trimoxazole and ampicillin 3 and amoxicillin 2. An Italian study estimated the incidence of TEN at about 1.2 cases per million per year [3]. A study based on computerized Medicaid billing data for 1980–84 from the states of Michigan, Minnesota and Florida reported an incidence of SJS of 7.1, 2.6 and 6.8 per million per year, respectively; penicillins, especially aminopenicillins, were most frequently implicated [4]. In West Germany, the overall annual risk of TEN and of SJS was estimated over the years 1981–85 as 0.93 and 1.1 per million, respectively; drugs most frequently implicated were antibiotics (sulphonamides and beta-lactam agents), and analgesics and non-steroidal anti-inflammatory agents (NSAIDs) [5]. In this study, it was possible to attribute the cause of the TEN to a drug in 88% of cases. Another study estimated the incidence for West Germany and Berlin for SJS and TEN as up to 1.89 per million inhabitants per year [6]. An ongoing international case–control study of TEN and SJS in relation to the use of drugs is being carried out, based on data collection in France, Italy, Germany and Portugal [7]. The incidence of SJS/TEN with long-acting sulphonamides, sulphones, antibiotics, anticonvulsants, NSAIDs or allopurinol is fortunately rare, occurring only once per 10 000–100 000 courses of drug given [8,9]. The incidence of TEN (cases/million/year) has been reported to be 2.7 times higher, and the fatality twice as high (51% compared with 25%), in the elderly compared with younger adults; the same drugs (NSAIDs, antibacterials and anticonvulsants) are incriminated in both groups [10].

Patients with AIDS have a dramatically increased incidence of TEN [11]; 14 of 80 consecutive cases of TEN patients were HIV infected, and 15 cases of AIDS-associated TEN occurred in the Paris area over a study period, compared with the expected 0.04 cases [12]. Sulphonamides (sulfadiazine, co-trimoxazole, sulfadoxine), clindamycin, phenobarbital and chlormezanone were implicated [12],

as were sulfadiazine and pyrimethamine/clindamycin [13]. Patients with AIDS are more likely to demonstrate multiple cutaneous drug reactions [14].

Aetiology

Immunology

SJS and TEN, like erythema multiforme, would seem to have an immunological pathogenesis. In general, $CD4^+$ T cells predominate in the upper dermis, while epidermal $CD8^+$ T cells and macrophages are variable and Langerhans' cells virtually disappear. Keratinocytes express HLA-DR and ICAM-1, and there is endothelial cell ICAM-1, vascular cell adhesion molecule 1 (VCAM-1) and E-selectin expression [1–7]. $CD3^+$ activated T cells expressing the skin-homing receptor (cutaneous leukocyte antigen, CLA) in both skin and peripheral blood parallel the severity of the disease, and tumour necrosis factor-α (TNF-α), IFN-γ and interleukin-2 (IL-2) are overexpressed in peripheral blood mononuclear cells, suggesting an important role for T cells in TEN [7]. Soluble TNF-α (sTNF-α), sTNF-R1 and sTNF-R2 levels were significantly higher in TEN blisters than in burns [8]. sTNF-R1 and sTNF-R2 were significantly more abundant in TEN blisters than serum, indicating that TNF-α processing was mainly a local event in TEN skin [8]. Significantly higher levels of sIL-2R and lower levels of IL-1α were present in blister fluid, but not serum, of patients with TEN compared with patients with burns [9]. Cytokines released by activated mononuclear cells and keratinocytes may contribute to local cell death in TEN. Prominent involvement of the monocyte–macrophage lineage, including factor $XIIIa^+$ $HLA\text{-}DR^+$ dendrocytes and $CD68^+$ $Mac387^+$ macrophages before, during and especially after epidermal necrosis has been reported [6], with dense labelling of the epidermis for TNF-α. Factor-$XIIIa^+$ dendrocytes appear activated in the skin, and depleted from lymph nodes [10].

Keratinocytes from TEN patients have been reported to undergo extensive apoptosis [11]. Activated lymphocytes might induce apoptosis via an interaction between *Fas* antigen (CD95), expressed by keratinocytes after exposure to IFN-γ, and its ligand *Fas*-ligand (FasL), expressed on the surface of and secreted by lymphocytes [12]. Sera from TEN and SJS patients contained high concentrations of soluble FasL (sFasL), and induced abundant keratinocyte apoptosis *in vitro*, compared with sera from patients with an erythema multiforme-type drug eruption [13]. Moreover, peripheral blood mononuclear cells from TEN and SJS patients secreted high levels of sFasL on stimulation with the causal drug [13].

Alternatively, it has been proposed that keratinocyte necrosis may be mediated by cytotoxic lymphocytes via the perforin granzyme route. The key role of drug-specific T lymphocytes in the mechanisms of most drug reactions has been confirmed by *in vitro* studies of many clones of T lymphocytes [14]. $CD3^+$, $CD8^+$, $CD28^-$, KIR/KAR^+ (killer inhibitory receptor), CLA-positive cells demonstrating cytotoxic T lymphocyte (CTL)- and NK-like cytotoxicity predominated in blister fluid obtained early in one study [15]. In a case of co-trimoxazole-induced TEN, blister fluid lymphocytes were predominantly $CD8^+$, DR^+, CLA^+, $CD56^+$ perforin-positive T lymphocytes, cytotoxic only in the presence of the drug towards autologous Epstein–Barr virus (EBV) transformed lymphocytes and allogeneic cells sharing HLA-Cw4 [16]. Cytotoxicity occurred in the presence of either co-trimoxazole, sulfamethoxazole, or the nitroso metabolite of sulfamethoxazole, but not with the hydroxylamine metabolite of sulfamethoxazole. In a patient with carbamazepine-induced TEN, lymphocytes were more susceptible to cytotoxic killing by liver microsome-induced carbamazepine intermediates than by the parent drug [17].

Inducible nitric acid synthase is demonstrable in skin in TEN/SJS, which might indicate that nitric oxide mediates

apoptosis and necrosis [18]. The matrix metalloproteinase MMP2 has a significant role in epidermal detachment, inflammation and re-epithelialization. Increased levels of the activated forms of MMP2 were higher in TEN blister fluid compared with bullous pemphigoid, second-degree burns or suction blisters, indicating a potential role for MMP2 in the inflammatory reaction and repair process in TEN skin [19].

The reason why some individuals develop such marked immune reactions against medications is unknown. A widely accepted hypothesis is that patients suffering from severe drug reactions are exposed to increased amounts of reactive (oxidative) metabolites because of decreased production of normal soluble non-toxic metabolites, and/or a lowered ability to detoxify reactive metabolites [20]. Alteration in detoxification enzymes could be explained on a genetic basis (e.g. slow acetylation genotype) or on a functional basis (e.g. enzyme dysfunction in AIDS or other diseases). This 'reactive metabolites' hypothesis for drug eruptions still lacks definitive proof.

Drugs implicated in Stevens–Johnson syndrome

Drugs potentially causing SJS are listed in Table 74.2 [1–8]. A retrospective study from Malaysia reported that the most common causes of SJS were sulphonamides, tetracycline and the penicillin derivatives [8]. In the USA, NSAIDs were reported to be an important cause [9]. Severe SJS-like reactions have been described resulting from sulphonamides with or without trimethoprim [10–12] and following malaria prophylaxis with Fansidar (pyrimethamine and sulfadoxine) [13,14]. Patients with AIDS are at an increased risk of developing severe SJS reactions to co-trimoxazole and thiacetazone [15–17]. The culprit drugs in a study from Thailand included the following: antibiotics (penicillin, sulphonamides, tetracycline, erythromycin); anticonvulsants (phenytoin, carbamazepine, barbiturates); antitubercular drugs (thiacetazone); analgesics (acetylsalicylic acid, fenbufen); sulphonylurea; and allopurinol. The total mortality rate was 14%: 5% for SJS and 40% for TEN [7]. Data from surveillance networks in France, Germany, Italy and Portugal on 245 people hospitalized because of SJS or TEN [18] indicated that for drugs usually used for short periods, relative risks were increased as follows: co-trimoxazole and other sulphonamide antibiotics 172, chlormezanone 62, aminopenicillins 6.7, quinolones 10 and cephalosporins 14, and for paracetamol (acetaminophen) 0.6 in France but 9.3 in the other countries. For drugs used for months or years, the increased risk was largely in the first 2 months, and was as follows: carbamazepine 90, phenobarbital 45, phenytoin 53, valproic acid 25, oxicam NSAIDs 72, allopurinol 52 and corticosteroids 54. For many drugs, including thiazide diuretics and oral hypoglycaemic agents, there was no significant increase in risk. The excess risk did not exceed five cases per million users per week for any of the drugs. Acetylsalicylic acid and other salicylates are not associated with a measurable increase in the risk of SJS or TEN [19].

Other drugs implicated in SJS include the antiretroviral drugs nevirapine [20–23] and abacavir [24], lamotrigine

[25], terbinafine [26], nystatin [27], ciprofloxacin [28], the antimalarials mefloquine [29] and hydroxychloroquine [30], cyclophosphamide [31], methotrexate [32], rituximab [33], the specific tyrosine kinase inhibitor STI571 used in leukaemia therapy [34], propylthiouracil [35], ranitidine [36], mebendazole and metronidazole [37], bezafibrate [38], diltiazem, nifedipine and verapamil [39], sertraline [40], fluoxetine and fluvoxamine [41] and tetrazepam [42]. SJS has followed vaccination [43], ingestion of a health drink (Eberu) containing ophiopogonis tuber [44] and use of cocaine [45].

Drugs and other factors implicated in toxic epidermal necrolysis

There is a degree of overlap between SJS and TEN; SJS may evolve into TEN, and several drugs can produce both entities (Tables 74.2 & 74.3) [1–17]. A large number of

Table 74.3 Drugs causing toxic epidermal necrolysis.

Antibiotics	*Anticonvulsants*
Sulphonamides	Barbiturates
Co-trimoxazole*	Phenobarbital*
Sulfadoxine	Carbamazepine*

Piroxicam*	Allopurinol*
Tenoxicam*	Chlorpromazine
Isoxicam	Dapsone
Diclofenac†	Gold
Fenbufen	Nitrofurantoin
Salicylates	Pentamidine
Naproxen	Tolbutamide
Pyrazolon derivatives	Vaccination

* Definite high risk.
† Probable low-risk association.

different drugs have been implicated anecdotally, but the most common triggers (Table 74.3) include antiepileptic drugs (phenytoin, barbiturates, carbamazepine and lamotrigine [18–20]), sulphonamides and trimethoprim [21], ampicillin and other β-lactam antibiotics [22], allopurinol [23], NSAIDs (especially pyrazolon derivatives, e.g. phenylbutazone, and oxicam derivatives) [23] and pentamidine. A high proportion of adult cases of SJS or TEN related to anticonvulsants occur in patients receiving radiotherapy for brain tumour. It is suspected that cancer and/or radiotherapy increases the risk.

In France, a survey showed two main classes of drug were most often responsible: antibacterial agents (especially sulphonamides); NSAIDs including oxyphenabutazone, and fenbufen; and phenytoin [24]. The incidence of erythema multiforme, SJS and TEN in a US series with the following drugs were reported as follows: phenobarbital 20, nitrofurantoin 7, co-trimoxazole and ampicillin each 3, and amoxicillin 2, per 100 000 exposed patients [7]. Review of the English language literature from 1966 to 1987 suggested that allopurinol, NSAIDs, phenytoin and the sulphonamide antibiotics were most frequently responsible [25]. A study from the USA reported that penicillins, especially aminopenicillins, were most frequently implicated [9]. In West Germany, drugs most frequently implicated were antibiotics (sulphonamides and β-lactam agents) and analgesics and NSAIDs [10]. In India, by contrast, one-third of cases were the result of drugs used for the treatment of tuberculosis, especially thiacetazone and isoniazid [26]. The absolute incidence of phenytoin-induced TEN is very low, with nine cases reported in the USA over a decade, compared with 2 million Americans who took phenytoin [11]. Similarly, 4 in 232 390 patients on co-trimoxazole developed erythema multiforme or SJS, while only 1 in 196 397 prescribed cephalexin developed TEN [21]. The risk of SJS/TEN is highest in the first 8 weeks of therapy with phenytoin, phenobarbital, carbamazepine and lamotrigine; the risk with valproic acid is less [27]. Terbinafine [26–28] and antiretrovirals including nevirapine [29] have also been associated with TEN. In Europe, nevirapine has replaced sulphonamides as the leading cause of SJS and TEN related to AIDS [30]. By contrast, the following medications are not associated with a moderate or high risk of causing TEN: contraceptive pills, benzodiazepines, thiazide diuretics, sulphonylurea antidiabetics, angiotensin-converting enzyme inhibitors, β-blockers, acetyl salicylic acid and fibrate cholesterol-lowering agents [17].

More than 100 different medications have been reported as having caused TEN, but case reports are of limited significance because publications are biased toward 'original' and new associations. Nonetheless, other antibiotics, antifungals and antiprotozoal drugs incriminated include ciprofloxacin [31,32], vancomycin [33,34], ofloxacin [35], thiacetazone [36], fluconazole [37], griseofulvin [38,39], Fansidar [40] and foscarnet [41], as well as the antimalarials mefloquine [42] and hydroxychloroquine [43]. Miscellaneous causes include fluoxetine and fluvoxamine [44,45], tetrazepam [46], diltiazem, nifedipine and verapamil [47], thalidomide [48], methotrexate [49,50], cytosine arabinoside [51], IL-2 [52], etretinate [53], omeprazole [54], ranitidine [55], famotidine [56] and cimetidine [57], atorvastatin [58], valdecoxib and celecoxib [59,60]. Even acetaminophen (paracetamol) has rarely been recorded as causing TEN [61].

Immunization with diphtheria–pertussis–tetanus (DPT), measles, poliomyelitis, smallpox and influenza vaccines has been recorded as a cause of TEN [11,62,63]. Single cases of TEN have followed use of the radiological contrast media diatrizoate solution for excretory pyelography [64] and iopamidol for cardiac catherization [65], use of a terconazole vaginal suppository [66] and contact with a toxic fumigant, acrylonitrile [67]. TEN has been described in association with graft-versus-host reactions [68,69] and with lupus erythematosus [70]. It is not yet clear whether SJS and TEN are always drug-induced or may have other causes. A few well-documented cases have been attributed to *Mycoplasma pneumoniae* or *Klebsiella pneumoniae* infections.

Pathology

The histology of early lesions is characterized by moderate perivascular mononuclear cell infiltration in the papillary dermis, with epidermal spongiosis and exocytosis. Satellite cell necrosis, with close apposition of mononuclear cells to necrotic keratinocytes, may be seen. In established TEN (Fig. 74.4), there is full-thickness necrosis of the whole epidermis with blister formation. The necrotic process involves the epithelial lining of sweat ducts, while hair follicles are much less affected. There is little in the way of any dermal abnormality. Macrophages and dendrocytes with a strong immunoreactivity for TNF-α predominate in a cell-poor infiltrate [1]. TEN may be rapidly differentiated from the staphylococcal scalded skin syndrome (SSSS), in which blister formation results from intraepidermal subcorneal splitting caused by a toxin produced by *Staphylococcus aureus* group II, phage type 71, by examination of frozen sections of blister roof material [2,3]. The level of splitting is subcorneal in SSSS, while in TEN it is much lower, because the full thickness of the necrotic epidermis forms the roof of the blister. Differentiation from graft-versus-host disease may be difficult [4]. Direct immunofluorescence is negative, with the exception of a possible 'lupus band test' in cases associated with SLE.

Clinical features

Stevens–Johnson syndrome [1–6]

SJS is a severe illness of usually sudden onset, associated with marked constitutional symptoms of high fever, malaise, myalgia, arthralgia and extensive erythema multiforme of the trunk, with occasional skin blisters and erosions covering less than 10% of the body's surface area.

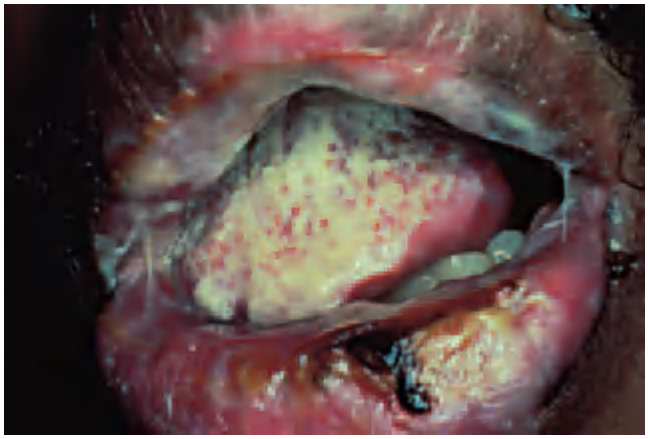

Fig. 74.5 Stevens–Johnson syndrome. Severe erosions at the lips.

Fig. 74.6 Toxic epidermal necrolysis showing dusky erythema and stripping off of necrotic epidermis.

A prodromal systemic illness lasting 1–13 days before the eruption may occur. The skin lesions are variable in extent, and consist of typical maculopapular lesions of erythema multiforme, bullous or, rarely, pustular lesions. New crops of lesions develop over a period of 10 days, or sometimes 3–4 weeks. There is significant involvement of mucous membranes: the frequency in one review of 81 cases was oral mucosa 100%, eyes 91%, male genitalia 57% and anal mucous membrane 5%, while bronchitis and pneumonitis occurred in 6% and 23% of cases, respectively [6].

The oral mucous membrane shows extensive bulla formation followed by erosions and a greyish white membrane, so that the mouth and lips show characteristic haemorrhagic crusting (Fig. 74.5) [7]. The most common change in the eyes is a severe catarrhal or purulent conjunctivitis, but bulla formation may occur. Corneal ulceration is frequent, and anterior uveitis or panophthalmitis may occur. The eye changes often regress completely, but synechiae, corneal opacities and rarely blindness are possible sequelae. Genital lesions are frequent; retention of urine may occur, as may involvement of the bladder. Respiratory symptoms may occur, and often the radiological changes within the lungs are far greater than the symptoms. Abnormalities of liver function may be present. Renal involvement with haematuria or even renal tubular necrosis has been reported and may lead to progressive renal failure. Less common symptoms include diarrhoea, paronychia, shedding of nails, polyarthritis and otitis media. Untreated, this disease used to have a mortality of 5–15% from infection, toxaemia or renal damage, but the mortality rate is now lower. The eruption usually heals without sequelae, although the eyes may be permanently damaged.

Toxic epidermal necrolysis [8–17]

SJS should be differentiated from TEN, in which typically sheet-like erosions involve more than 30% of the body surface with widespread purpuric macules or flat atypical target lesions, and in which there is severe involvement of conjunctival, corneal, irideal, buccal, labial and genital mucous membranes [8–10]. SJS may, however, evolve into TEN.

Clinically, TEN presents with a prodromal period with flu-like symptoms (malaise, fever, rhinitis and conjunctivitis), sometimes accompanied by difficulty in urination, which usually lasts 2–3 days; however, it may last from 1 day to 3 weeks before signs of skin involvement develop. The acute phase of TEN is characterized by persistent fever, severe mucous membrane involvement and generalized epidermal sloughing to leave large raw painful areas, and lasts from 8 to 12 days. There may be an initial 'burning' maculopapular, urticarial or erythema multiforme-like eruption. This may start on the face and on the upper part of the body and rapidly extends. Most frequently, the initial individual skin lesions form poorly defined macules with darker purpuric or blistering centres, progressively merging on the chin, upper parts of chest and back. Less frequently, the initial manifestation may be a more confluent erythema. Sometimes the lesions are predominantly in photoexposed areas.

There is rapid progression to areas of confluent erythema, often starting in the axillae and groins, followed by blistering and sloughing of large areas of skin (Fig. 74.6). Nikolsky's sign, the ability to extend the area of superficial sloughing by gentle lateral pressure on the surface of the skin at an apparently unaffected site, may be positive. Detachment of the full thickness of the epidermis at sites of pressure or trauma, such as the back, shoulders or buttocks, leaves a dark red oozing dermis. In other areas, the pale necrotic epidermis remains *in situ*, with a wrinkled appearance. Blisters on the palms and soles may remain intact. However, the entire skin surface may be involved, with up to 100% of the epidermis sloughing off. Only the

Acute	Chronic
Similar to burns: depends on extent	*Ocular complications* (up to 35%)
Massive fluid and electrolyte loss (3–4 L/day)	Conjunctivitis, ectropion or entropion, corneal scarring
Prerenal renal failure	Symblepharon, Sjögren-like sicca syndrome
Bacterial infection and septicaemia	*Other mucous membrane involvement*
Hypercatabolism: insulin resistance	Oesophageal stricture
Diffuse interstitial pneumonitis	Phimosis
Mucous membrane involvement	Vaginal synechiae
	Oro-genital ulcers
	Miscellaneous
	Wound infection
	Pigmentary changes
	Nail dystrophy
	Hypohidrosis
	Scarring alopecia
	Contractures
	Development of melanocytic naevi

Table 74.4 Complications of toxic epidermal necrolysis.

hairy portion of the scalp is never affected. The process tends to occur in waves, over a 3–5-day period (sometimes a week), but involvement of the whole of the body surface occurs within 24 h in approximately 10% of cases.

Mucous membranes (particularly the buccal, and less commonly the conjunctival, genital, perianal, nasal, tracheal, bronchial, pharyngeal and oesophageal membranes) are involved in nearly all patients (85–95%). Widespread painful erosions cause crusted lips and increased salivation, and redness and soreness of the eyes is conspicuous, with photophobia. Mucous membrane lesions may precede the skin lesions by up to 3 days in one-third of cases [10]. Urethritis develops in up to two-thirds of patients, and may lead to urinary retention. Stomatitis and mucositis lead to impaired oral intake with consequent malnutrition and dehydration. Intestinal involvement has been documented [12]. Healing occurs by re-epithelialization; this may occur within a few days on the anterior thorax, but is slower on the back and at intertriginous areas. Most patients' skin lesions are completely healed in about 3–4 weeks, but mucosal lesions take longer and the glans penis may take up to 2 months to heal over.

Investigations. Approximately 50% of patients have a slight increase in aminotransferases, and approximately 10% have overt hepatitis. A rise in serum amylase is often present during the first few days, probably secondary to involvement of salivary glands. Anaemia is constant after a few days, and lymphopenia is usual, with a selective and transient depletion of $CD4^+$ T lymphocytes. Neutropenia is observed in approximately 30% of patients, and thrombocytopenia in 15%; eosinophilia is very unusual. Hypophosphataemia is nearly constant, and hyperglycaemia is frequent, as are increased urea and creatinine levels. Subclinical interstitial oedema is often noted on early chest X-rays.

Complications (Table 74.4). Acute complications are similar to those of extensive burns. The total daily fluid loss averages 3–4 L in adult patients with TEN affecting 50% of body surface area. It induces a reduction of intravascular volume and functional renal failure. If not corrected, hypovolaemia may lead to haemodynamic alterations and organic renal failure. Pneumonia or pneumonitis occurs in up to 30% of patients, contributed to by sloughing of the tracheobronchial tree [18]. Adult respiratory distress syndrome (ARDS) is one of the main complications. Anaemia or leukopenia, caused by selective depletion of $CD4^+$ helper T cells, is moderately common [16]. Oesophageal and intestinal erosions, with an endoscopic appearance reminiscent of ulcerative or pseudomembranous colitis, are recorded [19]; strictures may result. Disseminated intravascular coagulation is documented. Septicaemia, primarily the result of *Staphylococcus aureus* or *Pseudomonas* but on occasion caused by Gram-negative organisms or *Candida*, may result from infection of the skin, lungs, urinary tract catheters and intravenous (especially central) lines. Patients are usually febrile and shivering, even in the absence of infection. Hypothermia is infrequent and usually a marker of severe infection and irreversible septic shock. Protein loss, from skin lesions and increased catabolism, may reach 150–200 g/day. Inhibition of insulin secretion and/or insulin resistance in peripheral tissues is frequent, resulting in elevated plasma glucose levels and glycosuria.

Mucocutaneous complications of TEN [20,21] include wound infections, pigmentary changes (either hyper- or hypopigmentation) which may or may not resolve with time, nail shedding or dystrophy, hypohidrosis or hyperhidrosis, scarring alopecia and hypertrophic scarring which may lead to contractures. Development of melanocytic naevi has been reported [22]. Mucosal involvement may lead to chronic xerostomia, oesophageal strictures,

phimosis, and chronic oro-genital erosions or vulvovaginal stenosis [23]. Appearances may resemble scarring from cicatricial pemphigoid or lichen planus.

Ocular complications occur in 40–50% of survivors [16], and include conjunctivitis, watery eyes because of tear duct obstruction, pseudomembrane formation, photophobia, ectropion, entropion with trichiasis, symblepharon and corneal vascularization, corneal opacities, and corneal ulceration and scarring [19]. Blindness may result. Lacrimal duct destruction may result in xerophthalmia. A Sjögren-like sicca syndrome may be seen [24]. A 'post-SJS/TEN' ocular syndrome with punctuate keratitis and formation of a corneal pannus may result in photophobia, burning eyes and visual impairment. Ankylosymblepharon (fusion of eyelids to each other and to the globe) may follow secondary infection.

Prognosis

There is an appreciable mortality as a result of TEN, increasing from 5% in SJS, to 10–15% in transitional SJS–TEN and 30–40% in TEN. ARDS and multiple organ failure are the usual causes of death [1]. They are often precipitated by sepsis with septicaemia, mainly resulting from *Staphylococcus aureus* and *Pseudomonas aeruginosa* [2]. Other causes of death are pulmonary embolism and gastrointestinal bleeding. Early withdrawal of the causative drug improves the prognosis, and drugs with a long half-life are associated with an increased risk of death [3,4]. Increased age in most [5] but not all [1] studies, extensive TEN, delay (more than 3–4 days) in referral to a regional centre [6], early thrombocytopenia and early empirical antibiotic treatment elsewhere are associated with a worse prognosis. It has been claimed that severe granulocytopenia is a poor prognostic indicator [7], although this has been disputed on the basis that lymphopenia is more usually found in severe TEN [8]. A specific severity-of-illness score to determine prognosis for cases of TEN (SCORTEN) based on seven independent risk factors for death as assessed on the first day of hospitalization, has been advocated (Table 74.5) [9].

Table 74.5 SCORTEN prognosis score.

*Parameter**
Age > 40 years
Presence of a malignancy
Epidermal detachment > 30%
Heart rate > 120/min
Bicarbonate < 20 mmol/L
Urea > 10 mmol/L
Glycaemia > 14 mmol/L

1 point awarded for each parameter; SCORTEN derived by totalling scores

SCORTEN	Probability of death (%)
0–1	3
2	12
3	35
4	58
≥ 5	90

* Worst recorded value in the 24 h after admission.

Diagnosis

Toxic shock syndrome, which usually occurs in menstruating women, may cause widespread erythema and desquamation, but skin tenderness and bullae are absent. Similarly, SSSS can generally be differentiated on clinical appearances and on the basis of histology. Linear IgA bullous dermatosis, whether idiopathic or drug-induced (e.g. vancomycin), may mimic TEN clinically [1], as may a widespread bullous fixed drug eruption [2,3]. The subcorneal aseptic pustules of acute generalized exanthematous pustulosis (AGEP) or acute pustular psoriasis (von Zumbusch) are usually distinctive but may coalesce to produce extensive superficial detachment mimicking TEN. Paraneoplastic pemphigus may closely resemble SJS, but direct immunofluorescence is positive.

Identification of the responsible drug is often difficult, because patients frequently take more than one medication (an average of 4.4 in one series) [4,5]. A helpful guideline is that most drugs that cause TEN have been first given between 1 and 3 weeks previously [6–8]; another very suggestive guide is that of recurrence within 48 h on administration of a drug previously recorded as having caused a similar reaction. A given drug is unlikely to be responsible for TEN if it was first given 24 h previously, or if the duration of treatment exceeds 3 weeks [4,7]. In case–control analyses, the risk with drugs used on a long-term basis was restricted to the first few weeks [8]. However, phenytoin-induced TEN may occur any time between 2 and 8 weeks after initiation of therapy, and may progress despite discontinuation of phenytoin days or weeks earlier [9]. Skin testing is unfortunately unreliable. Relevant positive patch tests were found in only 9% of 22 patients with SJS/TEN, compared with 50% of 14 patients with AGEP [10]. The *in vitro* lymphocyte transformation test is of no value [11]. In summary, there is no reliable test to confirm the aetiological role of a given drug in an individual case [6]. Re-exposure to drugs suspected of causing a reaction has resulted in fatality, and should not be carried out for diagnostic purposes [12].

Treatment [1–10]

The management of TEN is summarized in Table 74.6, and is perhaps best carried out on a dermatology intensive care or a burns unit. Clearly, presumptive causative drugs should be stopped as soon as possible. It should be remembered that HIV-1 infected patients with TEN are an occupational risk for health care workers [11]. The main principles of symptomatic therapy are the same as for major burns and include fluid replacement, anti-infectious therapy, aggressive nutritional support, warming of environmental temperature and skin care with appropriate dressings. The extent of the detachment of the epidermis should be evaluated daily as a major prognostic factor. It is expressed as a percentage of body surface area (BSA), using burn tables or the simple rule that one hand (palm and fingers) corresponds to 1% of the BSA. Hyperventilation and mild hypoxaemia on blood gas analysis indicate a high risk of progression to ARDS.

There is a significant incidence of disabling long-term complications in survivors, especially in relation to ocular and other mucous membranes. It is therefore particularly important to be aware of these and to take preventative

Table 74.6 Management of toxic epidermal necrolysis.

Intensive therapy or burns unit
Air-fluidized bed
Maintain fluid and electrolyte balance (replace up to 5 L/day)
Maintain body temperature
Maintain nutrition; oral hygiene
Frequent ophthalmological assessment
Antiseptic/antibiotic eye drops 2-hourly
Disrupt synechiae frequently
Limitation of infection
Neutropenia: reverse barrier nursing
Frequent cultures of erosions, and blood cultures
Culture tips of Foley catheters and intravenous lines
Prophylactic broad-spectrum systemic antibiotics (controversial)
Topical cleansing/antibacterial agents
0.5% silver nitrate solution on gauze *or* 10% chlorhexidine gluconate washes *or* saline washes *or* polymixin/bacitracin *or* 2% mupirocin
Avoid silver sulfadiazine
Wound care
Remove necrotic epidermis (controversial)
Paraffin gauze or hydrogel dressings
Biological dressings (xenografts, allografts, skin substitutes)

measures. Physical contact with patients during nursing procedures may produce loss of large sheets of skin, and the use of a turning frame or a ripple or air-fluidized bed will lessen discomfort and facilitate nursing care. Trauma, as with adhesive dressings or ECG electrode attachment pads, should be minimized. Eyelids and conjunctivae should be lubricated with soft paraffin, and gently separated to prevent the formation of adhesions. Opthalmological advice should be sought. Use of gas-permeable scleral contact lenses resulted in improved quality of life in 90% of patients by reducing photophobia and discomfort, and also improved visual acuity and healed corneal epithelial defects in 50% of patients [12]. Amniotic membrane has been used as a dressing for eye lesions in TEN [13]. Autologous germinal cells taken from the limbus and grafted on a support of amniotic membrane may be beneficial in the most severe cases [14]. Skin or other infection must be treated promptly. Good mouth care is important in preventing parotitis. Vaginal examination should be repeated in women and appropriate dressings used to avoid synechiae if erosions are seen. The issue of whether necrotic tissue should be removed is controversial; some authorities feel that this impairs healing. Eroded areas should be treated with biological [15] or synthetic dressings. Use of silver nitrate impregnated dressings [16] has been advocated.

There is no consensus on the merits of therapy with moderately high-dose corticosteroids for TEN. Some authorities maintain that high-dose steroid therapy promotes or masks the signs of infection, delays healing, precipitates gastrointestinal bleeding, prolongs hospitalization and increases mortality [1,2,17–19]. However, others favour steroid therapy on the basis that it may reduce inflammation and keratinocyte necrosis [20]. It is generally agreed that if steroids, or any other immunosuppressive agent, are to be given, then they should be administered as early as possible in the evolution of the disease. There have been anecdotal reports on the beneficial use of plasmapheresis [21–23], but this has been questioned [24]. Both cyclophosphamide [25] and ciclosporin A [26–28] have produced improvement in anecdotal cases. Thalidomide therapy for TEN was associated with increased mortality [29]. *N*-acetyl cysteine has been documented to be useful in a few patients [30], perhaps because it enhances drug metabolism. On the basis that potential *Fas* (CD95) -mediated keratinocyte death in TEN might be blocked by naturally occurring *Fas*-blocking antibodies included in human immunoglobulin preparations, there have been several reports, mostly favourable, on human intravenous immunoglobulin (IVIG) therapy for TEN [31–39]. Early infusion of high-dose (1 g/kg/day for 3 days in adults) IVIG appears safe and well tolerated, but there may be variations in the efficacy of different batches of IVIG [36]. However, a recent report found no benefit from IVIG therapy [38], and there is currently no consensus on the best management for TEN [40]. There has been a single case report on the efficacy of treatment with monoclonal chimeric IgG anti-TNFα antibodies [41]. Because of the rarity of the condition, controlled trials assessing these different treatment approaches are very difficult to carry out.

Prevention and future use of drugs

Patients should be advised to avoid re-exposure to the suspect drug(s). Published cases of recurrences have all been attributed to the same generic drug or to compounds chemically closely related (e.g. aromatic anticonvulsants). Therefore, there is no rationale for restricting the use of all classes of 'high-risk drugs'. Because some familial cases have been reported, first-degree relatives should be alerted to their elevated risk of reaction to the same drug(s). Cases should be notified to regulatory agencies.

Chapter 75

Topical Therapy

J. Berth-Jones

Dermatologists have the good fortune to work on the most accessible organ of the body. This gives us numerous advantages and greatly facilitates not only the diagnosis but also the treatment of skin disease. While systemic administration of drugs is often necessary in dermatology, many inflammatory and neoplastic conditions can be effectively managed using the wide range of externally applied physical or pharmacological modalities that are available, the latter being the subject of this chapter. Some of these are time-honoured treatments which have been used for a century or more, while others belong to the ever-expanding range of newer and increasingly potent agents constantly being developed and formulated for topical use.

Topical treatment offers the potential to achieve high concentrations of a drug in the skin with minimal exposure of other organs. This can greatly increase efficacy and also safety relative to systemic administration. When side effects do occur, they are most likely to take the form of localized reactions.

Prescribing topical treatment

Prescribing topical medication requires careful consideration of several factors if optimal results are to be achieved. When the treatment contains an active pharmaceutical agent it is necessary to specify the concentration of the drug, the vehicle and the frequency of application. The patient requires advice on the quantity to be used, precisely where it should be applied and often further explanation about precise timing of application in relation to bathing and other treatments. The prescriber needs to be aware of the hazards associated with a topical treatment, particularly the likelihood of the medication inducing irritant or allergic reactions. It is also important to understand the factors that influence systemic absorption.

Drug concentration

The conventions for defining the concentration of a drug in topical formulations are summarized in Table 75.1. The efficacy of a topically applied drug is usually not proportionate to the concentration. Doubling or halving the concentration of a drug often has a surprisingly modest effect on the response. In the case of topical corticosteroids, for example, different concentrations of active drug often have a similar biological effect [1]. However, the effect of changing the concentration in an individual case may be much greater than the apparent effect when two concentrations are compared in a clinical trial. There may also be differences between adults and children. The difference in efficacy between two concentrations of tacrolimus for example, appears to be larger in adults than in children.

Table 75.1 Prescribing conventions for specifying concentration.

1 The concentration of a drug contained in a topical medication is usually written as a percentage representing the proportion of the formulation, by weight, which is the active constituent. A concentration of 1% indicates that 1 g of drug will be contained in 100 g of the formulation. A wide range of concentrations can be specified in this way. Thus, salicylic acid may be used in concentration as high as 60% for treatment of plantar warts or corns, whereas calcitriol is used at a concentration of 0.003% in treatment of psoriasis. A very low concentration such as this is more often written as 3 μg/g

2 A frequently used alternative, especially for liquid preparations, is to express the percentage of the drug as a proportion of the volume of the formulation. Thus, a 1% solution contains 1 g of drug in 100 mL of the formulation. The abbreviations w/w (weight in weight) and w/v (weight in volume) are often employed to indicate which convention is being used

3 Another convention often used to describe the concentration of a solution is in 'parts'. Thus, a 1 part in 1000 solution of potassium permanganate contains 1 g in 1 L of solution, which could be expressed as 0.1% (w/v)

Choice of vehicle

Topical medication must be applied to the skin in a suitable vehicle. This term encompasses all the constituents of the formulation apart from the active pharmaceutical agent. The properties of some types of vehicle are summarized below. The choice of vehicle depends on the anatomical site to be treated and the condition of the skin. As a rule, acutely inflamed skin is best treated with fairly bland preparations, which are least likely to irritate. Moist or exudative eruptions are conventionally treated with 'wet' medications such as lotions or creams, while dry skin responds well to the occlusive action of ointments. Hair-bearing skin, especially the scalp, can be treated with medicaments formulated into shampoos, lotions, gels or mousses. The cosmetic properties of the vehicle assume particular importance when treating the face. Oily skin affected by acne is often best treated with lotions, while the more sensitive skin affected by rosacea may benefit from the emollient effect of a cream.

The characteristic features of various types of formulation are as follows (British Pharmacopoeia; BP).

Ointments. These are semi-solid vehicles composed of lipid; for example, white soft paraffin BP (petrolatum). They have useful occlusive and emollient properties. Some ointments contain emulsifying agents such as polyhydric alcohols (macrogols, polyethylene glycol) or cetostearyl alcohol (e.g. Emulsifying Ointment BP). The latter have the advantage of being less greasy, with good solvent properties, and are easily washed off. Ointments require fewer preservatives than other vehicles because they contain no water and do not sustain growth of microorganisms.

Creams. These are semi-solid emulsions containing both lipid and water. Emulsions are suspensions, either of lipid droplets in water or of water droplets in lipid (see emulsifiers, p. 75.7). In the former category are aqueous or vanishing creams (e.g. Aqueous Cream BP). These are water-miscible, cooling and soothing, and are well absorbed into the skin. In the latter category are water-in-oil creams (e.g. Oily Cream BP). These are immiscible with water and more difficult to wash off. They are emollient, lubricant and mildly occlusive (but less so than ointments).

Pastes. These are semi-solid preparations containing a high proportion of finely powdered material such as zinc oxide or starch. Protective (fatty) pastes are greasy and therefore messy and water insoluble. They are difficult to apply and remove, but their stiffness permits accurate localization of the paste and any constituent medication. They are occlusive, protective and hydrating. The consistency of these pastes can be 'softened' by adding oils or 'hardened' with hard paraffin. Drying pastes, also called cooling pastes, are mixtures of powder with liquid. These are non-greasy, water-miscible and easy to apply and remove. They are drying and soothing, and can be used in conjunction with dressings as paste bandages or as vehicles for active medicaments.

Lotions. These are liquid formulations that are usually simple suspensions or solutions of medication in water, alcohol or other liquids. Those containing alcohol often sting, especially when applied to broken skin. When left on the skin the liquid will evaporate, leaving a film of medication on the surface. Aqueous suspensions of powders such as calamine, which require shaking prior to each application, are known as *shake lotions*.

Gels. These are thickened aqueous lotions. They are semi-solid preparations containing high-molecular-weight polymers, such as carboxypolymethylene (Carbomer BP) or methylcellulose, and can be regarded as thickened aqueous lotions. Lotions and gels are especially suitable for treating the scalp and other hairy areas of skin. Like lotions, gels tend to dry when left on the skin. Gels can provide cosmetically acceptable formulations for use on the face.

Powders. These are applied directly to the skin and are also known as *dusting powders*. They can reduce friction (talc) or excessive moisture (starch). They are occasionally used to deliver drugs such as antifungal agents applied to the feet.

Paints. These are liquid preparations, either aqueous, hydro-alcoholic or alcoholic (*tinctures*), which are usually applied with a brush to the skin or mucous membranes and then evaporate. Collodion preparations are also sometimes referred to as paints.

Collodions. These (e.g. Flexible Collodion BP) are liquid preparations consisting of cellulose nitrate in organic solvent. They evaporate rapidly to leave a flexible film that can hold medicaments in contact with the skin. They are most frequently used to apply salicylic and lactic acids to warts. They may also be used as protectives to seal minor cuts and abrasions. They are easy to apply and are water repellent, but are inflammable.

Microsponges [2]. These are a novel approach to formulation, involving the use of porous beads, typically 10–25 μm in diameter, forming a reservoir loaded with the drug. This approach has been used for cosmetics and sunscreens as well as for medications such as benzoyl peroxide and retinoids. The aim is to provide sustained release of the drug while reducing irritation.

Liposomes. These are structures comprising an aqueous phase surrounded by a lipid capsule, ranging widely in diameter from several nanometers to several micrometers. They may contain several lipid layers so that the structure can be likened to that of an onion. Under certain conditions liposomes can release their contents close to a target cell, fuse with the cell membrane or be endocytosed by the cell [3]. They can be formulated into creams and gels. This technology is used in cosmetics but has so far had little impact on dermatological treatment. However, it may prove useful for reducing irritation from topical use of agents such as tretinoin, benzoyl peroxide and dithranol, and in reducing the staining of skin and clothes from the latter [3–5]. Liposomes do not appear to penetrate intact into the intracellular compartment of the epidermis, although an *in vitro* study using reconstructed human skin has suggested that liposomal lipids can be incorporated into the intercellular lipids of the stratum corneum and cell membranes in the uppermost viable layers of the epidermis [6].

Frequency of application

The frequency of application must be specified in order to maximize the response while avoiding side effects such as irritation. Excessive frequency of application may also result in unnecessary systemic exposure to the drug. Emollients should be applied frequently enough to maintain their physical effect. This may require several applications daily. Active preparations are usually applied just once or twice a day. As a general rule, twice daily application of drugs such as corticosteroids or deltanoids is only marginally more effective than once daily application, while requiring double the amount of medication and increasing systemic exposure to the drug. The pharmacological actions of a drug may persist long after it has left the surface of the skin. Thus, the ability of a potent topical corticosteroid to inhibit flares of atopic dermatitis when applied just twice weekly [7] seems unlikely to be explained simply by persistence of a reservoir of the drug. Increasing the interval between applications can be a useful method of gradually reducing the intensity of a treatment, especially when it is difficult to do so by using a lower concentration or less potent agent.

Quantity to be applied

The total quantity to be dispensed should be specified, and it is helpful to inform the patient how long the prescribed quantity is expected to last. There is a tendency, especially in the case of topical steroids, for patients to be overcautious in their interpretation of the advice to 'apply sparingly' which will be found on the package insert. Minute quantities are rarely effective. Conversely, inappropriate use of active medicaments as emollients is not only wasteful but often hazardous. The potential for systemic absorption must be taken into account when prescribing, for example, topical corticosteroids, deltanoids or salicylic acid.

Estimates of the quantity of cream or ointment required for a single total body treatment of a male adult have varied considerably. In one study, a range of 12–27 g (average 18 g) was required for applications by 'trained operators' [8], while a range of 8–115 g (average 44 g) was required when the treatment was self-administered. In another study, in which treatment was applied by nurses, an average of 12 g of ointment was required [9]. In a more recent study, male patients treating themselves applied an average of 20 g of ointment, and females applied 17 g [10].

Based on these latter figures, the quantity required for 1 week of once daily application to the whole body would be approximately 140 g for males and 120 g for females, while for twice daily application, male and female patients require 280 and 240 g/week, respectively.

Table 75.2 provides approximate quantities required for single applications to specific anatomical regions in adults, while Table 75.3 provides a guide to total quantities required for a week of twice daily total body treatment for children of various ages. These guidelines can only be approximate and should be interpreted very flexibly. In addition to the obvious large differences between

Table 75.2 Approximate quantities (g) required for each application of medication to different anatomical regions. (Adapted from [10].)

Region	Males	Females
Trunk (including buttocks)	6.6	5.8
One leg	2.9	2.5
One foot	0.9	0.7
One arm and forearm	1.7	1.3
One hand	0.6	0.5
Face, neck and ears	1.3	0.9
Whole body	20	17

Table 75.3 Quantities (g) of medication required for twice daily application to the entire body at various ages. (Adapted from [13].)

individuals of any age in body surface area, the condition of the skin may influence how far the medication will spread. Creams and ointments seem to cover a very similar area per unit of weight [8,9].

Simple practical guides to the quantity of a topical medication to apply are provided by the fingertip unit [10] and the rule of hand, as follows.

The *fingertip unit* is an approximate but practical measure of topical medication. It is the quantity of ointment extruded from a tube with a nozzle of 5 mm diameter (note that nozzles do vary somewhat) that extends from the distal crease of the forefinger to the ventral aspect of the fingertip (Fig. 75.1). This unit weighs approximately 0.49 g in males and 0.43 g in females [11] and covers, on average, an area of approxiamtely 300 cm^2. The number of units required for a single treatment of each anatomical region in adults and children of various ages is given in Table 75.4.

The '*rule of hand*' states that an area of the size that can be covered by four adult hands (including the digits) can be treated by 1 g of ointment or 2 fingertip units [12].

The figures discussed above are based on application of active medicaments. Emollients are applied for their physical properties rather than for delivery of a drug, and are generally used much more liberally. Emollient treatment of the whole body may require 100 g/day when the skin is very dry.

Advice to patients

Detailed instructions are often required as to the timing of applications. In many cases it is most convenient to apply the medication immediately after bathing. If other topical treatments are in use it is important to explain how the applications should be timed relative to each other. For example, application of an emollient immediately after application of an active agent will inevitably dilute the active medication and probably spread it over areas of skin where it is not required. When using a medication with a tendency to induce irritation it is helpful to warn patients about this in advance and to give advice on the best course of action when this occurs.

If it is planned to use any form of occlusion, bandaging or other dressing with topically applied medication, detailed instruction is required and this should ideally take the form of a demonstration by a specially trained nurse. Occlusion will invariably increase the level of penetration of a drug into the skin. The mechanism of this effect is not fully understood but seems to be partly the result of retaining a reservoir of the medication on the surface of the skin, and partly the effect of increased hydration of the stratum corneum. The simplest method of occlusion is the use of polythene gloves on the hands or 'clingfilm' on the feet or limbs. Self-adhesive hydrocolloid dressings can be very useful for limited areas on the limbs or trunk. 'Wet wrap' bandaging is described in the treatment of atopic dermatitis. Various additional types of bandaging (e.g. paste bandages) can be used to increase the penetration of topical medication and have the added benefit of preventing scratching.

Age	Face and neck	One upper limb	One lower limb	Trunk	Whole body
3–6 months	1	1	1.5	2.5	8.5
1–2 years	1.5	1.5	2	5	13.5
3–5 years	1.5	2	3	6.5	18
6–10 years	2	2.5	4.5	8.5	24.5
Adult	2.5	4.5	7.6	13.5	40

Table 75.4 Fingertip units required for a single treatment of various regions in children and adults. (Adapted from [10,13].) Note that the unit is measured using an adult finger.

When self-treatment fails, the efficacy of topical therapy can almost invariably be improved if the treatment can be applied by a specialist nurse in an outpatient department. Many dermatology departments are able to provide this service for patients with severe skin disease who are able to attend on a daily basis. The response to treatment is improved even further by admission to hospital for a period of rest and regular supervised treatment.

Hazards associated with topical treatment

The most frequent adverse effects associated with topical medication are localized irritant or allergic reactions. Irritant reactions can be minimized by applying treatment at the optimal concentration and treatment intervals and by selection of the correct vehicle. Sensitization is more difficult to anticipate and to prevent. Contact allergy can develop not only to the active medicament but also to constituents of the vehicle. Almost any component may sensitize: notable examples include ethylenediamine [14], propylene glycol [15], emulsifiers [16], sorbic acid [17,18], cetyl and stearyl alcohols [19] and fragrances [20]. Patients with chronic venous eczema or leg ulcers appear to be particularly susceptible [21,22]. Sensitivity to topical medication is often overlooked as the symptoms tend to be attributed to the disease being treated.

Systemic side effects from topically applied medication are relatively rare. Nonetheless, all topically applied drugs are absorbed to some degree and on occasions unexpected systemic toxicity occurs. Absorption varies very considerably depending on the region of skin being treated (Table 75.4) [23]. Occlusion greatly enhances absorption [24,25]. Systemic exposure can be greater than expected in children because of their relatively high ratio of skin surface to body mass. In the elderly, penetration of drugs may be increased as a result of changes in the structure of the skin. This effect is most pronounced on those drugs that are most hydrophilic [26]. Inflammation of the skin impairs barrier function and significantly increases drug absorption. This is especially significant in the erythrodermic patient [27–29].

Formulation of topical treatment

The formulation of the vehicle in which a drug is delivered topically to the skin is critical in obtaining effective and consistent results. The vehicle has many roles. It must provide rapid delivery of the drug to the stratum corneum and into the viable layers of the skin. It must be soothing and comfortable to use and preferably also cosmetically acceptable. The vehicle must also provide a chemical environment in which the drug remains sufficiently stable prior to use to have a practical shelf life.

Most topical treatments are now commercially formulated in vehicles that have been carefully designed for optimal results. Some caution is therefore required when adding diluents or other medicaments to such a

formulation. The role of the dermatologist in formulating topical treatment has been reduced over recent years by stricter financial, legislative and safety controls, which have resulted in the increasing reluctance of pharmacists to prepare extemporaneous or personalized formulations. Nonetheless, an understanding of the parts played by the various constituents of vehicles remains important. Only the most frequently used components are reviewed here. Further information regarding many of the materials and formulations discussed in this chapter is available in the British and US pharmacopoeias (BP, USP) and British Pharmaceutical Codex (BPC).

The simplest role of a vehicle is dilution of an active drug to the desired concentration. Agents such as beeswax, liquid paraffin, polyethylene glycol and powders are often added for their physical properties to adjust the thickness or texture of the medication. In addition to this, various constituents act as emollients, emulsifiers, fragrances, humectants, penetration enhancers, preservatives or solvents. Some of the constituents most often employed are listed in Table 75.5 and some are discussed further below. A single constituent often serves more than one function.

Table 75.5 Frequently employed constituents of vehicles.

Lipids
Castor oil
Cetyl alcohol
Cocoa butter
Isopropyl myristate
Isopropyl palmitate
Lanolin
Liquid paraffin
Stearic acid
Stearyl alcohol
White soft paraffin (petrolatum)
Emulsifiers
Alkyl sulphates and sulphonates
Glyceryl monostearate
Lanolin and derivatives
Phosphoric acid esters
Polyethylene glycols
Polyvalent metallic soaps
Propylene glycol fatty acid esters
Quaternary ammonium cationic compounds
Sorbitan monolaurate, monopalmitate and mono-oleate
Triethanolamine oleate
Humectants
Glycerin
Propylene glycol
Urea
Pyrrolidone carboxylic acid
Gelatin
Sorbitol
Penetration enhancers
Azone
Dimethyl sulfoxide
Propylene glycol
Salicylic acid
Urea
Preservatives
Benzyl alcohol
Butylated hydroxyanisole
Butylated hydroxytoluene
Chlorocresol
Edetic acid/disodium edetate
Hydroxybenzoates (parabens)
Propylene glycol
Sodium metabisulphite
Sorbic acid/sorbates
Solvents
Acetone
Ethanol
Ether
Chloroform
Glycerin
Isopropyl alcohol
Methanol
Propylene glycol
Water

Lipids

Lipids incorporated into vehicles can act as diluents and solvents but are especially valuable as emollients: they have the ability to form a coating on the surface of the stratum corneum which inhibits evaporation of water, thus providing a softening and moisturizing effect. Generally speaking, the greater the proportion of lipid in the formulation, the greater will be the emollient action. Ointments are therefore more emollient than oily creams, which are more so than aqueous creams, while most lotions have no emollient effect. Lipids from a variety of sources are incorporated into topical treatments for skin disease.

