7 Rohleder N, Schommer NC, Hellhammer DH *et al.* Sex differences in glucocorticoid sensitivity of proinflammatory cytokine production after psychosocial stress. *Psychosom Med* 2001; **63**: 966–72.

Pathology [1,2]

The histological changes are not specific, and are those of a subacute or chronic eczema. In infancy, early lesions show acanthosis and sometimes spongiosis, oedema of the dermis and infiltration with lymphocytes, histiocytes, plasma cells and eosinophils, sometimes in large numbers. In later age groups, the histology is that of lichenification, sometimes with more eosinophils in the dermis than are found in lichen simplex, and with an increase in the number of Langerhans' cells. Eosinophilia in tissues as well as in peripheral blood is found in many cases of atopic dermatitis, but is of no help in determining the role of allergy in producing the symptoms.

Clinical features

Atopic dermatitis is an itchy, chronic, fluctuating disease that is slightly more common in boys than girls. The age of onset is between 2 and 6 months in the majority of cases, but it may start at any age, even before the age of 2 months in some cases.

The clinical features include:

1 Itching
2 Macular erythema, papules or papulovesicles
3 Eczematous areas with crusting.
4 Lichenification and excoriation
5 Dryness of the skin
6 Secondary infection.

The distribution of the eruption varies with age, as described below.

Infantile phase

The lesions most frequently start on the face (Fig. 18.5), but may occur anywhere on the skin surface. Often, the napkin area is relatively spared. When the child begins to crawl, the exposed surfaces, especially the extensor aspect

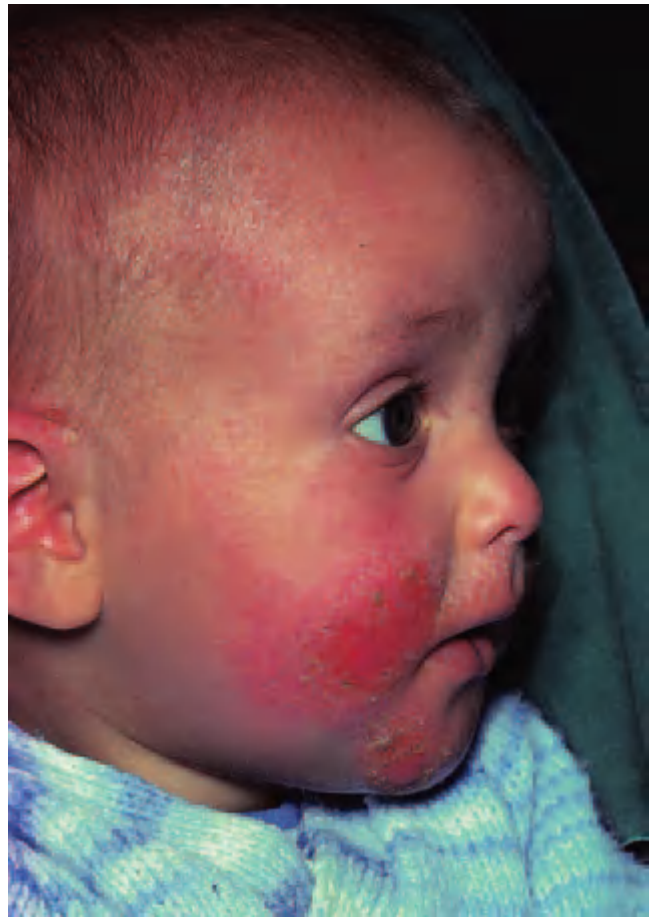

Fig. 18.5 Atopic dermatitis: infantile phase.

Fig. 18.6 Flexural atopic dermatitis of the wrist in a child.

Fig. 18.7 Atopic 'dirty neck'. Reticulate pigmentation on the neck of a patient with long-standing atopic dermatitis.

of the knees, are most involved. The lesions consist of erythema and discrete or confluent oedematous papules. The papules are intensely itchy, and may become exudative and crusted as a result of rubbing. Secondary infection and lymphadenopathy are common. The disease runs a chronic, fluctuating course, varying with such factors as teething, respiratory infections, emotional upsets and climatic changes.

Childhood phase

From 18 to 24 months onwards, the sites most characteristically involved are the elbow and knee flexures, sides of the neck, wrists and ankles [1] (Fig. 18.6). The sides of the neck may show a striking reticulate pigmentation, sometimes referred to as 'atopic dirty neck' [2,3] (Fig. 18.7). The anatomical basis for this distribution is unknown. Sometimes only one site is involved. The erythematous and oedematous papules tend to be replaced by lichenification. Some patients with atopic dermatitis (Fig. 18.8) are apparently unable to lichenify, even after prolonged rubbing, and they may be very difficult to treat. Patients with an extensor distribution of eczema in later childhood are uncommon, and may take longer to remit. This distribution is said to be commoner in Asian or black children (Fig. 18.9), but frequently they show the typical distribution [4]. As well as the typical mixture of papules and lichenification, true eczematous lesions with vesiculation may occur, often in discoid patches. Involvement of the hands, often with exudative lesions, and sometimes with nail changes, is common (Figs 18.10 & 18.11). Acute generalized or localized vesiculation should always suggest the possibility of secondary bacterial or viral infection (p. 18.21).

Fig. 18.8 Atopic dermatitis: erythema, papules, excoriations, crusting and secondary infection but, in this case, little lichenification.

Fig. 18.9 Marked lichenification on the knees of an African child. The popliteal fossae were spared.

Adult phase (Fig. 18.12)

The picture is essentially similar to that in later childhood [5], with lichenification, especially of the flexures and hands. Localized patches of atopic dermatitis can occur on

Fig. 18.10 Atopic eczema of the fingers of a child.

Fig. 18.11 Nail involvement in atopic dermatitis in childhood.

Fig. 18.12 Adult flexural dermatitis.

the nipples, especially in adolescent and young women. Involvement of the vermilion of the lips and the adjacent skin is commonly an atopic manifestation. Follicular lichenified papules are a frequent feature in black people and the Japanese. A distribution on the face, upper arms and back may correlate with areas of maximal thermal sweating or *Malassezia* sensitivity [6]. Photosensitivity is not uncommon, especially in adults with atopic dermatitis. The mechanisms involved are several and complex. Many such cases do not show sensitivity when tested with the monochromator. Rajka [7] has suggested that infrared and ultraviolet radiation may both contribute. Management of such cases requires a combination of approaches used for ordinary atopic dermatitis and for photosensitivity, neither alone sufficing.

Atopic hand eczema (see Chapter 17)

A patchy, somewhat vesicular and lichenified eczema is a common manifestation of atopic dermatitis in childhood. The nails are often involved, resulting in coarse pitting and ridging. The picture may closely resemble the discoid eczema of young adults, in whom it is not usually so apparently linked with an atopic predisposition. A more diffuse, chronic lichenified eczema of the hands is frequently found in cases of extensive atopic dermatitis which persist into adult life, and atopic dermatitis is frequently a contributory factor in many cases of what usually has to be called constitutional hand eczema [8]. A previous history of atopic dermatitis is also a significant factor in the development of occupational dermatitis [9]. Involvement of the feet is also common and almost half the patients with atopic hand eczema will have eczema on the feet [10].

Associated disorders

Other manifestations of atopy (Fig. 18.13)

Allergic rhinitis (hay fever) and asthma are beyond the scope of this book. They occur in 30–50% of cases of atopic

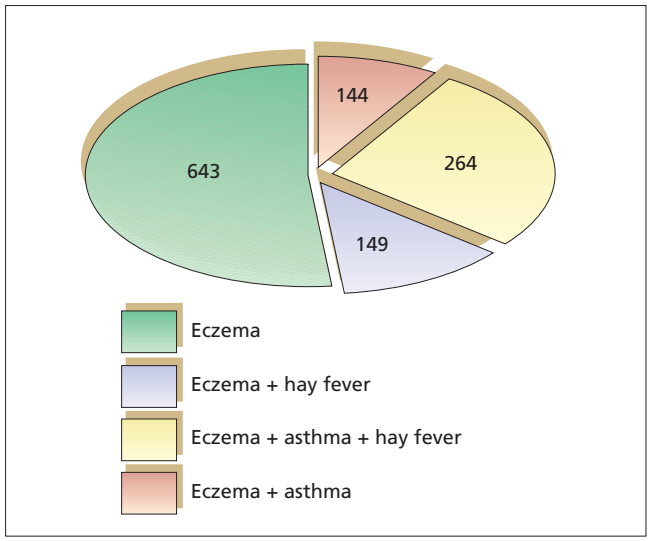

Fig. 18.13 The incidence of atopic respiratory symptoms in 1200 patients with atopic dermatitis. (From Rajka [2].)

eczema [1–3]. The age of onset is later than that of the eczema. Latent asthma may be detected by bronchial inhalation tests in a proportion of patients with atopic dermatitis without clinical asthma.

Dry skin

This is a common feature of atopic dermatitis and figures prominently in its management. It is likely that it occurs because of increased transepidermal water loss through an abnormal stratum corneum [4,5]. Recent studies have suggested that it may be a consequence of abnormal ceramide synthesis and have an important role in the development of inflammation. Ceramide-containing emollients may be helpful in managing the condition [6]. Ichthyosis vulgaris and keratosis pilaris may also be seen in association with the condition.

Other patterns of eczema

Infantile seborrhoeic dermatitis

This condition is discussed in Chapter 14. It normally starts earlier than atopic dermatitis, and it may be possible to distinguish between the two conditions clinically [7]. However, there are a number of children who present with what appears to be seborrhoeic dermatitis and then progress to typical atopic dermatitis [8].

Allergic contact dermatitis

It is clear that atopic dermatitis patients are at greater risk of developing irritant contact dermatitis than non-atopic patients [9]. However, there is a dispute about whether they are at greater risk of developing allergic contact dermatitis [10]. Nonetheless, patients can develop sensitivity to a variety of contact allergens such as topical medicaments, including topical corticosteroids [11,12]. Recently, the risk of protein contact sensitivity, such as that associated with latex in rubber gloves, has been highlighted [13,14].

Fig. 18.14 Lip-lick cheilitis.

Lip-lick cheilitis

SYN. PERIORAL ECZEMA; 'LICK ECZEMA'

Moist or fissured eczema around the mouth is common in children with atopic dermatitis. It can also occur as a result of food allergy, and in children with no known atopy or allergy. Frequently spreading some distance around the mouth, it may become secondarily infected and crusted (Fig. 18.14). Its persistence, and perhaps its origin, is attributable to habits of lip licking, thumb sucking, dribbling or chapping. It is easily transformed into a true perioral dermatitis by the application of potent corticosteroids (Chapter 44). The regular application of 1% hydrocortisone ointment is usually most helpful. Contact sensitivity, for example to toothpaste ingredients, can occasionally be demonstrated.

Several other patterns of eczema are seen in individuals with atopy, but they are also seen in non-atopic individuals. These include eczema with a predominantly follicular accentuation, and discoid eczema. Certain well-defined conditions appear more common in atopic individuals; pityriasis alba and juvenile plantar dermatosis are discussed in Chapter 17. Nodular prurigo can quite frequently complicate the atopic diathesis (Chapter 17).

Infra-auricular dermatitis is quite frequently seen in atopic dermatitis patients, and infra-auricular fissures appear to be quite specific to atopic dermatitis [15].

Drug sensitivity

Drug reactions of the anaphylactic type are more common in atopic persons because of the increased propensity to

produce IgE after natural exposure to antigens. Anaphylactic reactions to injected antigens can occur in persons with no other atopic manifestations. Anaphylactic reactions to topically applied drugs have been reported [16]. Other types of drug reaction with different immunological mechanisms occur with equal frequency in atopic and non-atopic individuals.

Reactions to insect stings and bites

The frequency of reactions to insect stings is similar in non-atopic and atopic populations [17].

Food allergy

Abdominal symptoms due to food allergy are more frequent in patients with atopic disorders, but are not restricted to them. The role of food allergy in asthma and allergic rhinitis is probably minor. The role of food intolerance in the management of atopic dermatitis is discussed on p. 18.28.

Alopecia areata

There is a statistically significant association between alopecia areata and atopy.

Urticaria

The majority of cases of urticaria cannot be shown to be due to IgE or any other allergic sensitivity. Those cases in which an allergic basis is found occur more often in atopic individuals (Chapter 47). Contact urticaria—for example, on the hands—occurs not infrequently in atopic dermatitis, and may present as an acute exacerbation of the dermatitis [18]. It occurs particularly in food handlers and slaughterhouse workers [19], and more recently has been reported in health carers because of latex protein sensitivity [13].

Complications

Impact on quality of life

Psychosocial aspects

Atopic dermatitis has a profound effect on many aspects of patients' lives and the lives of their families [1–4]. In children, one of the most disturbing impacts of the disease is on the sleep pattern. This can lead to behavioural difficulties in the most severely affected children [5,6]. The patient's dermatitis can also interfere with the functioning of the family [7]. Increasingly, a demonstration of improvement in the quality of life of patients forms part of the assessment of new therapies [8].

Growth delay

Growth delay can be associated with atopic dermatitis [9]. It used to be seen in severe cases before the advent of corticosteroid therapy, and can therefore be attributed to the disease. However, suspicion must also clearly rest on both oral and topical steroid therapy, which can cause growth stunting in any child on long-term therapy [10]. Prepubertal children with atopic dermatitis show features consistent with constitutional growth delay [11].

Bacterial infections

Secondary bacterial infection with staphylococci or streptococci is virtually an integral part of the clinical picture [12]. It contributes to many exacerbations of the disease, even without grossly visible purulent exudate. Widespread impetigo may sometimes closely mimic Kaposi's varicelliform eruption. Indeed, any acute vesicular eruption in an atopic should suggest the diagnosis of secondary bacterial or viral infection.

Fig. 18.15 Kaposi's varicelliform eruption: eczema herpeticum.

Viral infections

Patients with atopic dermatitis, both active and quiescent, are liable to develop acute generalized infections with herpes simplex (eczema herpeticum) and vaccinia (eczema vaccinatum) viruses, to produce the clinical picture of Kaposi's varicelliform eruption (Fig. 18.15) [13] (see Chapter 25). Such episodes may present as a severe systemic illness with high fever and a widespread eruption. However, there may be no systemic disturbance, and at times the eruption may be quite localized, often to areas of pre-existing atopic dermatitis. The individual lesions start as the characteristic viral papulovesicles, but not necessarily with a herpetiform grouping. There may then be rapid evolution to a state in which extensive purulent exudate masks the initial papulovesicles, or superficial scattered erosions may be the only clue to the cause of a rapid deterioration of the dermatitis. The differential diagnosis includes bacterial impetigo and chickenpox. Herpes zoster and chickenpox apparently behave as in normal persons.

There is a lack of agreement about whether viral warts are more prevalent in atopic dermatitis. An initial uncontrolled study suggested an increased frequency of viral wart infections [14], but a more recent epidemiological study cast doubt on this observation [15].

Similarly, the frequency of molluscum contagiosum in such patients is not clear. However, the clinical impression is that widespread molluscum contagiosum is more common in the atopic child.

An abnormal response to a Coxsackie infection in an atopic has been described [16]. Acquired immune deficiency syndrome (AIDS) may aggravate atopic dermatitis, and 'recall' atopic dermatitis has been described in AIDS patients [17]. A condition resembling atopic dermatitis has been seen in association with human T-lymphocyte virus type I (HTLV-I) infection (see Chapter 17) although this may be coincidental [18].

Sudden death

Sudden death was once reported to occur, especially in young infants with severe atopic dermatitis soon after admission to hospital [19]. However, it is now extremely uncommon.

Ocular abnormalities (see also Chapter 63)

A number of ocular changes can occur in atopic dermatitis [20]. The Dennie–Morgan fold is often present as a fold of skin under the lower eyelids [21]. However, this change is not specific to atopic dermatitis, and is commonly seen in non-atopic black children [22].

Conjunctival irritation is a common syndrome in atopic persons. As in hay fever, it may represent a true allergic reaction, or it may be due to a non-allergic irritability such as occurs in the nose or skin. Keratoconjunctivitis has been recorded [23].

Keratoconus [24,25], or conical cornea, is a rare condition. It may occur in the absence of any other disease or in association with atopic dermatitis. It is due to a degenerative change in the cornea, which is forced outwards by the intraocular pressure, to give rise to marked visual disturbances. Onset is in childhood, and after some years progress of the disease becomes arrested. Contact lenses may be helpful.

Cataract associated with atopic dermatitis (Fig. 18.16) has certain peculiarities which distinguish it from other types of cataract [24]. It occurs in up to 10% of the more severe adolescent and adult cases, but overall it is uncommon. It is associated with atopic dermatitis rather than with other atopic diseases. It may start in early childhood or up to the age of 30 years, but the peak incidence is between 15 and 25 years. It is almost always bilateral. The appearances on slit-lamp examination are characteristic, but not diagnostic. In the early stages, translucent glob-

Fig. 18.16 Atopic cataract.

ules and small opacities appear at the pole in front of the posterior capsule and also in the anterior subcapsular zone. Progression may be slow, or alarmingly rapid over a few days, and seems to be related to severe facial involvement [26]. The final appearance may resemble a mature, cortical, senile cataract.

Atopic cataracts may resemble those induced by topical or systemic steroids. The potential for cataract formation is an important reason for examining the eyes of any patient with atopic dermatitis when psoralen and ultraviolet A (PUVA) therapy is being contemplated.

Retinal detachment has been reported, particularly in Japanese patients [27], and appears to be identical to the retinal detachment seen following trauma [28].

Miscellaneous

Cartilaginous pseudocyst of the external auricle may be more common in children with atopic dermatitis [29], as may olecranon and pretibial bursitis [30]. A case of Sézary syndrome has been described in a patient with severe atopic dermatitis [31].

Natural history and prognosis [1–5]

Hospital-based studies suggest the age of onset is less than 6 months in 75% of cases and before the age of 5 years in 80–90%. However, community-ascertained cases may have a later age of onset than that reported in hospital-based studies [6]. The reported prognosis differs considerably according to how the cases are selected, the criteria for diagnosis, and many other variables. There is a general tendency towards spontaneous improvement throughout childhood and often some slight relapse during adolescence. Relatively few typical cases persist over the age of 30 years; perhaps half of all cases clear by the age of 13 years. The reported clearance rates range from 40% to 60% within 10–20 years [2,6]; 84% within 5–20 years [5]; and

50% at 10 years [3]. There is often a change in the distribution of the rash from the head and face to the flexural areas at around the age of 2 years (p. 18.18).

It is difficult to predict the prognosis in an individual case. It is worse if both parents are affected. The severity in infancy and the natural history in other members of the family serve as rather unreliable guides. The personality of the child and its parents, and environmental factors, are equally important [2,3]. The presence of a pronounced epidermal component adversely affects the prognosis; such cases are also more likely to develop ocular complications. Some 30–50% of cases of infantile eczema subsequently develop asthma or hay fever [7,8]. The atopic patient remains particularly at risk from occupational irritant hand dermatitis as an adult [9].

Diagnosis

The diagnosis of atopic dermatitis is usually based on clinical criteria. The UK refinements of the Hanifin and Rajka's diagnostic criteria (see Table 18.1) appear to be valid for both adults and children of white and non-white groups. However, these criteria were developed primarily for epidemiological use and were considered less reliable in children under 1 year of age.

Differential diagnosis

In the individual patient, one must consider a number of other conditions. Scabies should always be excluded, and can cause confusion when superimposed on pre-existing atopic dermatitis. In the first few months of life, the differentiation of infantile seborrhoeic dermatitis from atopic dermatitis can be difficult [1], although with time the distinction becomes apparent. Immunodeficiency states should also be considered in infants in whom the disease is unusually severe, when there are recurrent systemic or ear infections, and if there is failure to thrive, malabsorption or petechiae. Recurrent infected eczema in Jamaican children may be associated with HTLV-I infection (Chapter 17).

In adults, flexural eczema may be a consequence of secondary dissemination of other types of eczema, for example in nickel allergy.

Genetic and metabolic disorders

An eruption resembling atopic dermatitis, with or without other atopic disorders, and sometimes with raised IgE levels, may be found in several syndromes:

1 Agammaglobulinaemia
2 Anhidrotic ectodermal defect
3 Ataxia–telangiectasia
4 Coeliac disease [2]
5 Cystic fibrosis heterozygote [3]
6 Experimental histidine depletion [4]
7 Hearing loss (genetic) [5]
8 Hurler's syndrome
9 Jung's disease (Chapter 17)
10 Nephrotic syndrome [6]
11 Netherton's syndrome (ichthyosis, bamboo hairs) [7]
12 Phenylketonuria
13 Wiskott–Aldrich syndrome (infections and thrombocytopenia).

A rash resembling atopic dermatitis is common in phenylketonuria, although disturbances in phenylalanine metabolism cannot be detected in ordinary atopic dermatitis.

Hyper-IgE syndrome [1,2]

SYN. JOB'S SYNDROME; BUCKLEY'S SYNDROME

This is a syndrome which develops in infants or children. It resembles atopic dermatitis, but tends to involve particularly the scalp, axillae and groins. The associated features include persistent secondary bacterial infection, fluctuant cold abscesses, contact urticaria, bronchitis and more severe lung damage. The key laboratory finding is the great

elevation of serum IgE levels (greater than 2000 i.u./mL), often with some eosinophilia. Other immuno-globulins are often normal. Neutrophil chemotaxis is impaired.

Hypereosinophilic syndrome [1,2]

Eosinophilia is a common feature of many diseases, including several skin diseases. However, the hypereosinophilic syndrome is a rare disorder, usually affecting middle-aged males, in which there is an intense blood eosinophilia in the absence of any of the usual causes. Only a few such cases can be attributed to an eosinophil leukaemia. The clinical manifestations appear to be attributable to the eosinophilia itself, and include cardiac involvement, and involvement of the nervous system, liver, lungs and gut. The skin changes include a non-specific, itchy, maculopapular eruption; urticaria or angio-oedema; an eruption resembling atopic dermatitis; or erythroderma [3,4]. Lymphomatoid papulosis [5] and aquagenic pruritus have also been associated. Distinguishing between atopic dermatitis and cases in which only the skin is involved may be difficult or even semantic. Treatment of cases with severe organ involvement is unsatisfactory, but has included the use of systemic steroids and cytotoxic drugs such as hydroxyurea.

Pachydermatous eosinophilic dermatitis

Nir and Westfried described a generalized rash associated with marked blood and skin eosinophilia, and called it hypereosinophilic dermatitis [1]. More recently, a variant of this disorder has been described in three black South African teenage girls, and designated pachydermatous eosinophilic dermatitis [2]. This condition is thought to resemble severe atopic dermatitis or onchodermatitis. However, the three patients had peculiar hypertrophic genital lesions, peripheral blood eosinophilia and an eosinophil-rich lymphohistiocytic cutaneous infiltrate.

Investigation

The diagnosis of atopic dermatitis is rarely aided by investigations. Estimation of total serum IgE, specific radioallergosorbent tests (RASTs) and prick tests usually serve only to confirm the atopic nature of the individual. It is possible that such confirmation may be of value occasionally in adult-onset dermatitis. However, one must remember that 20% of patients with atopic dermatitis have normal total IgE levels and negative RASTs, whereas 15% of apparently healthy individuals have a raised IgE [1].

The value of investigations in identifying trigger factors in atopic dermatitis is disputed. How helpful specific RASTs to foods or aeroallergens are for disease management is unclear [2–4], although it is suggested that if they are negative, allergy is unlikely [5]. It may be that skin prick test positivity to food allergens in young children with severe atopic dermatitis and a high serum IgE indicates a high risk of developing later allergic respiratory disease [6].

If one suspects immunodeficiency with atopic dermatitis, then the appropriate investigations should be performed—for example, immunoglobulin levels and subclasses, IgE levels, white-cell count, platelets, complement levels and function, and T, B and phagocyte cell numbers and functions. If clinically appropriate, one may also consider testing for HTLV-I and human immunodeficiency virus (HIV).

Bacteriology and virology swabs may be helpful in identifying causes for deterioration of atopic dermatitis. Although atopic dermatitis skin is often colonized by *Staphylococcus aureus*, bacterial culture can identify antibiotic resistance and detect β-haemolytic streptococci. Herpes simplex is usually readily cultured, but a Tzanck smear, an immunofluorescence slide test, or electron microscopy can also be helpful, and will provide more rapid confirmation of infection.

Patch testing may also help to identify a contact allergen responsible for deterioration of the skin condition, particularly in adults [7,8]. The 'atopy patch test' for aeroallergens [4] and foods [9] in atopic dermatitis, and the skin-application food test (SAFT) in the management of the IgE-mediated contact urticaria syndrome in children with atopic dermatitis [10], are recommended by some authorities.

Treatment [1–3]

Atopic dermatitis is a chronic condition that is variable in severity and age of onset. Many current therapies are based on small studies or even anecdotal evidence. Nevertheless, treatment should be tailored to an individual's needs, bearing in mind age, sex, social conditions, sites of involvement and severity. A treatment strategy based on consistent advice and cooperation between health carers and the patient should be developed. It is clear that these aspirations are frequently not realized in practice [4–6]. However, recent years have seen the emergence of several new treatments that hold promise for the near future (see below).

First-line treatment

General advice

In order to develop a strategy the patient's specific requirements (in the discussion below the term patient refers either to the individual or the carers in the case of a baby or child) should be discussed and achievable aims agreed. These may include improvement in a range of factors such as decreasing itch, improving sleep, reducing absenteeism from school/work or improving family interactions.

It is the clinician's responsibility to determine a balance between effective control of the condition and improved quality of life, and safe long-term therapy. Education about atopic dermatitis by doctors, nurse specialists, self-help groups and national support groups, is very helpful in achieving these aims. As part of the discussion, patients should be taught current knowledge of the disease, the types of trigger factors, the treatment options and their likely benefits and risks. Demonstration of the use of topically applied medications, bandages or wet wraps, will improve compliance and disease control [7].

Reduction of trigger factors

Atopic dermatitis can be aggravated by a variety of trigger factors. These will vary between patients, and may differ at various times in an individual patient.

Most patients have dry skin, and soaps and detergents can irritate the dermatitis [8]. A dispersible cream can be used as a soap substitute to cleanse the skin. Simple measures such as turning down the central heating, not heating the bedroom, avoiding contact of wool with the skin and wearing cotton clothing, may make life more comfortable for the patient.

Formal dietary manipulation is really a second-line treatment, but if the patient clearly identifies aggravating foods then avoidance can be tried. Many patients have already started a restricted diet before seeing a doctor, so dietary assessment is important to confirm adequate nutrition. Airborne allergens are also aggravating factors, but formal manipulation of the environment is not required for most patients. Regular cleaning of the bedroom in particular, with hoovering and damp dusting, may be helpful. Animal dander can aggravate atopic dermatitis and contribute to HDM antigen levels, and so the keeping of household pets should be discouraged. Flares of the dermatitis may be associated with the introduction of a new trigger factor into the environment, or even a new environment, such as a change of childminder, and so the trigger factor history should be reviewed frequently.

Not only can stress aggravate atopic dermatitis, but the severely affected child is also a source of stress to the whole family [9,10]. The doctor's role in giving simple reassurance and listening to family problems should not be underestimated. Stress can respond to treatment, and the dermatitis can be improved by using a variety of cognitive behavioural techniques and group therapy [11].

Atopic dermatitis is not a contraindication to routine childhood vaccinations. Although egg protein is present in some vaccines the amount is so small that it should not be a problem in practice, unless the child has documented severe systemic reactions to egg protein. If in doubt, vaccination should be supervised in an environment where resuscitation equipment is available.

Parents should be advised about the risk of herpes simplex infection in a child with atopic dermatitis, and told to avoid contact of active cold sores with the child's skin.

Topical therapy

The principles of topical therapy are discussed in Chapter 75, and knowledge of such principles is essential for

effective management of atopic dermatitis. In general, in chronic lesions of atopic dermatitis ointments are to be preferred, particularly when lichenification is prominent. In certain individuals, ointments can cause irritation, and less oily preparations may be required. If lesions are exudative, then creams or lotions may be required for a short time until ointments become more appropriate.

Bathing and emollients

Bathing is soothing for the majority of patients, and is helpful as long as the skin is moisturized immediately afterwards. Foaming detergents and soaps should be avoided and a soap substitute used for cleansing [8]. Dispersible bath oils are helpful, but do not maintain skin hydration as long as emollients applied immediately after the bath. The regular use of emollients may even protect against inflammation provoked by irritants such as detergent [12] and increase the benefit obtained from topical corticosteroid therapy [13]. Indeed, ceramide-rich emollients may lead to improvements in childhood atopic dermatitis through a specific barrier repair mechanism [14]. In order to identify the emollient which best suits an individual, it may be useful to provide small quantities of several agents, so that they may choose which they prefer. Then a generous quantity should be prescribed to encourage frequent use throughout the day.

Topical corticosteroids

Topical steroids are the predominant treatment for the inflammation of atopic dermatitis, and if not abused are very safe. Anxiety among both the general public and family doctors about potential adverse effects of topical steroids has led to undertreatment of the skin in many sufferers [15].

The strength and mode of application of the topical steroids depends on the severity of the dermatitis, the sites to be treated and the age of the patient. Less potent topical steroids should be used on the eyelids, the face, the axillae, and the groins and inner thighs. Less potent topical steroids are also usually employed in children who are less than 1 year old, because systemic absorption occurs even with 1% hydrocortisone ointment.

A general principle is to use a topical steroid strong enough to settle severe dermatitis by twice-daily application for 3–7 days, and then to reduce either the frequency of application or the steroid potency for maintenance therapy. In adults, a sequence of a potent steroid followed by a moderately potent steroid would be appropriate, whereas in children moderately potent and mild topical steroids are preferable. A recent study has shown no differences in efficacy or side effects between pulsed potent corticosteroid creams and the continuous use of mild topical corticosteroids in patients with mild to moderate disease [16]. Once-daily treatment in the evening, with morning application of emollients, may be as effective as twice-daily corticosteroid treatment.

Corticosteroid resistant or infected or crusted dermatitis may respond better to steroid/antibiotic or steroid/antiseptic combinations. However, in young children there is some concern about the potential systemic toxicity of some antiseptics, such as clioquinol, if large surface areas are to be treated.

Monitoring corticosteroid use. Topical steroids can cause side effects if abused. Complications related to systemic absorption are rare. It is advisable to educate patients about the quantities to apply—for example, the fingertip unit [17]—and to ask them to estimate the quantity used per month. Height and weight should be monitored in young children if they have severe dermatitis requiring moderately potent or potent steroids. Local side effects, such as permanent telangiectasis on the cheeks in babies and striae of the breasts, abdomen and thighs in adolescents, may be minimized if appropriate steroid strengths are used. Particular care is required around the eyes, as glaucoma may be induced by topical steroids [18].

Ichthammol and tar

Preparations containing ichthammol and coal tar may be helpful as maintenance treatment in patients with lichenification. Generally, a 1–10% coal-tar solution in an appropriate cream or ointment is preferred to crude coal tar. Localized areas can be treated with bandages impregnated with these agents applied overnight.

Oral therapy

Antihistamines

Itch is the most difficult symptom of atopic dermatitis to treat, and currently there is no specific antipruritic treatment [19]. The use of anti-inflammatory preparations and emollients, and reduction of trigger factors, are still the first measures.

H_1-receptor antagonists are used predominantly for their sedative effect [20]. Agents such as promethazine or trimeprazine given 1 h before bedtime can be useful when there is severe nocturnal itching. However, they can cause drowsiness and lack of concentration the next morning. In infants, these preparations may occasionally cause paradoxical excitation. They are best used in short courses, for example 10–14 days, as tachyphylaxis can occur with prolonged use [21]. Most studies conclude that non-sedating antihistamines are of little value for the pruritus of atopic dermatitis [20], but in some cases with an allergic component—for example, contact urticaria—they may be of value [22].

Antibiotics

Exudation and pustule formation often implies staphylococcal infection of the skin, and oral antibiotics such as flucloxacillin or erythromycin are indicated. Colonization of the skin by these bacteria may exacerbate the dermatitis, and antibiotics may be helpful even if frank infection is not apparent. In patients with recurrent flares of atopic dermatitis associated with infection, long-term antibiotic treatment, topical steroid-antibiotic combination creams, and measures to reduce staphylococcal colonization of the nose and perineum should be considered [23].

Herpes simplex infection should be treated with oral aciclovir. If the patient is febrile or toxic, intravenous aciclovir should be used.

Second-line treatment

The majority of patients will respond to first-line treatment regimens. Patients who fail to respond should be reviewed to check compliance, to exclude antibiotic-resistant infection or herpes simplex infection, and to consider second-line treatment.

Intensive topical treatment

The strength of topical steroid treatment can be increased for a short period as an outpatient. If this is ineffective, inpatient treatment will often control severe exacerbations of dermatitis, and the skin frequently improves using the same treatment that was unsuccessful as an outpatient.

Wet-wrap technique

This can be a useful technique for the control of severe atopic dermatitis in younger children. Two layers of absorbent tubular bandage are applied to the skin. The inner layer is presoaked in warm water and the outer layer is dry. A generous quantity of a low-potency topical corticosteroid is applied to the skin before the dressings. The dressings can be used overnight or changed every 12 h. This regimen can be used in hospital or for short-term outpatient treatment. Close supervision should be maintained, because suppression of the hypothalamopituitary axis can occur when topical steroids are employed [24]. Regimens using emollient only under the wet dressings have become popular, but have not been subject to adequate clinical trial.

Immunomodulatory creams

In recent years, research has been undertaken on two non-steroidal anti-inflammatory topical compounds, tacrolimus (FK-506) [25] and pimecrolimus (ascomycin; SDZ ASM 981), and these are increasingly available for clinical use.

Tacrolimus ointment has been shown to be effective and safe during treatment of up to 1 year in adults (0.1% ointment) and children (0.03% ointment) [26,27]. It is indicated for moderate to severe atopic dermatitis that has failed to respond to conventional therapies and does not cause cutaneous atrophy [28].

Pimecrolimus 1% cream is a selective inhibitor of inflammatory cytokine release that has shown very promising results in the management of atopic dermatitis in adults and children as young as 3 months of age [29,30].

Studies comparing these preparations with potent topical corticosteroids with respect to both efficacy and safety are awaited eagerly.

Allergy management

Eighty per cent of patients with atopic dermatitis show IgE hyperreactivity to common allergens. Some authorities argue that the intrinsic type (with no demonstrable IgE hyperreactivity) is important to identify because it will never progress to allergic respiratory disease and such patients will not benefit from allergy management [31]. Although it is clear that reactivity can be demonstrated *in vivo* and *in vitro*, it is less clear how well such reactivity correlates with clinical improvement following allergen avoidance.

Foods

Dietary factors may aggravate the dermatitis of 15–35% [32] of children with atopic dermatitis, but in older children and adults this is far less common. Approaches to dietary management range from intensive investigation using double-blind food challenges [33] to empirical diets [34]. The clinical benefit of dietary management is still debated, because there are few controlled studies of its value [32]. Even so, because some children benefit who have failed to respond to simple general and topical therapy, there is much to be said for a 3–4-week trial period on a modified elimination diet. Increased suspicion may be caused by a history of urticarial reactions or gastrointestinal reactions to foods. A positive specific raised IgE, particularly the specific circulating titres (IgE cap), may have a predictive value in young children [35,36]. Commonly, dairy produce, beef, eggs, chicken, fish, wheat, citrus and berry fruits, food additives, chocolate and nuts may be excluded. Decreased itch and improvement of the dermatitis show the benefits of a relevant exclusion diet. It is important that the diet is appropriately supervised by a paediatric dietitian. If such measures do not reveal an obvious dietary culprit, a normal diet can be resumed, with the suspected foods reintroduced every 3–4 days.

It must be remembered that there have been occasional severe anaphylactic reactions when a food to which an atopic is very sensitive has been reintroduced [37]. Fre-

quently, in children, an inadequate, unbalanced diet is given before medical advice has been sought, and malnutrition may be present, usually because of cow's milk avoidance. It is important to thoroughly review the child's diet with the help of a dietitian in these circumstances. Extensively hydrolysed cow's milk formulates can be used as a cow's milk substitute, and recently an amino acid-based formula has been found to be an effective substitute in children with dermatitis [38].

Breastfeeding for at least 6 months in infants with atopic dermatitis is usually suggested [32]. However, the protective effect of breastfeeding against the development of atopic dermatitis remains controversial [39].

In older children and young adults, dietary management is rarely helpful [40], and screening tests are not helpful in this age group (roughly over 6 years) because of false-positive reactions. However, occasionally patients benefit from a diet free from food additives [41].

Inhalants

Although a variety of inhalants have been implicated in exacerbations of atopic dermatitis [42], HDM allergen appears to be the most important [43]. Clinical improvement in children's dermatitis has been noted following intensive eradication of mite allergens from the bedroom [44,45]. However, the benefit of HDM eradication on adults with atopic dermatitis is less convincing [46]. There is some suggestion that early avoidance of airborne allergens, along with common dietary allergens, may reduce the chances of later developing atopic conditions [47].

Contact allergy

Contact urticaria is usually quickly recognized from the history, and avoidance of the responsible foods is advised. Tests to identify such foods are not usually required (see investigations).

Delayed hypersensitivity to medicaments and fragrances may be responsible for treatment failure, particularly in adults with periorbital eczema [48], and patch tests are useful if this is suspected. However, because of irritancy, interpretation of patch tests can be difficult in atopics. It may be necessary to admit the patient to hospital to settle the eczema before performing patch tests. Contact allergy may be found in children, and this possibility must not be forgotten [49].

Third-line treatment

Phototherapy

Numerous types of phototherapy have undergone trials for the treatment of severe atopic dermatitis, and seem to be effective. These include UVB, narrow-band UVB, medium and high-dose UVA1 and PUVA [50–53]. Some studies suggest that air-conditioned treatment cabinets improve patients' tolerance of phototherapy [54]. A practical consideration is the relative timing of the use of phototherapy and immunosuppressant therapy, because of concerns about skin cancer development in later life.

Oral immunosuppressants

A number of systemic therapies are available for recalcitrant cases. Limited effectiveness or concerns over toxicity may restrict their long-term usefulness.

Low-dose ciclosporin therapy has been shown to be effective in the control of adult [55] and childhood atopic dermatitis [56,57]. Occasionally, permanent remission appears to be induced [58]. Renal toxicity, hypertension and the risk of skin cancer are limiting factors.

Oral corticosteroids have a limited but definite role in the management of severe exacerbations of atopic dermatitis, but long-term treatment often requires doses which may produce significant adverse effects.

Some authors claim that long-term azathioprine may be less toxic than other oral immunosuppressives, but the onset of its effect is slow [59,60].

Other therapies

Evening primrose oil is often recommended for patients with atopic dermatitis. A meta-analysis of placebo-controlled studies suggested a slight benefit [61], but this is strongly disputed [62].

Clinical trials of Chinese herbal medicines have been performed, and decoctions of a standard formulation appear to be helpful in adults and children [63,64]. Concern has been expressed about their potential for hepatotoxicity [65].

The value of oral sodium cromoglycate is still unclear, but high doses may be helpful in some patients [66]. Topical sodium cromoglycate solution has been helpful in children [67]. Several other drugs have been reported to be effective in atopic dermatitis, including IFN-γ [68], thymopentin [69], type 4 phosphodiesterase inhibitors [70], intravenous immunoglobulins [71], oral ketoconazole [72], mycophenolate mofetil [73,74], and montelukast [75]. Extracorporeal photopheresis has also been shown to be of benefit [76].

Desensitization and immunotherapy

Desensitization plays a very limited part in the management of patients with atopic dermatitis, even when an allergic factor has been firmly established clinically [77]. Trials of hyposensitization have shown variable results [78], but occasional cases of atopic dermatitis may benefit. A recent review of immunotherapy concluded that there

were encouraging results, but the studies were small in size and few in number. A new area of study which promises hope of controlling skin disease is sublingual immunotherapy [79]. Other approaches to alter the immune status of atopic dermatitis sufferers have included the use of intradermal injection of killed *Mycobacterium vaccae* suspensions [80] and probiotic suspensions added to milk formulas in infants [81].

Disease prevention and occupational advice

There is conflicting evidence about whether maternal avoidance of milk, eggs and other dietary allergens during the last trimester of pregnancy and during lactation can reduce the incidence of atopic disorders [1,2]. The evidence that breastfeeding or diets to avoid potential allergens during the first 6 months of the infant's life will significantly protect against atopy or reduce its manifestations is also contradictory [1]. However, a cohort study of 1265 children followed for 10 years suggests that a diverse solid-food diet during the first 4 months of life roughly doubled the risk of developing atopic dermatitis [2]. It seems prudent to recommend breastfeeding children at special risk. There is interest in reducing exposure to dietary allergens, aeroallergens and irritants in children at high risk of developing atopic manifestations [3]. Some early evidence suggests that this approach may reduce the incidence of atopic manifestations [4].

Atopic dermatitis will often improve about the time of puberty. This is often the time when adolescents are deciding what occupation they should undertake. Exposure of the skin to irritant chemicals and physical trauma should be avoided as far as possible. Adolescents with atopic dermatitis would be well advised therefore to avoid occupations such as car mechanics, engineering, hairdressing or nursing.

Chapter 19

Contact Dermatitis: Irritant

S.M. Wilkinson & M.H. Beck

Introduction

Irritant contact dermatitis in a broad sense represents the cutaneous response to the physical/toxic effects of a wide range of environmental exposures. A burn results when the effect on the skin is irreversible and necrosis occurs. Reversible cellular injury may cause contact urticaria or dermatitis dependent on the nature of the insult. Where there is no apparent cellular injury various sensory symptoms such as stinging, smarting and burning may occur. The following types of irritant contact reaction may be distinguished:

1 Burns
2 Irritant contact dermatitis:
(a) acute (toxic) irritant contact dermatitis
(b) cumulative irritant/insult contact dermatitis
3 Transient or immediate-type non-immune contact urticaria
4 Symptomatic (subjective) irritant responses
5 Other: pigmentary and granulomatous responses and those localized to appendageal structures (Table 19.1).

Allergic contact dermatitis and light-related skin reactions are covered in Chapters 20 and 24. Damage to the skin from physical and mechanical factors, thermal injury and ionizing radiation is discussed in Chapters 22 and 76. Pigmentary, follicular and granulomatous responses are covered in Chapters 58 and 69.

Table 19.1 Other irritant contact responses of the skin and their causes.

Folliculitis	Tar and oils, arsenic trioxide, fibreglass
Acne	Halogenated aromatic hydrocarbons
Miliaria	Aluminium chloride, occlusion
Pigmentary	
Hyperpigmentation	Phototoxic agents, metals (arsenic, silver, gold, mercury, bismuth)
Hypopigmentation	Substituted phenols & catechols
Granulomatous	Silica, talc, beryllium
Alopecia	Borax, chloroprene dimers

History

Contact dermatitis was first described to plants as long ago as 2000 BC, when an extract of the castor oil bean was rubbed into the scalp, as an irritant, to promote hair growth [1]. Whilst presumably recognized, there appears to be little subsequent documentation of irritant contact dermatitis other than in an occupational setting. For example, Agricola documented deep ulcers of the skin amongst metal workers in 1556. The apparent lack of interest may date back to ancient times and the Greek prejudice against manual labour, as a result of which in some cities it was illegal for a citizen to ply a manual trade. Consequently, medical works tended to concentrate on the afflictions of the citizen rather than of the work force. Increased awareness of occupational disease is noticeable from the 1700s and the Industrial Revolution. Ramazzini (1633–1714) described fissures on the hands of washerwomen and ulcers on the legs of salt miners. In England, during the 19th century, there was a revival of interest in occupational dermatoses, with Willan describing

dermatitis from shoemaker's wax and Bateman eruptions due to lime amongst builders [2,3].

Epidemiology

Few population studies differentiate between irritant reactions and allergic contact dermatitis, and study populations are also often either selective or poorly defined. A questionnaire study of 20 000 persons in an industrial town in the south of Sweden [1] revealed a point prevalence of hand eczema of 5.4% (with a 1-year period prevalence of 11%). Females were twice as commonly affected as males, and in 35% of cases the hand eczema was thought to be irritant in nature. Atopic hand dermatitis accounted for 22% of cases, and allergic contact dermatitis only 19%. The most frequent sources of exposure were 'unspecified' chemicals, water, detergents, dust and dirt. Those involved in hairdressing, service work and medical and nursing occupations had the highest frequency of hand dermatitis. A retrospective study of hand eczema in Germany showed that 24% of those studied had an irritant pathoaetiology [2]. In one large study of adverse reactions to cosmetics [3], 16% were thought to be irritant in type.

'Sensitive skin' might be considered a marker of a form of skin irritancy. In a questionnaire-based study [4] of 3300 women and 500 men, 51.4% of women and 38.2% of men considered that they were susceptible. Fifty-seven per cent of women and 31.4% of men had had an adverse reaction to a personal care product during their lives. Amongst women, symptoms of subjective skin irritation (burning, stinging, etc.) occurred more frequently in those who considered they had a sensitive skin (53%) than in those who did not (17%). Dry skin and a predisposition to blushing/flushing were factors associated with a sensitive skin. An atopic background was a predictive factor for the presence of sensitive skin, as the incidence of atopy was higher among those with sensitive skin (49%) than among those in the non-sensitive group (27%). However, equal numbers of atopics and non-atopics constituted the sensitive skin group, indicating that other variables were involved. In North America, there has been shown to be no ethnic difference in the prevalence of sensitive skin, although there are racial differences in how it is perceived. Euro-Americans experience greater reactivity to wind and less to cosmetics; Afro-Americans have reduced reactivity to most environmental factors; Asians have greater reactivity to spices, change in temperature and wind, and itch more frequently; Hispanics react less to alcohol. Overall, however, there were more similarities than differences [5].

Pathogenesis

The skin barrier

The skin provides the first and most important line of defence against exogenous noxious agents, and this is one of its primary physiological functions. This defence is far from perfect, as many substances penetrate readily into and through the epidermis, even when it is intact. The surface film is the first line of defence. It is composed of sebum emulsified with sweat and breakdown products from the horny layer [1]. The buffer capacity of the surface film varies considerably from one body region to another [2] but, in reality, it has a negligible influence on percutaneous absorption [3], stratum corneum hydration [4] and on the barrier function of the skin [5].

The principal epidermal barrier resides almost entirely in the stratum corneum [6]. This is normally renewed every 17–27 days [7,8], but barrier function can be restored in 2–5 days following stripping [9] or superficial injury. The stratum corneum appears to function as a homogeneous unit [6], the largest amount of penetrant always being found in the outermost layers. Damage to the stratum corneum is normally followed by an increase in percutaneous absorption and in transepidermal water loss, the increase in transepidermal water loss being proportional to the decrease in thickness of the horny layer [10].

For certain materials, there may be a second barrier at or near the dermal–epidermal junction or basement membrane [11] but, for most substances, the horny layer remains the principal barrier.

The mechanism of action of irritants

An irritant is any agent, physical or chemical, which is capable of producing cellular perturbation if applied for sufficient time and in sufficient concentration. Immunological memory is not involved and dermatitis occurs without prior sensitization. Many chemicals penetrate the skin, and many substances will alter or damage skin cells. Dermatitis arises when the defence or repair capacity of the skin is exhausted, or when the penetration of chemicals excites an inflammatory response. Strong irritants will induce a clinical reaction in almost all individuals, whereas with less potent irritants the response may be physiological rather than apparent, dermatitis only developing in the most susceptible or in situations where there is repeated contact with irritants.

The relationship between physicochemical structure and cytotoxic activity remains to be fully elucidated, but it would appear that hydrophobicity (log P) and dissociation constant (pK_a) are among the factors which contribute to irritation potential [1,2] (Table 19.2). For sodium lauryl sulphate, concentration has been shown to be a more important determinant of subsequent dermatitis than exposure time [3]. The nature of the response is in part determined by the irritant [4].