Vegetable oils

Oils can be obtained from numerous vegetable sources by pressing or by solvent extraction. Vegetable oils are largely composed of triglycerides, which tend to contain large proportions of unsaturated fatty acids such as the 18-carbon fatty acids oleic acid (monoenoic) and linoleic acid (dienoic). The presence of these unsaturated fatty acids renders vegetable oils vulnerable to oxidation. This results in rancidity, which manifests as an unpleasant odour and is a major constraint on the use of vegetable oils in medicaments.

Arachis oil, derived from the groundnut or peanut, has been the subject of some concern recently over possible contamination with allergens that could cause hypersensitivity reactions in peanut-sensitive individuals. Cocoa butter, also known as theobroma oil, is a product of the cocoa bean and consists chiefly of the triglycerides of palmitic, stearic and oleic acids. It also contains antioxidants, which make it remarkably stable for a vegetable oil and which can even help to preserve other constituents with which it is compounded. It is brittle at room

temperature but melts at between 30 and 35°C. Castor oil is obtained from the castor bean *Ricinus communis* and is composed almost entirely of triglycerides of the 18-carbon long-chain fatty acid ricinoleic acid. Olive oil contains a large proportion of oleic acid.

Mineral oils and greases

Extracts of crude oil (crude petroleum) resembling those we use today have been used for treatment of skin disease since a US patent was obtained, in 1872, by Robert Chesebrough for a product he called vaseline.

Emollient products extracted from crude oil can be produced as fluids, semi-solids or solids and include Liquid Paraffin BP, Mineral Oil USP, Yellow and White Soft Paraffin BP, Petrolatum USP. The extraction process involves treatments to remove elements other than hydrogen and carbon. Aromatic and unsaturated compounds are also eliminated, leaving a diverse range of hydrocarbon molecules, some straight chained, some branched and some polycyclic [1]. As a result of their fully saturated nature, these hydrocarbons are far more stable than the constituents of vegetable oils. They are remarkably inert and are not vulnerable to oxidation or rancidity. For this reason, mineral oils have substantially replaced vegetable oils as the lipids used in emollients and topical treatments.

Lanolin

The use of wool extracts for cosmetic and medicinal purposes dates back at least as far as ancient Greece. Lanolin (wool fat) is extracted from wool and is essentially the product of the sheep sebaceous gland [2]. It is available in abundance and, because its natural purpose is to protect the skin and wool of the sheep, it is perhaps an obvious choice of lipid material for use as an emollient.

Lanolin comprises a complex mixture of higher fatty acids esterified with mono- and dihydric alcohols, including aliphatic alcohols, and cholesterol and related sterols. Its precise composition varies qualitatively and quantitatively with humidity, temperature and method of collection. It is prone to auto-oxidation and is therefore often formulated with the antioxidant butylated hydroxytoluene. Lanolin is miscible with water and is a useful emulsifying agent when mixed with other lipids.

Lanolin has gained a reputation as a frequent contact sensitizer, although this remains questionable [3]. Small quantities of anionic detergent may be present in lanolin and may increase the apparent incidence of hypersensitivity [4]. It has also been suggested that misleadingly high proportions of positive patch tests to lanolin and wool alcohols have arisen partly because of selection of groups of patients who are particularly vulnerable to irritant reactions which are misinterpreted as allergy [3]. Sensitization to lanolin in the general population remains rare, of the order of 1 in a million, even though this material has so many applications that it is ubiquitous [3].

Partly because of its reputation as a sensitizer, numerous lanolin extracts and derivatives are often used instead of the natural material. These are produced by a range of processes including hydrolysis (to yield the constituent acids and alcohols), acetylation, ethoxylation and solvent fractionation. Eucerin (Wool Alcohols BP) is the wool alcohol fraction of wool fat, and contains cholesterol and isocholesterol. It is mixed with liquid, soft and hard paraffin to form Ointment of Wool Alcohols BP, which, on the addition of water, produces Hydrous Ointment BP, a vehicle for many water-in-oil (W/O) creams.

Fatty acids and alcohols

Long-chain fatty acids (e.g. palmitic and stearic acids and their alcohols, cetyl and stearyl) are very frequently used as emollients and, in creams, also serve as emulsifiers. Cetostearyl alcohol is a frequently used mixture of cetyl and stearyl alcohols. They can be obtained by hydrolysis of triglycerides from many different animal and vegetable fats and oils.

Waxes

Beeswax is secreted by worker bees to make the cell walls of the honeycomb. It has a melting point of approximately 60°C and is composed mainly of free cerotic acid and myricyl palmitate. It is used as a thickening agent for creams, ointments and lip salves. Emulsifying wax comprises cetostearyl alcohol, sodium lauryl sulphate and water. This is a constituent of emulsifying ointment BP.

Polyethylene glycols

Polyethylene glycols, also known as PEGs or macrogols, are dihydric alcohols. They are polymers of ethylene glycol linked by ether bonds with the general formula $H(O\text{-}CH_2\text{-}CH_2)_n\text{-}OH$ in which n may range from 2 to 90 000. PEGs can be designated by a number indicating the average molecular weight. At low molecular weights, up to 2000, they are hygroscopic. They variously serve as emollients, emulsifiers or thickeners and can also be used to impart a pleasant feel or texture to a formulation.

Cetomacrogols are cetylethers of polyethylene glycol (e.g. cetomacrogol 1000 is the monocetyl ether of polyethylene glycols with average molecular weight 1000). It is useful as a non-ionic emulsifying agent.

Emulsifiers

An emulsion is a two-phase system consisting of two immiscible components: one (the dispersed or inner phase) being suspended in the other (the continuous or outer phase) as small droplets. One phase is aqueous, the

other oily. Stable emulsions remain in this form; unstable emulsions, with a large droplet size, tend to separate as cream does from milk. Production of a stable emulsion requires the presence of an emulsifier, which is a large molecule with both strongly polar (water-soluble) and non-polar (oil-soluble) groups allowing it to bridge the gap between polar and non-polar substances. A large and chemically diverse range of compounds can be used for this purpose; some examples are given in Table 75.5.

W/O systems result from the dispersion of an aqueous phase in an oily phase, as in Oily Cream BP. Oil-in-water (O/W) systems are formed when oil is the dispersed phase and water the continuous phase, as in Aqueous Cream BP. The former constitute, in general, oily creams or 'cold creams', the latter aqueous or 'vanishing creams'. It is sometimes possible to produce both types of emulsion in the same system [5]: these are called ambiphilic creams. Emulsions can be diluted with the outer (continuous) phase only. A simple method of determining the nature of an emulsion is to interpose on a filter paper a drop of the emulsion between one of oil and one of water. In 15 min the continuous phase will mix with, or be dispersed by, one or other of the neighbouring drops. Alternatively, it may be tested by adding a larger quantity of water. If the emulsion separates, it is of W/O type; if not, it is of O/W type, the continuous phase being (within limits) able to expand and still retain its contained disperse phase.

The relative affinity of an emulsifier for water and for oil is quantified by a value denoting its emulsification tendency known as the hydrophilic lipophilic balance (HLB) value [6]. Emulsifiers with an HLB value of 3–6 tend to give W/O systems and those with higher values O/W systems.

Humectants

These are compounds with a high affinity for water (hygroscopicity). They draw water into the stratum corneum and therefore have an emollient effect on dry skin. However, most of the water is drawn out from within the skin and in dry atmospheric conditions water loss from the skin surface may be increased by the presence of humectants.

Penetration enhancers

Agents that have been shown to enhance penetration of drugs through the skin include propylene glycol [7,8], azone [9], urea [10] and dimethyl sulfoxide (DMSO) and related compounds [11–14]. Mechanisms for this effect include hydration of the stratum corneum and keratolytic actions. The effect of salicylic acid as a penetration enhancing agent seems to be variable. *In vitro* studies have suggested that penetration of drugs is enhanced but this effect was not observed during *in vivo* studies of steroid penetration through normal skin [15,16]. However, in treatment of psoriasis, the addition of salicylic acid does seem to improve the response to topical corticosteroids [17,18].

DMSO is a highly polar, stable substance with exceptional solvent properties [19–23]. It releases histamine *in vivo* and may induce weals when applied topically. It reacts with water, liberating heat. The stratum corneum retains significant amounts of DMSO and, as most drugs are more soluble in DMSO than in water, this tends to promote percutaneous absorption [22]. This quality has been shown to be of particular value in increasing the effectiveness of idoxuridine in herpes simplex [24] and zoster [25]. Toxicological considerations have precluded its more widespread use.

Powders

Inorganic powders are an important component of many dermatological treatments and include zinc oxide, titanium dioxide, talc, bentonite and calamine. Organic powders include various starches and zinc stearate. *Zinc oxide* is widely used as a component of many dusting powders, shake lotions and pastes. It has covering and protective properties, gives consistency to creams and pastes, and is said to have cooling and slightly astringent properties. *Titanium dioxide* is chemically very inert and for this reason it can be used instead of zinc oxide in pastes containing salicylic acid. Like zinc oxide, it has useful UV-reflecting properties. *Talc* is inert magnesium polysilicate, with a very low specific gravity. It contributes 'slip' and has a cooling effect. *Calamine* may be either zinc carbonate or zinc oxide, coloured with a little ferric oxide, and has bland, soothing and antipruritic properties. *Starch* is more absorbent than inorganic powders, but tends to deteriorate and is prone to microbiological decomposition. Some powders, for example *bentonite* (colloidal hydrated aluminium silicate), *aluminium magnesium silicate*, *tragacanth*, *methylcellulose* and *carbomer* are used in gels or as stabilizers in shake lotions.

Preservatives

Ointments and some creams with oil as the continuous phase do not usually require preservatives. Lotions, O/W creams and gels, however, because they contain accessible water, are easily contaminated by moulds or bacteria. Animal and vegetable oils, unless protected from oxidation, tend to become rancid. The ideal preservative should be non-toxic, non-irritant, non-sensitizing, odourless, colourless and effective even at very low concentrations and under conditions of normal usage. In addition, it must be chemically compatible with both the vehicle and the active ingredients.

The parahydroxybenzoic acid esters (parabens) are effective and widely used preservatives. Because, indi-

vidually, they are only sparingly water soluble, and as their effects are additive, mixtures are usually preferred. This also increases their spectrum of activity and lowers the risk of sensitization. Considering their widespread use, their sensitizing potential appears to be low [26].

Chlorocresol is a preservative used especially in the UK. It is more effective in acid than in alkaline solution. It has a low sensitizing potential. It is used in several corticosteroid creams.

Sorbic acid (2,4-hexadienoic acid) is also a good preservative, which maintains its activity in the presence of non-ionic detergents. It also has a low sensitization index. It can only be used, however, in preparations with a pH of less than 6.5.

Propylene glycol can inhibit the growth of moulds and fungi, and can therefore be used as a preservative.

Organic mercurials such as thiomersal are used as preservatives in many ophthalmic preparations and in some vaccines and prick-test solutions and are occasionally incorporated in some topical preparations [27]. Ethylenediaminetetra-acetate is a widely used preservative in ear, nose and eye drops. Gallates and other antioxidants such as butylhydroxyanisole and butylhydroxytoluene are used to prevent rancidity in oily and fatty preparations.

Other preservatives, including those mainly used in cosmetic products, are discussed in Chapters 19 and 20.

Topical treatments used in the management of skin disease

Antiperspirants

Most antiperspirants marketed for cosmetic purposes contain aluminium chloride hexahydrate. In contemporary products, refined formulations of aluminium chlorohydrates (or aluminium zirconium complexes) are often used to maximize precipitation of aluminium hydroxide within the sweat duct [1]. Cosmetic antiperspirants are often combined with antimicrobial agents that reduce axillary odour by inhibiting the action of bacterial metabolism on various components of apocrine sweat. Fragrances are often added to mask or adjust the odour in various ways [2].

In treatment of hyperhidrosis of the axillae, palms and soles, higher concentrations of aluminium chloride hexahydrate (e.g. 20–25% in ethanol) are generally used as first-line treatment. These are more effective, more irritant and more likely to damage clothing than cosmetic formulations. Blockage of the sweat duct is regarded as the principal mechanism of action [1,3], although secondary degeneration of the secretory cells may develop after long-term use as a result of the increased pressure in the duct [4]. For maximal efficacy, the treatment should be applied when the skin is dry and sweating is minimal. Application at night is often recommended; this also helps

to minimize damage to clothing. Polythene occlusion may enhance efficacy and irritancy. Irritation often limits the use of this treatment but may settle with reduced frequency of application and with use of a mild or moderately potent topical steroid.

Traditional remedies that have fallen out of favour include the aldehydes. These are believed to work by a similar mechanism to aluminium salts. Aqueous glutaraldehyde solution (up to 10%) can be applied on a swab to the soles of the feet [5,6]. The keratin stains orange-brown when higher concentrations are used. Formaldehyde solution BP (1–3%), used as a twice daily soak, also helps mild cases. Both compounds are frequent sensitizers, and are therefore not ideal for prolonged use. Methenamine, an agent that releases formaldehyde and ammonia, seems to cause less sensitization and has been used as a 10% solution or at 5% concentration in a firm gel-stick formulation [7].

Anticholinergic agents inhibit the anomalous sympathetic (cholinergic) innervation of the sweat glands and can be applied topically to minimize the side effects associated with systemic administration. Poldine methylsulphate [8] and glycopyrronium bromide [9] can be very effective when administered by iontophoresis. Dry mouth is common and visual accommodation may be disturbed for 24–48 h following treatment. Iontophoresis with tap water is also effective, by an unknown mechanism [10,11], and avoids these side effects. Glycopyrrolate cream 2% or lotion has been used with success in patients suffering from severe gustatory sweating following parotidectomy [12].

Surgical treatments and injection of botulinum toxin are considered in Chapter 45.

Antibiotics

Topical antibiotics are most frequently used in the treatment of superficial infections such as impetigo, superficially infected surgical wounds or infected leg ulcers, and also in acne vulgaris and rosacea.

When treating infected skin lesions it is important to establish the identity and antibiotic sensitivity of the organism whenever possible. Although staphylococcal infections are common, it should not be assumed that a cutaneous infection is brought about by this organism. Before using an antibiotic, consideration should always be given to the alternative of using an antiseptic, in order to reduce the risk of promoting antibiotic resistance. Antiseptics usually have the added advantage of covering a wider spectrum of organisms.

The value of many antibiotics is limited by their tendency to sensitize when used topically (e.g. chloramphenicol and neomycin). Once sensitization has developed this generally precludes future systemic use of the antibiotic. It is therefore preferable, when possible, to select an antibiotic for topical application that is not related to agents used systemically.

The topical antibiotics most used in treatment of acne and rosacea are tetracyclines, erythromycin and clindamycin. Topical metronidazole has proved useful in rosacea. In general, topical antibiotics work about as well as benzoyl peroxide or tretinoin in acne vulgaris. As in other indications, consideration should be given to alternatives to topical antibiotics, especially for long-term treatment, in order to reduce the emergence of resistant organisms. The detailed use of antibiotics in acne and rosacea is described in Chapters 43 and 44, respectively.

Bacitracin

This is an antibiotic that is too toxic for systemic use. Its antibacterial action is principally against Gram-positive organisms, so it is generally used topically in combination with other antibiotics, such as neomycin or polymyxin B. Allergic reactions of an anaphylactoid nature have been recorded [1]. In leg ulcer patients it was reported to be the most potent sensitizer of all the topical antibiotics tested [2].

Clindamycin

This is an effective topical treatment for acne vulgaris [3]. It is as effective as oral minocycline 50 mg twice a day [4], and oral tetracyline [5]. It was somewhat less effective than topical nicotinamide gel in a trial involving 76

patients [6]. It was found to be as effective as 5% benzoyl peroxide gel in patients with papular or pustular acne [7]; fewer side effects were seen with topical clindamycin. A small trial in rosacea has indicated that the response was comparable to that from oral tetracycline [8].

Erythromycin

Only the lipid-soluble forms (e.g. the base, propionate or stearate) are effective in acne vulgaris. Several authors have considered the problem of erythromycin-resistant propionibacteria [9,10]. It is equivalent in effect to topical clindamycin, is safe and well tolerated [11,12]. A topical 2% erythromycin gel has been shown to be as effective as 1% clindamycin phosphate in patients with mild to moderate acne [13], and 1.5% erythromycin and 1% clindamycin phosphate solutions were found to be equally effective [12].

Fusidic acid

Derived from *Fusidium coccineum*, this antibiotic is active against staphylococcal infections and effective in erythrasma [14]. It is used as a first-line treatment for pitted keratolysis [15] although there is surprisingly little published about this indication. It is also used in combination with topical steroids in the treatment of infected eczema.

Sensitization occurs only very rarely [16,17], but bacterial resistance is not uncommon.

Gentamicin sulphate

The particular dermatological value of gentamicin sulphate lies in its broad spectrum of activity, including against *Pseudomonas aeruginosa*. Contact allergy is fairly frequent in patients with chronic otitis externa [18] and, compared with other agents, it remains a common sensitizer [19]. Cross-sensitivity can develop with other aminoglycosides [20].

Metronidazole [19]

Metronidazole 0.75–1% has been shown to be a safe and effective treatment for rosacea [21,22]. Topical metronidazole has also been used with some success in patients with decubitus and other ulcers, eliminating malodour in 36 h [23]. In a double-blind placebo-controlled trial, topical metronidazole was ineffective in reducing the inflammatory lesions of acne [24].

Mupirocin

This topical antibiotic is derived from *Pseudomonas fluorescens* [25]. It is chemically unrelated to other antibiotics, and its mode of action in arresting bacterial protein synthesis is novel [26]. It is active against a wide range of Gram-positive organisms and some Gram-negative organisms [27]. Naturally, it is not active against *Pseudomonas* and may allow overgrowth of this organism. It can be highly effective in cutaneous bacterial infections [28,29]. It has also proved useful in the elimination of nasal carriage of staphylococci [30], including multiply-resistant organisms, but strains resistant to mupirocin are now an increasing problem.

Neomycin and framycetin

SYN. SOFRAMYCIN

These are aminoglycoside antibiotics with a broad spectrum of action against Gram-positive and Gram-negative organisms. Both are considered too toxic for systemic use. Many preparations containing one or other of these are marketed in the UK, and are widely used, although sensitization reactions are common, especially around leg ulcers, under occlusion and in patients with chronic otitis externa, pruritus ani or vulvae, or with recurrent eye problems. Neomycin was among the most common sensitizers reported by Wilkinson *et al*. [31]. Simultaneous contact allergy to neomycin, bacitracin and polymyxin has been reported [32].

Polymyxin B

This antibiotic is used in several proprietary topical formulations for application to skin, eyes and ears. It has useful activity only against Gram-negative organisms and is therefore usually combined with other antibiotics. The relatively low toxicity of polymyxin to keratinocytes may explain the good cosmetic results observed when it is used following dermabrasion [33].

Silver sulfadiazine

First introduced over 20 years ago [34,35], this compound has become established as a safe and convenient dressing for burns [35]. Even when applied over wide areas, systemic absorption is minimal and the risk of renal damage is thought to be slight [36]. It is applied as a 1% cream. It appears to have a low potential for sensitization and is useful in the management of leg ulcers where it provides good prophylaxis against *Staphylococcus aureus* and some Gram-negative organisms. Some patients may become sensitive to the cetyl alcohol contained in the base of one proprietary formulation. When sulphonamide-resistant Gram-negative bacilli were present, a silver nitrate/chlorhexidine cream was found to be of value [37].

Tetracyclines

These are used alone in the topical treatment of acne [38],

but are also present in several proprietary topical corticosteroid preparations. Bacterial resistance is common, especially in staphylococci. Tetracyclines tend to stain skin and clothing yellow.

Antifungal agents

Topical application of antifungal agents is used by dermatologists mainly for treatment of mild dermatophyte and yeast infections. As management of specific infections is described elsewhere, this chapter provides only a description of the antifungal agents available for topical application. Severe and extensive infections and infections of hair and nails are usually treated systemically (see Chapters 62 and 63). The most frequently prescribed topical antifungal agents are allylamines, imidazoles, morpholines and polyenes. Older compounds such as tolnaftate and undecylenate acid are mainly sold over-the-counter.

Allylamines

These inhibit fungal synthesis of ergosterol, an essential component of fungal cell membranes, by inhibiting squalene epoxidase. This also results in toxic accumulation of squalene within the organism, which is fungicidal. This class includes naftifine, butenafine (neither are marketed in the UK) and terbinafine. The fungicidal nature of these compounds results in rapid response of dermatophyte infection to topical application. Naftifine and butenafine also possess anti-inflammatory activity. Terbinafine is active topically against pityriasis versicolor as well as against dermatophytes.

It is of concern that a strain of *Trichophyton rubrum* apparently resistant to squalene epoxidase inhibitors has recently been reported [1].

Imidazoles

This is a large group of compounds which includes bifonazole, clotrimazole, econazole, fenticonazole, ketoconazole, isoconazole, miconazole, oxiconazole, sulconazole, terconazole, tioconazole and others. These have largely similar properties and act by inhibiting synthesis of ergosterol. They are fungistatic. They are active against a wide range of fungal organisms including *Candida* and *Pityrosporum* yeasts as well as dermatophytes. They also have potentially useful antibacterial properties and, at least *in vitro*, can suppress growth of *Staph. aureus* [2]. The range of formulations includes creams, powders, sprays, suspensions and nail lacquer.

There are also combined formulations available which contain imidazoles and corticosteroids. The precise role of these combined formulations is controversial. They can occasionally be useful to accelerate resolution of symptoms when infected skin is very inflamed and pruritic. However, it is also possible that they may impair the response to the antifungal agent [3] and the familiar hazards of topical corticosteroids include the potential to mask a persisting infection.

Morpholines

Amorolfine inhibits two separate stages in the synthesis of ergosterol and is fungicidal. It is marketed as a nail lacquer containing 5% amorolfine, for treatment of onychomycosis. An advantage of amorolfine in this application is that, in addition to efficacy against dermatophytes, it is also active against other filamentous fungi that cause onychomycosis, such as *Scytalidium* spp. and *Scopulariopsis* spp. The water-resistant properties of the lacquer allow the convenience of once or twice weekly application. Twice weekly application may be marginally more effective [4]. Cure rates are approximately 50% at 6 months. Amorolfine can act synergistically with other antifungal agents including azoles and allylamines, improving cure rates when topical amorolfine is combined with systemic itraconazole [5] or terbinafine for 3 months [6].

Polyenes

The important member of this group is nystatin—one of the earliest antifungal agents developed. It derives its name from the New York State health laboratory where it was discovered in the 1950s. Nystatin is a fungal metabolite with activity against *Candida albicans* and several other *Candida* species. It damages the fungal cell membrane by binding irreversibly to ergosterol, an action that is fungistatic at low concentrations and fungicidal at high concentrations. It is not effective against dermatophytes. It is a safe and well-tolerated compound which is not significantly absorbed when taken orally or when used topically on skin and mucous membranes. Nystatin is available in a range of formulations including cream, ointment, oral suspension, lozenges and pessaries. There are also a range of creams and ointments containing combinations of nystatin with antiseptics, antibiotics and various potencies of corticosteroids.

Ciclopirox olamine [7]

This hydroxypyridone compound has a different mode of action to most other antifungal agents and does not directly inhibit sterol synthesis. It binds with high affinity to trivalent cations such as Fe^{3+}, which are essential for the functioning of numerous enzymes including cytochromes. Several metabolic pathways are likely to be disrupted by this process, including mitochondrial electron transport. It demonstrates activity against a broad spectrum of dermatophytes, yeasts and moulds including *Scytalidium* spp. and *Scopulariopsis* spp. and is also effective against Gram-positive and Gram-negative bacteria including methicillin-resistant *Staph. aureus*. Ciclopirox is commercially formulated in a variety of creams, lotions, powder and as a nail lacquer but is not currently marketed in the UK.

Tolnaftate

This compound is available in a variety of formulations (creams, lotions, powder) that are generally sold over-the-counter for topical treatment of dermatophyte infections. It is a thiocarbamate derivative, chemically unrelated to other antifungal drugs, and is an inhibitor of squalene epoxidase. It is considered less effective than more recently developed agents but is superior to placebo [8].

Undecylenic acid

Undecylenic acid, a mono-unsaturated fatty acid, is largely used as an over-the-counter topical treatment for dermatophyte infection. In addition to its fungistatic activity, it has antiseptic and antiviral properties. Formulations include cream, ointment, paint, spray and powder. It is probably less effective than newer agents although it has proved superior to placebo and equivalent to tolnaftate in controlled trials [8,9]. Sensitization is occasionally reported.

Other topical antifungal agents

Whitfield's ointment, a combination of 6% benzoic acid and 3% salicylic acid, is effective in treatment of superficial

dermatophyte infections. Studies in the tropics suggest that cure rates are quite acceptable when very low cost is a priority [10]. However, this formulation is not very cosmetically acceptable.

The antiseptic properties of benzoyl peroxide have been put to use in treatment of dermatophyte infection and pityriasis versicolor, although this compound is irritant and bleaches clothing so some caution is required [11].

Zinc pyrithione 1% and selenium disulphide 2.5% are used in shampoos to treat dandruff and seborrhoeic dermatitis. Both compounds have also been shown in placebo-controlled trials to be effective in treatment of pityriasis versicolor in the same concentrations. Zinc pyrithione shampoo can be lathered over the affected skin for 5 min then rinsed off every day for 2 weeks [12]. Selenium sulphide has been shown to be effective used in the same way but applied for 10 min/day for 7 days [13]. Some irritation may develop.

Resorcinol (1,3 dihydroxybenzene) is an antiseptic agent and preservative which is also added to some shampoos to suppress dandruff by inhibition of *Pityrosporum* yeasts.

Azelaic acid demonstrates antifungal properties and is discussed under the heading of depigmenting agents.

Antiparasitic agents

The principles of treatment of lice infestations and scabies are discussed in Chapter 33. Insecticide resistance has emerged as a significant problem in the treatment of head lice [1] and may necessitate treatment with a second agent or by using non-pharmacological approaches.

Pyrethroids

Pyrethroids are highly effective [2,3] and are now probably the most widely used agents. These are insecticides that are neurotoxic to parasites. Permethrin 5% cream is a first-line treatment for scabies. It should be applied from the neck down for 12 h. The 5% 'dermal cream' for treatment of scabies should not be confused with the 1% 'creme rinse' marketed for treatment of head lice. This has caused treatment failure in scabies [4]. The creme rinse is applied to the scalp for 10 min to treat head lice. For pubic lice, the 5% cream should be used as for scabies.

Phenothrin is another pyrethroid used for head and pubic lice. For head lice, the formulations available include in an aqueous 0.5% lotion (washed off after 12 h), an alcoholic 0.2% lotion (washed off after 2 h) and a 0.5% concentration in a mousse (washed off after 30 min). For pubic lice, the aqueous lotion should be applied to the whole body for 12 h.

Whether treating head lice, pubic lice or scabies, two treatments at an interval of 1 week are generally recommended for both these agents.

Malathion

Malathion is an organophosphorus cholinesterase inhibitor that paralyses parasites. In treatment of scabies, a 0.5% aqueous lotion is applied to the skin for 24 h and repeated after 1 week. For head lice, 0.5% aqueous or alcoholic lotions can be applied for 12 h on three occasions at 3-day intervals. For crab lice, the aqueous preparation should be applied all over the body for 12 h and repeated after 7 days.

Other antiparasitic agents

Benzyl benzoate is also believed to be neurotoxic to parasites. It can be used as a scabicide in a 25% emulsion applied daily for 3 days but is somewhat irritant. Carbaryl is another organophosphorus insecticide that can be used for head and pubic lice. It is available as 1% aqueous and 0.5% alcoholic lotions which are usually left on the skin for 12 h. A single application may be effective but is often repeated after 7 days. Gamma benzene hexachloride (lindane), used as a 1% lotion, is an effective scabicide although it has been withdrawn in the UK as a result of concern over systemic absorption and possible neuro-

toxicity [5]. It is applied for 12 h and this is sometimes repeated after 1 week. The risks seem small but are relatively greater in infants and young children, and when multiple applications are used. Both topical and oral ivermectin have been successfully used for both scabies and head lice [6–8]. A 1% solution in propylene glycol applied twice with a 1-week interval has proved highly effective in scabies [9]. Crotamiton has weak scabicidal activity and is an antipruritic. It is often used as a follow-up treatment to other therapies.

Antiviral agents

There are few topical agents available with specific antiviral activity although many antiseptics, especially povidone iodine [1,2], are known to inactivate viruses. The use of imiquimod, 5-fluorouracil and podophyllin in treatment of viral warts is discussed elsewhere in this chapter. Aciclovir, penciclovir and idoxuridine are used topically in management of herpes simplex and the latter is also used for herpes zoster.

Aciclovir and penciclovir

Topical aciclovir is used in the treatment of primary and recurrent herpes simplex types I and II [3]. The drug is a nucleoside analogue and is phosphorylated by a viral thymidine kinase to an active form that inhibits effective replication of viral DNA. A recommended regimen is application of 5% aciclovir cream at 4-hourly intervals for 5 days. Both labial and genital lesions can respond. Severe episodes are best treated systemically. Some protective effect may be obtained by regular prophylactic application of aciclovir cream [4]. Penciclovir has a similar mechanism of action. This is applied as a 1% cream 2-hourly for 4 days. Both of these agents should be applied as early as possible in the course of the episode.

Idoxuridine

Idoxuridine was the first agent to become available for topical treatment of herpes infections. It is a thymidine analogue that inhibits viral DNA replication. It is effective in reducing symptoms in treatment of herpes simplex [5] and zoster infections [6] applied topically at concentrations of 5–15%. A 5% solution in DMSO can be applied to affected areas of skin with a brush 4 times daily for 4 days. At lower concentrations, idoxuridine appears effective in treatment of genital warts [7]. Topical use of idoxuridine can occasionally sensitize [8].

Astringents

Astringents are compounds used to reduce exudation, acting by precipitation of protein. Those most frequently employed are aqueous solutions of potassium permanganate, aluminium acetate and silver nitrate.

Potassium permanganate

This is an oxidizing agent with antiseptic and fungicidal activity. It is used at concentrations of 1 : 4000–1 : 25 000. It can be applied as a rinse or soak or as a bath. A bath containing 1 : 25 000 $KMnO_4$ can be prepared by adding 2 g to each 50 L of water. The astringent and antiseptic properties of this solution are invaluable in treatment of very acute exudative eczematous dermatoses. However, it is messy and stains the skin and other materials.

Aluminium acetate

Also known as Burow's solution, this astringent is also mildly antiseptic and has the advantage of not causing the

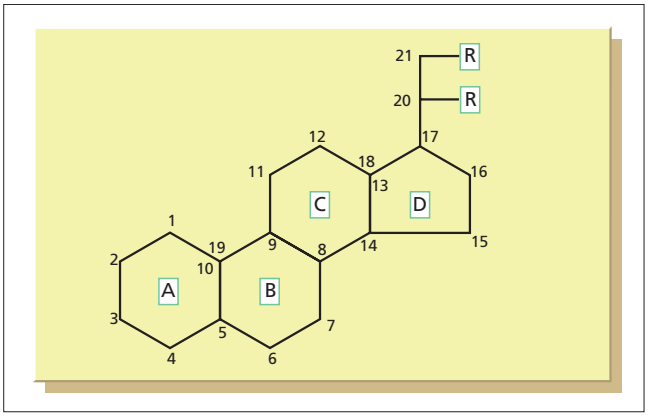

Fig. 75.2 The configuration of the basic corticosteroid structure.

staining associated with potassium permanganate. The solution is prepared using aluminium sulphate, acetic acid, tartaric acid and calcium carbonate. The solution contains 5% aluminium acetate and is diluted 1 : 10–1 : 40 with water for use in soaks, rinses or wet dressings.

Silver nitrate

In concentrations of 0.1–0.5% silver nitrate is an effective astringent and antiseptic, often used in management of leg ulcers and burns. Higher concentrations may cause pain. Silver nitrate causes staining of skin and most other materials.

Corticosteroids

Topical corticosteroids have now been in use for treating skin disease for over half a century, since the introduction of 'compound F' or hydrocortisone (cortisol) in 1952 [1]. Their impact has been immense. In addition to becoming the mainstay of treatment in eczematous dermatoses, they are used, either regularly or occasionally, in the management of most inflammatory skin diseases.

During the decades since hydrocortisone was introduced, numerous analogues have been developed from this molecule. The basic structure of the steroid moiety is shown in Fig. 75.2. Modifications to both the ring structure and the side-chains have increased specificity of action, increased penetration, dramatically increased potency and, to some degree, reduced side effects.

Hydrocortisone has considerable mineralocorticoid activity, which can be reduced by methylation or hydroxylation at position 16. Esterification at positions 16, 17 and 21 increases lipid solubility, promoting greater penetration of the stratum corneum barrier. This strategy lead to the development of highly lipophilic compounds such as betamethasone dipropionate and triamcinolone acetonide. Fluorination of the 9α position, the introduction of an unsaturated bond between the first two carbon atoms and changes in the nature of the side-chains, particularly in the 21 position, brought about enhanced glucocortioid activity [2]. Fluticasone propionate has a fluoride thioester carbothiate at C21, a propionate ester at C17 and a methyl group at C16; this molecule is inactivated rapidly on first passage through the liver, confering greater systemic safety. Similar properties are demonstrated by methylprednisolone aceponate and mometasone furoate, while systemic exposure to prednicarbate is minimized by metabolism within the skin.

In view of the great differences in potency between different corticosteroids, it is essential for the dermatologist to be able to rank or classify them by potency in order to predict the response and possible adverse effects. This classification ideally needs to take account not only of the relative potency of the molecules, but also factors such as the concentration and the nature of the vehicle, which can significantly alter penetration.

Perhaps the ideal approach would be a large series of clinical trials to compare clinical efficacy of all the available corticosteroids. However, even if this were possible, it is by no means certain that the same ranking would be obtained in two different diseases. Many different approaches have therefore been developed to compare potencies of topical corticosteroids. Some of these employ various animal models of inflammation such as the implantation of a pellet of cotton into a subcutaneous pocket in rats. The potency of the antimitotic action of steroids can be assayed by applying the compound to the skin of hairless mice and measuring the level of suppression of the mitotic index after tape stripping [3]. However, the most widely used approach has been the vasoconstrictor assay, which depends upon the vasoconstricting property of glucocorticosteroids. This has the advantage of using human subjects and evaluates not only the intrinsic potency of the molecule but also its ability to penetrate the stratum corneum from a specific vehicle and even takes into account certain aspects of the removal and metabolism of the drug [4,5]. The degree of pallor produced following application of a compound to the skin seems to correlate fairly well with clinical potency and with the potential for side effects such as atrophogenicity. Typically, pallor reaches a peak at around 9–12 h after application and then falls, initially fairly rapidly over the next 10 h, then more slowly [6]. The total duration of action varies considerably between different compounds.

The various classifications adopted to provide a guide to the relative potencies of different compounds are substantially based on the vasoconstrictor assay but also take into account other evidence such as comparative clinical trials. The *British National Formulary* employs a four-point scale: mild, moderate, potent and very potent. In the USA, topical corticosteroids are ranked using a scale ranging from class 1 (super potent) to class 7 (mild).

Mechanism of action

Corticosteroids diffuse through the stratum corneum barrier and through cell membranes to reach the cytoplasm of keratinocytes and other cells present in the epidermis and dermis. Diffusion through the stratum corneum is generally considered to be the rate-limiting step in delivery of the drug. In the cytoplasm they bind to a specific receptor, the glucocorticoid receptor (GR). Clinical potency of corticosteroids seems to be strongly related to receptor binding affinity, which is very sensitive to certain structural changes in the steroid. Thus, the introduction of a double bond in the A ring, esterification in the 17α position, and fluorination at position 9α increase binding affinity, whereas esterification in the 21 position reduces binding affinity (Fig. 75.2).

The glucocorticoid receptor (glucocorticoid receptor α; GRα) is a protein of molecular weight 330 kDa and is a member of the same receptor superfamily as receptors for other classes of steroid, thyroid hormone, calcitriol, etc. When not associated with a steroid ligand, this receptor is found in the cytoplasm as a component of a heterotetrameric structure containing two molecules of the 90 kDa heat shock protein hsp90, and a 59-kDa protein p59. Interestingly, p59 seems to belong to the family of immunophilins that interact with other immunosuppressant drugs. The binding of the receptor to its ligand results in activation of the receptor, which dissociates from the other components of the tetrameric complex [7]. The ligand-bound receptor then enters the nuclear compartment and interacts with specific response elements on the genome, glucocorticoid response elements (GREs). This modulates transcription of numerous genes. In addition, the ligand-bound receptor can inhibit, directly or indirectly, the activity of other transcription factors including NFκB, AP-1 and NFAT [8]. These interactions lead to changes in the expression of a wide range of genes, resulting in diverse cellular effects, which include suppression of the production of inflammatory cytokines, inhibition of T-cell activation, changes in the function of endothelial cells, granulocytes, mast cells and fibroblasts, and inhibition of proliferation. Part of the anti-inflammatory activity of corticosteroids may be explained by their ability to induce synthesis of lipocortin [9,10], a family of glycoproteins that regulate the activity of phospholipase A_2. This enzyme effects the production of arachidonic acid, the precursor for leukotrienes and prostaglandins.

The transcriptional activity of the steroid receptor seems likely to be regulated by an alternative isoform of the receptor known as glucocorticoid receptor β (GRβ), formed by alternative splicing. GRβ is an endogenous inhibitor of glucocorticoid action, which does not bind steroid ligands but competes with ligand-bound receptor for binding to GREs [11]. Staphylococcal superantigen can up-regulate expression of GRβ [12], providing a potential mechanism by which these bacteria might induce corticosteroid resistance.

Side effects of topical corticosteroids

The potential side effects of topical corticosteroids are significant but must be kept in proportion. When these compounds are prescribed appropriately, they can be of enormous benefit and clinically significant side effects are rare, especially in the short term (over a few days or weeks). Dermatologists have been very successful in making pharmacists, general practitioners and the public aware of the hazards. Patients are now frequently encountered whose dermatosis requires potent corticosteroids but who are denied effective treatment by the inappropriate prescription of hydrocortisone or simple emollients. Others apply the medication so 'sparingly' that it is completely ineffective. At times, the fear of using topical corticosteroids can be quite out of proportion to the likelihood of side effects developing. This situation is often termed 'steroid phobia'.

With the exception of structural changes introduced to minimize systemic exposure to topical corticosteroids, it has proved difficult to separate the various unwanted actions of these compounds from those that are so desirable. The side effects of topical steroids are directly related to their potencies. It is often appropriate to use more than one compound simultaneously so that mild or moderate steroids are used on areas where they are often effective, such as the face and flexures, while the more potent preparations are used only where they are required.

Local effects

The most common side effects are localized to application sites. The most worrying is cutaneous atrophy because this may become permanent. Other problems include the development of contact allergy and the risk of promoting infection. When treating the face, there are the additional risks of inducing acneiform eruptions. There are also potential risks from absorption and systemic exposure to the steroid.

Atrophic changes affect both the epidermis and the dermis. The epidermis becomes thinned. This results initially from a reduction in the size of epidermal cells, which reflects a reduction in metabolic activity [13]. After intense or prolonged steroid exposure, the number of cell layers is reduced, the stratum granulosum disappears and the stratum corneum is thinned [14–16]. There is suppression of many aspects of cell metabolism including the synthesis of stratum corneum lipids, synthesis of keratohyalin granules and the formation of corneodesmosomes required for structural integrity of the stratum corneum [17]. Inhibition of melanocyte function may develop, giving rise to localized hypopigmentation. This complication is

most likely to occur with steroids applied under occlusion or with intracutaneous steroid injections [18,19].

In the dermis, topical corticosteroids induce resorption of mucopolysaccharide ground substance. This is likely to explain the rapid development of thinning, which reaches approximately 15% reduction in skin thickness after 3 weeks of treatment under occlusion with 0.1% betamethasone valerate [20]. Collagen synthesis is suppressed within 3 days of treatment with this compound [21]. Even mild corticosteroids such as hydrocortisone have been shown to inhibit collagen synthesis [22,23]. In a study in which betamethasone valerate was applied for 3 days there was still significant inhibition of collagen synthesis 2 weeks after treatment was discontinued [24]. When steroid exposure persists, thinning becomes clinically evident and fragility and striae may develop. The loss of connective tissue support for the dermal vasculature results in erythema, telangiectasia and purpura. With long-term use of potent preparations, these atrophic changes can become irreversible (Figs 75.3 & 75.4). The areas most vulnerable to developing atrophy are those where the skin is already relatively thin, including the flexures and especially the face (Table 75.6). In general, potent steroids should be used on the face only when treating severe dermatoses such as chronic discoid lupus erythematosus.

Contact allergy may develop to corticosteroids as well as to preservatives and other components of the vehicle. Contact sensitivity to hydrocortisone was first reported in 1959 but was initially considered a rare problem [25]. It is now clear that this is, in fact, a common event. In a large series of patients who were patch tested, 4.9% yielded positive results to one or more corticosteroids [26]. Tixocortol pivalate, considered the best patch test reagent for screening, was positive in just over 90% of those with a positive test to one or more corticosteroids. The most frequent sensitizers in this series were hydrocortisone, budesonide and hydrocortisone butyrate. Sensitivity to more than one topical corticosteroid is common and four groups have been identified within which cross-reactivity is most likely to occur (Table 75.7) [27]. Reactivation of contact dermatitis after inhalation of a corticosteroid may also be under-recognized [28].

Caution is required when applying topical corticosteroids in the presence of infection as there is a risk of exacerbation. Clinically unequivocal bacterial superinfection of eczema is usually treated prior to use of topical corticosteroids. However, there is evidence that colonization with *Staph. aureus* can be reduced by improving the condition of the skin with potent or very potent topical corticosteroid treatment [29,30]. It is advisable to avoid the use of topical corticosteroids, whenever possible, in the presence of active viral infection including lesions of herpes simplex, viral warts or molluscum contagiosum. When dermatophyte infections are inadvertently treated with corticosteroid, the symptoms and signs may transiently improve, giving rise to the situation known as tinea incognito. Scabies presents a similar trap, as the pruritus can be improved by topical corticosteroids while the infestation persists unless a scabicidal treatment is also applied. However, topical corticosteroids are invaluable for treating the eczema associated with scabies. Infantile gluteal

granuloma (see Chapter 14) is found only in infants who wear napkins (diapers) and is often associated with the use of topical corticosteroids. Impairment of the immune response to *Candida* by steroids has been suggested as the cause [31].

The use of topical corticosteroids on the face can result in eruptions resembling rosacea (Fig. 75.5) and perioral dermatitis (Fig. 75.6) (see Chapter 44). Eruptions of inflammatory papules may also develop around the eyes and have been termed periocular dermatitis [32]. On other occasions, an eruption more closely resembling acne vulgaris, comprising inflammatory papules and pustules as well as comedones, may develop in treated areas of skin, usually on the face or upper trunk. Comedones have also been induced in perianal skin by the application of potent steroids [33]. The mechanisms involved in these eruptions are not well understood.

Fig. 75.5 Steroid rosacea.

Fig. 75.6 Perioral dermatitis induced by a potent topical steroid. (Courtesy of St John's Institute of Dermatology, London, UK.)

It is possible that the use of topical corticosteroids on the eyelids and periorbital skin can result in some exposure of the eye to the steroid. The use of corticosteroid eye drops is known to raise intraocular pressure, increase risk of cataract formation and to aggravate infections, especially herpes simplex. There have been only occasional reports of such ocular complications arising from the use of topical steroids applied around the eyes to treat skin disease [34–36]. Glaucoma has also been reported in a patient

regularly treating hand eczema with betamethasone valerate at night, presumably resulting from inadvertent contamination of the eyes with the steroid [37]. These scant reports should be offset against the benefit of treating periocular skin disease, especially atopic dermatitis which is associated with keratoconus (probably as a result of frequent rubbing around the eyes) [38].

Locally applied corticosteroids have been demonstrated to impair wound healing and re-epithelialization in a variety of animal and humans models [39–41].

The question of whether tachyphylaxis develops during continued treatment with corticosteroids remains controversial. It is certainly common for patients to report that a topical corticosteroid which was highly effective during the first few days of application has subsequently lost efficacy. On occasions, withdrawal of corticosteroids is followed by a flare of disease. The hypothesis that these phenomena are caused by tachyphylaxis is supported by data from vasoconstrictor assays showing that successive applications of topical corticosteroids are associated with a decreasing response [42]. Furthermore, inhibitory effects on epidermal cell proliferation decreased during repeated administration of topical corticosteroids to hairless mice [43].

However, tachyphylaxis has not been shown to occur in clinical trials of corticosteroids in treatment of atopic dermatitis or psoriasis. It has therefore been proposed that patients report that the effect of the corticosteroid is diminishing when the underlying disease activity is increasing. Physicians observing patients intermittently may mistake stable disease activity for a failure to improve, even when there has been improvement from baseline, and may interpret this as tachyphylaxis. In a survey of dermatologists with 70 respondents, 57% believed that tachyphylaxis occurred within 8 weeks of initiating treatment of chronic plaque psoriasis with a potent corticosteroid. When this was put to the test in a clinical trial of 12 weeks' treatment duration, tachyphylaxis was not observed [44].

Rebound phenomena when topical corticosteroids are withdrawn have principally been of concern in the management of psoriasis. In several cases, withdrawal of treatment with potent or very potent corticosteroids has been followed by the eruption of severe generalized pustular psoriasis. This seems to have been especially likely to happen after potent or very potent corticosteroids have been used in large quantities or applied under occlusion [45]. In these cases it is likely that significant systemic exposure to the steroid was occurring and this was consequently withdrawn at the same time. The risk of this happening when unoccluded treatment with topical corticosteroids is used for chronic plaque psoriasis of moderate severity and disease extent are clearly very small, as this treatment has been so widely used, especially in the USA, yet generalized pustular psoriasis remains rare. Nonetheless, this phenomenon has resulted in a general reluctance of dermatologists in the UK to rely on topical steroids in the treatment of psoriasis vulgaris and this approach has the undoubted benefit of sparing patients other side effects such as cutaneous atrophy.

Vascular effects of corticosteroids include initial vasoconstriction of the superficial small vessels, followed by a phase of rebound vasodilatation. After prolonged treatment the vasodilation may become fixed and more conspicuous as a result of dermal and epidermal atrophy (Fig. 75.6) [46].

Systemic effects

Inhibition of the pituitary–adrenal axis by excessive application of moderately potent topical steroids or by relatively modest use of stronger steroids is well documented [47]. Temporary reversible suppression was seen after using 49 g/week of superpotent steroids for 2 weeks [48] in eight out of 40 patients, and similar results were seen in two further studies [49,50]. Significant suppression was reported in three patients using less than 50 g/week [51]. Recommended weekly dosage is less than 50 g of superpotent steroids and 100 g of potent steroids. In addition, prolonged usage at this level is best avoided. Children and babies have a high ratio of surface area to body volume and are more vulnerable to pituitary–adrenal suppression as a result of systemic absorption. Even hydrocortisone applied topically may suppress the adrenocortical response in some children [52]. Cushingoid features may be seen in infants inappropriately treated [53]. Severe medical problems are fortunately rare despite alarmingly abnormal biochemical parameters.

Vehicles and formulations

There is a large range of topical formulations of corticosteroids on the market. At first glance this may seem more than necessary but it is undoubtedly helpful to have a range of compounds available in a range of formulations. It is clearly important to be able to adjust the potency of the steroid being used so that the least potent compound that is effective can be employed at each site and at each stage in the progression of the dermatosis. It is necessary to be able to avoid corticosteroids to which patients are known or suspected to be sensitized. It is also helpful to have a range of formulations for each compound. Thus, ointments are helpful when eczema is dry, while creams are more effective if the eruption is moist or exudative. Lotions, gels or a mousse formulation are useful for the scalp. When the distribution is limited, as is often the case in lichen simplex chronicus or prurigo, the use of a steroid-impregnated tape will simultaneously prevent scratching and increase drug penetration by effective occlusion [54].

Several antimicrobial agents are commercially formulated in combination with topical steroids including clioquinol, clotrimazole, fusidic acid, miconazole, neomycin and nystatin. These compound formulations are the subject of some controversy. They can be helpful when there is a clear indication for each constituent but are probably used more often when the diagnosis is unclear in the hope of 'covering all the possibilities'. The latter approach is not recommended. Disadvantages include the risks of obscuring the diagnosis, promoting development of microbial resistance to antibiotics and sensitization of patients to antimicrobial agents that may then be impossible to use topically or systemically in future. The aminoglycosides, including neomycin, carry a particularly high risk of sensitization [55].

The case for use of these combinations is much stronger in the treatment of eczemas with evidence of secondary infection, although many dermatologists still prefer to give an antibiotic systemically. It seems very likely that some cases of atopic dermatitis are exacerbated by the presence of *Staph. aureus* on the skin. Superantigen production by these bacteria may have a role in this exacerbation of the disease [56] and may also have the effect of reducing sensitivity to corticosteroids [12].

There is also a special case for combining clioquinol with topical steroids in treatment of nickel dermatitis. This antiseptic is a potent chelating agent that can effectively inactivate nickel [57].

There are also commercially developed formulations combining corticosteroids with other active constituents. Mixtures containing tar, salicylic acid or calcipotriol can be useful in treatment of psoriasis. As in the case of antimicrobial agents, it is important that these compounds should only be used when there is a clear indication for each constituent and potent corticosteroids should only be used when they are really necessary.

Many dermatologists have found it useful to create their own formulations by dilution of proprietary products or addition of other medicaments such as tar and salicylic acid. There are some disadvantages to these practices. The stability of the steroid in a different formulation is unpredictable [58]. Changes in the vehicle may also alter levels of steroid penetration into the skin and systemic absorption [59].

Occlusion and topical steroids

The penetration of a topical corticosteroid can be greatly increased by occlusion using polythene film or gloves, or by using hydrocolloid dressings [60]. Polythene gloves are most easily used overnight, although they are uncomfortable, especially in warm weather. A similar occlusive effect is obtained when a steroid is covered by paste bandages and by the use of wet wrap bandaging in the treatment of atopic dermatitis. Using corticosteroids in this way will undoubtedly increase adverse as well as beneficial effects. However, judicious use of occlusion can be an invaluable strategy in the management of pompholyx, a refractory plaque of psoriasis on the leg, or a patch of lichen simplex. The incorporation of a corticosteroid such as fludroxycortide (flurandrenolone) into the adhesive of a plastic tape provides another effective method of using occlusion.

Whole-body occlusion of corticosteroids was formerly used, but adverse effects were common so this has fallen out of favour.

Intralesional steroids

Recalcitrant dermatoses (e.g. alopecia areata, keloid scars, lichen simplex, nodular prurigo) may respond to injection of steroid into the lesions. Triamcinolone is often used, but dermal atrophy and leukoderma may occur.

Indications for topical corticosteroids

The anti-inflammatory, immunosuppressant and antiproliferative properties of corticosteroids find numerous applications in dermatology, which are considered in more detail in the relevant sections of this text. Table 75.8 lists some of these applications together with the potencies of compounds that are most often used and the level of evidence available to support their efficacy [61].

Table 75.8 Indications for topical corticosteroids, efficacy and potency of preparations generally employed.

Indication	Potency	Evidence grade	Occlusion and intralesional use
Actinic prurigo	P, VP	C	
Alopecia areata	P, VP	B	Ocl, I/L
Aphthous stomatitis	P	A	
Atopic eczema	M, Mod, P	A	
Bullous pemphigoid	P, VP	D	
Chronic actinic dermatitis	Mod, P	C	
Contact allergic dermatitis	Mod, P	B	
Contact irritant dermatitis	M, Mod, P, VP	C	
Cutaneous T-cell lymphoma	Mod, P	B	
Discoid eczema	P, VP	C	
Discoid lupus	P, VP	B	I/L
Geographic tongue	P	C	
Granuloma annulare	P, VP	E	Ocl, I/L
Granuloma faciale	Mod, P	E	Ocl, I/L
Grover's disease	P	D	
Hailey–Hailey disease	M, Mod, P	C	
Juvenile plantar dermatosis	Mod, P	C	
Langerhans' cell histiocytosis	Mod, P	C	
Lichen nitidus	P	E	
Lichen planopilaris	P, VP	D	I/L
Lichen planus	P, VP	C	Ocl, I/L
Lichen sclerosus	P, VP	A	
Lichen simplex	P, VP	A	Ocl, I/L
Lymphocytoma cutis	P	E	I/L
Lymphomatoid papulosis	P, VP	E	
Morphoea	P	E	I/L
Necrobiosis lipoidica	P	D	Ocl, I/L
Pemphigoid gestationis	P, VP	C	
Pityriasis rosea	Mod, P	E	
Pompholyx	P, VP	A	Ocl
Polymorphic eruption of pregnancy	P	B	
Pretibial myxoedema	P	C	Ocl
Prurigo nodularis	P, VP	E	Ocl, IL
Pruritus ani	M, Mod	A	I/L
Pruritus vulvae	Mod, P	B	
Psoriasis	M, Mod, P, VP	A	Ocl
Pyoderma gangrenosum	P, VP	D	
Sarcoidosis	P, VP	C	Ocl, I/L
Scleromyxoedema	P	E	Ocl, I/L
Seborrhoeic eczema	M, Mod	A	
Strawberry haemangioma	VP	D	
Subacute cutaneous lupus	Mod, P	E	
Subcorneal pustular dermatosis	Mod, P	D	
Sweet's syndrome	P	D	I/L
Urticaria pigmentosa	P, VP	C	Ocl
Vitiligo	P, VP	A	

Potency generally employed: M, mild; Mod, moderate; P, potent; VP, very potent.
Level of evidence available for efficacy [61]: A, double-blind trial; B, clinical trial; C, small trial or more than 20 cases reported; D, at least five cases reported to respond; E, less than five cases reported.
Modalities other than simple external application: Ocl (occlusion) and I/L (intralesional injection) indicate that these approaches have been reported to be useful in selected cases.

Cytotoxic and antineoplastic agents

Bleomycin

Bleomycin is a cytotoxic agent with antitumour, antibacterial and antiviral activity. It binds to DNA, causing strand scission and elimination of pyrimidine and purine bases.

A number of reports document successful treatment of recalcitrant viral warts with intralesional injections of 0.1% bleomycin [1–3]. Two large double-blind placebo-controlled trials gave similar results [2,3]. Seventy-five to 95 per cent of warts on the hands and 60% of plantar warts cleared following 1–3 injections. Local pain is significant, but tolerated by patients who had previously received many unsuccessful treatments. The mechanism of action in warts is not yet known. The small volumes used do not cause systemic toxicity. Treatment of a periungual wart resulted in a permanent nail dystrophy [4]; Raynaud's phenomenon may occur after treatment on digits. The compound must be handled with care.

Bleomycin has also been used in treatment of oral leukoplakia. A 1% solution in DMSO administered for 5 min over 14 consecutive days reduced the size of lesions and histological dysplasia in a trial with 22 patients [5].

5-Fluorouracil

This pyrimidine analogue is an antimetabolite that inhibits pyrimidine metabolism and DNA synthesis.

In the form of a 5% cream, 5-fluorouracil (5-FU) is a very effective treatment for multiple solar keratoses. Lesions on the scalp and face respond more readily than lesions on the limbs. A commonly used regimen comprises twice daily application for 2 weeks but there are many variations on this which are used to improve tolerability. A single daily application is sometimes adequate. Some dermatologists suggest a 1 week on, 1 week off regimen, or use the treatment for 1 week each month, or use it continuously but omit treatment at the weekend. Some patients require longer periods of treatment, and others are cleared only by occlusion of the agent with polyethylene film. A brisk inflammatory response should occur within the keratoses, otherwise clearing is incomplete. Severe ulcerative reactions occur in a few patients. Combination with a fluorinated steroid has been shown to limit the intensity of the inflammatory response without reducing the efficacy of 5-FU [6]. Combination of topical 5-FU applied twice daily with oral isotretinoin 20 mg/day for a median treatment duration of 21 days proved highly effective in a series of cases with disseminated actinic keratoses [7]. Actinic cheilitis and keratosis of the lip can be improved, although the treatment may cause some transient discomfort and dysplastic changes can persist histologically after apparently satisfactory clinical response [8].

5-FU can be effective in Bowen's disease, with 24 out of 26 lesions being cured in a series with 10-year follow-up [9]. However, a recent comparison with photodynamic therapy indicated that the latter was more effective [10]. Bowenoid papulosis can be treated with 5-FU and erythroplasia of Queyrat can also respond [11].

In treatment of basal cell carcinoma (BCC), topical 5-FU is considered most useful for low-risk lesions on the trunk and lower limbs [12]. It has proved successful in reducing the number of lesions appearing in the basal cell naevus syndrome [13]. Intralesional 5-FU has also been used with success in this indication [14].

5-FU, applied daily under adhesive plasters, proved effective in a placebo-controlled trial for the treatment of common viral warts [15]. Applied once or twice a week it has also been shown to be effective and well tolerated in curing resistant vaginal condylomas [16]. A proprietary combination of 5-FU and salicylic acid, applied on a daily basis, resulted in complete healing of genital warts in an average of 12 days [17].

5-FU can also be effective in extramammary Paget's disease [18]. It has been used with variable results in naevoid keratotic conditions including Darier's disease [19], and in superficial actinic porokeratosis [20].

T4 endonuclease V

This is a bacterial DNA repair enzyme that excises damaged sections of DNA. This is the initial step in repair of a DNA strand that has sustained photodamage. Remarkably, in a placebo-controlled study of 1 year duration, a liposomal formulation containing this enzyme has been demonstrated to reduce the occurrence of new neoplasms in patients with xeroderma pigmentosum [21]. This has implications not only for patients with this rare group of diseases; if one enzyme can be delivered into cells simply by application to the skin within liposomes, then it is possible that many other enzyme treatments might be delivered in similar vehicles.

Mechlorethamine

Mechlorethamine (mustine, nitrogen mustard) is a cytotoxic drug that is highly active when applied topically. It is an alkylating agent and acts by binding covalently to DNA and thus inhibiting replication. Its use is often constrained by its marked tendency to induce contact allergic dermatitis. Immediate hypersensitivity reactions can also occur but are less common. It is also potentially carcinogenic, although the precise level of risk is difficult to establish as many groups of treated patients have received additional carcinogenic treatments. Mechlorethamine has a number of dermatological applications.

The most frequent use is probably in the treatment of cutaneous T-cell lymphoma. Concentrations used most frequently are 0.01–0.02% and the treatment is applied once daily [22]. Aqueous solutions and also ointment formulations are highly effective. The latter seem to carry a lower risk of sensitization, although irritant reactions still occur. In a large, recently published series, 137 patients with stage T1 or T2 disease were treated with topical mechlorethamine alone for a median period of 5 years. Complete remission was achieved in the majority and only four progressed to a more advanced stage [22].

Topical mechlorethamine 0.02% can be highly effective and seems to be well tolerated in children with Langerhans' cell histiocytosis [23]. In this series, treatment was initially applied daily to affected areas of skin and the children were bathed to remove excess medication 10 min after the application was completed. The frequency of application was later reduced to every second or third day as the skin improved. Only two out of 20 children treated developed an irritant dermatitis [24].

Topical mechlorethamine has been recognized as effective in the treatment of psoriasis since a placebo-controlled trial was published in 1970 [25]. A solution containing 0.05% was effective after weekly application for 4–20 weeks but most patients eventually became sensitized and this has proved a major disadvantage. Some patients

have successfully maintained long-term control of the disease using a concentration of 0.02% [26]. The risk of sensitization can be reduced by concurrent use of ultraviolet B (UVB) [27] or psoralen with UVA (PUVA) [28].

An encouraging report of alopecia areata and totalis responding to topical mechloethamine 0.02% has not yet been followed up by further reports of success [29]. In a subsequent report, no response was obtained in seven patients with alopecia totalis, although the treatment was well tolerated [30]. However, a recent study on a mouse model of alopecia areata did yield a positive response [31].

In single cases, pyoderma gangrenosum [32], and ulcerating lesions of chronic granulocytic leukaemia [33], have been reported to respond to topical mechlorethamine.

Imiquimod

This interesting compound belongs to a group known as imidazoquinolones. The actions of these compounds seem likely to be mediated by the Toll-like receptor 7 (TLR-7) [34]. This is a cell surface receptor found on cells of monocyte lineage. The naturally occurring ligands for TLRs are highly conserved microbial products, essential for microbial survival, which are responsible for stimulating the relatively primitive innate immune response. Interaction of TLR-7 with ligands activates a signalling pathway leading to release of large amounts of interferon-α, interleukin-12 (IL-12), tumour necrosis factor-α (TNF-α) and other potent cytokines. In addition to stimulating the innate response, these cytokines promote the development of antigen-specific cell-mediated immune responses. Imiquimod is therefore viewed as an immune response modulator.

The first clinical application in which imiquimod proved useful was for treatment of genital warts. In large placebo-controlled [35] and open-label [36] trials, imiquimod 5% cream applied three times weekly for 16 weeks produced complete clearance in 48–50% of patients. Relapse rates in those who had cleared (relapse being defined as recurrence of at least one visible wart) were 13% at 3 months [35] and 23% at 6 months post treatment [36]. Common warts may also respond. Thirty per cent of patients were cleared in a series of 50 treated with 5% imiquimod cream on 5 days each week for up to 16 weeks [37]. Sixteen of 18 children with warts of 2–7 years' duration were cleared of lesions after applying 5% imiquimod cream twice daily for 2–11 months [38]. Facial planar warts responded convincingly in a report of a single case [39]. In one case, stucco keratoses responded to imiquimod [40]; interestingly, human papillomavirus was detected in the lesions. Molluscum contagiosum has also been reported to respond in an uncontrolled study [37].

Imiquimod would seem to have potential in many additional applications including treatment of *in situ* malignancy. Actinic keratoses have been shown to respond in a placebo-controlled trial. Eighty-four per cent of patients were cleared after using imiquimod three times weekly for up to 12 weeks [41]. There was no response to the vehicle control. Fourteen of 15 patients with Bowen's disease had no residual lesion after daily application for up to 16 weeks [42]. Local skin reactions were common but these are thought to reflect the immune response to the tumour. In a series of similar size, actinic cheilitis responded well to imiquimod applied three times weekly for up to 6 weeks [43]. Partial and complete responses have been observed in treatment of cervical, vaginal and vulvar intraepithelial neoplasia and Bowenoid papulosis, although results have not been consistent [44–46]. Extramammary Paget's disease resolved in response to imiquimod in two cases treated daily or on alternate days, as tolerated, for 7.5 and 16 weeks [47]. Both of these patients experienced systemic symptoms (flu-like illness and nausea). Complete resolution was reported in a case of porokeratosis [48].

Trials on BCC have demonstrated unequivocal efficacy in dose ranging and placebo-controlled studies. In superficial BCC, resolution occurred in 81–88% of lesions treated daily, or on 5 days per week, for 6 or 12 weeks [49,50]. Treatment for 6 weeks appeared as effective as 12 weeks. Applying imiquimod on 3 days weekly for 6 weeks produced cure rates of 76%, or 87% when occluded [51]. In nodular BCC, daily treatment has yielded somewhat lower cure rates at 71% or 76% after 6 weeks or 12 weeks, respectively [52]. Treatment on 3 days weekly cured 50%, and 65% with the use of occlusion [51].

Imiquimod may find at least a palliative role in treatment of lentigo maligna and melanoma. In treatment of lentigo maligna, several cases and small series have reported apparently complete clinical resolution [53–55], in some cases confirmed histologically. However, one report describes lentigo maligna that apparently resolved following treatment with imiquimod but the course of the resolution was complicated by the development of a nodular melanoma and microsatellites; these were excised with the patient remaining disease-free after 17 months of follow-up [56]. Complete clinical and histological resolution has been reported in two cases of cutaneous metastatic melanoma [57], while marked improvement has been observed in additional cases [58,59]. In a further case, the cutaneous metastases resolved but lymph node metastasis developed [60].

Imiquimod may prove effective in suppressing the recurrence of keloids following excision. In an uncontrolled study with 12 subjects, the cream was applied nightly for 8 weeks, starting immediately after excision [61]. No recurrences were seen at 6 months.

Diclofenac

This compound is a non-steroidal anti-inflammatory drug that appears to be effective in topical treatment of actinic keratoses. A gel formulation containing 3% diclofenac and 2.5% hyaluronic acid has been developed specifically for this purpose. The mechanism of action remains uncertain. It has been proposed that excessive arachidonic acid metabolism resulting from overactivation of cyclo-oxygenase enzymes is carcinogenic [62]. If so, diclofenac may help suppress actinic keratoses by inhibition of cyclo-oxygenase.

In an open-label study, this formulation was applied twice daily until patients were clear, or for up to 180 days. Twenty-two (81%) of 27 patients who completed the study, and were assessed 30 days after treatment was discontinued, had a complete response and another four (15%) showed marked improvement [63]. These results have been supported by double-blind trials in which 3% diclofenac gel has been applied twice daily for 30–90 days and proved superior to vehicle in clearing solar keratoses [62,64,65]. Consistently, the largest and most statistically significant difference between diclofenac and vehicle has been observed at follow-up 30 days after treatment has been discontinued. This has occurred even when the difference has not been significant at the end of treatment [65]. As assessed at this follow-up visit, the proportions of patients completely cleared have been approximately 16% when treatment duration was 30 days [52], 31% when this was 60 days [52], 38% for 12 weeks [65] and 47% when the duration was 90 days [64]. It would therefore seem that the clearance rate continues to increase with increasing treatment duration.

The treatment seems to be well tolerated, although pruritus has not been uncommon and dermatitis, confined to the treated site, has developed occasionally.

Podophyllin and podophyllotoxin

Podophyllin (podophyllum) is a plant extract traditionally used to treat genital warts. Podophyllotoxin is the most active constituent. This is now available in standardized formulations free of the unwanted constituents of podophyllin. Podophyllotoxin is an antimitotic agent which arrests cells in metaphase by binding to tubulin. Podophyllin is known to be highly mutagenic and although podophyllotoxin may be less hazardous, both of these treatments should be avoided in pregnancy. Irritant reactions are common with these agents.

Podophyllin 0.5% in ethanol may be applied on 3 consecutive days each week to treat penile warts [66]. Podophyllin 10–25% in tincture of benzoin compound may be applied once or twice a week to genital or perianal warts (washed off after 6–12 h). Podophyllotoxin can be used at a 0.5% concentration in ethanol as a once daily application. It will clear 60–70% of genital warts within 3–5 days [67]. A cream formulation containing 0.15% podophyllotoxin is also available and can be applied twice daily for 3 days each week.

Depigmenting agents

Depigmenting agents are most frequently used by dermatologists in the treatment of melasma. Hydroquinone, used alone in concentrations usually ranging from 2 to 5%, or in combination with retinoic acid in 0.025–0.1%, is currently the most widely used treatment for this indication.

Post-inflammatory hyperpigmentation is another commonly encountered problem and this is particularly difficult to treat as much of the pigment is often contained in dermal melanophages. Nonetheless, depigmenting compounds such as tretinoin, hydroquinone or azelaic acid are sometimes prescribed.

In severe cases of vitiligo when depigmentation is already extensive, depigmenting agents can improve the appearance of the skin by removing residual patches of normal pigmentation.

Solar lentiginosis is another indication for which depigmenting agents can prove useful. Retinoic acid has the best evidence base in this indication.

There is also a demand among populations with pigmented skin for agents to reduce the intensity of pigmentation for purely cosmetic purposes. In parts of Africa, treatments abused for this purpose include very potent topical corticosteroids, mercury compounds and high concentrations of hydroquinone [1–3].

Hydroquinone

Hydroquinone (1,4 dihydroxybenzene) is widely used as a depigmenting agent both in clinical and cosmetic contexts.

The efficacy of 4% hydroquinone cream in treatment of melasma was demonstrated in a placebo-controlled trial in which treatment was applied nightly for 3 months [4]. Higher concentrations are sometimes used in extemporaneous formulations for severe or resistant cases of chloasma or for post-inflammatory hyperpigmentation. The efficacy of hydroquinone in post-inflammatory hyperpigmentation is likely to be highly variable as this is a very heterogeneous entity. Hydroquinone is used at 5% concentration as a constituent of Kligman cream (see below) [5]. It can cause both irritant and allergic reactions. The addition of a weak topical steroid reduces the irritant effect. It is unstable and tends to darken as a result of autooxidation. Hydroquinone probably reduces pigmentation, at least partly, as a result of inhibition of melanin synthesis, because it is known to inhibit tyrosinase. However, the mechanism is not fully understood. It has also been proposed that its action may be partly mediated by release of free radicals. In animal models, the effect of the drug is potentiated by the use of buthionine sulfoxime or cystamine to inhibit synthesis of the protective free radical scavenger glutathione [6].

Epidemiological studies indicate that a very large proportion of the African population (perhaps the majority of women) have used hydroquinone cosmetically as a skin lightening agent [1–3]. This practice has been strongly associated with the development, in these black-skinned individuals, of exogenous ochronosis [1–3,7,8]. This disease, like endogenous ochronosis (alkaptonuria), derives its name from the colour of the cutaneous pigment deposits that characterize these conditions (Greek *ochro*, yellow). When these are examined histologically they appear yellow or brown, although clinically the pigment appears dark brown or black. Endogenous ochronosis is an inborn error of metabolism in which deficiency of homogentisic acid oxidase results in accumulation of homogentisic acid, a metabolite of tyrosine and phenylalanine. Oxidation products of homogentisic acid are thought to constitute the pigment deposited in the skin, cartilage and elsewhere.

The pigment in exogenous ochronosis strongly resembles that in the endogenous form and may result from inhibition of homogentisic acid oxidase by hydroquinone. Milder cases show only macular sooty pigmentation while more advanced cases develop irregular stippling, papulation and pigmented colloid milia [8,9]. These features tend to be most prominent over the areas of skin most intensely exposed to the sun. Histologically, deposits of pigment are observed in the papillary and reticular dermis and probably represent accumulations of the pigment in association with degenerated collagen [9,10]. In many countries, the concentration of hydroquinone in cosmetic products has been legally restricted to 2% with the aim of reducing the risk of causing ochronosis. However, it is not established that this risk is dependent on the concentration [11].

In striking contrast to Africa, exogenous ochronosis seems to be rare in the USA, even though hydroquinone-containing compounds are widely used there [12,13]. Possible explanations put forward for this paradox include under-reporting, combined use with other compounds in Africa, the need for intense solar irradiation as a synergistic factor, the use of different formulations (especially hydroalcoholic solutions) in Africa, or that the use of these compounds in the USA may be relatively cautious.

Exogenous ochronosis occurs almost entirely in black skin. It does not seem to be a hazard in white skin, although occasional cases have occurred in Hispanics. The relatively high levels of enzyme activity associated with melanin synthesis in black skin and additional stimulation of these pathways by intense sun exposure seem to be required for ochronosis to develop.

Monobenzyl ether of hydroquinone

Skin bleaching with 20% monobenzyl ether of hydroquinone (monobenzone) is generally reserved for treatment of carefully selected cases of vitiligo. The resulting depigmentation may be permanent so this treatment is only suitable for those with extensive disease in whom the appearance of the skin would be improved by removing the residual pigment. Patients should be warned that results are unpredictable. Treatment may need to be prolonged and is not always successful [14]. Depigmentation may be permanent and may occur at sites other than those being treated. Conversely, spontaneous repigmentation may occur unexpectedly after cessation of the treatment, slowly or rapidly, at both treated and untreated sites [15]. Contact dermatitis can develop [14,16]. It has also been reported that this treatment may cause corneal and conjunctival pigmentation [17].

The addition of monobenzone to cosmetic skin lightening preparations caused an epidemic of leukomelanoderma in South Africa during the early 1970s [9].

Additional phenol derivatives

Mequinol (4-hydroxyanisole, 4-methoxyphenol) is another phenol derivative with depigmenting properties. It is a constituent of a commercially formulated solution containing 2% mequinol and 0.01% retinoic acid marketed for treatment of solar lentiginosis. In trials with treatment duration of 24 weeks, this combination appeared more effective than either of the constituents used alone, or than placebo [18]. Mequinol 20% cream has been successfully used to remove residual pigmentation in severe vitiligo with efficacy considered comparable to monobenzone [19].

N-acetyl-4-*S*-cysteaminylphenol (*N*-Ac-4-*S*-CAP) produces reversible depigmentation in the Yucatan pig model [20,21]. In one report of its use in melasma, 8% of

patients showed complete depigmentation, 66% marked improvement and 25% moderate improvement [22].

Retinoic acid

Retinoic acid (tretinoin) has been successfully used to reduce pigmentation in a variety of disorders including melasma [23], solar lentiginosis [24,25] and post-inflammatory hyperpigmentation [26]. In most trials, tretinoin 0.1% cream has been used for 40 weeks. Retinoid dermatitis is a common side effect and may result in post-inflammatory hyperpigmentation. Some mild reduction of pigment may occur in normal skin surrounding the treated areas. The mechanism of action is not fully understood but may be at least partly explained by reduction in melanogenesis consequent upon reduction of tyrosinase activity [27].

Attempts have been made to use other retinoids for this purpose with variable results. All-*trans* retinol gel 10% proved effective, although irritant, in a Japanese study [28]. A study on the use of topical 0.05% isotretinoin in melasma showed no difference from placebo after 40 weeks [29].

Kligman cream

This formulation comprises 5% hydroquinone, 0.1% tretinoin and 0.1% dexamethasone in hydrophilic ointment [5]. It has been widely used as a depigmenting treatment, especially for melasma. The combined formulation is considered more effective than any of the individual constituents.

Azelaic acid

This dicarboxylic acid is a relatively safe, although mildly irritant agent, with several roles in dermatology.

As a depigmenting agent, azelaic acid is moderately effective in treatment of melasma. The proposed mechanism is direct or indirect inhibition of tyrosinase [30]. Azelaic acid 20% cream proved more effective than 2% hydroquinone cream after 24 weeks of treatment [31]. In two other studies with the same treatment duration, 20% azelaic acid proved equivalent in efficacy to 4% hydroquinone cream [32,33]. Another study on facial hyperpigmentation in darker skinned individuals compared a combination of azelaic acid 20% cream with glycolic acid 15% or 20% lotion, versus 4% hydroquinone cream; similar efficacy was observed from the two regimens [34]. The addition of tretinoin enhances the depigmenting effect [1,2]. Azelaic acid has also proved effective in treatment of Kitamura's reticulate acropigmentation [35].

Azelaic acid also has antineoplastic properties, inhibiting mitochondrial function and DNA synthesis [36], and has been used as a palliative treatment for lentigo maligna and malignant melanoma [37–39]. However, because some cases of lentigo maligna have progressed to invasive melanoma while using this treatment, it must be regarded as purely palliative in these indications [37].

Azelaic acid 20% cream is effective in treatment of acne vulgaris [40]. This is likely to be a result of a combination of antimicrobial and anti-inflammatory properties. It can inhibit growth of *Propionibacterium acnes* and *Staphylococcus epidermidis* and inhibits production of free radicals by polymorphs [41]. The latter property may also explain why it is effective in rosacea [42,43]. It may also prove to have a role as an antimycotic inhibiting growth of dermatophytes [44,45], and as a topical antimicrobial agent with activity against antibiotic-resistant *Staph. aureus* [46].

Kojic acid

This is a fungal metabolite known to inhibit tyrosinase [47]. It is a constituent of over-the-counter depigmenting creams sold mainly in Japan. In treatment of melasma, 1% kojic acid proved equally effective as 2% hydroquinone when each was used in combination with glycolic acid [48].

Liquiritin

This compound, which can be extracted from liquorice (*Glycyrrhiza glabra*) and other herbal sources, has been reported to effectively reduce the pigmentation of melasma in a double-blind trial [49].

Depilatories

Depilation can be defined as temporary removal of hair, while epilation denotes permanent destruction of the follicle. Epilation therefore requires physical methods of destruction of the follicle such as electrolysis, lasers and intense pulsed light. Depilation can be achieved by shaving, waxing, plucking, threading and by use of topical depilatory creams. Systemic androgen antagonists have a part to play in some cases. All these techniques are described further in Chapter 63; only topical treatments are discussed here.

Traditional depilatory creams depend upon breaking the disulphide bonds in hair. Three main classes are currently used. The oldest are various sulphides, which have a powerful effect but may irritate, and which in the presence of water generate hydrogen sulphide which has an unpleasant odour. Strontium or barium sulphide 20% are widely used. They are effective on the terminal hair in the axillae. Thioglycollates are being used more frequently, but they are slower to work than sulphides. Concentrations of 2.5–4% produce an effect in 5–15 min. Substituted mercaptans (thioalcohols) are most widely used. They work slowly, but are suitable for use on the face.

Eflornithine hydrochloride is an irreversible inhibitor of ornithine decarboxylase, an enzyme required for hair growth. This is marketed as a 13.9% cream, which can slow the growth of facial hair. A response takes 4–8 weeks to develop and the effect wears off over a similar period when the treatment is discontinued. The benefit seems to

be rather modest in many cases, with only 32% of patients reporting marked improvement [1,2]. Some irritation may occur.

Dithranol

Dithranol (anthralin) [1] is a time-honoured topical treatment for psoriasis, similar in its irritating and staining properties to chrysarobin, which it supplanted in the early 20th century, but more effective. It is used in ointments, pastes, creams and as a pomade for use on the scalp.

The mechanism of action of dithranol is still uncertain. It inhibits glycolytic enzymes *in vitro* [2]. Reactive oxygen species are generated during auto-oxidation of dithranol [3] and these may inhibit mitochondrial function [4]. It has been suggested that enzyme inactivation may result from lipid peroxidation, leading to cross-linkage of enzyme proteins [5]. *In vitro* studies with human skin showed decreased oxygen consumption and inhibition of the pentose phosphate shunt [6]. The level of cyclic guanosine monophosphate is known to be increased in psoriasis. Dithranol has been shown to restore cyclic nucleosides in skin to normal levels [7]. It induces a marked antiproliferative effect [8,9].

The use of dithranol has proved remarkably safe. Staining of the skin and of other materials is certainly inconvenient although, as a result, the appearance of the skin provides a reliable guide to compliance (Fig. 75.7). Local reactions are common and irritation of normal skin accidentally contaminated with dithranol can be severe (Fig. 75.8). However, there is no evidence of systemic toxicity and it is not considered to be carcinogenic.

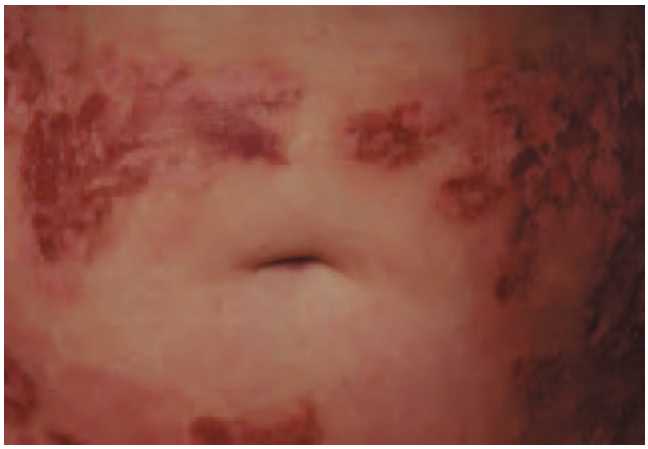

Fig. 75.7 Staining of the skin resulting from dithranol treatment.

Fig. 75.8 An irritant reaction following accidental contamination of normal skin with dithranol.

Dithranol, especially when incorporated in zinc oxide, is slowly oxidized by alkaline impurities to an inactive pink anthrone [10]. The effect of salicylic acid in preventing this has been known for a long time [11–13]. Salicylic acid neutralizes hydroxyl ions in an alkaline medium, and perhaps reacts with free zinc ions to form an inactive zinc–dithranol complex. It has been found that zinc ions and salicylic acid, like dithranol itself, inhibit glucose-6-phosphate dehydrogenase, thus further justifying the time-honoured combination of these three agents [6]. The combination of tar with dithranol is said to reduce dithranol irritancy without inhibiting therapeutic effect [14].The use of a water-soluble antioxidant, ascorbic acid, has allowed the production of stable dithranol cream preparations [10]. These are not as therapeutically potent as equivalent strengths of pastes or ointments but show much greater patient acceptability for home usage [15]. The development of lipid-encapsulated cream formulations also seems likely to increase acceptability by further reducing staining and irritation [16,17].

Short-contact applications of strong dithranol pastes or creams are known to be almost as effective as prolonged contact and facilitate treatment on an outpatient basis and self-treatment at home [18–20].

Dithranol has also been used to stimulate an inflammatory response and regrowth of hair in patients with alopecia areata [21], and for the treatment of warts [22].

Emollients

The word emollient is derived from the Latin verb *mollire*, to soften. The term is used by dermatologists to denote materials that soften and moisturize the surface of the skin. Most of the formulations used as emollients are creams, ointments, bath oils or soap substitutes. Emollient creams and ointments are formulated using the various materials described earlier in this chapter as constituents of vehicles and are essentially vehicles without a drug to deliver. They are applied to the skin purely to take advantage of their physical properties (protecting, lubricating and moisturizing effects). The efficacy of an emollient is not related to the cost, although this may have some impact on cosmetic acceptability. The most effective emollient is probably white soft paraffin (petrolatum).

The value of bath oils is not well established, although these are widely used in the UK. Most contain lipids such as liquid paraffin, which probably help reduce the drying effect of bathing by protecting the stratum corneum with a layer of lipid. Some also contain antiseptics and antipruritic compounds which can be of additional value. The use of bath oils is best avoided for elderly patients as they tend to make the bath slippery.

The use of soaps on inflamed skin, especially in atopic dermatitis, is generally considered harmful and likely to exacerbate damage to the stratum corneum [1,2]. Compounds used as soap substitutes are lipid materials containing emulsifiers such as Aqueous Cream BP or Emulsifying Ointment BP. Most emollient creams can be used in this way. These can effectively remove lipid-soluble dirt and contamination from the skin surface while avoiding the damage done to the stratum corneum by irritant surfactants. Patients with dry skin conditions report that soap substitutes improve the condition of the skin [3]. Paradoxically, the introduction of washing with common toilet soap was accompanied by improvement in atopic dermatitis in one study [4], possibly reflecting increased compliance with other aspects of treatment.

Immunomodulators

SYN. CALCINEURIN INHIBITORS

Several topical medications alter immune responses, but are discussed elsewhere in this chapter—for example, corticosteroids or imiquimod, which is viewed as an immune response modulator. This section considers the calcineurin inhibitors.

These compounds have been developed for topical treatment of atopic dermatitis but seem likely to find numerous additional applications. There are currently two agents, tacrolimus and pimecrolimus, available in this class and others are likely to follow. The mechanism of action is similar to that of ciclosporin. Lymphocyte activation is suppressed by inhibition of calcineurin, a calcium- and calmodulin-dependent serine/threonine phosphatase. This cytoplasmic enzyme activates the

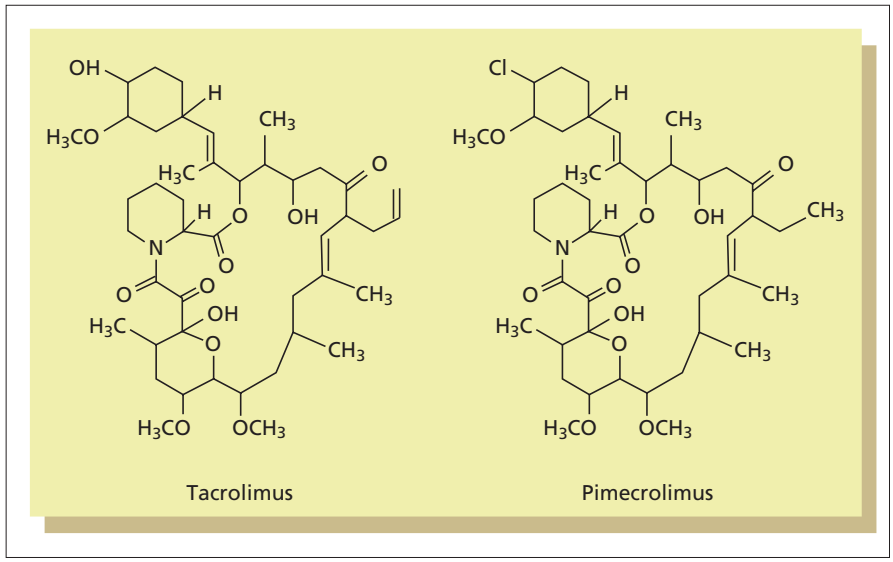

Fig. 75.9 The structures of tacrolimus and pimecrolimus.

nuclear factor of activated T cells (NFAT), a transcription factor regulating numerous lymphokines in both Th1 and Th2 lymphocyte subsets, and constitutes an important link in signal transduction from the T-cell receptor to the nucleus [1]. Similar mechanisms operating in other cell types, including mast cells [2,3], antigen-presenting cells [4] and keratinocytes [5], may provide additional targets for these drugs. In contrast to ciclosporin, these molecules have a sufficiently low molecular weight to penetrate the stratum corneum, at least when barrier function is impaired as is the case in atopic dermatitis. They are therefore active when applied topically. Both compounds have been under investigation in clinical trials for over 9 years now. A notable advantage of these agents is that they do not induce cutaneous atrophy [6,7], even with long-term regular application [8–10], and it is therefore possible to apply them to facial and flexural areas where prolonged use of topical corticosteroids causes concern. Theoretically, the local immunosuppression related to these compounds could increase the risks of infections and neoplasia. In the numerous trials on atopic dermatitis, infections have not been more frequent than expected. The risk of neoplasia also remains theoretical.

Tacrolimus

Tacrolimus (FK-506) is a macrolide lactam antibiotic (macrolactam) discovered in Japan where it was first isolated from a soil fungus, *Streptomyces tsukubaensis*. It has been used systemically in transplantation for over 15 years and is known to be effective, used systemically, in treatment of psoriasis [11]. It has a molecular weight of 822 Da and a complex structure (Fig. 75.9). The efficacy of tacrolimus in atopic dermatitis has been demonstrated in several placebo-controlled trials in both adults [12,13] and children [14,15]. In comparative trials, tacrolimus ointment 0.1% applied twice daily is comparable in efficacy to potent topical corticosteroids such as hydrocortisone butyrate 0.1% [16] and betamethasone valerate 0.12% ointment [17]. It is been more effective than hydrocortisone acetate 1% ointment in children [15] and was more effective than the moderately potent alclometasone dipropionate 0.1% ointment in treatment of eczema on the face and neck in adults [18]. In children, a lower concentration of 0.03% tacrolimus has proved nearly as effective as 0.1% [14,15], while in adults there is a more marked difference between these concentrations and 0.1% is clearly more effective [16,19]. The most frequently encountered side effect is a burning sensation lasting for a few minutes after application. This tends to resolve after a few days and is rarely of sufficient severity to require withdrawal of the treatment. Systemic exposure is low and drug levels in blood are usually too low to measure [14,20,21]. Using data obtained from application of 0.3% tacrolimus ointment, systemic bioavailability has been estimated at 0.5% of that obtained by intravenous administration [21]. It is therefore unlikely that topical application of tacrolimus will exhibit systemic activity. Furthermore, systemic exposure tends to fall as the eczema improves, indicating that penetration of the drug is reduced as barrier function is restored [22].

Additional applications for topical tacrolimus have currently been less formally investigated and it should be noted, in particular, that extensive safety data relating to systemic exposure are available only for atopic dermatitis. The use of topical tacrolimus in Netherton's syndrome (ichthyosis linearis circumflexa) can result in clinically significant systemic exposure to the drug [23], indicating that some care is required.

Reports indicate that topical tacrolimus is effective in

treatment of several other varieties of eczema including chronic actinic dermatitis [24], endogenous hand eczema [25] and eyelid dermatitis [26]. In a guinea pig model, irritant and allergic contact dermatitis have been suppressed [27]. Treatment of psoriasis has so far proved less successful [28], although the author has treated facial and flexural psoriasis with unequivocal improvement and similar reasonably successful results have been reported by others [29]. This relatively modest response in psoriasis is somewhat surprising given that systemic use of calcineurin inhibitors (ciclosporin and tacrolimus) is highly effective and a good response has also been observed when tacrolimus was applied under occlusion in a microplaque assay [30]. It would seem, however, that penetration of the drug through the plaques of psoriasis vulgaris is not adequate. Sadly, the efficacy of topical tacrolimus in the Dundee experimental bald rat model of alopecia areata [31] has not so far been reproduced in the treatment of human cases of this disease. Development of a more appropriate formulation might improve results in psoriasis and alopecia areata.

There are more encouraging reports of efficacy of topical tacrolimus in a variety of other dermatoses including oral and genital erosive lichen planus [32–36], pyoderma gangrenosum [37–39], cutaneous graft-versus-host disease [40], rheumatoid leg ulceration [41], cutaneous sarcoidosis [42], steroid-induced rosacea [43], uraemic pruritus [44], vitiligo [45,46], discoid lupus erythematosus [47], eosinophilic folliculitis [48] and epidermolysis bullosa [49]. Oral and perineal lesions of Crohn's disease have responded [50] and topical tacrolimus has been effective in suppression of skin allograft rejection [51]. Improvement has been observed in Netherton's syndrome [23,52], although, as discussed above, significant systemic absorption may occur in this disease. Three cases of erosive pustular dermatosis of the legs responded to topical tacrolimus [53].

Pimecrolimus

Pimecrolimus (SDZ ASM 981) is another macrolactam with a structure similar although not identical to tacrolimus and molecular weight 810 Da (Fig. 75.9). The relatively small differences in structure compared to tacrolimus confer greater lipophilicity but reduce potency. Most of the clinical research on this compound has so far been in atopic dermatitis. Placebo-controlled trials have demonstrated efficacy and safety of pimecrolimus 1% cream in adults [54–56] and children from 3 months of age upward [57,58]. In a comparative study, this treatment was less effective than betamethasone valerate 0.1% cream [55]. Used in long-term studies, pimecrolimus has effectively inhibited flares of the disease and reduced the requirement for topical corticosteroids [56,58]. Systemic absorption of pimecrolimus has been low and usually undetectable [59,60]. Topical pimecrolimus has been safe and well tolerated. Although a burning sensation is sometimes reported in the treated areas, this usually resolves after a few days. Infections have not been increased and there has been no evidence of increased neoplasia.

Experience with pimecrolimus in other skin diseases has been very limited so far. In animal models, pimecrolimus inhibits induction of contact allergic dermatitis [61]. An initial report suggests that it may suppress established nickel dermatitis [62]. Used systemically [63] and also applied topically under occlusion, it can be effective in psoriasis [64]. A response has also been reported in a case of seborrhoeic dermatitis [65].

Ciclosporin (cyclosporin)

Despite the best endeavours of many investigators over the years to develop topical uses for ciclosporin, this has failed to find any consistently useful role. Ciclosporin has a high molecular weight of 1202 Da and this is probably the reason why it does not penetrate through the skin in sufficient concentration to be effective. Early reports of efficacy in oral erosive lichen planus may have been the result of significant systemic absorption. A controlled study using triamcinolone as comparator found no difference between the treatments and the improvement observed was only modest [66].

Retinoids

The retinoids can be defined either as compounds related structurally to retinol (vitamin A) or as compounds that are able to interact with retinoid receptors. The latter definition has become more useful as an increasing number of synthetic 'retinoids' are developed with diverse structures. Topical retinoic acid has been used in treatment of acne vulgaris for over three decades. During this period much has been learned about the fundamental part played by endogenous retinoids in the regulation of cell differentiation and proliferation and about the mechanisms involved. Retinoids are now used for many indications including psoriasis, photo-ageing and numerous disorders of keratinization as well as for suppression of dysplasia and malignancy.

The activity of endogenous retinoids within the cell is regulated by binding proteins known as cellular retinol binding proteins (CRBP I and II), and cellular retinoic acid binding proteins (CRABP I and II). These proteins are widely distributed throughout the body in many cell types. CRABP II predominates in skin, and is found in keratinocytes and fibroblasts [1]. This protein is up-regulated by retinoic acid [2] and by other compounds demonstrating retinoid activity, and is believed to have a role in regulating the availability of free retinoic acid within the cell.

Within the nucleus, retinoids bind to specific receptors, retinoic acid receptors (RAR α, β and γ) and retinoid X receptors (RXR α, β and γ). Alternative splicing of each of these receptors generates further diversity (the subtypes being known as RAR-α1, RAR-α2, etc.) [3]. All-*trans* retinoic acid is the endogenous ligand for the RARs while 9-*cis* retinoic acid is the endogenous ligand for the RXRs. The receptors most abundantly expressed in the epidermis are RAR-γ and RXR-α, while RAR-α and RXR-β are present at relatively low levels. These receptors bind to specific elements of DNA, known as response elements, within the regulatory regions of numerous genes and this interaction may increase or decrease transcription of the gene. There are usually several such response elements involved in regulating the transcription of any single gene. The retinoid receptors are mainly active as heterodimers of RXR and RAR. RXRs can also dimerize with several other similar receptors such as the vitamin D receptor, the thyroid receptor and orphan receptors (which have no established endogenous ligand). This range of different receptors and their dimers, the various possible states of binding with different ligands and the wide range of different response elements allows for the highly diverse and complex signalling required to regulate cellular metabolism. The end result of these processes acting on numerous different genes is that retinoids demonstrate a tendency to normalize keratinocyte differentiation in diverse circumstances where this is disturbed.

Metabolism of retinoids takes place within keratinocytes. The initial step is usually 4-hydroxylation by cytochrome P-450 enzyme systems, such as CYP 2S1 and CYP 26, which can be induced by their substrate and may show considerable interindividual variation [4]. This variation may explain some of the variability between individuals in responses to topical retinoids.

Systemic retinoids are known to be highly teratogenic when administered in doses sufficient to induce the mucocutaneous symptoms associated with hypervitaminosis A. This has led to some concern about the potential for the topical application of retinoids to exert teratogenic effects. Fortunately, this risk is entirely hypothetical. Systemic exposure to retinoids applied topically seems to be minimal [5,6], but it is generally recommended that even the topical use of retinoids should be avoided during pregnancy.

The naturally occurring 'endogenous' retinoids include retinol, which is metabolized within most cells, including keratinocytes, to retinoic acid. This process seems to be regulated by a variety of mechanisms so that the level of free retinoic acid is tightly controlled. Retinoic acid can isomerize to 13-*cis* and 9-*cis* retinoic acid, a process that occurs readily in the presence of visible light.

The synthetic retinoids currently used in the topical treatment of skin disease are adapalene, bexarotene and tazarotene. All these compounds are effectively absorbed into the epidermis when applied topically.

Retinol

SYN. VITAMIN A

Retinol is used widely in cosmetic products and tends to be regarded as a vitamin supplement rather than a medicament in this context. However, it is clear that retinol applied topically to the skin is absorbed into the epidermis and exhibits many of the pharmacological properties of retinoic acid. Topical application of retinol increases levels of retinyl esters within the epidermis [7]. These are esters of retinol with long-chain fatty acids which constitute an intracellular reservoir of inactive retinol. Esterification of retinol is induced by retinoic acid and this probably represents an autoregulatory mechanism that inhibits excess synthesis of retinoic acid [8]. In addition, topically applied retinol induces 4-hydroxylase activity, and thus increases metabolism and inactivation of retinoic acid [9]. Levels of CRABP II and CRBP are also induced by topical application of retinol [7].

Retinol increases epidermal thickness in a manner similar to retinoic acid but causes much less irritation [7,10]. Retinol 10% gel has been used as a component of a depigmenting regimen with results considered comparable to those obtained from retinoic acid. However, this high concentration was irritant [11].

Retinoic acid

SYN. TRETINOIN; ALL-*TRANS*-RETINOIC ACID; VITAMIN A ACID

Retinoic acid is well absorbed into the skin when applied topically and exerts potent local effects on cellular metabolism. This is the endogenous ligand for the RARs. Isomerization of retinoic acid results in formation of 13-*cis* and 9-*cis* retinoic acid [12], the latter being the naturally occurring ligand for the RXRs. These isomerizations are accelerated in visible light.

Retinoic acid is most frequently used in treatment of acne vulgaris. It is normally applied once or twice daily at a concentration of 0.01–0.025% in a lotion, cream or gel. Higher concentrations (e.g. 0.1%) have often been used in the past. It is particularly effective in reducing comedones [13,14] and is therefore often used in cases where these non-inflammatory lesions are prominent. It may cause some initial exacerbation of the symptoms for the first 6 weeks of treatment. During this period comedones are expelled and then prevented from reforming if its use is continued. Inflammatory lesions of acne are also reduced, possibly as a secondary event following the reduction in comedones. Irritant reactions are common and may even accelerate the response. However, neither erythema nor peeling is essential for response to be achieved [15]. The irritation can be managed by reducing the concentration or frequency of application. Topical retinoic acid is also effective for treatment of comedonal acne induced by systemic corticosteroids [16].

Topical retinoic acid improves several features of photo-ageing including fine and coarse wrinkling, and dyspigmentation [17]. The clinical improvement is accompanied by reversal of epidermal atrophy and dysplasia, and increasing collagen synthesis in the papillary dermis [18]. Similar effects can also be induced in intrinsically aged skin [19]. Treatment may need to be applied daily for 4 months or more to achieve these effects. A formulation containing 0.05% retinoic acid in an emollient cream base is marketed specifically for treatment of photo-ageing. Lower concentrations can also be effective [20].

Tretinoin has both a therapeutic and prophylactic effect on chemically induced skin tumours, and may be both a promoter and inhibitor of UVB carcinogenesis. Clinically, it exhibits an antineoplastic effect, and may be used to treat small solar keratoses either alone [21] or in combination with 5% 5-FU cream [22]. It also has a 'normalizing' effect on the histological appearance of dysplastic naevi [23].

Despite theoretical mechanisms and early claims that it could be effective, topical application of retinoic acid has not found a role in the treatment of psoriasis.

Retinoic acid can be effective in reducing various forms of hyperpigmentation (see depigmenting agents above).

Another interesting property of tretinoin is its ability to accelerate wound healing [24]. It needs to be applied before wounding, preferably for several weeks. Results of application after wounding have not been consistent, probably because of the irritant effect. The ability of retinoic acid to promote healing has been used to improve results from procedures such as chemical peeling [25] and dermabrasion [26].

A number of other conditions have been treated with topical retinoic acid with varying success. It is of value in the treatment of senile comedones [27]. Comedo and warty naevi may show some response, as may plane warts and reactive perforating collagenosis. Some cases of Darier's disease respond, especially if mild or localized [28]. Keratosis pilaris was reported to respond by eight of 49 respondents in a patient survey [29]. Of the ichthyoses, the lamellar variety appears to be helped most, although ichthyosis vulgaris was also responsive in a four-centre trial [30], as was erythrokeratoderma variabilis [31]. It can be useful in oral lichen planus [32], and in geographic tongue [33]. Fox–Fordyce disease (apocrine miliaria) has been effectively treated with a 0.1% solution [34]. Hydrocortisone cream (1%) has been recommended to control the associated axillary discomfort [35]. Hypertrophic scars and keloids have been reported to respond to a daily application of a 0.05% solution [36,37].

Although sensitization to retinoic acid has been reported this seems to be a rare event [38].

Isotretinoin

SYN. 13-*CIS* RETINOIC ACID

Isotretinoin is readily isomerized to tretinoin and vice versa. It therefore exhibits a similar receptor specificity to tretinoin, interacting with RARs. Isotretinoin is used both topically and systemically for treatment of acne vulgaris. When used topically it is considered somewhat less irritant than tretinoin but may be more so than adapalene [39]. The efficacy of isotretinoin 0.05% gel in acne vulgaris has been confirmed in comparison with placebo [40], and seems similar to that of retinoic acid [41]. In a trial comparing topical isotretinoin with benzoyl peroxide, the latter treatment improved inflammatory lesions more rapidly, although both comedones and inflammatory lesions eventually responded to a similar degree [42]. Topical isotretinoin is believed to work mainly by inhibiting comedogenesis, although it is also known to penetrate into sebaceous glands [43] and may reduce sebum secretion [44].

Isotretinoin cream does not appear effective in treatment of chronic plaque psoriasis [45]. However, it shares with tretinoin the ability to reduce features of photo-ageing [46,47]. It also demonstrates antineoplastic properties. A limited degree of response is seen in treatment of

actinic keratoses when applied twice at a concentration of 0.1% for up to 24 weeks [48], and a degree of efficacy was shown in a trial on topical treatment of BCC although complete regression was only observed in four out of 50 cases treated [49].

In isolated reports, topical isotretinoin has proved helpful in treatment of perifolliculitis capitis abscedens et suffodiens [50], oral [51] and vulval [52] leukoplakia, oral lichen planus [53], hyperkeratosis of the nipple [54] and actinic granuloma [55]. It has not proved effective in melasma [56]. In treatment of Darier's disease, isotretinoin can prove helpful in treatment of small areas of hyperkeratosis but is also irritant [57,58].

Adapalene

Adapalene is a synthetic retinoid that has been developed for treatment of acne vulgaris. In randomized comparative trials, adapalene gel 0.1% has proved equally effective and better tolerated than retinoic acid gel 0.025% [39]. In comparison with topical isotretinoin, adapalene was slightly more effective and less irritant [59,60]. Adapalene appears to retain comedolytic activity while showing less potential for irritancy than retinoic acid. It exhibits specificity for RAR-β and -γ receptors with low affinity for RAR-α relative to retinoic acid [61]. It is highly lipophilic, a property likely to enhance efficacy by increasing penetration of the hair follicle. In addition, adapalene has anti-inflammatory properties that may improve both efficacy and tolerability [61]. Formulations available are cream, aqueous gel, lotion and single use pledgets, all containing 0.1% adapalene.

Bexarotene

Bexarotene is a novel synthetic retinoid with specificity for RXRs. Compounds with this pattern of receptor specificity are sometimes called rexinoids. It has proved helpful in the treatment of cutaneous T-cell lymphoma and can be used orally as well as topically in this indication. In a study on early (plaque stage) cutaneous T-cell lymphoma, topical treatment with bexarotene gel in concentrations ranging up to 1% applied up to four times daily achieved complete clinical clearance in 21% of cases and partial response in a further 42% [62]. The median time to response was 20 weeks. Topical bexarotene is produced as a 1% gel formulation. Treatment is usually commenced cautiously with applications on alternate days and gradually stepped up to four times daily [63].

Tazarotene

Tazarotene is a synthetic retinoid. It is a pro-drug that is rapidly hydrolysed to its active form, tazarotenic acid. The molecule has a rigid structure, in contrast to that of retinoic acid which can undergo conformational changes. Tazarotene exhibits a degree of receptor specificity, interacting with RAR-α, -β and -γ. The latter receptor is likely to be most important in the epidermis. Tazarotene does not bind to RXRs and, unlike retinoic acid, it is not susceptible to isomerization into a conformation that might do so [64].