In the laboratory, barrier disruption has been shown to induce interleukin-1α (IL-1α) release from a preformed pool in mouse epidermis [5] and upregulation of tumour necrosis factor (TNF)-α and granulocyte–macrophage colony-stimulating factor (GM-CSF). There is then a rise in Langerhans' cell-derived IL-1α stimulated by GM-CSF and IL-1α production [6]. Concurrently, the loss of the normal extracellular calcium gradient stimulates lamellar body secretion and barrier repair [6]. Oxidative stress also contributes to the development of inflammation with various irritants [7].

Detergents at lower levels of exposure predominantly affect the horny layer, causing dryness and scaling by destroying lysosomal enzymes in the horny layer [8], whereas at higher concentrations they will dissolve cell membranes and damage lysosomes [9]. With repeated exposure, there will be signs of chronic inflammation, with increased DNA synthesis, acanthosis and changes in cellular metabolism [8,10].

Detergents and other irritants such as croton oil and phenol esters are chemotactic for polymorphonuclear leukocytes at non-toxic concentrations [11], and may cause pustular reactions. Organic solvents such as methanol or chloroform will damage blood vessels causing hyperaemia [12], and dimethyl sulphoxide (DMSO) is a very effective degranulator of mast cells [13].

Irritants affect everyone, although individual susceptibility with regard to the development of dermatitis varies greatly. The body's immune response is important in generating dermatitis, and this has been shown in the attenuated response to irritants in CD4-deficient mice [14].

Pathology

Whereas allergic contact dermatitis reactions are histologically almost always eczematous and rather monomorphic, those elicited by irritants show much greater pleomorphism. Histological changes vary according to the chemical nature and concentration of the irritant, the type and duration of exposure, the severity of the response and the time of sampling. Some irritant reactions may be histologically indistinguishable from allergic contact dermatitis, whereas others may possess morphological features characteristic of a certain type of chemical. More than one pattern of response may be induced by the same irritant.

Histology

Mild to moderate acute reactions to most irritants are characterized by spongiosis, intracytoplasmic vacuolation and nuclear pyknosis [1,2]. In general, spongiosis is less marked than that seen in allergic contact dermatitis, although more highly vesicular changes may be induced by such irritants as croton oil. With more severe irritation, necrolysis or cytolysis of epidermal cells occurs, leading to intra- or subepidermal vesicles and bullae. Such changes are seen particularly with cantharidin and trichloroethylene [3]. Parakeratosis is a common feature of acute reactions to one of the most widely studied irritants, sodium lauryl sulphate (SLS), possibly arising from enhanced keratinocyte proliferation [4] (Figs 19.1–19.4).

Electron microscopy has provided additional information on the nature of the cellular damage following acute exposure to various irritants. Ultrastructural changes include disruption of cell membranes and organelles, lipid accumulation, alterations in keratin filaments and modification of the stratum corneum [2,5–7].

Chronic or cumulative irritant contact dermatitis differs from acute reactions in that the histological picture is predominantly one of hyperkeratosis with areas of parakeratosis, moderate to marked acanthosis and elongation of rete ridges [8].

The role of Langerhans' ($CD1a^+$) cells in the induction and elicitation of allergic contact dermatitis is now well established, but it remains unclear whether these cells also actively respond to irritants. Studies of acute irritant contact dermatitis have demonstrated histological changes in Langerhans' cells, ranging from signs of cytotoxicity, such as reduced dendrite length, condensed nuclear chromatin and loss of integrity of organelles and membranes, to indications of cellular activation, including widened rough endoplasmic reticulum and increased numbers of Birbeck granules [9,10]. Epidermal density changes have also been described following the application of SLS, nonanoic acid, dithranol and croton oil [10–13].

Some indication that Langerhans' cells may have functional significance in irritant contact dermatitis has emerged recently from experiments by Brand and coworkers, in which increased numbers of Langerhans' cells were detected in regional draining lymph vessels, concomitant with increased lymph-cell antigen-presenting capacity [14,15].

Disruption and/or degeneration of collagen is commonly seen in irritant reactions, and oedema has been described by some investigators [16,17]. A number of irritants induce more specific changes in dermal cells, examples being DMSO, which acts as an effective mast cell degranulator, and organic solvents, which affect principally the vasculature, leading to capillary dilatation and hyperaemia.

Quantitatively and, to a limited extent, qualitatively, the cellular response to irritant-induced skin damage is dependent upon the nature and concentration of the irritant, the severity of the reaction, the time of sampling and the species under investigation. In mild to moderate reactions, the infiltrating cells are predominantly mononuclear, consisting mainly of helper–inducer T lymphocytes ($CD4^+$) with an accompanying admixture of suppressor/cytotoxic T cells ($CD8^+$), macrophages and $CD1a^+$ cells. B cells, natural killer (NK) cells and follicular dendritic cells are absent or rare [13,18–20]. Polymorphonuclear leukocytes, which play a significant role in guinea-pig responses, are generally only seen in substantial numbers in human reactions where there is severe epidermal damage with necrosis and the formation of subcorneal and intraepidermal bullae, or where infection has occurred.

The majority of the infiltrating inflammatory cells seen in irritant contact dermatitis reactions express human leukocyte antigen (HLA)-DR, with significant numbers of T lymphocytes also expressing the receptor for IL-2 (CD25) [20–22].

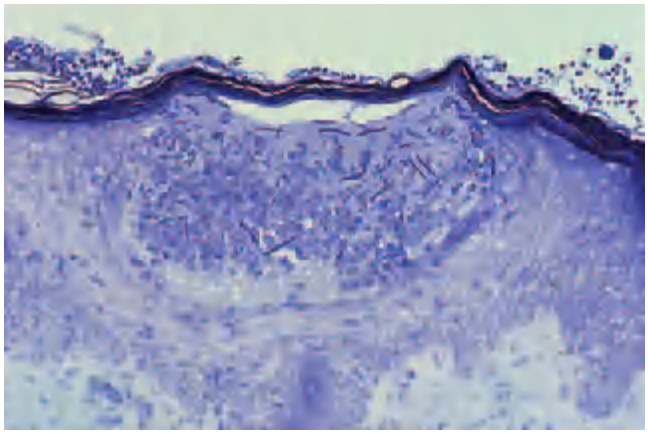

Fig. 19.1 Pustular reaction induced by 48-h patch testing with croton oil (0.08%). Toluidine blue stained, 1-µm resin section; original magnification × 200. (Courtesy of J.D. Wilkinson and C.M. Willis, Amersham General Hospital, Amersham, UK.)

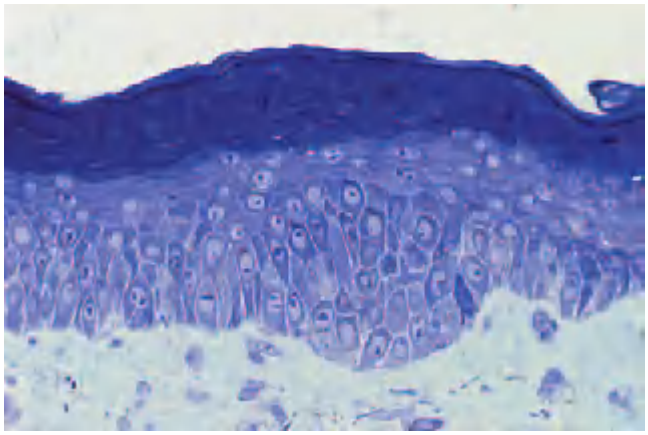

Fig. 19.2 Deeply stained parakeratotic layer induced in the epidermis by 48-h patch testing with sodium lauryl sulphate (5%). Such an appearance is characteristic of this irritant, and is probably related to increased epidermal cell division. Toluidine blue stained, 1-µm resin section; original magnification × 400. (Courtesy of J.D. Wilkinson and C.M. Willis, Amersham General Hospital, Amersham, UK.)

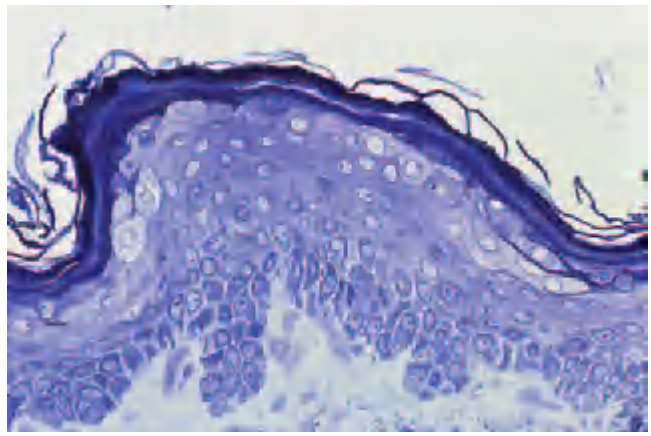

Fig. 19.3 Hydropic swelling of keratinocytes within the upper epidermis following 48-h patch testing with dithranol (0.02%). Toluidine blue stained, 1-µm resin section; original magnification × 400. (Courtesy of J.D. Wilkinson and C.M. Willis, Amersham General Hospital, Amersham, UK.)

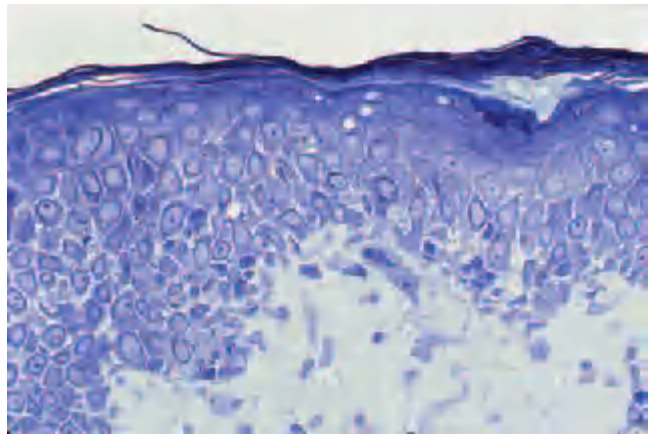

Fig. 19.4 Forty-eight-hour patch-test reaction to benzalkonium chloride (0.5%), exhibiting similar histopathological features (i.e. spongiosis and exocytosis) to those of allergic contact dermatitis. Toluidine blue stained, 1-µm resin section; original magnification × 400. (Courtesy of J.D. Wilkinson and C.M. Willis, Amersham General Hospital, Amersham, UK.)

Follicular pustules tend to develop, particularly in individuals with atopy, following exposure to such irritants as croton oil and metal salts. However, the presence of follicular spongiosis is said to be more typical of an allergic contact dermatitis [23].

Immunopathology

Identification of the inflammatory mediators involved in irritant contact dermatitis is valuable both as a possible means to distinguish irritant from allergic reactions and as an indicator of potential therapeutic avenues. Substances derived from arachidonic acid, in particular leukotrienes and prostaglandins, are present in the reactions to at least some irritants [1,2], in particular elevated levels of prostaglandins E_1 and E_2, as well as 12-hydroxyeicosatetraenoic acid (12-HETE). The pattern of release is determined by the nature of the irritant [3]. Elevation of prostaglandins and leukotriene-B4 correlate with the degree of inflammation, which is not the case for IL-1α.

Cytokines are hormone-like secreted proteins that regulate the growth and differentiation of many cells, including those of the immune system. It is now widely recognized that keratinocytes produce a number of these cytokines and play an active role in the inflammatory process. Among the pro-inflammatory cytokines which have been found to be released from epidermal cells following exposure to some irritants are TNF-α, IL-1, IL-6 and IL-8 [2,4,5]. GM-CSF and T-cell-derived cytokines, including IL-2 and interferon-γ (IFN-γ), have also been observed, subsequent to irritant application or tape stripping. Cytokines exhibiting anti-inflammatory characteristics, such as IL-10, are likely to play an important role in the regulation of irritant reactions, but have, as yet, only been studied in the tape-stripping model of barrier function impairment [6].

Keratinocyte involvement in irritant contact dermatitis is not confined to the production and release of cytokines, but extends to the up-regulation and expression of immune-associated adhesion molecules, both in response to cytokine release and as a result of direct irritant induction. These molecules include intercellular adhesion molecule 1 (ICAM-1), which acts as ligand for the leukocyte function-associated antigen 1 (LFA-1) constitutively expressed by leukocytes [7,8], and certain integrins that are involved in a variety of cell–cell and cell–matrix adhesion interactions [9]. Expression of the class II major histocompatibility complex (MHC) molecule HLA-DR by keratinocytes has been described, but appears not to be a predominant feature of the majority of irritant reactions [8,10].

Activation of protein kinase C-mediated events, leading to cell proliferation and differentiation, has been shown [11,12].

Differentiation from allergic contact dermatitis

With some irritants, the histopathological changes are obvious and sometimes even characteristic, whereas with others the epidermal and dermal appearances are indistinguishable from allergic contact dermatitis. In general, however, spongiosis is more marked in allergic reactions, whereas epidermal necrosis, acantholysis and pustulation are normally seen only with irritants.

Despite considerable effort, immunocytochemical analysis of the cellular infiltrate has so far failed to reveal any significant differential diagnostic features [1]. The problem is compounded by the fact that many allergens are also potentially irritant. Avnstorp *et al*. [2] found a histological diagnostic specificity of 87% and sensitivity of 81% for allergic reactions, with 100% specificity and 46% sensitivity for irritant reactions.

Early studies in man showed little evidence of differential cytokine release between allergic and irritant contact dermatitis, suggesting that, although their initiating events vary fundamentally, the cascade mechanisms responsible for the induction and release of regulatory mediators are similar [3,4]. Subsequently, quantitative differences have become apparent, with absent production of IL-4 in irritant compared with allergic dermatitis [5].

In mice, the chemokine IP-10, along with IL-1, was shown to be induced in allergic but not irritant contact dermatitis [6]. Subsequently, expression of IP-10 in man has been shown to mimic this pattern within the first 3 days, using SLS as the irritant. IP-9, IP-10 and Mig are all induced by IFN-γ and interact with the CXCR3 receptor that is almost exclusively expressed on activated T cells. Examination of the cellular infiltrate revealed that 50% of the T cells expressed CXCR3 in allergic compared with 30% in irritant contact dermatitis [7]. It was assumed that the differences reflected the presence of IFN-γ, which also mediates keratinocyte expression of ICAM-1 and HLA-DR. Other qualitative differences were noted, including increased expression of IL-8 in irritant contact dermatitis, which attracts neutrophils by binding to either CXCR1 or CXCR2 expressed on neutrophils.

Protective mechanisms have also been shown to be important in preventing the development of allergic contact dermatitis; specifically, glutathione and related thiols detoxify exogenous electrophilic compounds such as dinitrochlorobenzene [8].

Predisposing factors (Table 19.2)

Individual

Age, skin colour, race, phenotype and presence of eczema elsewhere may all affect the skin's response to marginal irritants. There is also significant individual variation in the patch test result with the same irritant on retesting [1,2].

Genetic/racial background. Twin studies suggest that genetic factors may influence susceptibility to irritants [3]. A TNF-α gene polymorphism has recently been demonstrated as a marker for susceptibility to irritant contact dermatitis [4].

A high baseline transepidermal water loss (TEWL) value points to an increased susceptibility to irritants [5,6]. Those with fair (Celtic) skins are not only more susceptible to UVB, but may also be more sensitive to chemicals [7]. Traditionally, Afro-Caribbean, Asian or Hispanic skin was thought to be more resistant, but some studies measuring TEWL after SLS exposure have cast doubt on this [8]. However, black skin is thicker and more compact than white skin, and irritant responses relate both to mean corneocyte thickness and skin surface contour [9]. A comparison of matched Caucasian and Japanese women showed the Japanese to have a greater tendency to irritation [10].

Age. Although the skin of the very young is usually regarded as being more vulnerable, there is very little evidence to substantiate this, except perhaps in the neonate [11] or premature infant [12].

Older individuals react less strongly to some irritants [13]. There is often a reduced inflammatory response and TEWL is reduced, which may represent a reduced potential for percutaneous penetration [14]. This is true of repeated irritation as well as a single insult. Onset of the reaction and subsequent recovery are also delayed [15]. *In vitro*, keratinocytes from older individuals demonstrate comparatively reduced secretion of IL-1 in response to

SLS and, in an elderly age group, higher secretion in photo-aged skin than in intrinsically aged skin [16].

Sex. Women more frequently report skin disease than men, and epidemiological studies of hand eczema show that they are more often affected. This is particularly true of the younger age group, where many female-dominated occupations involve exposure to wet work. They do not appear to be any more susceptible to skin irritation than men and these differences presumably relate to differences in exposure between the sexes [17]. Female skin, however, may be more reactive in the premenstrual phase of the cycle [18]. In a large group of individuals, use of the 4-h patch test has shown men to be more sensitive than women [1].

Neurological factors. Experimentally, sleep deprivation and the stress of an interview, but not exercise, resulted in delayed barrier recovery following tape stripping. Simultaneous increases in plasma cortisol, noradrenaline, IL-1α, IL-10, TNF-α and NK cell number and activity were measured. Cytokine responses to the interview stress were inversely correlated with barrier function recovery [19].

Site. The effect of irritant contact varies from region to region on the body. This partially reflects differences in thickness or type of stratum corneum and density of transepidermal shunts (hair follicles, sweat ducts), as well as potential for occlusion by body folds. In addition, there are probably inherent differences in keratinization and in composition of the intercellular lipids, especially ceramides and glucosylceramides, which play an important part in the barrier function of the skin [20].

The skin of the face, the scrotum and back of the hands is more permeable than skin elsewhere [21], and therefore more vulnerable to the effects of irritants and, in the case of exposed skin, more prone to chapping. The skin of the palms and soles is, in comparison, so thick that it is almost impermeable to everything except water and caustics.

The structure and total lipid concentration of the stratum corneum have a significant effect on stratum corneum permeability [22], and may account for some of the site differences and also for some of the changes in barrier function following damage to the skin or associated with abnormal keratinization [23–25].

Fat-soluble chemicals can be absorbed through the sebaceous glands and epithelium of the follicular root sheath, and may cause both allergic and non-specific inflammation in the deeper parts of the skin, even when there is an undamaged horny layer. In general, however, except for ions and large polar molecules [26,27], the appendageal route is an insignificant one so far as the penetration of most irritants and allergens is concerned [28].

As a consequence of the above factors, the intensity of an irritant response varies according to body site with, for example, the strongest reactions to DMSO occurring on the face and upper back, and the weakest reactions on distal parts of the limbs. Barrier recovery also varies according to body site, with the face and back healing most rapidly [29].

Skin disease and atopy. Percutaneous absorption is facilitated by inflammatory changes in the epidermis [30]. Thus, an irritant contact dermatitis can promote penetration of allergens and, conversely, an allergic contact dermatitis can facilitate the penetration of irritants. Stripping of the skin by means of adhesive tape can significantly reduce barrier function [31] and, although the stripping leads to a burst of regenerative mitotic activity, it may take anything from 2 to 6 weeks for barrier function to be restored completely [32]. The presence of eczema or recently healed disease may predispose to further dermatitis [33].

Atopics, particularly those with atopic dermatitis or a past history of hand dermatitis, seem to have more easily irritated skins. In a study using serial dilutions of sodium lauryl sulphate, individuals with active and healed atopic dermatitis and with respiratory atopy alone had a lower threshold for irritation than normal controls [34]. This was most severe in those with current skin disease. Other studies do not show this predisposition, which may reflect patient selection and complexity of the processes involved [35].

Environmental

Although toxic chemicals are the principal cause of irritant reactions, there are often significant contributory factors, including the potentiating effects of temperature, climate, occlusion and mechanical irritation.

The development of irritant dermatitis is partially temperature-dependent—higher temperature leads to a reduction in barrier function [1] and increases the penetration of SLS detergent through the skin [2]. Exposure to hot detergent appears to be more irritant than cold [3,4], and cement dermatitis often flares during the summer in hot, humid climates [5].

Low humidity. Low ambient humidity is the single most important factor with regard to the water content of the stratum corneum; a change to a low dew point can occur suddenly during winter, and can cause chapping even in normal persons [6]. Experimentally, low humidity has been shown to stimulate epidermal DNA synthesis and amplify the proliferative response to barrier disruption [7]. Susceptibility to SLS irritation is greatest during the winter in the Northern hemisphere [8] when stratum corneum hydration is reduced. Chapping, and atopic and hyperkeratotic forms of hand eczema, are often worse in temperate climates during the winter.

Low-humidity dermatosis has occurred in factories where the ambient humidity was too low [9]. Although the effects of temperature and humidity are to some degree interrelated, cold alone will reduce the water content and plasticity of the stratum corneum and lead to cracking. Simultaneous exposure to these and other factors may maintain a dermatosis or cause transition from simple chapping or low-humidity dermatoses to a more 'eczematous' dermatitis. In mice, epidermal IL-1 is constitutively expressed and released in greater amounts following tape stripping in a low humidity environment [10].

Occlusion. Occlusion promotes percutaneous absorption [11,12], and may facilitate skin irritation and enhance the effect of irritants to which an individual has already been exposed [13]. Water is imbibed by the keratin, which swells, producing wrinkling, as is seen after prolonged immersion in water. Increasing the water content of the stratum corneum by occlusion can enhance percutaneous absorption of certain substances many times [14]. It is of practical importance that rubber and plastic gloves, wristwatch straps, rings, waterproof adhesives, shoes, boots, clothes and the natural folds of the skin provide such occlusion. Soft paraffin by itself also has an occlusive effect [15].

Chemical and physical

Different groups of chemicals show significant differences in absorption and diffusion characteristics [1,2]. Results obtained from hydrocortisone, for example, cannot be presumed to reflect the situation for water or other molecules [3].

The main barrier to water transport through the skin is attributed to stratum corneum lipids and to high-molecular-weight proteins of the corneocyte [4]. The stratum corneum, having a predominantly lipid intercellular composition, is more susceptible to lipid-soluble irritants [5], and modifying factors in respect of barrier function may be quite different for hydrophilic and hydrophobic substances [6,7]. When the lipids of the stratum corneum are removed by solvents, water transport rates through the skin increase [8]. Subsequent immersion in water for 2 min will remove as many of the water-soluble substances from the keratin layer as a 2-h immersion in water not preceded by defatting [9]. A detergent effects the combined removal of both lipids and water-holding substances and thus predisposes to chapping and dermatitis [10]. Combined exposure to both solvent and detergent has been shown to have an additive effect on inducing dermatitis [11].

Alkaline solutions have a deleterious action on the horny layer and promote percutaneous absorption. Cross-links in the keratin are broken, and water can penetrate into the fibrils and cause swelling of the horny layer. If reducing substances are present in alkaline solution the disulphide links are also broken, which leads to greater damage [12]. However, change in pH was found not to influence irritancy of alkaline detergents between pH 7.4 and 10.8 [13].

Physical injury often plays a role in dermatitis, e.g. rough sheets have produced facial dermatitis in neonates [14], and frictional factors were contributory in cases of hand dermatitis among post office workers [15]. Fibreglass [16,17] and rockwool [18] can also cause an irritant dermatitis which is aggravated by rubbing (see Chapter 21).

Identifying irritants [1]

The need to reduce the use of animals for irritant testing has increased the amount of research directed towards the development of *in vitro* tests. None of these can as yet replace human or animal testing entirely, but they do allow a staged process of toxicological evaluation. Initially, this involves a literature search, and a search for any unpublished toxicological data. To this can be added an assessment based on chemical structure. Subsequently, *in vitro* testing methods can be used to assess both corrosion and irritation, although finally animal/human test methods may be needed to assess acute or cumulative irritant potential *in vivo*.

In vitro techniques used to assess for corrosion have gained governmental recognition and rely on viability assessments in skin culture models [1]. *In vitro* tests for irritation are varied and none is yet sufficiently well

validated for regulatory purposes. They include testing on the chorioallantoic membrane of hens' eggs, red blood cell assays and cytotoxicity testing on Balb/c 3T3 fibroblasts. The effects on cellular homeostasis and viability may be measured by uptake of neutral red, and changes in cellular protein levels by subsequent staining with Kenacid blue [2]. Dimethylthiazoldiphenyl tetrazolium bromide MTT assay, neutral red release assay [3] and release of pro-inflammatory mediators from cultured human keratinocytes [4], have all been proposed as possible models for the initial assessment of irritancy potential of surfactants and other chemicals. Correlation with *in vivo* tests is not absolute and results should always be interpreted critically as the epidermal barrier does not exist in cell culture models [5].

Most irritancy testing in animals and humans is done on a predictive basis, using a variety of techniques, such as the Draize test [6], the chamber-scarification test [7,8] and the 21-day repetitive insult test [9,10]. Strong irritants may cause dermatitis on first exposure, whereas weak irritants may only be detected by repeated application [9,10]. Internal standards are necessary to allow comparison with other established irritants [11].

The use of ethical tests in human volunteers is likely to prove the way forward where testing *in vivo* is considered essential. Closed 48-h patch tests on the intact skin of eczema-prone subjects may be used as a simple screen of irritancy for products intended for use on the skin. However, there are generally significant interindividual variations [12]. Recent protocols for human testing include 4-h irritant patch tests measured against standard internal controls [13].

Barrier function tests [14] and other bioengineering techniques [15,16] can be applied to increase panel sensitivity and reduce morbidity, as the differences in irritant potential can be detected earlier. A high baseline TEWL, for example, may act as a predictor for susceptibility to irritants [17]. Other techniques which have been used to try to identify hyper-reactors for inclusion in screening panels include ammonium hydroxide blistering [18], the SLS test [7], the chloroform pain threshold test [19] and the lactic acid stinging test [20]. Frequent or repeated use of a product, especially on those with hyperirritable skins or in those claiming an adverse reaction from a product, is another way to maximize the chance of reproducing a reaction in humans [21]. Comparative usage tests between similar products can be performed in the same way [22]. It is always important to bear in mind, however, that in an individual it is not possible to predict the strength of reaction to one irritant by knowing the strength of reaction to another [23].

However, not all irritant reactions are erythematous or impair barrier function. The immediate-type non-immunological contact reactions, and immediate and delayed symptomatic contact reactions encountered when applying some substances to the skin, produce principally subjective responses, such as stinging and smarting, and require a different approach [20] such as the lactic acid stinging test.

Clinical features

Irritant contact reactions [1–3] are inflammatory reactions of the skin to an external agent or agents in which,

although inflammatory and immunological mediators may be activated, no memory T-cell function or antigen-specific immunoglobulins are involved.

Irritants produce a wide range of responses on the skin which are not necessarily eczematous. These may range from purely subjective sensations, such as stinging, smarting, burning, or sensations of dryness and tightness, through delayed stinging or transient urticarial reactions to more persistent irritant reactions or irritant contact dermatitis. Irritant contact dermatitis has a spectrum of clinical features, ranging from a little dryness, redness or chapping through various types of eczematous dermatitis to an acute caustic burn. Irritants may also penetrate skin via appendageal structures and cause folliculitis and other types of reaction (Table 19.1).

The same chemical may cause different irritant reactions depending on concentration; DMSO, for instance, is able to induce both conventional irritant dermatitis and immediate non-immunological contact urticarial reactions [4]. Reaction patterns vary between species, mast cells providing an important component of the cellular response in guinea pigs [5] but being generally less evident in humans [6]. The response may also vary according to site and mode of application [7], vehicle [8] and between individuals.

Although the nature, concentration and duration of contact with the irritant chemical are of primary importance, mechanical, thermal, climatic and constitutional factors are important modifying and/or enhancing factors in many irritant responses (Table 19.2).

Chemical burns

A chemical burn (Fig. 19.5) results when there is irreversible cell damage, and necrosis occurs. There is usually rapid onset of painful erythema, often within minutes, at the site of exposure. This is followed by blistering and the development of necrotic ulcers. Weals may be seen as a result of toxic degranulation of mast cells. Symptoms

Fig. 19.5 Caustic 'burns' from wet cement. (Courtesy of J.D. Wilkinson and C.M. Willis, Amersham General Hospital, Amersham, UK.)

coincide with the exposure, but with some chemicals, including phenols and weak hydrofluoric acid, the onset may be delayed [1]. With ethylene oxide gas, used to sterilize medical instruments, textiles and plastic materials, the chemical can remain on items for several days if not allowed to evaporate. The possibility of exposure may therefore not be obvious. Damage continues to occur until all of the agent has chemically reacted or has been neutralized as a result of treatment.

Most acids (e.g. sulphuric, nitric, hydrochloric, chromic) coagulate skin proteins, and as a result form a barrier which impedes further penetration. Some acids can discolour (e.g. nitric acid turns the skin yellow). Ulceration of the skin and nasal passages 'chrome ulcers' used to occur, prior to modern safety precautions, in tanners, textile workers, smelters and electroplaters, due to corrosion by chromate fumes. Hydrofluoric acid [2] differs in that it causes a liquefactive necrosis, and penetration can continue for several days after exposure, even down to bone. Pain, which can last several days, is typical of burns due to hydrofluoric acid and other fluorides. It is related to the ability of the fluoride ion to bind calcium and disrupt neural function. If more than 1% of the body surface area is affected, systemic toxicity can develop.

Alkalis (e.g. sodium, calcium, potassium hydroxides; wet concrete [3]; sodium and potassium cyanides) degrade lipids, and saponification of the resulting fatty acids forms soaps which aid penetration deeper into the skin. As a consequence, damage is more severe than with most acids, and pain is also a feature. The dead skin turns brown and later black, usually without blistering, and forms a hard eschar.

Phenols [4] and unhardened phenolic resins penetrate the skin easily and rarely can cause nerve damage in the absence of visible skin change. Vasoconstriction may contribute to the necrosis that develops, and in the case of systemic absorption can lead to shock and renal damage.

Irritant contact dermatitis

The clinical appearance of irritant dermatitis (eczema) is essentially no different from that due to other causes; allergic or endogenous. Diagnosis therefore is essentially clinical after exclusion of contact allergy.

Acute irritant contact dermatitis

Acute irritant contact dermatitis is often the result of a single overwhelming exposure to an irritant or caustic chemical (Fig. 19.6), or a series of brief chemical or physical contacts. This results in acute inflammation of the skin, and is usually associated with an immediate sensation of burning or stinging. Differentiation between an acute (toxic) contact dermatitis and a primary chemical burn is not always possible. The initial reaction is usually strictly limited to the site of application or contact, the concentration of the substance diffusing outside the area of contact almost immediately falling below the critical threshold necessary to provoke a reaction [1].

Fig. 19.6 Acute irritant contact dermatitis following immersion in concentrated bleach. (Courtesy of A. Yung, Leeds General Infirmary, Leeds, UK.)

Irritant effects may be considerably enhanced by occlusion, and care must always be taken to ensure that irritants do not penetrate gloves or protective clothing. Most cases of acute irritant dermatitis occur as a result of accidents at work. Some substances—for example, gentian violet [2] and dequalinium chloride—are toxic only under certain conditions, such as under occlusion, on mucosal surfaces, or when the stratum corneum barrier is breached.

The rapidity of an acute irritant response usually makes the cause obvious, especially with strong alkalis or acids, which will produce a toxic reaction within a few minutes. The duration of application necessary to provoke a reaction with less potent irritants will vary considerably. The clinical spectrum of acute irritant dermatitis may range from a mild irritant reaction with transient erythema or chapping to a much more florid dermatitis with oedema, inflammation, pain and vesiculation. In more severe cases there may be exudation, bullae formation and tissue necrosis indistinguishable from a chemical burn. Caustic burns from lime [3] or cement [4] may cause extensive tissue damage. In patients with accidental or sporadic exposure, the dermatitis usually heals quickly, unless there is skin necrosis. In mild cases, the skin may revert to normal within a few days, but in more severe cases several weeks may be required for complete resolution.

Delayed irritancy

Delayed irritancy—or, rather, a delayed time course of irritation—has been reported in respect of several substances, including SLS [1], propylene glycol [2] and certain diacrylates [3]. This may sometimes cause problems in the interpretation of patch-test reactions because the inflammatory response occurs late (at 48 h), and may therefore simulate an allergic contact reaction.

Cumulative irritant contact dermatitis [1]

SYN. CHRONIC IRRITANT DERMATITIS; 'WEAR AND TEAR DERMATITIS'; TRAUMITERATIVE DERMATITIS

This type of dermatitis develops as a result of a series of repeated and damaging insults to the skin. These insults may include both chemical irritants and a variety of harmful physical factors, such as friction, microtrauma, low humidity [2], the desiccant effects of powder [3], soil or water and temperature.

Once the stratum corneum barrier has been breached, a great number of normally innocuous substances can perpetuate an irritant contact dermatitis. Scratching, rubbing and even topical treatment may on occasions become causes of persistence. Chronic irritant dermatitis may therefore be due to the summation of various adverse factors, many of which would not in themselves be strong enough to cause irritant dermatitis but which, taken together, are enough to weaken the skin and lead to the development of cumulative irritant contact dermatitis [1]. These minor irritants may also act as perpetuating factors once the dermatitis has become established. Among this great variety of causative factors, there may be some which are overlooked by the patient because they do not appear to be related to the onset of the dermatitis (Figs 19.7–19.9).

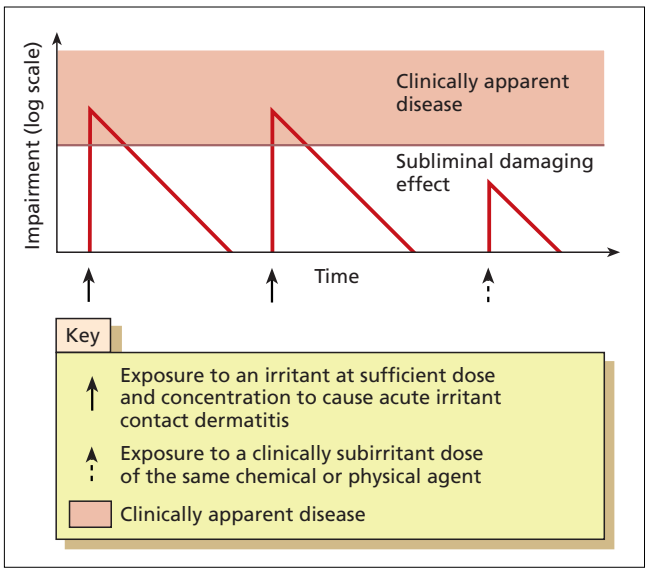

Fig. 19.7 Acute irritant contact dermatitis. The damaging effects on the skin of acute (non-cumulative) exposure to irritants. (From Malten [1].)

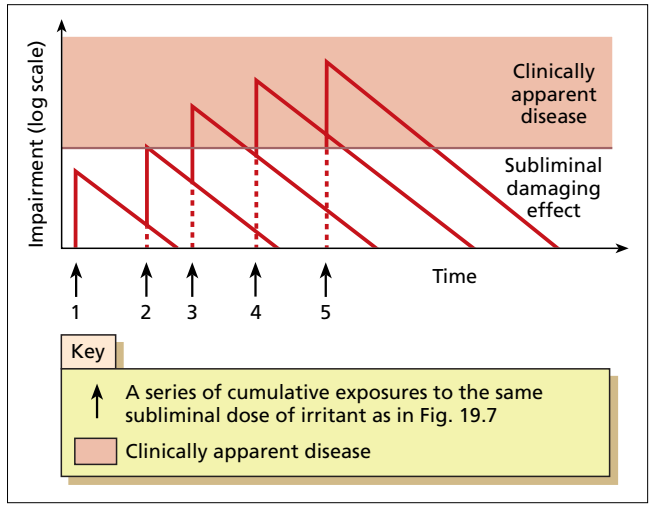

Fig. 19.8 Cumulative irritant contact dermatitis. The damaging effect on the skin of cumulative doses of a subliminal irritant. (From Malten [1].)

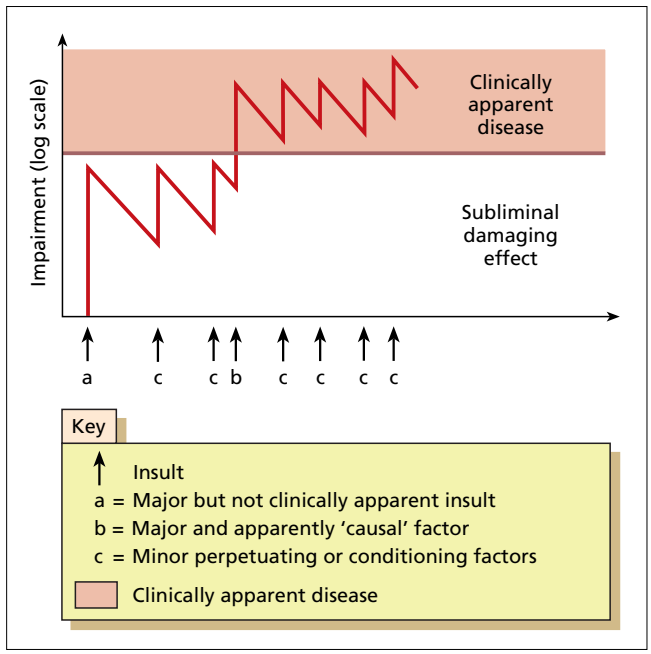

Fig. 19.9 Cumulative irritant contact dermatitis—mixed causation. (From Malten [1].)

Cumulative irritant dermatitis most commonly affects thin or exposed skin—for example, the dorsa of the hands, fingertips and the webs of the fingers (Figs 19.10 & 19.11), or the face and eyelids in those with cosmetic intolerance [4] or low-humidity dermatosis [2]. The face, eyes and upper respiratory tract are often affected by volatile types of irritant (Fig. 19.12) especially in those exposed industrially [5].

Irritant contact dermatitis often begins with a few localized patches of dry, slightly inflamed or chapped skin

(Figs 19.13 & 19.14), and the tendency to disseminate is normally less than with constitutional or contact allergic forms of eczema. Irritant contact dermatitis tends to be more static and monomorphic than other forms of eczema [1,6], but constitutional and allergic factors frequently coexist (Figs 19.15 & 19.16).

Occupations with a high incidence of cumulative insult dermatitis are listed in Table 19.3 (see also Chapter 21). Most workers, however, even those working in high-risk occupations, usually develop only minor degrees of

Acids
Cutting oils
Organic solvents
Oxidizing agents, including sodium hypochlorite
Reducing agents, including phenols, hydrazine, aldehydes, thiophosphates
Certain plants, for example spurge, Boracinaceae, Ranunculaceae
Pesticides
Raw food, animal enzymes and secretions
Desiccant powders, dust, soil
Miscellaneous chemicals

dermatitis, and constitutional factors are therefore probably important in those who develop more severe forms of dermatitis. Nearly 80% of those with chronic disability dermatitis were found to be atopic in one survey [7]. Other factors are also important, such as additional exposure to irritants at home or in the pursuit of hobbies, for example car maintenance or gardening, accidental exposure to strong caustics or irritants, adverse climatic and environmental conditions, lack of attention to industrial hygiene and poor working technique. Excessive use of abrasive or solvent cleansers may be more damaging to the skin than some of the substances which they are designed to remove. Common irritants are listed in Table 19.4.

Hand dermatitis

The pathogenesis of hand eczema is often complex. Constitutional, irritant and allergic factors frequently coexist. Although hand eczema is more common in women [1], this seems to be the result of increased irritant exposure rather than an inherent susceptibility [2]. Allergy can never be completely excluded, nor is any pattern of hand dermatitis pathognomonic for a single causation. In spite of this, there are certain types of hand dermatitis that are

Fig. 19.17 A unilateral dry palm is characteristic of *Trichophyton rubrum* infection.

Fig. 19.18 Tinea incognito on the dorsum of the hand.

at least suggestive of irritant contact dermatitis. These include a patchy 'housewife'-type eczema affecting principally the dorsa, sides and webs of the fingers, or a 'ring' eczema—both are patterns associated with wet work and exposure to detergent. What may start as dryness can develop into patchy or diffuse erythema with scaling, fissuring and even vesiculation.

However, vesicles are less commonly seen in irritant than allergic or constitutional eczema, and the principal clinical features are usually dryness or chapping. The wrists and distal arms may also be affected. With increased mechanization in the house and more widespread use of protective gloves and hand creams, this pattern of hand eczema is less common than in the past.

Another common pattern of irritant hand eczema is the 'apron' or extended fingertip eczema, with dryness, redness and fissuring affecting principally the palmar aspects of fingers and distal palm. This pattern of dermatitis commonly occurs in those who frequently hold wet cloths containing detergent or household chemicals in the unprotected hand. Friction, irritants and repetitive wetting/desiccation all play a part. A similar pattern may be seen in occupations where employees are repeatedly exposed to solvents, friction or irritating food components. Discoid or nummular hand eczema is another rarer pattern of irritant contact dermatitis, affecting especially the dorsa of hands or fingers.

The differential diagnosis of hand dermatitis includes fungal infection, which simulates a unilateral palmar dermatitis (Fig. 19.17) and can resemble eczema on the dorsum of the hand (Fig. 19.18). Skin scrapings are important to exclude tinea as the cause of a hard to treat 'dermatitis'. Psoriasis frequently affects the palms, resulting in a hyperkeratotic appearance. This can be difficult to distinguish from dermatitis when there are no lesions elsewhere. Further, there may be a history of exacerbation when the disease leads to the Koebner phenomenon on the hands as a result of manual work. The presence of scaling erythema over the interphalangeal joints is often a helpful clue (Fig. 19.19) to the diagnosis. Scabies in the interdigital spaces can simulate an irritant dermatitis (Fig. 19.20).

Fig. 19.19 Erythema and scale over the interphalangeal joints is a clue to the diagnosis of psoriasis.

Cosmetic dermatitis

Cosmetics, toiletries and skin-care products, including sunscreens, quite frequently cause adverse reactions [3]. In most cases, these are only mild or transient, and most consumers simply change to an alternative product. In a

Fig. 19.20 Scabies affecting the finger web spaces. (Courtesy of A. Yung, Leeds General Infirmary, Leeds, UK.)

minority, reactions may be more severe, with redness, oedema, dryness and scaling. The eyelids are particularly susceptible to irritants [4], as are atopic individuals and those with very fair, rosaceous or seborrhoeic skins. It is of interest that irritant reactions are commoner in younger (premenopausal) women. Those using many products are at risk of 'cosmetic exhaustion', a form of cumulative cosmetic irritant contact dermatitis. Allergy is only excluded by comprehensive patch testing to both product and ingredients.

Volatile/airborne irritant contact dermatitis

Irritants, as well as allergens, may cause volatile contact dermatitis [5]. Volatile irritants are a not infrequent cause of eyelid dermatitis. In any exposed-site dermatitis, one should consider the possibility of irritant volatile fumes or airborne particles. The fumes can be from acids, alkalis, solvents, resins or any other irritant chemical, such as ammonia or formaldehyde. Irritant dusts include those of some (mostly tropical) woods, cement, fibreglass or rockwool, some metals and metal salts, and powdered chemicals.

Cheilitis

Cheilitis is a common problem, often of multifactorial aetiology. Atopic eczema frequently predisposes to its development [6]. The most common identifiable causes of cheilitis are irritant dermatitis, due to lip licking, cosmetics and medication, and allergic contact dermatitis, particularly from ricinoleic acid and the patient's own lip preparations [7].

Napkin (diaper), peristomal and perianal dermatitis

Irritant dermatitis will develop in situations of prolonged or too frequent contact with degraded urine or faeces/faecal residues [8]. Sweat, occlusion, irritant cleansers, secondary infection and secondary medicament allergy are all additional complicating factors. It occurs most frequently in the very young, or in the elderly in situations of urinary or faecal incontinence. Measures to improve continence in the elderly and sufficiently frequent changes of absorbent [9] napkins in infants are important, as are mild cleansers and protective pastes or silicone-based creams. Any dermatitis or secondary infection should be controlled with appropriate-strength topical steroids or steroid–antimicrobial combinations. In napkin dermatitis, secondary candidal infection is sufficiently common that routine treatment with an imidazole antifungal is of benefit [10].

A similar situation appertains to perianal dermatitis, where mucus or faecal leakage may occur in association with haemorrhoids and/or poor sphincter function. A bidet, or 'wet' cleansing routine using aqueous cream or equivalent, are of benefit.

With peristomal dermatitis, there is the additional complication of the need to maintain a protective seal between the stoma bag and skin. The use of corticosteroid-containing lotions, either aqueous or alcoholic, has been shown to be effective without interfering with stoma adhesion [11]. Dermatitis, as well as being caused by leakage, may also be due to continuous occlusion and repeated stripping of the skin. Where there is erosive disease, the use of topical sucralfate has been shown to promote healing in peristomal disease but not erosions from other causes [12]. The sucralfate acts as both a physical barrier and, it is suggested, by binding to basic fibroblast growth factor preventing its degradation, as a stimulus to healing.

Other sites

Irritant dermatitis at other sites occurs less frequently, but may develop on the feet from spillage under shoes or on the thigh from the habit of keeping an oily rag in a pocket.

Phototoxicity [1]

A number of chemicals only cause irritation after absorption of photons; the photoactivated chemical has altered properties which are directly tissue damaging. They include psoralens, porphyrins, tetracyclines, non-steroidal anti-inflammatory drugs, phenothiazines and amiodarone. This is discussed in greater detail in Chapter 24.

Mechanical irritation

In an experimental setting, distortion of the skin at the edge of adhesive tape (Fig. 19.21) has been shown to be directly related to the development of irritant dermatitis [1]. Koebnerization of eczema as both primary and secondary events following injury has been reported [2]. Friction is reported to cause nipple dermatitis in association with jogging [3] and ill-fitting bras [4]. Dermatitis has similarly been reported under other items of clothing at sites of friction. The presence of a rash, particularly in the summer months, suggested that damp clothing/skin

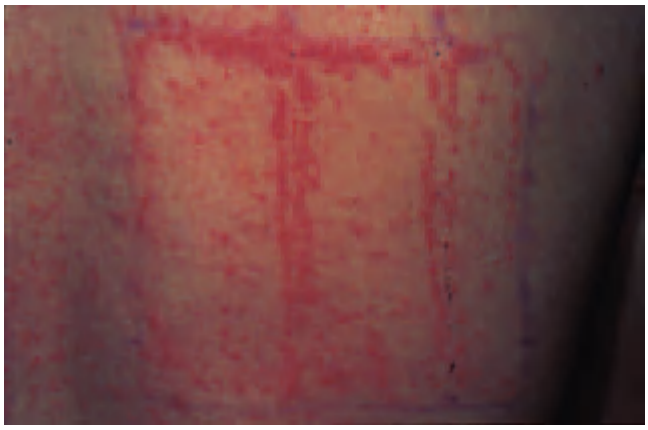

Fig. 19.21 Dermatitis developing at the edge of Scanpor tape after patch testing.

Fig. 19.22 In the same patient, frictional dermatitis under a bra strap (contact allergy excluded).

from sweating was implicated in the pathogenesis in 15 patients reported by Ramam *et al*. [5] (Fig. 19.22). Localized dermatitis from prosthetic limbs is also frequently trauma-induced [6]. In a retrospective review of physical irritant contact dermatitis [7], 35.3% of cases were induced by friction, 32.7% by drying and 11% by heat. The majority of cases had an occupational origin, with 36.3% of cases affecting the hands and 26.4% the face.

Fibreglass dermatitis [8] is usually irritant in nature, and is the result of skin injury by direct penetration of fibre particles. It is directly proportional to the diameter (greater than 3.5 μm) and inversely proportional to the length of the fibres. Pathologically, the changes are eczematous, with spongiosis. This is discussed in greater detail in Chapter 21.

Mechanical injury by plants is also common [9]. Most injuries to the skin by thorns or spines are purely mechanical. However, glandular hairs of some plant species inoculate pharmacologically active substances, and certain spines and thorns give rise to distinctive reactions, which suggest that the mechanical effects may be enhanced or modified by as yet unidentified toxic agents. The small bristles, or glochidia, of some species of cactus are retained in the skin and produce an eruption of very persistent, small, irritable papules. *Opuntia ficus-indica*, the Sabra, which is widely grown in the Mediterranean area, is a common offender, and the eruption has therefore been described as 'Sabra dermatitis' [10]. Similarly, trichomes of other plants have caused an irritating eruption of the interdigital spaces simulating eczema [11] or tinea. Barley awns cause an extensive papular dermatitis in farm workers. The sharp-tipped leaves of palms or yuccas and the thorns of roses may become deeply embedded in or near bones or in joints, especially in children's hands. They may then cause a chronic septic arthritis or intense periosteal reaction, which may mimic bone tumours [12]. Small thorns may induce foreign-body granulomas.