It has been developed mainly for treatment of psoriasis and acne vulgaris. It is also known to be effective in treatment of psoriasis when administered orally.

The efficacy of topical tazarotene in psoriasis has been established in placebo-controlled trials, around 65% of patients showing 50% or greater improvement after 12 weeks of treatment with 0.1% tazarotene gel once daily [65]. In more recent studies investigating a cream formulation, 39–51% of patients were reported to experience clinical success after application of 0.1% tazarotene cream once daily for 12 weeks [66]. In a comparative study, the global improvement on 0.1% tazarotene gel applied once daily was slightly less than that obtained from 0.05% fluocinonide cream applied twice daily. In all these trials, and in contrast to fluocinonide, the response to tazarotene was notably well maintained during the 12 weeks after treatment was stopped [67]. Psoriatic onycholysis and nail pitting were improved by tazarotene in a small controlled trial [68]. Irritant reactions at the application site are common so tazarotene is sometimes used in conjunction with a topical corticosteroid. It has also been used with phototherapy. There are isolated reports of severe genital ulceration [69] and of pyogenic granuloma developing during topical treatment of psoriasis with tazarotene. The latter is a well-recognized side effect associated with systemic retinoids [70].

Tazarotene 0.1% gel has been shown to be effective in acne vulgaris in a placebo-controlled trial even when applied once daily for short contact periods of 30 s to 5 min [71]. In comparison with tretinoin in a 0.1% microsponge gel, tazarotene 0.1% gel proved more effective. The tolerability of the two treatments was considered comparable [72]. In a comparative study using once daily applications, tazarotene 0.1% gel proved more effective than adapalene 0.1% gel although it was also slightly more irritant [73].

Tazarotene seems to share with retinoic acid the ability to improve photo-ageing. In a trial of 1 year treatment duration, 0.1% tazarotene cream applied once daily significantly improved several features of photo-aged skin [74].

In small trials, tazarotene 0.1% gel was effective in management of oral lichen planus [75], and an O/W emulsion containing 0.01% tazarotene applied each night for up to 8 weeks proved helpful in keratosis pilaris [76]. In single cases or small series, useful responses to topical application of tazarotene have been reported in lamellar ichthyosis [77–79], X-linked ichthyosis and ichthyosis vulgaris [78], confluent and reticulate papillomatosis [80],

elastosis perforans serpiginosa [81], Darier's disease [82,83] and warty dyskeratoma [84], pseudoacanthosis nigricans [85], spiny keratoderma [86], keratoderma blenorrhagica [87] and discoid lupus erythematosus [88].

Tazarotene is produced in gel and cream formulations at concentrations of 0.1 and 0.05%. The higher concentration appears more effective in psoriasis but also more irritant. In treatment of acne, the higher concentration is used most frequently.

Sensitizing agents

These chemicals (dinitrochlorobenzene, squaric acid, diphencyprone, etc.) are known as universal sensitizers. Almost every individual will develop allergic dermatitis after repeated contact with these substances on the skin. Animals are also readily sensitized. For many years dermatologists have tried to use the induction of contact sensitization, using these and other allergens, to manipulate immune responses to advantage in a wide variety of benign and malignant skin diseases [1]. Numerous attempts have been made, with some reported success, to use sensitizers to stimulate an immune response to malignancies including melanoma [1,2]. Currently, topical sensitizers have found two main roles in dermatology: for the treatment of alopecia areata and viral warts [1]. The sensitizers that have been most intensively investigated are dinitrochlorobenzene (DNCB), squaric acid dibutylester and diphencyprone. The earliest of these to be used was dinitrochlorobenzene, which was found to be mutagenic. The use of squaric acid dibutylester or diphencyprone avoids this hazard and diphencyprone has the advantage of a practical shelf life. The latter has therefore become the most widely used sensitizer for treatment of alopecia areata and warts. Diphencyprone does not cross-sensitize patients to any other household or medicinal substances. An additional advantage of this compound is that it is photochemically unstable and degrades in the presence of visible light, so accidental spills will not indefinitely contaminate the environment; however, it also follows that diphencyprone must be stored in the dark.

The precise mechanisms by which induction of contact allergy can induce hair regrowth in alopecia areata have not been established. It seems likely that regulatory mechanisms activated to modulate the contact allergic reaction also down-regulate the autoimmune reaction responsible for the alopecia. Increased production of IL-10 may explain this effect [3]. There is no doubt that these agents can stimulate regrowth of hair. DNCB [4], squaric acid

dibutyl ester [5] and diphenylcyclopropenone [6] have all been shown to stimulate hair regrowth on treated areas of the scalp in studies using untreated areas as a control. The same effect has been achieved, in sensitized individuals, by use of *Primula* leaves [7] or by nickel patch-test reagent [8]. The demonstration of hair regrowth on one side of the scalp that has been treated with allergen, while there is none on the other side, constitutes a well-controlled experiment which has been repeated regularly by the author. Sensitization can usually be achieved by application of 2% or higher concentration of diphencyprone to a small area of the scalp once weekly until a reaction is seen. Subsequent treatment can begin with a 0.01% solution and usually continues on a weekly basis, adjusting the concentration as required to maintain mild dermatitis. Attempts have been made to achieve the same effect by use of a simple inflammatory response induced by contact irritants. Phenolics, cantharides, camphor and other irritants have been used for many years, mostly without controlled trials [9]. Trials using croton oil and retinoic acid have not confirmed a response to these irritants [8,10]. With the possible exception of dithranol [11], it has proved difficult to establish the efficacy of irritants.

The efficacy of topical sensitizers in treatment of warts is still not so clearly established. Published controlled trials have been small and inconclusive [1,12]. Uncontrolled data are fairly convincing but inconsistent, perhaps because treatment regimens have also been variable [1]. The best results with diphencyprone have been obtained by first sensitizing patients at a site remote from the warts and then applying diphencyprone 0.01–6% to the lesions at intervals of 1–4 weeks. Complete clearance was reported in 70% of patients with this method [13]. Again, the mechanism of action has not been fully clarified but it is likely that the induction of an inflammatory reaction within the wart induces an influx of immunocompetent cells which can then promote an appropriate immune response to the infecting human papillomavirus.

The induction of contact allergic dermatitis is occasionally complicated by the development of pigmentary disturbances including vitiligo. This treatment modality is therefore probably best reserved for patients with white skin.

Sunscreens

It is likely that in the early evolution of *Homo sapiens*, pigmentation of the skin developed primarily as protection from the risk of sunburn. Subsequent migration away from our equatorial origins reduced the risk of sunburn and skin pigmentation was lost in order to facilitate adequate penetration of UVB into the skin for photochemical synthesis of vitamin D. The adverse consequences of this loss of endogenous sunscreen may not have impaired reproductive potential of the species because the deleterious effects of sunlight tend to occur mainly in later life. However, individuals with white skin are clearly at greater risk from malignant melanoma, non-melanoma skin cancer, preneoplastic disorders and the premature ageing effects of UV irradiation. The sadly fashionable trend over recent decades to purposely expose the skin to solar irradiation in order to obtain a suntan has undoubtedly increased the frequency of these diseases.

It seems a logical approach to attempt to replace the pigment with an exogenous sunscreen applied to the skin surface and a large number of formulations are marketed for this purpose. Used properly, these compounds can reduce UV exposure and probably also the risks associated with photodamage, notably neoplasia. Regrettably, sunscreens are often used in such a way as to make it possible for individuals with pale skin, who could not normally withstand any significant sun exposure without burning, to lie in the sun for hours on end. Such 'abuse' of sunscreens seems likely to be harmful because it can result in significantly greater cumulative UV irradiation than would otherwise be possible. This is especially likely to happen if sunscreens with low sun protection factor ratings (see below) are used.

The ideal sunscreen should completely block the transmission of both UVB (280–315 nm) and UVA (315–400 nm) while at the same time being cosmetically acceptable and pleasant to use. Additional important properties are durability on the surface of the skin and water resistance. The latter is especially important if the sunscreen is

Table 75.9 Compounds used as active constituents of sunscreens.

Physical agents	Chemical agents
Zinc oxide	*Para*-aminobenzoic acid (PABA) and derivatives UVB
Titanium dioxide	Anthranilates UVA
Ferrous oxide	Cinnamates UVB
	Salicylates UVB
	Octocrylene UVB
	Benzotriazoles (Tinosorb) UVB, UVA
	Dibenzoylmethanes (Parsol 1789) UVA
	Benzophenones UVA
	Camphor derivatives (Mexoryl) UVA

to be used when swimming. Sunscreens are generally more effective in blocking UVB than UVA but effective filtration of UVA is important because these wavelengths contribute to photo-ageing [1], cutaneous immunosuppression [2,3] and carcinogenesis [4], and can have a central role in photodermatoses such as polymorphic light eruption [5]. No single compound can achieve all the desired aims so most commercial formulations contain a mixture of active constituents. These fall into two broad categories: physical sunscreens which act by reflecting and scattering UV light, and chemical agents which absorb UV light [6–8]. Frequently used compounds are listed in Table 75.9.

Physical agents such as titanium dioxide and zinc oxide can block a broad spectrum of UVB, UVA and visible light (ability to block the latter can be useful in some photodermatoses). However, their efficacy against UVA and visible light depends on particle size. Larger particle size results in superior efficacy but reduced cosmetic acceptability because of the increased whitening of the skin (which is, of course, reflection of visible light). There has been some concern over the potential for the interaction of both zinc and titanium oxides with UV light to release free radicals [9] but fortunately the harmful effects of these seem likely to be very limited as the oxide particles do not seem to penetrate below the surface layers of the stratum corneum into viable skin [10].

Chemical agents are each effective against a different range of wavelengths of UV light. Some absorb UVB and others UVA. Relatively few absorb long-wave UVA approaching the visible range, exceptions being butyl methoxydibenzoylmethane which has an absorption spectrum of 320–400 nm, and terephthalylidene dicamphor sulphonic acid, with absorption spectrum 290–400 nm. Chemical sunscreens can occasionally cause dermatitis. Irritant, allergic, phototoxic or photoallergic reactions may occur and may be caused not only by the active constituents but also by the base or by additives such as fragrances and stabilizers. Benzophenones are probably the most common sensitizers, while dibenzoylmethanes, *para*-aminobenzoic acid (PABA) and cinnamates may cause photoallergic dermatitis [11,12].

The concept of sun protection factors (SPF) was introduced to help consumers evaluate the level of protection from UVB and the risk of sunburn. Unfortunately, different systems of assay are used in different countries, making direct comparisons very misleading. However, all depend on deriving a ratio of the time or the amount of energy to reach a given end-point (such as minimal erythema) when using the screen, compared with that required without using the screen. Thus:

$$\text{SPF} = \frac{\text{Dose of UVB radiation producing minimal erythema with sunscreen}}{\text{Dose of UVB radiation producing minimal erythema without sunscreen}}$$

It should be noted that the SPF is based on application of an adequate quantity of the sunscreen, usually 2 mg/cm^2 of skin. This is probably more than is routinely applied by most users. As a guide, SPFs of up to 10 can be regarded as mild, 10–15 as medium and over 15 as strong protectors. International agreement is needed to standardize end-points, light sources and conditions of testing. As a result, the classification of sunscreens into the broad categories listed above is helpful but comparisons between one product and another are not as accurate as they might appear. This is especially true of comparisons between products with high SPF values (above 15). There is currently even less standardization of the assessment of protection against UVA. Measurement of resistance to water has also not been standardized but can be assessed by several methods [13,14].

While it would seem likely that correct use of sunscreens will reduce the risk of malignancy, this has not been easy to confirm, especially in retrospective studies. Part of the difficulty is the likely association between use of a sunblock and sun exposure.

Suncreens have been shown to reduce UV-induced immunosuppression, which is considered to have a role in cutaneous carcinogenesis. Both the sensitization [15] and elicitation [2] phases of immune responses can be preserved by sunscreens.

In a placebo-controlled trial on a high-risk population, appropriate strength sunscreens have been shown to be effective in reducing the incidence of actinic keratoses [16]. In an Australian prospective controlled study, regular use of sunscreen reduced the total number of SCCs but not of BCCs [17]. A study of BCCs indicated that there were fewer p53 mutations in those BCCs that developed in patients who had used sunscreen. This might be indicative of effective protection against UV-induced DNA mutation by the sunscreen [18], while some BCCs develop as a result of other causes.

The prevention of melanoma by the use of sunscreens is a further controversial topic because two case–control studies have linked sunscreen usage to a higher incidence of melanoma [19,20]. This may be related in part to the likelihood that the subjects studied had previously used

sunscreens that provided protection against UVB radiation alone, and exposed themselves to higher doses of solar radiation than those who did not use sunscreen. Other studies have examined the development of naevi as a marker for risk of melanoma. A retrospective epidemiological study from Israel found that use of sunscreen was associated with a higher number of naevi [21]. Conversely, a prospective controlled trial from Vancouver demonstrated a reduced rate of development of naevi over a 3-year period in children provided with sunblock and instructed on its use. The effect was especially evident in those children who were freckled [22].

In addition to the protection of healthy skin, sunscreens have an important role in the management of patients with photodermatoses. The most common of these, polymorphic light eruption, often seems to show rather limited benefit from sunscreens but may be effectively prevented by formulations that block a broad spectrum of UVA including longer wavelengths [5]. Sunscreens effective in blocking the offending wavelengths of UV light can also be helpful in management of less common photodermatoses including actinic prurigo, chronic actinic dermatitis, hydroa vacciniforme, lupus erythematosus, porphyrias and solar urticaria (see Chapter 24).

Whether sunscreens are applied to prevent solar damage to healthy skin or to alleviate a photodermatosis, it is important that these should not be regarded as the only means of limiting sun exposure. Staying indoors during the hours of peak sunlight intensity and, when outdoors, covering the skin with suitable clothing and headwear, constitute more effective strategies than using sunscreens.

Tars

Tars are distillation products of organic material. There are three main sources of therapeutic tars: wood, shale and coal.

Wood tars

Oils of cade (juniper), beech, birch and pine are widely used, particularly in Scandinavian countries. Wood tars lack certain basic chemical structures characteristic of coal tars, such as pyridine, quinoline and quinaline rings [1]. They may sensitize but do not photosensitize.

Wood tars are used for treating eczema and psoriasis in some countries. Oil of cade is particularly used in scalp preparations or when tar preparations are needed on the face. They are normally applied in 1–10% strength in ointments or pastes, or as a paint in 95% alcohol.

Shale tars

Oils were extracted from shale (sedimentary rock containing fossilized fish) for centuries before crude oil became available. Various extracts and distillates have long been used for medicinal purposes. Ichthammol (ichthyol) is a shale tar (bituminous tar). This contains a very high proportion of sulphur (about 10%), as compounds of thiopen. Shale tars have antiseptic and anti-inflammatory properties but are generally less effective than coal tars and may have a different mode of action. They are not photosensitizers. Ichthammol is often used in paste bandages for treating atopic eczema.

Coal tar

Coal tar [2–4] is a black, viscous fluid with a characteristic smell. Attempts to remove the colour, odour, photosensitizing property and carcinogenicity have not been entirely successful [5], and variations in this natural product have made the assessment of active ingredients particularly difficult [3,4]. Of some 10 000 different constituents believed to make up coal tar, only 400 have been identified. These constitute 55% of the whole.

All coal tars are products of different distillates of heated coal. The content of the tar depends on the type of coal used and the temperature of the distillation. 'Low-temperature' tar was found to contain a greater number of components but to be less effective in producing orthokeratosis in mouse-tail skin than 'high-temperature' tar [3,4]. It was also more irritating. However, a comparison of high- and low-temperature tars showed no eventual difference in effect in the treatment of psoriasis itself, although crude (high-temperature) coal tar gave quicker results [6]. This suggests that the reversal of parakeratosis is only one factor in the control of psoriasis. The authors of this study point out that dithranol was not very effective in the mouse-tail test [7].

The hydrocarbons, which constitute about half the composition of tar, include benzol, naphthalene and anthracene. The high-boiling-point tar acids (phenolics) include isomers of substituted polyhydroxyphenols, and it seems likely that it is such phenols which may be responsible for the therapeutic effect of tar [3,4,8]. However, the exact mechanism by which tar exerts its effect remains unknown. These high-temperature fractions may have a direct effect on the granular layer by release of lysosomes followed by mitotic stimulation. Low-temperature extracts appear to cause epidermal thickening without restitution of the granular layer [3,4], and may be the reason for the indifferent action of some synthetic and proprietary tar preparations [3,4,9]. Until a more suitable preparation is available, many dermatologists will continue to believe that crude tar remains therapeutically superior [9,10].

The combination of tar with UV light (the Goeckerman regimen) has long been known to be helpful in psoriasis. In recent years, attempts have been made to identify the critical wavelengths of radiation involved [11,12]. Generally, UVB radiation has been found to be more effective than UVA [13,14]. Refined tars are less phototoxic than the crude product, but phototoxicity is directly related to therapeutic efficacy. UVA [15] did not appear to be a useful adjunct to tar and UVB in the treatment of psoriasis in one study. Laboratory studies have shown that tar plus UV light reduces epidermal DNA synthesis [12,16]. This may be related to the formation of cross-links between opposite strands on the DNA double helix [17].

A cytostatic effect of crude coal tar has also been postulated [18] following the finding that prolonged application to normal skin produces epidermal thinning associated with retention hyperkeratosis. More studies are still required, particularly to identify the more active fractions of tar distillates.

The well-established carcinogenicity of pitch and heavy tar fractions has aroused renewed interest in the current climate of therapeutic conservatism. Concerns about the oncogenic potential of polycyclic hydrocarbons [19] and consumer protection [20,21] have been fuelled by reports that urine from patients with psoriasis using crude coal tar was mutagenic to certain bacterial strains [5]. Reports of malignant tumours in humans in relation to tar therapy are rare. Rook *et al*. [22] reported five cases and Greither *et al*. [23] reported 13. Most had genital or groin involvement, but these are nowadays unlikely sites for tar application. Reassuringly, several large long-term follow-up studies have shown no increased incidence of skin tumours [14,24–27].

Coal tar is now mainly used in treatment of psoriasis and is the basis of the Goeckerman regimen (see Chapter 35). Prior to the advent of topical corticosteroids, coal tar was widely used in treatment of eczematous dermatoses and it can still prove useful as a steroid-sparing agent and antipruritic. Coal tar can be added to paste bandages although ichthammol is often preferred.

Vitamin D analogues (deltanoids, secosteroids)

The therapeutic potential of vitamin D in psoriasis has been recognized for many years. Systemic use of these compounds can be highly effective but requires monitoring to avoid causing disturbance of calcium homoeostasis. Used topically, considerable efficacy can be maintained with a wide safety margin. The advent of calcipotriol in the early 1990s has greatly increased the use of this modality. Tacalcitol and calcitriol, which were known to be effective even earlier, have only more recently become widely available for treatment of psoriasis. The novel analogue maxacalcitol is also known to be effective.

Vitamin D is not strictly a vitamin because an exogenous source is not essential. Photochemical cleavage of 7-dehydrocholesterol to form vitamin D (cholecalciferol) takes place in the skin and requires fairly minimal exposure to UVB to generate physiological quantities of the product. It is this break in the steroid nucleus that characterizes vitamin D and its analogues and gives rise to the term secosteroids. Cholecalciferol requires two hydroxylations for activation. The first is 25-hydroxylation, which takes place mainly in the liver and is not a tightly controlled step [1]. 25-Hydroxycholecalciferol is the main storage form of vitamin D within the body. This is finally 'activated', mainly in the kidney, by a very tightly regulated hydroxylation to 1α,25-dihydroxycholecalciferol [2,3]. As the latter has three hydroxyl groups, it is also known as calcitriol (Fig. 75.10). Calcitriol is a potent hormone first characterized by its ability to increase calcium absorption from the gut. It has subsequently become recognized that the receptor for this potent hormone is expressed in virtually all types of cell. Calcitriol is of

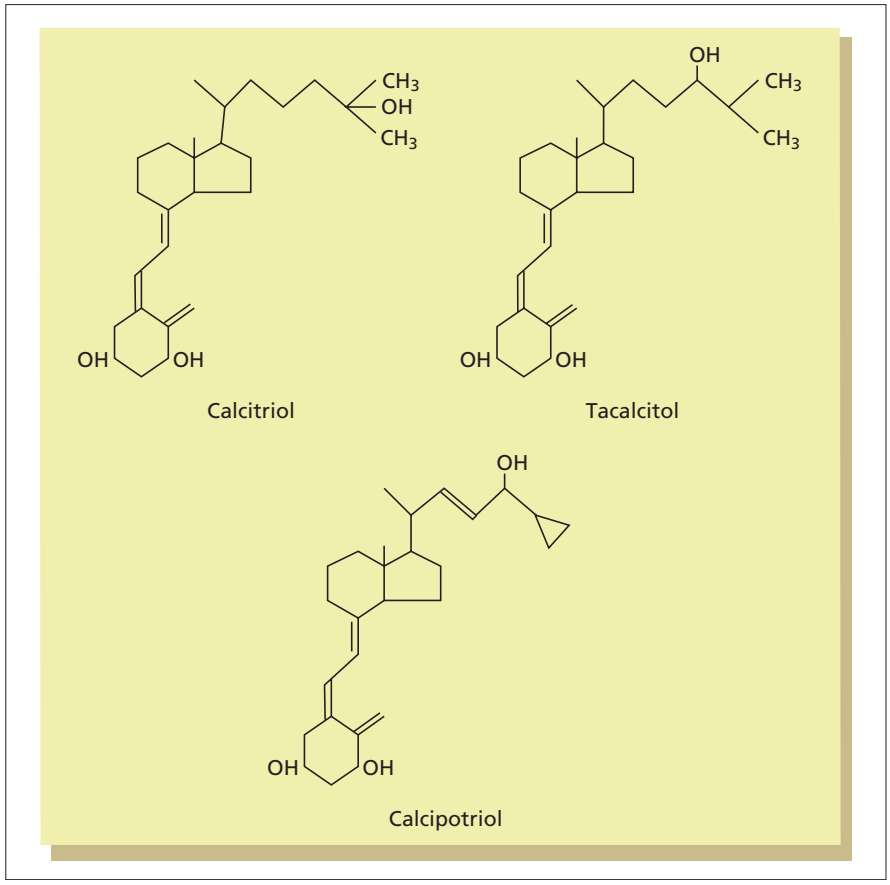

Fig. 75.10 Formulae of calcitriol, tacalcitol and calcipotriol.

fundamental importance in the regulation of differentiation and proliferation.

The vitamin D receptor is a phosphopeptide with molecular weight of approximately 60 kDa, able to move freely between the cytoplasm and the nucleus. It is a member of the steroid receptor superfamily, being similar in structure to the retinoid receptors, the thyroid hormone (T_3) receptor and receptors for other classes of steroid hormone. It is active mainly as a heterodimer in combination with the RXR [4]. The vitamin D receptor complex regulates transcription of numerous genes by binding to regulatory regions of DNA–vitamin D response elements. These are specific but heterogeneous regions of DNA generally situated upstream of regulated genes [4].

The therapeutic actions of vitamin D appear to result from a potent antiproliferative effect [5–8], the ability to promote differentiation [9–12] and perhaps also from immunosuppressive activity. *In vitro* secosteroids inhibit IL-2 release and lymphocyte activation [13,14], and release of IL-8 [15]. They also up-regulate expression of the receptor for the anti-inflammatory cytokine IL-10 [16]. They inhibit monocyte differentiation into dendritic cells, possibly by promoting expression of colony-stimulating factor 1 [17]. They inhibit keratinocyte synthesis of RANTES and IL-8 [18]. *In vivo*, they have been shown to inhibit expression of IL-8 [19], IL-6 [20] and other cytokines. During treatment of psoriasis they have been reported to reduce infiltration with lymphocytes and neutrophils [8,21,22] and to reduce expression of IL-8 and adhesion molecules (ICAM 1, ELAM 1, LFA 1, VLA 3, VLA 6) [23,24].

Vitamin D, especially in activated (1α-hydroxylated) forms, increases calcium absorption from the bowel. At a low level this can be compensated by increased calcium excretion in urine but at higher levels of exposure the serum calcium will rise. All the analogues currently used in treatment of psoriasis are 1α-hydroxylated compounds, which effectively bypass the regulatory step of 1α-hydroxylation. They can potentially cause hypercalcaemia in overdose. This 'calciotropic activity' of vitamin D analogues constitutes the main constraint on the safe use of these compounds. The goal of secosteroid research, to develop an analogue that would normalize proliferation and differentiation without influencing calcium metabolism, has yet to be effectively realized.

In comparison to traditional treatments for psoriasis, vitamin D analogues have the advantage that they are more pleasant to use than tar or dithranol. They also have the advantage over topical corticosteroids that they are not atrophogenic. However, they can all cause irritant reactions that are concentration dependent [25]. Sensitization can also occur but seems to be rare [26]. A characteristic pattern of circumlesional scaling appears around psoriatic lesions treated with vitamin D analogues (Fig. 75.11), which gives a guide to compliance almost as reliable as the staining produced by dithranol [27]. It is not clear whether this is a manifestation of irritancy or a pharmacological effect.

Fig. 75.11 Circumlesional scaling characteristic of psoriasis lesions treated with vitamin D analogues.

Tacalcitol (1,24 dihydroxycholecalciferol)

This analogue has been used for topical treatment of psoriasis for many years in Japan, where the concentrations employed have ranged from 1 to 20 μg/g [28,29]. In Europe, tacalcitol is often used once daily at a concentration of 4 μg/g. Efficacy of this regimen has been demonstrated in placebo-controlled and dose-ranging studies [30,31]. Tacalcitol 4 μg/g applied once daily is less effective than calcipotriol 50 μg/g applied twice daily [32]. However, the lower concentration of tacalcitol results in a low irritant potential and it can therefore be safely used for treating facial or flexural psoriasis [33]. A long-term trial has indicated that, in patients who have responded well, the benefit can be maintained for up to 18 months, although only 64 out of 299 subjects completed the full duration of this trial [34]. Tacalcitol has been used in conjunction with both UVB [35] and PUVA [36] and accelerates the response to these treatments, potentially reducing the UV exposure required.

Currently, the recommended maximum dose of tacalcitol 4 μg/g is 10 g/day. However, no significant increase in serum or urine calcium was observed with daily doses of 15–20 g for up to 26 days [37]. It also appears safe to

use tacalcitol at the higher concentration of 20 μg/g [29]. Hypercalcaemia has not yet been reported in association with topical application of this analogue. Sensitization may rarely occur [38].

Other indications in which topical tacalcitol has been employed with reported success include Nekam's disease [39], confluent and reticulate papillomatosis [40], Grover's disease [41], subcorneal pustular dermatosis [42], Hailey–Hailey disease [43], disseminated superficial actinic porokeratosis [44] and prurigo [45].

Calcitriol (1,25 dihydroxycholecalciferol)

Calcitriol is the naturally occurring form of activated vitamin D. This is known to be active both topically and systemically in treatment of psoriasis [46,47]. Like other analogues, it is rarely used systemically because of the need to monitor calcium homoeostasis although the hazards are probably not out of proportion to the potential benefit.

Calcitriol has been used topically at various concentrations ranging from 0.3 to 15 μg/g [48,49]. At the higher end of this range, changes are seen in urine and/or serum calcium levels, especially when large areas of skin are treated. At the lower end, efficacy is very limited. When applied twice daily at a concentration of 3 μg/g, controlled trials have demonstrated that a degree of efficacy can be maintained with minimal risk of effects on calcium homoeostasis [50]. The efficacy of this regimen was comparable to that of short-contact dithranol therapy in an 8-week trial with 114 subjects, although the overall improvement was not very impressive in either group, suggesting that the dithranol regimen may not have been optimal [50]. Calcitriol 3 μg/g is less effective than calcipotriol 50 μg/g [51]. In a long-term study, it was disappointing that only 75 out of 253 subjects continued to use the treatment for 1 year. Lack of efficacy was given as the main reason for withdrawal by 108 of the subjects. Twice daily treatment with calcitriol has shown a dose-sparing effect on UVB exposure when used in conjunction with broad-band phototherapy [52]. Calcitriol ointment 3 μg/g seems to have very little potential for irritancy or sensitization [53].

Calcipotriol (calcipotriene, MC 903)

Although developed relatively recently, calcipotriol has now been more intensively investigated than any other secosteroid for the treatment of psoriasis. The molecule has a cyclopropane group at the end of the side-chain, which facilitates rapid metabolism (Fig. 75.10). It is therefore ideal for topical administration and can be safely used in higher concentration than calcitriol or tacalcitol [54]. Placebo-controlled and dose-ranging trials demonstrated maximal response at the concentration of 50 μg/g [55,56]. Virtually all subsequent research has investigated the use of calcipotriol at this concentration.

Efficacy and safety of calcipotriol in childhood psoriasis has been confirmed in trials on children from 2 years upwards [57,58]. It has also proved useful in an infant [59].

Reports indicate that topical calcipotriol can be useful in generalized pustular psoriasis [60,61] and in erythrodermic psoriasis [62,63]. However, absorption of the drug can be significantly higher in these circumstances and careful monitoring is required. In one case, generalized pustular psoriasis was thought to have been precipitated by calcipotriol [64]. Acrodermatitis continua [65] and nail psoriasis [66,67] may respond, although results are not consistent.

In comparative studies, calcipotriol 50 μg/g generally compares well to other topical treatments for psoriasis [68]. It has shown efficacy similar to potent topical corticosteroids such as betamethasone-17-valerate [69] and superior to tacalcitol 4 μg/g [31], calcitriol 3 μg/g [50] and to self-treatment with dithranol [70]. The response has been relatively well sustained over time in long-term trials [71,72]. It is notable, however, that only 26% of the patients on this treatment are able to discontinue the vitamin D analogue altogether (the rest requiring continuous treatment).

The use of calcipotriol has also been investigated in a wide range of combinations with other antipsoriatic medication. Combinations with topical corticosteroids can be particularly useful to increase efficacy and reduce irritation. When each medication is applied once daily, the combination with moderately potent or potent steroid reduces irritation and a potent steroid increases efficacy relative to twice daily application of calcipotriol alone [73]. A combined formulation (Dovobet®) containing betamethasone dipropionate 0.05% and calcipotriol 50 μg/g has proved more effective applied once daily than twice daily application of calcipotriol alone. The combined formulation was also less irritant [74]. A regimen combining short contact dithranol with twice daily application of calcipotriol proved more effective than dithranol alone [75].

Topical calcipotriol can also be used concomitantly with second-line therapies and exerts a useful dose-sparing effect when combined with UVB [76,77], PUVA [78–80], ciclosporin [81], retinoids [82] and fumaric acid esters [83].

Occlusion with polythene or hydrocolloid dressings can be used to augment the efficacy of calcipotriol [84]. This technique can be particularly useful for refractory plaques of psoriasis on the shins. Systemic absorption is also likely to be increased.

Calcipotriol not uncommonly induces irritant reactions, especially when applied to the face. Sensitization can also occur to calcipotriol although this seems to be rare [85–87]. In one case, propylene glycol in the base was responsible for the reaction [88].

The maximum recommended rate of usage is 100 g/week of ointment. Exceeding this dose can induce hypercalcaemia although the safety margin seems reasonable and the use of higher doses can improve efficacy [89]. It is advisable to monitor urine and serum calcium in situations where there is a risk of inducing hypervitaminosis D (e.g. when the recommended dose is exceeded or when calcipotriol is used for indications other than psoriasis vulgaris, especially if large areas of skin are treated). Monitoring of serum calcium presents little difficulty but measurement of urine calcium excretion depends on obtaining accurate 24-h urine collections.

There are now a wide range of dermatoses in addition to psoriasis that have been reported to respond to calcipotriol, although the evidence is largely anecdotal in nature. These include confluent and reticulate papillomatosis [90], disseminated superficial actinic porokeratosis [91], erythema annulare centrifugum [92], extragenital lichen sclerosus [93], Flegel's disease [94], Grover's disease [95,96], inflammatory linear verrucous epidermal naevus [97], keratosis lichenoides chronica [98], lichen amyloidosus [99], lichen planus [100], nodular prurigo [101], naevoid hyperkeratosis of the nipple [102], morphoea [91], pityriasis rubra pilaris [91], Reiter's syndrome [91], ichthyoses [103,104], vitiligo [105] and Vorner's syndrome (epidermolytic palmoplantar keratoderma) [106].

Calcipotriol has not proved beneficial in trials on actinic keratosis [107], alopecia totalis [108], Darier's disease [103], hereditary palmoplantar keratoderma [103], keratosis pilaris [103] or seborrhoeic dermatitis [109].

Maxacalcitol (22-oxa-calcitriol)

This is an effective but currently unmarketed analogue with efficacy similar to calcipotriol [110].

Traditional remedies

Camphor

Camphor is an extract from the camphor laurel *Cinnamonum camphora*, best known as a moth repellant. It is sometimes added to lotions for its antipruritic and cooling effects. It is widely used in proprietary chilblain preparations.

Dyes

Gentian (crystal) violet. This is a triphenylmethane dye, which has antiseptic properties against bacteria and yeasts. Employed for many years as a topical treatment for bacterial and fungal skin infections, its use was drastically curtailed after experimental studies demonstrated that it interacted with DNA of living cells [1] and was linked to malignancies in mice [2]. No reports of human malignancy attributed to the use of gentian violet on the skin have been found in the recent literature. It is now licensed for topical application, as a 0.5% aqueous solution, to unbroken skin, and is not recommended for application to mucous membranes or open wounds. It has the advantages of being cheap, chemically stable and easy to prepare.

Brilliant green. This is also a triphenylmethane dye and has properties similar to gentian violet. It was often used in combination with the latter but does not seem to increase the spectrum of activity [3]. It has suffered similar restrictions in usage, as have other members of the group, such as malachite green.

Magenta. Magenta, or basic fuchsin, is a major component of Castellani's paint. It is known to have activity against Gram-positive bacteria and fungi, but is no longer used because of potential carcinogenicity. Colourless Castellani's paint, the same formula without the magenta (boric acid, resorcinol, phenol), has been used to reduce secondary bacterial contamination in onycholysis and in chronic paronychia.

Eosin. This is the disodium salt of tetrabromofluorescein. It is used as an astringent for areas of weeping eczema or superficial ulcers, and in dermatoses such as seborrhoeic dermatitis. Efficacy equivalent to flumethasone pivalate 0.02% has been demonstrated in infantile seborrhoeic dermatitis [4], and greater than clobetasone butyrate 0.05% in napkin dermatitis [5]. It has the advantage of being used in aqueous solution (usually 2%), which avoids problems with stinging, but allergy can occur, especially in patients with leg ulceration [6].

Menthol

Menthol is still mainly extracted from the Japanese mint (*Mentha arvensis*) although synthetic sources are now available. It is added to calamine and other lotions and creams to induce a cooling sensation and relieve pruritus.

Miscellaneous agents

Capsaicin

Capsaicin is a remarkably potent compound extracted from hot peppers and responsible for the gustatory discomfort they induce. It is a very stable alkaloid probably produced by these plants to prevent the seeds being eaten by animals. Capsaicin stimulates release of substance P, which is subsequently depleted in sensory neurones [1]. It is also a potent ligand of the vanilloid receptor (VR1), which is expressed on sensory neurones [2]. Stimulation of this receptor by capsaicin can result in a refractory state in the neurone, probably explaining the hypoalgesia that can be induced by capsaicin.

The first application to be established for this drug was in treatment of post-herpetic neuralgia [3]. However, an increasing range of conditions are being reported to benefit including diabetic neuropathy [4], glossodynia [5], nodular prurigo [6], notalgia paraesthetica [7], pruritus ani [8], and pruritus caused by pityriasis rubra pilaris [9], psoriasis [10,11], PUVA [12] or uraemia [13].

Minoxidil

This vasodilating agent was initially introduced as a systemic treatment for hypertension and was found to cause hypertrichosis. Subsequently, lotions containing minoxidil have been employed in various situations where hair is wanting. Formulations containing 2% and 5% solutions of minoxidil are currently available commercially. The most established indication is androgenetic alopecia although results are usually modest. Minoxidil can also accelerate hair regrowth after chemotherapy and there is possibly some modest benefit in patients with alopecia areata.

Topical application of minoxidil has proved remarkably safe. One potential hazard arising from long-term use is sensitization to the minoxidil or to components of the vehicle. A more common problem is hypertrichosis, usually on the face but sometimes more generalized [1]. This seems most likely to result from contamination of facial skin with minoxidil but systemic absorption has also been proposed to explain the most generalized cases. It is more problematic in female patients and is more likely to occur when the higher concentration is used.

The mechanism by which minoxidil stimulates hair growth remains to be established. It may exert direct effects on keratinocyte differentiation and proliferation within the hair follicle [2], it may alter the pattern of androgen metabolism in the dermal papilla [3] and it may improve vascularization of the papilla [4].

Androgenetic alopecia shows a positive although modest response to topical minoxidil in males and females. In a double-blind multicentre trial of 2% minoxidil in the USA, 256 females with androgenetic alopecia were treated for 32 weeks. Terminal (non-vellus) hairs increased from 140 to 163/cm^2 compared with a rise from 139 to 149/cm^2 in the placebo group. At the end of the study no dense regrowth was observed. Investigators reported moderate regrowth in 13% of the patients on active treatment and minimal regrowth in 50%, whereas the patients' assessments were more optimistic at 20% and 40%, respectively. The patients receiving placebo reported moderate and minimal regrowth in 7% and 33%, respectively [5]. In a similar European trial involving 294 female subjects, there was an increase in non-vellus hair of 33/cm^2 in

the active group and 19/cm^2 in the placebo group [6]. In an Australian trial on males with early pattern alopecia, only 12% had moderate regrowth after 48 weeks [7]. Response to the 5% lotion is somewhat better. In a recent study of 48 weeks' treatment duration completed by 351 male subjects, 5% solution was superior to 2% lotion and placebo from 8 weeks onward. At 48 weeks the mean terminal hair count had risen from 151 to 170/cm^2 in the 5% group, from 144 to 156 in the 2% group and from 152 to 156 in the placebo group [8]. In male patients topical minoxidil is sometimes combined with oral finasteride [9].

Alopecia areata is sometimes treated with topical minoxidil, although cosmetically useful responses have not been frequent in most studies. The best results were reported by Fenton *et al*. [10] who conducted a double-blind crossover trial in which 30 subjects applied 1% minoxidil (lotion or ointment) or placebo twice daily, each for 3 months. By the end of the study 16 patients had grown cosmetically acceptable terminal hair, only one of them while on placebo. In a subsequent trial of very similar design on 23 patients, 13 demonstrated some degree of regrowth on the active medication while none did so on placebo—however, the result was cosmetically satisfactory in only one case [11]. In another study using 1% lotion on 48 subjects with severe disease, no difference was detected from placebo [12]. Similarly, no difference was observed between placebo and 3% minoxidil lotion after 3 months in a trial on 30 subjects with extensive disease [13]. In a study comparing 1% and 5% solutions, a total of 66 patients applied treatments twice daily [14]; patients with extensive (75% or greater) scalp hair loss showed a response, defined as terminal hair growth, in 38% of cases with 1% minoxidil versus 81% with 5% minoxidil. However, even in this high-dose group, only 6% showed a cosmetically acceptable response. A slightly higher rate of cosmetic response, 11%, was observed in an uncontrolled study in which 45 patients with severe disease applied 5% minoxidil twice daily and 0.5% dithranol (anthralin) cream once daily for 6 months [15]. Application of 2% minoxidil three times daily appeared to prolong the response to a 6-week tapering course of prednisolone in a double-blind study, although the numbers were too small to achieve statistical significance relative to placebo [16].

Other applications for topical minoxidil have included reduction in the duration of alopecia caused by chemotherapy. In a controlled trial on patients undergoing chemotherapy for breast carcinoma, the duration of baldness was 87 days in patients applying 2% minoxidil solution twice daily, versus 137 days in those applying placebo [17]. Additional applications have included stimulation of growth in hair transplants [18] and prevention of hair loss that may occur as a complication of cosmetic surgery [19].

Nicotinamide [1]

The marked anti-inflammatory properties of topical nicotinamide, the amide derivative of vitamin B_3 (niacin), have been used to treat acne vulgaris. A 4% alcoholic gel is available. It is not yet certain by what mechanism the preparation exerts its anti-inflammatory effect. In a multicentre trial, it gave a global reduction in acne of 82% compared with 68% for 1% clindamycin gel over an 8-week period. An advantage of nicotinamide is that it avoids the problem of antibiotic resistance.

Chapter 76

Radiotherapy and Reactions to Ionizing Radiation

M.F. Spittle & C.G. Kelly

Introduction

The clinical effects of ionizing radiation on the skin have been known since the discovery of X-rays in 1895 [1]. At first, the physical aspects of dosimetry were little understood—a fact that did not hamper the enthusiasm with which both benign and malignant diseases were irradiated. Both the dosage and indications for irradiation were initially empirical, and the dermatologist may still see the late effects on the skin and subcutaneous tissues of overdosage due to inexperience. Indications for treating benign disease by irradiation have declined since the advent of topical steroids. If the effect of irradiation is understood, this treatment still has a specific place in the dermatologist's armamentarium for patients in whom disease is otherwise refractory to treatment [2,3].

Since the introduction of supervoltage irradiation, which gives a maximum dose below the surface of the skin, the acute skin reaction is rarely seen in the treatment of deep-seated malignant disease. However, if the skin is particularly at risk from recurrence as, for example, in the primary treatment of breast cancer, it can be fully treated.

It is in the best interest of patients suffering from skin tumours to be seen in a clinic where the expertise of specialists in radiotherapy and oncology, plastic surgery and micrographic surgery, as well as dermatology, are present.

Types of ionizing radiation

X-rays are part of the electromagnetic spectrum. They have a shorter wavelength and are more energetic and penetrating than ultraviolet (UV) radiation.

Orthovoltage radiation includes beams softer than 1 million electron volts (MeV).

Grenz (German for border) rays are the most poorly penetrating ionizing rays. At 6–15 kV, these are at the borderline with non-ionizing radiation. As 90% of this radiation is absorbed in the upper 1 mm of the skin, it is important to treat only diseases of very superficial pathology with this beam. Dose-dependent pigmentation of the skin may occur, but alopecia will not, as the energy of the beam does not reach the depth of the hair follicle. Doses of 100–300 Gy have rarely been associated with malignancy [1], but there is a wide margin of safety with Grenz rays. However, the minimum voltage consistent with the depth of pathology should be chosen.

The most commonly used forms of radiotherapy in dermatological practice are superficial X-rays and electron beams.

Superficial X-rays, up to 100 kV, are used in the management of benign skin disease. The higher voltages are used for hypertrophic disease needing treatment to a greater depth, for example keloids. Fall-off of energy below the surface of the skin occurs in an exponential manner (Fig. 76.1) and there can still be substantial dose delivered at several centimetres depth.

Beta rays are electrons and can be derived from radioactive isotopes, such as ^{90}strontium or be produced by a linear accelerator. The energy of electrons is almost totally absorbed at a depth proportional to the given voltage. A useful treatment depth in centimetres is approximately one-third of the MeV energy, so a 4.5-MeV electron beam will be useful for treating to 1.5 cm and a 9-MeV beam to 3 cm (Fig. 76.2).

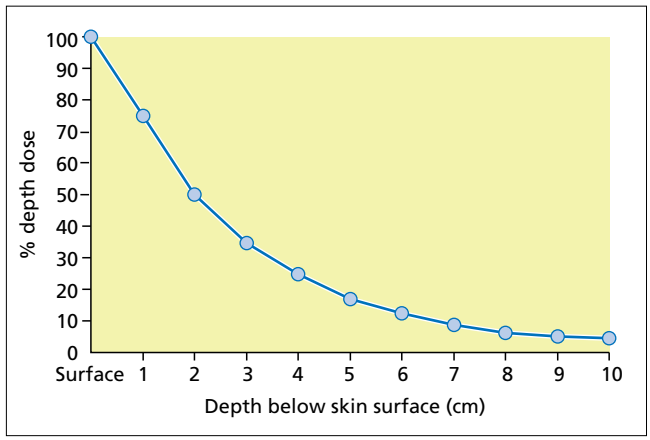

Fig. 76.1 Approximate per cent depth dose values for 90 kV superficial X-ray beam.

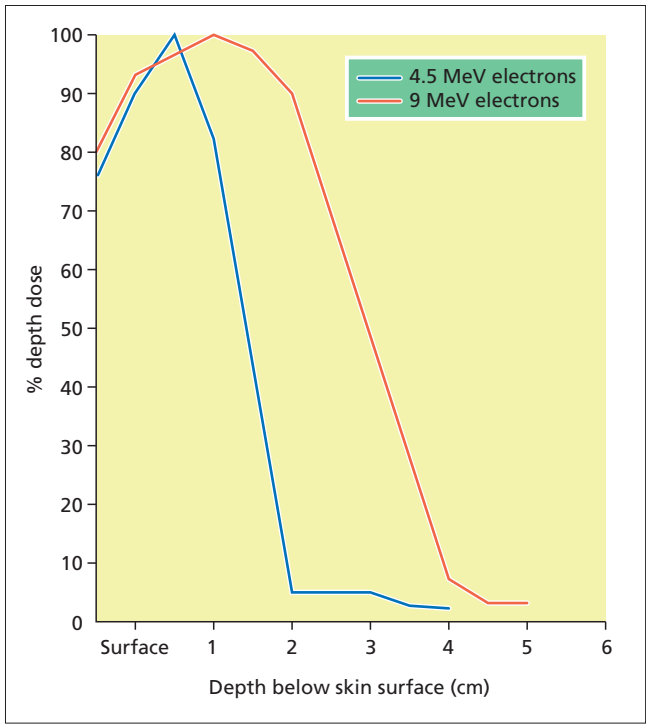

Fig. 76.2 Approximate per cent depth dose curves for 4.5 and 9 MeV electron beams.

As can also be seen in Fig. 76.2, the width of the peak of the beam also increases with electron energy. The peak can also be shifted to the left by the use of tissue equivalent material placed on the skin surface and acting as a degrader.

It is possible to irradiate the whole skin area with an electron beam. The minimal depth dose characteristics that may be achieved avoid the irradiation of subcutaneous structures which would occur if X-ray therapy that is absorbed exponentially was used. This technique is used in the treatment of mycosis fungoides [2]. Multiple radiation fields are combined to give a homogeneous dose to the whole skin down to a depth of approximately 1 cm.

Electron-beam therapy is used to irradiate skin cancers in sites where the malignant lesion to be treated is large or overlying cartilage or bone. The mode of absorption of high-energy X-rays produced from a linear accelerator or of gamma rays is relatively independent of the atomic number of the tissue irradiated. Low-voltage X-rays are absorbed disproportionately in high-atomic-number materials. If this fact is not understood, necrosis may occur in cartilage or bone underlying large superficial lesions. Therefore, superficial X-ray therapy should be avoided when treating lesions overlying the nose, ear, hand and tibia to a radical dose. Modern high-voltage electron therapy is indicated in these sites [3].

Conventional photon beams or other less commonly used forms of radiotherapy such as fast neutron beams are rarely indicated in dermatological radiotherapy.

Dose

The SI unit of absorbed dose is 1 J/kg and is called the gray. Note that 100 rad = 1 J/kg = 1 Gy; 1 rad = 1 cGy (centigray). The dose prescription is defined by the total dose given, the energy of the beam, the number of fractions given, the total number of days over which treatment is given and the volume or area treated. For example, a typical prescription for the treatment of a small basal cell carcinoma (BCC) might be '35 Gy using 90 kV SXT beam given in five fractions over 5 days to a 3-cm area'. This time–dose relationship is crucial to understanding the biological effect.

Radiosensitivity

All radiation is destructive. Abnormal cells repair radiation damage less well than normal cells. This inability to repair is reflected in death at mitosis. Anaplastic cells and those with a high mitotic index are more radioresponsive than differentiated cells. Radioresponsiveness and radiocurability are dissimilar and are functions of differences in cell population kinetics. Radiotherapy is usually given as a fractionated course, as the intervals between doses allow for the recovery of normal cells. The effect of a dose of radiation is reduced by increasing the number of fractions in which it is given or by lengthening the total overall treatment time. The effect of irradiation can be modified by anoxia, infection, oedema, trauma and any inborn

genetic susceptibility. The face tolerates irradiation well, and radical dosages may be accompanied by good cosmetic results [1].

When benign conditions are being irradiated, the minimum dose and the lowest voltage appropriate to achieve the desired effect should be chosen. The threat of radiation carcinogenesis must clearly be seen in the context of the clinical indication for treatment. There is a threshold for somatic radiation changes which need not be breached in the treatment of benign conditions. The late radiation sequelae of treatment given many years ago are inexcusable with modern standards of dosimetry and equipment, and should not be seen in the treatment of benign diseases [2].

Indications for radiotherapy

Benign disease

Radiotherapy is used much less now in the management of benign skin conditions than formerly and then usually only after other treatment modalities have failed or are contraindicated. In some conditions such as psoriasis and eczema there is a response to radiotherapy but this is often only temporary [1]. Coupled with the risk of late radiation-induced malignancy, this has led to a decline in its use in all but the most refractory of cases. It is also still used occasionally in the management of keratoacanthoma where the differentiation from squamous cell carcinoma cannot be made with complete confidence [2–4]. Other rare uses are in Darier's disease [5], familial benign chronic pemphigus [5] and acrodermatitis continua of Hallopeau. Radiotherapy was used in the management of acne and rosacea in the past, and there may be patients still presenting with radiation sequelae or late radiation-induced tumours resulting from treatments given years ago for these benign conditions, and others such as ringworm [6].

Keloids

This is probably the most common benign condition now treated with radiotherapy. Keloids resistant to intralesional steroids or other conventional treatment may respond well to radiation. Excision of the keloid with early irradiation of the scar and stitch marks is more successful, but in some sites—for example, the tip of the shoulder and the upper middle chest, where surgery is inadvisable—good response of pain, itch and redness can be achieved, with some regression of the keloid itself. Relatively high doses are necessary; these will cause temporary hyperpigmentation, which will remain for many months in pigmented skin. Doornbos *et al*. [1] noted that 17 of 18 unexcised keloids that were less than a year old regressed with 1500 cGy given in three treatments over 6 days at 120 kV. Older keloids respond less well to irradiation. The most satisfactory management of keloids is postexcision irradiation, where a dose–response relationship can be seen. Total doses less than 900 cGy, irrespective of fractionation and postsurgical interval, did not prevent recurrence. Three doses of 400 cGy were given by Kovalic and Perez [2], with a 73% success rate. Using the commonly employed dose of 900 cGy, Lo *et al*. [3] described an 85% success rate and Borok *et al*. [4] a 96% response rate. No late sequelae or carcinogenesis was described by any of the previously quoted authors with follow-up in excess of 30 years.

As well as using superficial X-rays, treatment can be given using a radioactive iridium wire implant. At the time of excision a small plastic tube is inserted beneath the incision, with both ends of the tube exposed. The patient is then transferred to the radiotherapy department within 24 h, and the tube is loaded with iridium wire, and the scar irradiated to a dose of 20 Gy at 2 mm from the wire over 2 days. Escarmant *et al*. [5] describe the results of treating 783 keloid scars in 544 patients with interstitial iridium implants.

Malignant disease

Radiotherapy for the common skin cancers

For most small BCC or squamous cell cancers without nodal involvement, surgical excision or radiotherapy will give excellent cure rates [1–4]. The decision as to which is the most appropriate modality will depend on several factors. These include the size and location of the tumour, any involvement of underlying tissues, and the likely functional and cosmetic outcome of either treatment. The patient's overall condition is important, as is the complexity of any surgery required; even the distance from the patient's home to the radiotherapy centre may play a role in determining the choice of treatment. The decision as to which modality of treatment to use should not be made solely on the basis of the patient's age.

Radiotherapy has a role to play in the treatment of almost all malignant skin conditions. Its use has been variable for several reasons. In some areas, traditional referral patterns have curtailed its use and the siting of radiotherapy departments in the larger conurbations has not given universal access to all patients. The past experience of radiation and lack of multidisciplinary meetings and clinics where the results of carefully considered fractionated radiotherapy could be seen by all attending have also reduced its use in appropriate cases [5]. Radiation damage, with skin atrophy, telangiectasia, necrosis and ulceration, occurred in the past, but this is now rare with better dosimetry, a wider range of radiotherapy modalities and more careful fractionation.

There is little difference in outcome between external beam radiotherapy with either superficial X-rays or an electron beam [6]. Locally placed moulds or applicators have also been used for malignant skin tumours, placing a radioactive source over the tumour and leaving this in position for a predetermined period [7,8].

Radiotherapy can be especially useful for tumour sites around the nose, ears and the eyelids, where surgical removal may result in a poor cosmetic result or loss of function [9]. The areas which have traditionally been considered as not suitable for radiotherapy, such as over the nose, pinna, dorsum of the hand or anterior lower leg can be treated if careful consideration is given to the volume treated, the total dose and the fractionation. It is also important to consider the general state of the patient and the condition of the skin in the site to be treated [10–13].

There are some patients who, for practical reasons, cannot have radiotherapy. If patients are unable to lie still because of confusion or neurological disease, then it can be impossible to deliver radiotherapy effectively and safely.

Radiotherapy doses for skin cancer

Radiotherapy doses have evolved empirically over a long period of time and there is a wide range in use around the UK. As a rule, the greater the fractionation employed, that is the more the total dose is broken down into smaller fractions, the better the cosmetic effect (Table 76.1). This is obviously very important to some patients, but others are content to accept a poorer cosmetic effect if it allows fewer visits to hospital.

Table 76.1 Commonly used superficial radiotherapy dosage regimens for skin basal cell carcinoma and squamous cell carcinoma.

Total dose (Gy)	No. of fractions	Fractionation interval
18	1	–
28	2	7 weeks apart
35	5	Daily (for tumours less than 4 cm in diameter)
45	10	Daily (for tumours more than 4 cm in diameter)

These fractionation regimens are only examples. Many centres will have other similar but locally derived dose fraction regimens.

Radiotherapy for particular skin tumours

Basal cell carcinoma. Radiotherapy is useful for the primary treatment of small BCCs or larger lesions where surgery

will leave a poor functional or cosmetic result. Radiotherapy also has a role to play after primary surgery if the margins are ambiguous and further surgery is thought not to be appropriate for the patient. It should not be used for re-treating BCCs which have recurred after previous radiotherapy. The morphoeic BCC subtype and the presence of underlying bone or cartilage involvement are relative contraindications to the use of radiation treatment; but even in the latter situation, radiotherapy can be given safely and effectively [1].

Squamous cell carcinoma. As with BCC, radiotherapy can be used as either the primary modality of treatment or as adjuvant treatment after surgery if there is a narrow surgical margin of clearance, the margin often being determined by the particular anatomical site of the tumour. The technique and dose are the same as those for treating BCC, but a wider margin is taken around the tumour and the patient is subjected to a more frequent and longer follow-up. If the squamous cell carcinoma has developed on the face, it is mandatory to check for cervical lymphadenopathy. Radiotherapy can be useful in palliation of advanced skin tumours and in some patients give long-term survival [2].

Bowen's disease. Radiotherapy can be a very effective treatment for Bowen's disease [3], but lesions on the leg have to be treated with more caution [3,4], as there is a danger of ulceration and very slow healing if large areas are treated. This condition can also be treated with a local mould, although this would be a relatively uncommon treatment modality.

Malignant melanoma. Malignant melanoma cells are not insensitive to radiotherapy, as is sometimes stated (Fig. 76.3a,b), but they do require higher dose-per-fraction regimens to overcome their ability to sustain more sublethal damage than other cell lines. Treatments may be hypofractionated, with patients receiving larger single doses in fewer fractions—for example, treatment being given three times rather than five times per week. Radiotherapy is also useful for palliation of both cutaneous and visceral metastases from melanoma [5].

There have not been any published prospective randomized controlled trials comparing surgery in melanoma with surgery and adjuvant radiotherapy, but there have been studies suggesting improved local control if post-operative radiotherapy is given [6,7].

Lentigo maligna and lentigo maligna melanoma. Radiotherapy has been used very successfully in both of these conditions. In one German study, there was no recurrence in any of 42 patients with lentigo maligna, with a mean follow-up of 15 months, and only two patients with lentigo maligna melanoma out of 22 showed local recurrence.

(a)

(b)

Fig. 76.3 A patient with malignant melanoma treated with primary radiotherapy. (a) Before treatment; (b) after treatment.

Cosmetic results were also reported as good or excellent in the majority of patients [8]. Similar complete responses for lentigo maligna were seen in studies from Australia [9] and Canada [10], again with good cosmetic results.

Merkel cell carcinoma. These tumours of neuroendocrine origin are most common on the head and neck, but can occur elsewhere on the skin. They have a tendency to recur locally after surgical removal and improved local control has been shown with a combination of wide excision and adjuvant post-operative radiotherapy [11–16].

Some authors even advocate irradiating the draining lymphatic nodes, especially if sentinal node biopsy is not performed. These are radiosensitive tumours and radiotherapy has been used as a primary treatment [16].

Cutaneous T-cell lymphoma. Radiotherapy can be used as both a localized treatment for isolated patches or plaques and for treating all of the skin by whole-body electron beam therapy [17–19]. With the latter, the patient takes up standard pre-determined poses for a number of fields allowing maximum cutaneous exposure to the beam. If

treated early in the course of the disease, the patient can remain well and disease-free for a considerable period of time, but there is still doubt as to whether patients can be cured with this technique [20]. The eyes are shielded and the patient is made aware that he or she will lose their nails with this technique. Despite its drawbacks, radiotherapy is the most effective modality in achieving a complete response to treatment in cutaneous lymphomas.

Cutaneous Kaposi's sarcoma. It is well known that these tumours are sensitive to radiotherapy. Either superficial X-rays or electron beams can be used, depending on the thickness of the lesion(s) and consequently the depth of treatment required. Radiotherapy is also used to palliate systemic disease such as pulmonary masses [21,22].

Dermatofibrosarcoma protuberans. This low-grade sarcomatous tumour has a propensity to recur after surgery alone, and local control is improved by giving adjuvant radiotherapy [23,24].

Carcinoma metastatic to the skin from other primaries. Skin metastases tend to originate from the most common parenchymal tumours such as breast, colon and lung, but occasionally isolated skin metastasis occurs from tumours originating in the thyroid or urinary system. The latter two sites should be borne in mind if a patient presents with a single bizarre metastasis with no obvious evidence of previous primary tumour.

Acute radiodermatitis [1]

The minimal single dose that produces an observed erythema is called the 'erythema dose', and before the existence of other measurements much importance was placed on the dose needed to achieve this end. However, there is great individual variation, and field size, quality of radiation, area of skin irradiated, sex, race and age of the patient are some of the many factors affecting this parameter. The erythema dose was superseded by the roentgen and then the rad. The international unit of radiation dose is now the gray—the centigray is often used clinically.

The clinical course of the acute radiation reaction depends on the size of the dose and fractionation used. Large single fractions of irradiation are rarely given in clinical practice. An initial erythema and oedema may be seen within 24 h of irradiating the skin, and then a secondary and progressive erythema is manifest on the third to the sixth day. If the dose has been sufficiently high, vesicles and bullae may form, which subsequently dry and desquamate. The desquamated skin is usually dark. The perifollicular cells appear more resistant to radiation, and re-epithelialization is initiated in the perifollicular areas, which coalesce to cover the denuded surface. Postinflammatory pigmentation may occur at the periphery of the field and within the field in dark skins, and this pigmentation may last for many months. If the epithelium is irradi-

ated to a high dose, it will appear atrophic and smooth, it is unable to form pigment, and is devoid of hair, sweat and sebaceous glands. This thin epithelium reacts poorly to trauma and has less tolerance of further radiation. Hyperkeratosis, telangiectasia and dyspigmentation may eventually occur, and malignant lesions supervene.

Treatment. There is little which influences the natural history of the acute radiation reaction. Trauma, heat, cold, friction and infection may cause ulceration, as such skin cannot readily repair damage. Mild steroid creams may give some symptomatic relief. Vigorous and repeated washing should be avoided in the acute stage.

Chronic radiodermatitis

The skin is atrophic and shows telangiectasia due to dilatation of a reduced or poorly supported skin vasculature. Dyspigmentation occurs; pigmentation usually is reduced or absent, but there may be small islands of increased pigment production and retention. Decreased sebaceous activity is invariable. The skin is usually atrophic, but increased fibrosis occasionally causes stiffening and tethering. Radionecrotic ulceration may occur, especially in areas of moisture and trauma, and is found in the most poorly vascularized central area of the irradiation scar. Areas of ulceration often show irregular new vessel growth, and histological examination may reveal pseudoepitheliomatous hyperplasia at the edge of an area of extreme atrophy or necrosis. Where there is underlying bone sequestration, radical surgery is necessary to obtain healing.

Chronic radiation change may be confused with a recurrence of a malignant lesion, but the severe pain associated with radiation necrosis is seldom seen with the malignant disease. The effects of normal ageing and sun exposure may combine with the effects of ionizing radiation, and produce accelerated changes of atrophy, necrosis or malignant change. This may also be seen when psoralens and UVA (PUVA) are used on irradiated skin.

Late radiation changes leading to necrosis should never be seen when modern techniques of fractionation to a radical dose for skin malignancies are used. Orthovoltage irradiation of skin overlying subcutaneous bone or cartilage, as on the lower leg, nose and ear, may occasionally result in radionecrosis, as there is a disproportionate absorption of radiation in these high-density tissues, and as cartilage has a particularly poor blood supply. Thus, supervoltage irradiation should be used in these sites. Radionecrosis typically occurs approximately 1 year following complete healing of the skin after radiotherapy, and is often precipitated by trauma or infection. Excision and grafting provide the only satisfactory treatment of extensive radionecrosis. Small areas may slowly heal with conservative management.

Histopathology

In acute radiodermatitis, there is oedema and sparseness of connective tissue beneath the epidermis. There may be flattening and loss of epidermal rete ridges with separation of the elastic tissue from the basal layer. Capillary endothelium may be hypertrophic and congested capillaries a feature. Haemorrhage and thrombosis are often observed.

Special stains may show subtle changes in the DNA–RNA structure of epithelial cells as early as the third day [1,2]. During the healing phase, the patchiness of the pathology is a striking feature. Atrophy may be bordered by epidermal hyperplasia, pigmentation is very irregular, and blood vessels are of variable size and shape; deeper vessels may be fibrosed. The fundamental pathology of chronic radiodermatitis is fibrosis of the vessels, with occlusion and varying degrees of homogenization of the connective tissue. Residual vessels may be enormously dilated. Bizarre, large, stellate fibroblasts may be seen in the dermal connective tissue in some cases. Fibrosis of the deep dermis and subcutaneous tissue may occasionally occur after supervoltage radiotherapy [3].

The changes in the epidermis vary from simple atrophy to acanthosis and extreme dyskeratosis. There is usually loss of adnexa such as hair follicles.

Radiation-induced tumours

The type of tumour induced by radiation depends on both the cellular structure and the anatomical location of the damaged tissues. Basal cell epitheliomas occur following radiation to the face, scalp and trunk, whereas on the hands squamous cell tumours may occur. These are much more rarely seen since the development of more sophisticated radiotherapy machinery and a greater knowledge of radiobiology. It has not been possible to demonstrate any precise quantitative relationship between the development of cutaneous epitheliomas and the amount of radiation received on the skin surface, nor is it known what total dose or fractionation regimen would be most carcinogenic. It has long been known that carcinomas occur more profusely in areas subjected to many small doses administered at intervals over a long period. Multiple basal cell epitheliomas on the skin over the spine following radiotherapy to the lumbar spine for ankylosing spondylitis have been reported [1]. Some may show

the histological appearances of the pre-malignant fibroepithelioma of Pinkus. Radiation-induced basal cell epitheliomas of the scalp may be seen 20–50 years following X-ray epilation for ringworm infection. Late radiation changes are not always visible on the scalps of these patients, and hair growth may be relatively normal.

The doses of radiation used to treat benign dermatological conditions should never produce late radiation damage of even mild type [2]. In general, radiation-induced cancers have occurred after inappropriate doses, often of many thousands of centigray, given over a long period, frequently by lay therapists for conditions such as hirsutism or greasy skin and large pores [3], which are not indications for treatment by radiotherapy today. Shielding of structures especially sensitive to irradiation—for example, the adolescent thyroid [4]—was not routinely carried out. Although a greater knowledge of the limitations and effectiveness of radiation should prevent the occurrence of late radiation damage including carcinogenicity, the long latent period often demonstrated in those cases warns against early complacency [5,6].

Treatment. Most radiation-induced tumours should be excised. However, where there is no radiation damage evident on the skin, a subsequent radical dose of radiotherapy can be tolerated, but this would be indicated in very limited clinical circumstances.

Atypical fibroxanthoma

SYN. PSEUDOSARCOMA OF THE SKIN

This tumour, seen particularly in fair-skinned males who have suffered actinic damage, may also follow radiation damage [7–9]. It usually occurs on the face, but occasionally on the trunk or limbs. The clinical course is benign, despite the highly anaplastic histological appearance. Twenty-one tumours initially labelled as spindle cell squamous carcinomas were found by Hudson and Winkelmann [7] to be atypical fibroxanthoma.

Fibrosarcoma

Sarcoma appears to arise in irradiated skin much less frequently than carcinoma, and many of the tumours are low grade, showing no tendency to produce distant metastases [10]. At least some of the reported sarcomas are in reality spindle cell carcinomas [11]; this may be shown by the attachment of the tumour to the epidermis or by the presence of horny pearls. Radiation fibromatosis [12] is a diffuse proliferation in which bizarre and sometimes monstrous fibroblasts appear in the dermal connective tissue; the appearance can easily be mistaken for fibrosarcoma. Only exceptionally does fibromatosis undergo malignant change. It does appear that irradiation of an already chronically inflamed skin is more likely to be followed by a fibrosarcoma than irradiation of normal skin.

The fibrosarcomas, like the carcinomas following radiation, appear usually after repeated exposures to low-voltage rays and rarely from supervoltage radiation. The latent period in one series [13] averaged 26 years.

Chapter 77

Physical and Laser Therapies

N.P.J. Walker, C.M. Lawrence & R.J. Barlow

Cryosurgery

Various methods of freezing skin have been described [1]. These achieve the following minimum temperatures: salt–ice mixture (–20°C); carbon dioxide snow (–79°C); dimethyl ether and propane (Histofreezer; –50°C); nitrous oxide (–70°C) and liquid nitrogen (–196°C). Because of its very low temperature, liquid nitrogen works faster than other methods. It is also easy to use, inexpensive and readily available. Liquid nitrogen is therefore the most widely used cryotherapy agent. All significant studies of cryotherapy technique have used liquid nitrogen, and it is the only agent discussed in this chapter. The effectiveness and freeze times of other cryogens has not been established.

Cryotherapy is believed to cause cell death in four ways.

1 Ice crystals formed in the cell damage cellular components [2]

2 Uneven intracellular ice formation during freezing leads to osmotic differences arising during thawing, which in turn cause cell disruption

3 Cold injury to small blood vessels results in ischaemic damage

4 Immunological stimulation produced by the release of antigenic components results in cell damage.

The extent of injury is determined by the rate of freezing, the coldest temperature reached, the freeze time and the rate of thawing. Maximum damage is produced by rapid freezing and slow thawing. Repeating the freeze–thaw cycle produces much greater tissue damage than a single freeze because the greater conductivity of the previously frozen skin and the already impaired circulation both allow a greater and faster depth of cold penetration.

It is suggested that a temperature of –30°C is required to produce cell death. In practice, tissue temperatures achieved during cryotherapy do not need to be measured because clinical studies have determined the duration of liquid nitrogen spray freeze times for common skin conditions.

Clinical methods

In day-to-day use, liquid nitrogen *must* be kept in unsealed containers designed for the purpose. If containers are sealed, explosion will occur. One litre of liquid nitrogen held in an unsealed vacuum flask will last approximately 6 h. Liquid nitrogen can be applied using cotton wool swabs dipped into the liquid, but a liquid nitrogen spray is faster and more convenient.

Clinical uses

Liquid nitrogen cryotherapy has been used to treat a wide range of skin diseases (Table 77.1) [3]. The simplicity and speed of cryosurgery treatment are benefits, but cryotherapy can easily be performed incorrectly and ineffectively. The correct technique and freeze times are required to

produce results similar to those described in published studies [4].

Cryosurgical treatment of basal cell epitheliomas gives cure rates that compare favourably with other modes of therapy [5–7], provided the correct technique is used and the treatment limited to small (less than 20 mm), well-defined, previously untreated tumours. Less favourable results are obtained with lesions on the inner canthus of the eye, nasolabial and retro-auricular folds and the hair-bearing scalp. The temperature reached and the number of freeze–thaw cycles are also critical. Debulking the tumour using curettage or electrosurgery prior to cryotherapy is advocated by some authors [8,9]. Lower leg Bowen's disease is best treated by curettage, which is superior to cryotherapy [10], which in turn is superior to radiotherapy [11].

Side effects [1]

Cryotherapy pain is significant but usually transient, and tissue swelling is common. Inflammation can be reduced with topical steroid applications [12]. Haemorrhagic blisters may occur but blister formation is not necessary for the cure of lesions such as viral warts. Sun-damaged and senile atrophic skin, and areas previously treated with topical steroids or X-irradiation, are more likely to blister or become necrotic after freezing. Skin necrosis is a desirable part of the treatment of neoplastic and many pre-neoplastic lesions, and several weeks may elapse before healing is complete. Hypopigmentation is common after liquid nitrogen cryosurgery, is particularly noticeable in dark-skinned patients and may be permanent [2,13]. Temporary post-inflammatory hyperpigmentation is to be expected following less severe freezing. Nerve damage resulting in paraesthesiae, distal anaesthesia and motor paralysis occasionally occurs [14]. Similarly, deep freezing over the lacrimal ducts may, very rarely, lead to permanent ductal obstruction [1].

Curettage

Curettage is only possible when the curetted material is more fragile than normal skin (e.g. basal cell carcinoma; BCC), or there is a natural cleavage plane (e.g. seborrhoeic wart) between the lesion and the surrounding skin. On mobile or fragile skin areas, a starting point for curettage can be made by fulgurizing the rim. Stop bleeding using either a chemical haemostatic agent (e.g. aluminium chloride 30% in isopropyl alcohol), cautery or electrodesiccation. Do not use alcohol-based skin-cleansing solutions during cautery or electrodesiccation because of the fire

Fig. 77.1 Curettage and cautery of an actinic keratosis. (a) After local anaesthetic injection, this hyperkeratotic actinic keratosis was (b) curetted off and (c) the wound cauterized. (d) At 4 months the wound had healed leaving a barely visible scar.

risk. The resulting wound heals by re-epithelialization from the retained follicular and edge epithelium.

Benign lesions

Curettage of *viral warts* is sometimes effective. Treatment is painful and there is a risk of scarring and recurrence. Solitary warts on the face of adults can usually be removed by curettage, otherwise viral warts should only be curetted off when other methods have failed. Curettage is probably justifiable in painful plantar warts that have not responded to other therapies. Nerve block anaesthesia may be required [1]. There is a risk of painful scar formation. Peri- and subungual warts are difficult to curette off; the nail may have to be partially removed to allow adequate curettage. Genital or perianal warts that have not responded to cryotherapy, podophyllin or imiquimod can be curetted off. *Seborrhoeic warts* can be treated by cryotherapy or curetted off. In contrast, *pyogenic granulomas* and *hypertrophic* or *solitary actinic keratoses* (Fig. 77.1) are best treated using curettage, as this provides material for histological confirmation of the diagnosis.

Non-melanoma skin cancers

The technique is the same for both BCC and squamous cell carcinoma (SCC) (Fig. 77.2). Tense the anaesthetized skin around the lesion and scrape off the bulk of the tumour using a small sharp curette [2]; the curette should not be so sharp that there is a risk of it slicing through the underlying dermis. The fragmented specimen should be mounted on a small piece of filter paper, where it is allowed to congeal slightly before being dropped into formalin. In this way the pathologist receives a single sample rather than multiple small floating fragments. Cauterize, using a hot wire with a beaded tip, or electrodesiccate the wound surface. Repeat the curettage using a smaller curette to search for residual pockets of tumour. At this stage, the curette will be scraping against the normal dermis and less material will be removed. If the curette penetrates the dermis and enters fat, curettage should be abandoned as it is impossible to distinguish between the softer tumour tissue and the underlying fat. The wound will need to be excised down to and including fat. Perforation of the

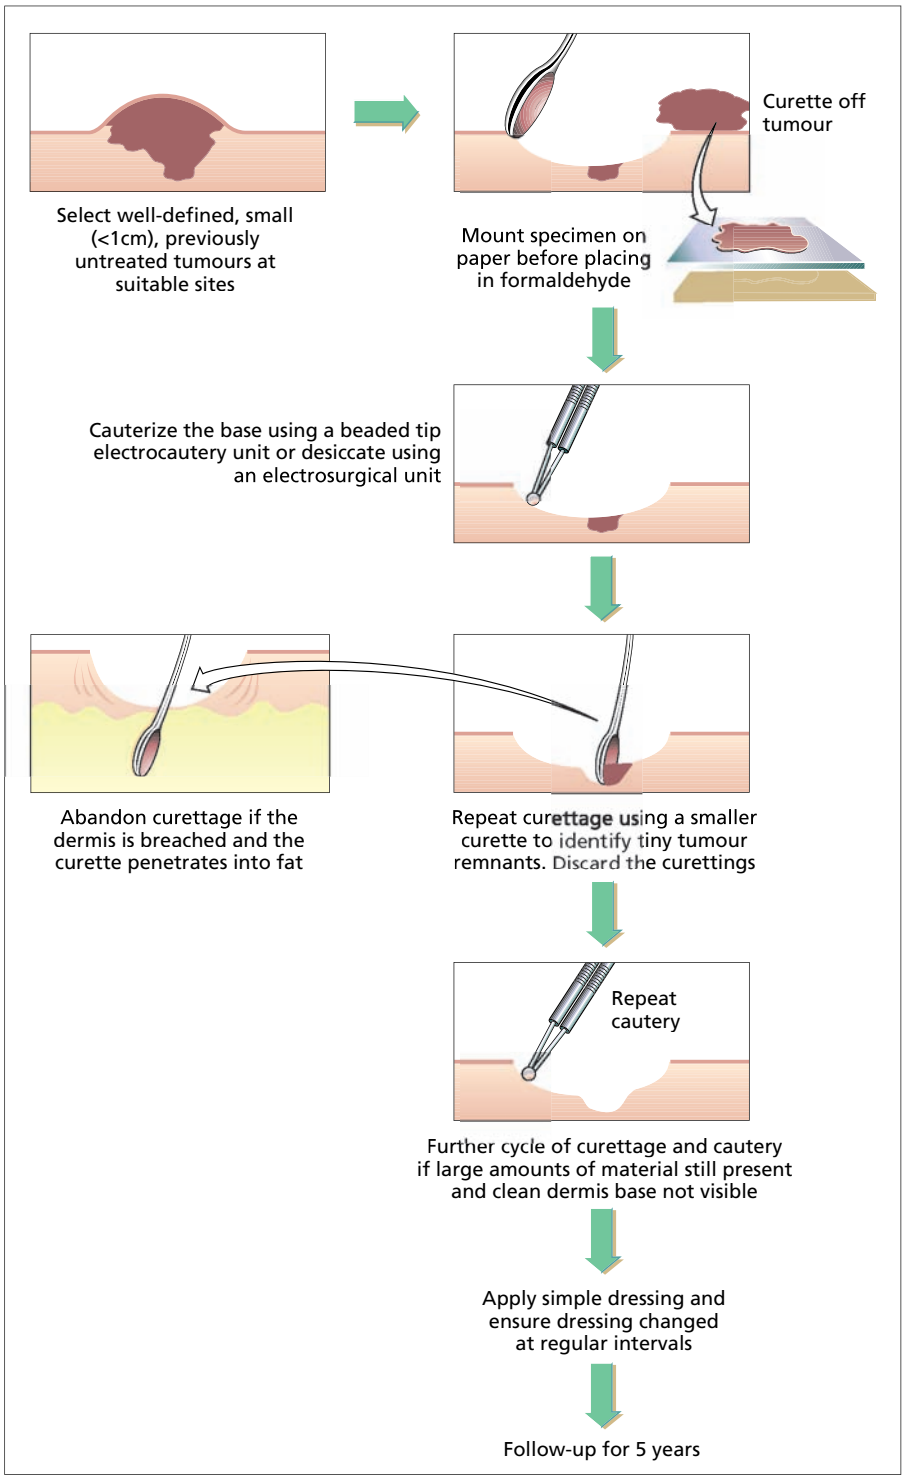

Fig. 77.2 Schematic diagram of the stages of curettage and cautery of a basal cell carcinoma. (From Lawrence [14].)

dermis is particularly likely to occur if an incisional biopsy has been taken prior to treatment. Repeat the cautery or electrodesiccation. A third cycle of curettage and cautery is required if a large amount of material is removed at the second stage. The histological specimen only confirms the diagnosis; it provides no indication about the adequacy of treatment. Do not curette recurrent tumours because of the high recurrence rates [3].

Basal cell carcinoma

Curettage of BCCs depends on the tumour being easier to scrape off than the surrounding normal tissue. Thus, if strands of fibrous tissue separate clumps of tumour (as occurs in morphoeic, recurrent or invasive BCCs) or the adjacent skin tears easily, cannot be tensed or hair roots impede curettage, the results will be poor and curettage

Table 77.2 Types of basal cell carcinoma (BCC) that should not be treated by curettage.

Large tumours (≥ 2 cm diameter)
Tumours at sites where curettage produces a poor cosmetic result, is technically difficult or is associated with a high risk of recurrence
Morphoeic, infiltrating or basisquamous BCCs
Recurrent tumours
Ill-defined tumours
Tumours penetrating muscle, fat, bone, etc.
Tumours where an incisional biopsy has been performed (risk of perforation of the dermal sling)

should be avoided. High recurrence rates occur after curettage of recurrent [3], morphoeic [4] or large tumours [4,5], or treatment by inexperienced operators (Table 77.2) [6]. When small (less than 20 mm diameter) [4–8] non-recurrent tumours [3,9,10] on suitable sites (Table 77.3) are curetted by experts [6,11], the 5-year cure rate is 95% or better (Table 77.4). Cautery and electrodesiccation can be used interchangeably and their use improves cure rates [12]. Paradoxically, despite these high cure rates, histological examination after curettage and electrodesiccation shows that some residual tumour is present in almost 30% of cases [13,14]. Thus, cure must also depend on other factors, such as residual tumour cell mass, inflammatory reaction and healing responses.

Squamous cell carcinoma

Experience shows [8,10,15] that well-differentiated, primary, slow-growing SCCs arising on sun-exposed sites can be cured by curettage and cautery (Table 77.5). However, SCCs with a higher risk of recurrence or metastasis should not be treated by curettage. These high-risk SCCs include lesions arising on scars, ears, lips, areas of radiation or thermal injury, chronic ulcers or sinuses, Bowen's disease and non-sun-exposed sites; and large (more than 20 mm), thick (more than 4 mm), poorly differentiated and recurrent SCCs, or those arising in an immunocompromised patient [16,17].

Intraepidermal carcinoma (Bowen's disease)

Intraepidermal carcinoma, especially on the lower leg, heals better after curettage than cryotherapy [18], as the extent of treatment is more predictably determined by the operator. Radiotherapy, 5-fluorouracil and excision are all alternatives.

Electrosurgery

Electrosurgery includes electrodesiccation, electrofulguration, cutting diathermy (syn. electrosection, electroresection) and electrolysis [1,2]. Coagulation or tissue destruction is produced by the heat created as the electrical current passes through the tissue. Although not strictly an electrosurgical technique, electrocautery is usually also included because of its development from the established method of using heat in the form of hot oils, cautery irons, etc., to control bleeding.

Electrocautery

SYN. CAUTERY; HEAT CAUTERY; HOT-WIRE CAUTERY

The cautery machine power output should be controllable so that the tip temperature can be adjusted rather than being dependent on the battery power. A variety of tips are available. The *beaded tip* is best for haemostasis after curettage and shave biopsy; this should be just hot enough to char a cotton swab, but not red hot as the platinum tip may melt. If the beaded tip drags on the tissue as it is drawn across the wound, the tip temperature is too low. After use, any remaining debris should be burnt off the tip by briefly allowing it to become red hot. The needle-like end of the *cold point cautery tip* is heated, by conduction, via a wire coil, and is used to treat spider naevi. The *flat blade* can be used for pedunculated lesions or shave excisions, but has to be glowing red hot to cut through tissue, producing a heating artefact on the excised material. Furthermore, the red-hot blade has to be quickly passed through the skin to avoid excessive heat damage at the wound site, so the direction and depth of the cut cannot be adjusted easily and the blade may accidentally cut or burn deeper into the tissue than required.

Electrosurgery

SYN. SURGICAL DIATHERMY; COLD ELECTROCAUTERY

Waveform

Electrosurgical equipment converts domestic alternating current into high-frequency alternating current. When this passes through a high-resistance medium, such as the skin, heat is produced, resulting in tissue coagulation, desiccation or cutting, depending on the electrical waveform. A highly damped waveform (intermittent pulses of electrical discharge separated by intervals of zero voltage) results in electrodesiccation and/or fulguration. In contrast, a continuous waveform produces a cutting effect and a moderately damped or blended waveform (a

mixture of continuous and highly damped waveforms) chiefly produces coagulation [3].

Unipolar/monoterminal/bipolar diathermy

Apart from the waveform produced, electrosurgery equipment also varies in the way the current is discharged and collected. Unipolar (monopolar) current is delivered via an active electrode, usually a needle or ball tip, resulting in a high concentration of current at the electrode tip. The current disperses through the patient's body and is collected via a dispersive (syn. indifferent, passive, return, earthing, ground) electrode with a large surface area. The current density falls with increasing distance from the active electrode and there is minimal risk of tissue damage as the current is collected over the large area of the dispersive electrode. If, because of faulty application or equipment, there is only a small area of skin–electrode contact, a burn may occur at the dispersive electrode. Also, if the current is channelled at narrow points along its path (e.g. the finger), an area of high-current density leading to tissue damage can occur. Bipolar electrodes avoid these hazards by producing and collecting the current using forceps so that current only travels in the tissue held between the tips. Monoterminal electrosurgical equipment (e.g. Birtcher Hyfrecator) produces a high-voltage low-amperage current, and is designed to be used without a dispersive electrode. However, there is a risk of a small but painful discharge occurring between the patient and the operator or other earthed point (e.g. the metal edge of an electrically insulated couch) [4]. This can be prevented by maintaining a large area of skin contact between the operator and patient during use, or using a dispersive electrode.

Electrodesiccation/electrofulguration

This is produced using a monoterminal or unipolar electrode. Electrodesiccation occurs when the needle remains in contact with the skin and no spark occurs. Because the current concentration is greater at the point of contact, the tissue damage is deeper compared with electrofulguration. During the latter, the needle tip is not in contact with the skin and a spark jumps between the skin and the needle, but its energy is spread over a greater area. The resulting heat causes superficial damage to the tissues and is an effective way of stopping bleeding. Various needle tips have been developed for specific circumstances [5]. Because of the risk of virus transmission, a different clean needle must be used for each patient [6].

Pacemakers and electrosurgery

There have been reports of electrosurgery interfering with pacemaker function temporarily and causing temporary asystole if there is no underlying cardiac rhythm, or causing a demand pacemaker to switch to a fixed-rate mode [7]. The effect lasts only as long as the unit is being operated. When diathermy finishes, the pacemaker reverts to normal function. There are also anecdotal reports of the pacemaker failing shortly after electrosurgery [8]. Only older (pre-1990) pacemakers seem to be vulnerable. Modern pacemakers are considered to be resistant to these problems. All types of electrosurgical equipment, except cautery, can cause problems, although bipolar diathermy is the least hazardous. Short bursts (less than 5 s) should be used, the patient's heart rate can be monitored and resuscitation equipment should be available. Diathermy should not be performed within 15 cm of the heart, the pacemaker or its leads. If monopolar diathermy has to be used, the path from the active electrode (diathermy tip) to the dispersive electrode should be at least 15 cm from the heart, the pacemaker and its leads.

Spider naevi

Spider naevi are probably best treated using a pulsed dye laser. They can be also be destroyed using cold point cautery or electrodesiccation, but with greater risk of scarring.

Xanthelasma

Electrodesiccation and curettage of xanthelasma is relatively simple. The anaesthetized skin overlying the xanthelasma is fulgurized and disrupted. The underlying fatty deposits can be electrodesiccated, scraped off using a sharp curette and left to heal by second intention. Trichloracetic acid and ablative laser therapy can also be used.

Small seborrhoeic and plane warts

Eyelid seborrhoeic warts can be softened and removed by electrodesiccation, provided the anaesthetized eyelid margin is pulled away to prevent conjunctival damage.

Surgical paring and electrofulguration of rhinophyma

Cutting diathermy (syn. electrosection) using a unipolar diathermy and dispersive plate is particularly useful for treatment of rhinophyma, where bleeding can be a problem [9]. Re-epithelialization takes place, with surprisingly little scarring, from the abundant pilosebaceous follicles that remain in the dermis (Fig. 77.3). Carbon dioxide laser resection is also effective.

Electrolysis

Hair is not an electrical conductor and thus electronic tweezers do not produce permanent hair removal; this can only be achieved if the electrical current reaches the

(a) (b) (c)

Fig. 77.3 Shave excision and electrosurgery of a rhinophyma. (a) This disfiguring rhinophyma was reduced in size and (b) the nose shape recreated by shave excision and electrodesiccation of the bleeding surface under local anaesthetic, (c) resulting in an acceptable cosmetic result at 4 months.

germinal bulb via a needle inserted to the correct depth [10]. Galvanic electrolysis involves the use of low-voltage low-amperage direct current passed down a needle inserted into the follicle. The current causes dissolution of the follicular epithelium and hence detachment of the hair shaft. This technique is effective but time consuming. High-frequency electrodesiccation is a faster alternative, which destroys the follicle by heating. Insulated needles deliver the electrical current to the base of the follicle. Side effects of electrolysis include self-limiting redness and wealing, post-inflammatory pigmentation, and scarring. Compared with laser hair removal, electrolysis is better for sparse hairs and fair hair.

Infrared coagulation [1–3]

The infrared coagulator produces ordinary light (non-coherent) with a spectrum of 400–2700 nm. Power is generated from a tungsten halogen bulb and is transmitted along a quartz glass light guide—at its end this has a sapphire cap, which is placed in contact with the skin. The heat imparted causes thermal injury to a depth dependent on the duration of exposure, which can be set on an automatic timer and varied from 0 to 1.5 s; for example, a 1-s exposure will remove tissue to a depth of approximately 0.75 mm.

The major characteristics are:

1 Non-laser radiation of maximum output 960 nm (near infrared)
2 Tungsten halogen bulb power source—15 V, 150 W
3 Pulsed energy
4 Solid quartz glass light guide
5 Diameter of treated area 2–10 mm, the larger diameters enabling more rapid treatment
6 Sapphire cap to light guide—sapphire is transparent to near infrared but rapidly conducts away heat generated in the upper dermis
7 Minimum optical hazard—the appearance of bright visible radiation causes aversion of the eyes if it is pointing in their direction, thus preventing infrared damage
8 It is portable, and relatively cheap.

It has been used mainly for tattoos [1], a variety of superficial vascular lesions [2], warts and myxoid cysts of the digit. Tattoos [1] can be treated with remarkably little morbidity. The area to be treated is mapped into overlapping circles similar in diameter to the sapphire tip, and each circle is treated with a pulsed exposure of approximately 1.25 s. An ice cube applied to the skin for 5 s before and after treatment is used to minimize conducted heat damage to surrounding skin. The immediate appearance of the coagulated tissue is white and slightly contracted; the eschar, which develops over several days, drops off in 2–3 weeks. Serous exudate, pain and swelling during the healing phase are generally insignificant.

Telangiectases, port-wine stains and angioma serpiginosum have been treated using short exposure times (e.g. 0.75–0.875 s, also with ice). It is evidently less specific and probably less effective, with a greater risk of scarring, than an appropriate laser.

Caustics and chemical peeling

Caustics

In experienced hands, caustics provide a simple and readily available means of destroying many superficial skin lesions. The operator should be well acquainted with the action and degree of penetration of individual caustics, and the toxic effects that may result from absorption, especially if they are to be used on large areas, and particularly when applied to the face [1,2]. In treating individual lesions, caustics are usually applied by means of a cotton-bud applicator or a wool-tipped orange stick, pointed if necessary.

Aluminium chloride hexahydrate

A 20% solution (Driclor; Anhydrol Forte) usually applied on a cotton-bud is a very useful styptic for superficial wounds such as those following shave excision. Ferric subsulphate (Monsel's solution) is widely used, but may leave a pigmented scar.

Silver nitrate [3]

This is used in the form of a pencil or as a strong solution to suppress exuberant granulation. It is haemostatic and may be used to arrest bleeding after curettage. Repeated use tends to lead to unsightly staining of the skin.

Phenol (liquefied phenol)

This is a valuable superficial caustic, which should, however, be used cautiously. It should not be diluted as this increases its absorption and potency [4,5] and thus also its nephrotoxicity. Ochronosis may occur from prolonged absorption. It is not a haemostatic, and bleeding limits its effectiveness. When used as a treatment for ingrown toenails it is important that the phenol is applied to a 'dry' nail bed and that sufficient time is allowed for it to take effect [6].

Potential toxicity and cardiac arrhythmias remain a major concern, especially with more extensive use, and it should not be used during pregnancy. Phenol is used in a soap–croton oil–water mix for chemical face peels (see below). A glycol-spirit solution can be used for neutralization if required.

Trichloroacetic acid

This is an effective haemostatic caustic, which has many uses. The 30–50% concentration can be used as a styptic, and is frequently employed in conjunction with superficial curettage in the treatment of solar keratoses and seborrhoeic warts. The supersaturated solution can also be used on its own to treat many benign and dysplastic skin lesions. Trichloroacetic acid 50% is similar to phenol in its destructive effect on the epidermis.

Trichloroacetic acid may be a useful treatment for xanthelasmas and solar lentigos. It must be applied with great care, however, especially around the eyes. Its action is rapid, and a white 'frosting' occurs within a few seconds of application. The caustic action can be partially neutralized by applying alcohol, water or sodium bicarbonate-soaked gauze, but this is unlikely to have any effect once the acid has penetrated the skin.

Excess sebum should first be removed using detergent, ether or acetone. Trichloroacetic acid should then be applied with an 'almost dry' cotton applicator. The concentration to be used will vary according to site, the condition to be treated and whether the trichloroacetic acid is being used as a styptic or a superficial skin caustic.

Weaker solutions of trichloroacetic acid are sometimes used for treating wider areas of skin (see below). Because of deliquescence, trichloroacetic acid should be kept in a closed, coloured and corrosion-resistant bottle.

Dichloroacetic acid

This is also a powerful caustic and skin styptic.

Monochloroacetic acid

This should not be considered as a superficial caustic. It penetrates rapidly and may remove the whole epidermis

by blister formation. It may be used for mosaic warts, and can also be used for resistant periungual warts.

Alpha-hydroxyacids [7]

These acids (e.g. glycolic acid) can be used to produce superficial or freshening peels and, at high concentration, medium-depth chemical peels.

Chemical peeling [1,2,7–10]

This procedure can be used to improve the appearance of ageing, wrinkled or sun-damaged skin. It is less effective in dealing with acne scars but is a valid dermatological manoeuvre for these and other superficial lesions on the face.

Chemical face peeling is used in conjunction with or as an alternative to dermabrasion. Patients with a dry skin and a fair complexion are the best subjects. A variety of preparations in differing concentration can be used alone or in combination, depending on the desired outcome [11]. Trichloroacetic acid is probably the most commonly used agent. Weak preparations (10–15%) may be used for light 'freshening' peels, and higher concentrations for medium-depth or deep peels. Alpha-hydroxy acids (mild), Jessner's solution (mild) and phenol (deep) may also be used. The neck should only be included with caution as the skin in this area is more prone to scarring and hyperpigmentation. Weaker preparations are generally used on eyelids, and care must be taken not to cause hypertrophic scars, which may occur around the mouth or mandible. Prolonged erythema and increased sensitivity to sunlight, and pigmentary changes (both hyperpigmentation and hypopigmentation) may follow the procedure.

Intralesional therapy

Intralesional triamcinolone [1]

Aqueous suspensions of triamcinolone acetonide (10 mg/mL [Adcortyl] and 40 mg/mL [Kenalog]) [2] are available. Intralesional hydrocortisone acetate (25 mg/mL) can also be used. Triamcinolone acetonide 10 mg/mL is sufficient for all conditions except keloids. The amount injected ranges from 0.1 to 0.5 mL of 10 mg/mL solution, depending on the size and nature of the lesion. The injection should be given using a 27–30-gauge needle, deep in the dermis when possible, to minimize the risk of collagen atrophy. The manufacturers recommend that no more than 30 mg of triamcinolone acetonide should be given in one session, with a maximum of 5 mg at any one site. (Steroid equivalence: 5 mg prednisolone = 4 mg triamcinolone = 20 mg hydrocortisone.) Plasma cortisol levels are suppressed for a few days by 20 mg of intralesional triamcinolone acetonide given into various sites; higher doses suppress cortisol levels for longer [3]. Cushing's syndrome has occurred 2–3 weeks after a single treatment with 40 mg triamcinolone acetonide injected into keloids [4]. Local side effects include collagen atrophy [5], hypopigmentation [6], skin necrosis [6], perilymphatic linear depigmented and atrophic streaks [7,8], and telangiectasia [9].

Needleless injection of steroids

Intralesional triamcinolone is also given using a needleless injector (Dermojet or Portojet). The injection is slightly less painful but is principally employed because the injections can be given quickly [10]. There is a danger of intraocular injection if this technique is used around the eye [11]. Dose-for-dose, needleless injection of steroid appears to be less effective than needle injection, probably because some steroid solution spills onto the skin.

Uses

Intralesional triamcinolone therapy is used for inflammatory acne cysts, lichen planus, lichen simplex, lupus erythematosus [12], chondrodermatitis [13], orofacial granulomatosis [14], granuloma annulare, psoriasis and nail psoriasis [15], alopecia areata and many other steroid-responsive conditions [16].

Intralesional therapies for skin malignancies

Intralesional *methotrexate* is reported to be a painless and effective method of treating keratoacanthoma, with faster than spontaneous resolution [1,2]. Intralesional *5-fluorouracil* injections are very painful but when used for 4–6 weeks destroy small nodular BCCs [3] and some SCCs [4]. Intralesional *interferon-α2b* has been used to treat Bowenoid papulosis [5], melanoma [6], BCC [7,8] and SCC [9]. Up to 80% of small, solid or superficial BCCs injected, using high-dose therapy, appear to resolve, although adverse effects occur in 80% of patients at this dose. In contrast, only a minority of aggressive pattern, invasive BCCs respond [10]. Intralesional *interleukin 2* in 1–4 weekly doses produced complete response in eight of 12 BCC patients treated [11]. Intralesional *bleomycin* followed by electrical stimulation (electrochemotherapy) has been used for a range of skin tumours, including SCC [12].

Sclerotherapy (see also Chapter 50) [1]

The injection of sclerosant chemicals is a useful means of obliterating dilated superficial veins, particularly on the legs. The superficial vessels should only be treated after any proximal points of reflux have been dealt with. Patients who seek treatment therefore require a thorough assessment of their vascular system, and the history and physical examination may be supplemented with non-invasive venous assessment using ultrasonography.

There are a variety of sclerosants that can be used, and some are available in different concentrations. They may be divided into detergents (sodium morrhuate, sodium tetradecyl sulphate, polidocanol) [2], osmotic solutions (hypertonic saline) and chemical irritants (chromated glycerin). Each has advantages and disadvantages.

Side effects [3] include telangiectatic matting, post-inflammatory hyperpigmentation, ulceration, thrombophlebitis and, rarely, systemic reactions (urticaria, anaphylaxis).

Miscellaneous physical procedures

Keloid therapy

Keloids spread beyond the original wound and remain elevated, whereas hypertrophic scars are localized to the injured area and flatten spontaneously with time [1]. Both are more common in young individuals, Afro-Caribbeans

and at particular sites, especially the central chest, back and posterior neck, followed by the ears, deltoid areas, anterior chest, beard area and the rest of the neck [2,3]. Patients with one keloid, except those on the earlobe [4], are believed to be at risk of further keloids. Many treatments have been suggested, including excision, superficial X-ray therapy (although this may provoke malignant tumours [5]), cryotherapy [6,7], pressure [8,9], ultrasound, laser excision [10], intralesional steroids, interferon-α2b [11] and verapamil [12]. Most reports have claimed partial benefit, few have admitted failure. Despite systemic or local side effects [13], intralesional steroid, in the form of triamcinolone 10–40 mg/mL, injected into the scar every 2–3 weeks, is probably the most effective therapy, particularly for presternal and small keloids. High pressure is required to inject steroids into hard keloids, and a Luer-lock glass or hubless disposable syringe is recommended [14].

Pedunculated or easily excised keloids (e.g. on the earlobe) are best treated by intramarginal excision and pre- and postoperative steroid injection [15]. On the earlobe, part of the skin covering the keloid can be salvaged to cover the defect created by removal of the latter [16]. Most authorities recommend a combination of surgery and triamcinolone injections. Some suggest that triamcinolone should be given before, during and after surgery [4], others use steroids during and after surgery [17], whereas others only use steroids postoperatively, to avoid the risk of wound dehiscence [18]. All agree that triamcinolone 40 mg/mL is usually required. On balance, it seems best to give steroids both intra- and postoperatively—approximately four times at 2–3-week intervals, starting 2–3 weeks after suture removal (which should be delayed for 10–14 days because of the risk of steroid-induced wound dehiscence). Freezing the keloid with liquid nitrogen before injection is said to make triamcinolone injection easier [19]. However, this may increase the risk of hypopigmentation. With repeated injections it becomes possible to inject more triamcinolone into the keloid, which can be felt to expand slightly as the steroid is injected. Remember that both cryotherapy and triamcinolone injections may produce skin depigmentation [4]. Alternative therapies include topical clobetasol propionate cream or flurandrenolone tape. The latter carries less risk of steroid atrophy of the adjacent skin because only the keloid is covered. Intralesional interferon-α2b appears to reduce keloid size and inhibit collagen production [11]. Intralesional verapamil is said to reduce keloid size [12] by inhibiting proline incorporation into collagen [20]. Silicone gel sheeting is advocated for larger keloids but the evidence that it is effective is not conclusive [21,22].

Minor surgical procedures

Using an orange stick, small quantities of caustic agents can be precisely applied. When 90% liquid phenol is used to treat molluscum contagiosum or small cysts, the orange stick tip may need to be sharpened so that it just fits the cavity being treated. Remember that phenol melts some plastics.

Mollusca can be squeezed to express the cellular debris from the centre of the lesion before phenol application. The tip of the orange stick is dipped into the phenol, any excess wiped off, and the stick is then placed in the centre of the lesion and gently twisted. The solution does not need to be neutralized. After initial whitening, the molluscum becomes inflamed and then resolves 7–10 days later. Treatment is painful and not usually tolerated by small children.

Xanthelasma can be treated using the blunt end of an

orange stick, dampened with trichloroacetic acid, dabbed on to the affected area. *Multiple small facial epidermoid* or *acne cysts* can be treated in a similar way. The cyst is incised, the contents expressed and phenol carefully applied to the cyst lining using an orange stick. No dressing is required, but a local anaesthetic is necessary.

Milia are tiny keratin-filled epithelial-lined cysts with no connection to the overlying skin. They can be removed via a small skin incision made with a sterile no. 21 or 19 venesection needle. No anaesthetic is required. Prick the needle tip into the skin and, by pulling the cutting edge upwards, incise the skin overlying the milium. Hook or squeeze out the cyst through the skin incision.

Comedones may be emptied using a comedone expressor—a small metal instrument with a cup-shaped end, which has a central hole.

Haemostasis

Bleeding from open wounds can be stopped readily using an absorbable haemostatic dressing such as Surgicel (glucosic copolymer), Kaltostat (calcium alginate), Oxycel (oxidized cellulose) or Gelfoam (porous gelatin matrix), although the mechanism of action of these agents is poorly understood. These materials may behave like a foreign body while dissolving in the wound and increase the risk of infection, so large pieces should be removed before wound closure.

Chemical haemostatic agents [1] are effective on oozing skin wounds (e.g. after curettage and shave excision) but are ineffective in the presence of arterial bleeding, and should not be used in sutured wounds as they cause cell death, which predisposes to infection. Application should be followed by pressure on the wound for 2–3 min to allow haemostasis to occur without the chemical being washed away. Ferric subsulphate (Monsel's) solution carries the risk of iron tattooing [2]. Silver nitrate sticks are effective but caustic, and may leave scars. Aluminium chloride, either 35% in isopropyl alcohol or 20% in ethyl alcohol, is effective; occasionally, it causes histiocytic reactions in treated skin [3].

Soft-tissue augmentation and facial line correction

The use of biocompatible materials to augment soft-tissue defects forms an integral part of a coordinated and planned approach to the management of the ageing face and rhytides. They can be used alone or in combination with botulinum toxin injections and peels. These materials may also be used to correct scars from conditions such as acne and chickenpox. A whole variety of materials is available [1], and patients for whom this type of treatment is being considered must be carefully evaluated and the techniques available discussed. Patients must be given realistic expectations. Some of the materials are biological or naturally occurring such as those based on collagen or hyaluronic acid—although they may be subject to complex manufacturing processes to produce the final material. Autologous fat can be used, although sometimes it does not persist, and there are currently over 60 autologous and synthetic products available. The choice of material will depend on the defect being treated, and requires a thorough knowledge of the aetiology of the defect and the materials available.

As fat is an autograft, *autologous fat implantation* (*microlipoinjection*) is potentially a useful method of soft-tissue augmentation, but it can only be placed subcutaneously. Fat injected into dermis does not survive [2]. The fat is harvested under tumescent anaesthesia using a syringe, via a wide-bore needle. Any contaminating blood is washed off and the fat reinjected using a 16–18-gauge needle. Intravascular injection, and infection, must be avoided. Microlipoinjection is used to increase lip size, obliterate age-related guttering on the hands, and in breast enlargement, melelabial sulci, idiopathic fat atrophy, after lupus profundus and for some acne scars, but cannot be used for small or superficial scars. Grafted fat persists for 1–2 years, although this varies with site and the cosmetic defect treated [3].

Bovine collagen (Zyderm I (35 mg/mL collagen) and Zyderm II (65 mg/mL)) has been used to correct superficial facial scars and wrinkles. The effect is temporary; after 6 months top-up treatment is required. Glutaraldehyde cross-linked collagen (Zyplast) was introduced with the aim of prolonging the effect, but appears to be little different [4]. Approximately 3% of patients react to the test injection [5]. Late allergic reactions are rare but may occur years after collagen injections [6,7]. Soft and distensible postoperative, chickenpox and acne scars respond well [8], unlike rigid fibrotic or ice-pick scars. Hyaluronic acid is also being developed for use in soft-tissue augmentation.