The common blackthorn, *Prunus spinosa* [13], is notorious among country dwellers for the chronicity of the granulomas it may cause. The persistent nodules are usually on the wrists and fingers.

Non-immune contact urticaria

Immediate contact reactions may be either allergic or toxic. They are transient, developing within minutes, and fade quickly (usually within hours). They may appear on both normal and damaged/eczematous skin, and may present as only a transient symptomatic erythema or as a contact urticaria.

For some agents which cause immediate-type reactions, it is still unclear as to whether or not the mechanism is immunological. Non-immunological immediate contact reactions occur without prior sensitization. The reactions remain localized, and may present as a transient erythema or as an urticarial weal and flare, depending on concentration, area of contact, mode of exposure and agent involved [1,2]. Substances reported to cause non-immunological contact urticaria are listed in Table 19.5. The most potent of these, such as benzoic acid, sorbic acid, cinnamic acid, cinnamic aldehyde and nicotine acid esters, may induce a local reaction within 45 min in more than 50% of those tested. Reactions may occur at concentrations as low as 0.1% for benzoic acid, sorbic acid and sodium benzoate [3–5], and as low as 0.01% for cinnamic aldehyde. Reactions are not enhanced by occlusion, but may affect mucosal surfaces; low concentrations of cinnamic aldehyde are sometimes added to toothpaste and mouthwashes to impart a sensation of 'freshness'. Studies on an unselected population have shown that reactions to urticants are not predictable; an individual who reacted strongly to one urticant did not necessarily react to another. In addition, there was no significant correlation between age or sex and urticant response [6].

Symptomatic (subjective) irritant responses

With some irritants there is little or nothing to see, but individuals complain of a subjective sensation of stinging, burning or smarting. These sensations most commonly affect the head and neck and may present as one form of cosmetic intolerance. With soaps and detergents, the perceived sensory symptoms correlate with and predict the development of clinical signs of irritant dermatitis [1].

Sensory symptoms are not limited to chemical exposure, the itch and prickle from woollen garments being well known amongst patients with atopic eczema. Experimental studies have shown this to be due to stimulation

of nerve fibres which transmit pain. It required a 100-mg force on the end of a 40-μm diameter textile fibre to trigger the nerve receptor. Thus, garments which induce the sensation will have protruding fibre ends that can withstand 100 mg pressure without buckling. Prickle was not experienced if the fabric was rubbed over the skin, if the skin was cold or if the area of contact was less than 1 cm^2. Moisture increased the severity of the sensation [2].

Immediate-type stinging

Some chemicals will cause painful sensations within seconds of contact [3]. These include acids, where the stinging may be a prodrome to the development of more severe cutaneous damage. Other chemicals, however, will cause stinging without any significant cutaneous damage. The best known of these are chloroform and methanol (1 : 1), and 95% ethanol. Responses vary according to site and individual susceptibility, and probably relate indirectly to stratum corneum thickness. The sensation abates quickly following removal of the irritant substance.

Delayed-type stinging

Delayed-type stinging [3] may occur following contact with a number of substances (Table 19.6). Typically, there is no immediate stinging, but discomfort develops within 1–2 min, reaches a maximum in 5–10 min, and fades slowly over the next half hour. The reaction normally only affects the face, especially in association with heat and humidity or sweating. The sensation is not alleviated by washing off the offending chemical. It is an idiosyncratic response, and only a proportion of the population will be affected.

The original cases occurred following use of a sunscreen containing amyldimethyl-*p*-aminobenzoate (ADP Padimate) [4]. Individuals can be screened to ascertain whether they are stingers or not by the application of 5% aqueous lactic acid to the nasolabial fold after induction of sweating. Among the substances able to induce this reaction are the sunscreen agent 2-ethoxyethyl-1-methoxy cinnamate, the insect repellent diethyltoluamide, several dermatological therapeutic agents and vehicles/solvents used in both cosmetics and medicaments. Preparations can now be screened for stinging potential by testing a predetermined panel of 'stingers and smarters'.

Little is known of the mechanisms involved in subjective irritant reactions. It is presumed that penetration of the irritant is primarily via sweat ducts and hair follicles, is not related to pH and that the reaction involves stimulation of sensory nerve endings. The reaction is substantially reduced in the absence of sweating. White people seem to be more sensitive than black people; atopics or those with easily irritated skins are also more susceptible [5,6]. Eyelid skin is especially vulnerable. It would appear that susceptible individuals have a lower skin capacitance and greater degree of skin reddening than normal controls. This was taken to indicate a tendency to barrier impairment and vascular hyperreactivity in affected individuals [7], although the sensation does not correlate with a predisposition to irritant dermatitis or non-immune contact urticaria [8].

Specific irritants

Substances which commonly cause irritant contact dermatitis are listed in Table 19.4. Certain, mostly 'wet', occupations, have an increased risk of irritant contact dermatitis; these are listed in Table 19.3.

Water [1]. Wet work occurs in a wide range of occupations. Water is hypotonic and acts as a cytotoxic agent on eroded skin. If the surface lipid layer has been removed previously by suitable solvents, including detergents, water may dissolve the hygroscopic substances needed to keep the skin pliable. Hard water is more irritant than soft [2]. Lime, magnesium and iron from hard water deposited in skin fissures may cause mechanical irritation. Irritation of the skin may arise from poorly controlled chlorination or bromination of swimming and spa pools [3,4].

Skin cleansers [5–8]. Soap, detergents and waterless cleansers containing organic solvents are the commonest irritants. They raise the pH and dissolve lipids. Added silica or sand tends to damage by mechanical abrasion. It is difficult to evaluate the role of soap in the causation of cumulative insult dermatitis and difficult to prove that it is, in fact, a perpetuating factor. In many occupations, for example the metal industries, the procedures used for hand cleansing may be more harmful to the skin than the work itself. Aromatics in the solvents in 'waterless cleansers' are particularly hazardous [9].

Detergents, surface-active agents, sulphonated oils, wetting agents, emulsifiers [6,10–12]. These are used for domestic and industrial cleaning, skin cleansing, and as wetting and emulsifying agents in many industries. Washing powders contain detergents, perborates, phosphates, optical bleaches and perfume. Some also have added soap and, to prevent precipitation of calcium soap, chelating agents. The irritant effect is different, being dependent on the chemistry of the detergent [13]. Most are alkaline, but even at neutral pH they remove the surface lipid film and the water-holding substances in the horny layer as well as the vital lipids from the semipermeable membrane of stratum corneum [14]. They denature protein and damage the cell membranes. Oxidation has been shown to increase the irritant potential of some surfactants [15]. Enzymes used in detergents may [16] or may not [17] act as irritants.

Preservatives. Most quaternary ammonium compounds have an irritant effect, particularly in superficial cracks in dry skin. Other preservatives, as well as being potentially allergenic, can be irritant [18].

Alkalis. Alkaline solutions saponify the surface lipids and dissolve water-holding substances, break the cross-linkages of keratin and cause swelling of cells. Soap, soda, ammonia, potassium and sodium hydroxides, cement, chalk, sodium silicate, trisodium phosphate and amines (e.g. in epoxy hardeners or as an antistatic agent [1]) are the commonest irritants.

It should be noted that soda ash (anhydrous sodium carbonate) is three times stronger than washing soda. Stearyl amine is used as an emulsifier in mixtures of oil and gravel. Alkalis are used in many industries (dyeing, tanning, rubber, plastic, glass, etc.). Copying papers based on the diazo process are developed by ammonia gas, which sometimes causes irritant dermatitis of the face.

Acids. Acids are widely used in industry, for example chromic acid for rust-proofing iron and hydrofluoric acid [2] for glass etching, rust stain removal [3], and in the electronics [4] and petroleum industries. Sulphuric, hydrochloric and nitric acids are other common inorganic acids. Hydrochloric acid is used by masons for the cleaning of building stones, but sometimes also for cleaning their hands. Acetic [5] and oxalic acids are the most often used organic acids. Acid anhydrides such as phthalic anhydride

are stronger irritants than the corresponding acids. Weaker acids may be used as preservatives and have caused dermatitis due to their presence in animal feed [6].

Oils. The major offenders are metalworking fluids [7], which may be neat oils, oil-in-water emulsions ('soluble oils'), semisynthetic or synthetic, in roughly increasing order of irritancy [8]. The less viscous a neat oil, the more irritant it tends to be, although chlorination or sulphonation may make viscous oils more irritant. Oil acne/folliculitis is a localized form of irritancy (Chapter 21). In water-based metalworking fluids, the principal irritant is the emulsifier or wetting agent, although other factors, still poorly understood, may increase irritancy [9,10].

Organic solvents [11–13]. These include aliphatic petroleum solvents such as white spirit. Commonly, they contain 18–20% of aromatics [14]. Prime-grade kerosene contains about 2% of aromatics and is less irritant. The much more irritating diesel oil and fuel oil are used, for example, as solvents for oil in casting moulds [15].

Other organic solvents include the following: aromatic hydrocarbons such as benzene, toluene and aromatic petroleum solvents; chlorinated hydrocarbons such as trichloroethylene, perchloroethylene, methylene chloride and chlorobenzene; alcohols such as methanol, ethanol, isopropanol and propylene glycol; esters such as ethyl acetate; ketones such as acetone and methyl-ethylketone; ether alcohols such as ethylene glycol monomethylether; nitroparaffins such as nitroethane; turpentine; carbon disulphide.

Thinner is commonly a mixture of alcohols, ketones and esters, but sometimes also toluene, turpentine and dipentene (limonene). These are used in many industrial processes, including cleaning textiles and metals, the graphics industries, floor laying (where glue is used), wood-finishing, dyeing, painting, etc. They also act as solvents for many technical products, for example polishes and disinfectants. Sometimes, they are used as hand cleansers in dirty work, as in the rubber, plastics and metal industries. They remove the lipid film and water-holding substances, and damage cell membranes. Their irritating capacity depends on their chemical structure, and commonly the following range is valid:

aromatic > aliphatic > chlorinated > turpentine > alcohols > esters > ketones.

Oxidizing agents. Organic peroxides such as benzoyl peroxide and cyclohexanone peroxide are used in hardening polyester resins. Some are used in hair bleaching and some for bleaching textiles, oils and flour. They are strong cytotoxic agents and may cause unusual urticarial reactions [16].

Benzoyl peroxide and ammonium persulphate may be present in flour, and the cytotoxicity of persulphates may also cause irritation during their manufacture [17]. Sodium hypochlorite (bleach) is used, as well as for cleaning, by printers and dyers to remove staining from their hands. Its cytotoxicity makes its medical use in Dakin's solution (Eusol) unsuitable for clean wounds and ulcers [18].

Ethylene oxide is used as a sterilizing agent and may remain on instruments or rubber articles [19].

Reducing agents. Phenols [20], hydrazines, aldehydes [21], sulphureted hydrogen and thioglycolates are common in industry. Penta-, tetra- and trichlorophenols are used as wood preservatives [22]; thioglycolates for cold waving (Chapter 21). Thioglycolates break cross-linkages, including the strong disulphide bonds in keratin, in an alkaline environment. Keratin fibrils take up water, and percutaneous absorption is thereby increased.

Other organic and inorganic substances. Some other substances may also act as strong cytotoxic agents. Examples are as follows: formaldehyde, industrial processing of polyethylene with formation of acrolein [23], crotonaldehyde, thiomersal [24], allyl alcohol, cresol in pesticides (dog collars prepared with a flea repellant have caused irritant dermatitis) and halogenated acetophenones; alkyl bromides and chlorides in paint removers or fumigation [25]; bromine and chlorine derivatives in chemical synthesis; styrene; organic silicones can cause blepharitis; acrylic monomer, diallylglycol carbonate monomer [26] and epichlorohydrin in plastic processes; arsenic in wine culture [27]. Metal polishes, fertilizers and rust-preventive products often contain irritant agents [28]. Alkyl tin compounds are used as preservatives [29], and as antifoulants in marine paints [30]. Mercuric salts, cobalt, zinc chloride [31], etc., have an irritant effect.

Unsaturated aliphatic chains give compounds a more irritating effect—for example, allyl alcohol, diallylphthalate (in polyester resins), cinnamaldehyde compared with hydrocinnamaldehyde (in perfumes) and acrolein [23].

Plants and woods [1–4]. Citrus peel, flower bulbs, garlic, flour, wood dust, spices, corn [5], onion, pineapple, pelargonium, iris, stinking mayweed, buttercup, daffodil [6] and the mustard family can act as irritants, and some can cause bullous reactions even without ultraviolet irradiation (Table 19.7). Spines can cause mechanical damage [7,8]. Thus, barley awns are sharp and may cause papular eruptions and severe pruritus all over the body.

Animal products. Vesicular or papular dermatitis may be caused by caterpillars [9], carpet beetles and moths.

Wet work with fish [10], shrimps, meat and herring in canning industries or restaurants may cause an irritant effect [11,12]. Herring brine contains trimethylamine. Separating the pancreas from the intestines involves contact with enzymes which can give rise to loosening of the nails in butchers. Irritation also arises from proteolytic enzymes in pineapple and papaya [13] and in baking [14].

Table 19.7 Irritating plants.

Ranunculaceae
Ranunculus (many species of buttercup)
Anemone
Clematis
Helleborus
Araceae
Dieffenbachia (ornamental plant in tropics and house plant in Europe)
Euphorbiaceae (spurge; the milky latex of many species is intensely irritating)
Hippomane manchinella (the manzanillo tree of the Caribbean contains a powerful irritant)
Cruciferae
Brassica nigra and other 'mustards'
Compositae
Achillea (milfoil and related species)
Anthemis (mayweeds)
Matricaria

Topical medicaments [15]. Tar, dithranol, potassium permanganate, gentian violet, mercury, hexachlorophane, etc. can, in susceptible persons, even in low concentrations, cause overtreatment dermatitis, which also occurs after prolonged use of wet dressings, particularly under occlusive bandaging. Occlusive transdermal drug delivery systems can also cause irritation [16].

Physical and mechanical factors. These include the following: heat, steam, cold, high or low humidity [17], electricity, sunlight, UV light and other rays; friction, pressure, trauma, rubbing, scratching and scrubbing; metal particles, metal dust, adhesive plaster, fibreglass and rockwool [18–20], textile particles, jute, wood dust, sand, asbestos, silica, cement [21], plaster, hot-metal particles from welding, and glass spicules [22].

Investigations

Irritant contact dermatitis is essentially a clinical diagnosis based on knowledge of the nature and conditions of an individual's exposure in the context of their dermatitis. A complicating allergic contact dermatitis always needs to be excluded by patch testing but patch tests do not aid in the diagnosis. Investigations are most frequently used in the context of scientific studies but may also predict an individual's susceptibility. None can be reliably used clinically on a large scale.

Quantifying the irritant response

Although visual appraisal of skin erythema and surface changes is still widely used to assess irritant reactions, a number of non-invasive techniques have been developed in recent years which permit objective evaluation of key changes to the skin. The optimal method to be used varies with the nature of the irritant [1].

Erythema. Among the most overt clinical features of irritant reactions is erythema, which may be quantified using a number of different approaches. Laser Doppler flowmetry (LDF) provides a measure of superficial blood flow by transmitting monochromatic light from a helium–neon laser through optical fibres to the skin surface. The light is Doppler-shifted by moving blood cells in the upper dermis, remaining unchanged in the surrounding stationary tissue. By means of a differential signal detector and signal processing arrangement, the back-scattered or reflected light is interpreted. The final output, which is linearly related to the product of the number of blood cells and their average velocity in the measured volume, is expressed in relative and dimensionless units. Studies by a number of investigators have shown that LDF generally correlates well with visually assessed erythema, and is capable of discriminating between negative and weakly positive irritant reactions [2,3].

Alternative methods for objectively quantifying erythema rely upon the generalized increase in red blood cells resulting from both increased blood flow and blood vessel dilatation. Those which are based upon remittance spectroscopy emit red and green light from a tungsten halogen lamp or LED source. Oxyhaemoglobin in the blood vessels absorbs a proportion of the green light, and largely reflects the red light. Changes in the quantity of oxyhaemoglobin significantly alter the amount of green light absorbed, but have very little influence on the red light. An erythema index can therefore be calculated from the ratio between the reflected green and red light, such that the greater the erythema, the higher the value of the erythema index [4].

Erythema may also be quantified using tristimulus colorimeters, virtually all of which employ a system for colour definition known as the Commission Internationale de l'Eclairage (CIE) L*a*b* colour system. This provides a three-dimensional coordinate system where L* represents an axis for brightness, a* represents a green–red axis and b* represents a yellow–blue axis [5,6].

Transepidermal water loss. In addition to inducing erythema, irritants commonly affect barrier function, leading to alterations in TEWL. Measuring instruments employ open chambers, through which, when applied to the surface of the skin, water vapour evaporates, creating a water-pressure gradient from which the evaporative TEWL, expressed in $g/m^2/h$, is calculated [7]. Many variables influence TEWL measurements. Some relate to the environment and to instrument operation, necessitating a careful adherence to 'good laboratory practice', as outlined in a report from the Standardization Group of the European Society of Contact Dermatitis [8]. Others relate directly to the individual; age and anatomical site are among the most important variables. Measurements of TEWL have proved valuable in predicting susceptibility to skin irritation, assessing the protective effects of barrier creams, and evaluating the irritancy potential of different chemicals [9–12].

Hydration. Changes in the hydration state of the skin also commonly occur in irritant contact dermatitis, and, again, this parameter may be objectively measured. Several different devices are available, based on differing biophysical approaches. Using the principle of capacitance,

hydration of the stratum corneum can be measured to a depth of approximately 0.1 mm. In contrast, skin conductance has also been used as a measure of hydration. Studies suggest that capacitance may be more effective in the assessment of dry skin, whereas conductance is better suited for studies of water accumulation in the stratum corneum [13]. A third method uses the principle of impedance-based capacitance to assess hydration levels.

Skin thickness. Although not extensively applied, high-frequency ultrasound has also proved valuable for the assessment of another aspect of the irritant response, namely changes in skin thickness [14].

Management

Chemical burns

Initial treatment of chemical burns [1] requires irrigation with large volumes of lukewarm water. Where the chemical is insoluble in water a soap solution may be used instead. High pressures should not be used, to avoid splashing other areas of the body or bystanders with the corrosive material. Whilst neutralizing solutions could represent an alternative treatment, an exothermic reaction might result in increased tissue damage and potential delay in treatment, and they are not generally recommended [2].

Nevertheless, for some chemicals specific antidotes can be used subsequently, e.g. 2.5% calcium gluconate gel for hydrofluoric acid. Application should be repeated 4-hourly and disappearance of pain is a sign of successful treatment [3]. If the pain fails to resolve infiltration or regional infusion have been used [4].

When there is a risk of toxicity from systemic absorption, as with chromic acid [5], early debridement of necrotic areas reduces blood levels, and consideration should be given to the use of dialysis to remove circulating chromium. Ulcerated areas should be managed with antibacterial creams to prevent secondary infection whilst re-epithelialization occurs. If there is a surrounding inflammatory reaction a moderately potent topical corticosteroid can be applied. Vapour permeable dressings are recommended in view of the role of TEWL in stimulating barrier repair [6].

Frequent review is required because the ulcers can progress over several days. Subsequent management with excision/debridement and/or grafting may speed the healing process. Where the ulcer extends into the dermis healing frequently results in a scar and pigmentary change is common. Several chemicals (e.g. hydrofluoric acid, phenolic compounds, chromic acid, gasoline) carry a significant risk of systemic toxicity even when cutaneous involvement is small (~1%). In these instances, regular monitoring of blood, liver and kidney function, with appropriate supportive treatment, is required [7].

When the chemical is a sensitizer, allergic contact dermatitis may subsequently occur on re-exposure to non-irritant concentrations, as burns and irritant dermatitis appear to promote sensitization [8–10].

Irritant contact dermatitis

The successful management [1] of irritant contact dermatitis requires both prevention and subsequently treatment if dermatitis develops.

The most important aspect of treatment is avoidance of the cause (Table 19.8). In an occupational setting, automation of the production process may avoid exposure but can be expensive. A cost-effective compromise is the use of personal protective equipment and/or substitution of a chemical. It should be remembered that natural rubber latex gloves provide protection against water miscible substances but may be inappropriate for other exposures (Table 19.9). With organic solvents and chemicals the choice of glove material may vary [2]; advice may be found on the material safety data sheet.

Once present, dermatitis requires palliation of symptoms with topical steroids and emollients. The efficacy of topical corticosteroids in irritant contact dermatitis has been questioned [3,4] although another study has shown

Table 19.8 Advice to patients with hand eczema.

To speed healing and prevent your dermatitis from returning, you must now take great care of your hands and allow your skin to heal and recover its natural resilience/strength (this may take many months, even though the skin may look normal before then)

1 Use a hand cream many times a day so that the skin does not become dry
2 Use the steroid creams/ointments prescribed by the doctor
3 Washing hands. Use lukewarm water and soap substitute (e.g. aqueous cream). If soap is used, find a soap with no fragrance, tar or sulphur, use it sparingly, rinse thoroughly and then dry thoroughly (especially finger webs and wrists)
4 Avoid contact with detergents and other cleaning agents. Always dilute them according to manufacturers' instructions. Keep outside of container clean or you will contaminate your hands with the neat product
5 If gloves are worn, use plastic rather than rubber, preferably with a cotton lining
6 When washing up, use running water and a pot brush rather than a cloth
7 Washing machines and dishwashers are a great help, but avoid contact with detergent powder or liquid—use a measure with a handle
8 Avoid contact with shampoo. Either use plastic gloves or get someone else to wash your own and your children's hair
9 Do not apply hair products with bare hands, e.g. setting mousse/gel/lotions, colourants, creams, brilliantine. Some of these are irritant, but the friction of running hands through hair is considerable
10 Do not peel citrus fruits with bare hands, e.g. oranges, lemons, satsumas
11 Avoid contact with polish, e.g. metal, shoe, floor, car, furniture, window and wax polishes. NB: Spray polish carries a long way
12 Avoid contact with solvents, e.g. white spirit and brush cleaners, petrol, trichlorethylene, xylene, carbon tetrachloride, e.g. dry cleaning and stain-removal agents. Solvents pass through rubber gloves. Buy vinyl for these jobs
13 Wear gloves in cold weather
14 Water softeners are helpful, but too expensive unless you are not contemplating moving house for a long time. Try adding water softener, e.g. Calgon, to dish water, washing water, baths, etc.; less soap/detergent is then required
15 Individuals with hand eczema are at increased risk of contracting infection through damaged skin and should wear gloves when in contact with blood or potentially infectious biological secretions, e.g. when handling soiled linen, cleaning lavatories, etc.
16 If the skin becomes inflamed and throbs, it is likely to be infected. Visit your doctor, who may take a skin swab and prescribe antibiotic treatment
17 Patients with hand eczema should not be involved in commercial food preparation because the bacteria that cause infection may also cause food poisoning

Your hand eczema should improve if you follow all these suggestions. Once the skin appears to have healed, you should always continue to take care of your hands

Table 19.9 Recommended glove materials for chemical protection. (From Berardinelli [2].)

Glove materials	Nitrile	Butyl	Neoprene	Fluorocarbon	PVC	PVA	Notes
Aliphatic hydrocarbons	+			+		+*	Except cyclohexane*
Aromatic hydrocarbons	+			+		+*	Except ethylbenzene*
Halogenated hydrocarbons			+		+*		Except methyl chloride* & halothane*
Aldehydes, amines, amides	+*						Except butylamine* & triethylamine*
Esters			+*			+†	Except butylacrylate* & octylphthalate†
Alkalis		+		+		+	
Organic acids	+*	+	+†				Except acrylic*†, methacrylic*† & acetic* acids
Inorganic acids	+*		+†		+‡		Except chromic†, hydrofluoric*, nitric*‡ & sulphuric*‡ acids

PVA, polyvinyl alcohol; PVC, polyvinyl chloride.

benefit [5]. Retinoids and vitamin D analogues are not of any value [3].

Experimentally, an emollient alone has been shown to improve barrier repair [6,7]. The choice of emollient may be important. Studies have shown that barrier repair may be impaired or accelerated according to the constituents of a physiological lipid mixture [8]. It has been suggested that conditions in which the lamellar body secretory system is impaired or immature (radiation dermatitis, sunburn, irritant dermatitis due to some surfactants and retinoids, and premature infants of less than 33 weeks' gestation) should be treated with non-physiological lipids, e.g. petrolatum. Whereas most other causes of irritant dermatitis, where lipid metabolism has not been deranged (e.g. diaper dermatitis), should be treated with a mixture of cholesterol : ceramides : free fatty acids, in a 3 : 1 : 1 ratio, to achieve most rapid return to normal barrier function [9].

In severe cases, phototherapy or systemic drugs such as azathioprine and ciclosporin (cyclosporin) may be required. Where there is secondary infection, topical or systemic antimicrobial agents may be necessary.

Non-immune contact urticaria

The mechanism of action of non-immunological contact reactions is not known, but is presumed to be via direct release of inflammatory mediators, including prostaglandins and leukotrienes [1]; the reaction is blocked by non-steroidal anti-inflammatory drugs and ultraviolet light, or by pretreatment with capsaicin, but not by antihistamines [2–4].

Symptomatic irritant responses

Treatment is largely that of avoidance, although strontium salts have been shown to inhibit the sensation [1]. Currently this seems of little practical value.

REFERENCE

Prevention

Identification of the susceptible individual and appropriate career advice prior to employment may reduce an individual's risk of developing dermatitis. Skin irritation thresholds to SLS have been shown to correlate with the subsequent development of dermatitis in hairdressers [1]. Education of an individual or workforce is a prerequisite [2]. Whilst preventative measures may be available, individuals may not make use of them if they do not understand the rationale for so doing.

Mechanization

In general, increased use of mechanization for wet or irritant work, thus avoiding exposure, will help to reduce the incidence of irritant contact dermatitis.

Personal protective equipment

Prolonged use of gloves may increase TEWL [3,4], but in general their protective effects outweigh any potential to induce dermatitis. In a study of hairdressers, unprotected wet work for greater than 2 h per day was the most significant risk factor for the development of dermatitis [5].

Topical preparations

Barrier creams are designed to reduce the penetration of hazardous materials into the skin. Some are specifically formulated for individual chemical exposure. It is said that water-in-oil emulsions protect against aqueous irritants and oil-in-water against lipophilic materials [1]. At best they have only a marginal effect [2,3], and inappropriate use may exacerbate dermatitis. Most claim to give 4 h protection, although others suggest applying 'as necessary'. They are, in general, more effective as a means of preventing excessive soiling of the hands, and therefore may help to avoid the need for strong cleaners which are often more damaging than agents causing the soiling. They may be effective against airborne irritants on the face [4]. The use of barrier creams should not be over promoted as this may engender a false sense of security rather than a reliance on more effective measures. If they are used, instruction in their application is essential if areas of skin are not to be missed [5].

Emollients or hand creams will help to prevent dryness or chapping of the skin, and may also help to prevent subsequent development of dermatitis [6–8]. They are promoted as after-work creams, and controlled trials have shown their effectiveness [9]. Conversely, prolonged use of emollient has been shown to increase susceptibility to irritant dermatitis [10] in an experimental setting. The relative risk/benefit may therefore depend on the circumstances of use.

Soaps and skin cleansers should have a reduced potential to cause irritation, and soap substitutes have been shown to be effective in preventing dermatitis [11].

Other practices associated with hand washing should also be critically evaluated. In medicine, the habit of using a brush when scrubbing for a surgical procedure has been shown to increase TEWL without any additional benefit in reducing bacterial contamination [12].

Prognosis

Following experimental induction of contact dermatitis with 1% SLS, the response to further irritant exposure on previously irritated skin returned to normal after 4 weeks [1]. As the duration of the initial stimulus extends, recovery time is prolonged with the skin remaining abnormal 10 weeks following a 3-week induction [2].

Clinically, assessment of the prognosis of irritant contact dermatitis is mostly based on occupational studies in which exposure to irritants has been prolonged. In one study, only one-third had complete remission of their dermatitis [3]. Atopic individuals are known to have a worse prognosis [4,5]. A change of job may be helpful if undertaken early, but is of less benefit in those with established and chronic dermatitis [6]. Some individuals simply exchange one inappropriate job for another [7]. Delay in diagnosis and assessment worsens prognosis.

Although too frequent or too extreme exposure to irritants will normally lead to dermatitis [8], some workers exposed to irritants seem to develop hardening. Experimentally, following repetitive irritation with SLS for 3 weeks the skin returned to normal reactivity after 3 weeks, but subsequently became hyporesponsive up to 9 weeks following the initial insult [9].

The use of inappropriate cleansers [10] and lack of knowledge as to the cause of their dermatitis [11] will also affect a patient's overall prognosis and outcome.

Persistent postirritant dermatitis

Some hand eczemas which start as irritant or allergic contact dermatitis subsequently persist when the original cause has been eliminated. Whether, in these individuals,

there is some inherent constitutional factor which leads to persistence, or whether some eczemas simply become self-perpetuating, remains unclear. In the occupational setting this has been labelled 'persistent postoccupational dermatitis' [7], and affected 11% of individuals in the absence of any other contributory factor or known constitutional tendency. It seems probable that a similar situation would appertain following non-occupational exposures.

Chapter 20

Contact Dermatitis: Allergic

M.H. Beck & S.M. Wilkinson

History [1]

The term 'allergie' was first coined by the scientist von Pirquet in 1906 [2]. The word was derived from the Greek *allos* and *ergon*, meaning other or different work [3]. However, idiosyncratic reactions to various substances had been recognized since the 17th century [2]. In 1829, Dakin observed the selectivity of *Rhus* dermatitis [4] and Fuchs suggested that 'dermatitis venenata' was an expression of constitutional idiosyncrasy in 1840 [5]. The word 'idiosyncrasy' was again applied by Neisser in his descriptions of iodoform dermatitis in 1884 [6].

Allergic sensitization of the skin was first proved experimentally by Bloch and Steiner-Woerlich using *Primula* extract on humans [7]. Thereafter research on the pathogenesis of allergic dermatitis has largely involved animal experiments using guinea pigs. Landsteiner and Jacobs [8] performed the basic experiment, which showed that a simple chemical capable of causing contact dermatitis must be combined with proteins in order to sensitize. Up to 1940 it was not known whether sensitization depended on a factor localized in the skin, but in 1942 Landsteiner and Chase [9] succeeded in transmitting sensitivity from one guinea pig to another by the use of a mainly mononuclear peritoneal exudate from sensitized guinea pigs. In the same year, Haxthausen's transplantation experiments [10] finally proved that allergy was due to a factor supplied to the skin from within.

Patch testing is the diagnostic tool for allergic dermatitis and it is Josef Jadassohn who is generally accepted as the founder of this technique in 1895 while working at Breslau University, publication taking place the following year [11]. Nevertheless, anecdotal observations of a similar nature had been made prior to this, usually by applying the suspected causative agent to intact skin [12]. By 1847 Stadeler had developed a rudimentary patch test using blotting paper to reproduce lesions provoked by *Anacardium occidentale* [13].

Bruno Bloch was a dermatological pioneer who was able to expand and enhance Jadassohn's technique while working in Basel in 1911, when he also produced a grading system for patch-test reactions [14]. He then moved to Zurich where he introduced the concept of a standard series of allergens [15]. He furthermore conceived important ideas about both cross-sensitization and systemic allergic contact dermatitis [1]. Marion Sulzberger had been an assistant to both Bloch and Jadassohn before returning to New York where he introduced the patch-test technique and was a strong advocate and promoter of its use in the New World. Another former assistant of Bloch's, Paul Bonnevie, Professor of Occupational Medicine in Copenhagen, expanded the standard series to what could be considered the prototype of our present-day series.

By the early 1960s, Scandinavian dermatologists were developing a standardized protocol for patch testing and their group was expanded to involve, initially, other European members before it finally evolved into the International Contact Dermatitis Research Group (ICDRG) [1]. Further national and international research groups have proliferated in the last 20 years, a fitting recognition of the significance of the findings and researches of these earlier pioneers.

Epidemiology [1–3]

Prevalence and incidence (definition). Definition of these terms is important as they mean two different things. Prevalence relates to the number or proportion of individuals who are identified with the condition being studied (e.g. contact dermatitis, nickel allergy) at a given point in time, or over a certain period of time. Incidence relates to the number of new cases developing over a defined period of time and is expressed as number of cases per unit of time.

Methodologies

Epidemiological studies may be undertaken on the general population or on selected groups, for example those referred for patch testing or those with a specific occupation. Studies on the general population need to be large to gain useful information and are challenging to perform. For reasons of expediency, questionnaires have been used but when performed alone underestimate considerably those suffering from dermatitis [4,5]. Population assessments made on individuals attending a general practitioner or referred to a dermatologist may be unreliable, particularly in the UK where prompt access to a dermatologist is achieved only by the fortunate few. In a UK survey, only 21% of those with skin disease thought to justify medical care had seen their general practitioner about it in the previous 6 months [6]. In another large-scale study of a Swedish population of over 107 000, only 50% of the patients with dermatitis had seen a doctor within the previous year [4].

The reporting of contact dermatitis also varies according to the method of collection and the type of person collecting the data. Results from the UK EPIDERM occupational dermatoses surveillance study show how reports of occupational dermatoses differ according to whether the returns are made by dermatologists or by occupational health physicians [7] (Table 20.1). The differences probably reflect the different types of occupational population accessed by the two groups. Occupational physicians will relate to large industries and collective working groups, whereas dermatologists will mainly receive individual referrals, accounting for the comparatively high representation of, for example, hairdressers, florists and beauticians seen by them [7].

Table 20.1 Occupational skin disease: estimated rate per 100 000 workers reported to EPIDERM (Occupational Dermatoses Surveillance Scheme, University of Manchester) [7].

Dermatologists	
Hairdressers and barbers	116.3
Printers	85.8
Beauticians	76.8
Other chemical operatives	69.1
Window dressers, floral arrangers	68.1
Occupational physicians	
Other chemical operatives	183.8
Glass product and ceramic makers	101.2
Vehicle and metal assemblers	94.8
Engineering labourers	82.4
Machine tool operatives	67.9

Case definition

Dermatitis is commonly multifactorial. It is therefore difficult to analyse the relative prevalence of irritant versus allergic contact dermatitis as the two commonly coexist, and constitutional eczema may also be involved. Ideally, all those studied should be examined and those with dermatitis patch tested, but this is not always a practical proposition when large numbers of an unselected group are being assessed.

Apparent differences in overall sensitization frequencies may be due to differences in population structure, especially in relation to age and sex. This can be compensated for either by using standardized populations or by reporting results within specified age bands, and by reporting results for each sex separately [8].

However, in a particular clinic the incidence of allergic contact dermatitis is reflected not only by the sex and age of the patients but also by the industrial development in the area and the degree of interest dermatologists take in the various facets of contact dermatitis (e.g. occupational dermatitis, medicament allergy or leg ulcers). Furthermore, local prescribing habits can influence patch-test results [9]. It has been suggested that all comparative patch-test data should include an analysis of patient details, the MOAHL index [9,10], where M is percentage of males tested, O is percentage occupational, A is percentage of atopics, H is percentage of patients with hand eczema, and L is percentage of patients with leg ulcers or stasis eczema. The percentage of atopics is important, particularly in relation to irritant contact dermatitis [11]. Certain body sites, especially the lower legs in those with stasis eczema or leg ulcers [9] and the ears [12], eyelids [13] and perineum [14], have a particularly high level of allergic contact dermatitis from medicaments. Inclusion of a significant number of any such cases in a patch-test series will affect the overall sensitivity rates for various allergens [9]. Further enhancement to the index has been suggested by including the proportion of those with facial dermatitis and also those above the age of 40. The MOAHLFA index has been suggested (where F is face and A is age) [15].

Prevalence [1]

General population studies

Contact dermatitis accounts for 4–7% of all dermatological consultations [2,3]. Skin disease, chiefly dermatitis [4,5], accounts for almost half of all reported cases of occupational disease [5,6]. Over 20% of females will suffer from hand eczema at some stage in their lives [7]. In one population study in southern Sweden, hand eczema was shown to affect 11.8% of the population aged 20–65 years over a 12-month period [8]. A recent follow-up study indicates that this frequency has dropped to 9.8% despite a rise in the level of childhood eczema [9].

A number of other studies on the prevalence of contact dermatitis in the unselected general population have been undertaken but those that include clinical assessments and patch tests are rare, making it more difficult to ascertain the prevalence of allergic contact dermatitis. Hellgren [10] studied the prevalence of skin diseases in certain Swedish counties and found that 4.8% of the population

were suffering from contact dermatitis diagnosed clinically at the time of examination. Similar figures have been obtained by Johnson *et al*. [11]. In another part of Sweden, the minimum prevalence of hand eczema was estimated by Agrup [12] who sent questionnaires to all persons aged over 10 years in a population of over 107 000; this was supplemented by examination, including patch tests, of those giving a positive reply. The prevalence was 1.7%, with one-third of these having a diagnosis of allergic contact dermatitis. In general, irritant dermatitis was more common than allergic contact dermatitis, but the latter had a worse prognosis. Clinical examination of a random sample of people living in the Netherlands found the prevalence of hand dermatitis to be 5.2% in men and 10.6% in women [13]. Among 1200 women seen during a compulsory health examination in a small Norwegian town, 13.2% of the housewives had some degree of dermatitis of the hands [14]. A questionnaire sent to more than 2500 women in Denmark revealed that over 20% had at some stage suffered from hand dermatitis [7]. Further studies in that country on an unselected population found that 15.2% of those sampled were allergic to a panel of 23 selected allergens [15]. Sensitivity to nickel was present in 6.7% of the population (11.1% women, 2.5% men). In Germany a similar study revealed higher figures, with frequency estimates of allergic sensitization being 28.0% for the overall population, including 11.4% for fragrance mix, 9.9% for nickel and 3.2% for thimerosal [16].

Selected population studies

Most other epidemiological studies have been based on patients already attending dermatology clinics, or have involved either specific occupational [17–19] or other population groups.

The selective nature of patients patch tested in dermatological clinics for investigation of contact allergy is not necessarily representative of the general population; nevertheless, the findings may reflect the relative frequency of the causes of allergic contact dermatitis in that population. Patch testing can be used to generate information on individuals, groups of patients and allergens, and also to assess risk factors in groups of workers [20] and particular subgroups of the population [21].

Dermatology patients

Among 43 000 Danish patients examined by patch tests during a period of 20 years, the percentage of patients with positive reactions to one or several of 23 standard test substances remained largely constant throughout [22]. Some allergens became rare, but this was balanced by an increase in other sensitizers. The prevalence of allergy to specific allergens in patch-tested patients is discussed later in the chapter. Only a few studies have explored the relationship between sensitization and the presence of dermatitis [7,23–26]. Variations in the reading or interpretation of patch-test results will affect the perceived prevalence of contact dermatitis [27].

In general, the commoner allergens are similar from one country to another, although there are differences in rank order [28–32]. The commonest allergens appear to be similar in Europe, the USA and Asia. Some environmental allergens are widely dispersed and the level of sensitivity remains fairly constant, but cosmetics and fragrance materials are becoming increasingly important sources of sensitivity [18–20]. Medicament allergens, such as benzocaine, neomycin and lanolin, are common in all countries [33–35]. However, there may be differences in prescribing habits even within the same country, which can be reflected by the pattern of medicament sensitization. Corticosteroid allergy has been shown to have a very different profile in Oxford compared with Manchester by virtue of differences in prescribing habits leading to greater usage of non-fluorinated corticosteroids in the latter catchment [36]. A similar discrepancy in corticosteroid allergy frequencies has been noted between Belgium and the Netherlands [37].

Young females tend to have more cosmetic and occupational sensitivities; in older people, many sensitivities will be of past relevance only, and there will be a higher prevalence of medicament sensitivity. Nickel sensitivity is common in women and, unless allowance is made for this, false occupational associations may be inferred. Allergens can come and go [38] and the prevalence of a sensitivity to an individual substance will depend on many variables, including the selection of individuals to be tested [39], exposure levels, fashion, environment, introduction of new materials and loss of others, maximum permitted concentrations and usage.

The incidence and prevalence of allergic reactions will therefore parallel the extent of such exposure, and occasionally this may lead to localized 'epidemics' of sensitivity to a particular allergen. One product, 'Eau de Javel', affected the whole pattern of sensitivity to chromate in France [40]. Photoallergy to chlorinated salicylanilides used in antibacterial soaps in the UK occurred as an epidemic in the 1960s [41], as did allergy to the preservative methylchloroisothiazolinone/methylisothiazolinone in cosmetics and medicated wipes in the Netherlands in the 1980s [42]. Cosmetic and preservative exposure varies from country to country and from region to region, according to the degree of usage [42]. This principle may extend to other allergenic sources, so there is a rationale for each centre and country developing its own epidemiological base.

Patterns also change with fashion, as shown by the virtual disappearance of suspender dermatitis from nickel, to be replaced by an increase in dermatitis from earrings, watches and jeans studs [43,44]. The sensitizers found

vary with the patients' social backgrounds, and they may change over the years.

Differences in environmental exposure influence the nature of sensitizers; for instance *Toxicodendron* spp. dermatitis is extremely common in the USA but virtually absent in Europe, whereas *Primula* dermatitis is well recognized in the UK but practically nonexistent in many other countries [45,46]. The introduction of new potential sensitizers will increase the incidence of contact dermatitis due to them in the exposed population; at the same time, allergens that were previously common may disappear. The sudden appearance of *Parthenium* dermatitis in some parts of India from a contaminated shipment of American wheat [47,48] serves as an example of the former, and the decline in sensitivity to turpentine [49] is an example of the latter.

Technological advances have led to new and more widespread exposures to allergens such as epoxy and acrylic resins in the occupational setting [50], although the potential for contact allergy may be reduced by improved personal protective equipment, better containment of sensitizing chemicals and allergen substitution. Similarly, in the domestic environment, phosphorus sesquisulphide allergy in the UK is disappearing because production of 'strike-anywhere' matches has diminished in this country.

Occupational studies

The incidence of occupational dermatitis in most western European countries is in the range of 0.5–1.9 cases per 1000 workers per year [51]; skin diseases account for 13–34% of all occupational diseases [6]. Risk factors are proportional to both constitutional susceptibility (atopy) and exposure [1]. Skin disease (contact dermatitis) is a significant occupational problem, accounting for 46–60% of days lost at work [6,11], with atopics [52–54] and those with nickel or chromate sensitivity [55] having a particularly poor prognosis.

Occupational disease surveillance and compensation registries identify occupations at high risk of dermatitis (see Table 20.1). Most are unable to distinguish between irritant and allergic dermatitis. Some countries have mandatory reporting. In the UK, EPIDERM is a scheme accepting reports made on a voluntary basis from dermatologists and occupational physicians [56]; in a recent study covering the years 1993–99, 52% of dermatitis cases reported by dermatologists and 30% of those reported by occupational physicians had allergic contact dermatitis as the primary cause or as a contributory factor [50]. The higher rate reported by dermatologists might be a reflection of their more frequent use of patch testing. The commonest allergens were rubber chemicals (including those in gloves), nickel and resins. The numbers and proportions of cases of contact dermatitis within occupations remained fairly constant over the 6-year reporting period, although nursing personnel showed an increase, perhaps as a result of increased exposure to agents required to reduce infectious disease transmission [50]. In northern Bavaria there is a mandatory reporting and follow-up investigation scheme [57]. In a recent survey of occupations at higher risk of dermatitis, positive patch tests of occupational and clinical relevance occurred in 52% of those with occupational skin disease, including 73% of construction workers, 72% of hairdressers and barbers, but only 20% of food industry workers [57].

Other occupational groups have a high prevalence of dermatitis [20,23,58]. Among bricklayers in Bergen [59] and building workers in Stockholm [60], 8% had dermatitis; among furniture-makers in Bergen, 12% had teak dermatitis [61]. The incidence, or number of new cases at a specified moment or during a period of time, is particularly high among apprentice hairdressers and nurses [62] compared with the normal population [63].

The pattern of employment has a significant effect on the incidence of skin disease [23], but most common allergens are widely dispersed and, except within small occupational groups, the pattern of sensitivity in a population mainly reflects environmental rather than occupational allergens [39]. Chromate, however, remains a predominantly occupational allergen [28]; the incidence of sensitivity in the normal population is reported to be low [64].

Pathogenesis

The immunology of allergic contact dermatitis is discussed in detail in Chapter 10. There are two main processes [1]: (i) sensitization (induction, or afferent limb, of sensitivity); and (ii) elicitation (or efferent limb) of contact dermatitis.

Sensitization

Allergic contact dermatitis is due to delayed-type or cell-mediated immunity [2]. The induction of sensitivity is the primary event, which has to take place before clinical expression of dermatitis can occur. The main events are described below.

Binding of allergen to skin components. An allergen penetrating the skin associates with major histocompatibility complex (MHC) class II molecules [3] either directly or via antigen–peptide binding sites in the groove of the MHC class II molecule [4] on antigen-presenting cells (APCs). These MHC class II molecules are coded on the human leukocyte antigen (HLA)-D region genes, and are present on epidermal dendritic cells and Langerhans' cells. Epicutaneously applied allergen associates with these APCs within 6 h [5]. The 'danger model' proposed by Matzinger

[6] supposes that sensitization does not occur unless other co-stimulatory factors are also present and produced as a consequence of cell 'stress'. Interleukin-1β (IL-1β), tumour necrosis factor-α (TNF-α) and granulocyte–macrophage colony-stimulating factor (GM-CSF) are all required for the activation, maturation and migration of Langerhans' cells [7]. The danger hypothesis has been adapted to contact hypersensitivity, and evidence produced to support a role for irritant dermatitis in the generation of contact hypersensitivity [8]. In the absence of these co-factors it is assumed that tolerance would develop.

Recognition of 'complete' or conjugated antigen. Sensitization is possible only if the connection to the regional lymph nodes is intact [9]. The allergen-carrying Langerhans' cells travel via the afferent lymphatics to the paracortical areas of the regional lymph nodes, where they become apposed to T lymphocytes. The binding is assisted not only by physical factors—the ruffled membrane and dendritic nature of the Langerhans' cells and the intricate structure of the paracortical areas—but also by specialist cellular adhesion molecules (CAMs). These CAMs act at different loci to encourage binding. For example, leukocyte functional antigen-1 (LFA-1) on CD4 helper cells interacts with intercellular adhesion molecule-1 (ICAM-1) on Langerhans' cells, and CD2 on T cells binds to LFA-3 in plasma membranes on most nucleated cells [10]. With recognition of the antigen, many mediators or cytokines are released by this apposition, for example IL-1 by APCs and IL-2 by T lymphocytes [11].

Proliferation and dissemination of sensitized T lymphocytes. The cytokines cause blast formation [12] in the lymph node and the proliferation of antigen-specific cytotoxic $CD8^+$ (Tc1) and also $CD4^+$ (Th1) lymphocytes [13]. The type of T-cell response generated is dependent on the pathway by which the antigen is processed: small lipid-soluble molecules such as urushiol enter the cytoplasm and are presented on MHC class I as an endogenous antigen; polar haptens are more likely to be presented on MHC class II [14] as an exogenous antigen.

The T cells disseminate via the efferent lymphatics throughout the body and interact with Langerhans' cells and residual antigen in the skin [15]. Contact hypersensitivity is mediated through a subset of T cells that express cutaneous lymphocyte-associated antigen (CLA). Localization to areas of inflammation occurs via production of the chemokine CCL27 by basal keratinocytes, which binds to dermal glycoprotein; CLA-positive lymphocytes also express CCR10, the receptor for CCL27 [16]. The cytotoxic T cells induce keratinocyte death through release of Fas ligand and perforin-mediated pathways [17].

On first exposure to a strong sensitizer such as dinitrochlorobenzene (DNCB), most subjects develop a local reaction after 5–25 days. During this period, sensitization has been accomplished, and the residues of the allergen in the skin react with the newly formed sensitized T lymphocytes. Such a response has been termed a 'late' reaction. There is evidence to suggest that allergen-specific T lymphocytes may persist at the site of original contact for some months following an initial sensitization exposure [18], and this may explain the 'retest' or 'flare-up' reactions following re-exposure.