The use of permanent materials such as injectable medical grade *silicon* (polymerized dimethylsiloxane), *gelatin matrix implant* (*Fibrel*) and *polytetrafluoroethylene* (*Gore-Tex*) has lost favour because of permanent imperfect results and reports of inflammatory reactions [9,10].

Lasers and flashlamps (intense pulsed light sources)

The term 'laser' is an acronym for *l*ight *a*mplification by *s*timulated *e*mission of *r*adiation. The first laser was developed by Maiman [1] in 1959, using a ruby crystal to produce red light of wavelength 694 nm. This was followed by the development of other laser systems, notably the neodymium:yttrium-aluminium-garnet laser (Nd:YAG) in 1961 [2], the argon laser in 1962 [3] and the carbon dioxide (CO_2) laser in 1964 [4]. Goldman *et al*. [5] established a role for lasers in dermatology by reporting the use of the ruby laser in the treatment of tattoos, the argon laser in the treatment of vascular lesions [6] and the Nd:YAG laser in the treatment of tattoos, port-wine stains and cutaneous malignancies [7]. In 1983, Anderson and Parrish [8] postulated the theory of selective photothermolysis, which has been applied in lasers and flashlamps to target chromophores such as haemoglobin and melanin, and treat superficial vascular malformations, tattoos and benign pigmented lesions. More recently, observations relating to light-assisted hair removal have been explained in terms of an 'extended theory of photothermolysis' [9,10]. Flashlamp technology is relatively recent, and produces high-intensity pulsed light in the 500–1200 nm range. Filters are used to remove shorter wavelengths where necessary.

Laser safety and laser–tissue interaction

Safety

Various safety measures are required to prevent accidents resulting from exposure to direct or reflected beams. These include the ignition of inflammable materials, including anaesthetic gases, and damage to the skin or eyes. Non-beam hazards include inhalation of the 'plume' arising from tissue destruction, contact with high-voltage electricity or fluid leakage from the laser cavity.

Physics

The generic name of a laser reflects the components of the solid, liquid or gas that constitutes its active medium and determines the wavelength(s) of the radiation produced. The beam may be continuous, pulsed or quality switched (Q-switched). Continuous wave light is a constant beam and has relatively low power. This can be interrupted to produce pulses with higher peak powers than in continuous mode and to allow cooling between pulses. Q-switching is a means of creating a very short pulse (nanosecond domain) with high peak power. The pulse width is varied so that it approximates the thermal relaxation time (see below) of the target chromophore.

The energy contained within light is expressed in joules and its fluence or energy density in J/cm^2. Power is the rate at which work is performed and is measured in Watts (W) or J/s.

The concept of selective photothermolysis has been applied to the removal of superficial vascular malformations, exogenous tattoos, certain benign pigmented lesions and hair. It postulates that light can be used to selectively damage or destroy a target chromophore if the following conditions are met.

1 Its wavelength is selected so that there is as big a difference as possible between the absorption coefficient of the target and the surrounding tissue.
2 The fluence is sufficiently high.
3 The pulse duration is less than or equal to the thermal relaxation time (TRT). The TRT is the time taken for the target to dissipate half of the incident thermal energy and is largely determined by the size of the chromophore. The TRT varies from a few nanoseconds (melanosomes) to several hundred milliseconds or more (leg venules).

It is likely that damage to large targets can be maximized by means of 'thermokinetic selectivity' [10]. Structures such as the hair follicle are relatively large but contain the same chromophore as smaller targets, in this example the melanosome, which one would want to protect during photoepilation. Because large structures cool slower than small structures, it is proposed that they reach higher and potentially damaging temperatures if the light source is manipulated appropriately. This is achieved by means of a pulse that is longer than the TRT of the epidermis and shorter than that of the follicle.

Some tissue targets, notably the hair follicle, are not uniform in their absorption of light, and it is possible that light-assisted hair removal is better explained by an 'extended theory of selective photothermolysis' [9]. This distinguishes between an 'absorber' chromophore (in which heat is generated) and a distant 'target', to which heat is transmitted and which is damaged as a result.

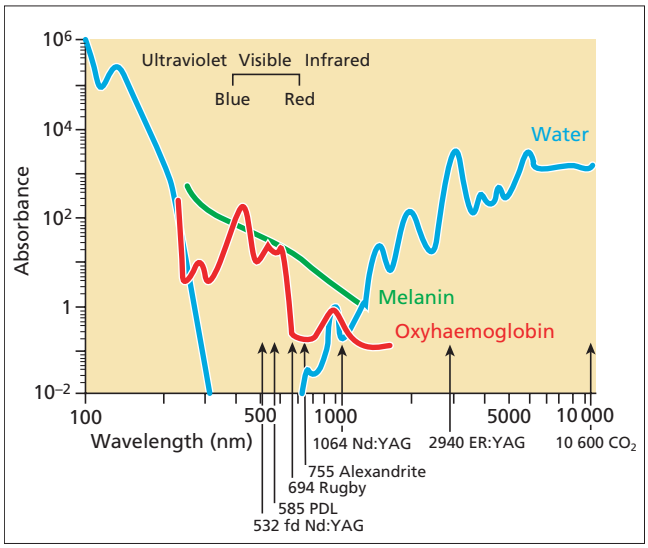

Fig. 77.4 Absorption spectra of principal tissue chromophores. (Reproduced with permission of Dr M. Waner.) Nd, neodymium; Er, erbium; YAG, yttrium-aluminium-garnet; PDL, pulsed dye laser; fd, frequency doubled.

The absorption spectra of important tissue chromophores are shown in Fig. 77.4 in relation to the wavelengths of the lasers widely used in dermatology [11]. As can be seen, haemoglobin has a number of different absorption peaks, whereas absorption by melanin diminishes in proportion to the wavelength of incident light. Consideration must also be given to the depth of the target structure and whether a long wavelength with deep penetration, albeit relatively poorly absorbed, may be preferable to a short wavelength with the opposite characteristics. In some situations, particularly in relation to melanin, a single wavelength may not be necessary and it may even be preferable to use flashlamps because of their broad emission spectrum (500–1200 nm). These are cheaper to manufacture than lasers and can be used with light filters (515–755 nm) to allow a potentially wide range of applications. It is possible to vary their pulse durations from 0.5 to 88.5 ms and to introduce intervals between pulses of 1–300 ms. At present they cannot substitute for lasers where focused high-energy beams are required.

Tissue cooling

Light wavelengths or spectra of 500–1200 nm are preferentially but not specifically absorbed by either haemoglobin or melanin, depending on the wavelengths employed. Epidermal melanin will therefore absorb both direct and back-scattered light from all such devices, whether or not it is the intended chromophore. Heat damage to the epidermis may result in blistering, dyspigmentation or scarring, and is particularly likely in pigmented skin. To reduce this risk, the wavelength should be optimized with respect to the absorption characteristics and depth of the target chromophore. Further enhancing safety in these patients is the use of long pulses [12] and cooling of the epidermis. The latter may be performed before, during or after the light pulse, or all three.

Cooling may take three forms:

1 *Cold air convection*. Air, chilled to temperatures as low as –30°C, is directed onto the area to be treated.

2 *Contact cooling*. This may involve simple application of ice-packs or more sophisticated systems that pass chilled water between colourless and transparent (usually sapphire) plates. Although a good method of cooling during light delivery, condensate on the plates can obscure the skin and require frequent wiping.

3 *Cryogen spray (dynamic) cooling*. A liquid cryogen is sprayed onto the skin immediately before the laser pulse. Evaporate cooling has a high heat transfer coefficient and this is therefore the most efficient way of precooling. With timed automated control this method is also relatively predictable and reproducible.

One important benefit of epidermal cooling has been to allow treatments at higher fluences than otherwise considered safe, and thereby to reduce the number of treatments required. It has also made possible or safer the treatment of patients with pigmented skin. Furthermore, cooling decreases the pain associated with treatment, thus reducing the need for topical or local anaesthetic. Cooling may, however, cause cryogen injury if used inappropriately.

Laser treatment of vascular and pigmented lesions and hair removal

Vascular lesions

Light–tissue interaction

A wavelength of 577 nm was used in early pulsed dye lasers for selective photothermolysis of superficial blood vessels because of its highly selective absorption by oxyhaemoglobin [1]. This has been replaced with 585–600 nm light, which has the advantage of deeper dermal penetration, although with reduced absorption at the longer wavelengths [2]. A pulse duration of approximately 0.45 ms was included in the design of early pulsed dye lasers (PDLs), on the basis of a calculated TRT of less than 1 ms for vessel diameters of 10–50 μm. The theoretical models may have slightly underestimated the TRT, which was measured in a subsequent *in vivo* study as 1–10 ms for vessel diameters of 30–150 μm [3]. As a consequence, newer PDLs allow pulse durations of up to 40 ms. Another laser useful for vascular anomalies is the potassium titanyl phosphate (KTP) laser (532 nm), light from which is well absorbed but is most useful for very superficial vessels. The alexandrite (755 nm) and Nd:YAG (1064 nm) lasers emit light with longer wavelengths and therefore relatively deep dermal penetration, the latter absorbed by a low absorption peak at 900–1000 nm.

Devices in common use

Pulsed dye lasers (585–600 nm) 4.5 and 1.5–40 ms

These contain a rhodamine dye, which is excited by a xenon flashlamp to produce light at 585–600 nm in pulses of 4.5 ms (short pulse PDL) or 1.5–40 ms (long pulse PDL). Light penetrates the dermis to a depth of 1.2 mm [4] and photocoagulates vessels of up to 100 μm in diameter. Purpura is associated with the short pulse width, which causes cavitation and rupture of the capillary wall.

Neodymium:yttrium-aluminium-garnet laser (1064 nm)

Used with long pulses (up to several hundred milliseconds) and epidermal cooling systems, the Nd:YAG laser may have a role in treating relatively deep and large vessels, including those on the legs.

Frequency doubled Nd:YAG or potassium titanyl phosphate crystal laser (532 nm)

Nd:YAG laser emissions can be passed through a KTP crystal to double the frequency to 532 nm. They may be flashlamp or diode pumped and are characterized by trains of short pulses that summate to give a wide pulse effect which is not associated with purpura. Light produced by KTP lasers is highly absorbed by haemoglobin (and melanin) but its wavelength penetrates only superficially. They are widely used, with or without cooling devices, to treat small facial vessels and superficial hypermelanosis.

Intense pulsed light source (500–1200 nm)

This device emits non-coherent light over a broad spectrum. Filters are used to eliminate wavelengths shorter than selected thresholds. There is contact cooling and its potential advantages are the large spot size and reduced likelihood of purpura.

Superficial vascular anomalies

Haemangiomas

These almost always appear after birth and may grow for months. They are often managed conservatively because most regress, sometimes leaving redundant atrophic skin. Intervention may be warranted when functional impairment results from the site and/or size of the haemangioma or where psychological development in childhood is a major consideration. Treatment with the short pulse PDL has been reported to reduce size and colour in up to 67% of superficial haemangiomas. Early proliferative haemangiomas associated with functional impairment or surface ulceration may respond to laser treatment with a reduction in size, together with improvement in the colour and integrity of overlying skin [5]. On the other hand, a randomized controlled study of 121 infants with early haemangiomas showed no advantage to PDL treatment over observation alone [6]. Where appropriate, treatment can be attempted with systemic corticosteroids, interferon or vincristine.

Port-wine stains, or capillary malformations

These may become thickened and darker because of progressive vascular ectasia. The 585 nm short pulse PDL is probably the treatment of choice for paediatric port-wine stains because vessel diameters are relatively small [7]. At 585 nm, the absorption coefficient of haemoglobin is a factor of five higher than at 595 nm and, used in conjunction with the long pulse, may be most suitable for resistant or adult port-wine stains (Fig. 77.5) [8]. Very exophytic lesions are probably best treated with the CO_2 laser [9]. Factors favouring a good response to PDL treatment are youth as well as flat and scarlet (as opposed to purple) port-wine stains on the head and neck (excluding the cheeks or midline) [10,11]. The use of spray cooling with higher fluences in both short [12] and long pulse (1.5–4.0 ms) [13] PDL has considerably expedited treatment of

Fig. 77.5 Port-wine stain: (a) before, and (b) after treatment with a pulsed dye laser, showing considerable but incomplete lightening and polka dot patterning.

port-wine stains. Lesions immediately become purpuric if treated with adequate fluences and pulse durations of 10 ms or less. Although reduced by both cooling and long pulsing, a degree of post-treatment purpura formation is thought to be necessary for effective treatment of lesions [14]. Partial re-emergence may occur after successful treatment [15]. Flashlamps have also been used to treat port-wine stains with good effect [16].

Telangiectasiae

These are acquired capillary malformations and may occur in association with photoageing or as part of rosacea and erythrodysaesthesia. Although they respond to conventional PDL treatment [17,18], there is associated bruising and often subsequent 'polka dot' patterning. Treatments

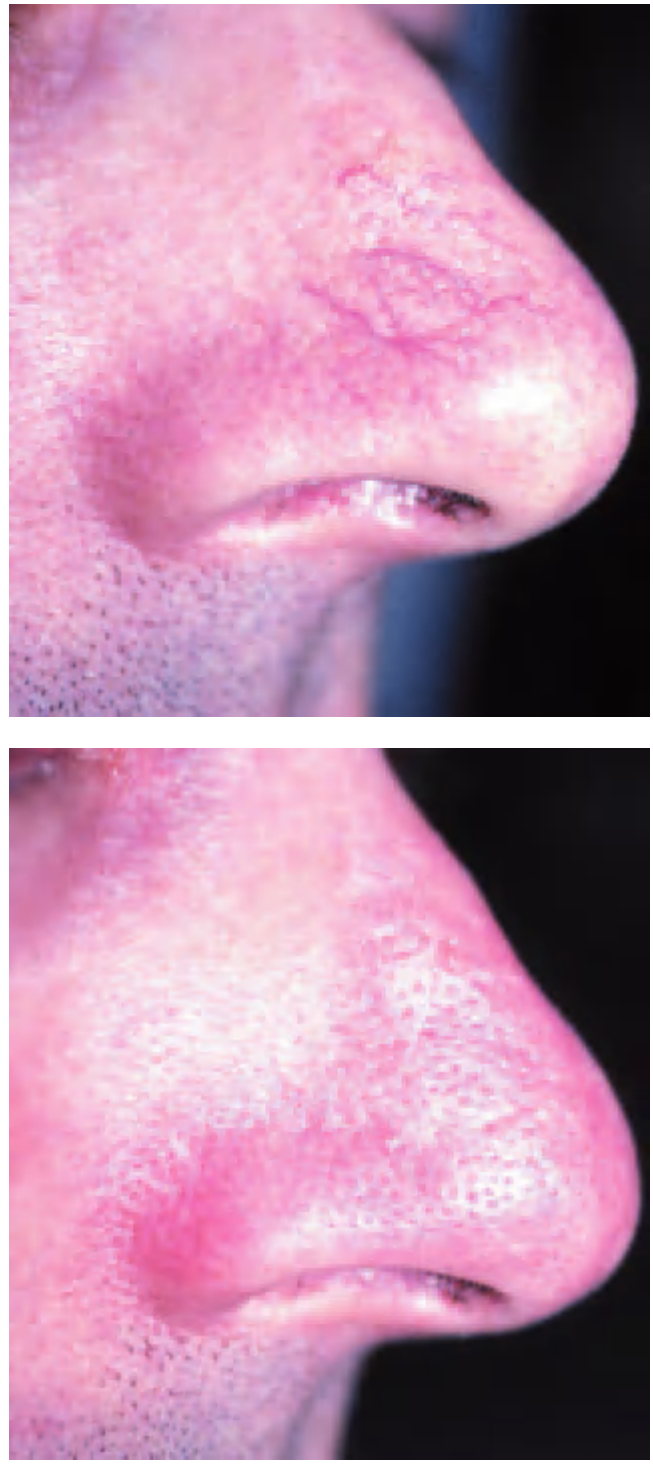

Fig. 77.6 Large nasal telangiectasiae: (a) before, and (b) immediately after KTP laser treatment, showing disappearance of vessels and absence of bruising.

with longer pulses and subpurpuric fluences are cosmetically preferable and may also be effective. Vessels can be treated individually (Fig. 77.6) or in groups, using small and large diameter KTP laser spot sizes, respectively

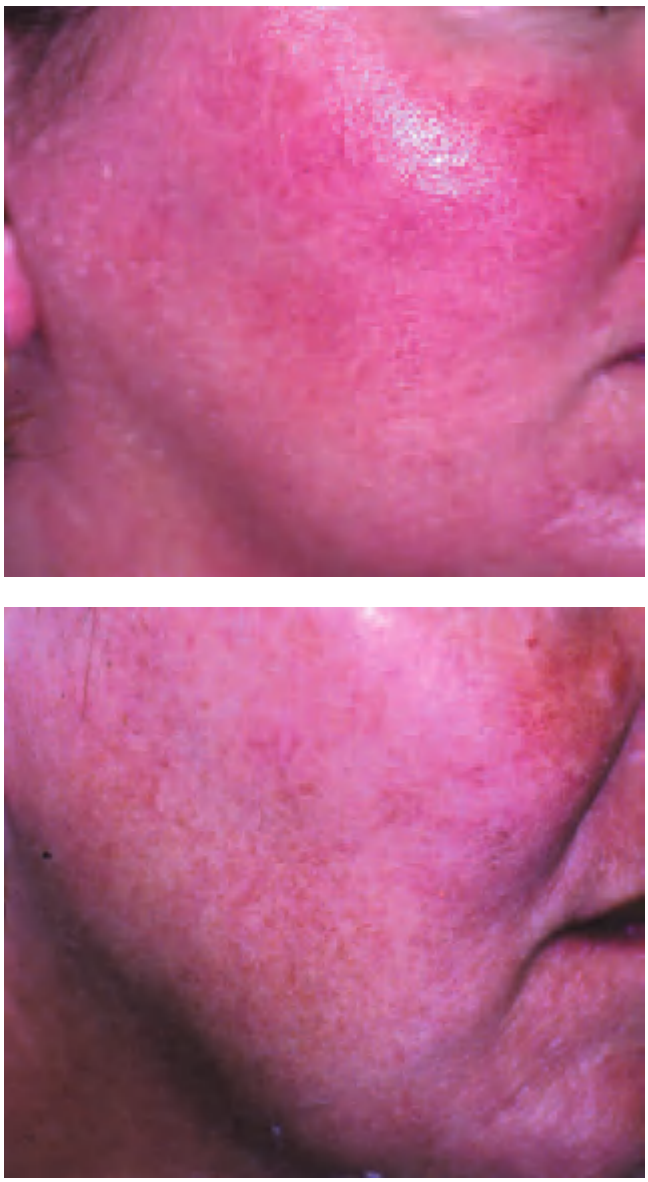

Fig. 77.7 Fine cheek telangiectasiae: (a) before, and (b) after one treatment with a flashlamp.

[19]. Flashlamps are an alternative non-bruising modality (Fig. 77.7), although several treatments may be required [20].

Leg venules

These are best treated by sclerotherapy because of their relatively high hydrostatic pressure and because of their depth and large size. If sclerotherapy is contraindicated, these vessels should respond best to large spot sizes (3–4 mm), high fluences (relative to wavelength) and long pulse durations, used in conjunction with effective cooling devices. Wavelength should be chosen according to the depth of the target vessel. Accordingly, long pulse (1.5–4.0 ms) PDLs were developed with wavelengths in the 585–600 nm range and, used with fluences of 7–9 J/cm^2 [21,22], may sometimes be useful for superficial vessels less than approximately 0.5 mm in diameter. Longer wavelengths are used to target a different absorption peak of haemoglobin and achieve deeper penetration. The 3-ms alexandrite laser (755 nm), used with a fluence of 86 J/cm^2, has been reported to clear as many as 75% of leg vessels less than 3 mm in diameter [23]. Nd:YAG lasers with fluences higher than 100 J/cm^2 and with pulse durations of up to 1 s may be useful for larger vessels [24]. However, complications are common and include ulceration, dyspigmentation and scarring. The current consensus seems to be that laser therapy should be considered for patients in whom sclerotherapy is undesirable or contraindicated and who have small superficial single vessels. There are few data on the efficacy of the intense pulsed light source in this context but its emission spectrum and large applicator head would suggest a role in treating widespread fine telangiectasiae. Other cutaneous vascular lesions that have been reported to respond to laser treatment include venous lakes, angiofibromas, angiokeratomas and pyogenic granulomas [25,26].

Topical anaesthesia is usually satisfactory for treating facial lesions in adults but local or regional anaesthesia may be required. Treatment in other anatomical sites can usually be tolerated with topical or no anaesthesia. Depending on the size and site of the lesion, children under 12 years of age may need treatment under general anaesthetic. Emollients and analgesics relieve postoperative pain, swelling and erythema. Some patients develop crusting of the treated area. Complications resulting from PDL treatment include infection, dyspigmentation and both atrophic and hypertrophic scarring. Test treatments have been reported to be poor predictors of outcome.

Other applications

Viral warts

PDLs are used to treat viral warts [1]. The rationale for this seems to be that photocoagulation of the underlying dermal vessels may compromise the viability of the abnormal epidermis [2]. Treatment of resistant warts, particularly if on plantar surfaces, is often only partly successful [3], in which case CO_2 laser ablation may be more effective, despite the greater likelihood of pain, infection and scarring [4].

Hypertrophic scars

PDLs have been reported to improve the colour and contour of erythematous and hypertrophic scars in studies that have sometimes been supported with objective measurements such as reflectance spectrometry and silicone profilometry [5]. The mechanism of action is unknown, although it is also possible that destruction of small vessels plays a part [6].

Psoriasis

Localized and resistant plaque psoriasis has been reported to respond in 21 patients who were treated at 2-week intervals with both the short and long pulse 585 nm PDL. No significant difference was found between the two lasers and 40% of treated areas were reported to be clear of psoriasis at 6 months postoperatively [7]. Although non-toxic, treatment is often painful and can cause dyspigmentation and scarring.

Narrow-band UVB treatment can also be administered to psoriatic patients by means of a 308-nm excimer laser, the advantages of which are sparing of uninvolved skin and fewer treatments than with conventional phototherapy [8].

Tattoos and benign pigmented lesions

Laser–tissue interaction

Melanin absorbs light in the 500–1200 nm range (Fig. 77.4). At the shorter wavelengths absorption is higher and penetration less deep than the longer wavelengths. The Q-switch is an electro-optical device that is used to produce pulses of only a few nanoseconds. These are designed to be within the estimated TRT of melanosomes (0.5–1 μs) [1], although longer than that of tattoo particles, which is in the picosecond domain. Flashlamps can pulse within a millisecond range, which is relatively long in this context. Light may fragment and disperse melanin and tattoo ink, thereby altering its optical properties. It also seems likely that some is removed by transepidermal elimination and some by lymphatic drainage [2].

Devices in common use

Q-switched Nd:YAG laser (1064 nm) and frequency doubled Nd:YAG laser (532 nm)

The Q-switched Nd:YAG laser emits light that penetrates

2–3 mm into the dermis and is therefore suitable for the removal of deeper dermal pigmentation [3]. By passing the beam through a KTP crystal, the frequency is doubled and the wavelength halved (532 nm). The shorter wavelength penetrates less deeply and is therefore more useful for the removal of epidermal pigment.

Q-switched ruby laser (694 nm)

This laser emits red light (694 nm), which penetrates less than 1 mm into skin [4] but is better absorbed by melanin than longer wavelength light.

Q-switched alexandrite (755 nm) and diode lasers (810 nm)

These also emit red light at intermediate wavelengths, allowing somewhat deeper dermal penetration, although with some loss of absorption.

Intense pulsed light source (500–1200 nm)

These emit non-coherent light over a broad spectrum, with potential advantages in terms of penetration and absorption.

Tattoos

Q-switched treatment of tattoos is cosmetically superior to older destructive modalities [5]. Black or blue tattoo pigments absorb radiation across a broad range of wavelengths in the visible and near infrared spectrum. Green inks respond optimally to the Q-switched ruby (694 nm) [6] and Q-switched alexandrite (755 nm) lasers, but often persist [7]. Conversely, red pigments respond best to the green light emitted by the frequency doubled Nd:YAG laser (532 nm) [8]. The Nd:YAG laser is effective for blue or black tattoos but is relatively poorly absorbed by green pigments [9]. It has been successfully used to treat tattoos in pigmented skin [10]. Red, brown or flesh-toned inks may contain iron oxide or titanium oxide and can oxidize to a slate-grey or black colour during laser treatment. This may be exacerbated with subsequent treatments [11]. As these pigments may be used in cosmetic camouflage, tattoo test patches are important. Yellow and pastel colours are difficult to treat and complete resolution is unusual. Amateur tattoos usually require fewer treatments than professional tattoos [12].

Benign pigmented lesions

Epidermal pigmentation

Ephelides (freckles) and lentigines respond quickly and well to treatment with the Q-switched KTP (532 nm)

(a)

(b)

Fig. 77.8 Ephelides: (a) before, and (b) after treatment with a fd Q-switched Nd:YAG laser.

(Fig. 77.8) and Q-switched ruby laser (694 nm), although the former may bruise [13]. There are limited published data on the use of the intense pulsed light source in this context. Its emission spectrum and large beam diameter would suggest a useful role, even if the pulse width seems relatively long. Café-au-lait patches usually lighten in response to lasers, but pigmentation sometimes recurs.

Dermal pigmentation

In a study in which six patients with speckled and lentiginous naevi (naevus spilus) were treated with both a Q-switched ruby and Q-switched Nd:YAG laser, all showed 90% or greater clearance of the lesion after 1–5 treatments, the Q-switched ruby laser being the more effective. One patient is reported as showing transient hypopigmentation and another as developing hyperpigmentation peripheral to the treated lesion [14].

Naevus of Ota has been treated with the Q-switched ruby [15], alexandrite [16] and Nd:YAG lasers [17]. As might be expected, the relatively deep dermal pigmentation responds optimally and with fewer complications to treatment with the Q-switched Nd:YAG laser [18,19]. In some patients, pigmentation may re-emerge after treatment [20].

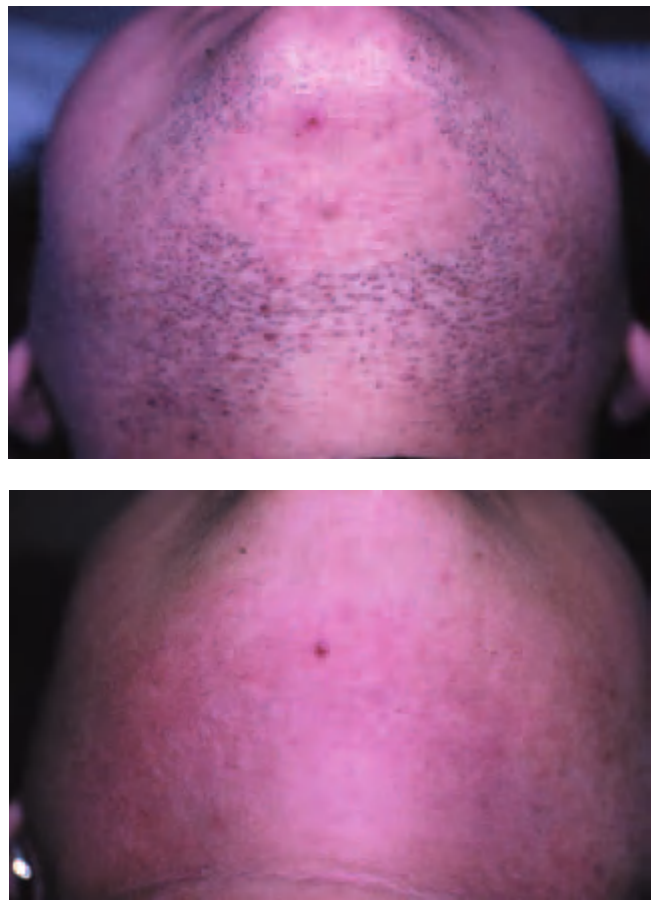
Both congenital and acquired melanocytic naevi have been treated with argon, ruby [21,22], alexandrite and

Nd:YAG lasers, although this remains controversial. The long-term effects of non-lethal laser irradiation on melanocytes are unknown, as is laser 'debulking' of congenital melanocytic naevi (CMN). Even after multiple treatments of CMN, many lesions repigment. In a study in which 31 CMN and clinically benign or atypical moles were treated with the Q-switched ruby laser, normal mode ruby laser or both, only 16 were visibly lighter 4 weeks after treatment. Subsequent excision for histological examination showed fibrosis and a decrease in melanocytes [23].

The Q-switched ruby laser appears to be ineffective in treating lentigo maligna and at least one such lesion has subsequently developed lentigo maligna melanoma [24]. It may also be relevant that *in vitro* studies of melanoma cells treated with Q-switched lasers have demonstrated an altered expression of cell surface receptors as well as altered cell migration [25]. Melasma does not in general respond to laser therapy and, as with post-inflammatory hyperpigmentation, laser therapy may darken lesions [26]. Haemosiderin seen in association with venous stasis will only occasionally respond to laser treatment [27]. Hyperpigmentation secondary to administration of minocycline [28,29] and amiodarone [30] responds readily to treatment with the Q-switched ruby, alexandrite and Nd:YAG lasers.

Light-assisted hair removal

The mechanism for light-assisted hair reduction remains incompletely understood. It is likely that the theory of selective thermolysis applies in this context. However, the targets are likely to be stem cells (mainly in the lower isthmus) and blood vessels in the papilla, whereas the absorbing chromophore is melanin in the hair shaft and matrix cells. For this reason, fair or white hair is largely resistant to treatment. Radiation in the 600–1200 nm spectrum is absorbed by melanin and penetrates the dermis further at longer wavelengths. The normal mode ruby (694 nm), alexandrite (755 nm) (Fig. 77.9) [31], diode (800 nm) [32] and Nd:YAG (1064 nm) [33] lasers have all been used with fluences of 20–60 J/cm^2, depending on spot size. The TRT of a 200–300 μm follicle is approximately 25–50 ms, but much shorter pulse durations seem to be effective. In an early study, follicular damage was demonstrated using a ruby laser (6 mm spot, 30–60 J/cm^2) with a pulse duration of only 270 μs. Six months later only four had less than 50% regrowth and five showed complete regrowth of hair [34]. These results were maintained at 2-year follow-up, suggesting that permanent loss of terminal hair is possible after one treatment with the normal mode ruby laser, albeit in a minority of patients [35]. Immediate follicular disruption has been shown to be followed by conversion of the anagen to the telogen phase with a subsequent increase in the number of miniaturized hair follicles.



(a)

(b)

Fig. 77.9 Hirsutism on the neck of a female patient: (a) after a test treatment, and (b) after four treatments with a normal mode alexandrite laser, showing sparser and finer hairs.

It has recently been demonstrated that considerably longer pulses (30–400 ms) may be more effective in damaging the stem cells and papillary vessels, neither of which contains melanin nor is in direct contact with the melanin-rich components of the follicle. This observation has been explained in terms of an 'extended theory of selective photothermolysis' [36]. By using long pulses and by limiting the power of the light source, the heat generated by the 'absorber' (melanin in the hair shaft) can be kept below levels that would alter its structural and optical properties and thus interfere with further absorption of light. On the other hand, the heat generated may be high enough to diffuse into and denature the distant 'target' (the stem cells and papillary vessels). The delay between heating of the absorber chromophore and the distant target is referred to as the thermal damage time (TDT) and is significantly longer than the TRT.

In patients with pigmented skin, long wavelengths (1064 nm) and cooling devices are particularly important in reducing the risk of epidermal damage, with subsequent dyspigmentation or scarring. A small proportion of patients seem to experience a paradoxical increase in hair growth.

Flashlamps have been used to treat hypertrichosis [37] but it seems likely that subsequent blistering and dyspigmentation is more common than after laser treatment.

Laser resurfacing and non-ablative resurfacing

Cutaneous ablation [1,2]

Light in the mid and far infrared region of the spectrum is rapidly absorbed by water and therefore by body tissue. There is no selectivity of effect. When the light strikes the body tissue, the cells are vaporized almost instantaneously. Although vaporization is limited to those cells immediately in the path of the beam, there is a narrow band of thermal damage around the treatment site whose width depends on the laser type, the power density and the exposure times. The CO_2 laser was the first laser to be used extensively in this way. Although initially the outcome could be compromised by unwanted thermal damage and scarring, this risk has been markedly reduced by the development of a variety of scanning devices. The CO_2 laser is the archetypal surgical laser. Using a high-power density, via a focusing handpiece, the depth of an incision is controlled by the speed with which the beam is moved over the surface, enabling excisions to be performed as easily as with a scalpel. Lower densities are now achieved by using a scanner, and this allows a variety of skin lesions to be treated (Table 77.6).

Resurfacing

The development of scanning systems has allowed the

Table 77.6 Some therapeutic applications of carbon dioxide laser radiation.

Warts, condylomas
Cheilitis
Tattoos

CO_2 laser to be used to treat extensive areas of skin damaged by photoageing or scarring, with good results [3,4]. This procedure is associated with prolonged morbidity, and lasers with even higher tissue absorption (erbium:YAG, 2940 nm), and therefore even less dermal damage, may offer advantages. Initial results were often disappointing when compared with the results following CO_2 laser treatment, but the introduction of newer modulated erbium:YAG lasers has led to an improvement in clinical results [5]. Furthermore, using the erbium:YAG laser to remove the thermally damaged layer following CO_2 laser treatment speeds healing and may improve the outcome [6].

Non-ablative skin remodelling [1,2]

Although cutaneous 'resurfacing' can produce significant improvement in sun-damaged skin and scarring, this is not without a cost in terms of discomfort, a long period of recovery and significant risks. A number of lasers, intense pulsed light sources and radiofrequency devices are being investigated for their potential to improve sun-damaged, aged and scarred skin [3]. Studies using serial treatments at intensities that induce no more than a mild erythema lasting a few hours, have shown measurable improvement in vascular and pigmentary irregularities. There are some reports of improvements in fine wrinkles, although objectively the improvement is mild. There is a vast literature on the use of lasers for biomodulation and it is interesting that some of the studies of non-ablative skin remodelling show improvement at low intensities which is absent at higher ones [4]. As these technologies develop, they may find a place in the routine management of ageing skin in communities where this is considered a worthwhile use of resources.

Photodynamic therapy

Photodynamic therapy (PDT) is based on a mechanism whereby topical porphyrin precursors are converted by skin cells into porphyrin, and light exposure activates the porphyrin, producing oxygen radicals which cause cell death. It has been used in the treatment of non-melanoma skin cancer.

5-Aminolevulinic acid (ALA) is a porphyrin precursor. When applied to the skin, ALA is absorbed and converted by intracellular enzymes, maximally 3–5 h later, to photoactive protoporphyrin IX. Protoporphyrin generates cytotoxic singlet oxygen when irradiated with non-coherent and coherent (i.e. laser) light sources in the 400–640 nm range. Some reports suggest that protoporphyrins are concentrated in tumour cells [1], others show no difference between tumour and normal perilesional skin porphyrin fluorescence [2]. Overall it seems likely that at most the porphyrin concentration in BCC is approximately twice as great as that found in adjacent uninvolved skin. These differences could be due to enhanced absorption through a defective overlying stratum corneum, hence the use of surface débridement before porphyrin precursor application.

Currently, although ALA, a naturally occurring haem precursor, is the most promising topical sensitizer [3], it is hydrophilic and this property may limit its penetration into thick BCCs. Lipophilic esters of ALA, e.g. methyl 5-aminolaevulinate, may be better [4]. Photosensitizers can be injected, e.g. meta-tetrahydroxyphenylchlorin [5], but this renders the patient temporarily photosensitive.

The tumour surface is scraped to remove crust or scale. A thick layer of porphyrin precursor cream is applied to the affected area plus a 5-mm margin of perilesional skin and covered with an adhesive occlusive dressing for 3–6 h. The area is then irradiated using a light source that contains 630-nm red light to coincide with the maximal absorption peak of protoporphyrin IX. Red light also has the advantage of penetrating more deeply into the skin than lower wavelengths. Treatment time is around 15 min for a non-laser source. The process is painful but most

patients do not require injected local anaesthetic. The inflammatory reaction begins to appear almost immediately and discomfort may persist for 1–2 weeks. Complete healing takes 2–6 weeks. A second treatment is commonly given 2–3 months later if the first appears to have failed.

Bowen's disease and actinic keratoses

Thin *in situ* epidermal malignancies respond well with fewer side effects than are experienced after cryotherapy [6] or 5-fluorouracil (5-FU) therapy [7]. In comparison with these techniques, however, PDT is less easy to use over large areas.

BCC

In general, PDT is an unproven treatment for BCC. Most studies are small, give only 1–2-year follow-up and prefer to report cure rather than recurrence rates. PDT, using ALA, appears to work best on thin superficial BCCs, producing recurrence rates of around 10% [8–11]. Longer follow-up reveals a higher recurrence rate [12]. ALA penetrates BCCs > 2 mm thick poorly [13], resulting in high recurrence rates [14]. A recent randomized small study treating nodular BCCs showed a 10% 2-year recurrence rate after PDT compared with 2% for surgery. The poor results have led others to try two treatments 7 days apart [15], or use the lipophilic methyl 5-aminolaevulinate for PDT after first debulking the tumour by curettage [16]. These manoeuvres have not significantly improved the recurrence rates.

PDT is potentially a treatment option for large superficial BCCs or patches of Bowen's disease. However, as yet there is no convincing evidence that PDT is more cost effective than simple surgery, topical 5-FU, cryotherapy or superficial X-ray therapy for these lesions. PDT has the potential for fewer long-term side effects and better cosmesis. There is insufficient long-term cure rate evidence to justify its routine use in thick or nodular BCC.

Chapter 78

Dermatological Surgery

C.M. Lawrence, N.P.J. Walker & N.R. Telfer

Introduction

The acquisition of basic dermatological surgery skills is an important component of dermatological training. This chapter covers simple excisional surgery and provides an introduction to more advanced techniques that dermatologists should be aware of and may practice. The reader is also referred to the specialist journal *Dermatologic Surgery*, and introductory [1–3] and intermediate textbooks [4–6]. Other books deal more specifically with cosmetic dermatological surgery [7,8] or general aspects of plastic surgery [9–11].

Critical anatomical areas

It is essential to have a working knowledge of the important clinical anatomy of each operation site. The following is only a brief introduction to some of the critical anatomical details with which the operator must be familiar. Excisions down to superficial fat will rarely result in exposure of or potential damage to functionally important structures, except in a very thin subject. Incisions to deep fat or fascia and the removal of large cysts or lipomas may result in exposure of important structures. On the head and neck, division of larger arteries and veins will not cause vascular complications because of the extensive collateral circulation. However, it is important to be aware of the position of large arteries and veins in order to be prepared to deal with bleeding from these vessels. Division of sensory nerves may produce annoying sensory loss, but this will have little functional impact on the head and neck. Knowledge of the anatomy of the supraorbital, infraorbital and mental sensory nerves is important, as these are commonly used in peripheral nerve blocks.

Division of motor nerves is potentially disabling and thus it is essential to know the anatomy of the vulnerable superficial cranial and peripheral motor nerves.

Skin tension lines and the orientation of scars

Incisions should be designed to follow the wrinkles or relaxed skin tension lines (syn. stress lines; favourable skin tension lines; maximal skin tension lines) as the resulting scars will be stronger and less likely to stretch [1]. Relaxed skin tension lines run perpendicular to the direction of contraction of the underlying muscles and parallel to the dermal collagen bundles [2]; cutting transversely across these weakens the skin much more than a cut running parallel to the collagen bundles [3]. In the absence of wrinkles, relaxed skin tension lines can be identified by asking the patient to grimace or by skin manipulation. Langer's lines [4] (syn. resting stress lines) were mapped on cadaver skin, and differ from relaxed skin tension lines on the limbs and trunk [3]; they should not be used for identifying the elective direction of excision.

Head and neck

Cosmetic units

Cosmetic results of surgery are better if all the incisions remain within a cosmetic unit [5]. These are areas of skin that share similar characteristics (e.g. the nose, cheek and periorbital skin). The junction lines separating these areas are also important because scars placed in junction lines are usually unobtrusive whereas scars that cross a junction line (bridge two cosmetic units) are very obvious. It is thus important to try to design a repair so that the scars follow relaxed skin tension lines and remain within the same cosmetic unit, or run in the junction lines between two adjacent cosmetic units.

Blood vessels and lymphatic supply of face

Larger vessels, particularly the temporal artery, can be avoided by hydrodissection (see p. 78.32). The facial artery (Fig. 78.1) at the nasolabial fold, and its continuation into the angular artery at the medial canthus, are frequently divided when excising tumours at these sites. The external jugular vein runs under the platysma muscle but on top of the sternocleidomastoid muscle, and may be easily damaged during superficial incisions on the neck at this site (Fig. 78.2a). Emissary veins, connecting the intracranial and extracranial venous circulation, run across the subgaleal space towards the back of the scalp (parietal emissary vein) and just above the forehead (frontal emissary vein) [6]. These veins may be damaged when undermining the subgaleal space at these sites. Lymphatic drainage sites should be examined for metastases during follow-up of patients treated for squamous cell carcinoma or melanoma [7]. Division of skin lymphatics during incisions under the eye may result in temporary but unavoidable lower eyelid lymphoedema. Postoperative lymphatic leakage sometimes occurs after lower limb or axillary excision. This resolves spontaneously with conservative management.

Sensory nerves of face

Nerve blocks. Sensation to the face is supplied by the trigeminal (Vth) cranial nerve. The three branches readily blocked in skin surgical procedures on the head and neck

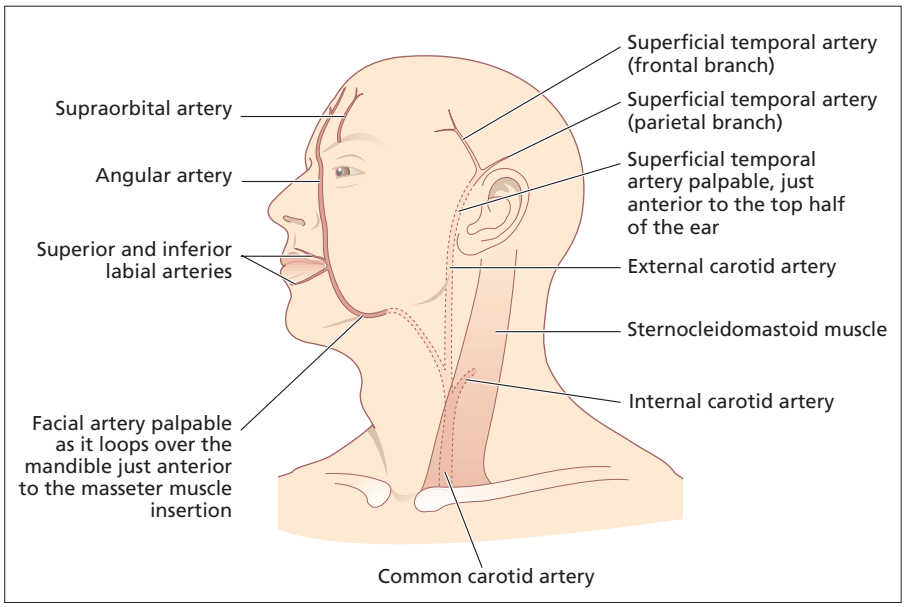

Fig. 78.1 Arteries of the head and neck encountered in skin surgery. The labial artery lies on the inside (mucosal) surface of the lip approximately 5 mm from the visible vermilion border. (---) Arteries rarely encountered; (—) arteries frequently identified during superficial skin surgery on the face.

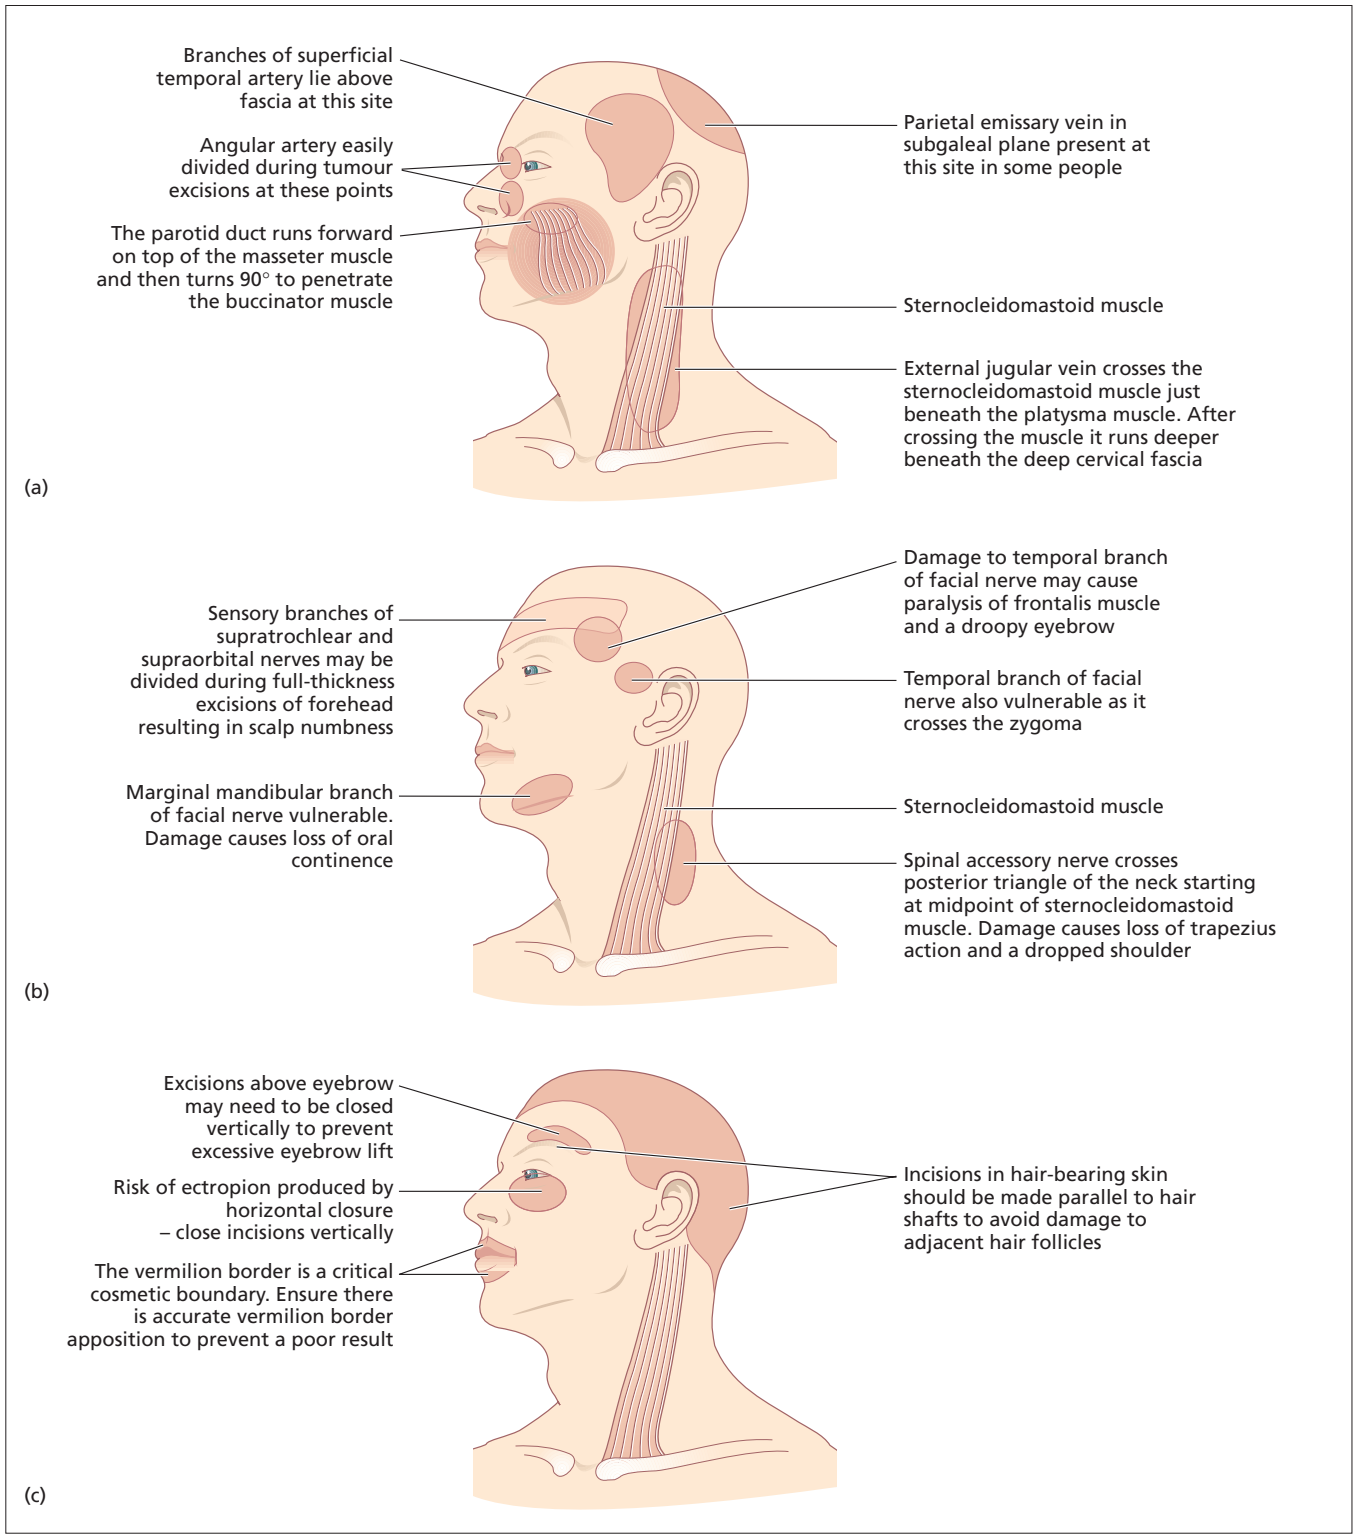

Fig. 78.2 Potential surgical hazard sites during skin surgery on the head. (a) Potential blood vessel and duct, (b) nerve and (c) cosmetic hazards on the head and neck. (From Lawrence [9].)

include the supraorbital, infraorbital and mental nerves (Fig. 78.3). These emerge from the skull via palpable foramina, which all lie in the same plane, just medial to a vertical line running through the pupil [8]. Blocking the great auricular, transverse cervical and lesser occipital

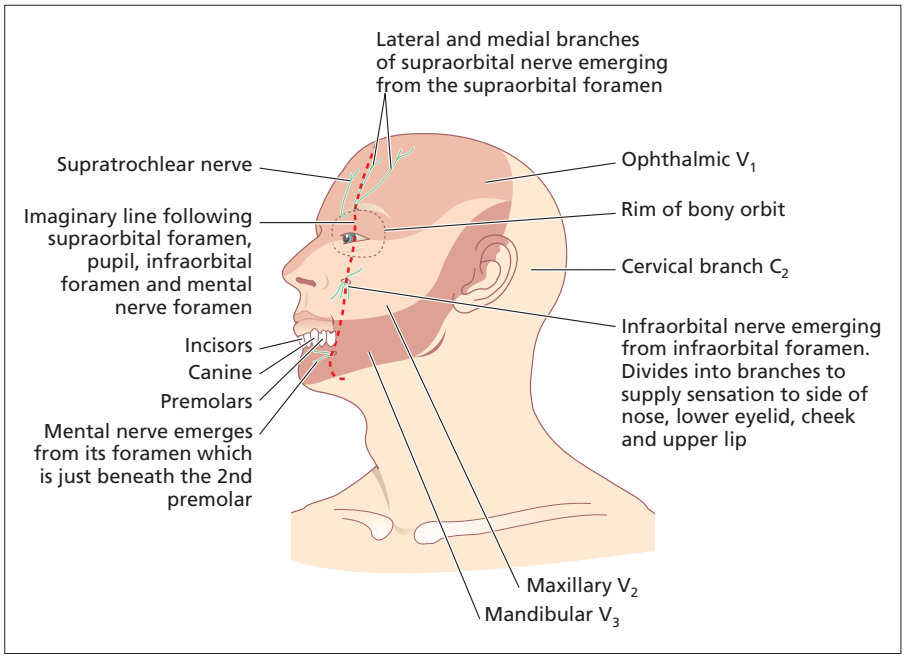

Fig. 78.3 Sensory nerves on the face used in nerve-block anaesthesia. Sensation on the face is served by the three main divisions of the trigeminal nerve: the ophthalmic, maxillary and mandibular divisions. Three important branches of these nerves—the supraorbital, infraorbital and mental nerves—emerge in the same plane along a vertical line running through the pupil.