Elicitation

If a sensitized person is re-exposed to a specific allergen in sufficient concentration, the clinical reaction subsequently develops much more quickly, usually within 24–48 h; however, depending on the degree of sensitivity, penetration and other factors, this may vary from a few hours to many days. Antigen-presenting Langerhans' cells pass to the regional lymph nodes and bind with specific T lymphocytes [19]. They may also bind with the specific T lymphocytes present in the epidermis [20,21]. Furthermore, IL-1-secreting keratinocytes may acquire Ia/HLA-DR status and also present antigen to the specific T lymphocytes [22], augmenting the cascade of cytokine, immune cell and inflammatory response. This cascade is autoregulating, possibly mediated via $CD4^+$ Th2 cells [13].

A delayed reaction time (sometimes also referred to as a 'late' reaction) describes a delayed elicitation response following antigenic challenge in persons who are already sensitized. There has been confusion over the use of this term, as it has been used to describe not only reactions that have taken more than the usual 4 days to develop but also acute primary sensitization reactions which, in normal clinical practice, often present as more sudden and florid reactions around 21 days after challenge. A delayed reaction time is found with low degrees of sensitivity (when there are very few memory T cells), following exposures to small amounts of allergen (when it takes longer to augment the T-cell response) and in situations of delayed penetration of allergens (e.g. neomycin in petrolatum).

Historically, although it was known that idiosyncrasy was specifically directed against certain substances, in 1911 Bloch [23] showed that a sensitive person might react to substances of related chemical structure, a phenomenon later termed 'cross-sensitization'. Some sensitizers only provoke a reaction if activated by light, as found by Epstein in 1939 [24].

Predisposing factors

Individual

Constitution. Sensitization presupposes individual susceptibility. This has been investigated using epidemiological, family and twin studies [1]. In humans, susceptibility does not seem to follow Mendelian inheritance and, in some cases, may occur by non-antigen-specific amplification of the immune response [2]. Nearly everyone can be sensitized with *Primula* extract, and most with 2,4-DNCB. However, experiments with the latter indicate that nearly all susceptible subjects will be sensitized after one or two applications of the allergen in a suitable concentration; repeated applications increase the number of persons sensitized only marginally [3]. Some individuals are thus resistant to sensitization. This resistance may have been acquired by repeated exposure to subsensitizing doses of the allergen [4].

The capacity for sensitization varies from person to person, but certain individuals are more prone to developing sensitivity to a particular substance, for example nickel [5]. The 'heritability' of nickel sensitivity has been calculated to be about 60% [5]. This may be a genetically determined trait but, if so, it is not known whether the property inherited is an increased capacity for conjugation to form an effective antigen, for sensitization or for facilitation of percutaneous absorption [6]. In guinea pigs, the capacity for sensitization, both in general and to particular substances, has been shown to be inherited [7–9]. In humans, such studies are less likely to be conclusive because of the difficulty in distinguishing between genetic and environmental factors. One experiment compared the susceptibility of parents and their children to contact sensitization with DNCB and *p*-nitrodimethylaniline. Children whose parents became sensitized were sensitized more commonly than were children whose parents were not sensitized [10]. However, another study failed to show any difference in capacity for sensitization to DNCB between monozygotic and dizygotic twins [11]. Studies of HLA types and blood groups have not proved very helpful to date [2,12–16]. A statistically significant increased proportion of rapid acetylators has been found in contact allergic patients [17]. The authors were unable to say whether this state was contributory or was a genetic marker for the ability to become sensitized.

Siblings and children of patients suffering from allergic contact dermatitis have an increased incidence of positive patch tests [18], and first-degree relatives of nickel-allergic subjects have increased prevalence of the same disorder [19].

Sex [1]. Women have stronger cell-mediated immune responses than men [2] and yet, at least experimentally, women do not appear to be more susceptible to sensitization [3]. However, sensitization is accomplished more easily with some allergens, for example lanolin, fragrance and *p*-phenylenediamine, perhaps as a result of prior 'conditioning' exposure and subclinical sensitization [4]. In one study, women were found to have greater reactivity to DNCB than men [5] whereas, in another, men were more susceptible to DNCB sensitization than women [6]. The reason for the female preponderance in clinical patch-test studies is mainly explained by the large number of metal-sensitive females [7], which is largely the result of ear piercing [8] and the greater exposure to fragrances, cosmetics and hair dyes. It is of interest that nickel sensitivity seems to be less common in men even if they wear earrings [9].

Hormones. Hormones have some effect on contact dermatitis [10,11]. In one study [12], the response to DNCB was enhanced in women taking an oral contraceptive. Pregnancy and the use of gestagens may, unpredictably, either improve or aggravate contact dermatitis [13,14]. Contact dermatitis may flare premenstrually, and cutaneous reactivity to patch testing may vary according to the stage of the menstrual cycle [15]. No systematic studies on the capacity for sensitization in relation to the menstrual period have yet been performed.

Race. Racial differences appear to exist, judging from experimental sensitization to poison ivy and DNCB, where Afro-Caribbeans are generally more resistant than white people [1,2], although weak reactions to the eliciting dose are difficult to discern on Afro-Caribbean skin [2]. Afro-Caribbeans are also generally more resistant to irritants. Although there are differences in prevalence of sensitization to individual allergens among racial groups, this is felt to be a reflection of exposure rather than predisposition [3,4].

Age. Age has little influence on capacity for sensitization [5]. Children are sensitized as easily as adults, and both infants and elderly people can be sensitized to poison ivy (*Toxicodendron* spp.). *Toxicodendron* dermatitis is very common in American children [6]. This suggests that the paucity of other types of contact dermatitis may be due to the simpler environment of childhood [7] and, being younger, they have had less time to develop sensitivities. Susceptibility to sensitization with DNCB declines after the age of 70 years but is otherwise constant [8]. However, the number of positive patch-test reactions tends to increase with age [9,10], due to the accumulation of allergies acquired over a lifetime, and occupational sensitization may occur only after decades of contact with a sensitizer [11]. Sensitivities may also fade with time [8,12], but this is probably due more to lack of exposure rather than age *per se*. However, the inflammatory response is diminished in elderly patients [13]. Young adults are more likely to have occupational or cosmetic allergies; elderly people are more liable to medicament and 'historic' sensitivities. Age is an important factor in any patch-test study [14].

Contact dermatitis in children [15]. This seems to be increasing [16], and either a child's environment is now less simple or dermatologists have been underestimating

the frequency of allergic contact dermatitis in children, possibly because of their reluctance to patch test younger children. There have now been several series of results of patch testing in children, summarized by Goossens *et al*. [15]. The increased prevalence of sensitivity in children is partly the result of increased exposure to nickel-containing objects and an earlier age of ear piercing [17]. Patch tests in unselected populations of healthy schoolchildren [18] and under-18s [19] found positive reactions in 13.3 and 20%, respectively.

The commonest allergens are nickel (especially in girls), fragrance, thimerosal, medicaments, rubber chemicals, chromate and resins in footwear [15]. Sensitivity to balsam of Peru has been reported to be common in young children [20,21], but this was before fragrance mix was a standard-series allergen. Reactions to thimerosal are also unexpectedly high in young people [22,23], although the relevance of these reactions remains obscure [24,25]. The increased level of reactivity to thimerosal has been blamed on vaccines and inoculations [26].

Small children pose practical problems with patch testing. There is a limited area to which a series of patch tests can be applied and they may become restless once the tests are applied, creating problems with adhesion. It is advised that more than one session of patch tests should be undertaken if necessary and a stronger adhesive used to keep the test units in place [27]. It has also been suggested that children are more susceptible to irritant patch-test reactions than adults [28]. This is not our experience, except for nickel and cobalt, and although positive patch-test reactions are less common than in adults, most reactions appear to be relevant apart from thimerosal. Lower concentrations for certain allergens have been suggested but most published reports have advocated no change. Although an abbreviated standard series based on previous published results has been suggested for children [29,30], we endeavour to perform a full adult standard series plus relevant extra tests wherever possible.

Medication. Drug influences on skin-test reactivity have been reviewed by Schopf [1]. Antihistamines and sodium cromoglicate (disodium cromoglycate) appear to have little effect, whereas prednisolone (dose > 15 mg/day) [2] and potent topical steroids [3] both suppress allergic contact reactions. Similarly, other immunomodulators such as ciclosporin and azathioprine may reduce the intensity of allergic contact reactions. Aspirin will depress skin reactivity to trafuril [4]. Therapeutic UVB or psoralen UVA (PUVA) therapy may also temporarily reduce contact allergic reactions [5–7].

Coincidental diseases. Patients with acute [1] or debilitating diseases such as cancer [2], Hodgkin's disease and mycosis fungoides [3] have impaired capacity for contact sensitization. This may also apply to patients who for other reasons have impaired T-lymphocyte function, for example patients with sarcoidosis [4], lepromatous leprosy [5] and parasitosis [6]. The relationship of allergic contact dermatitis to constitutional eczema and irritant contact dermatitis is discussed in the next section.

Local (relationship of skin damage, irritancy and constitutional eczema to contact allergy). It is convenient to categorize eczemas as endogenous or exogenous, and the latter can be divided into contact irritant and allergic. It is common to see combinations of these disorders, particularly on the hands. Pre-existing or concomitant constitutional and/or irritant contact dermatitis damages the skin, affecting its barrier function and producing increased opportunities for allergen absorption and secondary sensitization.

It is known that hand eczema predisposes to nickel sensitivity and vice versa [1], and that the prevalence of chromate, cobalt and balsam sensitivity is increased in men with hand eczema [2]. The longer the duration of eczema, the greater the chance of sensitization. Occlusion greatly promotes percutaneous absorption and probably contributes to the extremely high incidence of medicament dermatitis in stasis eczema, otitis externa and perianal dermatitis [3–6], and is also a factor in dermatitis from shoes and rubber gloves.

The relationship of atopy, particularly atopic eczema, to predisposition to allergic contact dermatitis has prompted much debate. Atopics are known to exhibit down-regulation of Th1 cells [7,8], which should mean a decreased tendency to development of allergic contact dermatitis; indeed, patients with severe atopic dermatitis may have a diminished capacity for DNCB sensitization [9]. However, clinical studies are conflicting, some showing an increase in prevalence of contact allergy, especially to medicaments [10,11], others the same [12] and others a decrease [13–19]. In a study of 101 sets of twins, no correlation was found between positive patch tests and atopy [20], and the prevalence of allergic contact dermatitis in atopics was found to be similar to that in patients suffering from discoid or seborrhoeic eczema [12]. An increased level of nickel sensitization noted in one study [21] contrasts with another [22] where there was no increase. Confounding factors include the fact that in many cases of chronic atopic eczema there has been considerable exposure, both in extent and time, to medicaments and emollients applied to broken skin, which might explain the increased rate of allergy to medicament components noted in some studies. False-positive patch-test reactions to nickel, chromate and cobalt [23], and probably other marginally irritant allergens, are frequently seen in patients with atopic eczema and can be difficult to interpret. At this time no certain conclusion can be made about the relative risk of contact sensitization in atopic patients.

As sensitivity is more easily acquired if an allergen is applied to damaged skin, concomitant irritant contact dermatitis will promote sensitization and lower the threshold for elicitation of an allergic contact dermatitis in those exposed to associated allergens. In experimental sensitization, skin damage may be produced by previous application of sodium lauryl sulphate. The enhanced risk of sensitization may be due to: (i) increased absorption of allergen as a result of skin barrier disruption; (ii) priming of the immunological response with prior recruitment of immunocompetent cells, cytokines, etc.; or (iii) accumulation of mononuclear cells. Furthermore, by adapting Matzinger's 'danger model' concept for sensitization [24], it has been suggested that contact allergy can *only* develop in the presence of cytokine release from non-immune skin cells (principally keratinocytes) provoked by a coexisting irritant (often the same as the allergen) or trauma [25,26]. If there is no concomitant irritancy, then tolerance rather than allergy will follow.

In guinea pigs, sensitization is facilitated by acanthosis induced by detergents or paraffins, even in the absence of dermatitis [27–29]. Although the mechanism for this promotion of sensitization by acanthosis is unknown, it may be relevant to burns and other types of skin damage known to increase the chance of sensitization [30].

Once allergy is established, it seems reasonable to suppose that an allergen may be able to reactivate or maintain dermatitis in low concentration. However, even when

such exposure seems to have ceased, a hand eczema that started as a contact dermatitis may continue as an apparently 'constitutional' post-insult form of dermatitis [31].

Environmental

By definition, the environment will influence exposure to potential allergens, which in turn will affect liability to contact allergy. For the individual, certain immediate environments, including those encountered in the home, at work and during spare-time activities, are particularly relevant. However, more general influences are important, including climatic, geographical, ecological, socioeconomic and cultural factors. Some of these may also affect the individual's response to allergen exposure. Climate, geography and ecology are often interrelated.

Climate. Climate, by virtue of varying UV exposure, heat and relative humidity, may play a part in liability to contact allergy. UVB exposure has been shown to diminish the skin's immune response to contact allergens [1–3]. Experimental sensitization with DNCB in humans is more easily achieved in winter than in summer [4], and elicitation of contact dermatitis is more difficult on sun-damaged skin [5]. UVA exposure, however, does not appear to have the same effect, and there is evidence that the reduction in immune responsiveness is transient, perhaps due to an adaptive mechanism preventing immunosuppression from ongoing UVA exposure [3]. UVB exposure from the sun may therefore temporarily reduce contact allergic reactions, although there is conflicting evidence about the effect of sunshine on patch-test reactions [6–9]. Conversely, chapping of the skin during winter predisposes to irritant contact dermatitis and also increases the incidence of false-positive patch-test reactions to substances such as formaldehyde [10], mercurials [11] and propylene glycol [12]. Warshaw and Hermann [13] found that positive reactions to propylene glycol were frequent in winter but not reproducible on re-examination in summer. Holland *et al*. [14] found many positive reactions in summer but far fewer during cooler weather in October. Occlusion and increased sweating may increase allergy from shoes and clothing. Kanan [15] also noted an increase in cement dermatitis in Kuwait during the summer months. Exposure to UV-absorbing chemical filters increases where there is a higher exposure to sunshine, with a consequent increase in contact and photocontact allergy from this source during the summer months, when photoallergy from other causes would also be anticipated to be more of a problem. These conflicting observations indicate that several factors must influence the seasonal liability to contact dermatitis.

Flora and fauna. Plant dermatitis commonly shows a distinct seasonal pattern, the allergenicity of some plants such as *Primula obconica* varying considerably with light and season [11]. Many allergenic plants, especially those belonging to the family Compositae, are destroyed by cold and frosty weather but return during the warmer

spring and summer months. Distribution of allergenic plant material will be facilitated by dry and windy climates. Similarly, geographical location is a very important influence. Exposure to *Toxicodendron* spp. is mainly confined to North America. Compositae allergy is seen in many parts of the world but the plants responsible vary: in the USA ragweed is the main cause, in Europe it is chrysanthemums and garden weeds, in India the weed *Parthenium*, and in Australia a number of wild Compositae found in the 'bush' [16]. Occupational contact allergy from plants is often seasonal, for instance in lichen pickers [17] and from plant and vegetable cultivation [18–20].

Fauna are not a major seasonal cause of contact allergy, although European fishermen are liable to contact dermatitis of exposed skin during the summer when handling nets containing marine organisms known as bryozoans [21]. The disorder is known as 'Dogger Bank Itch' in the UK. The allergen has been identified as the (2-hydroxyethyl)dimethylsulfoxonium ion [22].

Socio-economic and cultural. The relationship of contact dermatitis to socio-economic groups has not been studied in detail, but exposure to cheap (nickel-releasing) metals used as jewellery might be expected to be relatively increased in those with less disposable income. Similarly, the pattern of perfume and cosmetic use and exposure might vary according to social class.

Cultural factors are important and not always fully appreciated as a predisposing cause for contact allergy, particularly the use of sensitizing traditional herbal medicines and balms to treat skin disorders in the Middle and Far East [23–25]. Furthermore, ingested herbal folk remedies containing *Toxicodendron* have caused outbreaks of systemic allergic contact dermatitis in Korea [26].

Hair dyes are used much more commonly by men in the Middle East and the Indian subcontinent, including use on the beard [27,28]. Indian women may become sensitized to dyes and adhesives used in kumkum and bindi applied to the forehead [29,30]. Western culture, in contrast, is associated with higher cosmetic use and leisure pursuits, including lying in the sun and seaside holidays requiring the application of sunscreens.

Chemical

Skin cells, especially their nucleic acids and proteins, are composed of molecules that contain nucleophilic atoms, i.e. negatively charged and electron rich. Most allergens (haptens) are 'simple' chemicals of low molecular weight (less than 500–1000 Da) that contain electrophilic atoms [1,2], i.e. positively charged and electron deficient. Interaction between these two types of atoms leads to strong

Hapten group	Example
1 Acids	Maleic acid
2 Aldehydes	Formaldehyde
3 Amines	Ethylenediamine, *p*-phenylenediamine
4 Diazo compounds	Bismark brown, Congo red
5 Esters	Benzocaine
6 Ethers	Benzyl ether
7 Epoxides	Epoxy resin
8 Halogenated compounds	Dinitrochlorobenzene, picryl chloride
9 Quinones	Primin, hydroquinone
10 Metals	Ni^{2+}, Co^{2+}, Cr^{3+}, Hg^{2+}, etc.
11 Unsaturated compounds	Δ^3-Carene (turpentine)

Table 20.2 Classification of haptens based on functional grouping. (From Dupuis & Benezra [4].)

covalent bonding to form a hapten–protein complex or 'complete antigen'. Metal and metal salts can bond to electron-rich atoms (ligands) by taking some of the electrons and forming coordinate bonds [3]. Dupuis and Benezra [4] have classified haptens into seven groups according to their chemical reactivity in relation to putative carrier proteins. Haptens can also be classified according to functional groups (Table 20.2).

Some molecules, although themselves not allergenic (pro-haptens), are converted into electrophilic molecules by the skin's detoxification processes, such as hydroxylation systems, monoamine oxidases and peroxidases. Peroxidases can convert electron-rich aromatic derivatives into electrophile quinones, for example poison ivy catechols are changed into highly reactive orthoquinones [5]. Hydrolysis can convert tuliposides into allergenic tulipalins [6]. Other pro-haptens can be transformed into haptens by the effect of atmospheric oxygen or UV irradiation [7]. Cutaneous enzymatic transformation of a chemical into many different metabolites, depending on the pathway taken, makes determination of the allergenicity of the original chemical more difficult. It also explains the difficulty in deciding if multiple sensitivities are cross-reactions or concomitant sensitization.

Enzymatic systems may also play a preventative role, as with glutathione in some drug-induced reactions [8].

Assessment of sensitization potential. The sensitization potential is the relative capacity of a given agent to induce sensitization in a group of humans or animals [9,10]. Both in guinea pigs and humans, an estimate of the sensitizing index requires patch-test exposures modified to increase the sensitizing impact. Such predictive patch tests are used to compare the sensitizing properties of new products or chemicals with those of known substances [11]. Many test procedures have been developed over the last 40 years to evaluate the sensitizing properties of new chemicals. Kligman and Basketter [12] have critically evaluated the various methods of predictive testing. Most previous methods could not reveal even potent sensitizers. Kligman and Epstein [13] have described a 'maximization test', based on the application of a high concentration of the chemical to be studied on a skin area previously irritated by sodium lauryl sulphate. This method was later modified by Marzulli and Maibach [14], who used repeated patch tests with high concentrations of the allergen to be studied. Jordan and King [15] have shown that some substances giving negative reactions in maximization tests in males sometimes sensitize females. This may reflect previous subliminal exposure to substances such as the ingredients of cosmetics [16].

Ethical considerations may prevent experimental sensitization in humans. The guinea-pig maximization test described by Magnusson and Kligman [17] gives results that compare favourably with predictive patch tests in humans. To enhance sensitization, the guinea-pig maximization test employs a combination of patch testing and intradermal injection of allergen in a simple solution of Freund's adjuvant. Other tests, such as the Buehler test [18] and the open epicutaneous test [19], use the epicutaneous route only, whereas the Draize test [20] and Freund's complete adjuvant test use a purely intradermal method of sensitization [21]. There is, however, no absolute conformity in the sensitizing potential of a substance in mouse, guinea pig and human.

The 6th Amendment of the EC Cosmetic Directive, which came into effect in January 1997, is committed to banning all animal testing [22]. The murine local lymph-node assay [23] uses a smaller number of animals, and the mouse ear swelling test [24] avoids post-mortem examination of tested animals. These newer methods are gaining regulatory acceptance [25].

The theoretical allergenicity of a compound may be studied by reference to databases [26] of cases of reported sensitivity and the results of previously performed guinea-pig maximization tests. By comparing the structure of known allergens with that of any new compound, its likely allergenicity can be assessed. Molecular modelling for sesquiterpene lactones [27] and primin [28] and relative alkylation index for sultones [29] are examples of how structure–activity relationships [30] can be used to assess allergenicity.

Sensitization risk. The risk of sensitization depends not only on the sensitization potential of the substance applied but also on its concentration per unit area of the skin [31], where the area of application is above 1 cm^2 [32], and individual susceptibility. With high concentrations of a strong allergen such as DNCB, individual susceptibility is of little importance; nearly everyone is capable of being sensitized.

In personal care products the concentration of any allergen is adjusted so that the risk of inducing sensitization is small, although there may still be sufficient to induce dermatitis in an individual already sensitized [33]. An approach to sensitization risk assessment for such products has been described [34]. This involves an assessment of both exposure, including knowledge of skin absorption, and sensitization potential, based on literature review and known structure–activity relationships. If *in vivo* testing is needed, various animal tests or human repeat-insult patch tests would then be performed. Legislative measures have been introduced in an attempt to reduce the prevalence of contact dermatitis [35].

Development of dermatitis. Some persons sensitive to a substance may tolerate normal contact with it, and are said to have a latent sensitivity. There is no immunological difference between latent and expressed sensitivity.

Whether sensitivity is manifest or latent is determined partly by the threshold of sensitivity, i.e. the lowest concentration of allergen giving a positive patch-test response. The dose at induction determines in part the strength of response at challenge, higher induction doses resulting in greater reactions at challenge [31]. Persons who are clinically sensitive to poison ivy invariably have a positive reaction to pentadecylcatechol (PDC) 1 : 10 000, but many who react only to 1 : 100 PDC are clinically immune [36,37]. Patch-test sensitivity and clinical sensitivity are not necessarily proportional. The threshold determined by patch tests depends on a number of technical factors, such as the base used and the region where the tests are applied. It also varies from time to time in the same person. The threshold may fall after repeated contact with an allergen, and positive test reactions in latent allergy may reveal candidates for future allergic contact dermatitis.

Patch testing with a new substance may reveal that some persons are already sensitive to it, either from contact with related substances or from exposure to the compound in other forms. Negative reactions in 200 persons do not exclude the possible occurrence of sensitivity in 1 of 38 consumers (99.5% level). This frequency would immediately preclude any practical use of the substance. It has been calculated that negative patch tests in 5300 subjects indicate that sensitivity would be liable to occur in less than 1 of 1000 consumers.

Immunological tolerance. The sensitization reaction induces effector T cells and suppressor T cells, the latter curtailing the immune response so that the epidermal reaction regresses and does not continue indefinitely [38]. Theoretically, therefore, preferential stimulation of suppressor cells could lead to antigen unresponsiveness [39]. This can be achieved by administering the allergen (in previously unsensitized individuals) by non-cutaneous routes, such as intravenously, orally or peritoneally [40–42], thereby bypassing epidermal Langerhans' cells. This tolerance is also achieved by applying the allergen to skin with no Langerhans' cells, for example mouse tails [43], or skin in which Langerhans' cells have been inhibited by UV radiation [44] or depleted by glucocorticoids [45].

Suppressor T cells, or their precursors, are sensitive to cytostatic drugs, so that administration of cyclophosphamide can reverse a tolerant state [46].

Pathology

Biopsies are of limited help in contact dermatitis. Most types of eczema show identical pathological changes, and allergic and primary irritant contact dermatitis cannot be distinguished with certainty [1]. The role of basophils and mast cells remains controversial [2,3].

Ultramicroscopic examination suggests that Langerhans' cells play an important role in allergic contact dermatitis [4–6]. Recent studies on the histology, immunocytochemistry and electron microscopy of the early cellular events in patients with induced allergic and irritant responses are discussed in Chapter 19.

Clinical features

Contact dermatitis can mimic or be associated with any type of eczematous eruption. The diagnosis is based on a careful history combined with a sound knowledge of common allergens and irritants in the environment.

History

A comprehensive history, to elicit potential allergens, is essential, and some knowledge of chemistry and industrial processes is of value. Sensitization and subsequent contact dermatitis may result from a single exposure to a strong allergen [1], although usually several or many exposures are necessary before sensitization and dermatitis occur.

Primary site. This must be ascertained by questioning the patient carefully. By definition, contact dermatitis must begin in sites where contact has taken place with the responsible agent(s), and the sites of origin are an important clue to the cause. Patients are frequently assessed at a stage when there has been worsening and secondary spread of the dermatitis, obscuring the original pattern.

Fig. 20.1 Medicament contact dermatitis. (Courtesy of Dr J.D. Wilkinson, Amersham General Hospital, Amersham, UK.)

Duration and behaviour. Once the date of onset and the primary site(s) have been identified, it is necessary to establish the subsequent behaviour of the disorder. In particular, did the condition spread and if so where? Has the problem been persistent or intermittent? Repeated sudden exacerbations may point to an allergic contact dermatitis. Are there any obvious exacerbating factors?

Improvement of dermatitis during weekends or holidays favours an occupational origin. Relapse at weekends suggests a hobby or non-occupational allergen. Seasonal variation (worsening when light intensity is greatest) suggests a plant allergen, perhaps with photoaggravation, or photoallergy. Plant dermatitis may recur in atypical patterns. Dermatitis around a wound, especially leg ulcers, suggests sensitization to medicaments (Fig. 20.1) and exacerbations and recurrences induced by particular medicaments or cosmetics suggest contact allergy from these sources.

Previous history. A history of previous dermatitis may provide a clue to the origin of a relapse. For example, earring dermatitis may precede nickel dermatitis of the hands by several years. Previous dermatitis, especially if localized to the lower legs, may have been caused or complicated by repeated use of applications containing sensitizers, for example antibiotics, lanolin and preservatives in creams. It is useful to ask specifically about skin reactions to cheap metal, perfume and adhesive plasters.

Fig. 20.2 Acute allergic contact dermatitis in a patient allergic to acrylates used in the printing industry. (Courtesy of Dr J.D. Wilkinson, Amersham General Hospital, Amersham, UK.)

A history of infantile or childhood flexural eczema, asthma, hay fever or conjunctivitis may point to an atopic diathesis. Atopic eczema predisposes to irritant dermatitis of the hands, and in such cases constitutional factors may be the major but not necessarily the sole cause [2].

Sources of allergy

A search for possible sources of allergic contact dermatitis should include a review of all the patient's activities but initially should concentrate on (i) occupation, past and present; (ii) hobbies; (iii) cosmetics, clothing and personal objects; (iv) home environment; and (v) current and previous topically applied medicaments both prescribed and 'over the counter'. Most patients believe that newly encountered items are the cause of dermatitis, whereas in fact those that have been in use for a long time are commonly responsible.

Occupational (Fig. 20.2). A precise history backed by a thorough knowledge of the materials handled at work, machinery operated and personal protection employed will be necessary when occupational dermatitis is suspected. However, no dermatologist can rely entirely on his or her knowledge of industrial processes, and a factory visit may be required to become familiar with the process described, especially if it is strange or new [3]. Health and safety data sheets must be examined as these may give the chemical names of materials used, as well as an indication of their irritancy or allergenicity. A telephone number or email address may be given for further enquiries, if required. The presence of other similar cases will alert one to an increased probability of occupational dermatitis. There are increasing reports of allergy to components of cleansers, creams and conditioners supplied at work, and workers must be asked about use of these [4].

Problems associated with housework should not be overlooked. The amount of housework performed and methods employed are extremely variable. The number of children and availability of labour-saving devices should be determined. Few volunteer information about domestic work outside their own home, and all must be directly questioned about it.

Patients who are unemployed may, in fact, be engaged in casual work, and even employed persons should be asked about second jobs.

Hobbies. Common sensitizers, well known as industrial allergens, are introduced into most homes for do-it-yourself work. Cement, glues, paint, wood and wood preservatives are handled by many householders. Another important source of hobby dermatitis is gardening. Other pursuits, such as car maintenance, sports, cookery and photography, should be considered.

Personal objects. These are items either worn or applied to the skin, and include textiles, footwear, protective clothing and gloves, jewellery, spectacles, hearing aids, medical appliances, cosmetics, toiletries, fragrances and medicaments. Untoward reactions to cosmetics, toiletries and topical applications are the commonest single reason for hospital referral with allergic contact dermatitis. The number of products used may be large, and some may be used only intermittently. Often, only prescribed therapies are declared and repeated specific enquiry must be made about over-the-counter preparations, including cosmetics used as moisturizers, herbal treatments and borrowed medicaments. Often patients will not mention 'hypoallergenic' products in the mistaken belief that they could not be responsible. Applied cosmetics may be removed by employing creams, lotions or wipes, the use of which may easily be overlooked. Patients should be specifically asked about the use of nail varnish, false nails and hair dyes. Skin cleansing and hair products, which are 'rinse off' as opposed to 'leave on', may also be responsible. Many patients have a poor recollection of products used, and most forget some items. They should be invited to bring all their topically applied items when they attend for patch testing.

Clinical examination

Eczematous responses (dermatitis)

The severity of the dermatitis is determined by the intensity of exposure and the level of sensitivity. The clinical picture is also to some extent dependent upon the site of dermatitis and on the causative agent. The distribution of the dermatitis may suggest a cause, for example that due to nickel or textiles.

The primary signs in contact dermatitis are erythema, swelling, papules and papulovesicles, which reflect the sequence of inflammatory changes in the dermis and the intracellular and intercellular oedema in the epidermis. In more acute and severe cases this spongiosis may progress to disruption of the intercellular bridges and the development of vesicles or blisters; if they burst, a weeping dermatitis results. The dominant symptom is itching.

If contact dermatitis persists, it may be due to continued or repeated exposure to the allergen or to secondary irritants or allergens. The skin becomes dry, scaly and thicker as a result of acanthosis, hyperkeratosis and oedema, and cellular infiltration in the dermis. Lichenification and fissuring may develop later (Fig. 20.3). These clinical features of chronic allergic contact dermatitis cannot always be distinguished from constitutional (Fig. 20.4) or irritant contact dermatitis, and the aetiology is indeed often mixed.

The distribution of the dermatitis is of diagnostic importance but its morphology is usually of no help in

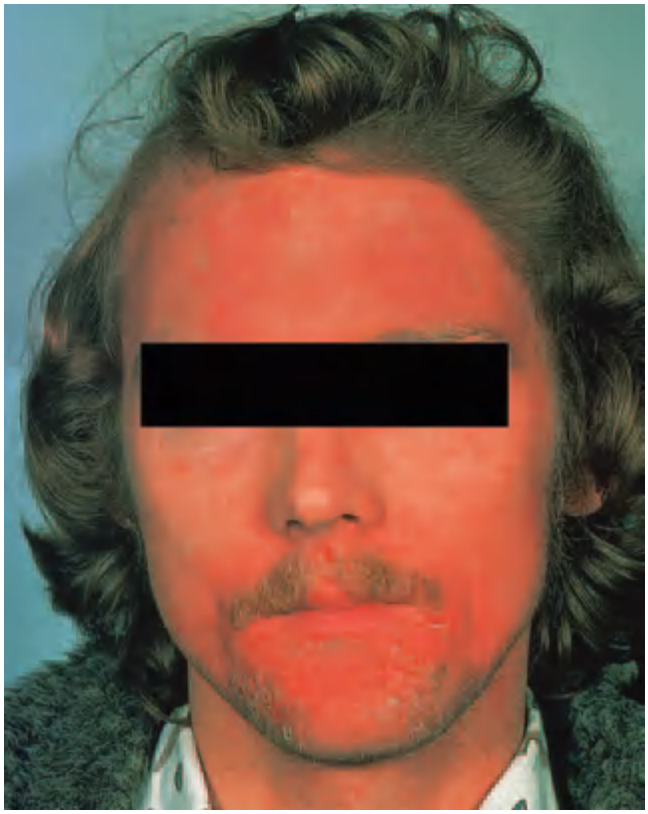

Fig. 20.4 A 'seborrhoeic dermatitis-like' pattern of allergic contact dermatitis due to phosphorus sesquisulphide ('strike anywhere' matches). (Courtesy of Dr J.D. Wilkinson, Amersham General Hospital, Amersham, UK.)

tracing the cause, with some exceptions, for example exceptionally strong allergens may provoke a bullous eruption even after brief contact.

Primary patterns [1]

Anatomical patterns of dermatitis often suggest a specific cause, but in other cases the pattern merely indicates a range of possible allergens, such as in shoe dermatitis.

Sometimes, the dermatitis is sharply limited to the usual site of contact, but because the area of contact with most objects varies, the distribution may be more erratic. Some allergens may be spread locally by the fingers or be carried to distant body regions. Even when there is no eruption on the hands, allergens on the fingertips may cause dermatitis elsewhere, for example the genital area, eyes, or face and neck.

Once the primary site has been established, questioning should focus on those allergens that are particularly frequent causes of dermatitis in that region.

Hands and arms [2–4]. Hand dermatitis is usually multifactorial [5]. About two-thirds of all cases of contact dermatitis involve the hands, which are the most important

Fig. 20.5 Acute vesicular eczema in a patient allergic to 1,2-benzisothiazolin-3-one mimicking constitutional pompholyx. (Courtesy of Dr J.D. Wilkinson, Amersham General Hospital, Amersham, UK.)

site for both irritant and allergic contact dermatitis [1,2,6]. The hands are also a common site for constitutional patterns such as pompholyx, vesiculo-squamous and hyperkeratotic eczema. It may be difficult to differentiate between hyperkeratotic eczema and psoriasis [7]. Atopic eczema often affects the hands [8]. No pattern of hand eczema is characteristic of a particular aetiology, and allergic contact dermatitis may mimic constitutional patterns.

Housewives' dermatitis and most occupational dermatitis remain confined to the hands [9]. Although the majority of cases are of primary irritant nature, the yield of relevant positive reactions to patch tests is remarkably high [1,2]. Fortunately, many of the sensitizers found are included in the standard patch-test series, but obviously the selection of substances for further testing must be guided by history and occupation [10].

Unusual allergens may be traced by relating the shape and site of the eczematous patches to items handled. Rubber gloves may induce a clear pattern of dermatitis over the sites where they are worn.

Vesicular palmar contact dermatitis may mimic constitutional eczema and may also result from contact with or ingestion of an allergen to which the person is already sensitized. This has been shown to occur by oral challenge with nickel [11], chromate [12], balsams [13] and garlic [14]. Chromate in cement, *N*-isopropyl-*N*'-phenyl-*p*-phenylenediamine (IPPD) and 1,2-benzisothiazolin-3-one (Fig. 20.5) are three allergens particularly liable to induce a palmar pattern of allergic dermatitis. Discoid patterns of eczema are seen with chromate allergy.

Irritants affect mainly the dorsa of the hands, the webs, and the backs and sides of the fingers. Dermatitis caused by liquids often starts in the webs of the fingers, and extends to the front of the wrists and up the forearms. A recalcitrant type found in domestic workers begins under a ring and spreads to the neighbouring webs and adjacent

Fig. 20.6 Characteristic 'streaky' contact dermatitis on the wrists in a patient allergic to *Primula obconica*. (Courtesy of Dr J.D. Wilkinson, Amersham General Hospital, Amersham, UK.)

part of the palm. However, allergic contact dermatitis may also start under a ring [6].

Streaky dermatitis on the fingers, dorsa of the hands and forearms is mainly caused by plants (Fig. 20.6), and is allergic (e.g. *Primula obconica* and poison ivy), irritant (e.g. *Dieffenbachia* and spurge) or phototoxic (e.g. giant hogweed and rue).

Dermatitis of the hands in those involved with agriculture and food preparation may be associated with immediate-type hypersensitivity to animal and plant proteins [15,16]. Allergic contact dermatitis of the fingertips is seen with plant allergens such as tulipalins in horticulturists ('tulip fingers') [17]. Garlic allergy in chefs typically affects the non-dominant thumb, fore and middle fingers [18] (Fig. 20.7).

The arms are affected by the same allergens as the hands, but usually later. If protective gloves have been used at work, the forearms may be the major sites of occupational dermatitis (Fig. 20.8). Allergy to nickel, chromate and *p*-tertiary-butylphenol formaldehyde resin may develop at the wrists from sensitivity to the metal, leather and glue, respectively, in watchstraps containing these allergens. Dust (exotic woods, cement), nickel and textiles produce dermatitis in the elbow flexures, and this must be distinguished from atopic dermatitis.

Face [19,20]. Dermatitis of the face may occur alone or in association with hand eczema. Facial allergic contact dermatitis from fragrances, preservatives and other constituents of skin-care products and cosmetics, including

Fig. 20.7 Fingertip pattern of allergic contact dermatitis from garlic affecting the non-dominant thumb, forefinger and middle fingers.

Fig. 20.8 Contact allergy to epoxy resin and hardener affecting unprotected forearms.

nail varnish, is common [21]. Nail varnish allergy often affects the face in well-localized patches, and may be associated with eyelid dermatitis and more extensive involvement of the neck, chest and even further afield [22]. The clinical presentation can even suggest artefact because the affected sites are so well demarcated [19,23]. A similar distribution may be seen from allergy to acrylic nails [24].

Allergy to rubber sponge cosmetic applicators has also been reported in this site [25]. Facial allergic contact dermatitis must be distinguished from intolerance, irritant contact dermatitis and constitutional eczemas, but it is sometimes multifactorial.

Fig. 20.9 Contact dermatitis presenting as acute oedema, as seen in patients sensitive to *Primula* and *p*-phenylenediamine-type hair dyes and in those with volatile patterns of contact dermatitis. (Courtesy of Dr J.D. Wilkinson, Amersham General Hospital, Amersham, UK.)

Dermatitis to a cosmetic may start with dryness, tightness and itching. Most women change to another brand at this stage and never reach the dermatologist. They are referred only if symptoms persist or are severe. Allergy cannot be totally ruled out unless all ingredients of all cosmetics have been tested individually at appropriate concentration and in a suitable vehicle. Ideally, the raw material should be the same as that used in the suspect product, because batch differences, source and purity may all be important. In practice, however, most cosmetics are initially tested 'as is'. A repeat open application test (ROAT) [26] or use test [27] may be performed to try to identify the offending cosmetic, although these will not necessarily differentiate between irritant and allergic reactions.

The forehead is affected by allergy to anything applied to the hair and also to chromate in leather hatbands. Spectacle frames containing nickel or plastics may cause dermatitis on areas of contact with the cheeks, nose, eyelids and ears [28–30].

The patterns of dermatitis caused by airborne or volatile allergens [31] and photosensitizers can often be distinguished by involvement of the eyelids in the former, and by triangles of relatively spared skin below the chin and behind and below the ear lobes in the latter.

Eyelids [32]. Allergens affecting the face may initially produce eyelid dermatitis, as the skin of the eyelids is thin, sensitive and may be contaminated by the fingers (e.g. nail varnish [33]), airborne droplets (e.g. fragrance sprays) or volatile substances (e.g. epoxy resin). Eye creams, eye shadows, mascara and eye make-up removers may be responsible, often for irritant dermatitis, but patch testing may reveal relevant allergens.

Some allergens provoke acute oedema (Fig. 20.9) and intense pruritus, but no manifest eczema followed by desquamation. *Primula obconica* and poison ivy [34] may cause such a reaction involving the eyelids, or a streaky pattern of dermatitis at contact sites, which may be haemorrhagic. Reactions to hair dyes and 'strike-anywhere' matches may also present in this way.

Dermatitis is frequently caused by remedies for ocular disorders [35]. Common sensitizers in eye drops and ointments are neomycin, framycetin, gentamicin, tobramycin, chloramphenicol, sulphonamides, local anaesthetics, antihistamines, β-blockers [36,37], anticholinergics [38] and sympathomimetics [39]. Eye drops and contact lens solutions contain preservatives (benzalkonium chloride, EDTA, mercurials), which may also sensitize [35].

Lips or perioral area [40]. Lipstick dermatitis is sometimes limited to the vermilion border, which appears dry, scaling or cracked; occasionally the perioral area is also affected. Eosin was a common sensitizer in lipsticks before 1960 [41] but since its allergenicity was found to be due to impurities there have been no further reports of adverse effects, and lipstick dermatitis is less common. Sensitivity has been reported to flavourings [42,43], shellac [44] and excipients, for example ricinoleic acid [40], castor oil [45], gallates [46,47] and UV filters [48] in lipsticks and lipsalves.

Allergy to toothpaste is a recognized cause of cheilitis and perioral eczema [40,49]. Flavours are the usual cause, such as cinnamic aldehyde [50,51], spearmint oil, peppermint oil, anethole and L-carvone [52].

Allergic reactions to dentures and fillings are considered in the section on mucous membranes (see p. 20.26). Angular cheilitis is usually due to badly fitting dentures, but cheilitis may exceptionally be caused by sensitizers habitually carried to the mouth, such as nail varnish or nickel-plated objects [53] (e.g. keys, pins or musical instruments).

Ears. External otitis has a complex aetiology (see Chapter 65) and usually runs a chronic relapsing course. Neurodermatitis (lichen simplex chronicus) is also common, and may be superimposed on seborrhoeic eczema.

Secondary medicament contact dermatitis, which is often unsuspected, is particularly common in the ear [54,55]. Dermatitis can also be both caused and maintained by habitual scratching with hairpins (nickel), matches (phosphorus sesquisulphide and chromate) [56] or fingertips (nail varnish, nickel, *Primula obconica*).

Dermatitis from hearing-aids occurs but is often a non-specific consequence of occlusion [57]. Hearing-aids may contain acrylates [58–60] and plasticizing and stabilizing chemicals [61]. Headsets may contain urea and phenol-formaldehyde resins, or rubber in earphones.

Spectacle-frame dermatitis may be of irritant origin, especially behind and over the ears. Metals, particularly nickel and palladium, may cause allergy, and some frames causing dermatitis have been wrongly described as being nickel-free or titanium [62–64]. Plastic components,

including epoxy resins [65], acrylates [66], plasticizers [61,67], UV inhibitors [68] and dyes [69,70], have been identified as the cause of the dermatitis. Earplugs for noise protection may contain antiseptics, dyes, rubber and plastic chemicals [71], and finishes including formaldehyde resins. Elastic on shower caps, and hair dyes, cause dermatitis in the retro-auricular area.

Earrings and clips commonly cause dermatitis on the ear lobes from the presence of nickel, and less commonly from gold [72]. Piercing of the ear lobe may be the sensitizing event in nickel dermatitis, leading to a chronic contact dermatitis [73,74].

Scalp. The scalp tends to be relatively spared from involvement by allergic contact dermatitis. Dermatitis caused by fragrances, biocides and amphoteric detergents in hair cosmetics is usually limited to the ears, neck and face, but may be preceded by persistent itching of the scalp. Permanent hair dye, *p*-phenylenediamine, and related semi-permanent dyes still remain an important source of dermatitis. Correctly used, permanent hair dyes are applied to the hair and not the scalp, followed by oxidation and rinsing. Bleaches contain ammonium persulphate, which may cause peculiar urticarial eruptions [75] as well as contact dermatitis. Glyceryl monothioglycolate, used for acid or cold perms, although a significant sensitizer in hairdressers, only occasionally causes problems in their clients [76]. Hair-styling products such as mousses, gels, waxes and holding sprays often contain fragrances and preservatives that may be allergenic, but they also contain conditioning quaternary ammonium compounds, which are often irritant. Medicated shampoos may contain tar extracts, zinc pyrithione or other agents, and many shampoos contain formaldehyde, formaldehyde releasers or isothiazolinones, added as preservatives. Cocamidopropylbetaine is also found in many shampoos. All these materials may potentially sensitize, although allergic subjects may tolerate them because of the short duration of contact, provided the hair is thoroughly rinsed after washing [27,77,78]. Scalp dermatitis from allergy to azo disperse dyes in a nylon wig has been reported [79].

Neck. Nickel from clasps of necklaces or zip fasteners produces a small area of dermatitis on the nape of the neck. Nail varnish (Fig. 20.10) or *Primula obconica* from fingertips may be the cause of a patchy allergic dermatitis sometimes simulating lichen simplex.

Textiles (finishes in collars, dyes) and necklaces (nickel, exotic wood) may cause a collar-like dermatitis, or eruptions on the sides of the neck. Dermatitis from airborne allergens and photosensitizers is sharply limited by the collar to the 'V' of the neck if blouses or open-necked shirts are worn.

Perfume may cause both allergic contact dermatitis and phototoxic dermatitis (Berloque dermatitis) on the neck, especially the sides. A characteristic pattern of photoallergic pigmentation was also seen in men photosensitized to musk ambrette [80].

Fig. 20.10 A patch of 'lichen simplex-like' eczema on the nape of the neck associated with allergy to tosylamide formaldehyde resin (nail varnish). (Courtesy of Dr J.D. Wilkinson, Amersham General Hospital, Amersham, UK.)

Axillae. Many cases of dermatitis are irritant due to sweating, occlusion and the use of antiperspirants, which often contain aluminium salts to block the sweat glands. Allergic sensitivity may occur to fragrances used to mask the odour [81,82] and to antiseptics intended to reduce the bacterial flora [83,84]. The dermatitis produced by textiles tends to be periaxillary.

Trunk. The distribution of a clothing dermatitis may provide a clue to the responsible garment. In both sexes, nickel buttons and zip fasteners cause dermatitis localized to where they are worn, but a more widespread secondary spread eruption is often associated. Chromate sensitivity from leather and rubber allergy from elastic may present as truncal eczema [1]. Dermatitis from dresses, blouses and sweaters usually predominantly affects the neck and folds of the axilla, and spares areas of skin covered by undergarments. The allergens are usually textile dyes or finishes.

UV filters cause a diffuse allergic or photoallergic dermatitis. Outdoor workers sensitized to Compositae may have a diffuse dermatitis or dermatitis of an airborne pattern, which affects all the exposed areas, including the trunk if they remove their clothing to work. Detergents and fabric conditioners are commonly blamed for truncal

skin eruptions but objective confirmation is usually lacking. Perfume residues might possibly cause problems in fragrance-allergic individuals. Diffuse papular eczema may be a feature of medicament sensitivity with secondary spread.

Anogenital. The anogenital region is a common site for medicament sensitization [85,86]. There is often experimentation with a wide range of prescribed and over-the-counter medicaments for pruritus, skin eruptions and haemorrhoids, many of which contain sensitizers, most commonly perfume, local anaesthetics and balsam of Peru (*Myroxylon pereirae*). Other sensitizers prescribed by the medical profession include neomycin, hydroxyquinolines, ethylenediamine, corticosteroids and topical antifungals. Moist toilet tissues and wipes may contain unnecessarily high levels of preservative, which have been associated with an increased prevalence of allergic sensitivity [87,88]. Ectopic contact dermatitis from nail varnish may affect this site [89]. Nylon dyes, especially in tights, may also produce allergic contact dermatitis largely confined to this area.

Ingestion of contact allergens may cause pruritus ani particularly if they are excreted unchanged. Spices and medicaments may occasionally be suspected. Cashew nut oil in butter was found to induce perianal dermatitis in an individual allergic to the cross-sensitizing allergenic urushiol found in poison ivy [90].

Allergic contact dermatitis confined to the vulva is relatively less common [91]. Perfumes or antiseptics in soaps, sprays or sanitary pads [92] are said to be rare causes of genital dermatitis, although feminine hygiene sprays may cause both irritant and allergic reactions [93]. Medicaments used for vaginitis rarely provoke allergic reactions on the mucosa but sometimes produce a rash on the adjacent skin, and may cause connubial dermatitis in sexual partners. However, in one study of patients suffering from pruritus vulvae without associated inflammation, 49% had one or more relevant allergic reactions on patch testing, as did seven of 16 patients with lichen sclerosus. In over 50% of these patients, symptoms improved significantly or resolved when avoidance measures were taken [94]. Vulvodynia does not appear to be frequently associated with contact allergy [95].

Rubber accelerators in condoms can also be a cause of genital eczema or pruritus vulvae [96]. Genital dermatitis from transfer of material carried on the hands may occur in carpenters and cabinet-makers and those who work with resins.

Thighs. Dermatitis from nickel and rubber in suspenders is now rarely seen. Textile dermatitis starts at the edge of the underwear, and is usually more pronounced in the popliteal spaces or gluteal folds. Finishes in the material of the pockets or objects kept in the pockets (e.g. nickel coins or boxes of matches) may provoke a patch of dermatitis on the underlying skin (Fig. 20.11). Allergens may penetrate working clothes.

Fig. 20.11 Allergic contact dermatitis due to items kept in trouser pockets. (Courtesy of Dr J.D. Wilkinson, Amersham General Hospital, Amersham, UK.)

Lower legs. The lower leg is particularly prone to contact allergy. Allergic contact dermatitis from medicaments predominates, especially in those with varicose eczema and ulcers. The common allergens are topical antibiotics and components of creams and paste bandages, such as lanolin, cetearyl alcohol and parabens [97,98]. Allergy seems to occur readily to materials that are rarely problematic in other sites. Rubber allergy may be associated with compression bandaging and elastic hosiery. Allergy to colophony and derivatives may occur from dressing adhesives [99] and nylon dye allergy may be seen from hosiery.

Rubber boots provoke dermatitis either at their upper edge or on the calf in areas of greatest friction.

Feet. Dermatitis may result from shoes and stockings or remedies for 'athlete's foot', antiseptics and antiperspirants.

Generalized. Generalized erythroderma may be the result of a chronic contact dermatitis maintained by continued exposure to allergens in the environment, even in hospitals, for example contact with formaldehyde-disinfected mattresses or bed linen impregnated with topical medicaments. Patch testing is not possible until the skin has cleared.

Exposed sites [1]

Contact dermatitis from dust, sprays, pollens or volatile chemicals is typically confined to the exposed surfaces of the hands, arms, face and neck. The first attack often originates from direct handling of an allergen, but recurrences may be seen despite avoidance of direct contact. There is great diversity in the nature of airborne reactions, which may be irritant, allergic, phototoxic, photoallergic and contact urticarial [1]. Some agents may cause more than one type of reaction. Hence, phosphorus sesquisulphide may cause both contact urticaria and allergic contact dermatitis [2]; *Parthenium* may cause both allergic and, rarely, photocontact dermatitis [3]; and formaldehyde can cause irritant and allergic dermatitis, and contact urticaria [1].

Lists of airborne allergens have been published and updated by Goossens *et al*. [1,4,5]. Plants, natural resins and woods are among the commoner causes of this distribution of contact allergy. In the USA, the oleoresins of ragweed commonly cause allergic contact dermatitis. A similar pattern is found in the UK during the summer months from other Compositae weeds [6,7] which, when they occur in other parts of the world, also cause an 'airborne' pattern of dermatitis [8,9]. In India, *Parthenium* has been associated with widespread epidemics of severe dermatitis and even deaths [10].

Dermatitis from wood dust is common in carpenters and cabinet-makers. It normally starts on the eyelids or the lower half of the face, and is often preceded by a period of itching. Swelling and redness spread to the neck, hands and forearms. By the time the patient attends for treatment, a diffuse dermatitis may have developed, distinctly limited at the margins of the sleeves and collar. Because of the accumulation of dust and sweat, the elbow flexures and the skin under a tight collar are often lichenified. Cabinet-makers frequently develop a genital dermatitis from accumulation of sawdust on the clothes during sawing and planing, and by hand contact. Swelling and redness of the eyelids may be the only signs of recurrence. Exotic woods are more likely to sensitize than fir or spruce, although the latter may cause dermatitis in patients sensitive to colophony [11], turpentine and *Myroxylon pereirae* (balsam of Peru). Dermatitis in woodworkers may additionally be caused by liverworts [12] and lichens on the bark of trees [13]. Colophony can also give an exposure pattern of dermatitis from its presence in solder fluxes, paper dust, polish and linoleum flooring [14,15].

Resin systems, particularly epoxy resins, including the more volatile amine hardeners, may induce an airborne pattern of allergy, especially in the occupational setting. Other causes of this pattern include perfumes, metals, many industrial and pharmaceutical chemicals, pesticides, fungicides, animal feed additives, textile dyes and matches [5]. Equivalent patterns of airborne dermatitis may be seen with type I allergens, such as house-dust mite antigens in atopics [16].

Photocontact allergy causes a similar distribution, and is discussed on p. 20.29.

Mucous membranes

Application of DNCB to the oral mucosa may, in some cases, induce a low degree of contact sensitivity, but more often an immunological tolerance to later sensitization [1]. Similarly, prior exposure to nickel and chromate in orthodontic appliances seems to reduce the risk of later sensitization [2,3].

Contact inflammation of the mucous membranes is not common, and is often secondary to skin sensitization with the same substances. Reactions may be allergic or irritant in nature. Both immune and non-immune immediate-type contact urticarial reactions may occur.

The skin and mucous membranes differ in both anatomy and environment. In the mouth, except on the gums and hard palate, there is no horny layer with a barrier function and storage capacity. There is no lipid secretion but instead a continuous flow of saliva, which washes away foreign substances. Penetration of water-soluble substances is rapid. It is not known whether these differences are relevant to the paucity of allergic contact reactions in mucous membranes. The oral mucosa of sensitized animals has been shown to have an identical cellular phenotype and cytokine expression as the skin when challenged by the allergen [4].

Allergic reactions in the mouth show erythema and swelling but vesicles are rarely seen, except on the vermilion border. The symptoms are soreness and burning, and itching is uncommon. Eczematous reactions of the adjacent skin may occur, and these may be the only signs of an allergic contact dermatitis.

The burning mouth syndrome is an entity in which psychological factors are important. Sometimes, allergens such as metals, rubber, food additives and flavourings have been identified and the symptoms relieved by contact avoidance [5–7], but the return from investigations is often disappointing [8,9].

Orofacial granulomatosis has been associated with contact allergy to food additives and some of these individuals may obtain a favourable response, often only partial, to dietary elimination of the identified allergens [10].

Dentures are frequently incriminated as the cause of oral symptoms and lesions. Allergic reactions to denture materials have been found in some cases [11,12], due to traces of residual acrylic monomer following wearing of new dental appliances or following their repair with cold-curing resins. Most cases are caused by irritation from ill-fitting dentures. Candidal infection may also play a role [13], and is often present in angular cheilitis. Acrylate allergy has also been seen rarely after dental restorative work [14].

Mercury from amalgam fillings may cause local mucosal [15] or lichenoid [16–18] reactions; perioral dermatitis after dental filling may also occur, as may generalized skin eruptions [19]. Contact reactions have also been reported due to other metals [16–18,20], especially gold [16–18,21,22] used in dental restorative materials, and nickel and palladium in orthodontic appliances. There remains debate as to whether materials sensitize via the mucosal route [4,23] or whether there is only elicitation of pre-existing sensitivity (in those already sensitized) and the induction of tolerance (in those who have not already been sensitized) [3].

Toothpaste flavours can cause stomatitis, glossitis, gingivitis, cheilitis and perioral eczema [24].

The nasal mucosa may react to medications containing antibacterial agents and antihistamines. Corticosteroid allergy from nasal sprays has been reported, with one case of associated perforation of the nasal septum [25,26]. In the conjunctivae, various drugs are reported to have elicited allergic contact reactions, for example β-blocking compounds for the treatment of glaucoma [27], antibiotics, and preservatives in both drugs and contact lens solutions [28].

Genital mucous membranes may be affected by allergens causing dermatitis on the surrounding skin, particularly from medicaments [29,30].

Secondary patterns

Contact dermatitis may start at one site, but commonly other sites are subsequently involved, and sometimes several regions simultaneously. By the time the patient has been sensitized, many body regions may have been in contact with the allergen, some indirectly by contamination from the fingertips. Heavily contaminated areas, or those that were exposed last, tend to be the ones to react first, other sites flaring later. This has been shown experimentally with poison ivy [1], and is an obvious clinical feature in *Primula obconica* dermatitis. Regions close to the primary site of allergic contact dermatitis are easily contaminated by the allergen.

Such a simple explanation cannot account for the frequent spread of dermatitis from feet to hands and vice versa. This occurs primarily in constitutional eczema but may occur in contact dermatitis. Sometimes, a common allergen is found that could explain occurrence at both sites, yet often it is a pattern of secondary spread. Epstein [2] suggested that skin protein might have a regional specificity, identical for fore and hind legs, i.e. 'four-hoof disease'; Parish *et al*. [3] suggested 'auto-allergy'. No precise explanation exists.

Because of the similarity to Darier's trichophytids and eczematids [4], dissemination to distant regions has been termed an 'id-like' spread. Local aggravation may precede secondary spread by several days.

The pattern of spread is largely determined by the primary site. Dermatitis of the hands commonly spreads to the arms and face; dermatitis of the feet tends to spread to the legs and hands.

Many patients with stasis dermatitis have secondary eruptions by the time they are seen by a dermatologist, and are referred because of the alarming dissemination. This may be due to an 'id' reaction or secondary contact dermatitis. Dissemination from leg eczema commonly involves the arms and shoulders in a patchy fashion before becoming generalized, often beginning with pruritus and sometimes progressing to generalized erythroderma. On the face, diffuse redness and oedema are common. Eyelid dermatitis or a diffuse dry dermatitis of seborrhoeic type may be seen.

Severe nickel allergy may induce extensive patchy eczema, which is slow to respond to treatment, and this will not settle unless strict nickel avoidance measures are undertaken.

Contact allergy to components of topical treatments presents special difficulties. The allergen may be an active ingredient or an excipient. If the dermatitis spreads further in spite of treatment, it may wrongly be assumed to be an endogenous eczema. In contact dermatitis caused by topical steroid preparations, the action of the steroid may partially suppress the local reaction. The sensitivity becomes clinically manifest only as 'failure to heal' of the

original eczema, or with the development of a secondary eruption.

Constant alertness is therefore a prerequisite for the diagnosis of allergic contact dermatitis in which dissemination is a dominant feature. Patch tests should be delayed until the acute eruption has settled.

Systemically reactivated contact dermatitis [1]

Systemically reactivated allergic contact dermatitis, where ingestion or other systemic exposure to a contact allergen takes place in an already sensitized person, may result in a number of different patterns of skin eruption. The threshold of reaction varies in each individual case and depends on the dose given and the level of sensitivity. Reactions may occur not only after ingestion of the primary allergen but also after ingestion of secondary (closely related) allergens [2].

The most frequent types of reaction are focal flares of previous patch tests and sites of previous dermatitis [3], vesicular hand eczema, or much more widespread eczema and erythema, sometimes with additional urticarial features [4–7]. In severe cases vasculitis [8], erythema multiforme [9] and systemic upset may occur [1,10]. Involvement of the eyelids, body folds and buttocks induced by oral challenge with nickel in allergic subjects led to this particular reaction being labelled the 'baboon syndrome' [11]. This is often also the pattern seen in patients with a mercury exanthem [12]. In some patients following widespread reactions, and in others following attempts at 'desensitization', the level of patch-test reactivity appears to be reduced [10,13].

Probably all contact allergens can cause systemic reactions, provided the patient has a sufficient degree of pre-existing sensitivity and the dose administered is sufficiently large [14]. The causes are many, and include medicaments that may have been given not only by mouth but also parenterally, rectally, intravesically or as an inhalant. Dietary causes include metals, plants and spices.

Systemic contact dermatitis from medicaments has decreased as a result of reduced use of topical sensitizers such as the antibiotics streptomycin, sulphonamides and penicillin, and topical antihistamines such as promethazine. Nevertheless, exposure to other topical and systemic medicament sensitizers continues to give problems. Standard allergens responsible for these reactions include neomycin, quinolines [10], local anaesthetics [15], ethylenediamine and corticosteroids. In subjects with contact allergy to ethylenediamine, parenteral administration of aminophylline (which contains ethylenediamine) has resulted in widespread eczematous eruptions [16]. Ethylenediamine is structurally related to some antihistamines (e.g. hydroxyzine) and may therefore also trigger a systemic flare [2]. A positive patch test to tixocortol pivalate is an indication of hydrocortisone allergy. Systemic administration of hydrocortisone has induced recurrence and extension of dermatitis [17]. Furthermore, administration of parenteral adrenocorticotrophic hormone (ACTH), thereby raising endogenous hydrocortisone, has resulted in flares in hydrocortisone-allergic individuals [17]. Other systemic steroids have also induced systemic contact dermatitis [18,19]. Inhalation of budesonide has been associated with reactivation of positive patch tests, and continued exposure to budesonide from this source may therefore maintain dermatitis in sensitized subjects [20]. The reader should consult the more specialized literature for a full list of the many other medicament causes reported [21,22].

Persistence of dermatitis, especially vesicular hand eczema in metal-allergic subjects, has been blamed on dietary intake, particularly nickel [23]. Traces of metal dissolved by cooking acid or salty food in stainless steel may be of consequence in the persistence of dermatitis due to metals, such as chromium, nickel and cobalt [24–27]. However, the role of ingested or dietary nickel in hand dermatitis remains controversial [28–30], especially as a percentage of patch-test-negative patients also appear to have flares of vesicular hand eczema following oral metal challenge [31], and the challenge dosage has been artificially high. Nevertheless, dietary restriction of nickel helped about one-quarter of selected nickel-sensitive patients with resistant dermatitis [27].

Balsam of Peru [32], garlic, certain ingested food colours, preservatives and antioxidants have also been reported to cause flares of vesicular hand eczema [33,34].

Flares of dermatitis and perianal pruritus may occur in patients undergoing desensitization to *Toxicodendron* spp. [35], and systemic contact dermatitis may be induced following ingestion of cashew nuts, whose shells contain an oleoresin closely related to that of *Toxicodendron* spp. [36]. Similar problems may also occur after eating the fruit of the *Ginkgo* tree [37] and from other herbal medicines [38].

Cutaneous reactions to implanted metals (see p. 20.44)

Photoallergic contact dermatitis [1]

Certain substances are transformed into irritants or sensitizers (photosensitizers) after irradiation with UV or short-wave visible radiation (280–600 nm). The wavelength required is usually, but not always, the same as the absorption spectrum of the substance [2].

The initial phase of all photoreactions is dependent upon absorption of photons by light-sensitive chemicals. Following absorption, a higher state of energy (excited state) is induced in the molecule (photoactivation). Some of the energy may be released as fluorescence, i.e. emission of radiation at a longer wavelength, but not all fluorescent substances are photosensitizers. Alternatively there may be phosphorescence, heat or other energy transfer to another molecule, or photochemical alteration of the molecule [3].

Photoactivation is a physical phenomenon and may occur *in vitro*. When it occurs *in vivo* the activation may have a phototoxic (non-immunological) or a photoallergic (immunological) action. The photoactivated molecules may be transformed into new substances capable of acting as irritants or haptens. Photoallergic reactions are based on immunological mechanisms, and can be provoked by UV radiation only in a small number of individuals who have been sensitized by previous exposure to the photosensitizer. The reaction to a photoallergen is based on the same immunological mechanism as contact allergic reactions. In guinea pigs the sensitivity can be transferred with mononuclear cells [4].

Newly formed haptens may, by virtue of the excited state and free-radical formation, be able to combine chemically with other substances, for example protein, to produce a full antigen. The basic mechanisms of photosensitization have been reviewed by Thune [5]. The photoallergen tribromosalicylanilide has been shown to change into dibromosalicylanilide and monobromosalicylanilide [6,7], and with sulphonamides it has been suggested that an oxidation product is formed [7–9]. Some photosensitizers may, in the presence of UV radiation, produce only short-lived reactive molecules [10].

Several photoallergic substances simultaneously produce phototoxic reactions when applied in high concentrations and with a sufficient amount and type of radiation. Thus, in an individual case, the two reactions may be clinically indistinguishable, although it is reported

that phototoxic and photoallergic reactions can sometimes be distinguished histologically [11].

The allergens

The first significant recognized problems from photoallergy were related to the use of chlorinated salicylanilides in germicidal soaps in the early 1960s, with many thousands being affected [12]. Regulatory elimination of these photoallergens resulted in the disappearance of the allergy, but some affected individuals became persistent light reactors [12]. By the mid-1980s the most important photoallergen was the fragrance musk ambrette whose use is now prohibited [13,14]. In the present era, UV-absorbing chemical filters are virtually the only substances causing clinical photoallergic problems in the UK [15,16]. Exposure to UV filters is becoming more common as a result of their increasing use not only in sun products but also in cosmetics, including hairsprays. Their presence in cosmetics may be not only to prolong shelf-life but also to support 'antiageing' claims for the products. These UV filters can also induce conventional contact allergy. Nevertheless, many photocontact allergens have been identified with varying degrees of confirmatory evidence, and these are summarized below.

1 UV filters, including *p*-aminobenzoic acid and its derivatives, cinnamates, benzophenones and dibenzoylmethanes [16–22]. Benzophenone 3 (oxybenzone) appears to be the most frequently identified photoallergen since the 1990s [16,18,20].

2 Perfumes: musk ambrette [23] and 6-methyl coumarin [24], although now prohibited in Europe and the USA, caused significant problems in the 1980s, but these products have now virtually disappeared.

3 Halogenated salicylanilides: tribromosalicylanilide and tetrachlorsalicylanilide, used as antibacterials in soaps and detergents, caused many outbreaks of photosensitive eczema in the 1960s [4,6,12,25]. Fentichlor (bis(2-hydroxy-5-chlorphenyl)sulphide and bromosalicylchloranilide) is used as a topical antifungal agent in Australia and is used domestically in Sweden. It is a known photosensitizer [26].

4 Topical non-steroidal anti-inflammatory agents [27,28], especially ketoprofen, which may cross-sensitize with the UV filter oxybenzone [29–31].

5 Phenothiazines (tranquillizers causing occupational dermatitis in hospital personnel, topical antihistamines, insecticides) [32,33].

6 Sulphonamides used for topical treatment [2,33].

7 Bithionol and hexachlorophene in toilet soaps, shampoos and deodorants [34,35].

8 *N*-Butyl-4-chlorsalicylamide (Jadit—antifungal) [9].

9 Eosin: used to be present in lipstick [36].

10 Quinines: hair tonic, quinidine, quindoxin and olaquindox used in animal feeds [37–43].

11 Thiourea (in design paper) [44,45].

Clinical features

Photoallergic reactions can resemble sunburn, but usually show the same spectrum of features seen with allergic contact dermatitis (see p. 20.18). The dermatitis is localized to exposed areas of the skin, usually with well-demarcated margins where the skin is covered by clothing, e.g. at the collar and 'V' of the neck, below the end of the sleeves and trouser leggings. The area below the chin is usually spared. The most distinctive sign is the exempt 'Wilkinson's triangle' behind the earlobe [6,12]. There may nevertheless be some spread to covered sites. Asymmetry may result from increased UV exposure to one side of the body, for example those who drive with the vehicle windows open.

Photoallergy to UV filters in cosmetics may be clinically identical to that seen from conventional allergy to cosmetics (see p. 20.56). It may be widespread when related to liberal use of sunscreen agents. Furthermore, it may simulate sunburn and other causes of photosensitivity.

Musk ambrette, used in men's aftershave lotions and colognes, was the cause of a distinctive patchy pattern of photosensitivity on the face [13,14,23].

In some individuals, photoallergic reactions may progress to produce a light sensitivity that may persist a long time after the elimination of the sensitizer. This is known as persistent light reaction [46]. The phenomenon has been reported with many different substances, including chlorpromazine [33], halogenated salicylanilides [12,26,47], musk ambrette [13,48], promethazine hydrochloride [49,50], ketoprofen [51], quindoxin [40] and olaquindox [41,42]. This chronic photosensitive dermatitis presents as chronic eczematous changes on light-exposed areas with or without spread elsewhere [52]; on monochromator testing, these patients have abnormal responses to UV radiation with a shift to UVB sensitivity [53].

Photoallergy may simulate other photosensitive dermatoses and airborne contact allergy, and vice versa. Furthermore, there may be a combination of these disorders in the same person. It is also important to recognize that photoallergy may sometimes fail to follow the typical pattern of sparing of light-protected sites, and airborne contact allergy may paradoxically induce the classical photosensitivity distribution. Combined airborne and photoaggravated contact allergy is seen particularly with Compositae [54] and lichens [55]. A similar pattern of dermatitis may also be seen in patients sensitive to Colophonium, pine and spruce. It is therefore important to identify every potential component of these clinical presentations by screening for contact allergy using patch tests (especially to plants), for photoallergy with photopatch tests, and also for photosensitivity using phototesting.

Patients with established photosensitivity who have a flare of their dermatitis may have reacted to an increase in light levels or re-exposure to their primary or a cross-

reacting allergen by airborne contact. Alternatively, they may have developed a secondary allergic or photoallergic contact sensitivity to their sunscreen [56] or to one of their other medicaments.

The disorder of chronic actinic dermatitis (see Chapter 24) [57] may be associated with contact allergy, particularly to Compositae. Often there are multiple contact allergies. Phototesting reveals abnormal results but photopatch tests to Compositae and other allergens are generally normal. Nevertheless, persistent light reactivity following photoallergy may progress to chronic actinic dermatitis.

The intensity of response to phototoxic and photoallergic agents depends upon a number of factors:

1 nature and concentration of the substance applied;
2 duration of exposure to the substance;
3 percutaneous absorption;
4 intensity and wavelength of the radiation;
5 duration of radiation exposure;
6 radiation absorption in the skin, depending on the thickness of stratum corneum as well as the amount and distribution of melanin;
7 extraneous matter and secretions on the skin;
8 humidity.

Avoidance

Photoallergy in the UK is now only likely to occur to UV filters or very rarely to imported perfumed materials containing musk ambrette, which should be easy to eliminate. Once photoallergy has been demonstrated to a UV filter, the patient should be informed of the INCI (International Nomenclature of Cosmetic Ingredients) name and synonyms of the material to which they are sensitive. UV filters relying totally on opaque/reflectant micronized titanium dioxide and zinc oxide will be free of chemical UV-filtering agents, and can be used for coexistent photodermatoses in those allergic to chemical UV filters.

Investigation

Investigation of photoallergy by photopatch tests is described on p. 20.109.

Non-eczematous responses [1]

Well-recognized non-eczematous responses include contact urticaria, erythema multiforme-like, purpuric, lichen planus and lichenoid, lymphomatoid, pigmented, leukoderma, granulomatous, onycholysis and systemic.

Contact urticaria

Clinically this presents as an immediate wealing eruption at the site of contact, and may in some instances be associated with systemic features. The syndrome of contact urticaria is discussed in detail on p. 20.121.

Erythema multiforme-like reactions [2,3]

The characteristic presentation is that of a spreading eruption from the primary site, which may also involve distant sites. It has been called 'urticarial papular and plaque eruption' by Goh [4]. The rash has features of erythema multiforme, in that single lesions appear target-like, but the distribution is not necessarily acral as in classic erythema multiforme nor is the histology characteristic. There is sometimes a vasculitic purpuric element to the rash and, although the mechanism is unknown, it appears to represent an immune complex (type III) reaction as well as a delayed hypersensitivity (type IV) reaction. Many of these patients will give a very strong patch-test response to the causative allergen, often accompanied by a flare of their dermatosis.

It is often precipitated by strong allergens, such as quinones in exotic woods [2,5,6], and *Primula* [7,8]. Contact with other plant materials may cause this reaction, including poison ivy (*Toxicodendron* spp.) [9,10] and tea tree oil [11]. Ingestion of herbal remedies containing *Toxicodendron* [12] and sesquiterpene lactones [13] by sensitized persons has also induced erythema multiforme-like eruptions.

Topical medicaments, especially antimicrobials [3,14,15], corticosteroids [16–18] and anti-inflammatories [19–21], have all caused erythema multiforme-like eruptions. A nitroglycerin patch has also induced erythema multiforme at the applied site, with a secondary spread eruption [22]. Medicaments applied to mucosal surfaces may sensitize and may also be absorbed, causing systemic erythema multiforme-like reactions, for example sulphonamide in vaginal creams [23] and ocular preparations [24].

p-Phenylenediamine in hair dye [25] and temporary tattoos [26] and IPPD [27] in rubber and clothing dyes [28,29] are also recognized causes of this reaction pattern.

Purpuric reactions

Originally described from khaki uniforms [30], where the cause was not established, purpuric reactions are uncommon and have mostly been described recently from textile azo dyes [31–33] and also textile resins [31]. The presence of the rubber chemical IPPD in boots, diving suits, bandages and brassières is also reported as causing allergic contact purpura [34–38]. Purpuric reactions have also been described with allergy to diphenylthiourea in heat retainers [39], *p*-phenylenediamine in black hats [40] and as a secondary spread eruption from balsam of Peru [41].

Lichen planus and lichenoid reactions

These have been described following contact with colour developers used in the photographic industry [42,43]. The developers are *p*-phenylenediamine derivatives. New chemicals have been introduced to replace older more sensitizing ones, not always successfully.

p-Phenylenediamine-induced allergic lichenoid contact reactions from hair dye were recently reported from India [44]. We have also seen this pattern from hair dye in Asians in the UK. *Primula obconica* allergy has also produced a lichen planus-like eruption of the hands [45].

Lichen planus-like reactions of the buccal mucosa may represent allergy to metals [46–48] and other materials used in dental treatments [49,50]. Some patients have had improvement in their lichen planus following the removal of some or all of their fillings [51–54]. Oral lichen planus is more apparent where there is evidence of corrosion [55] and the aetiology of lichenoid lesions is likely to be multifactorial [53]. The histology may show features compatible with lichen planus or a non-specific chronic superficial perivascular dermatitis [1].

Lichenoid reactions to tattoo pigments are discussed in the section on granulomatous reactions below.

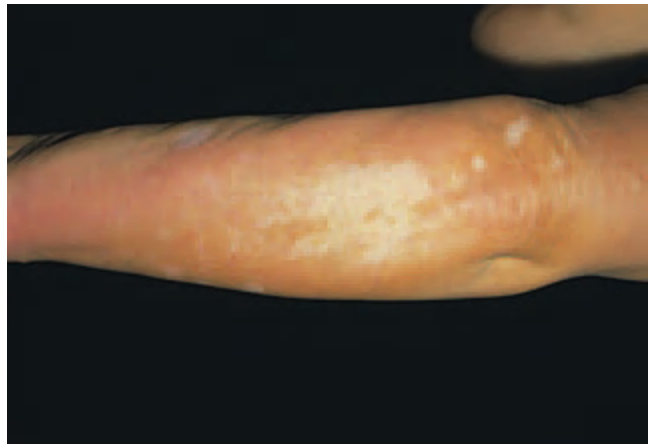

Fig. 20.12 Koebnerization of vitiligo as a result of previous *Primula obconica* allergy.

Lymphomatoid eruptions [56]

Occasionally, contact dermatitis presents with cutaneous lymphoma-like plaques and histopathology suggestive of mycosis fungoides [56]. These have been seen at the site of ear piercing in those sensitized to gold [57,58]. The reaction, however, tends to persist for months even when contact with metallic gold is avoided. The patch-test reaction to gold sodium thiosulphate in these patients is papular and very strongly positive. The histology of both the papular eruption and the patch-test reaction shows a dense T-cell infiltrate [59]. Other reported causes include matches [56], nickel [60,61], dental amalgam [62], medicament components [63,64] and isopropyl-diphenylenediamine [65].

Pigmented dermatitis [66]

Contact dermatitis may induce post-inflammatory hyperpigmentation, although distinctive patterns of pigmented dermatitis without a lichenoid appearance or histopathology are recognized. These patterns are much more commonly seen in the Far East. The first such cases of pigmented contact dermatitis in Europe were described by Osmundsen [67]. The hyperpigmentation occurred mainly on covered areas with or without dermatitis, and was traced to an optical whitener in washing powder, Tinopal CH 3566. Another outbreak was described by Ancona-Alayon *et al*. [68] in textile workers and was traced to contact with Naphthol AS, an azo-dye coupling agent. Cases also occurred on covered sites from garments in Japan [69], and this led to a systematic search for other causes of textile dermatitis. Chemicals implicated included the fungicide Biochek 60, an impurity of colour index blue CI Blue 19, and textile finishes [66].

Pigmented cosmetic dermatitis [70] is seen mainly in oriental women. Slight dermatitis may precede or coexist with the hyperpigmentation, which occurs mainly on the cheeks. The allergens associated with this have been found to be fragrances and pigments, especially D and C Red 31 and an impurity, and Yellow no. 11 in cosmetics and soaps [70,71]. Oral ingestion of flavourings allied to the fragrances, such as cinnamon, may cause not only a focal flare but also diffuse hyperpigmentation on the body [70].

Environmental agents, possibly pesticides and fungicides, have sometimes been thought to be a factor. In one study, a majority of pigmented dermatitis cases were found to have positive patch tests to chlorothalonil used as a fungicide in banana plantations. It is used in other parts of the world as a preservative of wood and paint [72].

Depigmented lesions [66]

Irritant and allergic contact dermatitis can induce hypopigmentation as a post-inflammatory effect or by koebnerization of vitiligo. This has to be distinguished from the direct melanocytotoxic effect of certain quinones and substituted phenols, which most commonly presents as an occupational vitiligo (Chapter 21). This effect occurs independently of their sensitizing potential.

A number of cases of persistent leukoderma following allergic contact dermatitis have been reported. In some it has been difficult to be certain whether the cause was post-inflammatory or melanocytotoxic. In particular, it is reported from *p*-phenylenediamine in hair dyes [73,74] and temporary tattoos [26,75], methacrylates [76], perfumes [77], *Alstroemeria* [78] and chloroxylenol [79]. *Primula* allergy has resulted in extension of pre-existing vitiligo in the sites affected by the dermatitis (Fig. 20.12). The allergic reaction to primin was followed by vitiligo at the positive patch-test sites [80].

Granulomatous reactions

Some topically applied metal salts produce non-allergic granulomatous skin reactions, for example zirconium in deodorants [81]. Granulomas occurring at the site of previous immunization with aluminium-adsorbed vaccines, or following the use of parenteral hyposensitization preparations, are often due to aluminium allergy [82–85]. Patch tests are positive either to aluminium chloride 2% aqueous or an empty Finn chamber [84]. Granulomatous reactions have also been found in association with allergy to gold in earrings [86].

Pigments in tattoos may cause allergic granulomatous and lichenoid reactions [1]. Metal salts are the usually identified culprits: mercury (red colour), chromium (green colour), cobalt (blue colour) and cadmium (yellow colour) [87]. However, in our experience most reactions are in the red areas, and patch testing with mercurials is negative, suggesting another cause. Unfortunately, tattooists are extremely secretive about the nature of the pigments they use.

Onycholysis

Onycholysis may be the only presenting feature in contact dermatitis to hairdressing chemicals. We have seen it as an isolated finding in nail varnish allergy, but more commonly it is found in women sensitized to multifunctional acrylates in false nails [88], when there may be concomitant dystrophy and persistent paraesthesiae [89].

Systemic non-eczematous

Extensive allergic contact dermatitis is not uncommonly associated with systemic upset from the metabolic effects of the disorder itself and secondary infection, particularly in those who are erythrodermic. Sultones occurring as impurities in lauryl ethyl sulphate have in the past caused several outbreaks of contact dermatitis characterized by intense oedema accompanied by general malaise [90,91].

Differential diagnosis

It should always be remembered that allergic contact dermatitis can mimic or complicate other types of eczema and other dermatoses. Sensitization to topical applications may be a complication of almost any dermatosis that leads to specialist referral. The diagnostic problem differs according to the site of the dermatitis. Patch testing will often be required before confirming the cause in its entirety.

Head. Allergic and photoallergic conditions of the face must be distinguished from a number of disorders.

Atopic eczema may be confined to the face, especially around the eyes and particularly the medial aspects. A

previous or family history of infantile or childhood flexural eczema, asthma, allergic conjunctivitis, hay fever or immediate skin reactivity to animals and certain foods may point to the patient's atopic status. Associated flexural eczema, ichthyosis or xeroderma may be features. Multiple positive radioallergosorbent (RAST) or prick tests to common environmental allergens are used by some to confirm an atopic diathesis.

Seborrhoeic eczema, which commonly starts around the alae nasi, is usually accompanied by dandruff or seborrhoeic eczema in the scalp and eyebrows, and by blepharitis; involvement of the presternal region, the external auditory meatus and the retro-auricular areas is common. Older patients frequently develop a flexural pattern of seborrhoeic eczema.

Psoriasis is normally easy to distinguish as there is evidence elsewhere on the body, although psoriasis in and around the ears and scalp margins may mimic a dry scaly contact dermatitis.

Cellulitis and erysipelas may be difficult to distinguish from an acute allergic contact dermatitis, but a background of pyrexia and systemic symptoms is generally the rule.

Angio-oedema, especially of the eyelids, is notoriously difficult to differentiate from contact allergy. The swelling would be expected to resolve within 24–48 h. Patch tests are helpful in reaching a conclusion.

Dermatomyositis may initially appear identical to allergic contact dermatitis, and we have seen and patch tested such cases. The purple/mauve hue of the eyelids is a major clue, and the hands, fingers and nail folds must be carefully examined. The characteristic associated muscle pains and weakness may not always be present.

Herpes simplex may be simulated by *Primula obconica* dermatitis on the face and elsewhere [1]. Haemorrhage into the blisters seems more common with the allergy.

Photosensitivity, including reactions to ingested drugs, cannot always be distinguished from photoallergic contact dermatitis, and may also simulate contact dermatitis from airborne sensitizers.

Hands and arms. Allergic and irritant contact dermatitis, and constitutional eczemas, may only be distinguishable by a careful history and patch testing. They commonly coexist. Superimposed irritant contact dermatitis from home and work exposures is common.

Indicators of atopic eczema are discussed above. The eczema may be confined to the hands, especially in later life. A nummular pattern of eczema is commonly constitutional but may be a feature of irritant and allergic contact dermatitis, particularly from chromate in cement.

Recurrent vesicular eczema of the palms may indicate constitutional pompholyx, although contact allergy can produce an identical appearance. Some contact allergies, for example from IPPD [2] and 1,2-benzisothiazolin-3-one, seem to induce a palmar pattern of dermatitis preferentially. *Primula* allergy often induces a haemorrhagic vesicular dermatitis of the palmar surfaces and fingertips. The relationship of pompholyx to ingestion of contact allergens, especially nickel, by sensitized subjects is controversial [3–5]. There is evidence that oral intake of balsams and garlic can induce palmar vesicular eczema in patch-test-positive subjects [6,7]. Tinea pedis can induce palmar pompholyx as an id eruption. Papules and vesicles on the hands and fingers are a feature of scabies, and this disorder must always be excluded by a careful history and examination for diagnostic burrows. The condition is normally associated with a more generalized pruritus and rash.

Psoriasis of the palms and hyperkeratotic eczema are often confused. Differentiation is sometimes somewhat arbitrary. Often, hyperkeratotic plaques are localized at points of contact with tools for example, but not all frictional hyperkeratosis is necessarily an expression of psoriasis. The possibility of psoriasis koebnerizing into areas of contact dermatitis should not be forgotten.

Tinea manuum is classically unilateral or asymmetrical. An inflammatory edge may be seen extending on to the dorsum of the hand. Nail dystrophy may be an association. Unilateral and bilateral low-grade scaling of the palms should be scraped for mycology. These appearances may be complicated by a vesicular id eruption.

Lichen planus confined to the palm can be difficult to distinguish from a palmar dermatitis, but normally there are more typical changes elsewhere on the skin or in the mouth. Lichen planus-like contact reactions from colour developers may occur on the hands and forearms [8].

Porphyria cutanea tarda may simulate a bullous contact dermatitis such as plant dermatitis. The formation of bullae after minor trauma and the presence of white atrophic scars and milia suggest the diagnosis, which can be confirmed by porphyrin assays.

Flexures and anogenital region. Seborrhoeic eczema and psoriasis may preferentially involve the flexures and be difficult to distinguish from allergic contact dermatitis, but there is often evidence of these conditions elsewhere.

Tinea is usually asymmetrical or unilateral and has an inflammatory edge. Scrapings for mycology should be taken from inflammatory flexural rashes. The typical coral-pink fluorescence under Wood's light will help to distinguish erythrasma from other flexural rashes.

Legs and feet. Persistent varicose eczema is an indication for patch testing as it is often complicated by sensitivity to topical medicaments and dressings, including rubber in support bandages and stockings.

Vesicular and vesiculobullous areas may occur in tinea pedis, and mycological specimens should be taken if this is suspected. In common with the hands, scabies affecting

the feet may induce a papulovesicular eruption and must be considered in the differential diagnosis.

Trunk. Papular drug eruptions or scabies may sometimes be difficult to distinguish from nickel or textile dermatitis. Systemic diseases such as dermatomyositis and mycosis fungoides sometimes show eczematous features.

Exposed sites. Photosensitive dermatoses and drug eruptions must be distinguished from contact allergy to volatile and airborne materials. Although not always reliable, sparing in certain sites—behind the ears and under the chin—might indicate a photosensitive eruption. Nevertheless, some patients will require thorough investigation with phototesting, patch and photopatch testing before a diagnosis can be made.

Generalized. Erythroderma is rarely primarily due to contact allergy, and other causes such as drug eruptions, constitutional eczema and psoriasis should be considered; the possibility of secondary contact allergy from topical medicaments must not be forgotten. Skin biopsy may be helpful in such cases.

Scabies can easily be overlooked as a cause of a widespread pruritic rash, especially as skin lesions may look classically eczematous. Careful examination of the hands, feet and genitals for diagnostic lesions is required.

Allergic contact dermatitis to specific allergens

Metals

Nickel [1–8]

Chemistry. In common with cobalt, but unlike chromium, the metal itself sensitizes and is, in practice, the most frequent source of sensitization [7]. Most salts, for example nickel chloride ($NiCl_2$) and nickel sulphate ($NiSO_4$), are readily soluble in water and sweat and have strong sensitizing properties. Some oxides (e.g. Ni_2O_3) and the hydroxide ($Ni(OH)_2$) can elicit contact dermatitis, but heated NiO does not. This compound is insoluble even in hydrochloric acid.

Table 20.3 European Union Nickel Directive (summary).

1 After piercing: posts, rings or other items used during the period of re-epithelialization shall not *contain* more than 0.05% nickel
2 Objects intended to be used in direct and prolonged contact with the skin shall not *release* more than 0.5 μg/cm^2/week of nickel. Examples include jewellery, watches, buttons and zips

Incidence and prevalence. Nickel is the most frequent contact allergen, and sensitivity is more common in women than in men [9]. The prevalence of nickel sensitivity recorded in a patch-test clinic is between 15 and 30%, and is influenced by the relative number of females tested [10–12]. Nickel is the most usual cause of contact dermatitis in women. All age groups are affected, but the prevalence of nickel sensitivity among females tends to rise from 10 years of age onwards [13]. The incidence of nickel dermatitis in Denmark varied with the total imports of nickel during and after the Second World War [14], which suggests that the level of sensitivity is determined by the total nickel exposure in the environment. In Denmark it was found that the prevalence of nickel dermatitis in the general population was 11.1% in women and 2.2% in men. Sensitization to nickel was found in 14.8% of those with pierced ears and 1.4% of those who had not had their ears pierced, confirming that ear piercing is a significant risk factor for the development of nickel sensitivity [15]. A previous study in Finland found the overall prevalence in the general population was 4.5%: 8% in women and 0.8% in men [16].

This female predominance is not universal. In Kuwait, nickel allergy was commoner in males [17], and in Nigeria [18] and Japan [19] the prevalence was similar in both sexes in patch-tested patients.

The prevalence may be higher in some occupational groups, for example hairdressers, in whom studies have shown that 27–38% are nickel allergic [20,21].

Legislation was introduced in Denmark in 1990 with the intention of controlling the use of nickel-releasing objects in contact with the skin. In 1994 the European Union passed regulations based on the Danish legislation (Table 20.3). These laws only relate to metallic items in prolonged and direct skin contact, for example jewellery, clothing items and spectacle frames. Other metallic materials with which there is relatively short-term contact (e.g. coins, keys and cutlery) have been excluded from the legislation. The level of allergy to nickel identified in under-18s attending for patch tests in Denmark has dropped considerably, from 24.8% in 1985–86 to 9.2% in 1997–98 [22].

Occurrence [23]. The commonest sources of metallic nickel are alloys and plated objects [24]. Sensitization is chiefly the result of frequent skin contact with corroded objects containing nickel [25]. A high rate of corrosion has been documented from nickel-plated items, nickel-iron, German silver, coin and several other alloys [25]. Chromium-plated metal is often first nickel-plated, and after long use the nickel may reach the surface, for example on water taps. Most stainless steels contain nickel but are incapable of releasing sufficient quantities to elicit contact dermatitis. Quantitative studies indicate that repeated exposure to occluded metal items releasing nickel at a rate greater than 0.5 μg/cm^2/week involves a significant risk of nickel sensitization [26,27], but thereafter very small amounts of nickel are sufficient to elicit dermatitis in sensitized persons.

Jewellery and metal components of clothing are the usual sources of nickel in prolonged contact with the skin. Transient but potentially frequent and repeated exposure may occur from handling coins, keys, scissors, knitting needles, thimbles, scouring pads and other metallic tools and utensils. Most silver coins, including the new 1 and 2 € coins, contain nickel and there is debate as to whether exposure might be a risk factor in those already sensitized to nickel [28–30]. Platers and some metal machinists are necessarily at risk of occupational nickel allergy [1]. Other sources include pigments in glass, pottery and enamel, electrocautery plates [31] and even soaps [32] and detergents [23]. Nickel has been identified in some eye shadows and mascaras [33,34].

Systemic exposure may take place from the diet. Certain foods and plants [35] contain much higher concentrations than others [36], as can particular sources of domestic water [37], and nickel may also be a contaminant in fertilizers [38] and fungicides. Stainless steel saucepans release negligible nickel, but cooking acid fruit in them, particularly when new, has the potential to contribute to dietary intake [39].

Systemic exposure from implanted metals is considered on p. 20.44.

Clinical features [40]. Classical nickel allergy is identified by patches of dermatitis at sites of contact with metal objects, most commonly the ears from earrings, the wrists from watches and bracelets, the neck from necklaces and their clasps, the central back and upper chest from bra components, the central abdomen from studs and zips in trousers, especially jeans (Fig. 20.13), and the dorsa of the feet from shoe buckles. Lesions on the upper cheeks and sides of the nose and face may relate to metal-framed spectacles. A discoid pattern around the lower trunk and thighs from metal studs in clothing is quite frequent, although the involvement of the thighs from metal suspenders has all but disappeared following the advent of tights (panty hose).

Fig. 20.14 Secondary eyelid dermatitis in a patient sensitive to nickel. (Courtesy of Dr J.D. Wilkinson, Amersham General Hospital, Amersham, UK.)

The eruption may be papular, nummular, diffuse or consist only of excoriated papules on almost normal-looking skin. Some patients are referred to dermatologists because of spread of dermatitis to distant regions. These secondary eruptions used to be a characteristic feature of nickel dermatitis [40,41], but now seem to be less common. The secondary rash normally starts shortly after, or at the same time as, the primary eruption. It affects the neck, face (especially the eyelids; Fig. 20.14), the elbow

flexures and the flexor surfaces of the arms; the anogenital area may also be affected, and the rash may be generalized. Flexural lesions may resemble textile dermatitis or atopic dermatitis.

The relationship between hand eczema and nickel sensitivity remains complex [42]; however, well-controlled statistical studies do support a connection between hand eczema and nickel allergy [43–45], and the nickel-sensitive woman does appear to have a predilection for hand eczema [42,46]. Hand eczema is often multifactorial, and is particularly common in women who have a heavy burden of housework or who are employed in other occupations that expose the skin regularly to trauma or wet work. There may be a vesicular palmar (dyshidrotic) pattern but other distributions occur without being diagnostic. Wet work, atopy and nickel sensitivity are associated with an increased risk of hand dermatitis [47], although atopy is probably the most important factor [48]. Analytical data demonstrate that consumer products such as personal care items, detergents and cleaning products do not contain sufficient nickel, cobalt or chromium to pose a risk to those who do wet work [23].

Sometimes, nickel allergy is directly of occupational origin, and in more than half of these cases it starts on the hands. It is normally associated with the metal and nickel-plating industries. The pattern of dermatitis on the hands is rarely diagnostic. Spread occurs to the elbow flexures, eyelids and face in the same manner as described above.

A recurrent vesicular palmar (dyshidrotic) pattern of eczema has been related to dietary intake of nickel. Ingestion of nickel sulphate caused a flare of vesicular hand eczema in nine of 12 patients studied by Christensen and Möller [49]. The significance of this has been disputed, as similar results have been demonstrated in non-sensitized patients and the challenge dose was artificially high [3,50–53].

Avoidance. Most people think of their environment in terms of objects rather than materials, and it is important to realize that they find it difficult to identify nickel, unless the possible causes of contact are specifically listed. The importance of minor items, such as eyelash curlers, zip fasteners and jeans studs, may not otherwise be appreciated. Many dermatologists provide all nickel-sensitive patients with a list of possible contact items. A dimethylglyoxime test kit (see p. 20.115) may also be of use in identifying nickel-containing objects among a patient's personal items, at work or in the home [25].

Nickel cannot be entirely avoided in daily life, but elimination of nickel from clothing and avoidance of nickel-containing jewellery may be sufficient to clear dermatitis. In our experience, initial compliance with avoidance advice is poor, particularly with clothing, and repeated explanations may be necessary. Waterproof tape and metal lacquer can be used to cover nickel-plated objects that cannot be replaced, although nickel can leach out if the contact site is sweaty and prone to friction. Contact may be difficult to avoid in certain occupations. Protection with rubber gloves may be insufficient, as nickel solutions may penetrate them [54]. Heavy-duty vinyl gloves have been suggested as an alternative.

It has been suggested that exposure of the oral mucosa to nickel (in the form of dental prosthetic devices) may protect against subsequent sensitization [55].

Prognosis. The prognosis of dermatitis from nickel in jewellery and clothing is excellent if further use of nickel-plated objects is avoided. Once the hands are involved, the eczema may remain chronic, persistent or intermittent. Ingestion of nickel is a possible cause of chronicity [56,57].

Specific therapies. Barrier creams and cleansers containing chelating agents may have potential, and a number have shown promise under experimental conditions [58–60]. Clioquinol is known to chelate nickel [61] and a topical clioquinol/steroid combination can be considered as a treatment.

Dietary reduction of nickel intake is recommended, by some, for those nickel-allergic subjects with recurrent palmar vesicular eczema. Knowledge of the nickel content of foods is at present imprecise, and the prescription of a low-nickel diet [62] is not always practical [52]. Nevertheless, there are strong advocates for this approach and a trial of dietary reduction may be worthwhile, although frequently disappointing in our hands.

Treatment with tetraethylthiuramdisulphide (disulfiram; Antabuse), which chelates nickel, has been reported as helpful, but has a significant prevalence of side effects [63]. Liver enzymes should be carefully monitored [64]. An alternative chelating agent, trientine, gave disappointing results in a small open trial [65].

Patch tests. Nickel sulphate 5% in petrolatum is used for patch tests. False-negative reactions are common with 2.5% nickel in petrolatum or 2% aqueous nickel [66]. False-negative reactions may also occur with 5% nickel sulphate in petrolatum because nickel ions penetrate the skin only very slowly [67]. Testing with nickel sulphate may produce irritant false-positive reactions with a deep erythema and pustulation, especially in atopics [68]. Some follicular reactions are irritant, but those with raised papules are often truly allergic in our experience. In cases of doubt, intracutaneous testing with 1 mol/L nickel sulphate in saline has been used to clarify the situation [69].