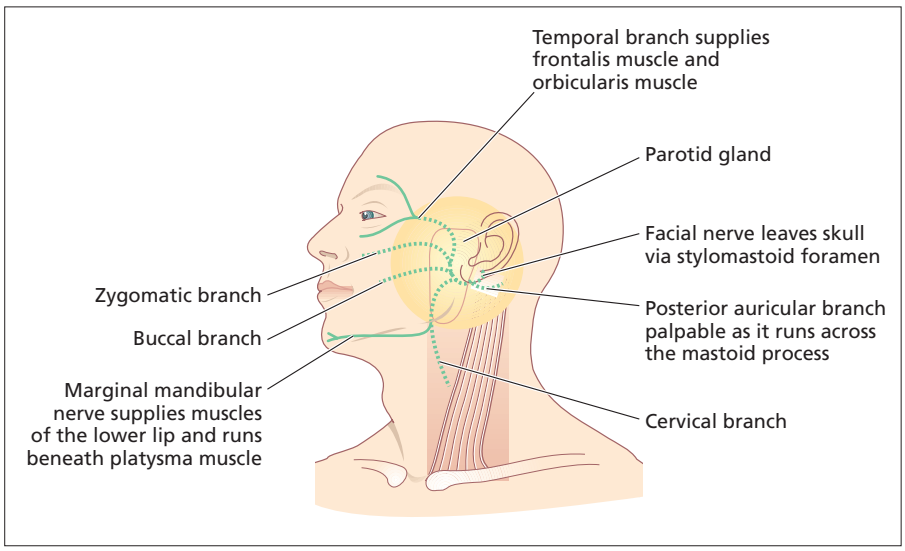

Fig. 78.4 Motor branches of the facial nerve vulnerable in skin surgery. (---) Nerves rarely encountered; (—) nerves at risk during superficial skin surgery on the face.

nerves as they emerge, approximately 10–20 mm above and below Erb's point, from the posterior border of the middle third of the sternocleidomastoid muscle [10] produces anaesthesia of a large portion of the scalp, neck and ear. Erb's point is identified by dropping a plumb line from the mid point of a line drawn between the mastoid process and the angle of the jaw. Where this line meets the posterior border of the sternocleidomastoid muscle is Erb's point. At this site, the spinal accessory (XIth) cranial nerve also emerges from behind the sternocleidomastoid muscle. This motor nerve is rarely affected by the local anaesthesia, as it lies deeper, on the floor of the posterior triangle, whereas the three named sensory branches of the cervical plexus curl round to lie on top of the sternocleidomastoid muscle [11].

Division of small sensory nerves. This is of little consequence, with the possible exception of scalp numbness following incisions on the forehead. Improvement in sensory loss can be expected for up to 1 year.

Motor nerves

Two branches of the facial (VIIth) cranial nerve, the marginal mandibular branch and the temporal branch, are vulnerable during skin surgery (Fig. 78.4). The temporal branch of the facial nerve supplies the frontalis and orbicularis muscles. Damage to the nerve supplying frontalis muscle results in difficulty raising the eyebrow, and the forehead furrows disappear. This can easily occur during excision of large tumours on the temple, lateral to the

Table 78.1 Undermining levels.

Site	Undermining level
Face	Mid-fat
Nose	Just above the periosteum and perichondrium
Forehead	Beneath the deep frontalis fascia (equivalent to the subgaleal plane)
Scalp	Subgaleal plane
Trunk and limb	
Small excisions	Deep fat
Large excisions	Just above the deep fascia

frontalis muscle, and as the nerve crosses the zygomatic arch. At both sites there is little tissue between the skin and periosteum (Fig. 78.2b). The marginal mandibular branch innervates muscles that move the lower lip. Damage can be devastating because it results in weakness of the lips, with dribbling when eating and drinking. The nerve is superficial and vulnerable as it emerges from under the parotid gland at the angle of the jaw, behind the point where the facial artery can be palpated as it crosses the mandible. More anteriorly, the nerve runs beneath the platysma muscle [12]. Variations in nerve position with age and neck position must also be considered. The remaining branches of the facial nerve are less vulnerable because they share several cross-connections and lie deeper. The other important motor cranial nerve is the accessory (XIth) nerve, which supplies the trapezius and sternocleidomastoid muscles. This may be damaged during dissection in the posterior triangle of the neck, causing weakness of the trapezius muscle and producing a dropped shoulder.

Undermining levels

When undermining to increase skin mobility, different levels are appropriate at different sites (Table 78.1).

Specific facial sites

If an incision runs across the vermilion of the *lip*, the vermilion border must be carefully marked before anaesthetic injection to avoid a poor cosmetic result (Fig. 78.2c). In older patients with poor lid elasticity, operations around the *lower eyelid* may result in ectropion if any downwards tension is applied to the lower eyelid. In a patient with poor lid elasticity, the procedure should be designed to increase rather than reduce eyelid tension; this usually means closing the wound vertically rather than horizontally. If an incision goes across the *hair line*, ensure that the scalp margin is reconstructed so that a smooth contour remains. Because hairs grow obliquely through the skin, any incision through *hair-bearing skin* should be made parallel to the hair shafts rather than vertically through the scalp so that fewer follicles are damaged.

Limbs

The only superficial motor nerve on the limbs is on the lateral aspect of the knee, where the common peroneal nerve (lateral popliteal) can be palpated against the bone as it winds round the neck of the fibula. Injury to the nerve at this site will produce a foot drop resulting from paralysis of foot dorsiflexors and elevators.

Equipment and sterilization [1–5]

Most dermatological surgical procedures can be safely performed in well-lit dedicated outpatient units using relatively simple equipment and surgical instruments [1–3]. However, the absence of a need for either expensive equipment or a completely sterile environment does not justify cutaneous surgery being performed in inadequate facilities or using inappropriate surgical equipment.

Dermatological surgery procedures range from superficial tissue destruction and removal through to surgical excision and complex wound repair. Consequently, a range of basic surgical instruments should be available to the skin surgeon, with selection depending upon the particular procedure being performed. The basic equipment, with optional items that should be available for more specialized procedures, is shown in Table 78.2. Advanced skin surgery (e.g. the removal and complex repair of difficult tumours and Mohs' micrographic surgery) requires both dedicated facilities and specialized surgical instruments to achieve the best results.

Most wound complications are associated with closure under excessive tension, haematoma formation and the presence of either necrotic tissue or foreign material. Wound infection, an uncommon complication of dermatological

Table 78.2 Essential and optional equipment. (From Burge *et al*. [1].)

Essential	Optional
The room	
An examination couch with adjustable backrest	Theatre table
A stool for the surgeon	
Good lighting: anglepoise lights	Overhead theatre lights
Equipment—preoperative preparation	
Autoclave for steam sterilization or electric oven for dry heat sterilization	
Skin preparation	
Chlorhexidine solution	
Chlorhexidine detergent (Hibiscrub®)	
Surgical gloves	
Sterile paper towels	Re-usable drapes
A window can be cut in the centre and the towel placed over the lesion	
Skin markers	Sterile pen and Indian ink
Gentian violet and pointed orange stick	
Skin marker pen	
Indelible felt-tip pen	
Anaesthetic	
Disposable syringes 2 mL, 5 mL fine needles	Dental syringe and fine needles
	Dental syringe vials
Lidocaine (lignocaine)	
1% and 2% plain and with epinephrine (adrenaline) 1 : 100 000 or 1 : 200 000	
Instruments	
Scalpel blades	
No. 15 for excision	
No. 22 for shave biopsy	
Scalpel handle	
Forceps	
Fine-toothed (e.g. Adson–Brown)	
Non-toothed	
Skin hook	
Can easily be constructed by pushing a sterile needle onto a sterile moistened cotton wool bud on an orange stick. Bend the needle into a curve	
Scissors	
Curved pointed iris scissors	
Blunt straight scissors	
Needle holders	
Small artery clamps	
Various sizes of absorbable and non-absorbable sutures attached to needles	Skin punch for biopsies, 3 mm and 4 mm
	Sharp ring curettes in various sizes
Haemostasis	
Gauze swabs	Hyfrecator
30–50% aluminium chloride in alcohol or Monsel's solution (67.5% basic ferric sulphate)	Electrocautery
	Diathermy
	Bipolar electrocoagulation
	Cryosurgery gun
	Supply of liquid nitrogen
	Silver nitrate sticks
Dressings	
Steri-strips	Opsite
Compound Benzoin tincture BP (Friar's balsam) for sticking plaster to skin	
Elastoplast	
Micropore	
Gauze	
Jelonet®	
Histopathology	
Specimen pots	EM fixative 4% glutaraldehyde
Fixative	
10% buffered formalin	Fixative or liquid nitrogen to store specimens for immunohistology

surgery, is more commonly related to surgical technique than poor operator cleanliness or instrument sterilization. However, correct hand washing techniques are vital to the prevention of cross-infection [4]. The tradition of protracted 'scrubbing up' is not essential prior to most dermatological surgical procedures—two washes in running water using 4% chlorhexidine or 10% povidine–iodine solution are sufficient. Between cases, alcohol-based [5] skin cleaning solutions are an alternative on clinically clean hands. The use of surgical gloves is mandatory for all procedures, and wearing eye protection is strongly recommended.

Dried tissue, pus or blood on instruments may harbour potentially dangerous organisms, and all instruments should be manually or ultrasonically cleaned and placed into sealed packs prior to autoclave sterilization [6,7]. Older methods of sterilization, for example boiling in water at atmospheric pressure and the use of various chemical agents (e.g. glutaraldehyde, phenolic agents) are no longer recommended [3]. The new variant Creutzfeldt–Jakob disease (vCJD) prion cannot be destroyed by sterilization, and equipment suspected of being contaminated must be quarantined. If contact is confirmed the equipment must be destroyed.

Safety aspects

Certain basic safety measures and protocols are essential within a dermatological surgery unit in order to minimize the risks of infection and accidental injury to both patients and staff [1].

The routine use of aseptic technique minimizes the risk of bacterial colonization at the operation site, and prevents contamination from adjacent sites. Antisepsis and sterilization are discussed elsewhere (see p. 78.5). Control of blood-borne infections, especially human immunodeficiency virus (HIV) and hepatitis, has two main components: prevention of transmission from patient to patient, and protection of the surgical team [2]. It is now mandatory for all British medical and nursing staff to be adequately vaccinated against hepatitis B, and for hospitals to have both dedicated infection control staff and protocols to ensure instrument sterility. One approach suggested by the US Centers for Disease Control and Prevention (CDC) is to treat *all* patients as if they were infected with HIV, hepatitis B or other blood-borne pathogens and to adopt 'universal precautions' [3].

Needle-stick injuries and other sharp instrument cuts are particularly important, and all members of the surgical team should take extreme care with the use and disposal of 'sharps'. It is extremely dangerous to either leave uncapped needles on the instrument tray or to attempt needle recapping by the two-handed method. Ideally, the surgeon should make a habit of both disposing of used needles and syringes *immediately* after use and removing all sharp disposable instruments (e.g. needles, scalpel blades) from the tray after the operation, placing these directly into 'sharps disposal' boxes. All relatives and those theatre personnel not directly concerned with the procedure should be excluded from the operating room. Clothing should be specific for surgery—apart from potentially introducing a variety of organisms to the procedure room, clothes may become contaminated.

At the preoperative consultation, a careful history may identify certain potential problems (e.g. diabetes, epilepsy) and the presence of cardiac pacemakers [4]. A full drug history is important—aspirin and anticoagulants promote bleeding and non-selective β-blockers (e.g. propranolol) may rarely interact with epinephrine (adrenaline) in local anaesthetics, resulting in malignant hypertension. On direct questioning, some people may admit to a tendency to faint very easily, and some patients with epilepsy may have a history of fits triggered by surgery or dental procedures. As there is always a risk of patient collapse in operating rooms, there must be adequate space available for an emergency resuscitation to be performed. Resuscitation drugs and equipment, together with both suction and an oxygen supply should be readily available [5]. All theatre personnel should be trained in advanced resuscitation techniques, including emergency electrocardiography and cardiac defibrillation [6].

Complications [1]

All dermatological surgical procedures may result in complications [1,2], most commonly bleeding, infection and poor wound healing (Table 78.3). Although complications will always occur, most can be prevented by a combination of thorough preoperative preparation and good surgical technique.

Patients on long-term anticoagulant therapy require careful assessment regarding the potential medical risks if therapy is temporarily discontinued to facilitate surgery and the risk of significant bleeding complications if therapy is unchanged [3]. In difficult cases, discussion with other specialists involved in the patient's care will often help resolve this issue. Drugs that block platelet function (e.g. aspirin, clopidogrel, ticlopidine) potentially

Table 78.3 Complications in wound healing.

Complications	Predisposing factors	Prevention
Infection	Infected lesions Poor sterility Steroids Adjacent infectious source Occlusive dressings Poor blood supply Fat, haematoma and foreign material Sutures Poor technique Excessive devitalized tissue from careless handling or electrocoagulation	Careful preoperative and operative techniques Sutureless closure Antibiotic sprays Prophylactic antibiotics for infected or potentially infected wounds
Delay in closure	Poor blood supply Excess movement Infection Tension Steroids Debilitated patient Poor nutritional status	Layered closure Gentle tissue handling Minimize devitalization of tissues Care in decision to operate Warmth Careful postoperative dressings
'Gaping scar'	Inadequate apposition Dermal instability Excess movement Infection Tension	Careful apposition Subcutaneous or subcuticular sutures Adequate postoperative support (e.g. antitension dressings)
Painful scars	Feet and fingers especially	Avoid pressure sites if possible Dressings to reduce subsequent pressure and/or movement Careful apposition
Hypertrophic scars	Site Tension Reaction to embedded material Trauma Individual susceptibility	Avoid 'cape' area if possible Good surgical technique including undermining of edges where necessary
Keloids	Previous history Black skin Upper half of body Tension	Avoid surgery where possible Antitension measures for 3 weeks Watch and prepare to treat
'Railroad tracks'	Skin sutures under too much tension	Good suture technique Use of 'non-reactive' suture material
Stitch marks 'abscess'	Sutures left in too long	Early suture removal
Wound edge inversion	Poor technique	Good surgical technique Occlusive or semi-occlusive dressings
Bleeding and/or haematoma formation	Bleeding tendency Aspirin Clopidogrel Ticlopidine Eptifibatid Tirofiban	Preoperative screening Good haemostasis Use of epinephrine (adrenaline) in local anaesthetic

increase the risks of bleeding complications. In most instances, aspirin can be continued without resulting in a worse surgical outcome, although intraoperative bleeding may take longer to control. However, at some sites (e.g. around the eye) or in procedures involving extensive undermining or complex wound reconstruction, it may be appropriate to withhold these drugs prior to procedures. If aspirin is stopped this must be done at least 10 days before surgery to allow a sufficient number of new platelets with normal clotting responses to be produced. Non-steroidal anti-inflammatory drugs (NSAIDs) present no significant problem and can be continued in all circumstances [4].

The use of epinephrine-containing local anaesthetics results in vasoconstriction and prolongs the duration of anaesthesia. Intra-operatively, bleeding can be controlled by a combination of electrosurgery, pressure and ligation. Postoperatively, the use of appropriate wound dressings is important—ranging from simple Band Aid dressings for superficial wounds to layered dressings with pressure pads for larger wounds where there is a significant risk of haematoma formation (e.g. following cyst or lipoma excision, widely undermined wounds). All patients should be given verbal and written information regarding wound care and how to contact the dermatology unit if problems arise. Haematoma formation may occur at various times after surgery and usually results in acute pain and swelling. The clinical appearances, together with the age and size of the haematoma, will dictate whether to open the wound, evacuate the haematoma and obtain haemostasis, or to manage the complication conservatively [5].

Wound infection is a major concern, but is fortunately relatively uncommon following skin surgery. If the risk of infection is higher than normal (e.g. following excision of an ulcerated tumour from a flexural site), prophylactic antibiotic therapy may be appropriate. Postoperative infection usually presents as erythema, pain and swelling in and around the wound, 4–8 days after the procedure. Depending upon the clinical appearances, management will range from wound care, topical and systemic antibiotics, through to incision and drainage of a frank wound abscess.

Other significant problems relate to both the cosmetic and functional results of surgery. The risks of scarring must be carefully explained prior to surgery, with special attention to the possibility of distortion of facial 'free margins' (e.g. vermilion, lower eyelid) and unsightly hypertrophic scars in high-risk body sites (e.g. upper arm, shoulders, chest). Altered pigmentation in and around the wound is an additional cosmetic risk in Asian and black patients. Nerve damage is a significant concern, as both sensory and motor nerves may be damaged during cutaneous surgery, particularly at certain 'high-risk' anatomical sites (see pp. 78.2–78.5).

Local anaesthetics [1]

Principles and types

An ideal local anaesthetic agent would be non-toxic, painless on injection, rapid in onset, highly effective and carry a low risk of sensitization. The best compromise is found in 0.5–2% lignocaine hydrochloride (lidocaine), an amide-type local anaesthetic, which is the agent of choice for most dermatological surgery. Other amide-type local anaesthetic agents include mepivacaine, bupivacaine and ropivacaine, which have a slower onset but more sustained duration than lidocaine (lignocaine) [1]. Local anaesthetics in 'multiuse' bottles generally contain parabens preservative, but those supplied in glass ampoules are often preservative-free.

Ester-type local anaesthetics, for example procaine (ester of *p*-aminobenzoic acid) are seldom used by dermatologists.

Epinephrine 1 : 80 000–1 : 200 000, when added to local anaesthetic solutions, prolongs the duration of anaesthesia and produces local vasoconstriction. By reducing absorption, it may reduce the risk of systemic lidocaine toxicity.

Toxic reactions [1,2]

Toxic reactions to lidocaine are rare, and more likely to occur with the use of high volumes of high-concentration solutions or if accidental intravascular injection occurs. Lidocaine toxicity usually presents as a sensation of numbness or tingling. Systemic reactions include vasodilatation, cardiac or respiratory depression, or central nervous system manifestations such as dizziness, drowsiness, tinnitus, slurring of speech, muscle twitching and seizures. These side effects are, to some extent, reversible with diazepam (Valium) but full resuscitation measures may be required.

Ester-type local anaesthetics should be used with caution in patients with renal impairment. They also cross-react with a number of drugs of the *p*-aminobenzoic acid ester type (e.g. sulphonamides, paraphenylenediamine)

[3,4]. Amide-type anaesthetics should be used with care in patients with hepatic impairment.

The maximum recommended dosage for lidocaine with epinephrine is 7 mg/kg or approximately 50 mL of a 1% lidocaine solution for an average adult. In practice, most dermatological procedures require substantially lower anaesthetic doses. In order to minimize the risk of accidental intravascular injection, it is a wise precaution to either aspirate prior to infiltration or, if using very fine (e.g. 30 gauge) needles, which will not aspirate blood, to keep moving the needle about in the skin while slowly infiltrating small volumes.

Systemic absorption of epinephrine may be associated with mild tachycardia and an excited state. More serious reactions are rare but, as with lidocaine toxicity, are more likely to occur with the use of high volume, high-concentration solutions or following accidental intravascular injection. The use of epinephrine in local anaesthetics should be avoided or used with caution during pregnancy, in combination with inhalation anaesthesia, or in patients suffering from severe glaucoma [5]. Interaction with non-selective β-blockers (e.g. propranolol) may rarely cause malignant hypertension [2], but this is not a risk with 'cardioselective' β-blockers (e.g. atenolol).

Patients should always be asked if they have had any untoward reactions to local anaesthetics (e.g. in dental procedures). These may have been nothing more than fainting, as vasovagal attacks are commonly associated with local anaesthesia, and should not be confused with serious toxic reactions. In cases of serious doubt, alternative methods of anaesthesia are necessary.

Methods

Local anaesthesia may be achieved *topically* using either tetracaine (amethocaine) cream (Ametop®) or a eutectic lidocaine–prilocaine cream (EMLA®) [4], or by *local infiltration*. Both EMLA® and Ametop® are applied under occlusion, 1–2 h before the procedure. Conjunctival anaesthesia is best achieved using proxymetacaine eye drops, which sting much less than tetracaine.

Other methods of anaesthesia include *field block* and *nerve block anaesthesia* [3,5], which produce temporary blockade of sensory nerve function in a given area. Field block involves infiltration of local anaesthetic at several points around surgical sites such as the nose and ear [2], and nerve block anaesthesia involves blockade of one or more major sensory nerves. The most useful facial nerve blocks in dermatological surgery involve branches of the trigeminal (Vth) cranial nerve (Fig. 78.3)—the supraorbital (forehead), supratrochlear (glabella), infraorbital (lower eyelid, nasal sidewall, upper lip) and mental (lower lip) nerves [4,5]. The choice of local anaesthetic method depends upon a number of factors, including the procedure itself, anatomical site and expected duration of the operation.

Controversy surrounds the use of epinephrine in digital nerve block ('ring block') anaesthesia because of a real or theoretical risk of digital ischaemia. Some believe it is absolutely contraindicated [6], whereas others describe routine use without incident [7,8].

In order to minimize discomfort when administering a local anaesthetic injection, consideration should be given to using a relatively fine needle, injecting slowly, and using both verbal and tactile distraction techniques. Injecting into the subcutaneous fat is less painful than intradermal infiltration, although it does take longer for the skin surface to become anaesthetic. Whenever possible, anaesthetic solutions should be at room temperature, and epinephrine avoided if not considered useful for the particular procedure. Pain on injection is less when lidocaine solutions are buffered with sodium bicarbonate immediately prior to use [9].

Other anaesthetic agents include the following:

1 *Ethyl chloride* and *liquid nitrogen* spray give short-lived periods of anaesthesia by skin refrigeration. This may be sufficient for quick superficial procedures such as the incision of small cysts and milia, abscesses or the curettage of multiple small warts.

2 The anaesthetic effect of *antihistamines* (e.g. 1% diphenhydramine hydrochloride solution) can be used when hypersensitivity to other agents is present or strongly suspected.

3 The intradermal injection of *normal saline* produces a brief anaesthetic effect [2].

4 *Hypnosis* and *acupuncture* may be useful when performed by an experienced practitioner and in a suitable subject.

5 *General anaesthesia* is rarely used in dermatological surgery. Patients requiring a general anaesthetic (e.g. children requiring treatment of large facial birthmarks) are best admitted to hospital either as a day case or overnight.

Biopsy techniques

Incisional and excisional elliptical biopsy

Elliptical excision biopsy is used for tumour or suspect mole removal. Incisional biopsy is used to take diagnostic biopsies of rashes and tumours before treatment is started. The technique has the advantage that the entire thickness of skin down to fat is excised. An appropriate margin can be selected if required and the incision line placed in the optimum direction [1].

For lesions on the face, orientate the ellipse so that the scar runs parallel to or within an existing skin crease (wrinkle line), or follows a boundary line between two adjacent cosmetic units. Excision direction is best assessed with the patient seated rather than lying flat, to allow for the effect of gravity on the skin crease lines. Wrinkle or smile lines can be exaggerated by asking the patient to grimace or smile, or by manipulating the skin [2]. In an excisional biopsy, measure the margin to be excised and mark the optimal line of closure before injecting the anaesthetic. When drawing on the skin, use a skin marker or Bonney's blue ink (a mixture of crystal violet and brilliant green), as other inks may tattoo the skin.

The ellipse length should be approximately three times the width, to produce an ellipse angle of approximately 30°, so that buckling does not occur when the wound is sutured (Fig. 78.5) [3]. A larger angle may suffice at some sites or in older people [4]. Make the incision as a single continuous sweep rather than a series of small nicks, and hold the blade at 90° to the skin, not angled inwards, so that the ellipse sides are vertical [5]. Ensure that the incision lines meet neatly without crossing over at the tip by starting and finishing each sweep with the blade held vertically. Incise down to fat. When the ellipse sides and tips are completely separate from the surrounding skin the ellipse should be sitting on a bed of fat. The fat under the ellipse should be cut through using scissors, while the ellipse is gently pulled away from the skin using a skin hook [6]. Undermine the edge at the appropriate level if there is any tension. Close the wound using both subcutaneous and surface sutures if necessary, using the correct suture technique.

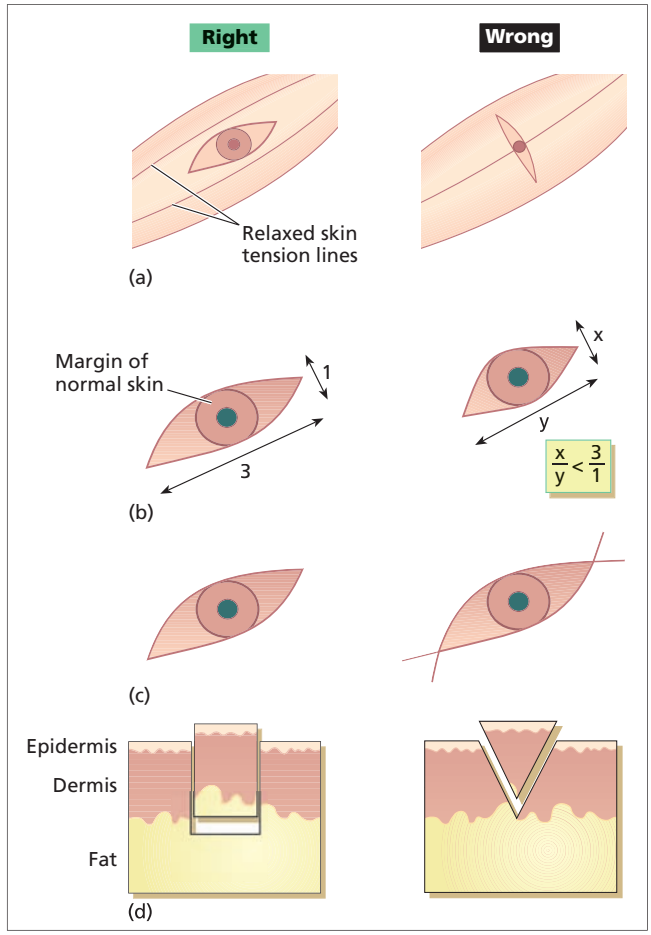

Fig. 78.5 Principles of elliptical excision. The ellipse is designed to follow skin-crease lines (a), and should be approximately three times as long as it is wide (b). Ensure that an appropriate margin of normal skin is also excised (b). At the ends of the ellipse, hold the blade vertically so that the incision lines do not cross over (c). The blade should be held at 90° to the skin when cutting the ellipse so that the wound has vertical sides down to fat. Do not bevel the blade towards the specimen as this makes the wound more difficult to close and may cut into the dermal component of the lesion (d). (From Lawrence [3].)

Punch biopsy

Punch biopsy produces a core of skin down to fat. It is quick and easy to perform, and leaves only a small wound. The disadvantages include the potential for sampling error and the difficulty in stopping bleeding if a small arteriole is punctured at the base of the wound. Punch biopsies can also be used to excise naevi on the back. At this site, wounds can be allowed to heal by second intention, with better cosmetic results than primary closure produces [7]. Subcutaneous tissue lesions can be sampled using a punch biopsy by pinching up a fold of skin to include the subcutaneous tissue before the biopsy is taken [8].

Disposable and reusable 2–8 mm diameter punches are available. When the skin is numb, drill the blade down to fat with gentle downward pressure [5]. To minimize the scar size, stretch the skin at right angles to the wrinkle lines while taking the biopsy so that, when the tension is relaxed, an oval rather than a round wound is produced, with its long axis parallel to the wrinkle lines [6]. The skin core may pop up when the surrounding skin is pressed down, or it can be hooked out using a needle. Cut through the fat at the base with scissors and remove carefully to avoid crushing the specimen. The wound can be sutured

or allowed to granulate; the latter produces an acceptable small round or oval scar. If the wound is to be allowed to heal by second intention, stopping bleeding using a collagen matrix dressing results in a better cosmetic result than using Monsel's solution [9].

Shave

Shave excision is a simple, rapid and effective method of removing benign papular naevi. It can also be used to obtain a tissue diagnosis in protuberant nodular skin tumours. Shave biopsy of dermatoses affecting the epidermis or high dermis results in adequate tissue for diagnosis, and the subsequent re-epithelialization from follicular epithelium produces a good cosmetic result.

Naevi

Inject the local anaesthetic directly into the naevus, as this stiffens the tissue and makes it easier to slice off. Holding a No. 15 blade horizontally, shave off the naevus flush with the skin. Stop bleeding using cautery, electrodesiccation or a chemical haemostatic agent. Any remaining wound edge tissue fragments can be destroyed using cautery or electrodesiccation. The wound will take 2–3 weeks to heal. In approximately 45% of head and neck and 30% of trunk naevi, no visible scar remains (Fig. 78.6). In the remainder, the scar is smaller than the original naevus on head, neck and limb sites and a little larger than the naevus on trunk sites. Pigmentation at the scar edge or centre remains in approximately 25% of initially pigmented naevi after shave excision; non-pigmented naevi rarely, if ever, leave a pigmented scar [10]. Persistent pigmentation is even more common when aluminium chloride haemostasis is used rather than cautery [11]. Recurrent or retained pigment does not need to be excised. If a further specimen is sent, the pathologist must be given the full history in order to interpret the changes correctly. Hairs remain in 25% of initially hairy naevi; these can be destroyed by electrolysis if necessary.

Skin tumours

Shave biopsy of a solid tumour is faster and easier than an incisional biopsy, which needs to be sutured. A fragment can be shaved off to confirm the diagnosis prior to definitive treatment. This type of biopsy will not help to distinguish a keratoacanthoma from a squamous cell carcinoma, and is unsuitable if histological examination of the deep margin or edge of a tumour is required to confirm the diagnosis. Bleeding can be stopped using silver nitrate stick coagulation, as the cosmetic outcome will be determined by the subsequent treatment. The fragile specimen should be mounted on paper before being placed in formalin.

(a) (b) (c)

Fig. 78.6 Shave biopsy of benign papular naevi. (a) This patient had a benign tan-coloured naevus on the face (b) removed by shave excision followed by cautery, (c) resulting in a good cosmetic result 6 months later.

Simple excision, suture technique and wound closure

Excision [1–3]

Skin biopsy specimens and cutaneous lesions can be removed using techniques other than elliptical excision, many of which (e.g. curettage, shave biopsy) do not result in a linear scar. Consequently, the decision to use formal surgical excision should balance the possible cosmetic advantages of other techniques (e.g. epidermal lesions and benign facial naevi) against the need to provide a full-thickness tissue specimen for histological examination (e.g. possible malignant melanoma).

Surgeon preparation

Dermatologists should be confident that they are competent to perform the proposed procedure and to manage any possible complications. If not, they should ask for a second opinion. The surgeon must be fully immunized against hepatitis B, and should observe safe practices with regard to handling sharps and tissue specimens. Surgical gloves should always be worn [4] and eye protection is strongly recommended.

Patient preparation

Patients should be fully aware of the significant risks, benefits and possible complications associated with the planned procedure. Informed consent [5] should be obtained, both verbally and in writing, for all invasive procedures. Usually, consent should be obtained from the parent or guardian in the case of minors, although some adolescents may be fully capable of both giving and withholding consent. Most patients about to undergo surgery are anxious and usually respond positively to appropriate reassurance as well as a calm and professional manner displayed by all members of the surgical team.

Examination and palpation of skin lesions will help to estimate their extent, depth and proximity to large blood vessels, nerves or other important structures. Langer's lines of skin tension [6] were previously used as a guide to incision, but the best cosmetic results are usually obtained by following the relaxed skin tension lines (RSTLs) [1,7], which tend to lie perpendicular to the major underlying muscles. Langer's lines and RSTLs often coincide, as on the neck. When they do not, as on the limbs, the choice depends on other factors. Excisions on the lower leg, for instance, close more easily along the long axis of the limb, rather than transversely. Testing for skin laxity by manipulating the skin usually clarifies the best direction in which to plan an excision. The size and type of excision made will also depend upon many factors, including the site and nature of the lesion to be excised and the nature of the planned skin closure.

The skin surface should be cleaned prior to operation with a detergent–antibacterial combination, most commonly containing either chlorhexidine [8] or povidone–iodine. This helps to reduce the risk of wound infection by removing pathogens and reducing the resident cutaneous bacterial flora [9].

Elliptical excision—general technique [2,3]

It can often be helpful to mark the planned lines of excision prior to cleaning the skin surface and infiltrating local anaesthetic. A reasonable period of time should be allowed for the anaesthetic to take full effect.

The small round-ended Gillette No. 15 blade is most commonly used to make two hemi-elliptical incisions perpendicular through the skin into the subcutaneous tissues. The length of the wound should be at least three times its breadth (the angles at the ends of the ellipse should not exceed 30°) taking care not to allow the incisions to cross each other ('fishtailing') at either end (Fig. 78.5). The skin ellipse is held firmly but gently with either fine-toothed forceps or a skin hook, and separated from its base. For both histological purposes and to facilitate wound closure the excised specimen should contain subcutaneous fat.

For standard histological processing the specimen should be placed in a formaldehyde–saline specimen bottle, clearly labelled with the patient's details. To prevent curling of small biopsy or excision samples, these may be placed on small squares of filter paper and floated into the formalin solution. When histological confirmation of tumour clearance is required, it can sometimes be helpful to 'colour code' or place a suture at the '12 o'clock' position of the surgical specimen to facilitate orientation and examination in the pathology department. For immunofluorescence or frozen section studies, specimens are placed on aluminium foil and immersed in liquid nitrogen.

Intraoperative bleeding is controlled by a combination of pressure, electrosurgery, clamping and ligation of vessels.

Depending upon the size of the defect and the body site, a variable degree of undermining of the wound edges will be necessary to facilitate the placing of subcutaneous absorbable sutures and to reduce wound tension. Finally, non-absorbable sutures are used to neatly appose and evert the wound edges [2,3].

The timing of suture removal depends upon the site and the amount of tension across the wound. With additional supporting surface tapes and buried sutures where appropriate, 4–5 days is usually sufficient for skin sutures on the face, 5–7 days for the scalp and neck and 10–14 days elsewhere.

Sutures [1–4]

An ideal suture would have high tensile strength, handle easily, provide good knot security and cause no tissue reaction. Skin sutures are of two main types: *absorbable* and *non-absorbable*.

Now that catgut is rarely used, popular synthetic *absorbable sutures* include Vicryl™ (polyglactin-910), Dexon™ (polyglycolic acid), PDS (polydioxane sulphate), Maxon™ (polyglyconate) and Monocryl™ (poliglecaprone), all of which cause very little tissue reaction and dissolve completely in 90–120 days. Absorbable sutures are usually placed either subcutaneously in the subcutaneous fat to close off potential dead space or as subcuticular intradermal sutures to close and evert wound edges.

Non-absorbable sutures include braided silk and synthetic monofilament sutures such as nylon (Ethilon™) and polypropylene (Prolene™). Most dermatological surgeons prefer the better tensile strength and low tissue reactivity of the synthetic monofilament sutures. Braided sutures such as silk and Dacron™ have better knot-tying properties but tend to drag through tissue, and their braided nature may increase the risk of wound infection. For wounds that are likely to remain under constant tension, such as those on the back or shoulders, a non-absorbable suture such as nylon can be used to close the deep subcutaneous layer. Alternatively, a running subcuticular Prolene suture can be left in place for long periods without leaving suture marks.

In general, skin suture needles are of the reverse cutting type (the sharp edge of the needle lies on the trailing rather than the leading edge). Suture sizes usually vary from 3/0 to 6/0, with suture selection depending on the wound size, anatomical site and surgeon preference.

Suture technique [2,3,5]

The ability to perform several different suture techniques is one of the skills needed in order to become proficient in dermatological surgery. The *simple interrupted suture* is the mainstay of final skin closure, although alternatives include a *running suture*, placed either as loops through the skin (*simple running suture*) or placed entirely within the dermis (*running subcuticular suture*). They are normally 4/0–6/0 gauge, and are placed close to the skin edge for fine approximation. If the wound tends to invert, then the deeper component of the suture can be placed more laterally to help evert the edges.

If there is tension across the wound, or a significant tendency to inversion, one or two *vertical mattress* sutures can be placed initially. A modification of this suture, the *half-buried mattress*, is also useful as a corner stitch when insetting the tips of skin flaps. The *horizontal mattress* suture (with or without bolsters) [6] can also be used to approximate long wounds or wounds under tension. Any wound tension must be managed by undermining and the use of buried sutures before the insertion of skin sutures. Failure to do this will increase the risks of infection and wound dehiscence, and often leave permanent unsightly, papular or linear suture marks.

There are various forms of *buried suture*, which are used to close off 'dead space' in a deep wound. Normally, this is obliterated by the use of interrupted *deep subcutaneous* or buried absorbable dermal sutures [7], or by using a '*purse-string*' variant of the horizontal mattress suture. Running sutures, both cutaneous and subcutaneous, can be used to save time, but may be less secure than interrupted sutures and can be tricky to remove. The running subcuticular suture, although difficult to learn, is an elegant suture technique, and it can be left in place for long periods without risk of leaving permanent suture marks.

Tape closures (e.g. Steri-Strips™) may be used in conjunction with interrupted sutures or on their own if there is good approximation and adequate subcutaneous or subcuticular support. They provide additional wound support both while skin sutures are in place and for the immediate period following suture removal. Cyanoacrylate tissue glues may also be useful, especially in children [8], and for securing skin grafts [9].

Stainless steel staples are a rapid and effective way to close longer skin incisions. They are strong, incite very little tissue reaction, and can be useful for closing scalp wounds and skin graft donor sites [10].

Particular forms of excision

Variations in detail and technique apply to particular lesions and areas of the body.

Pilar or epidermal cysts [1]

Small cysts are often deeper than they appear and may be difficult to locate after infiltration with local anaesthetic. Careful preoperative skin marking will often help in their intraoperative location. Larger, tense cysts of the scalp often extend deeply and their removal may be accompanied by significant bleeding. Many cysts can be removed by making an elliptical incision into the overlying skin (surrounding the punctum, if present) and using blunt dissection to separate the cyst from the tissues while pulling gently on the ellipse and the attached cyst. If the cyst ruptures, the remaining contents should be expressed and the whole of the cyst wall removed. Irrigation of the wound prior to closure will remove residual cyst contents which might otherwise cause a granulomatous tissue reaction. Excision of large skin cysts leaves subcutaneous dead space, which must be obliterated with deep sutures to minimize the risks of haematoma formation, infection and wound dehiscence.

Lesions on the shoulder and upper back

Surgical excision on the shoulders, upper back and deltoid areas frequently results in poor cosmetic results, with the formation of stretched and frequently hypertrophic scars. Although meticulous surgical technique, appropriate undermining and careful suture technique may minimize these problems, patients should be carefully counselled and only offered surgical excision in these areas when it is absolutely necessary. One suggested alternative to excision and repair in these areas is to excise the lesion with a narrow margin of normal skin and allow healing by secondary intention [2].

Benign naevi

Surgical excision, even by experts, leaves scars and consequently benign naevi are best either left alone or removed by shave excision when possible.

Non-melanoma skin cancer: basal cell and squamous cell carcinomas

Many different surgical and non-surgical techniques may be used to treat non-melanoma skin cancer [3,4]. The choice of treatment is based upon various factors relating to both the tumour [5] and the patient [6].

Small primary well-defined lesions in areas of skin laxity are often best excised. An adequate margin should always be obtained, and prior skin marking following careful examination in good lighting is advisable [5]. Cure rates following surgical excision of such lesions can be excellent [7–9]. Some sites, such as the lips, ear, scalp and periocular and nasolabial areas, have a higher rate of recurrence, and (for squamous cell carcinoma) metastasis. Management of lesions in these sites, particularly if recurrent, poorly defined or showing infiltrative growth patterns, is best performed by a specialist dermatological surgeon [5,10].

Mucous membranes

Excision of lesions in the mouth and on the tongue, lips and genitalia can be difficult, with restricted access and often profuse bleeding. Consequently, only simple procedures should be attempted by non-specialists, and more complex cases referred to colleagues in oral surgery, urology and gynaecology as appropriate.

Keratoacanthoma

This is often difficult to differentiate, both clinically and histologically, from squamous cell carcinoma. Small lesions are often suitable for surgical excision, and larger lesions should be subjected to a transverse incisional biopsy passing from normal adjacent skin through the centre of the lesion and extending through the subcutaneous fat [11].

Pigmented lesions (see Chapter 38)

The diagnosis and management of pigmented lesions is a key component of clinical dermatology and forms an important part of the multidisciplinary treatment of malignant melanoma, also involving pathology, plastic surgery and clinical oncology.

Blue naevi, pigmented basal cell carcinomas, seborrhoeic

keratoses and dermatofibromas are usually easily recognizable to the trained eye, although diagnostic difficulties occasionally occur. When diagnostic doubt exists, and especially when malignancy is suspected, the lesion should be excised and submitted for histopathological examination. When the lesion is too large to excise and repair directly, an incisional biopsy may be indicated (e.g. possible malignant change in a large congenital naevus or facial lentigo). In these cases, if malignant melanoma is proven on biopsy, a second procedure, possibly involving complex wound reconstruction, will often be necessary. In such cases, an initial incisional biopsy does not appear to influence the overall prognosis [12], although determination of key prognostic features (e.g. growth phase, depth of invasion, presence of vascular invasion) can only be made accurately from examination of the full excision specimen.

Hypertrophic scars

Although these may occur at any site, they are especially common in certain anatomical sites such as the upper back, shoulders and deltoid areas. Most will slowly resolve with time and regular gentle wound massage. Intralesional steroid injections can be helpful, but may cause skin and fat atrophy and should be used with caution. Hypertrophic scars may also be treated (and possibly prevented) by the use of Z-plasty techniques [13], with pressure dressings or devices [14], and silicone gel sheet dressings [15].

Wound closure [1–3]

A significant part of dermatological surgical practice involves the repair of surgical defects. Wounds can be allowed to heal by secondary intention healing, closed primarily, or repaired using skin grafts or skin flaps. Experience and careful consideration of the various wound closure options are necessary in order to offer patients the best possible cosmetic and functional results.

The M-plasty [4]

This is occasionally useful if one end of an elliptical excision will cross an important anatomical or cosmetic line. In this situation, an M-plasty will help to reduce the overall length of excision required by bringing the apex of the excision back within the original area to be excised.

'Dog-ear' repairs [5]

'Dog-ears' (folds or humps of skin) tend to occur when the length to width ratio of an excision is insufficient to prevent the skin at the poles from bulging outwards when the opposing skin edges are brought together. They tend to occur more commonly when there is limited laxity or movement in the surrounding tissues. Excisions where the angle at the apex exceeds 30° are also liable to produce 'dog-ears'. 'Pseudo-dog-ears' occur if too much fat is left at the poles of an excision.

There are several ways in which this problem can be surmounted [3].

1 The excision can be extended and the redundant overlapping skin excised.

2 One side of the pucker can be cut back flush with the skin and the excess skin from the other side identified by drawing it across the wound; this can then be cut off.

3 The excess skin of the 'dog-ear' can be removed by converting it into a T-plasty or an M-plasty. This is a useful technique when the length of the wound cannot be extended [6].

Wound edges of unequal lengths

This problem can often be resolved by using a halving technique: a suture is placed across the centre of the wound and subsequent sutures used to divide the two resultant defects into ever smaller compartments. Because of local skin elasticity, the shorter side tends to stretch to match the longer. For more disproportionate edges, a wedge may have to be removed from the longer side in order to make the sides of the resultant ellipse more equal,

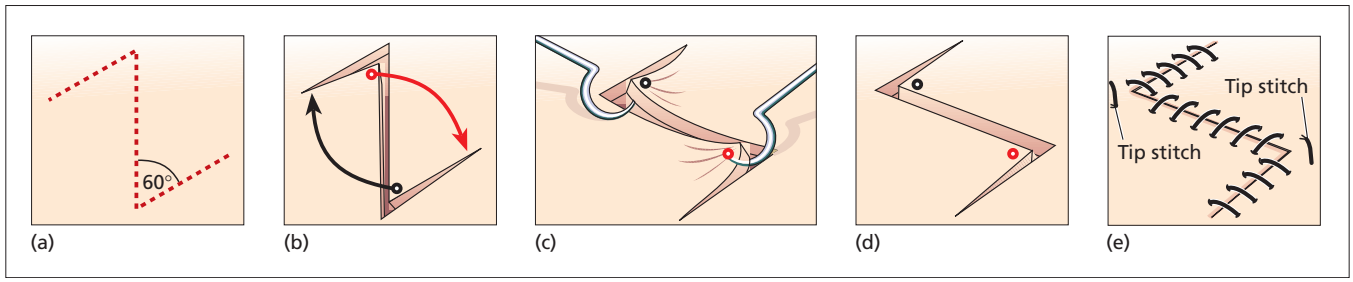

Fig. 78.7 Technique of Z-plasty. (From Eedy *et al*. [7].)

or the wound can be sutured in the normal way and a 'dog-ear' repair performed to remove the excess skin from one side.

Z-plasty

This is a technique that is used to treat scar contractures, skin 'webbing' and to break up or alter the direction of linear scars to try to improve the cosmetic or functional result. The size of the angle used determines the increase in the length of the scar that will result (Figs 78.7 & 78.8).

Dressings

Wound dressings are not essential [1], although optimizing wound care by using an appropriate dressing probably produces a predictably better result. An ideal dressing should meet the following criteria.

1 Soaks up excess exudate from the wound surface, thereby reducing the risk of bacterial penetration.

2 Maintains a moist wound–dressing interface to encourage migration of epidermal cells over the granulating tissue. Covered split-thickness wounds heal faster than dry wounds [2]. A scab is a poor barrier against loss of moisture from the dermal surface because it allows the surface to dry out, thus forcing the epidermis to grow under the dry wound surface. As the epidermal cells migrate, they secrete a proteolytic enzyme which dissolves the base of the scab; migration ceases when cell–cell contact occurs [3].

3 Does not contain organisms or fibres that may contaminate the wound. Cellulose-derived dressings may shed fibre fragments into the wound [4], causing a foreign body reaction and leading to increased risk of infection.

4 Is impermeable to bacteria.

5 Causes minimal injury to healing tissue when removed.

It is often claimed that a dressing that permits increased oxygen permeability aids wound healing. Such dressings do aid healing in split-thickness wounds [5]. However, in full-thickness wounds the same synthetic wound dressings create hypoxic conditions at the healing surface [6]. Paradoxically, tissue hypoxia in full-thickness wounds appears to stimulate rather than retard granulation tissue formation [7].

Basic dressing [8]

This includes contact, absorbent and outer layers [9]. The layer in contact with the wound is non-adherent, either because it contains a greasy ointment (e.g. tulle

dressing) or because it is made from a specially designed low-adherence material (e.g. polyethylene) [10]. The absorbent layer (e.g. cotton-wool, gauze) soaks up the excess wound exudate and cushions the wound. The outer layer (e.g. tubular bandage, elasticated tape) holds the other two layers in place and applies slight pressure. The basic dressing is left in place until suture removal, but needs to be changed if it gets wet or becomes saturated with exudate [11], as this greatly increases bacterial penetration. Many proprietary dressings combine two or all three components (e.g. Melolin® contains a polyethylene non-adherent layer attached to an absorbent cellulose component). The hydrogel (e.g. Vigilon®), hydrocolloid (e.g. Granuflex®), xerogel (e.g. dextranomer starch polymer), alginate (e.g. Kaltostat®) and synthetic foam dressings are designed to provide all three components, and these can also be used on pressure sores [12,13], leg ulcers [14] and full-thickness surgical wounds [15].

Pressure dressings

These are placed over the basic dressing. Most commonly, and on suitable sites, a piece of compressible padded dressing (e.g. cotton wool, sponge, eye pad) is pressed down onto the wound with an elasticated or *crepe bandage* for 48 h. Where bandage application is difficult, a *multi-tape dressing* can be used. Dental rolls are placed over and pressed down onto the dressing by using adhesive tape strips, and additional adhesive (e.g. collodion or tinct benz co.) is used to increase the tape adhesion. A *tie-over pressure dressing* is commonly applied over skin grafts, but can be used on any wound. Paired sutures are placed around the wound and tied together to hold down a three-layered contact, absorbent and compression dressing, so that the graft is held down onto the recipient site to prevent a haematoma forming beneath it.

Suggested dressing for wound types

Small full- or *partial thickness wounds* (shave and curettage sites) require a simple low-adherent dressing or paraffin tulle held in place with a conforming adhesive tape. Unsutured punch biopsy sites do not appear to benefit from occlusive dressings [16], but heal better with a collagen matrix dressing than they do after simply applying Monsel's solution to stop bleeding [17]. *Sutured wounds* (side-to-side closures and flaps) require a greasy antiseptic ointment application and an absorbent-backed, low-adherent dressing held in place with a conforming adhesive tape. A pressure dressing may also be required. After suture removal, apply adhesive tape strips for 5 days. On a *full-thickness graft*, apply a simple contact dressing (e.g. greasy antiseptic ointment and paraffin tulle) and then a tie-over pressure dressing which includes a sponge or cotton wool compressible pad. On *full-thickness wounds*, a variety of wound management methods are used. If acceptable to the patient, the wound can be left without a dressing and simply cleaned two or three times daily, and a sterile white soft paraffin or vaseline-based antiseptic ointment applied. Alternatively, the wound can be cleaned less frequently if a combination contact/absorbent dressing is applied. During the initial exudative stage (the first 4 days) the dressing will need to be changed at least once a day. Thereafter, the dressing should be changed if the wound surface starts to dry out or the dressing becomes saturated, wet or otherwise dirty. The wound should be cleaned with a simple antiseptic (e.g. aqueous chlorhexidine, 10 vol. hydrogen peroxide) before being re-dressed using a vaseline-based antiseptic ointment (Polyfax®), and simple contact dressing (e.g. polyethylene/cellulose dressing; Melolin®) held in place with adhesive tape. Alternatively, a semi-permeable adhesive polyurethane [18] or gel, or colloid dressing can be used and changed as necessary. *Split-skin graft donor sites* heal faster with a dressing that maintains a moist wound–dressing interface; for example, a calcium alginate [19] or semi-permeable adhesive polyurethane film [20]. A pressure bandage applied over the wound is also required, but bleeding will still occur. The exudate can either be allowed to drain through puncture wounds made in the lower portion of the polyurethane film, or can be removed by changing the dressing more frequently, although this may introduce infection and is painful.

Wound healing is delayed by topical steroid application [21], tobacco smoking [22] and possibly age [23] via a decrease in skin blood flow with increasing arteriosclerosis [24].