Cobalt [1,2]

Chemistry. Cobalt metal and its oxides (e.g. Co_2O_3 and CoO) and salts (e.g. $CoCl_2$ and $CoSO_4$) are sensitizers. Also, heated CoO elicits positive patch-test reactions (unlike NiO).

Prevalence. Little is known of the prevalence of allergy in the general population but one study showed that 1.1% of an unselected Danish population of 567 individuals were patch-test positive [3]. Of patients with dermatitis 4.6–9% are patch-test positive, with females predominating [4].

Occurrence [1,5]. Metallic cobalt is present in 'hard metal' used for metal cutting and drilling [6,7]. It is used in magnets. It is always present as a contaminant in nickel [5]. It occurs in alloys, for example vitallium used in dentures and in nails for pinning fractures [8].

Cobalt oxides, present as traces in cement, are sensitizers [9]; however, isolated cobalt allergy from cement is much rarer than its occurrence in association with chromium allergy [10]. The cobalt content of cement is about the same as that of chromium [9].

Oxides are found in paints [1], glass, china, pottery [11], ceramics [12], enamel (blue), coloured crayons and animal feed additives [13], as well as in multivitamin pills, light-blue tattoos [14,15], soaps [16], cosmetic pigments, hair dye and detergents [17].

The salts are seldom used for plating, unlike nickel salts, although cobalt chloride has sensitized in a metal-etching solution [18].

Organic cobalt compounds (e.g. cobalt naphthenate, resinate and stearate) are used as driers in paints and varnishes, bonders of rubber to metal [19] and accelerators for unsaturated polyester resins [20,21]. They may also be present as additives in lubricating oils.

Clinical features. As cobalt is an invariable contaminant of nickel, the clinical features of cobalt allergy can be identical to those of nickel allergy. Cobalt sensitivity might explain why some women with dermatitis typical of nickel have a negative patch-test reaction to nickel. Furthermore, its presence in cement may induce a clinical pattern identical to allergy from chromate in this source. Isolated cobalt allergy is seen in hard-metal workers and in the pottery and glass industries, when it is usually associated with hand dermatitis [22]. Stomatitis has been reported from dentures [23]. Allergic granulomatous reactions to blue tattoo pigment are recognized, but are rare in our experience [14,15]. Animal feed may induce contact allergy [24], and photocontact dermatitis has been reported from this source, as well as from cement [25]. Vitamin B_{12} is a cobalt-containing compound and cheilitis has been reported from oral vitamin B_{12} ingestion [23], and dermatitis from its parenteral use [26]. It can sometimes be difficult to identify the source of allergy when there is an isolated positive cobalt patch test.

The relationship of cobalt allergy to metal implants is discussed on p. 20.44.

Avoidance. This will depend on identifying a relevant cause and eliminating contact. In those with a nickel allergic pattern, the advice is the same as for nickel-allergic subjects (see p. 20.39); similarly for those with cement allergy, the advice is the same as for chromate (see p. 20.43). Reduction of the dietary intake of cobalt (monitoring plasma vitamin B_{12} if prolonged) may benefit some cobalt-sensitive patients [27].

Prognosis. Concomitant cobalt and chromate sensitivity is associated with more troublesome dermatitis than that which occurs with chromate allergy alone [28]. Possibly the same applies to a combined nickel and cobalt sensitivity because of the increased number of contact sources, which may cause recurrence of the dermatitis.

Patch tests. Cobalt chloride 1% in petrolatum is reliable for testing [17]. False-positive, irritant, purpuric reactions are common, especially in atopics.

Chromium [1–4]

Chemistry [5,6]. The metal itself, if not dissolved in oil [7] or acids or as a salt, seems to be non-sensitizing, unlike nickel and cobalt. This is probably due to the insoluble monomolecular layer of chromium (III) oxide (Cr_2O_3) on the surface [5].

Hexavalent chromium (occurring as an anion), for example in chromic acid or chromium (VI) trioxide (CrO_3) and in chromates and dichromates of potassium, sodium and ammonium, is the commonest sensitizer. It occurs in alkaline solution as chromate (K_2CrO_4) and in acid solution as dichromate ($K_2Cr_2O_7$). The less soluble lead chromate, barium chromate and zinc chromate ($ZnCrO_4$) are also allergenic [8].

The trivalent chromium compounds (occurring as cations), for example chromium trichloride ($CrCl_3$), are sensitizers [9] but, being less readily absorbed into the skin, they are of minor clinical importance [10,11].

Incidence and prevalence. In Europe, chromate was for many years a frequent cause of occupational allergic contact dermatitis and chronic incapacity [12–15]. The prevalence of sensitivity is commoner in men than in women and is higher in clinics where men with occupational dermatitis predominate. A study of construction workers attending occupational contact dermatitis clinics in Germany showed that potassium dichromate was the commonest allergen at 31.9% [16], whereas chromate sensitivity was found in less than 2% of patients attending the general patch-test clinic [17]. In some countries (including the UK) chromate sensitivity is less common [18].

In Scandinavian countries, the addition of ferrous sulphate to cement to convert the more sensitizing hexavalent chromate to the less sensitizing trivalent chromate (because it is less easily absorbed) appears to have decreased the risk of sensitization in construction workers [19–21], although other changes in cement manufacturing may also be contributing [22]. Chromate sensitivity in some European women was found to be related to chromate in household bleach [23,24], which was subsequently removed. The prevalence of chromate dermatitis seems to be decreasing since the introduction of these two measures, but the decrease may also be due to greater mechanization.

Occurrence [1,2,4,25]. The main source of hexavalent chromium is cement [19,26], although the amount varies widely [6,27–31]. Other important sources are antirust paints (lead chromate and zinc chromate) [8]. The dust liberated by drilling, cutting or sandpapering of metals painted with a primer containing chromate may cause contact dermatitis on the hands, arms and face. Further sources are plating salts [32], metal alloys, lithography/offset printing materials, anticorrosive oil, cutting oils [7,33], cooling water [34,35], foundry sand, polysulphide sealants [36], matches [37], photographic chemicals, chemicals for fat determination in milk [38], welding fumes [39,40], wood preservatives, wood ashes [41], wood pulp [42], mordant in wool dyeing, green baize, stains in glass, glazing enamels [43], catgut [44], violin strings [45], textiles [46], coating on zinc-galvanized iron sheets [33], glass polishing [47], flour [48], tyre-fitting solution [49], colour television manufacture [50], soaps [51] and detergents [52], and dental prostheses [53].

Among trivalent compounds, basic chromium sulphate used as a tanning agent for leather is the most important [10,54]. Chromium (III) salts [10] and oxides in tattoos [55] are less common sensitizers.

Clinical features. Acute weeping dermatitis is unusual, and more commonly there is a dry insidious eruption, which tends to fissure, particularly on the hands. Secondary lichenification is often a feature. There is frequently a concomitant irritant element with wet cement, which is

alkaline, hygroscopic and abrasive. Primary irritant dermatitis and discoid and atopic eczema may be mimicked, and a palmar distribution may be difficult to distinguish from chronic tinea manuum. Palmar vesicular eruptions have been blamed on traces of chromate in the diet [56]. Contact with leather footwear, gloves, belts and other clothing, or even handbags and purses, may produce dermatitis in those areas in contact with the material. Widespread eruptions may occur, with flexural accentuation and involvement of the ankles and dorsa of the feet from cement dust.

Prognosis. Chromate sensitivity tends to persist [57], and the prognosis of occupational dermatitis is poor as a result of its continuation and associated social and financial handicap [58,59]. Fewer than 20% of cases were clear of dermatitis when reviewed after 10 years [3]. In men, allergy to chromate carries a worse prognosis than does sensitization to other allergens [60]. Chronicity and frequent relapses are the rule; the latter are more frequent than in any other industrial dermatosis [12] and affected individuals have been labelled as 'chrome cripples'. Once established, hand dermatitis tends to continue, and superimposed shoe dermatitis may prevent any improvement unless chromate-free shoes can be acquired. Few of those affected give up their work despite the chronicity of the condition [13], and in one study only 8% of chromate-sensitized cement workers were clear of dermatitis 10–13 years after the initial eruption. Changing work to avoid contact with cement does not seem to improve the prognosis [59]. Many chromate-sensitized cement workers develop hardening and are able to continue at work, albeit with ongoing but manageable dermatitis. Positive patch tests have been reported in cement workers with no dermatitis [61]. Insufficient knowledge of the occurrence of chromate in the environment may account for the poor prognosis, and it is suggested that tiny amounts may maintain the dermatitis.

Avoidance. Avoidance of contact with sources of chromate, including leather footwear and gloves, will be necessary, although those cement workers with hardening can be encouraged to stay at their work bearing in mind the poor prognosis. Ferrous sulphate added to cement converts soluble hexavalent chromium to insoluble trivalent chromium, thus potentially preventing chromium sensitization by cement. Various reducing agents [62], chelating compounds and ion exchangers have been recommended as hand creams to prevent dermatitis in chromium-sensitive individuals [63,64] and these may have value, but long-term studies are lacking. It is not yet known whether reduction of the dietary intake of chromium might benefit chromium-sensitive patients [65]. Dapsone has been suggested as a treatment, but no controlled trial has been undertaken [66].

Patch tests. Sensitivity is demonstrated by a closed patch test with potassium dichromate 0.5% in petrolatum. At this concentration, weak irritant reactions are quite common especially in atopics, but lower concentrations will miss relevant positives [67]. Nevertheless, in the USA a concentration of 0.25% is recommended because of the potential for false-positive results. A compromise (0.375%) has been suggested, although there may still be a risk of false-positive and false-negative reactions [67]. Dilutions can be tested to assist in distinguishing allergic from irritant reactions.

Implanted alloys [1,2]

Orthopaedic metallic prosthetic implants are made from a variety of metals, often alloys and especially stainless steel. Stainless steels contain up to 25% nickel, but for orthopaedic use generally contain 13–16% nickel and a minimum of 17% chromium [3]. However, nickel release from stainless steels, apart from those containing sulphur, is very low [4]. Nickel, cobalt and chromate may also be used in wrought and cast alloys. Vitallium, a cast cobalt/chromium alloy, and titanium may also be used for implants.

Orthopaedic implants may be static (e.g. plate and screws) or dynamic (e.g. artificial hips). There are two potential concerns in relation to metal allergy and these implants, namely allergic skin disorders and loosening. There is little doubt that static implants can be associated with localized eczema over the site of implantation and more extensive skin eruptions in sensitized subjects, sometimes only resolving after removal [5–7]. The delay between insertion of the prosthesis and onset of dermatitis may be days or years [1]. Similar eruptions were reported in the early days of hip replacements when metal heads articulated with metal cups [8,9]. Since plastic joint surfaces have been used, this problem seems to have largely disappeared, and retrospective and prospective studies of hip joint replacements in known metal-allergic subjects are reassuring [10–14].

There is evidence of increased metal sensitization associated with loosening and failure of joints, particularly when these joints involve metal–metal contact [8,9,15]. It is suggested that the increased allergy is caused by, rather than being responsible for, loosening [16,17].

Titanium allergy is virtually unknown, and thus titanium is an alternative for patients with extreme sensitivity to other metals. The patient may need to be appraised that the metal is not thought to be as long lasting as stainless steel.

Reactions have also been reported to sternotomy wires [18], shrapnel [19], mitral valve prostheses [20], dental prostheses [21], fillings [22], pacemakers [23], and infusion and acupuncture needles [24,25]. The contention that nickel allergy is associated with restenosis of coronary artery stents [26] is questionable at this time [27].

Palladium [1]

Chemistry. Palladium is a relatively inexpensive metal of the platinum group of elements.

Prevalence. Of patients undergoing routine patch testing to palladium chloride, 3–8% were shown to be allergic [2]. Nearly always there is concomitant sensitivity to nickel, and guinea-pig experiments have suggested this may be a true cross-reaction [3]. There are, however, mixed views as to whether this association is concomitant sensitivity, cross-reactivity, or contamination of palladium chloride by nickel sulphate [4–6].

Occurrence. Palladium is increasingly used in dental alloys and prostheses. It can be used as a whitener in white gold. Occupationally, its main uses are in electrical components and as a catalyst.

Clinical features. The clinical relevance of a positive palladium chloride patch-test reaction is questionable in many instances, and may just be a reflection of nickel allergy. Stomatitis and lichen planus have nevertheless been related to palladium in dental materials [7–9]. Removal of prostheses or dental alloys containing palladium may need to be considered in these instances.

Patch tests. It is normally tested as palladium chloride 1% in petrolatum.

Gold [1]

Chemistry. Metallic gold is soft, malleable and ductile. It is stable and resistant to corrosion. Its strength is increased when alloyed with other metals. Gold salts, such as gold trichloride and potassium dicyanoaurate, are recognized as sensitizing as well as irritant [2].

Occurrence. Metallic gold is mainly encountered in jewellery and dental materials. Gold salts are used in the plating, electronics, photographic, glass and porcelain industries [1].

Prevalence. Metallic gold has, until recently, been regarded as safe and very unlikely to sensitize. However, since gold sodium thiosulphate was introduced as a patch-test allergen to identify gold allergy there has been an upsurge in reports. When gold sodium thiosulphate was added to the standard patch-test series, positive reactions were obtained in 8.6% of a series of Swedish patients [3], with subsequent surveys of various selected subgroups ranging from 1 to 23% positivity [1]. There is a female predominance [4], and where a relevance has been found it has usually been in the context of jewellery or gold dental work [5–8]. However, the allergic mechanism behind the positive patch tests, and their relevance, have been questioned [5,9,10].

Clinical features. In our experience a relevance for a gold sodium thiosulphate positive patch test is found infrequently, and generally these patients can wear jewellery and have gold dental fillings without problems. Nevertheless, analysis of the involved anatomical sites has been undertaken by others who have found that involvement of fingers, ear lobes and eyes by dermatitis predominates [5]. A seborrhoeic eczema pattern has been described [11], as have persistent papules and nodules on the ear lobes, with lymphomatoid or granulomatous histology [12,13]. Reported oral manifestations of allergy have included erythema, burning mouth, erosions, ulceration and lichen planus-like lesions [8,14,15]. Most gold-allergic patients have gold dental work but the majority of them have no symptoms [3,5]. Sodium aurothiomalate injections for rheumatoid arthritis have induced systemic contact dermatitis and 'fever' in those previously sensitized to gold [16].

Acral dermatitis has been described from allergy to gold salts in the gilding industry [17].

Patch tests. Many gold salts have been used for patch testing, but most centres now use gold sodium thiosulphate 0.5% in petrolatum [18]. Late reactions are common and an additional 7-day or even 2- or 3-week reading has been advised [19]. The appearance of a positive patch test may be 'dermal', with erythema and oedema but no vesiculation, and persistent patch-test reactions are well recognized [19]. The controversy over the debatable relevance has led many to advise against routine standard-series screening for gold allergy [10].

Mercury [1]

Chemistry. The metal and its inorganic salts, for example corrosive sublimate ($HgCl_2$), calomel (HgCl), fulminate ($Hg(CNO)_2$) and ammoniated mercury ($HgCl{\cdot}2NH_4Cl$), as well as organic compounds (e.g. mercurochrome, thimerosal and phenylmercuric salts; see p. 20.67), may all sensitize.

Occurrence. The metal is used in thermometers, instruments and amalgam (alloy of silver or copper and mercury) for filling teeth [2,3]. Mercury and inorganic mercurials may be used in disinfectants, fungicides, herbicides, insecticides, detonators, emulsion paints and jewellery, as well as in the production of caustic soda and chlorine. Ammoniated mercury has been used in the topical treatment of psoriasis, although concerns about toxicity have led to its withdrawal in the UK. Mercury and ammoniated mercury have been used in skin lightening creams [4]. Red mercuric sulphide (cinnabar, HgS) is used in red tattoos and in artists' paints; it may contain cadmium sulphide as an impurity and can thereby cause phototoxic reactions. Organic mercurials may be found in topical and parenteral medicaments (see p. 20.67).

Clinical features. The clinical features of mercury allergy can be divided into oral, contact dermatitis, systemic and granulomatous. Stomatitis has been described in patients already sensitized to mercury after amalgam fillings, and this settled when they were removed [5]. Reports of oral lichen planus in association with amalgam fillings are increasing [6,7]. A study consisting of 19 patients with lichen planus adjacent to amalgam fillings showed that 15 of these were allergic to mercury; 13 of these cleared on removal of the amalgam. This study also included 42 patients with oral lichen planus not anatomically related to fillings, 28 with other oral diseases and 46 with burning mouth syndrome. Only seven of these had a positive patch test to mercury [7]. Hypertrophic amalgam dermatitis simulating carcinoma of the tongue has been described in one patient [8].

Generalized exanthems and erythema multiforme have been reported from amalgam fillings and following the breakage of thermometers in the mouth and the use of an antiparasitic powder for the treatment of crab lice [9–11]. Recalcitrant eczemas in mercury-sensitized individuals are recorded as clearing after removal of mercury amalgam fillings [12], although most cases of systemic reactions from amalgam seem to develop a few hours after insertion and settle after 10–14 days [13]. In our view, malaise and general ill health are not related to allergy to mercury in amalgams.

Red mercuric sulphide (cinnabar) in a tattoo may induce granulomatous reactions in allergic subjects [14]. We have seen several granulomatous and lichenoid reactions confined to the red parts of tattoos, and none of the patients has been allergic to mercurials.

Patch tests. Mercury is normally tested at 0.5% in petrolatum, mercurochrome 2% in petrolatum or aqueous, mercuric chloride 0.1% in petrolatum and ammoniated mercury 2% in petrolatum. However, mercury compounds can be irritant, and aqueous solutions of mercury salts may react with aluminium in Finn chambers to cause false-positive reactions [15]. Patch testing with both mercury and ammoniated mercury is suggested if allergy is suspected [15].

Aluminium

Occurrence and clinical features. Aluminium is widely used but contact allergy is very rare. Most reported cases are from aluminium-adsorbed vaccines and parenteral solutions, with granulomatous reactions at the injection site [1–4]. It is found in antiperspirants, and axillary dermatitis (usually irritant) may occur. Allergy in a child with chronic otitis externa treated with aluminium acetate eardrops has been seen [5].

Patch tests. As Finn chambers are aluminium, a positive patch test, often annular in configuration, may develop under every single test site in sensitized persons [6]. Patch testing is best undertaken with plastic chambers if this diagnosis is suspected. Pure aluminium metal or salts, for example aluminium acetate 10% aqueous or aluminium chloride 2% aqueous, can be used for testing.

Other metals

Copper is a ubiquitous metal found especially in coinage, jewellery, pipes, electrical equipment and wiring. Its salts are used in insecticides, fungicides, wood preservatives, food processing, fertilizer and fur dyes. Contact allergy is

very rare. Dermatitis has been reported from copper intrauterine contraceptive devices and proven by patch testing and resolution of the dermatitis after removal [1,2].

Other metals used in dentistry may have the potential to cause contact allergy, including platinum, rhodium, indium and iridium [3–5].

Fragrances, balsams, flavouring agents and spices [1–3]

Perfumes are blends of ingredients producing an odour intended to be aesthetically pleasant or to mask other less pleasant odours. The components are either of natural origin or produced synthetically. Natural sources include extracts from plants, trees, lichens and animals (e.g. musk, civet) [1]. Commercially available perfumes are mixtures of essential oils from these sources and synthetic compounds, with usually at least 10, and up to several hundred, ingredients [4]. The scent is determined by the mixture of volatile substances. 'Fixatives' are added to delay evaporation, influencing the quality and persistence of the perfume. Common 'fixatives' are balsams, benzyl benzoate, benzyl salicylate and synthetic musks.

Tree balsams contain many different fragrance and flavouring components. Balsam of Peru is one such material that has been studied in depth [5]. It comes from the Central American tree *Myroxylon pereirae*, and was widely used earlier this century for treating wounds and also scabies [5]. The composition is still not completely known, but the balsam does contain benzyl benzoate, benzyl cinnamate, cinnamic acid alcohol and aldehyde, benzoic acid, vanillin, farnesol and nerolidol [6]. It may cross-sensitize with resorcinol monobenzoate used in cellulose ester plastics [7]. Other related balsams include balsam of Tolu, balsam of spruce, gum benzoin and storax.

Flavours may similarly be of natural or synthetic origin. Examples of natural flavours include citrus fruit peel, peppermint oil, spearmint and vanilla. Natural spices include nutmeg, mustard, cinnamon, cloves and oil of juniper. In the modern food industry a large number of synthetic flavouring agents are used. As with perfumes, flavours may be complicated mixtures.

Prevalence. In general, as measured by the frequency of allergic reactions to the fragrance mix patch test in routinely patch-tested patients, fragrances are the second commonest allergen (after nickel) [2]. Studies with this patch-test allergen indicate that fragrance allergy affects in the region of 1% of the adult population [8], whereas children and adolescents have shown rates of 1.8% [9,10]. In those clinics investigating allergic contact dermatitis the rates have varied between 5.7 and 17.4%, with roughly 10% being an average for European investigation clinics [1]. Sex incidence has generally only shown a slight preponderance of females, and in some instances it has been equal [11–13]. There is evidence from some centres that perfume allergy, detected by fragrance mix, is increasing quite significantly [1].

The pattern of allergy is also changing. In one UK centre, although the level of fragrance mix allergy has remained stable, a significant reduction of cinnamic aldehyde and cinnamic alcohol allergy has occurred when components of the mix have been tested [12]. This is thought to reflect a decreasing concentration of these materials in cosmetics in the last 17 years.

Routine patch testing with balsam of Peru as a marker of allergy to perfume and certain flavours has shown a positive rate of allergy of around 4% [14]. It is thought to be a decreasingly relevant marker of perfume allergy [15].

Occurrence. Fragrances are ubiquitous. Perfumes, cosmetics, moisturizers, deodorants, aftershaves, soaps, bath additives, aromatherapy oils and toilet tissues and wipes are typical sources. Medicaments and work creams and cleansers often contain perfume. In the domestic environment cleansers, fabric conditioners and polishes may all be perfumed. At work some materials (e.g. coolant oils) may contain a masking perfume [16,17]. Limonene is used in industrial and histology solvents and degreasing agents. D-Limonene has been shown to act as an allergen when it becomes oxidized [18,19]. It may therefore only become allergenic with prolonged exposure to air.

Flavours and spices are to be found in foods, beverages, and dental products including toothpastes and lipsalves.

Clinical features. Analysis of common patterns of perfume dermatitis has shown a tendency to involve the hands, face and neck (Fig. 20.15) in women; hands, face and lower legs in men; and axillae in both sexes [20,21]. A streaky pattern may be observed. There is evidence that allergy to more than one perfume component may result in a synergistic effect [1].

Connubial allergy is well recognized [22], and allergy to lavender applied to a pillow has been described [23]. Many affected persons suspect their allergy, but a substantial number do not. Furthermore, those who are aware of their allergy may continue to suffer dermatitis by failing to take appropriate avoidance measures, for example by unwittingly applying perfumed medicaments

Fig. 20.15 An urticated contact dermatitis in a patient allergic to fragrance. (Courtesy of Dr J.D. Wilkinson, Amersham General Hospital, Amersham, UK.)

and cosmetics to their skin. Aromatherapists and their clients are liable to sensitization in sites where there is contact with the essential oils [24–27].

D-Limonene in its oxidized state may cause allergic occupational hand dermatitis [19], which can also develop in bakers and chefs as a result of contact with sensitizing flavouring agents [27,28]. Peeling of citrus fruit in the domestic environment may also induce an allergic hand dermatitis.

Cheilitis may be a reflection of allergy to flavouring agents in toothpastes [29–32], lipsalves [33,34], food and drink [35].

Balsam of Peru is still used as a medicament, particularly in haemorrhoid preparations, and allergy is therefore relevant to perianal problems. Sensitizing balsams are also used in medicaments and balms for wounds, sprains and joint pains, particularly in the Far East [36,37]. Tincture of benzoin is used in a similar way, and may also be used under orthopaedic plaster casts [38,39]. Vesicular hand dermatitis has been related to dietary intake of flavours related to balsam of Peru [40].

Musk ambrette is a synthetic perfume component responsible for photoallergy and although its use has been stopped in the western world, perfumed materials from other parts of the world might still contain it.

Avoidance. Perfumes are marketed as concentrated liquids, in more diluted form such as eau de toilette, or as sprays, and all should be avoided. Application of perfume to clothing may still cause problems in allergic subjects, who often believe they will only react if perfume is applied directly to the skin. Occasionally, affected subjects are able to use a specific perfume without any problem. Other perfumed skin products to be avoided include deodorants, aftershaves, talcum powders, soaps and bath additives.

The presence of perfume in a cosmetic or wet wipe will be denoted by the INCI term 'parfum' and the presence of balsam of Peru by the INCI term '*Myroxylon pereirae*'. Some cosmetics' labels may suggest they are fragrance-free, yet the products are found to contain perfume when the full ingredient label is studied, reinforcing the need to avoid unlabelled products. Some plant extracts may potentially be a hidden source of fragrance in cosmetics as the INCI nomenclature may use the plant's Linnaean name rather than the word parfum. Some extracts, however, may only contain traces of fragrance chemicals.

Surprisingly, some prescribable moisturizers, emollients, bath additives and corticosteroids, as well as over-the-counter medicaments, contain perfume. Allergic patients with ongoing problems should be counselled carefully about avoidance of these sources.

In the domestic situation, perfume-containing sprays such as air fresheners, insect repellants and hairsprays should be avoided, as should skin contact with perfumed household cleansing products and polishes. Unperfumed soaps or soap substitutes are required for washing the skin. The levels of perfume residues from washing powders and fabric conditioners for clothes are probably too low to cause clinical problems, but in those with a clothing pattern of eczema extra rinsing and avoidance of fabric conditioners can be considered.

In the occupational environment many cleansers, conditioning creams and barrier creams are perfumed, and similar avoidance measures are needed. Some work materials, including cutting oils and paints, may contain masking perfume and enquiries may be necessary to establish their components.

Dietary measures may be helpful in those with vesicular palmar eczema and balsam of Peru allergy, but the response can be disappointing [41–43].

Patch tests. The complexity of perfumes is such that there is not a perfect screening patch test for perfume allergy. Before 1977, the main recommended marker for perfume allergy was balsam of Peru, which is still advised. It is tested at 25% in petrolatum, but is thought to identify only 50% of perfume-allergic subjects [44]. Screening for perfume allergy was significantly advanced by the development of fragrance mix as a result of Larsen's studies [45,46]. He advised a mix of eight substances (Table 20.4). The original mix has been modified so that now each component is present at 1% concentration [47]. The mix contains an emulsifier, sorbitan sesquioleate at 5%, which is reported to have improved the return of identified perfume allergies [48,49]. Fragrance mix will identify approximately 75% of perfume-allergic subjects, although this figure is reported to increase to 90% if balsam of Peru is also tested [50,51].

An improved return may be achieved by testing with patients' own perfumed products [52]. In addition, there is

Table 20.4 Ingredients of fragrance mix* [45–49].

Substance	Concentration† (%)
Cinnamaldehyde	1
Cinnamyl alcohol	1
Eugenol	1
Amyl cinnamaldehyde	1
Hydroxycitronnellol	1
Geraniol	1
Isoeugenol	1
Oak moss absolute (*Evernia prunastri*)	1

* Fragrance mix allergens contain sorbitan sesquioleate (5% in petrolatum) as an emulsifier.
† All ingredients are diluted in petrolatum.

evidence from Europe that 4-(4-hydroxy-4-methylpentyl)-3-cyclohexine carboxyaldehyde (Lyral®) is a perfume sensitizer that might be missed with fragrance mix testing [50,53,54]. In a multicentre study, 2.7% of patients routinely tested were found to be allergic to it [50]. Other potentially missed perfume allergens include sandalwood, narcissus and ylang-ylang oil [51].

Fragrance mix may give false-positive irritant reactions, and testing the ingredients separately may help exclude these. However, when individual materials are mixed they may combine in such a way as to produce compound allergy, or other synergistic effect inducing a true allergic reaction, despite the components themselves being negative. The reverse situation (quenching), i.e. the mix is negative and one or more components positive, has been reported but also questioned [55]. Nevertheless, it is worthwhile testing with the breakdown in addition to the fragrance mix when perfume allergy is suspected.

An extended additional flavours series of patch tests can be developed for those with cheilitis or oral problems.

Applied medicaments [1]

Prevalence and incidence. Of all allergic contact dermatitis, 30% is caused, or complicated, by sensitivity to medicaments [2,3]. The literature on contact dermatitis abounds with reports of reactions to medicaments, and it is not possible to review all of these. It is doubtful whether the incidence has changed significantly [4,5], although the incidence of sensitivity to a particular allergen varies from country to country [6–8] and from decade to decade, according to both local prescribing habits and the number of patients with leg ulcers and stasis eczema included in any series [3]. Cases are missed unless patch tests are routinely performed and if locally used medicaments are not included in a standard series. Meaningful sensitization indices for the various medicaments can be calculated only if prevalence of sensitivity is correlated with usage [3,9].

Clinical features. Certain sites appear to be prone to the development of allergic contact dermatitis from medicaments. This is probably the result of frequent medicament usage at these sites, occlusive skin conditions and pre-existing skin damage. Sensitization to medicaments is particularly common in patients with leg ulcers or eczema of the lower legs (Fig. 20.16) [1], and is found in about half of those with chronic stasis eczema. Even weak allergens appear to sensitize if used on the lower leg. Contact dermatitis is also common in patients with chronic perianal inflammatory disorders (Fig. 20.17), pressure sores [2], chronic otitis externa [3] and in those who frequently use ocular medicaments [4].

However, dermatitis from applied medicaments can develop anywhere. Sometimes, the sensitivity is obvious but often is occult and easily overlooked, and it will then be detected only by patch testing. In burns, the damaged skin may be incapable of reaction, and dermatitis may be apparent only at the periphery of the burn site.

Fig. 20.16 Medicament allergic contact dermatitis superimposed on stasis eczema. Topical antibiotics/antibacterials, preservatives, lanolin and other constituents of the medicament base are often to blame. (Courtesy of Dr J.D. Wilkinson, Amersham General Hospital, Amersham, UK.)

Fig. 20.17 Pruritus ani is often complicated by secondary contact dermatitis to local anaesthetics or other medicaments. (Courtesy of Dr J.D. Wilkinson, Amersham General Hospital, Amersham, UK.)

Sensitivity to a topically applied medicament may result in several types of reaction.

1 Local aggravation, with increased itching and redness.

2 Spread to other regions, in most cases preceded by local aggravation. This is especially common in patients with stasis eczema or leg ulcers.

3 A local reaction may not develop, and dissemination may be the only sign of sensitivity. This typically occurs with creams and ointments containing a potent steroid capable of suppressing the reaction locally, but not in other regions.

4 Sensitization can also manifest merely as failure to respond to treatment. The original condition may worsen or fail to improve, without there being any acute flares or spread to arouse suspicion. This is seen mainly when there is a low degree of sensitivity and low concentration of allergens, typically with parabens and lanolin, or where the contact allergen is a corticosteroid.

5 Persistent generalized erythroderma is a rare manifestation of allergic contact sensitization to medicaments.

6 Contact urticarial reactions have also been reported.

Systemic reactions. Patients sensitized by the topical use of a drug may develop systemic reactions if that drug, or one that is closely related, is then given systemically. A pattern of dermatitis with erythema of the buttocks and flexural involvement elsewhere has been termed the 'baboon syndrome' (see p. 20.28). Widespread dermatitis [5,6] or generalized exfoliative dermatitis [7] has been reported following challenge with a systemic drug to which the patient already has contact allergy.

Other patients may develop a systemic reaction after topical application of a medicament. Anaphylactic reactions have been reported, for example following the topical use of bacitracin [8], cephalosporins [9], rifamycin [10] and chlorhexidine [11]. Erythema multiforme-like reactions to topical medicaments have also been reported [12]. Some patients have positive patch-test reactions to a topically applied drug, having previously been sensitized by its systemic use [13].

Patients who have been sensitized by the topical use of promethazine hydrochloride may develop serious photosensitivity if the drug is given systemically. Care must always be taken in prescribing an antihistamine systemically if the patient is known to have been exposed to the same or a chemically similar drug topically. Patients who are known to be allergic to ethylenediamine should not be given promethazine hydrochloride, antazoline hydrochloride, piperazine or several other antihistamines [14].

Avoidance and prognosis. Sensitization from a single constituent may lead to recurrent dermatitis due to its inclusion in several proprietary formulations. In only a few countries are the contents of a proprietary cream stated on the package or listed on the data sheet and, even then, the information is often insufficient, constituents sometimes

being given as trade names or only 'active' ingredients listed. In order to reduce the risk of relapse, the ingredients of all topical medicaments should be established. Ideally, all topical medicaments, whether prescribed or purchased without a prescription, would exhibit full ingredient labelling.

It is also necessary to consider cross-sensitivity to other, untested medicaments. This has received particular study in relation to contact sensitivity to the aminoglycoside group of antibiotics. A similar situation may develop in patients sensitive to the 'para' group of chemicals, with cross-sensitization between local anaesthetics, dyes, sulphonamides, UV filters, etc.

Patch tests. Patients with suspected contact dermatitis should be tested with all the medicaments they have applied. The information obtained in the history may be incomplete, and commonly used medicaments should also be routinely tested. It is often helpful to have a vehicle and medicament series, or several 'site' series with the ingredients of the most commonly used topical preparations in that geographical location. Testing to the medicament ('as is') may miss allergens, because they may be present in insufficient concentration. Where there is a high index of suspicion, the individual components should be obtained and appropriately diluted for patch testing.

It is important not to forget self-prescription of over-the-counter preparations. Popular habits of self-treatment vary from country to country and region to region. Knowledge of these habits is obtained by experience, but local pharmacists can often supply information. Certain remedies may be popular in one country but almost unknown in another. 'Natural' or herbal treatments are increasing in popularity. Some of these are irritant, and others, such as Chinese herbal remedies [1] and tea tree oil [2], contain allergens.

Various pharmaceutical developments have been associated with successive waves of dermatitis from applied medicaments; for example sulphonamides from 1945 to 1950, then antihistamine creams, and later neomycin and ethylenediamine [3]. Sensitivity to neomycin, gentamicin, lanolin, balsams, mercurials and preservatives is still common today. Newer sensitizers include the imidazoles, topical non-steroidal anti-inflammatory drugs (NSAIDs), transdermal delivery systems and topical steroids. Photosensitivity also occurs with some topical NSAIDs. Less common medicament allergens are listed in Table 20.5 [4–73].

Sensitivity may be confirmed in some patients exposed to drugs, particularly the penicillins, by *in vitro* lymphocyte transformation tests [74,75] and, for type I reactions, by specific RAST. Skin tests may also sometimes be positive in those who have had eczematous or urticarial reactions to ingested drugs [76,77]. Care must be taken in re-challenging anyone who has had a type I reaction because anaphylactic reactions may be induced. Guidelines for investigating potential drug reactions have been produced [78].

Medicament allergens included in the European Environmental and Contact Dermatitis Research Group (EECDRG) recommended European standard series include the following.

Neomycin 20% in petrolatum

Neomycin has two active components, neomycin B and neomycin C, which are stereoisomers [79]. It cross-reacts with other aminoglycoside antibiotics. The pattern of cross-sensitivity has been studied in guinea pigs [80]. Clinically, neomycin is known to cross-react frequently with kanamycin and framycetin (Soframycin), which would be anticipated with the latter as it consists almost entirely (99%) of neomycin B [81]. Cross-sensitivity also occurs to a varying degree with gentamicin and tobramycin [80]. Neomycin classically produces late reactions.

Clioquinol 3% in petrolatum

In areas where there is high use of chlorquinaldol the retention of the quinoline mix may be of value due to the lack of cross-reactions between it and clioquinol [82].

Benzocaine 5% in petrolatum

Experience suggests that, in the UK at least, the replacement of benzocaine with a mixture containing cinchocaine (dibucaine) 2.5% and amethocaine (tetracaine) 2.5% will double the yield of allergic positive reactions [83]. Local anaesthetics are either of the ester or amide type, and cross-reactions can occur within groups. Although cinchocaine is an aminoalkylamide and lidocaine (lignocaine) is an aminoacylamide [84], most individuals do not cross-react [83]. Ideally, any reaction to the mix should be followed up by testing to the constituents and to lidocaine [85]. Not all reactions to local anaesthetic are detected by the mix and patch tests should always be directed to the particular exposure of the patient [86].

Corticosteroids (tixocortol pivalate 0.1% in petrolatum and budesonide 0.01% in petrolatum) [87]

When testing with corticosteroids it is not unusual to see reflex vasodilatation following the steroid-induced vasoconstriction and this should not be interpreted as a positive reaction. Conversely, an annular response is frequently allergic, as a result of central suppression of the reaction by the corticosteroid.

A reaction to tixocortol pivalate almost invariably means that the patient is allergic to hydrocortisone. In the UK, a reaction to budesonide almost certainly represents a cross-reaction to another corticosteroid, most likely an

Table 20.5 Other medicament allergens.

Antiandrogens
Spironolactone [4,5]

Antiseptic agents
Benzoyl peroxide [5] used to treat acne, chloroacetamide [6], chlorocresol [7] and chloroxylenol. Less common sensitizers are benzalkonium chloride [8], nitrofurazones [9] in ear drops, benzyl alcohol [10], iodine [11], chlorhexidine [12], proflavine [13], resorcinol, glutaraldehyde as sterilizing agent [14], 4-aminoquinaldine [15] and isopropyl alcohol in medical skin wipes [16]

Antibiotics
Common sensitizers are the aminoglycosides, including framycetin [17], virginiamycin [18], sodium fusidate [19], minocycline [20] and chloramphenicol [21]. Less common are penicillins [22], metronidazole [23] and tetracyclines (e.g. as syrups), bacitracin [24] and clindamycin [5]. Streptomycin is a strong sensitizer but dermatitis is now rare because of more careful use

Antimycotic agents
Most antimycotics have sensitizing properties: tolnaftate [25], nystatin [26], amorolfine [27], undecylenic acid [28] and naftifine [29]. Imidazoles are rare but consistent sensitizers and cross-reactions are frequent [30–32]

Antiviral agents [33]
Aciclovir, interferons, amantadine [34], tromantadine, lamivudine, trifluridine and idoxuridine have all been reported as causing contact dermatitis

Antihistamines
The phenothiazines [35] are the strongest sensitizers, but all can sensitize when used topically [36], including doxepin [37]

Cytotoxic drugs
Topical mechlorethamine (nitrogen mustard), carmustine [38] and 5-fluorouracil [39], as well as intravesical mitomycin [40], can sensitize. Occupational contact dermatitis has been described from azathioprine [41] and diethyl-β-chloroethylamine [42], and occupational contact urticaria from cisplatin [43]

Non-steroidal anti-inflammatory drugs
The arylpropionic acid derivatives, such as ketoprofen, ibuprofen, ibuproxam and tiaprofenic acid, cause contact and photocontact dermatitis, with cross-reactivity, if used topically [44,45]. Topical benzydamine is also a contact and photocontact sensitizer [46] and phenylbutazone is a cause of erythema multiforme-like reaction [47]

Ophthalmic preparations [48,49]
Treatments for glaucoma, particularly β-blockers, including timolol and levobunolol, cause problems. Patch tests with the eye drops may give false-negative reactions. Preferably test with higher concentrations or enhance penetration [50]. Other glaucoma treatments reported as causing contact dermatitis include the parasympathomimetic pilocarpine and sympathomimetics apraclonidine and dipivefrine [51]. Sodium cromoglicate used for allergic conjunctivitis [52]. Mydriatics may also cause problems, especially phenylephrine [53], with which false-negative patch tests occur. Tropicamide contact dermatitis is also reported [54]

Otolaryngological preparations [55]
Antibiotics are frequent sensitizers, particularly neomycin and polymyxin. Some are peculiar to the ear, such as furaltadone [56]

Psoriasis drugs [57]
Reactions to both tars and dithranol have been reported (see also vitamins)

Traditional Chinese medicaments
Sensitization, as well as irritation, has been reported from Hong Kong, Japan and Singapore [58], as well as from China [59]

Transdermal therapeutic systems [60]
Sensitization has been reported to both active (clonidine [61], nicotine [62], nitroglycerin, oestradiol, norethisterone [63] and testosterone [64], scopolamine and pyridostigmine bromide [65]) and inactive (ethanol [66], methacrylates [67] and hydroxypropyl cellulose [68]) ingredients

Vitamins
Vitamins A, E [69] and K [70], the vitamin D_3 derivatives calcipotriol [71] and tacalcitol [72], and dexpanthenol [73] have all sensitized in topical medicaments

'ester' such as hydrocortisone 17-butyrate or an 'acetonide' such as triamcinolone acetonide. A reaction to either of these steroids in the standard series should prompt further testing to an extended steroid series, as 50% of tixocortol pivalate-positive and 90% of budesonide-positive individuals react to other corticosteroids [88]. Our experience suggests that although intradermal testing may have a role, testing other corticosteroids at 1% in ethanol is more sensitive. Together with knowledge of cross-reaction patterns [89], this helps in deciding what topical steroid to use as an alternative. Empirically, fluocinolone acetonide (Synalar) preparations react least frequently [90], and are available in a range of potencies. In view of the potential cross-reactivity between these two corticosteroids and prednisolone and its derivatives, it seems prudent to advise the use of either betamethasone or dexamethasone if a systemic steroid is needed, in order to reduce the risk of inducing a generalized dermatitis.

Cosmetics [1–6]

Cosmetics have been defined as any preparation applied to the skin, mouth, hair or nails for the purpose of cleansing, enhancing appearance, giving a pleasant smell or providing protection [1]. There is consequently a considerable range of products that can be included within this definition, for example perfumes, deodorants, aftershaves, hairsprays, lipsticks, nail varnishes and extensions, moisturizers, emollients, cleansers, mascara, eye shadow, make-up, sunscreens, hair colours and styling agents, soaps, shampoos, shower gels, bath oils and toothpastes.

Good manufacturers aim to eliminate known sensitizers and irritants. However, because all cosmetics and toiletries have to be protected against bacteriological contamination and decomposition, and as most consumers require their cosmetics to have a pleasing smell, there are potentially sensitizing preservatives and fragrances in most cosmetic products. The substitution of one allergen by another may lead to the introduction of perhaps an even more sensitizing substance [7]. When entirely new products or ingredients are used on a large number of consumers, unexpected allergic or irritant reactions may occur, and it may be some time before the cause is identified.

The range of cosmetic allergens is potentially considerable. The more frequently detected allergens are discussed in the specific sections relating to perfumes (p. 20.48), preservatives (p. 20.59), *p*-phenylenediamine and related dyes (p. 20.71), UV filters (p. 20.73), and vehicles and excipients (p. 20.68).

Allergy to tosylamide formaldehyde resin in nail varnish has been shown to be relatively frequent in those who wear it, and to have important adverse consequences [8,9]. Allergy to acrylates used in artificial nail glues and sculptured nails can produce similar results [10–12].

There is an increasing vogue for including natural plant-based products in cosmetics, and these may be potentially allergenic [13–16].

Incidence and prevalence. Contact dermatitis to ingredients of cosmetics and toiletries is common in patients attending patch-test clinics; approximately 10% of patients investigated for contact dermatitis in a multicentre European study were allergic to cosmetic products [17]. The exact incidence and prevalence of sensitivity in the population is difficult to establish. In a UK study of 1022 persons, 8.3% had experienced some sort of adverse reaction to a cosmetic or toiletry in the preceding year; most reactions were irritant rather than allergic in nature [18]. In one American survey comprising 30 000 consumers, 700 reactions had occurred during 1 year [19]. Some reactions are transient, such as stinging and smarting [20], and contact urticarial [21]. Most people simply change brand and do not report adverse reactions to the manufacturer. It is nevertheless estimated that 1–3% of the population is allergic to a cosmetic or cosmetic ingredient [22], with a female predominance.

The commonest allergens are fragrances and preservatives [23,24]. Also of importance are *p*-phenylenediamine, UV filters, tosylamide formaldehyde resin in nail varnish, lanolin and derivatives and cocamidopropyl betaine, but there are potentially many others [1]. As many as 6.6% of women habitually wearing nail varnish are allergic to it, and 1.6% of patients routinely tested to the usual allergen, tosylamide formaldehyde resin, are patch-test positive [8,25].

Clinical features [1]. Cosmetic allergy is unsuspected in about half of those in whom it is subsequently diagnosed [23]. Apart from hair dye allergy, acute weeping and oedematous reactions are unusual. More commonly, there are erythematous scaling patches or a more diffuse erythema. Differentiation from atopic and seborrhoeic eczema and lupus erythematosus may be difficult, especially on the face.

Sites of involvement are very varied, and depend on the type of product containing the allergen(s) and where it has been applied. Patterns of perfume allergy are described on p. 20.48, and hair dye allergy on p. 20.72. The eyelids, face (Fig. 20.18) and neck (see Fig. 20.15) are sites commonly involved in cosmetic allergy, but hand involvement and more widespread dermatitis are seen. It is not always appreciated how often cosmetics, particularly moisturizers, are applied not only to dry skin but also to pre-existing eczemas, including constitutional forms. Flares may wrongly be blamed on the underlying disorder, and cosmetic allergy may go undetected unless appropriate patch testing is undertaken. In general, 'leave-on' products are more likely to sensitize than wash-off cosmetics, although dermatitis may be maintained from the latter source in allergic subjects [1].

Cheilitis is seen from lipstick, lipsalve and toothpaste allergy. Hair cosmetic allergy may cause a scalp margin pattern as well as periorbital swelling. A similar distribution is seen in hairdressers' clients allergic to permanent wave chemicals (usually glyceryl monothioglycolate) [26].

Nail varnish allergy is often ectopic, with patches and streaks on the face, neck (see Fig. 20.10) and behind the ears, and episodic periorbital swelling. The face and neck are involved in about 80% of cases, the eyes in about 50% and periungual dermatitis, although often absent or minimal, occurs in 60% [9]. The allergen is usually tosylamide formaldehyde resin, but allergy to other agents (e.g. dibutyl phthalate, methyl acrylate and nitrocellulose) has been described [27–29]. More widespread involvement of, for example, the chest and anogenital regions may be seen [9,30]. Onycholysis may occur [31], but this is more likely with allergy from acrylates in adhesives for false nails and from sculptured nails, which may also cause dystrophy and paronychia [10,32,33]. A similar, potentially widespread, ectopic pattern of contact allergy may occur from acrylate-based nail cosmetics [11]. The socio-economic and medical consequences of nail varnish allergy have been investigated and shown to be potentially severe, with sick leave, work loss and even hospitalization resulting [9].

Avoidance. Full ingredient labelling of cosmetics has made a major contribution to avoidance measures. It is important to give the patient the INCI name of the material to which they are allergic, as this is the nomenclature used on cosmetic ingredient labels in Europe. There is still potential for confusion, particularly for plants which, when used in cosmetics, are identified by their Latin name in the Linnaean system. Some plant extracts may potentially contain, or cross-react with, fragrances, and it may be difficult for the patient and the dermatologist to be absolutely sure if a product containing natural plant extracts is safe for fragrance-allergic subjects. Products not labelled should not be used. The reader is referred to the sections on individual cosmetic allergens for more details. It may be wisest to advise women who are allergic to tosylamide formaldehyde resin to stop wearing all nail varnishes, as some products claiming to be free of the resin have been shown to contain it [34].

An alphabetical list of INCI names has been published, and an up-to-date list can be obtained via the Internet on http://www.pharmacos.eudra.org/F3/inci/index.htm.

Fig. 20.18 Facial allergic contact dermatitis, often due to fragrance, preservatives or other ingredients of cosmetics. (Courtesy of Dr J.D. Wilkinson, Amersham General Hospital, Amersham, UK.)

Patch testing. The EEC-DRG standard series contains a number of cosmetic allergens, including fragrance mix, balsam of Peru (*Myroxylon pereirae*), parabens mix, quaternium-15, methylchloroisothiazolinone/methylisothiazolinone, formaldehyde, *p*-phenylenediamine and Colophonium (colophony). The British Contact Dermatitis Society (BCDS) include others in their recommended standard series: imidazolidinyl urea, diazolidinyl urea, methyldibromo glutaronitrile, chloroxylenol and 2-bromo-2-nitropropane-1,3-diol [35]. However, a wider screen of

allergens is advised when investigating cosmetic allergy; in particular, tosylamide formaldehyde resin (10% in petrolatum) and, if relevant, an acrylic nail chemical series when investigating facial and patchy disseminated eczemas and periungual problems. Patch testing with a series of UV filters is also advised. In addition, the main allergen suppliers have a range of other potential allergens, including more preservatives, antioxidants, surfactants, emulsifiers and other cosmetic excipients.

It is also most important to test all the cosmetics used by the patient. As a general rule, 'leave-on' products and perfumes can be tested 'as is' but, because of irritancy, soaps and shampoos should be diluted to 1% aqueous. There is still a risk of false-positive reactions and also, because of the dilution, false-negatives. We test toothpastes at 25% and hair dyes at 2%, both in petrolatum. Mascara and nail varnish are often irritant and should be applied to a chamber and left to evaporate before applying them as a patch test.

False-negative reactions and marginal irritant reactions are common when testing with cosmetics. Ideally, each component of a suspect cosmetic should be tested individually. Where there is high index of suspicion the individual components should be obtained. This is feasible if the manufacturer is willing to provide the raw ingredients. Each ingredient must be tested at an appropriate concentration in an appropriate vehicle. The test substance should also be of similar source/batch and purity to that contained in the product. Sometimes the allergy is to the substance itself, and sometimes to an impurity. The concentration necessary to test an individual substance is often greater than its concentration in the product. Manufacturers' patch-test kits, which contain ingredients at the concentration in which they are present in the product, are likely to be misleading and should not be used.

Testing with hair dyes is discussed on p. 20.72. The permanent wave chemical glyceryl monothioglycolate is tested at 1% in petrolatum.

Other tests. If cosmetic allergy is still suspected despite negative patch tests, the possibility of photoallergy should be considered and, if clinically indicated, photopatch tests should be undertaken.

ROATs (see p. 20.114) may also be worthwhile. Finally, after discussion with the patient, a usage test can be considered, with reintroduction of the suspected products, one at a time, and using each for up to 3 days.

Fertilizers	Insecticide (flypapers)
? Smoke from tobacco, coal and wood	

Antimicrobial agents and preservatives

Formaldehyde [1]

Chemistry [2]. Formaldehyde (HCHO) is a gas, and formalin is a solution of the gas in water (about 38%). Methylol groups can be combined with other compounds to form formaldehyde releasers, which are widely used as preservatives [3,4]. Formaldehyde may combine with other chemicals to produce resins, which may sensitize (see p. 20.86).

Prevalence. In individuals routinely patch tested for the investigation of contact dermatitis, the frequency of allergic positive reactions is generally 2–3%, although the North American Contact Dermatitis Group (NACDG) found 9.3% were positive between 1996 and 1998 [5–7].

Occurrence [2]. Formaldehyde is a ubiquitous allergen and Table 20.6 gives an idea of the wide variety of potential exposure that may occur. It can often be difficult to find a relevance for a positive patch test, but more commonly identified causes are cosmetic ingredients [1]. Shampoos may contain formaldehyde, although this is more likely to be of relevance in the context of hairdressers' hand dermatitis than in relation to transient use on the hair [8]. Some textile resins will release formaldehyde, and free formaldehyde may be found in treated cotton clothing and rayons (see p. 20.77). Cleaning products and polishes are considered to be an important source of exposure in the domestic environment [9]. Formaldehyde is used for the preservation of anatomical and pathological specimens, and those working with such specimens, for example histopathologists and embalmers [10], are at risk of allergy from free formaldehyde. It is used medically in renal dialysis [11] and may be found in orthopaedic casts [12]. It is also used as a treatment for warts and hyperhidrosis, especially of the feet, where powders containing paraformaldehyde may also be used. The very widely used surfactant sodium lauryl sulphate may be preserved with formaldehyde at a level of 0.1% [13,14]. It is used in detergents, shampoos, shower gels and bubble baths. Threshold concentrations for elicitation of contact dermatitis from formaldehyde are as low as 30 ppm in the axillae [15], and as low as 250 ppm under an occluded patch test [16].

In addition, formaldehyde-releasing chemicals must be considered, including certain preservatives and biocides widely used in industry (e.g. in cutting oils) and cosmetics (see below). Many of these releasers not only sensitize simultaneously with, but also independently of, formaldehyde [17–19].

Clinical features. The presenting dermatitis will depend on the source of contact, for instance a clothing pattern (see p. 20.78), a cosmetic pattern (see p. 20.57) or involvement of the hands in occupational dermatitis. Formaldehyde allergy is often only diagnosed retrospectively by finding a positive patch test, and relating this to the distribution of the problem by identifying formaldehyde or formaldehyde-releasing chemicals that come into contact with the affected site.

Avoidance. Avoidance may be difficult, bearing in mind the wide exposure possibilities, but it is important to recognize that avoidance steps are only required if the individual has skin problems that are relevant to the exposure. For those with a clothing pattern, avoidance advice is given on p. 20.79. If cosmetics and moisturizers come into contact with the affected sites, their ingredient labels should be carefully assessed in order that those containing not only formaldehyde but also the formaldehyde-releasing preservatives listed in Table 20.7 are avoided. It may also be necessary to contact manufacturers to enquire about the presence of formaldehyde in their products. The difficulties faced by patients in identifying formaldehyde in products is highlighted by the fact that in one study of sensitized persons with persistent dermatitis, all were still

Substance	Patch-test concentration
Quaternium-15	1% in petrolatum
Imidazolidinyl urea	2% in petrolatum (or 2% aqueous)
Diazolidinyl urea	2% in petrolatum (or 2% aqueous)
2-Bromo-2-nitropropane-1,3-diol	0.25% in petrolatum (or 0.5% in petrolatum)
DMDM hydantoin	2% aqueous

Table 20.7 Formaldehyde-releasing preservatives in cosmetics.

using at least one product containing formaldehyde. Only by detailed enquiries and access to product databases could the presence of formaldehyde be demonstrated [20].

A number of tests can be used to detect the presence of formaldehyde. The chromotropic test may give false-positive reactions and the alternative acetylacetone method may be more sensitive and specific (see p. 20.116). More recently, a closed container diffusion method for quantification of formaldehyde has been devised [21].

Prognosis. In a follow-up study of 57 patients with formaldehyde dermatitis, 29 (51%) still had frequent or persistent dermatitis several years later. Formaldehyde was identified in cosmetics, toiletries, household cleaners and other materials still being used by 38 of these patients. The authors concluded that patients who paid attention to their allergy had statistically significantly fewer eruptions than those who did not [22].

Patch tests. Patch testing is now recommended with formaldehyde 1% aqueous [23]. Previously, 2% aqueous was advised but false-positive reactions prompted a change in the recommended concentration, yet with the potential for the occasional false-negative reaction. It is a generally recommended standard allergen.

Formaldehyde-releasing preservatives/biocides [1]

Quaternium-15

Quaternium-15 is also known as Dowicil 75, 100 or 200, chlorallyl methenamine chloride, *N*-(3-chlorallyl)-hexaminium chloride, and 1-(3-chlorallyl)-3,5,7-triaza-1-azoniondamantane. It is water soluble, odourless and colourless. Its broad antimicrobial activity is independent of the pH of the product [1].

Prevalence. Quaternium-15 can sensitize either independently or via formaldehyde release, or both [2–4]. The prevalence of positive patch tests in those attending for routine testing in North America is high, with 9.0% positive in a NACDG survey of 3436 patients [1]. Equivalent returns in Europe have generally shown lower levels, although the prevalence is dependent on the amount of usage in a given country. In the UK in 1986, 2.6% were positive, whereas there were no positives in a Dutch survey of the same year [2,5].

Occurrence. Quaternium-15 is found widely in cosmetic products and hand creams, including barrier and other creams used at work. It is found in a small number of medicaments in the UK [6].

Clinical features. These are discussed in the sections on allergy to cosmetics (p. 20.56) and medicaments (p. 20.51).

Avoidance. The INCI name is quaternium-15. Only ingredient-labelled cosmetics should be used, and any product shown to contain it should be avoided. Knowledge of synonyms is helpful, particularly as non-cosmetic products, including medicaments, may not adhere to INCI terminology.

Patch tests. For quaternium-15, 1% in petrolatum is the generally recommended concentration and vehicle. It is recommended as a standard allergen in Europe and North America.

Diazolidinyl urea

Diazolidinyl urea is also known as Germall II. It is a broad-spectrum biocide, soluble in water and effective at various pH levels [1].

Prevalence. Studies in the Netherlands on routinely patch-tested individuals showed that 0.6% of 2142 patients were patch-test positive [7], whereas in North America 3.7% were positive [1]. In one study 81% of those allergic to it were also allergic to formaldehyde [8].

Occurrence. Diazolidinyl urea has been used since 1982, predominantly in cosmetics, shampoos and creams, including barrier and other work creams.

Clinical features. These are discussed in the section on allergy to cosmetics (p. 20.56).

Avoidance. The INCI name is diazolidinyl urea. Only ingredient-labelled cosmetics and creams should be used, and any product shown to contain it should be avoided.

Patch tests. Patch testing at 1% and 2% aqueous has been advised [9], but it is generally supplied at 2% in petrolatum, which we have found satisfactory. Although not a frequent sensitizer in the UK, the BCDS has recommended its inclusion in the standard series [10].

Imidazolidinyl urea

Imidazolidinyl urea is also known as Germall 115. It has broad-spectrum antimicrobial activity and is colourless, water-soluble and not pH dependent. It acts synergistically with other preservatives and will kill *Pseudomonas aeruginosa* [1]. It releases only small amounts of formaldehyde, and may therefore possibly be less of a problem than other formaldehyde releasers for formaldehyde-sensitive subjects [11].

Prevalence. It is not a common allergen in most European studies, for example positive reactions occur in 0.7% of routinely patch-tested persons in Belgium [12] and the UK [2]. In North America the NACDG has reported a figure of 3.1% [13].

Occurrence. Imidazolidinyl urea is used in cosmetics, shampoos and hand creams, including barrier and other work creams. It is found in a cream containing the corticosteroid fluticasone, marketed in the UK as Cutivate®, where its presence is denoted by the word 'imidurea'.

Clinical features. These are discussed in the section on allergy to cosmetics (p. 20.56).

Avoidance. Imidazolidinyl urea is the INCI name. Only ingredient-labelled cosmetics should be used, and any product shown to contain it should be avoided. Cutivate® cream should also be avoided as a treatment.

Patch tests. Although patch testing with 2% aqueous has been advised [14], 2% in petrolatum is generally used. Its inclusion in the standard series is recommended by the BCDS in the UK [10].

2-Bromo-2-nitropropane-1,3-diol

2-Bromo-2-nitropropane-1,3-diol is also known as bronopol and BNPD. It has broad-spectrum antimicrobial activity and is particularly effective against *Pseudomonas aeruginosa*. It is soluble in water, alcohols, glycols and, to a lesser degree, oils [1].

Prevalence. The reported prevalence of positive reactions to 2-bromo-2-nitropropane-1,3-diol in routinely patch-tested individuals in North America in 1994–96 was 2.3% [13]. In the UK, 0.8% were positive in a 1986 study [2].

Occurrence. 2-Bromo-2-nitropropane-1,3-diol is present in a wide range of cosmetics, moisturizers, shampoos, medicaments and hand creams. It is used as a preservative when testing milk samples, and outbreaks of dermatitis have been reported from this source [15]. In the USA allergic problems have arisen from Eucerin cream [16] and in the UK from metronidazole gel used to treat rosacea [17].

Clinical features. These are discussed in the section on allergy to cosmetics (p. 20.56). In the occupational setting the usual site of involvement is the hands.

Avoidance. The INCI name is 2-bromo-2-nitropropane-1,3-diol. The simpler name of bronopol may be used in other products. Only ingredient-labelled cosmetics should be used, and any product shown to contain it should be avoided.

Patch tests. The two recommended concentrations are 0.5% and 0.25% in petrolatum; 0.5% may occasionally give false-positive reactions. It is recommended by the BCDS for the standard series in the UK [10].

DMDM hydantoin

DMDM hydantoin is also known as Glydant and is a colourless liquid that contains 0.5–2% free formaldehyde and over 17% combined formaldehyde [1].

Prevalence. In the Netherlands, 1.2% of patients routinely patch tested to DMDM hydantoin showed allergic reactions [5], and the NACDG reported up to 2.6% positivity [13]. Testing with formaldehyde demonstrated concomitant sensitivity in eight of 15 (57%) individuals [18].

Occurrence. DMDM hydantoin is used in a wide range of cosmetics. Surprisingly, there are no reports in the literature of allergy from this source [11], but we have seen occasional allergies relevant to cosmetics.

Clinical features. These are discussed in the section on allergy to cosmetics (p. 20.56).

Avoidance. DMDM hydantoin is the INCI name, and it can be identified in a product provided it is fully ingredient-labelled. There is evidence from ROATs that formaldehyde-allergic patients should avoid products containing DMDM hydantoin [18].

Patch tests. Patch tests have been undertaken at 1–3% aqueous and 1% in petrolatum. We have found 2% aqueous satisfactory.

Other biocides

The above formaldehyde releasers are encountered particularly in cosmetics, including shampoos and other hair-care products. A much broader series of formaldehyde releasers is to be found in materials such as industrial and household cleaning agents, colouring agents, paints and lacquers, polishes and metalworking fluids [19]. A knowledge of these is helpful, particularly when identifying ingredients in the aforementioned materials.

Isothiazolinones [1]

Isothiazolinone preservative systems have effective broad-spectrum activity against both bacteria and fungi. A number of different formulations have been demonstrated to be sensitizing to the skin.

1 A mixture of 5-chloro-2-methyl-4-isothiazolin-3-one and 2-methyl-4-isothiazolin-3-one in a 3 : 1 ratio by weight. The INCI name is methylchloroisothiazolinone/methylisothiazolinone (MCI/MI). This mixture has various other names, including Kathon CG, Kathon WT, Euxyl K 100 and Acticide.

2 1,2-Benzisothiazolin-3-one (BIT), which is used under the commercial name Proxel in a range of biocides.

3 2-*n*-Octyl-4-isothiazolin-3-one, also known as Kathon 893, Kathon LP and Skane M-8.

There seems to be little in the way of cross-sensitization between these compounds [2]. A further isothiazolinone, 2-methyl-4,5-trimethylene-4-isothiazolin-3-one (MTI), has also sensitized but only in the laboratory setting [3].

Methylchloroisothiazolinone/methylisothiazolinone [4,5]

Prevalence. Since first marketed in 1980, there have been many reports of allergy, particularly from Europe, with a prevalence of positive reactions as high as 8.3% in routinely tested patients [6,7]. However, there has been considerable variability in the prevalence of allergy from country to country [7]. In the USA, rates of 2–3% have generally been the rule [7].

There has been much discussion about the reason for differing prevalence rates worldwide. It has been suggested that in some countries there has been lack of control over the amount of this biocide added to products that come in contact with the skin [7]. Furthermore, patch testing with concentrations as high as 300 ppm in some centres may have produced false-positive reactions, whereas other centres have tested with 100 ppm [7].

Levels below 15 ppm are felt unlikely to induce sensitization [8], and in those already sensitized this concentration has been shown to be insufficient to elicit a dermatitis in many instances [8,9]. A decrease in, and stabilization of, frequency of allergy is felt to reflect tighter regulation of concentrations used. The maximum allowable concentration in the European Union (EU) for both 'rinse-off' and 'leave-on' cosmetics is 15 ppm, with a lower recommended concentration of 7.5 ppm for 'leave-on' products in the USA [10].

Occurrence. MCI/MI is now mainly used in 'rinse-off' products, including liquid soaps and cleansers, shower gels, bubble baths and shampoos [9]. Nevertheless, some 'leave-on' cosmetics may contain it. It may be present in medicated wipes and moist toilet paper [11–13]. In 1990, a Danish study showed its presence in 48% of 'rinse-off' and 31% of 'leave-on' cosmetic products used there [14]. In 1988, 25% of all cosmetic products in the Netherlands were reported to contain it [4].

However, this biocide can be found in other situations, most notably soluble cutting oils, paints, glues, spin finishes, household cleansers, printing inks, latex emulsions, water cooling systems and as a slimicide in paper mills [1,15–25].

Clinical features. These are discussed in the section on allergy to cosmetics (p. 20.56). Shampoos do not usually cause problems from washing the hair but allergy may be associated with hairdressers' hand dermatitis. Hands are the usual sites for occupational allergic dermatitis, although an airborne pattern has been described [26]. A chemical burn from spillage of concentrated MCI/MI on to any part of the skin may be followed by a secondary delayed dermatitis from active sensitization [27].

A positive patch test to MCI/MI associated with perianal dermatitis suggests the possibility of moist toilet paper or wipes as a cause [11–13].

Patch tests. The recommended patch-test concentration and vehicle is now 100 ppm in water, as it has been suggested that 200–300 ppm might be associated with false-positive reactions and active sensitization [28]. However, there is also evidence that 200 ppm may identify sensitized subjects missed by the 100 ppm patch test [29,30]. MCI/MI is generally recommended as a standard allergen.

1,2-Benzisothiazolin-3-one

Occurrence. Sensitization normally occurs from manufacturing or handling the raw material, for example paint manufacture, water treatment or in the laboratory [31–33]. Painters and decorators may be exposed from not only paints but also wallpaper pastes [34,35]. Allergy has been reported in the pottery industry from its presence in mould-release agents. Other potential sources include soluble cutting oils, printing materials, water softener and air-freshener manufacture [1,36–40].

Clinical patterns. Classically, with hand dermatitis, a low-grade constitutional-looking palmar psoriasiform or pompholyx pattern occurs (see Fig. 20.5). In more severe cases an exposed-site pattern develops. Sensitized workers involved in manufacture may complain of a burning sensation of the eyes and face within the factory environment without there being observable dermatitis.

Patch tests. A number of patch-test concentrations in petrolatum have been suggested, varying from 0.05 to 1%. False-positive reactions have been reported with 0.1% in petrolatum [41], and as our experience is that false-positive reactions occur above 0.05% in petrolatum we advocate the use of this concentration.

2-n-*Octyl-4-isothiazolin-3-one*

Occurrence. 2-*n*-Octyl-4-isothiazolin-3-one may occur in leather, soluble cutting oils, paints and polishes, cleaning agents and wood preservatives [1].

Clinical features. Reports of contact allergy tend to be sporadic and anecdotal, and these include hand dermatitis associated with its presence in paints [35,42]. We have found a small number of positive reactions in individuals with possible shoe dermatitis, but of unproven relevance.

Patch tests. 2-*n*-Octyl-4-isothiazolin-3-one is usually patch tested at 0.1% in petrolatum.

Parabens (hydroxybenzoates) [1–3]

Parabens are esters of *p*-hydroxybenzoic acid. The four main esters used are methyl-, ethyl-, propyl- and butylparaben (hydroxybenzoate). They may have a synergistic effect when used in combination. They are more active against Gram-positive than Gram-negative bacteria (including poor activity against *Pseudomonas*). They are also active against moulds and yeasts. They are stable, colourless, odourless and poorly soluble in water [1].

Prevalence. There is a relatively low prevalence of positive reactions in routinely patch-tested patients, and rates between 1 and 1.7% are typical [4–6].

Occurrence. Parabens are very widely used preservatives in topical and parenteral medicaments, paste bandages, cosmetics and foods [2,7].

Clinical features. The striking feature of allergy to parabens is its relative infrequency compared with the degree of usage and exposure in the general population [1,2]. Relevant allergies are mainly from sensitization to medicaments (including paste bandages) used on varicose ulcers and eczema [8,9], but contact allergy may be superimposed on other constitutional eczemas and it may occur on high-risk sites such as the anogenital region [10]. Relevant problems from parabens in cosmetics are rare

[1]. Interestingly, many individuals allergic to parabens in medicaments can use cosmetics containing them on normal skin without any problem, the so-called 'paraben paradox' [11]. However, there are exceptions, and sometimes cosmetics containing parabens have to be abandoned [10,12]. Flares from parabens in food have been reported in sensitized subjects, but a low-paraben diet did not help subsequently [13].

Avoidance. The INCI name for this group of preservatives ends in '-paraben' according to the ester used. In individuals in whom cosmetic allergy may be relevant, the full ingredient label must be examined in order that they may be avoided. Terminology for medicaments may be different, and the name may end in '-hydroxybenzoate'. Furthermore, the commercial names may sometimes be used, in particular Nipagin, Nipsasol and Nipabutyl, but there are many others. Only medicaments and paste bandages whose ingredients are known in full should be used, avoiding those containing parabens or agents whose names are synonyms of parabens. It is advisable to avoid all parabens even if only one or two are positive in breakdown testing.

Patch tests. Hydroxybenzoates are normally tested as a mix of the four esters, each at 4% in petrolatum. The mix is marginally irritant, and testing with each ester individually will help to confirm whether the patch-test reaction is truly allergic [2,4]. Often more than one ester will react, which may be a marker of both concomitant sensitization and cross-sensitization. Parabens mix 16% in petrolatum is generally advised for the standard series.

Methyldibromo glutaronitrile [1]

Methyldibromo glutaronitrile (MDBGN), also known as dibromocyanobutane, is to be found in the preservative system Euxyl K 400 (also called Tektamer 38), which is a mix of MDBGN and phenoxyethanol in a ratio of 1 : 4. Euxyl K 400 is a broad-spectrum preservative with activity against fungi and bacteria. MDBGN is nearly always the allergen when sensitization to Euxyl K 400 occurs [2].

Prevalence. There is evidence that MDBGN is an emerging allergen in Europe and the USA [3–7]. Of particular significance are the findings of a multicentre European study monitoring rates of preservative allergy. The frequency of MDBGN allergy has risen from 0.7 to 3.5%, whereas the level of all other cosmetic preservative allergy has remained stable [6]. In one small US study involving 163 routinely patch-tested patients, 11.7% were allergic to MDBGN [4]. Rates for the NACDG have varied from 2.7 to 7.6% according to the test concentration used [7]. This has caused concern about the correct test concentration [2].

Occurrence [2,8]. MDBGN is widely used in cosmetics, sunscreens, shampoos, liquid soaps, and barrier and moisturizing creams used at work [9–13]. Other sources include moistened toilet tissues, ultrasound gel, adhesives, soluble cutting oils and latex paints [2,3,8,14–16]. The rising number of reports of allergy resulted in a proposal to restrict the use of this preservative to rinse-off products with a maximum concentration of 0.1% in Europe in 2002.

Clinical features. These are discussed in the section on allergy to cosmetics (p. 20.56). In the occupational setting the usual site of involvement is the hands. We have found a small number of subjects with unsuspected allergy who were clinically suspected of having occupational irritant hand dermatitis prior to patch testing. The source was their work cleansers and/or creams containing MDBGN, and following withdrawal of these the dermatitis resolved and they were able to continue in the same work [13].

Allergy to Euxyl K 400 in wipes and moistened toilet tissues is a potential cause of perianal dermatitis [3,14].

Avoidance. Methyldibromo glutaronitrile is the INCI name that should be sought on the full ingredient label. Many producers of work cleansers and creams now give a full ingredient list on the health and safety data sheet. Skin products whose ingredients are not known should not be used.

Other potentially allergenic sources may require specific enquiry as to the nature of the biocide/preservative used.

Patch tests. We prefer to test MDBGN at 0.3% in petrolatum, as we and others [6] have found it marginally irritant; 0.1% has been used as an alternative but may give false-negative reactions [17]. Euxyl K 400 is also available at 0.5% and 1% (containing 0.1% and 0.2% MDBGN) in petrolatum. A 2.5% concentration may increase the return, but with the risk of false-positive reactions [7]. It has been recommended for the BCDS standard series at a concentration of 0.3% [18].

Chloroxylenol (parachlorometaxylenol, PCMX) [1]

Chloroxylenol is a halogenated aromatic compound used not only as a preservative but also as an active disinfectant. It is water and oil soluble and active against Gram-positive and Gram-negative bacteria [2].

Prevalence. Generally, reports of chloroxylenol allergy have been sporadic, with few large-scale studies. In one UK study 1.8% of 951 routinely tested persons were patch-test positive, with a high level of current or previous relevance [1]. A report from the USA documents seven patients sensitized by medicated Vaseline or electrocardiogram paste [3]. A more recent British study yielded a lower prevalence rate of 0.4% [4].

Occurrence. Chloroxylenol is a potential allergen for the UK as it is found in Dettol, a widely used household disinfectant. This may also be used in diluted form as a wound cleanser. However, it is important to know that Dettol is used in many ways that may not always be predictable. Some people use the product to 'decontaminate' themselves or their environment. It is not uncommon for them to add Dettol to bathwater, and if they have a skin disorder that they consider represents an infection, they may add extra in the hope of its eradication. Persons with perineal inflammatory disorders are particularly liable to do this. Some may apply it neat to their skin in the hope of eradicating a genuine or imagined infection; the residual smell may be a helpful diagnostic indicator of use. Clothes and bedding may be washed in Dettol and inadequately rinsed, and then worn or used.

Chloroxylenol may also be found in a number of over-the-counter pharmaceutical preparations for cuts, grazes and infections [1]. Other sources include foot and talcum powders, soaps and cleansers, work creams, coolant oils, electrocardiograph pastes and, rarely, cosmetics [3,5–8].

Clinical features. In many cases there is a localized skin eruption at the site where a product containing chloroxylenol has been applied, or allergy may present as an unexpected exacerbation of pre-existing dermatitis.

Hand dermatitis is a potential problem for cleaners coming in contact with disinfectants when their hands are unprotected, and allergy to chloroxylenol in other work materials (e.g. coolant oils) may give a similar distribution of rash.

More widespread eruptions may be associated with its use for washing and bathing (Fig. 20.19), and also when applied to clothing. Recently, widespread hypopigmentation following contact allergy to chloroxylenol added to bathwater has been reported [9].

Often, the source is only identified retrospectively after finding a positive patch test.

Avoidance. Chloroxylenol is the INCI name. Cosmetics and work creams that contain it can usually be identified from the full ingredient label or data sheet. Labels on medicated foot powders and talcs generally acknowledge it as

Fig. 20.19 Allergy to chloroxylenol from washing with Dettol. (Geoffrey Auckland collection, Hope Hospital, Manchester, UK.)

an ingredient, but specific enquiries may be necessary to establish its presence in some topical medicaments and disinfectants.

Patch tests. Chloroxylenol is generally patch tested at 1% in petrolatum. It may cross-sensitize with chlorocresol [10]. It has been recommended as a standard allergen for the UK [1,4].

Chlorocresol (parachlorometacresol, PCMC)

Chlorocresol is identical to chloroxylenol, except for the absence of a methyl group on the benzene ring [2]. It is active against Gram-positive and Gram-negative bacteria, and is water and oil soluble [2].

Prevalence. Chlorocresol is a rare allergen. Only 0.4% of routinely patch-tested patients in Manchester were allergic to it in a 1991 study [11]; more recently, a multicentre UK survey confirmed a continuing low rate of 0.6% [4].

Occurrence. The major source is corticosteroid creams [10,12,13]. In the past, aqueous cream BP was preserved with chlorocresol, but this is generally no longer the case. We have only seen it as a sensitizer from topical medicaments, although it may be used in hand cleaners, metalworking fluids and occasionally cosmetics [14,15].

Clinical features. These are discussed in the section on medicament allergy (p. 20.51).

Avoidance. It is helpful to give a sensitized patient a list of corticosteroid creams that indicates what they contain and which are free from chlorocresol. Moisturizers should not be used unless they are fully ingredient-labelled or known to be free from this preservative. The INCI name is chlorocresol.

Patch tests. The recommended test concentration and vehicle is 1% chlorocresol in petrolatum. Although contact allergy is rare, its use in many popular corticosteroid creams available in the UK has prompted the BCDS to recommend its inclusion in the standard series [16]. Cross-sensitivity with chloroxylenol is well recognized [10].

Organic mercurials

Sensitizing compounds include phenylmercuric salts and thimerosal (thiomersal, merthiolate). Thimerosal is composed of an organic mercurial and thiosalicylate. Allergy may occur to one or the other moiety [1].

Occurrence. Organic mercurials are used as preservatives in vaccines [2–4] and antigen extracts [5], eye drops, contact lens solutions [6], and eye make-up and remover products [7]. Their use in all other cosmetics is banned by European legislation. Phenylmercuric salts have been used in contraceptive jelly, antifungal treatments, shoe linings and emulsion paints [8–10].

Prevalence. Positive reactions occur in 4–5% of individuals routinely patch tested with thimerosal; higher rates

have been reported in North America (10.9%) and Japan (9.5%) [10,11].

Clinical features. Allergy to organic mercurials in eye medicaments and contact lens preservatives will induce a localized dermatitis affecting the eyelids, with extension periorbitally. Palmar and fingertip dermatitis, isolated conjunctivitis, and even corneal neovascularization from contact lens solutions are described [12–14].

Many people have a positive patch test to thimerosal of no demonstrable relevance [15]. Sensitization is thought to develop from parenteral vaccinations and immunotherapeutic agents preserved with thimerosal [16–18]. Localized reactions from injections are rare but have been observed, with one case having a generalized dermatitis [19,20].

Allergy to the thiosalicylic acid component may be associated with photoallergy to piroxicam [21,22].

Patch tests. Phenylmercuric salts may be tested at 0.01% and 0.05% in petrolatum and water. Thimerosal is normally tested at 0.1% in petrolatum.

Other preservatives/biocides

Many other antimicrobial agents have been used as preservatives and biocides, and reported to sensitize. These include chloracetamide, triclosan (Irgasan DP300), benzalkonium chloride, sorbic acid, benzyl alcohol, captan, chlorhexidine, ethylenediamine tetracetate (EDTA), dichlorophene, iodopropynyl butyl carbamate and many more [1,2]. Sources where antimicrobial protection is required are legion, but include particularly medicaments, cosmetics, cleansing agents, paints and soluble coolant oils. The possibility of allergy to this group of materials must always be considered as a cause of dermatitis.

Vehicles and other cosmetic and medicament excipients

Lanolin [1]

Lanolin is a natural product obtained from sheep fleece. It is a complex and variable mixture composed of sterols, fatty alcohols, fatty acids and their esters. Wool wax alcohols (INCI name: lanolin alcohols) are obtained by hydrolysis of the oily wax fraction of the fleece. Although they are not all known, it is thought the allergens are mainly, if not all, in this fraction [2–5].

Attempts to reduce allergenicity include modification by acetylation, hydrogenation, ethylenation, transesterification and removal of the allergenic fractions by a purification process [1,2,5–8]. Allergenicity has been shown virtually to disappear by removing detergent residues and reducing the level of alcohols to below 3% (w/w) [9].

Prevalence. Prevalence of lanolin allergy in the general population is thought to extremely low [10]. Contact allergy is normally detected by patch testing with wool alcohols, and enhanced identification of allergic subjects

has been attempted by testing with a wider range of lanolin derivatives and lanolin itself. Most surveys of patients routinely patch tested to wool alcohols report positive reactions in 1.7–3.3% [11–13]. However, other studies, in which patch testing with lanolin derivatives including Amerchol L 101 (mineral oil and lanolin alcohol) was undertaken, have shown a much higher rate of positive reactions than those using wool alcohols alone [14,15].

The belief that lanolin is a frequent sensitizer has been questioned by Kligman [1,16,17], and there are grounds for this as experimental sensitization of animals and humans has not been achieved [16]. Furthermore, patch testing with wool alcohols at 30% in petrolatum (as generally recommended) and with Amerchol L 101, particularly if patch tested at 100%, may give false-positive results [11,17,18]. In addition, retesting showed that the allergy 'disappeared' in up to 40% of those originally considered to have positive reactions [8,18,19]. Nevertheless, there is good evidence of a high prevalence of allergy to lanolin in medicaments applied to varicose eczema [20,21]. The use of lanolin-containing medicaments on other chronic eczemas, particularly in elderly women, may be associated with the development of lanolin sensitivity [2,6]. However, usage on normal skin rarely seems to be associated with significant problems [22].

Occurrence. Lanolin is most commonly encountered in medicaments, emollients, bath additives and cosmetics. Other sources [1] include polishes, waxes, inks, adhesive tapes and bandages [23], anticorrosive coatings [24], sealants and cutting oil emulsions.

Clinical features. These are discussed in the sections on allergy to cosmetics (p. 20.56) and medicaments (p. 20.51).

Avoidance. Lanolin alcohols is the INCI name for lanolin, and its presence in cosmetics can be established by examining the full ingredient label. However, prescribed and over-the-counter medicaments are not always fully ingredient-labelled in the UK, and examination of the data sheet or contacting the manufacturer may be necessary to ascertain whether it is in a medicament. This also applies to other potential domestic and work exposures such as polishes, waxes, coatings and oils.

Patch tests. Many patients state that they are allergic to lanolin but patch testing does not substantiate this. Conversely, allergy may be unsuspected, particularly when there is an associated eczema being treated with a lanolin-containing medicament.

Standard testing with wool alcohols 30% in petrolatum is advised, but where medicament sensitivity is suspected or to be excluded, extra lanolin allergens should be tested. We use Amerchol L 101 50% in petrolatum and lanolin 'as is'. Weak positive reactions may be false positive, but can be exceedingly difficult to distinguish from weak allergic reactions.

Cetearyl alcohol

Cetearyl alcohol is the INCI name. It has emulsifying and stabilizing properties, and is also known as cetylstearyl alcohol and Lanette O. It is essentially a mixture of two long-chained stereoisomers, cetyl and stearyl alcohol. These alcohols are components of lanolin.

Prevalence. Reports of allergy are often anecdotal, although there is evidence of it being a significant allergen complicating varicose eczema and ulcers, with up to 16% positive reactions in patients with these conditions attending for patch testing [21,25,26].

Occurrence. Cetearyl alcohol is widely used in steroid creams, emollients and cosmetics. Sometimes only one of the stereoisomers is used. It is a component of emulsifying wax and therefore found in emulsifying ointment and aqueous cream BP.

Clinical features. These are discussed in the sections on allergy to cosmetics (p. 20.56) and medicaments (p. 20.51).

Avoidance. Cetearyl alcohol is the INCI name, but cosmetics labelled as containing cetyl or stearyl alcohol should also be avoided. Avoidance of medicaments, including emollients, is more difficult, as they are not always fully ingredient-labelled. Even when they are, they may not follow the rules for cosmetics. Emulsifying wax is an ingredient that may be listed without it being clear that the preparation contains cetearyl alcohol. The designations cetylstearyl alcohol or Lanette O may be used instead of the INCI name. It may be preferable to provide a sensitized individual with a list of products free of cetearyl alcohol.

Patch tests. Although it is an uncommon allergen, its ubiquitous presence in dermatological therapies means that identification of allergy is important. The BCDS has therefore recommended its inclusion in the standard series for the UK [27]. Patients suffering from varicose eczema should always be patch tested with it. It is normally tested at 20% in petrolatum.

Ethylenediamine dihydrochloride [28]

Ethylenediamine is a low-molecular-weight aliphatic amine. Some antihistamines are chemically related, which may be of significance to the sensitized patient.

Prevalence. Allergy to ethylenediamine is becoming less common, and sufficiently so for the EEC-DRG to

recommend omitting it from their recommended standard series [29,30]. In general, the prevalence of allergy reflects the amount of nystatin/neomycin sulphate/gramicidin/triamcinolone acetonide cream (see below) being used in the catchment area of those being tested, as this is the usual source of sensitization. This preparation has been reformulated in the USA, but the original formula may still occur in generic creams. It is still used and sensitizes sufficiently frequently in the UK for the BCDS to recommend the continued use of ethylenediamine in the standard series [27].

Occurrence. Ethylenediamine is used as a stabilizer in a combined preparation that contains nystatin, neomycin sulphate, gramicidin and triamcinolone acetonide, marketed in the UK as Tri-Adcortyl® cream and in the USA and other countries as Mycolog® cream. The equivalent ointment does not contain ethylenediamine. It is a component of parenteral aminophylline, which may also come in contact with the hands [31–33]. Other systemic and topical medicaments are also related to ethylenediamine, most notably hydroxyzine and probably cetirizine [34,35], as well as piperazines [36], which include the antihistamines meclozine and cyclizine [28]. Industrial exposure is potentially wide, as it and related amines are used as epoxy hardeners [37–39] and in coolant oil [40,41], wire-drawing lubricants [42,43], floor polish remover [44], antifreeze, synthetic waxes, anticorrosive paints and dye manufacture. It is used as a rubber stabilizer, but we have not seen sensitization occurring from rubber garments.

Clinical features. These are discussed in the sections on medicament (p. 20.51) and systemic contact allergy (p. 20.28).

Occupational patterns will depend on the source of the exposure, but the hands are the most likely site to be affected. In those sensitized to epoxy systems, there is often concomitant sensitization to epoxy resin, with an associated exposed-site pattern of dermatitis.

Avoidance. Avoidance of topical exposure to the creams containing nystatin, neomycin sulphate, gramicidin and triamcinolone acetonide is essential. It may also be necessary to avoid topical antihistamine creams and eye drops. Once sensitized, individuals may be at risk of systemic contact dermatitis. In the UK, avoidance of systemic hydroxyzine, piperazine and probably cetirizine is advisable [34,45–47]. Sensitized patients must also avoid parenteral aminophylline [48–50].

Avoidance of occupational exposure depends on identification of the source.

Patch tests. Ethylenediamine is tested at 1% in petrolatum. It is still recommended for standard testing in the UK because of the continued availability of Tri-Adcortyl® cream.

Other excipients

There is potential for virtually any vehicular component of a cosmetic or medicament to cause sensitization. If allergy is suspected, it may be necessary to widen the range of allergens tested. Examples include antioxidants (butylated hydroxyanisole, butylated hydroxytoluene, *t*-butylhydroquinone [51] and gallates [52–54]), surfactants (e.g. cocamidopropyl betaine, which may cause hand dermatitis in hairdressers from shampoos [55–57], and coconut diethanolamide [58–60]) and humectants (e.g. propylene glycol [61]). This list is by no means exhaustive but is a further indication of the range of possible excipient allergens in cosmetics and medicaments. Many such excipient allergens are available from the main allergen suppliers, suitably prepared for patch testing.

p-Phenylenediamine and related dyes [1–3]

p-Phenylenediamine (PPD) and *p*-toluenediamine (PTD) are aniline derivatives, whose main use is for dyeing hair. These chemicals are colourless until oxidized by hydrogen peroxide in the presence of ammonia, and polymerized by a coupler, often in the presence of other intermediates, to produce a variety of shades of colour that stay fast within the hair shaft [2]. Once oxidized, PPD is said to be no longer allergenic, although some cases of allergy have been reported [3]. Semi-permanent hair dyeing may be undertaken with related dyes, for example *o*-nitro-*p*-phenylenediamine (ONPPD).

There is structural similarity to some azo dyes (e.g. *p*-aminoazobenzene). Many disperse dyes used to dye synthetic clothing and fibres are azo dyes [4]. It may be difficult to make these dyes fast to the fibres, thereby allowing sensitization of the skin to take place [5].

Prevalence. It was estimated in 1973 that 40% of women in the USA use hair colours [6]. Of those patch tested in the mid-1990s by the NACDG, 6.8% were allergic to PPD [7]. At the same time, 4.8% were allergic to PPD in Germany and Austria, where there was considerable geographical variation in frequency (2.8–7.1%) [8]. In a large Belgian study of over 5000 routinely tested patients, 7.2% were allergic to PPD, 1.6% were allergic to PTD and 1.8% were allergic to ONPPD [9]. PPD is the second most common allergen of relevance to hairdressers in Europe [10].

Generally, routine patch testing to azo dyes is not undertaken, although this has been advocated [11]. By routinely testing with four azo dyes, 4.8% of patients were found to have positive reactions and this increased to 5.8% when 12 further dyes were routinely tested [11]. PPD allergy is not a good marker for azo dye allergy as cross-sensitization occurs in only 20% of patients allergic to azo clothing dyes [11,12]. If textile allergy is suspected, a special series of clothing dyes, including azo dyes, is normally tested (see p. 20.79).

Occurrence. PPD and PTD are found in permanent hair dyes, and ONPPD in semi-permanent hair dyes whose colour will persist for 5–10 shampooings. In the EU, PPD is allowed in hair dyes up to a concentration of 6% free base [13]. PPD has been used to dye fur [14]. PPD may be mixed with henna and used on the skin as a temporary tattoo [15–19]. Application of these is particularly likely

during beach holidays. Allergy to PPD is reported from a violin chin-rest and cello bowstring stain [20,21].

PPD derivatives are used as rubber antioxidants, particularly in heavy-duty black rubbers. Although reported to be in photographic developers (including those for radiography), photocopiers, petrol, oils, greases and printing inks, sensitization is rare from these sources.

Azo dyes are mainly encountered as disperse dyes for synthetic clothing. Allergy to azo dyes in maggots used for fishing bait has been reported [22].

Clinical features. PPD and related hair dye allergy can result in extremely severe skin reactions. The scalp is often relatively spared, but severe oedema and weeping of the scalp margin, ears and eyes, with more extensive secondary-spread eruptions, may be seen. However, there can be lower grade reactions, usually around the scalp margin. The patient does not always recognize the relationship of the skin eruption to dyeing the hair. Oxidized hair dye is not thought to be allergenic [23]. Nevertheless, allergic contact dermatitis from partners' hair has been described [24–26], perhaps as a result of poor dyeing technique, which is more likely with self-application of the dye.

Lichen planus-like presentations of hair dye allergy have been reported from the Indian subcontinent, and we have seen similar patterns in Asian patients in the UK [27]. Furthermore, in our experience, hair dye allergy is relatively common in both sexes in this ethnic group. An equivalent overrepresentation has been identified in African-Americans [28].

Hairdressers may become sensitized by the dyeing process, resulting in hand dermatitis. A pre-existing irritant hand dermatitis may predispose to this. Styling of dyed hair should theoretically not present a problem in view of the reported non-allergenicity of the oxidized dye.

Reactions in temporary tattoos may be delayed for about 2 weeks while sensitization takes place, but the subsequent reaction can be severe and persistent. Erythema multiforme-like and lichenoid eruptions are described, and both post-inflammatory hypopigmentation and hyperpigmentation can be a feature [15–19,29].

Immediate-type hypersensitivity presenting as an urticarial reaction to PPD is also recognized [30,31] and contact anaphylaxis is described [32].

Clinical presentation of clothing dye allergy is described on p. 20.78.

Avoidance. Permanent hair dyes will be clearly marked 'contains phenylenediamines', and that patch testing is advised on each occasion prior to dyeing the hair. Open testing on retroauricular skin, with a 2-day reading, has been confirmed to be an accurate method of identifying sensitized persons [33], but this is rarely done by the individual or the hairdressing salon. Once PPD allergy is diagnosed, the hair should not be permanently dyed. Semi-permanent dyes might be tolerated, but in the region of 25% of PPD allergic subjects are likely to have problems due to cross-sensitivity [2]. An open patch test with these dyes is also advised before use. Other alternatives include henna and colour rinses with temporary (non-PPD related) dyes.

Disperse azo clothing dye avoidance is discussed on p. 20.79.

Cross-sensitivity. Molecules with a similar structure may cross-sensitize with PPD, for example benzocaine, procaine, sulphonamides, diaminodiphenylmethane, *para*-aminobenzoic acid (PABA) UV filters and certain azo dyes, and patients should be counselled about this possibility [2,3].

Patch tests. A significant drop in the frequency of positive allergic reactions was noted when PPD base 1% in petrolatum was changed to PPD dihydrochloride by the allergen suppliers, and relevant positive cases were missed [34]. PPD base is again the preferred standard test allergen. In some individuals close examination of the patch test site is required, as a positive reaction may be obscured by the black colour left by the patch test. Fierce '+++' reactions to PPD are seen on occasions. In those with a recent severe presumed hair dye allergic dermatitis, and particularly those with a temporary tattoo reaction, we would recommend an initial test concentration of 0.5% in petrolatum. Related hair dye chemicals are also usually tested at 1% in petrolatum.

Azo dyes will normally be incorporated into a larger series of allergens for the investigation of textile dermatitis (see p. 20.79). They are also tested at 1% in petrolatum.

UV filters [1–3]

UV filters work by absorbing light chemically or by acting as a physical block. The latter agents are usually based on titanium or zinc oxide, which are not sensitizers. However, some chemical UV filters may be contact allergens, photocontact allergens or both. The main groups of light-absorbing chemicals are PABA and its derivatives, cinnamates and salicylates, which absorb predominantly UVB light; benzophenones, which also absorb some longer wavelength UVA light; and dibenzoylmethanes and camphor derivatives, which tend to absorb the longer wavelength UV light [2,3]. UV filters may be known by many synonyms; the INCI names are used here.

Prevalence. Ordinarily UV filters are not tested in the standard series, and aimed testing is generally the rule. However, many UV filters are included routinely in the photopatch-test series. The pattern of usage of UV filters varies and prevalence figures will reflect this.

Benzophenone 3 (oxybenzone) is the most frequently reported UV filter allergen [3–8]. Benzophenone 10 has also been identified as an allergen and photoallergen but is not commonly used in sunscreen manufacture [3,9].

Isopropyl dibenzoylmethane was a common photosensitizer in the past, and as a result has been withdrawn from the market [8,10]. Butyl methoxydibenzoylmethane is an occasional sensitizer and photosensitizer [3,6,9–12]. Allergy and photoallergy to PABA and derivatives are now less frequent, but these agents may still be found in cosmetics and sunscreens [6,13,14]. Cinnamates are commonly used as UVB filters and both allergy and photoallergy to them are seen occasionally [3–6,10]. A high prevalence of allergy to 4-methylbenzilidene camphor was noted in one survey, but other reports tend to be of single cases [10]. A small numbers of cases of phenylbenzimidazole sulphonic acid allergy and photoallergy have also been seen [3,6,10,15].

Occurrence. These chemicals are not confined to sunscreens. They may be added to cosmetics in small quantities to prevent photodegradation and also as an 'antiageing' agent. UV light absorbers may be added to plastics and spandex. Allergy from this source is unusual but has been reported, most notably from 2-(2-hydroxy-5-methylphenyl)-benzotriazole (Tinuvin P) [16,17].

Clinical features. Allergy and photoallergy from UV filters may coexist or occur separately. Clinical features are discussed under photocontact and also cosmetic allergy (see p. 20.56). It is important to appreciate that other photodermatoses can be complicated by photoallergy to UV filters being used to treat the disorder, and this may easily go unrecognized. The possibility of allergy and photoallergy to UV filters must be considered before individuals are diagnosed as having an idiopathic photodermatosis such as polymorphic light eruption.

Avoidance. Once allergy or photoallergy has been demonstrated, patients should be appraised of the need to avoid sunscreens and cosmetics containing the allergen, which will be identified by its INCI name. They should only use fully ingredient-labelled cosmetics (including hairsprays). In addition, a list of synonyms should be given to the patients as they may encounter sunscreens labelled differently in other countries.

Patch tests. UV filters are generally tested at 10% in petrolatum, although 5% has also been advocated. We believe that benzophenone 4 tested at 10% gives false-positive reactions and 5% may be a better test concentration. Sunscreens and cosmetics containing UV filters should also be patch tested, and if necessary photopatch tested at the same time.

Rubber

Chemistry. Rubber was used by the native South Americans before the voyages of Columbus in 1492. For 200 years, Europeans tried to duplicate the water-resistant shoes, coats and capes but were unsuccessful. In 1791 the first commercial application of rubber began when an English manufacturer patented a method of waterproofing cloth by treating it with a solution of rubber in turpentine. Charles Macintosh, in 1823, established a plant in Glasgow for the manufacture of waterproof cloth and rainproof garments. Initially, the resulting products became brittle in cold weather and tacky and malodorous in summer. In 1839, the American Charles Goodyear discovered that heating rubber with sulphur removed the unfavourable properties, in a process termed vulcanization.