Secondary intention healing

Full-thickness wounds remaining after malignant [1,2] or benign [3] tumour excision can be left to heal by second intention. The cosmetic result depends on wound site and patient age. The nasolabial fold, medial canthus, scalp and pre- and postauricular skin produce particularly good results, although the technique can be used in many sites, including the fingers [4]. Almost half of the reduction in wound size occurs because of scar contraction [5] and subsequent stretching of surrounding tissues [6]. Therefore, if the wound is next to a mucocutaneous junction, such as the lip, ala nasa or eyelid, scar contraction may distort this free margin, producing poor cosmesis and function. Most other head and neck sites heal well, although in general the cosmetic results are best on concave rather than convex skin surfaces [7]. The older the patient the better the result, probably because wound contraction is aided by the availability of loose adjacent skin and because hypertrophic scarring is less common in older patients. The method can be used if there is doubt about the adequacy of excision, or closure of the defect requires a larger or more complex procedure, which the patient will not tolerate. In some situations, such as excision of naevi on the back [3] or the treatment of acne keloidalis nuchae [8] and hidradenitis [9], secondary intention healing is the preferred method as it results in a superior cosmetic result.

When a tumour is being excised, the specimen is orientated with a marking suture before complete removal, so that if further excision is required the affected margin can be identified. When bleeding is controlled, a contact dressing is applied, and this is covered by a pressure dressing for 24–48 h. Thereafter, the dressing can be changed at 2–4-day intervals, depending on the amount of exudate. At each dressing change, the wound is cleaned to remove crust or debris and a greasy antiseptic ointment (e.g. Polyfax®, Flamazine® or Betadine® ointment) and non-adherent dressing are applied. On average, a 25-mm diameter head and neck wound takes approximately 35 days to heal [10]. If histology shows that the tumour has been incompletely excised, the involved margin can be re-excised 1–2 weeks after the first excision. Because vertical sections are taken and the entire excision margin is not examined, the technique does not provide the same complete excision margin control as the horizontal sections of Mohs' surgery [1]. These wounds are surprisingly pain-free. Bacterial contamination may occur, but tissue infection is rare; when present the wound edge is tender, red and swollen. A yellow exudate is common in the first few days. Before granulation tissue appears, a yellowish fibrin clot covers the wound. Exposed periosteum and perichondrium must be kept moist and viable by using a saline-dampened alginate dressing. This encourages granulation tissue to migrate over the exposed area and also reduces the risk of bone desiccation and necrosis [11]. If the periosteum has been stripped off, the exposed bone can be fenestrated or abraded to encourage the formation of granulation tissue and hence enhance re-epithelialization [12]. When the wound first heals, the scar often contains large looped vessels, which slowly disappear as the scar thickens. A slightly elevated, red, hypertrophic scar is then present, and the cosmetic result is not optimum until approximately 1 year (Figs 78.9 & 78.10).

Skin grafts

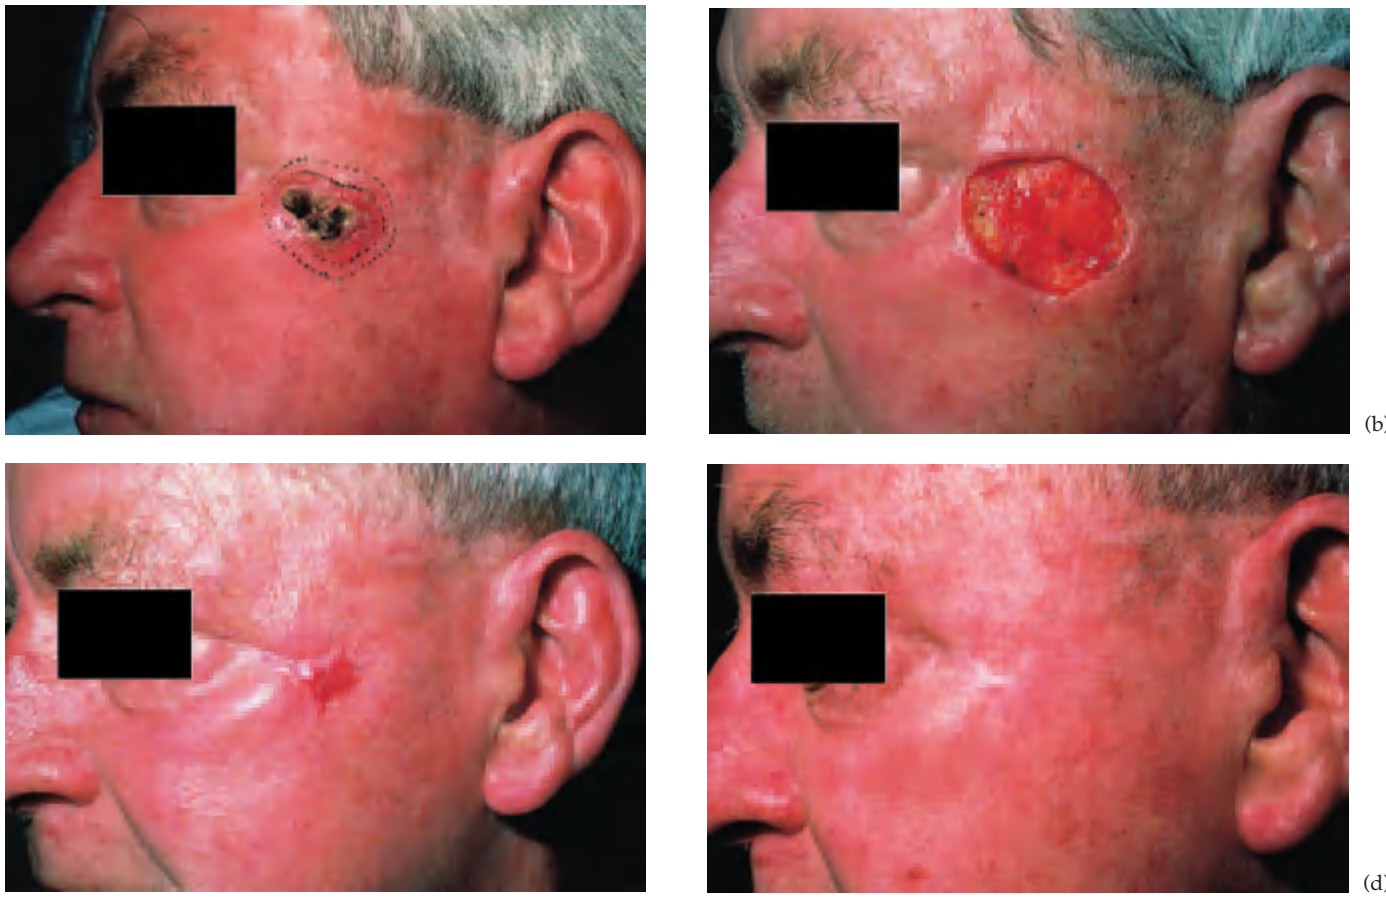
Skin of varying thickness can be used for skin grafting. A

(a) (b) (c)

Fig. 78.9 (a) This man had a basal cell carcinoma on the side of the nose; (b) this was excised and the wound was allowed to heal by second intention. (c) The cosmetic result 4 months later was good.

Fig. 78.10 (a) This man had a basal cell carcinoma on the temple (b) excised. (c) Three months later the wound had healed but the scar was thick and red. (d) 15 months later this scar had become considerably less conspicuous.

split-skin graft is not limited in size, because the donor site regenerates. Full-thickness and composite skin grafts potentially produce better cosmetic results than split-skin grafts, but are limited in size by the amount of skin that can be removed from the donor site without creating problems. Compared with flaps, grafts are technically easier to perform, but generally produce inferior cosmetic results.



(a) (b) (c) (d)

Fig. 78.11 Full-thickness graft on the nose. This basal cell carcinoma on the tip of the nose (a) was excised (b). The defect size and shape was recorded using a sterile paper template (c), the template was placed on the donor skin site (d) and the appropriate-sized piece of skin excised. The fat was trimmed off the undersurface of the donor skin, and this was sutured into place on the wound (e). A tie-over dressing was applied (f). Seven days later the dressing was removed and the graft was pink and had clearly taken (g). The subsequent cosmetic result at 3 months was excellent (h).

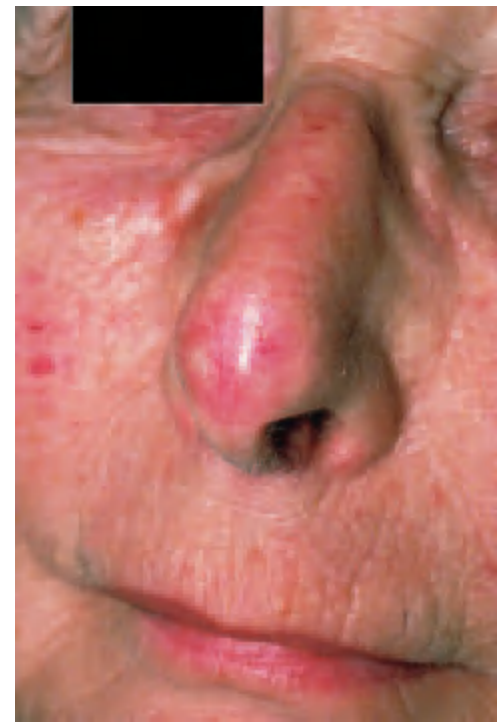
Full-thickness grafts

A full-thickness graft is used, in preference to a split-skin graft, when the cosmetic result and strength of the repair are important. Any site with matching and spare skin is a potential donor site [1]. Common donor sites include the skin behind and in front of the ear, nasolabial fold [2], upper eyelid, inner aspect of the upper arm, lower abdomen and supraclavicular fossa. The donor and graft sites should match for skin thickness, adnexal structures, surface markings, weathering and texture. After carefully assessing the amount and shape of skin required, the donor skin is excised down to fat [3]. The fat is then trimmed off the under surface of the graft to aid new blood-vessel penetration. Edge sutures are used to prevent shearing forces dislodging the graft, and a pressure dressing, usually held in place using tie-over sutures, is employed to prevent a haematoma lifting the graft off the recipient site (Fig. 78.11). In most instances, the donor site is chosen because there are redundant folds of skin present and the skin edges can be sutured easily after donor skin excision. At some sites (e.g. behind the ear), the donor

(e)

(f)

(g)



(h)

Fig. 78.11 (*cont'd*)

defect can be allowed to heal by second intention. Grafts take best on dermis and granulation tissue, will survive on fat, perichondrium and periosteum, but will perish on exposed bone or cartilage. Grafts fail because of infection or poor blood supply. The latter occurs because of faulty technique (e.g. incorrect haemostasis, suturing or wound care) or because the recipient site has an inadequate blood supply (e.g. previous radiotherapy or lower leg sites in people with compromised venous and/or arterial supply). All grafts contract, and near the lower eyelid this may lead to ectropion. Hence, at this and other critical sites, grafts should be 10–25% larger than the defect to

compensate for this. Depressed graft scars may be elevated by injection of autograft fat under the graft [4].

Composite grafts

Composite grafts are defined as those comprising two or more germ layers. In dermatology, these are grafts containing skin and cartilage components. When used to repair full-thickness ala rim defects using skin taken from the helix rim, graft survival is unpredictable [5]. In contrast, composite grafts containing skin and perichondrium, or perichondrial cutaneous grafts, are claimed to be better than full-thickness grafts for nose, ear and periocular defects, as they contract less, induce new cartilage formation, and maintain their thickness and epidermal appendages [6].

Split-skin graft

Except in extreme circumstances (e.g. extensive burns) split-skin graft size is not limited by the amount of donor skin that can be harvested, because the donor skin site will re-epithelialize by regeneration from retained follicular remnants. Split-skin grafts can therefore be used to cover very large wounds. Because the skin is thin and relatively transparent, split grafts are also sometimes used to cover tumour excision sites where the adequacy of excision is dubious, because recurrence is more easily identified through the thinner graft than it would be after full-thickness or flap closure. The disadvantages of split-skin grafts compared with full-thickness grafts are the relatively poor cosmetic result and greater graft shrinkage [1]. When a split graft is taken, skin is sliced off through the dermis, leaving behind parts of the adnexal and follicular structures from which epidermis migrates to cover the donor site. Split-skin grafts can be taken using a handheld knife or a mechanical dermatome (Fig. 78.12a). The latter is easier to use and produces a predictably good graft. *Meshing*, or cutting multiple parallel slits in the graft, allows it to expand rather like a fishnet stocking when stretched (Fig. 78.12b). The gaps are covered by epithelium migrating from the adjacent strips of the graft (Fig. 78.12c). A meshed graft will therefore cover a wider area, allow exudate to drain through the gaps (e.g. on the leg), and will conform to an uneven contour (e.g. ear). The common donor sites include the upper arm, upper thigh and abdominal wall. The donor site is best anaesthetized using EMLA® cream [7], and heals faster and painlessly with a dressing that maintains a moist wound–dressing interface (e.g. calcium alginate [8] and semi-permeable adhesive polyurethane film; Opsite®) [9].

Pinch grafts

Pinch grafts are occasionally useful for wounds of the lower leg, although the donor site heals leaving unsightly scars. The technique is simple [10], but without careful aseptic technique success rates are low [11]. The skin is elevated on a needle tip, the apex sliced off, and when multiple skin shaves have been harvested the grafts are placed at regular intervals on the clean granulating ulcer.

Fig. 78.12 Meshed split-skin graft. (a) A split-skin graft was harvested from the thigh skin using a power dermatome. (b) The skin was meshed on a mesher, and the meshed graft applied to the defect. (c) This was the appearance of the graft 11 months later.

As with all leg-ulcer skin grafting, if the causative factors are not eradicated before grafting, the ulcer will recur even if the graft is initially successful.

Grafting techniques used for repigmentation of inactive vitiligo

Epidermal grafts containing viable melanocytes can be harvested using suction blisters [12], or very thin split-skin grafts [13]. Before grafting, the epidermis is removed from the hypopigmented skin by freezing to create a blister [12], or by dermabrasion [13]. Alternatively, *mini-grafts*, or tiny (1.2-mm diameter) full-thickness punch grafts of normally pigmented skin are grafted, at 2-mm intervals, into similar-sized punch wounds sited in the depigmented skin [14]. Because melanocytes migrate approximately 2 mm away from the graft site, there is no need to graft the whole area, and because the punch grafts are so small there is minimal cobblestone effect at the recipient site. In both techniques, a hidden donor site, such as the upper inner thigh or lower back, is used. Grafts of cultured autologous melanocytes have also been tried [15].

Acne scar punch grafts

Ice-pick acne scars can be excised using a punch biopsy blade, and the wound filled with a slightly bigger punch biopsy-shaped piece of donor skin taken from a matching but unobtrusive site (e.g. behind the ear). Dermabrasion is usually subsequently required to reduce the cobblestone effect [16].

Flaps (Figs 78.13–78.16)

A flap is a section of full-thickness skin in which one portion, the pedicle, remains attached to the skin while the distal portion is undermined and moved to cover the defect [1]. The blood supply of any flap is therefore, at least initially, provided principally via its pedicle, and the broader the pedicle the better the blood supply. The length to width ratio of a flap should rarely exceed 3 : 1. The more closely a flap resembles a graft (thin, defatted skin) the greater is the contribution to its blood supply from the recipient site rather than the flap pedicle. The thinner the flap, however, the greater the contraction, and this is particularly important when using thin skin around the eye. Different techniques can be used for many repairs [2], although some techniques [3] are inherently suited to the nose [4,5], chin [6], eyelid [7,8], ear [9,10], forehead [11], scalp [12], cheeks [13] and lip [14,15].

Flaps can be confusingly categorized by the direction of movement, the name of the surgeon who first described the flap, the blood supply or the type of tissue moved. The most useful method relates to how the skin was moved to cover the defect—hence the description of advancement, rotation or transposition flaps (Table 78.4). Classification according to blood supply shows that dermatologists almost exclusively use random pattern flaps (the blood supply is inherent in the skin being moved). This may come from the dermal blood supply (reticular—the type most widely used by dermatologists), or the perforating vessels from the subdermal plexus (segmental, e.g. island pedicle flaps). In contrast, axial pattern flaps are designed to obtain their blood supply from one named artery. With the exception of the midline forehead flap [4], which is based on the supratrochlear artery, axial flaps are rarely used in dermatological surgery. Island pedicle flaps do not have a skin pedicle but get their blood supply from the tissue on the underside of the flap. This may be subcutaneous tissue, muscle or a named vessel.

As skin is moved to close the primary or original defect, a secondary defect is created which in turn also has to be covered. The essence of flap repair is to design the flap so that this secondary defect is created at a site where there is sufficient spare or loose skin to permit closure. On the face, loose skin is usually present in the middle of the forehead, the glabella region and bridge of the nose, the nasolabial fold, the front of the ear and the cheek. Hence, these areas of laxity will be exploited for most flaps.

Fig. 78.13 Rotation flap on the pre-auricular skin. (a) This oddly shaped defect was closed (b) by rotating and advancing the loose skin under the chin up to cover the defect. (c) The incision line was placed in the skin crease at the anatomical boundary between the ear and the cheek, (d) and hence is inconspicuous 4 months later. The back cut was enhanced by Z-plasty under the ear (not shown).

Advancement flaps are used where skin must move in one direction from an area of laxity to cover the defect. Although simple to conceptualize they have limited use. The secondary defect is closed last, and the flaps have limited mobility. In many instances, defect coverage is only achieved by stretching the flap rather than transferring

Fig. 78.14 Nasolabial fold flap. (a) This defect on the ala wall was covered by transposing a flap taken from the cheek skin (b). (c) The defect on the cheek was closed directly along the nasolabial fold, thus disguising the scar, and the flap of skin was then laid over the defect. (d) The flap was trimmed to shape and sutured into place. (e) The result 12 months later was good.

the tension to an area of lax skin. *Rotation flaps* usually require both advancement and rotation about a pivotal point on a broad pedicle (Fig. 78.13). Mobility is frequently limited, and long incisions and extensive undermining may be required to mobilize sufficient tissue; the secondary defect is closed last. *Transposition flaps* provide the greatest mobility, and the secondary defect is closed first (Fig. 78.14). As a result, the flap is pushed rather than dragged into the defect, so that if a transposition flap is designed properly virtually all the tension can be placed on the secondary defect rather than the flap, thus reducing the risk of ischaemic necrosis. These advantages make transposition flaps the most widely used (Fig. 78.15). A wide variety of flaps based on these three simple designs have been described, each with careful refinements for different sites (Table 78.4).

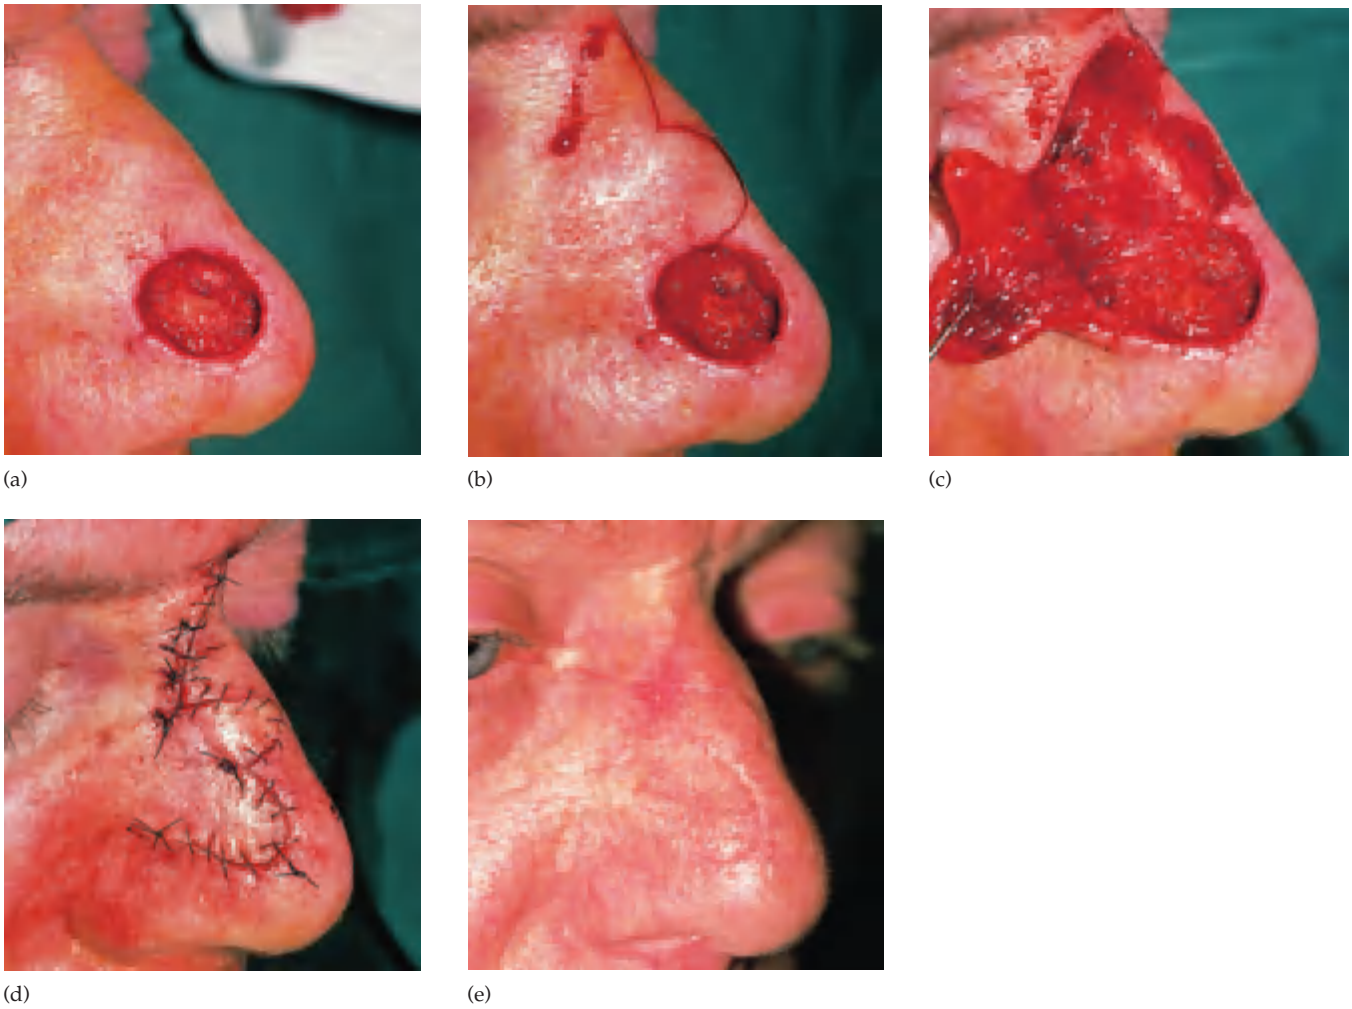

Fig. 78.15 Bilobed flap on the nose. (a) This defect near the tip of the nose was covered using a bilobed flap designed to cover the defect by exploiting the looser skin higher up on the side of the nose (b). (c) Both parts of the flap were raised together, and were transposed into the defect and the secondary defect; (d) the tertiary defect was closed directly. (e) The cosmetic result at 6 months was good.

Complications

Ischaemic necrosis of the flap usually occurs because of excessive tension resulting from poor design or mobility. Secondary infection is also more common if the flap has a poor blood supply [29]. On the head and neck, blood supply is excellent at all sites, but on the trunk, and especially on the lower limb, attempts at flap repair frequently result in failure because of relatively poor blood supply. Cigarette smokers are more likely to suffer from flap or graft necrosis than non-smokers (Fig. 78.16), although this can be reversed if smokers significantly reduce cigarette consumption 2 days before and 7 days after surgery [30]. If the flap scar is obtrusive, particularly on the nose, it can be revised by dermabrasion, which is best performed 6 weeks after surgery [31]. Manual dermabrasion [32] or scalpel sculpturing [33] may be less hazardous to the operator and equally effective.

Fig. 78.16 Complications—flap necrosis in a cigarette smoker. Despite warnings, this patient continued to smoke before and after surgery. Possibly because of this, the rotation flap on her temple necrosed at 7 days.

Table 78.4 Flap types and uses.

Flap type	Random pattern flaps (synonym/s)	Uses	Comments
Advancement	Crescentic advancement flap [16]	Cheek/nose, cheek/upper lip closures	In effect side-to-side closure with special attention to cosmetic boundaries. A useful technique
	Single advancement (U-plasty)	Cheek, temple, forehead [6], upper lip [15]	If designed with a broad base can be very effective on the cheek
	Double advancement (H-plasty)	Forehead defects, eyebrow repairs	Little mobility, multiple scars, numb scalp. Conceptually easy but difficult to get right
	Bipedical advancement [17]	Forehead, nasal side wall, chin	In effect side-to-side closure with parallel or V–Y relaxing incisions
	O–T-plasty (A–T-plasty, V–T-plasty, Dieffenbach's winged V-plasty [18])	Lower eyelid, upper lip [15], forehead [6]	A bilateral advancement flap useful around the eye, lip, nose [3] and hair margin
	Midline forehead island flap [19]	Medial canthus	A variety of island pedicle flap with a random pattern blood supply. Flap is tunnelled under the skin into the defect
	Island pedicle flap [20] (kite flap of Dufourmentel)	Upper lip [14], trunk and limb	Two pedicles can be used on the trunk and limb; one is used on repairs of the upper lip. The blood supply comes from the subcutaneous tissue attached to the underside of the skin. A similar design is used in an axial flap employed for defects on the nose tip and ala. The pedicle is based on the branch of the angular artery that supplies the nasalis muscle [21]
	Single advancement (unilateral Burow's wedge flap) [3]	Upper lip, temple, cheek, forehead	A useful flap which is both advanced and rotated into position and the redundant skin removed using a Burow's triangle
Rotation	Single rotation with back-cut (hatchet flap)	Cheek, temple, medial canthus	A useful technique [1] (Fig. 78.13)
	Sliding glabella rotation flap (V–Y advancement)	Medial canthus, dorsal nose [22]	Exploits the redundant skin in the glabella area. Skin movement includes both advancement and rotation as do many rotation or advancement flaps
	Double rotation (O–Z-plasty)	Forehead, scalp, chin [6]	Large area of undermining required. Only works on lax scalp
	Multiple rotation flaps (pinwheel design)	Scalp	Variant of O–Z-plasty
Transposition	Nasolabial flap [23]	Ala rim or side wall of the nose	Good results with careful attention to detail. Pincushioning can be a problem (Fig. 78.14)
	Basic transposition/rhombic flap	Cheek, nose, chin, medial canthus, upper lip	Rarely if ever used as the true geometric rhomboid. Basic transposition flaps are very useful and generally exploit the natural elasticity of the skin so that the flap shape adapts to fit the defect [24]. A Z-plasty adaptation [25] may enhance flap mobility [26]. The glabella transposition flap (banner flap) [27] is a named variant
	Median forehead pedicle flap	Nose tip or lower third of nose	Axial flap. Two-stage procedure; the flap knuckle or pedicle has to be separated later
	30° angle transposition flap [4] (Webster flap)	Dorsum of the nose	Not difficult. Bilateral and single flaps can be used
	Bilobed [28]	Nose side wall	A double transposition flap. Not as difficult to do as might appear (Fig. 78.15)

Micrographic (Mohs') surgery [1–4]

The concept of controlling the excision margins of infiltrative skin tumours by microscopic examination of horizontal sections cut from the periphery of an excision specimen that had previously been fixed *in vivo* was developed by Mohs in the 1940s [5]. This fixed-tissue technique, which produced excellent cure rates even in some of the most difficult of tumours, has now largely been replaced by the fresh-tissue technique [6]. There are other techniques and adaptations, which aim to achieve 100% histological margin control, that may be more appropriate for tumours with difficult morphology or because of local circumstances [7,8].

The principle of the technique is that the maximum confidence as regards tumour clearance is combined with the minimum loss of surrounding normal tissue. This is particularly important for tumours with an infiltrative growth pattern, especially in critical anatomical sites, and for recurrent lesions. Essentially, the technique involves excision of the lesion and microscopic examination of sections cut from marked, anatomically orientated, segments of tissue, so that the entire periphery of the excision specimen is examined (Fig. 78.17) [9]. Immunofluorescence or immunoperoxidase staining with cytokeratin antibodies may help in the histological interpretation of infiltrative lesions [10].

One of the major disadvantages of Mohs' original technique, other than the prolonged nature of the procedure (possibly continuing over several days) and the pain and discomfort of the *in vivo* fixative, was the presence of a postoperative eschar, which precluded immediate reconstruction and necessitated healing by secondary intention. With the fresh-tissue technique all but the most extensive lesions can be excised in one session, usually under local anaesthesia, and the area can be repaired immediately. If paraffin sections are used, repair is best delayed until the microscopic sections have been examined. This is not to deny the value of secondary-intention healing in appropriate situations [11].

The results of micrographic surgery are impressive, with a 98–99% 5-year cure rate for basal cell carcinomas and a 94.4% 5-year cure rate for squamous cell carcinomas [12]. It should be considered the treatment of choice for the management of certain lesions. Tumours with infiltrative growth patterns or morphoeic histology may extend 7–10 mm beyond the clinically defined margins [13], and if such a tumour overlies a putative anatomical fusion plane (e.g. ala base), the use of horizontal frozen sections may be crucial in ensuring complete resection. Although the main indication is for basal cell carcinoma, the technique has been used for a wide variety of cutaneous malignancies [14].

Hair transplantation [1,2]

The punch autograft, originally described in 1939, was for many years the major procedure in this field. Other surgical techniques were developed, sometimes to be used alone or as adjuncts to punch grafting. These included strip and fusiform grafting, scalp reduction of balding areas with or without tissue expansion, and a variety of scalp flaps. Although these techniques could at times produce acceptable results, often patients were uneasy with the unnatural appearance which was achieved. The development in the 1980s of mini- and micrografts has extended to its logical conclusion with the use of follicular unit transplantation. Now, with repeated sessions of 1000–1500 grafts implanted into small slit or needle tunnel recipient sites, graft counts of 60–100 hairs/cm^2 can be achieved with excellent cosmetic results. The major condition for which these techniques are used remains androgenic alopecia in its various forms. Areas of focal scarring can also be treated.

Careful preoperative assessment of the mental and physical status of the patient is crucial. It is imperative to exclude those subjects with known functional psychoses, those who are dysmorphophobic or cannot comprehend the nature of the treatment and its effects, and those with physical illness that might compromise healing or satisfactory hair regrowth (e.g. bleeding disorders, steroid therapy and previous hypertrophic or keloid scars). Every patient accepted for transplantation or other surgical corrective treatment must have received clear instructions on the details of the operation and its potential side effects, and have a realistic expectation of outcome.

The details of the techniques will not be considered here. In treating androgenic alopecia, the exact techniques used will depend on the pattern of loss. The final outcome will depend as much on the design of the hairline and appropriate patient selection as on technique. Some patients are happy with frontal density correction and less dense grafting on other more posterior vertex areas. Several sessions are usually required to achieve a satisfactory result.

In general, most patients detect early hair growth in the eighth to 12th week after treatment, good growth usually

being established at about the sixth month after graft insertion.

Complications are rare, and include arterial bleeding, arteriovenous and venous aneurysms, foreign body reactions, infection, poor graft survival and hypertrophic scarring.

Dermabrasion (surgical skin planing) [1–4]

The abrasive (planing) technique for the removal of superficial lesions, rhinophyma, pitted or depressed scars, tattoos and foreign bodies was first clearly described by Kromayer [1]. Its main value lies in treating lesions on the face where regeneration of the epidermis proceeds rapidly, generally without scarring, because of the abundance of pilosebaceous structures from which repair occurs as long as destruction does not extend to the subcutis.

Considerable advances in the technique have taken place in the last 25 years, caused especially by the high-speed rotary drill and the use of more efficient refrigeration [2]. Care must be taken to follow details of the technique rigidly to avoid damage to the patient or operator. Briefly, the technique (allowing for many individual modifications) is as follows [2,4].

1 The patient is sedated, with, for example, 10–20 mg i.v. diazepam.
2 The area is prechilled with cold packs.
3 The skin is cleansed with spirit or some suitable substitute after washing with soap and water.
4 The ears and nostrils are plugged with ointment-impregnated gauze, and the hair and ears are carefully protected by clipped towels.
5 The eyes are carefully protected, for example by ointment and lead shields, by thick gauze held by an assistant, or by the plastic cups used by sunbathers to protect the eyes.
6 The area to be treated is frozen by a continuous stream of Freon (dichlorotetrafluoroethane), and the skin is abraded to the required depth. The degree of freezing and of abrasion necessary must be learnt by experience. The abrading wheels ('brushes') may be of stainless steel wires or diamond fraizes.

Bleeding occurs for 15–30 min after treatment. Paraffin gauze, dry dressings or non-adherent dressings are applied and removed in 1–24 h. The crusts separate in 7–10 days. Healing is usually completed within 3 weeks, particularly if the wound is left open and dry. The pain and crusting can be minimized and the rate of healing improved by the application of a biosynthetic dressing such as Opsite®, Biobrane® or Vigilon®. Preoperative topical retinoic acid may reduce the risk of postoperative milia formation and promote healing.

Infection following dermabrasion is rare, although herpes simplex can be devastating and aciclovir prophylaxis should be given to those at risk. Mild irritation or discomfort from sunlight or cosmetics may occur for a few weeks. Persistent erythema, hyperpigmentation, hypertrophic scars and dermatitis are occasional complications.

Dermabrasion can be considered as a very useful part of cosmetic dermatological practice. Its value in the minimizing of pitted acne scars of the face is undoubted (although the small 'ice-pick' scars respond less satisfactorily than coarse irregular scars). Other conditions for which it has been recommended include traumatic and surgical scars, tattoos, telangiectasia, melasma, epidermal naevi, angiofibromas in epiloia, actinic keratoses, syringomas, wrinkles, cysts and multiple milia [2]. It has been combined with topical steroids in hypertrophic lichen planus, lichen simplex and localized lichenified psoriasis.

Botulinum toxins [1–3]

These potent neurotoxins have been used since 1979 for the treatment of strabismus and blepharospasm. They have been shown to be useful in the treatment of frown lines, disorders of the muscles of facial expression and hyperhidrosis [4]. The preparation of the toxin and its administration require great care, and although some authors advocate electromyographic guidance, most clinicians rely on clinical experience [5,6]. The effect of a single treatment may last up to 6 months, and with repeated injections the effect may become permanent. Botulinum toxin treatment is often a part of a structured approach to the management of the ageing face, which may include peels and dermal fillers.

Miscellaneous surgical procedures

Techniques

Hydrodissection

The skin can be lifted away from underlying critical arteries and veins by hydrodissection. Approximately 20 mL of saline is injected into loose tissue below the lesion, thereby lifting the area to be excised off any underlying vital structures. The injection must be given after local anaesthesia, just before excision. The technique works best where there is a boundary that will delay the spread of the saline, for example on the temple and the ear [1].

Snip excision

Small tags can be snipped off with a pair of sharp scissors without the need for local anaesthetic [2]. The tag should be pulled away from the skin and snipped off at its base; bleeding usually stops spontaneously. Haemostasis may be a problem with larger polyps with a well-developed blood supply; hence, an anaesthetic will be required. The wounds can be left to heal by second intention, with excellent cosmetic results [3].

Relaxing incisions

Relaxing incisions are one of several techniques used to increase skin mobility. Multiple, small, full-thickness incisions are made parallel to the skin edge at the site of greatest wound tension [4]. These allow the skin to stretch like a meshed graft, resulting in small elliptical defects, which heal by second intention. The technique is particularly useful for excisions on the lower leg, where it produces surprisingly good cosmetic results with less morbidity than split- or full-thickness grafts. The technique can be used with other ways of improving skin mobility [5]. Other types of relaxing incision include the V–Y-plasty [6], which should not be confused with the V–Y island pedicle advancement flap (Table 78.4).

Wedge excision—lip, lid and ear

On the eyelid, lip and ear, a tumour can be excised and the defect readily closed by removing a full-thickness wedge with an appropriate margin of uninvolved skin. The different layers at the defect edges are then sutured, and thus the technique varies with the site. The inherent tissue elasticity of the eyelid and lip allows considerable defects to be repaired by direct closure without distorting the free margins of these structures. On the lip, defects smaller than one-third of the lip length can be closed directly following a wedge excision [7], if necessary using a W-plasty correction on the lower lip to avoid excessive distortion [8]. On the eyelid, defects of up to 50% can be closed directly, provided the correct technique is used [9]. However, a wedge excision on the ear reduces its size considerably, and buckling of the ear may occur unless the technique is modified to avoid this [10]. In most instances this type of defect is not a problem, as spectacles can still be supported by the ear and differences in ear size are rarely noticed.

Fig. 78.18 Subfrontalis lipoma. This lipoma lies beneath the frontalis muscle. The muscle has been split vertically and is held back with forceps to reveal the lipoma.

Lipoma removal

Simple skin incision and lipoma excision ensures complete removal but produces a large scar. Scar size can be minimized by breaking up the lipoma into smaller fragments using blunt-ended forceps or a needle-holder inserted via a 4–6-mm punch biopsy wound made over the centre of the lipoma. The fragmented contents can then be squeezed out through the small wound. The fat can also be removed using liposuction [11]. A further development of this technique involves emulsification of the lipoma using an ultrasonic suction scalpel and removal of the fragments under endoscopic control [12]. A subfrontalis lipoma (Fig. 78.18) must be distinguished from a forehead epidermoid cyst. This can be particularly difficult to remove because of its site beneath the frontalis muscle of the forehead [13].

Tissue expansion

Tissue expansion may be helpful if there is insufficient local skin laxity to allow immediate closure and a graft

would produce a relatively poor cosmetic result. The skin needed to fill the defect can be stretched to the required size by steadily expanding saline-filled plastic bags placed under the skin adjacent to the proposed defect. For 8–12 weeks after insertion the bags are filled at intervals to produce a mound that stretches the overlying skin. When the defect is excised, the adjacent distended skin is then available to cover the resulting defect [14]. Because the skin used is almost identical to the piece excised, the cosmetic result is potentially excellent. Expansion does not simply stretch existing skin but actually appears to induce basal layer mitotic activity, an increase in dermal collagen, and development of an enhanced blood supply from the fibrous capsule around the implant. Atrophy of adjacent fat and muscle also occurs. By contrast, immediate tissue expansion or stretching the skin at the time of operation using skin hooks, Foley catheters [15] or sutures [16] increases available skin in the short term but appears to result in greater shrinkage and hence scar stretching.

Circumcision

This simple surgical procedure [17] may be indicated in the management of lichen sclerosus et atrophicus.

Specific diseases

Epidermoid cysts

Epidermoid cysts (sometimes incorrectly called sebaceous cysts) are lined by a keratinizing epithelium, which produces the cheesy, keratinous contents. Epidermoid cysts require excision if they are disfiguring or repeatedly infected. The inflamed tissue around an infected epidermoid cyst is friable, making it difficult to excise without fragmenting the cyst wall. An infected cyst should therefore be drained, and the patient treated with an appropriate antibiotic. When the inflammation settles the cyst can be excised. Cysts inflamed as a result of a foreign body giant cell reaction to released keratin are best treated by triamcinolone injection followed by subsequent removal. Freely mobile cysts can be easily shelled out through the smooth tissue plane that separates the very thin cyst wall from the surrounding tissue, although at this plane the cyst wall is easily punctured and must be handled gently. In all cases the entire cyst wall and punctum should be removed, the latter at the centre of a small skin ellipse, which can also be used to manipulate the cyst during removal. If the cyst ruptures during extraction, every effort should be made to remove residual wall fragments to prevent recurrence. To avoid long scars, very large cysts can be decompressed via a 4-mm punch biopsy before excision [1]. The wound is either left to heal for 4–6 weeks before definitive removal of the shrunken cyst or an attempt can be made to pull the cyst inside out through the circular wound using artery forceps [2]. Immobile cysts are surrounded by extensive scar tissue and usually have to be excised with the surrounding fibrotic tissue and overlying skin.

Hidradenitis

If medical treatment of hidradenitis suppurativa has failed, involved areas can be excised and the defects covered with skin grafts or flaps. However, cure rates of less than 20% are reported [3] and secondary infection is a frequent problem [4]. Alternatives such as excision followed by healing by second intention are well tolerated by the patient and produce good results [5]. An even simpler procedure involves deroofing the fistula leaving the floor of the track to re-epithelialize the wounded area. Excised tissue or suspect areas should be sent for histology because of the recognized complication of malignant change [6].

Vermilionectomy

This is sometimes called a mucosal advancement [7,8]. The vermilion, usually of the lower lip, is excised, principally because of actinic damage, and replaced by lip

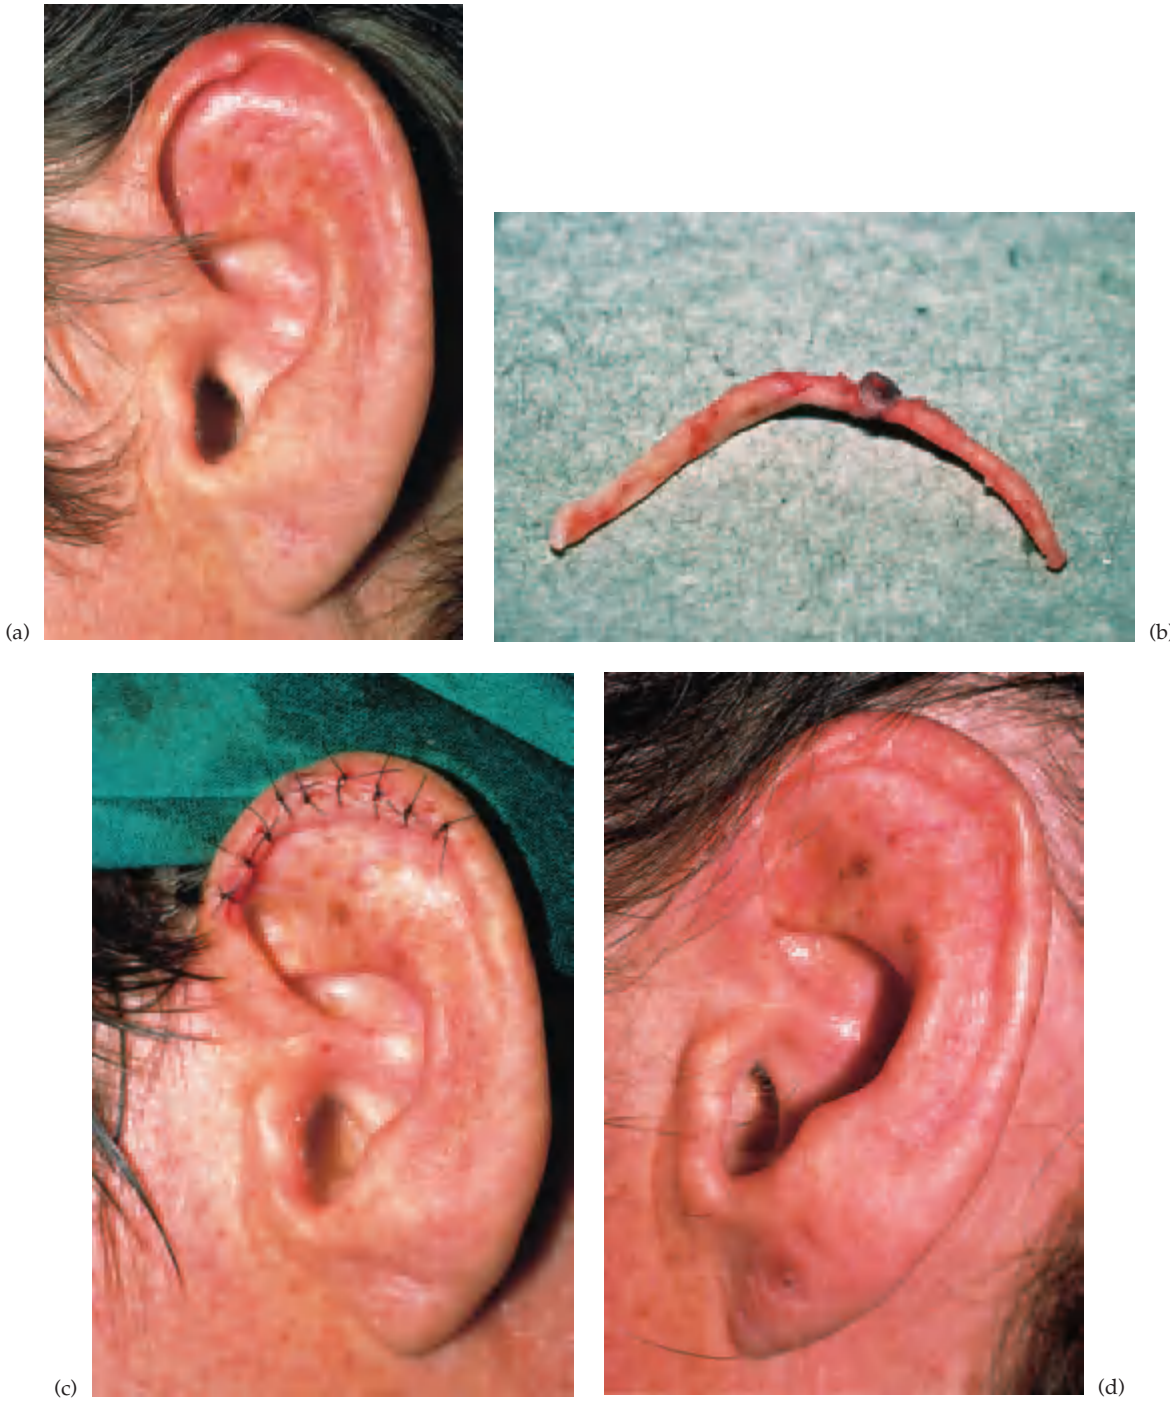

Fig. 78.19 Excision of chondrodermatitis nodularis helicis. (a) This helix nodule was treated by cartilage excision. An incision was made along the helix rim and the skin reflected to expose the cartilage. (b) A sliver of cartilage was taken to include the 3-mm punch biopsy of the skin nodule. Care was taken to ensure that the cartilage edges were smooth and gently shelving up to the uninvolved cartilage. (c) The skin edges were then sutured. (d) The result at 6 months was good.

mucosa pulled forward and sutured at the vermilion/skin border.

Split ear lobe

Split ear lobes may be congenital, or occur as a result of trauma or wearing heavy earrings. Simply de-epithelializing the sides of the cleft and suturing the exposed edges

usually results in a notch appearing at the lobe edge. A full thickness or single-sided Z-plasty correction of the cut edges, depending on lobe thickness [9], is advocated as the best way to ensure good cosmesis, although many other methods are described [10].

Partial or incomplete clefts can be repaired by excising and suturing the enlarged hole. However, if there is only a narrow band of skin separating the hole from the lower pole of the lobe, it is probably best to create a complete defect by cutting the small bridge of skin and closing the defect accordingly. Earrings can be worn again only in patients with thick lobes. Some repairs incorporate reconstruction of a new earring hole at the same time as repair of the defect [11].

Chondrodermatitis nodularis

Intralesional and topical steroids help in approximately 25% of cases. Surgical excision of the affected cartilage without removal of skin (Fig. 78.19) will result in cure in over 90% of helix lesions and 70% of those on the antihelix [12]. Recurrences will occur if rough or protuberant edges of cartilage are left at operation, but can be treated using the same technique [13]. Other methods, including cryotherapy, curettage and laser ablation, have been used, but with mixed and unpredictable results.

Myxoid cysts

Myxoid cysts are ganglia arising as a result of joint fluid leakage from the distal interphalangeal joint into the surrounding tissues. The principle of treatment is that the connection between the cyst and the adjacent joint must be disrupted to prevent the cyst refilling. This is presumably what happens after successful cryotherapy [14], intralesional steroid therapy or curettage, although the cure rate of these procedures is relatively poor. The connection between the joint and the cyst can be identified by injection of dye into the joint [15]. Dye injection, however, is difficult and not essential. The joint fluid leakage site can be assumed to lie between the proximal portion of the cyst and the joint. A proximally based flap can be raised, to include the cyst and skin between the cyst and joint. The cyst is incised and drained. The flap is then resited (Fig. 78.20). The resulting scar presumably seals off the leak from the joint capsule [16].

Axillary vault excision and other remedies for hyperhidrosis

Axilla. If medical treatments fail (see Chapter 45), botulinum toxin (see p. 78.31) can be used, and this blocks sweating for 4–6 months [17]. Axillary hyperhidrosis can also be treated by excision of the sweat-gland bearing axillary skin [18]. The operation is not difficult, but wide excision scars invariably stretch, and infections are common. Shelley described the use of a transverse excision in the centre of the hair-bearing dome of the axilla approximately 4.5×1.5 cm wide [19,20]. The sweat glands can be visualized on the undersurface of the adjacent skin and many of these can be snipped off or destroyed by electrodesiccation when the skin edges are undermined and everted. A light pressure dressing is applied for 24–48 h, and the wound is then left undressed and cleansed daily with a bactericidal antiseptic. Methods that attempt removal of the sweat glands using subcutaneous curettage [21] or liposuction [22], leaving the skin intact, are also described.

Palmar hyperhidrosis is difficult to treat. Endoscopic transthoracic sympathectomy [23] involves division of the sympathetic trunk running over the posterior wall of the chest cavity. However, side effects are significant, and over 80% of individuals develop compensatory sweating [24]. There is also a risk of Horner's syndrome and pneumothorax. In approximately 10% of cases [25], some recurrence of sweating occurs 1–2 years after surgery. The technique can also be useful in Raynaud's disease [26]. A similar approach can be used to reduce axillary sweating, when the second to sixth thoracic ganglia have to be destroyed. Access below the third thoracic ganglion is difficult, and this is believed to account for the poorer cure rate for axillary sweating [27]. Patients can also be successfully managed by repeated botulinum. Injections into the palm. The effects last about 6 months. Injections are painful. Transient weakness of the small hand muscles occurs in 40% [28].

Cosmetic procedures

Scar revision including acne scar correction

Pitted or 'ice-pick' acne scars can be treated by dermabrasion [1], very deep pitted scars do well with punch grafting [2] and the wide depressed scars respond to soft-tissue augmentation techniques including collagen [3] and Fibrel injections [4]. The flat purple–pink scars are best left to improve with time. Scar revision after surgery includes dermabrasion, which is best done 6 weeks postoperatively [5], and the treatment of keloids or hypertrophic scars [6].

Liposuction (lipectomy)

This involves selective removal of subcutaneous fat using a small cannula and suction equipment to produce a slimmer body shape [7]. The technique can be used at almost any body site, and can produce impressive results when performed by an experienced physician. Tumescent anaesthesia [8] evolved from the need to do liposuction under local anaesthesia; as a consequence it has become apparent that higher maximal lidocaine doses are possible using dilute anaesthetic solutions [9]. Liposuction has also been used to treat lipomas [10] and insulin-induced fat hypertrophy [11], in flap undermining, lymphoedema [12], breast reduction, lipodystrophy [13] and axillary hyperhidrosis [14], and to remove haematomas or extravasated corrosive drugs [15].

Blepharoplasty

This involves the removal of redundant skin and orbital fat from the upper [16] and lower [17] eyelids in order to correct unsightly bags or skin folds. Selection of the correct procedure to take account of individual variations in eyelid anatomy, identification of pre-existing eye disease, meticulous technique and the ability to adapt or include other procedures depending on the coexisting abnormalities present make this an operation for the expert [18]. Complications include blindness [19], excessive sclera show or ectropion, and failure to correct the original defect.