The term 'latex' defines an aqueous dispersion of a rubber. The rubber obtained from latex by drying or coagulation is called latex rubber. Natural latex is derived from the sap of the tree *Hevea brasiliensis*. During the world wars the availability of natural latex was limited and proved a stimulus to the development of various synthetic rubbers.

Rubber dermatitis is usually caused by accelerators, antioxidants and other chemicals used in its manufacture. More than 1000 substances are employed for these purposes [1,2].

Prevalence and incidence. The incidence of sensitivity is of the order of 5–10% of patients tested in most patch-test series [3]. Rubber dermatitis cannot always be suspected from the clinical appearance, and occurs with equal frequency in the two sexes [4]. However, the actual sensitizers differ, depending on exposure, the antioxidants in black rubber more frequently causing problems in men from occupational exposure.

Occurrence. Potential sources of exposure include the following.
1 Rubber industries and revulcanization shops: both non-vulcanized and vulcanized rubber-containing additives are sensitizers; in rubber-tyre factories, much dermatitis is irritant rather than allergic [5–7].
2 Other workplaces [7,8]: rubber gloves [9], other protection for hands and fingers, electric cords, tubes, handles (e.g. on hammers), packings, masks [10], rubber bands, etc.
3 Daily life [5]: shoes, gloves, clothing, condoms and many other articles.

Fig. 20.21 Allergic contact dermatitis to elastic in clothing. (Courtesy of Dr J.D. Wilkinson, Amersham General Hospital, Amersham, UK.)

Clinical features. Rubber sensitivity may be the primary cause of a dermatitis or it may become superimposed on an existing dermatitis, as sometimes occurs following the use of rubber gloves [1] (Fig. 20.20). It is not always obvious [2], and many cases will be missed if patients are not routinely patch tested with a series of the more common rubber chemicals. A positive patch-test reaction to a rubber chemical is usually relevant.

Dermatitis from rubber gloves may be diffuse, but is more often localized to the dorsa of the hands, especially over the knuckles and the wrist, where a sharp proximal margin is often evident. The eyelids and face may also be involved from touching the face while wearing gloves. Dermatitis may be caused by objects touched only briefly during a daily routine. A digitate and patchy dermatitis has occurred in previously sensitized patients following examination with surgeons' gloves [3].

Shoe dermatitis occurs in both adults and children, and in the latter group needs to be differentiated from juvenile plantar dermatosis [4]. Rubber chemicals may occur in almost any part of the shoe, and a rubber adhesive is commonly used to glue parts together. The dermatitis may occur on the dorsum of the foot, soles or toes, usually with sparing of the web spaces and instep. A secondary dermatitis, especially of the hands, is not uncommon [5–7]. The outer soles rarely cause shoe dermatitis. Primary sensitization from all-rubber boots and rubber shoes is common, especially in agricultural workers [8].

Antioxidants related to PPD are used in car tyres and wear-resistant rubber products. They often impart a dark or black colour to the rubber materials vulcanized with them. Not all cases have an occupational origin. Black rubber flexes or cables, hoses, grips and even scuba masks [9] or squash balls may be responsible. The ensuing dermatitis may sometimes be purpuric [10], and an erythema multiforme-like presentation has also been reported [11].

In some cases, the site of dermatitis may provide a clue as, for instance, when the dermatitis is due to a rubber finger-stall used when counting money [12] or rubber bands under a wrist watch [13]. Rubber dermatitis may also occur at the site of contact with rubber in clothing (Fig. 20.21) or dressings, on the face from swimming goggles [14], between the thighs or on the abdomen from hot water bottles, and on the knees from kneeling mats. Genital dermatitis or pruritus vulvae may occur following the use of condoms [15,16] and diaphragms, and may also result from rubber catheters [17], when the dermatitis also spreads down the thighs. An apparent worsening of venous eczema may be related to allergy to rubber in elastic bandaging [18], and such patients are prone to develop a secondary generalized eczema. A generalized dermatitis may occur after sleeping on a rubber mattress or using rubber pillows, or the dermatitis may be predominantly on the side on which the patient sleeps.

Avoidance and prognosis. Although it may be impossible to avoid contact with rubber entirely, many patients remain clear of dermatitis, and others may only have intermittent symptoms if they take simple precautions to avoid contact with rubber material. In many cases, hand eczema improves or clears if patients can be persuaded to change from rubber gloves to cotton-lined vinyl gloves.

Patch tests. Most rubbers contain up to 5% of potentially allergenic additives. Dermatitis from the smoked sheets of rubber used as raw material is rarely reported. The sensitizers in rubber change in accordance with industrial development, technical requirements and market prices. Unless the choice of substances kept for patch testing is constantly supplemented, rubber dermatitis will be missed. A list of potential sensitizers in rubber is shown in Table 20.8.

Most standard series contain rubber chemicals, both mixes and individual chemicals, as a screen for rubber-induced contact hypersensitivity. The mixes of rubber chemicals are useful because they allow allergy to be detected with fewer patch tests [1,2]. In order to avoid patch-test sensitization, the concentration of the individual chemicals must be reduced, and this involves the risk of false-negative reactions. This is especially so for mercaptobenzothiazole (MBT), and therefore MBT and MBT mix are usually both included in most patch-test series [3]. The concentrations of the individual chemicals in these mixes are therefore selected as a compromise. Too high a concentration will carry the risk of active sensitization, whereas too low a concentration of any of the individual ingredients may lead to false-negative reactions and missed sensitivities. PPD derivatives are sensitizing when tested at 2% in petrolatum, and should be tested at 0.25% and 0.1%. Simultaneous sensitivity to PPD and to the PPD derivatives in rubber is uncommon [4]. Carba mix and the diphenylguanidine in the carba mix often produce marginal irritant reactions. Although carba mix has been deleted from the European standard series, the predominant use of carbamates as accelerators in rubber gloves [5] argues for retention of the mix, as in the North American series, rather than relying on a cross-reaction with thiurams to detect the allergy.

Table 20.8 Common sensitizers in rubber.

Mercapto mix
Mercaptobenzothiazole (MBT)
Cyclohexylbenzothiazylsulphenamide (CBS)
Dibenzothiazyldisulphide (MBTS)
Morpholinylmercaptobenzothiazole
Patch-test concentration: 0.5% each = total 2% in petrolatum
Thiuram mix
Tetramethylthiuram disulphide (TMTD)
Tetramethylthiuram monosulphide (TMTM)
Tetraethylthiuram disulphide (TETD)
Dipentamethylenethiuram disulphide (PTD)
Patch-test concentration: 0.25% each = total 1% in petrolatum
Black rubber mix
Phenylcyclohexyl-*p*-phenylenediamine (CPPD)
Phenylisopropyl-*p*-phenylenediamine (IPPD) (identical to isopropylaminodiphenylamine)
Diphenyl-*p*-phenylenediamine (DPPD)
Patch-test concentration: 0.25% of CPPD and DPPD, 0.1% of IPPD = total 0.6% in petrolatum
Carba mix
1,3-Diphenylguanidine (DPG)
bis-(Diethyldithiocarbamato) zinc (ZDC)
bis-(Dibutyldithiocarbamato) zinc (ZBC)
Patch-test concentration: 1% each = total 3% in petrolatum

The mixtures mentioned are commercially available.

Where rubber allergy is suspected, additional testing with the ingredients of the mixes and additional rubber-related allergens may reveal what would otherwise have been a missed contact allergy [6,7]. Cyclohexylthiophthalimide, a common rubber antidegradant, frequently causes reactions but the relevance is often uncertain, particularly where there is no ingredient labelling [8,9]. Other allergens include trimene [10] and dithiodimorpholine [11]. It is also essential to test with a sample of the suspect rubber in case sensitization has occurred to a chemical not present in any standard or rubber series [12]. Delayed-type hypersensitivity reactions to natural rubber latex itself have been reported [13,14].

Synthetic rubbers such as styrene–butadiene, polybutadiene, polychloroprene (neoprene) and polyurethane (spandex) may contain similar accelerators and antioxidants, including thioureas [15]. Elastane (Lycra) does not contain rubber accelerators.

Sensitivity to a certain rubber chemical does not usually indicate any specific source. However, dihydroxydiphenyl is mainly present in dress shields and condoms [16]. Sensitivity to carbamates and thiurams suggests rubber gloves [17], mercapto compounds suggests shoes [18], and the PPD group is mainly associated with black rubber products such as tyres [19].

Clothing [1–6]

Textile fibres may be natural, for example cotton, wool, silk, linen, rubber, or they may be synthetic, for example cellulose derivatives (rayon), polyamides such as nylon, polyesters, acrylics and elastomers [2,4]. Apart from rubber, they rarely sensitize in their own right.

Commoner allergens in clothing include nickel (p. 20.37), chromate (in leather and as a dyeing mordant) (p. 20.42), rubber (p. 20.74), textile dyes, formaldehyde (p. 20.59) and resins.

Disperse dyes are the class of dye most likely to sensitize, particularly as it is not possible to make them completely fast to the fibres [2]. They are principally anthroquinone and azo dyes. Disperse dyes may contain more than one fraction, as well as impurities, all of which can sensitize [7,8]. A mixture of several different dyes may be responsible for the final colour [1]. Fibre-reactive dyes are covalently bound to the fibre and unlikely to cause problems from clothing, but may sensitize those handling the dye powder [9–11]. Clothing dermatitis has also been reported from acid, basic, direct, vat and solvent dyes, as well as coupling agents [1].

Finishes are used on textiles to give 'body' to inexpensive materials, and provide crease-resistant and stain-repellent properties [12]. Urea and melamine formaldehyde resin finishes are now being superseded by others, such as dimethylolalkyl carbamate, dimethylolethylene urea, dihydroxydimethylethylene urea and other similar reactive cyclic urea resins [1,4]. These new resins may be less sensitizing, particularly as they release less formaldehyde and remain relatively fast.

Optical whiteners are frequently added to clothes, and although in the past they were associated with contact dermatitis, there are no recent reports of allergy [2]. Fire retardants in clothing have also been reported to cause sensitivity [13,14].

Incidence and prevalence. Since 1970, textile dermatitis has probably become rarer, mainly due to changed methods of production, although accurate information on the incidence and prevalence of clothing allergy is lacking. In those undergoing patch testing, the frequency of allergy to textile dyes has varied from 1.1 to 5.8% and for resins from 1.2 to 2.3%, either from formaldehyde or the resin or both [6].

Most, but not all, patients with formaldehyde textile resin dermatitis are also sensitive to formaldehyde [15,16]. Between 1950 and 1965, formaldehyde resins used for crease-resistant finishes caused numerous cases of textile dermatitis [17–19]. Recent surveys confirm that the most commonly identified azo disperse dye allergens are Disperse Blue 124 and the very closely related Disperse Blue 106, followed by Disperse Orange 3, Red 1, Yellow 3 and Red 17 [20–22]. In particular, Disperse Blue dyes 106 and 124 have been reported as causing frequent problems in Canada, especially from blue/black polyester or acetate garment liners [21]. The most frequently reported sensitizing anthroquinone dyes are Disperse Red 11, Blue 3 and Blue 35 [3,20].

Occurrence [1]. Disperse dyes are used to colour artificial fibres such as polyester, acetate, acrylic and nylon. Both azo and anthraquinone dyes may cause dermatitis from modern artificial fibres, and non-disperse azo dyes from natural fibres [23]. Rarely, other chemicals such as Naphthol AS (a coupling agent for cotton dyeing) may sensitize [24]. Textile resins are added to cotton and mixed cotton/polyester fibres as well as rayon and crease-resistant linen.

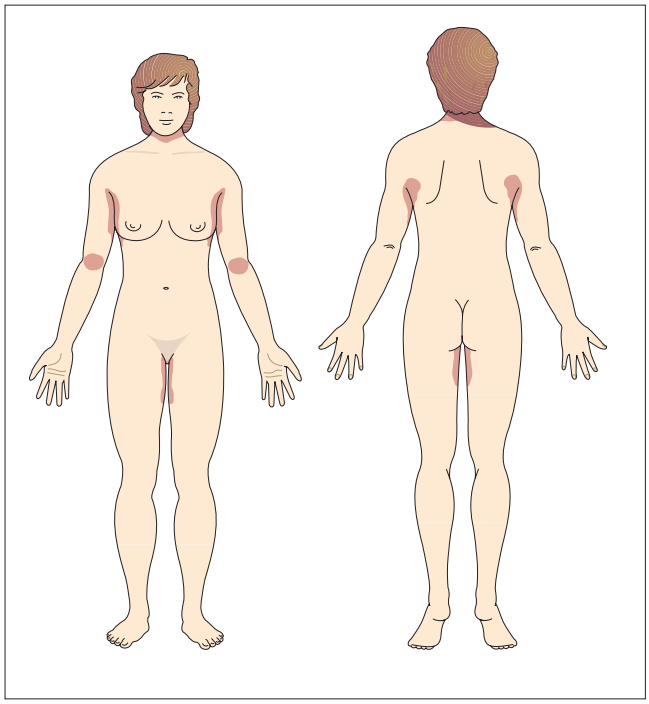

Fig. 20.22 Pattern of textile dermatitis.

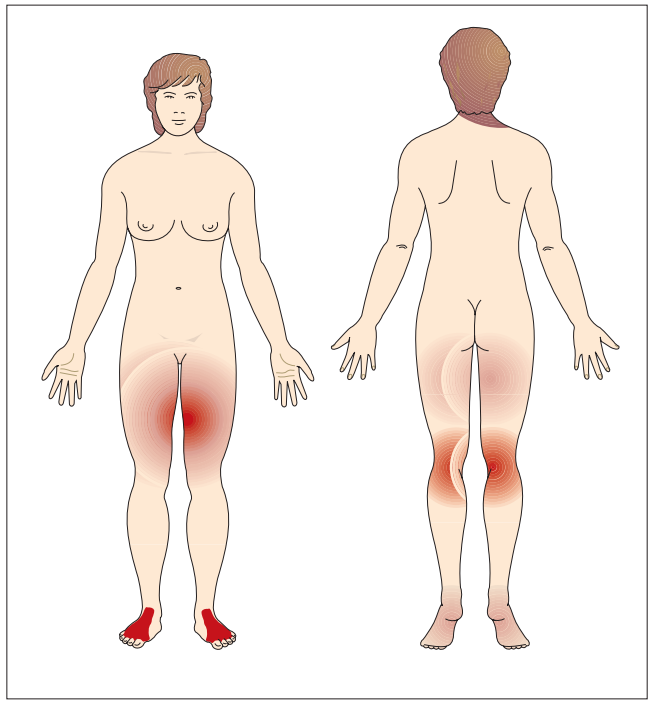

Fig. 20.24 Pattern of dermatitis from nylon stockings.

Fig. 20.23 Axillary dermatitis (sparing the axillary vault). The characteristic pattern of eczema seen in patients allergic to textile dyes and finishes. (Courtesy of Dr J.D. Wilkinson, Amersham General Hospital, Amersham, UK.)

Clinical features. The distribution of contact dermatitis, in areas of sweating and friction, is the same for dyes and finishes (Fig. 20.22). The eruption typically starts in the axillae, sparing the hairy part of the vault, and forms a crescentic patch on the anterior chest wall sharply limited by the underwear (Fig. 20.23). The anterior and posterior folds are also affected. The dermatitis is often sheeted, and the inner posterior thighs, popliteal fossae and lower leg may be involved when trousers or tights (panty hose) are the responsible garments. Allergy to dyes in socks, stockings and tights often starts on the dorsa of the feet, where they are occluded by footwear. The typical pattern for allergy to tights and stockings is shown in Fig. 20.24. Long sleeves cause eruptions in the elbow flexures, and collars provoke a rash around the neck. Later in the course of the disease, the chest and upper back may be involved, sparing areas protected by shoulder straps and underwear. In the flexures and round the neck the lesions are diffuse and oedematous; on the shoulders and chest they are usually papular. Papular dermatitis may cover the whole body, and eyelid dermatitis may rarely be a feature.

In the early 1970s permanent-press resins were also the source of an outbreak of follicular dermatitis due to a range of coloured Canadian perma-press sheets [12,25,26]. Patients developed a widespread itchy, follicular rash especially affecting the arms and legs, but also with eczema of the face and ears due to contact with pillowcases. Dyes have also been described as sensitizers in perma-press bed linen [27].

Some fabrics provoke a purpuric, sometimes lichenoid dermatitis in areas of contact, as seen with uniforms in the Second World War (khaki dermatitis) [28]. Textile dyes and resins will occasionally cause purpuric eruptions associated with contact allergy [29–32]. In the early 1970s a pigmented dermatitis was described that was caused by allergy to optical whiteners in detergents. It started on the inner aspects of the upper arms, from where it spread to the trunk, with indistinct coalescing macules as the major lesions [33]. In some cases, the dermatitis left persistent hyperpigmentation.

Patterns of allergy from nickel, chromate (in leather) and rubber are described in the sections discussing these allergens.

Avoidance [2,3]. Patients sensitive to formaldehyde or one of the formaldehyde resins should be advised to avoid treated fabrics, for example drip-dry, crease-resistant or durable-press cotton, cotton-mix and rayon clothes. Satisfactory alternatives include wool, silk and 100% nylon, polyester or acrylic fabric, as these rarely contain significant amounts of formaldehyde or formaldehyde resins. The washing of new clothes at least twice before wearing may also be useful as this will help to remove free formaldehyde [12].

A precise knowledge of the dye responsible for an individual's allergy is not helpful as cross-sensitivity is common and the finished colour is commonly a mix of several dyes. Strongly coloured synthetic clothing should be avoided, but lightly coloured garments may sometimes be tolerated. Pure natural fibres, such as cotton, wool, linen and silk of any colour, can generally be worn.

Patients with disperse dye stocking dermatitis can buy undyed nylon stockings and dye them by soaking in a potassium permanganate solution (0.3–0.6%) for 30–60 min. Stockings and tights (panty hose) without azo dyes may be commercially available, but manufacturers have to be contacted directly. Grey stockings and tights do not usually contain Disperse Yellow 3 or Orange 3. Lycra products are normally dyed with acid dyes rather than azo dyes.

The wearing of undergarments may protect the skin from allergy to outer clothing, although there is still the possibility that sweating could leach out allergens.

Patch tests. Patch testing with the suspected clothing can be undertaken, although there is a high risk of obtaining a false-negative reaction. Soaking 1 cm^2 of the fabric in water for 10 min before testing might increase the return, and extraction techniques have also been suggested [2,34,35].

Formaldehyde is a standard-series allergen. A PPD-positive patch test may alert one to clothing dye allergy, but it is an inadequate screen [3,21,23]. Standard-series screening with four textile disperse dye allergens has been advocated, and the possibility of using a textile dye mix explored, but further data are required [3,36–38]. The commercial allergen suppliers have developed screening series of clothing allergens and these will help detect most cases of textile allergy.

Shoes [1–4]

The commoner identified allergens in shoes are rubber chemicals, chromate (in leather), nickel in buckles, and *p*-tertiary-butylphenol formaldehyde resin (PTBPFR) [4]. However, many others have been described, including vegetable tanning agents, dyes, colophony, leather preservatives and polyurethane components [1].

A typical shoe will be formed from an upper, a sole, an insole, and heel and toe counters to stiffen the shoe and give it shape. Adhesives may be required throughout the shoe.

Uppers tend to be leather, rubber or synthetic material. Leather is tanned, usually with chromate, but other tanning agents, including vegetable tans, formaldehyde and glutaraldehyde, may be used [1–3]. Formaldehyde is associated with the tanning of white or water-resistant leather and is tightly bound, making sensitization less likely [2]. After tanning, the leather may be oiled, dyed and finished. Biocides such as 2-*n*-octyl-4-isothiazolin-3-one may be added to the oils and finishes [3,5]. Uppers may be made from, or be lined with, dyed fabric. Polyurethane, rubber and neoprene foams are used in the uppers, particularly of sports footwear [1]. Neoprene is a synthetic rubber to which phenolic resins, most notably PTBPFR, thioureas, carbamates, and other accelerators and additives, may be added [1,2].

Shoe soles are made from similar materials and more solid forms of rubber. Insoles can also be made of a similar range of materials. Fibreboard is a composite of fibres, usually paper but occasionally wood or leather in a glue matrix, which may contain biocides [1]. This material is used for insoles.

Counters may be made from many different potentially allergenic materials, including natural rubber, formaldehyde resins, biocides and pine oil [1].

The main adhesives are hot melt, urethane, neoprene and natural rubber. Hot melt adhesives do not tend to cause allergy but the others may, particularly rubber accelerators and PTBPFR. Additives include isocyanates, epoxy resins and biocides. Tackifiers may contain formaldehyde resins and colophony [1].

Prevalence. The prevalence of shoe allergy has ranged between 3 and 11% in patients referred for routine patch testing [1,6–8]. A wide age range is seen, with young children prominently represented in many studies [9–14]. In one study on 55 patients the breakdown of the most frequent positive reactions was as follows: rubber 43.1%, chromate 23.6%, PTBPFR 20.0%, colophony 9.0% and PPD 3.6%. However, a further 14.5% reacted to pieces of their shoes but not to the shoe allergens tested. Most patients were noted to have hyperhidrosis and 43% were atopic. Follow-up (average 3 years) of 48 patients after they had employed a number of strategies to avoid contact with the allergens responsible for their dermatitis revealed that 87.5% were clear or significantly better, 10% the same and only one person was worse [4].

Clinical features. Sweating causes allergens in shoes to leach out and migrate, and as a result of this the pattern of dermatitis is often not distinctive. It may be patchy or superimposed on a pre-existing constitutional eczema. Nevertheless, in many instances the distribution will reflect whether the sensitizer is present in the upper or sole of the shoe.

Dermatitis from the upper commonly starts over the dorsal surface of the big toes and spreads to the dorsa of the feet and the other toes. Outbreaks of dermatitis from tanning agents (chromate and vegetable) and adhesives have often followed this pattern [15–17]. The interdigital spaces are normally spared. The heels may be involved, but less frequently than the toes. On the heels, patches of dermatitis may correspond to the heel-cap, and on the dorsum of the foot they may correspond to the tongue of the shoe. Adhesives and rubber components may cause localized areas of dermatitis limited to the toecap [11]. Nickel allergy from shoe buckles and eyelets may cause a localized dermatitis on the adjacent skin. Indian sandal dermatitis has a characteristic pattern, is often severe, and affects mainly the first toe web and adjacent toes and the dorsum of the foot [18].

Involvement of the sole usually affects only the weight-bearing areas—the instep is frequently spared. In sports shoes, the sole is usually moulded to fit into the instep and the dermatitis may affect the whole sole [19]. Sometimes, only the forefoot is involved [2] (Fig. 20.25), and in children the condition must be differentiated from juvenile plantar dermatosis by patch testing.

Surprisingly, not all cases are bilateral [6,10], but the great majority are. Patients with shoe dermatitis often have evidence of dermatitis elsewhere, especially on the hands [9].

Boots produce a pattern similar to shoe dermatitis, sometimes with an additional eruption on the calves. An eczematous and purpuric allergic contact dermatitis has been reported in a patient sensitive to thiourea and IPPD [20,21].

Allergy to socks and stockings, agents such as perfumed sprays, talcs and antifungal powders used in shoes, and medicaments applied to the skin may simulate footwear dermatitis [22,23].

Avoidance. Individuals who are allergic to leather tanning agents and additives can be advised to wear synthetic fabric or rubber footwear. Some specialized outlets sell 'vegetarian' shoes that should not be leather.

Fig. 20.25 Forefoot dermatitis from shoe allergy.

However, with other allergens avoidance is often difficult. Manufacturers and distributors will not generally guarantee their shoes are free of rubber chemicals and PTBPFR in adhesives, and may know even less about other sensitizers. Patients allergic to rubber, PTBPFR and colophony should consider all-leather stitched footwear with no insoles, or injection-moulded plastic shoes, moccasins or wooden shoes. Certain manufacturers will produce bespoke shoes free of the allergen(s) but these are expensive. Sometimes, orthotists advising hospital orthopaedic departments are helpful in making special shoes.

Those allergic to dyes will need to avoid dyed fabric and nylon-lined footwear, as well as coloured nylon socks and stockings. Old socks may act as a reservoir of allergen and should be discarded with the incriminated shoes, medicaments, etc. [24].

Hyperhidrosis is common in shoe dermatitis, and the dermatitis may be helped by treating the sweating with iontophoresis, or by other means, and by wearing cotton socks to absorb the sweat [2].

Patch tests. Many of the commoner shoe allergens are found in the standard series, including dichromate, certain rubber accelerators and antioxidants, PTBPFR, colophony and nickel. In addition, a special shoe series should be used, and Chemotechnique have such a series of commercially available allergens. More extensive series have been advocated as a screen, but even these may miss some shoe allergens, including biocides, vegetable tans, hydroquinone and polyurethane agents [1].

Investigation of possible shoe allergy can be frustrating, as even with special screening series 10–20% of shoe allergies have only been identified by testing with pieces of the shoe itself [2]. Ideally, pieces for patch testing should be taken from the parts of the shoe in contact with the dermatitic area. They should be thin and 1 cm^2 or larger [1]. Some have suggested testing the pieces under a special large Finn chamber, whereas others recommend occlusive tape [1,2]. Further suggestions have been to soak the pieces in water for 15 min before they are applied, and to leave the test pieces in place for 4–5 days [2,25]. False-positive reactions may be seen from pressure, particularly around the edge, and false-negative reactions are common. Furthermore, positive reactions may develop as a result of contamination by a non-shoe allergen, for example a medicament or perfume to which the patient is allergic [23].

Resins and plastics

Resins are intermediate synthetic substances that are polymerized often using a hardener, plus other additives to produce a plastic end-product. Many low-molecular-weight materials including the monomers and oligomers used in resins are allergenic, but a fully polymerized resin should not be sensitizing. Many additives, fillers and hardeners also have allergenic potential. The systems most commonly associated with contact allergy include epoxy, acrylic and formaldehyde resins.

Epoxy resins [1,2]

In terms of usage, 75–90% of epoxy resins comprise diglycidyl ether of bisphenol A (DGEBA) [2]. They are reaction products of epichlorhydrin and bisphenol A. The monomer (molecular weight 340) is the main sensitizer, and oligomers with molecular weights above 900 do not sensitize [3,4]. Higher-molecular-weight resins may contain small amounts of the oligomers or monomer [5] but rarely sufficient for induction of sensitivity. However, they can elicit clinical and patch-test reactions in those already sensitized.

Non-DGEBA epoxy resins, such as cycloaliphatic epoxy resin, diglycidyl ether of bisphenol F (used in phenol epoxy novolac systems) and triglycidyl isocyanurate (TGIC), are also reported as sensitizers [6–12]. Sometimes, 'reactive diluents' in the resins used to reduce viscosity are responsible for their sensitizing capacity [13]. These diluents are usually glycidyl ethers or, occasionally, glycidyl esters and are thought to be present in over 50% of epoxy resin products [1,14]. Bisphenol A and epichlorhydrin themselves are seldom responsible for allergy from epoxy resins [15–17].

Resins containing latent hardeners are polymerized or cured by heat alone. Two-part resins require hardeners to be added immediately prior to their application. Some of these are cold-curing and some require heat to complete the polymerization. Hardeners are of many types: aliphatic amines, cycloaliphatic amines, aromatic amines, polyaminoamides, amidopolyamines, anhydrides, isocyanates, polyphenols and adducts. Formaldehyde resins may be used as hardeners [1,2].

The commonest sensitizers among the hardeners are amines, for example the aliphatic amines ethylenediamine, diethylenetetramine, triethylenetetramine, dipropylenetriamine and dimethylaminopropylamine [1]. Triethylenetetramine is a particularly strong sensitizer [18]. There are also sensitizing cycloaliphatic amines (e.g. isophoronediamine) and aromatic amines, such as diaminodiphenylmethane (methylene dianiline) and 2,4,6-tris-(dimethylaminomethyl)phenol [18–21].

Hardeners of the polyaminoamide type are much less likely to sensitize, and so are anhydrides (e.g. phthalic anhydride). They are used for thermal hardening. Adducts are non-sensitizing, providing they do not contain free amine.

Additives include colours, fillers, UV light absorbers, flame retardants and plasticizers.

Incidence and prevalence. Epoxy resin of the bisphenol A type is a standard allergen. However, figures for the prevalence of allergy in patch-tested patients with dermatitis will reflect the degree of occupational interest of a particular clinic, and also the local industry. Series of relatively unselected patch-tested patients have reported rates of 0.4–3% positive reactions, with a male preponderance [1]. However, higher rates (11.7–12.5%) are recorded for occupational referrals. Annually, approximately 1% of exposed workers are believed to develop an epoxy resin allergy [22,23].

Allergy to other components of epoxy systems is commonly concomitant with resin sensitization. Detailed analysis of 182 cases in Finland showed that 80% were allergic to DGEBA epoxy resins, 23% to polyamine hardeners, 16% to reactive diluents and 9% to non-DGEBA epoxy resins [1,24].

A high incidence of allergy among exposed individuals can occur in factory outbreaks, for example 56% in an aircraft construction factory, 45% in marble workers, 27% in ski-factory workers and 21% in paint factory workers [6,25–27].

Occurrence. The epoxy resins are among the most sensitizing substances that have been introduced to industrial work in recent years. Coatings, including paints, varnishes and metals account for roughly 45% of all epoxy resin use [2]. They are widely used in the construction industry, in cement to make it waterproof, and in floorings, grouts and filling materials, including those for marble and window frames. They are commonly used as binders and coatings for fibreglass and carbon fibre, for example in car body repairs and aircraft construction [1,2]. In the electronics industry they are used for insulation and in printed-circuit boards. They are efficient glues for metals, rubber, polyester resins and ceramics. Cardiac pacemakers [28] and hypodermic needles [29,30] may contain them. Dental personnel sensitized by epoxy acrylates in filling materials often also react to epoxy resin [14]. In the laboratory they have been found as sensitizers in microscopy immersion oil [31,32].

High-molecular-weight resins, which may contain residual low-molecular-weight resin [5], are used for

coating metal or wood [33]. Occasionally, uncured epoxy resins are used as stabilizers and plasticizers in, for example, polyvinyl chloride plastic. Thus, contact dermatitis may be elicited in consumers [34,35] as well as occupationally.

Non-DGEBA epoxy resins have found increasing use in electron microscopy, and in the aerospace and electronics industries [36]. TGIC is used, mainly as a hardener, in thermosetting one-component polyester powder paints [12,37–39].

Clinical features. Dermatitis is predominantly occupational. It usually affects the hands and arms (see Fig. 20.8), and often also the face and eyelids [40]. Facial and periorbital involvement may be indicators of associated or isolated allergy to the more volatile epoxy diluents and hardeners [40,41]. Partially cured epoxy resin dusts from sanding and drilling may induce dermatitis with a similar distribution.

Severe oedematous and weeping eruptions are not uncommon and widespread generalized eruptions can develop if exposure continues. Erythema multiforme-like reactions have also been described [42]. Other body sites, especially the genitals, may be affected following hand contact. Hand and fingertip dermatitis was a feature of window-frame restorers' dermatitis [21]. Localized dermatitis can sometimes be attributed to traces of free epoxy monomer found in a wide range of products, such as twist-off caps, coated door knobs, tool handles [34], microscopy immersion oil [31,32], stoma bags [35], clothing labels [43], portable infusion pumps [44], spectacle frames, plastic tubing in medical devices and gloves. A flare-up of hand eczema has been reported from an implanted epoxy resin-containing needle [29]. Children have been sensitized by a knee-patch adhesive in jeans [45].

Avoidance. Redeployment away from contact with epoxy resin is usually required for occupational dermatitis. Use of epoxy (usually two-part) adhesives and fillers in domestic and spare-time activities (e.g. car body repairs) should be avoided. Identification of epoxy chemicals in suspect materials by chromatography techniques may be helpful in confirming a suspected source of epoxy resin [46,47].

Prevention. Prevention of epoxy dermatitis is important, and includes education, instructions and warning notices for the workforce, stressing the need for 'good housekeeping'. High-molecular-weight epoxy resins and diluents are less sensitizing and, where possible and appropriate, are to be preferred. Aliphatic and aromatic amines may be replaced by polyaminoamides or amine-epoxy adducts [2]. If feasible, automation or a 'two in one' mixing package [48] is advised or, if not, mixing should be done in disposable containers.

Protective impermeable, preferably disposable, clothing and gloves should be worn [1]. Epoxy resin will nevertheless penetrate plastic and rubber gloves [49]. Heavy-duty vinyl gloves or multilayered gloves of folio type (4H-Glove; Safety 4, Denmark) provide the best protection [49,50].

Patch tests. Epoxy resin of the bisphenol A type is included in the standard series at 1% in petrolatum. Other components of epoxy resin systems are not, apart from ethylenediamine. Extra patch-test reagents, which incorporate the commoner amine hardeners and reactive diluents, are available from the commercial allergen suppliers, although these are not all-inclusive. Allergy to non-DGEBA epoxy resins and other components may still be missed unless the worker's own materials are tested [40].

A rough guide for patch-test concentrations (all in petrolatum) is 0.5% for non-DGEBA epoxy resins, 0.25% for reactive diluents and 1% for most polyamine hardeners, but a literature search should also be undertaken, and lower concentrations considered initially if in doubt.

Acrylic resins [1]

Acrylic resins are formed from acrylic and methacrylic acids and their esters, and cyanoacrylic acid and its esters. These resins show a wide range of sensitizing potential [2] and a complex cross-reaction pattern [3,4]. Multifunctional acrylates [1,5–7], epoxy acrylates [8], acrylamides [9], acrylonitrile [10] and acrylated polyester [11] are other sensitizers. Polymerization may be induced by heat, by adding initiators, accelerators and catalysts, by tiny amounts of water, by anaerobic conditions and by exposure to UV and visible light or electron beams depending on the nature and function of the acrylate [1]. Sometimes, additives such as dimethyl-*p*-toluidine [12], benzoyl peroxide, hydroquinone [13], *p*-methoxyphenol [13], pyrogallol, resorcinol or pentaerythritol tetrakis 3-mercaptopropionate [9] may elicit contact dermatitis.

Prevalence. Acrylate allergy is not routinely sought and levels of allergy will reflect the referral pattern to a particular clinic. A recent UK study examined the records of approximately 14 000 unselected patients and identified 440 who had been tested for possible (meth)acrylate allergy: 67 had one or more positive reactions; 47 cases were occupational, with dental personnel and printers being the most frequent, followed by gas workers and gearbox fitters who were using sealants, and beauty therapists; and 16 cases were sensitized by wearing acrylic nail cosmetics [14]. Most other series have concentrated on occupational exposure. Dental personnel and printers are confirmed as occupational groups particularly at risk of sensitization [6,9,15–19].

Occurrence [1]. Monomeric acrylates and methacrylates may be used to produce transparent plastics, (e.g. Perspex), dentures, hearing aids, limb prostheses, spectacle frames, nail cosmetics and bone cement for orthopaedic surgery. Other commoner exposures include coatings, paints, inks and adhesives (including those for stick-on nails). UV-cured monomers are also encountered in coatings, printing plates, printing inks and dentistry.

Multifunctional acrylates, which have at least two reactive acrylic groupings, are also used in UV-cured resins, as well as printed circuit boards, artificial nails, adhesives, dental materials and anaerobic sealants used in screw-locks and gas pipes. Epoxy acrylates are used in dental restorative materials. Acrylamide and derivatives have sensitized in printing plates and paint manufacture [9].

Cyanoacrylates are known as 'superglues' and are used extensively to bond metal, glass, rubber, plastics and

textiles. They are also used by surgeons to bind tissues and seal wounds, and by dermatologists to treat painful fissures of the hands and feet. Sensitization to cyanoacrylates is rare, as a result of almost immediate polymerization [20], but it has been reported [21–23].

Clinical features. The commonest sites of occupational allergy are the fingertips and hands (see Fig. 20.2), but the face, arms and eyelids may also be involved. Workers with fingertip dermatitis should always be asked about contact with screwlocks and glues, as this is a typical distribution of allergic dermatitis from this source [24]. A similar distribution may be seen in dentists and dental technicians [25–27]. Localized dermatitis is seen from limb prostheses [28] and from the use of diathermy plates during surgery [29,30].

Dermatitis from artificial nails may be associated with painful onycholysis, nail dystrophy, periungual dermatitis, paraesthesiae, and an ectopic dermatitis of the face and neck and sometimes other parts of the body [31–34]. Paraesthesiae can persist for some months after patients stop wearing the nails [35,36].

Stomatitis has been blamed on incompletely cured acrylate in newly made or repaired dentures [37,38], and gingivo-stomatitis on acrylates in a temporary crown [39].

Avoidance. Once identified, avoidance should be possible by removal of the cause, redeployment, adequate protection or altered work practice. Acrylates penetrate latex and vinyl gloves [40–42].

The 4H multilayer folio glove (Safety 4, Denmark) [43] is the best protection, but may be impractical for some activities. In those with finger problems (especially dentists), it may be possible to remove the 4H glove fingers and wear these under another more pliable glove, although ideally dental personnel should use a no-touch technique [44]. Double gloving, polyethylene gloves and nitrile gloves are possible, but potentially less effective, alternatives.

Education, instructions on handling, printed warning notices and 'good housekeeping' are important preventative measures.

Patch tests. Chemotechnique allergens include three (meth)acrylate series: adhesive, nail and printing. In general, methacrylated monomers are tested at 2% in petrolatum and acrylated monomers at 0.1% in petrolatum. The lower 0.1% concentrations have reduced the incidence of the previously noted problem of active sensitization [45]. Cyanoacrylates are tested at 10% in petrolatum.

Formaldehyde resins [1–3]

'Phenoplastics' are condensation products of formaldehyde and phenolic compounds, for example phenol, cresol, *p*-tertiary-butylphenol and resorcinol [1,2]. There are two main types of phenol formaldehyde resin (PFR): resol (phenol reacted with excess formaldehyde in alkaline conditions) and novolac (formaldehyde reacted with excess phenol in acid conditions) [1–3]. Fourteen different sensitizers have been isolated from PFRs [4]. The two types of PFR do not necessarily cross-sensitize and neither of them seems to cross-sensitize to any significant degree with PTBPFR [5,6].

'Amino-plastics' [1] are condensation products of formaldehyde or hexamethylenetetramine, and carbamide (= urea), thiourea, melamine, sulphonamide or anilide. They are often white or transparent. Formaldehyde, hexamethylenetetramine or low-molecular-weight condensation products can sensitize separately or simultaneously. Usually, sensitization occurs when the resins are handled in 'half-condensed' form.

Coexistent formaldehyde sensitivity is rare with PTBPFR and PFRs, but is quite common with urea and melamine formaldehyde resins [5–8].

Prevalence. Apart from allergy associated with clothing (p. 20.77), shoes (p. 20.80) and nail varnish (p. 20.56), formaldehyde resin allergy is uncommon. Many cases of PFR allergy are sporadic. Laminate manufacturers in Sweden were found to have a high frequency of allergy [9]. In a recent review, 17 cases of PFR allergy were seen in one clinic over a 15-year period. Commoner occupational associations were friction material (e.g. brake linings) production, work with fibreglass and contact with foundry sand [5]. Of routinely patch-tested patients, 0.3–2.6% are allergic to PTBPFR [10–12]. In many instances it is difficult to find a relevance for a positive patch test [13].

Occurrence. PFRs have electrical resistance and binding properties, resulting in their widespread use in electrical appliances, glues, laminated floorboards, plywood, fibreglass (including insulation), brake linings, clutch facings, grinding wheels, foundry sand moulds, abrasive cloths and papers, plastic moulds, telephones and steering wheels [1,2]. Finished plastics are often brown or black and of the Bakelite type. Cashew nut shell oil has been used to modify the PFRs incorporated into brake linings, and this has sensitized [14].

PTBPFR is used as an adhesive and is found in sealants and neoprene glues. Contact may occur directly following its use as a glue, particularly in shoemakers and cobblers [8,15,16], or when it is used to attach artificial nails [17], and indirectly from its use in shoes, watch straps and limb prostheses [13,18–20]. Other sources include furniture and upholstery glue [1] and marking pen ink [21].

Amino formaldehyde resins occur in textiles (p. 20.77) and in waterproof paper. They are also used for finishing parquet floors, for glueing wood, and in orthopaedic casts [7,22,23]. Tosylamide formaldehyde resin is extensively used in nail varnish. Formaldehyde, continuously liberated from formaldehyde resins in floors and walls, may elicit contact dermatitis in very sensitive people (p. 20.59).

Clinical features. Dermatitis from formaldehyde resins in clothing, shoes and nail varnish is discussed on pp. 20.77, 20.80 and 20.57, respectively. In most other cases of PTBPFR allergy, dermatitis is localized under leather watchstraps and limb prostheses, although the hands may be affected by contact with glues in the working and domestic environments.

Most cases of PFR allergy we have seen have had occupational dermatitis of the hands, with occasional manually transmitted spread to the face and genitals.

Patch tests. PTBPFR patch testing is discussed on p. 20.81 (shoes), amine formaldehyde resin on p. 20.79 (clothing) and tosylamide formaldehyde resin on p. 20.58 (cosmetics). PFRs are variable in composition and allergenicity [3]. There are a number of commercially available allergens: PFR-2 1% in petrolatum and monomethylol phenol 1% in petrolatum from Chemotechnique, and a novolac and resol resin each at 5% in petrolatum from TROLAB (Hermal). PFR-2 is the most successful in identification of allergic subjects [5,6]. However, testing with the patient's own resin at 1% and 5% in petrolatum, followed by testing controls if positive, is probably the most reliable method.

Other plastics

Other plastics are rarely the cause of allergic contact dermatitis outside industry. Other resin systems, most notably unsaturated polyesters and their hardeners, and isocyanates in polyurethanes may sensitize [1–3]. The literature contains many case reports of allergens traced to specific products, for example spectacle frames. Additives in cellulose acetate spectacle frames have caused dermatitis [4–7]. Similar chemicals may be responsible for the sporadic cases of dermatitis from hearing-aids, ballpoint pens and other plastic items. Other plastic additives such as plasticizers, antioxidants, UV light absorbers, initiators, cross-linking agents, flame retardants and pigments may sometimes sensitize during the manufacturing process or during use [1].

Plants [1–5]

Plant life is exceedingly diverse, with much geographical and seasonal variation, and consequently the range of reported allergens is huge, with considerable differences worldwide in the incidence and prevalence of allergy. The reader is therefore referred to the standard texts on this subject for in-depth analysis. We propose to concentrate only on those plant families frequently associated with contact allergy.

Incidence and prevalence. Accurate statistics for prevalence and incidence of plant allergy as a whole are not available. These parameters vary from country to country and depend on the local flora and the population's way of life. Numerous investigations have shown that 25–60% of North Americans are sensitive to poison ivy and other members of the Anacardiaceae family [6]. Occupational dermatitis to plants is common in gardeners, florists and undertakers [7,8], despite occasional grossly misleading impressions of its frequency—only two cases of tulip dermatitis could be traced in the files of the Leiden Hospital in the Netherlands [9] as it was an accepted occurrence and was therefore not reported.

It has been estimated that 5–10% of all cases of contact allergy seen in European dermatology clinics are caused by plants or their products [4]. Primin, found in *Primula obconica*, is recommended as a standard-series allergen in

Europe. Of 3075 patients patch tested in Denmark, positive reactions were recorded in 1.8%, about 95% of the positive reactors being female [10]; in the UK, positive reactions were recorded in 1% of 3462 patients routinely tested [11].

Sesquiterpene lactone mix in the standard series is used to identify Compositae allergy [12]. A multicentre European study showed varying frequencies of allergy in patch-tested patients, ranging from 0.1 to 2.7% according to the centre, with clinical relevance found in approximately three-quarters of cases [13]. In a large UK review of 7420 patients, 1.8% had positive reactions [14]. However, it has been suggested that the sesquiterpene lactone mix might only detect about one-third of those allergic to Compositae [15].

Anacardiaceae

Plants from this family have caused more contact allergy than all other plants combined [1]. Much of this sensitization relates to poison ivy, sumac and oak, which are species of *Toxicodendron* found extensively in North America. According to one source more than half the population of the USA are sensitive to poison ivy and its relatives [6]. The plants are generally found outdoors and recognized by their three-leafed configuration. Their diverse morphology and various habitats have been described by Guin *et al*. [16,17].

The main allergens found in the oleoresin (or urushiol) are derivatives of catechol, particularly pentadecylcatechols, phenol, resorcinol and salicylic acid [4]. Cross-reactions occur with cashew nut oil, which may be used industrially in resins, mucilages, printer's inks and electrical insulation [5]. Haitian voodoo dolls and swizzle sticks made from cashew nut shells have also sensitized [5]. Further cross-sensitivity is found with mangoes, gingko tree fruit, indelible laundry marking ink from the marking nut tree in India, furniture lacquer from the Japanese lacquer tree, *Lithraea* trees in South America, and plants and trees from the genus *Grevillea* found in Australia [4,5,18–22]. Localized outbreaks of dermatitis from contact with the Japanese lacquer tree have occurred in the UK [23,24].

Clinical features [5]. *Toxicodendron* spp. dermatitis occurs after contact with the sap of the plant. Classically the rash is streaky, with erythema, papules and vesiculo-bullous lesions on exposed sites. The hardened sap may leave a black spot on the skin in the areas of dermatitis and this may be helpful diagnostically [25]. Distant spread is common, particularly facial and genital involvement from contaminated hands. More profound erythema multiforme-like, exanthematous and urticarial eruptions, and even renal damage, may occur from systemic absorption [26]. Stomatitis and proctitis have occurred after chewing the leaves, and with hyposensitization [26]. Contamination of clothing, animals, garden tools, firewood, fishing rods and golf clubs may also act as sources of contact [5].

Phytophotodermatitis (Chapter 24) and *Primula* allergy have to be considered in the differential diagnosis.

Compositae

There are over 25 000 species of Compositae found throughout the world and more than 200 have been reported to cause allergic contact dermatitis [27]. They may be decorative plants (e.g. chrysanthemums, dahlias, sunflowers), weeds (e.g. ragweed, dandelion, tansy, marsh elder, feverfew, chamomile, yarrow, arnica, *Parthenium*) or foods (e.g. lettuce, endive, artichoke) [27].

The allergens are sesquiterpene lactones and more than 1350 have been described, including dehydrocostus lactone, alantolactone, costunolide and parthenolide [4,5,12,28]. In lettuce and chicory, lactucin and lactucopicrin have also been identified as sensitizers [29,30].

As might be expected, there is considerable but variable cross-reactivity among Compositae plants [31]. Cross-sensitivity with *Frullania* liverworts has been described [32–34]. Cross-sensitivity has also occurred with members of other plant families, most notably Lauraceae and Magnoliaceae [34–36].

Clinical features [37]. Six patterns of dermatitis are described, which are generally worse during the summer months in temperate climates.

1 *Pseudophotodermatitis*. Exposed sites are involved, including both eyelids, and photoprotected areas under the chin and behind the ears. In hot regions, during summer months, dry dead plant material contributes to the airborne pattern of dermatitis. In the USA many Compositae weeds, including ragweed (*Ambrosia* spp.), induce this pattern of dermatitis, almost exclusively in males [5,37]. A similar pattern is seen in Europe from Compositae flowers and weeds [28,38,39], in India from *Parthenium hysterophorus* (see below), and in Australia where it is known as bush dermatitis [40]. Chronic cases may produce a marked thickening of the facial skin—a leonine facies. Photosensitivity quite commonly coexists with Compositae allergy [41] (Fig. 20.26). In one UK study, 22% of the contact-allergic patients were also photosensitive [14]. True photoallergy to Compositae is, however, generally not a feature.

2 *Atopic eczema-like*. Compositae allergy may mimic late-onset atopic eczema, with a flexural accentuation of involvement, which may include the groins and genital area [42].

3 *Erythrodermatous exfoliative*. This pattern is classically seen from the weed *Parthenium hysterophorus*, which was

Fig. 20.26 Photosensitive eczema in a patient also allergic to Compositae (sesquiterpene lactones). A similar pattern may be seen in woodcutters sensitive to lichens, and in others with photosensitive eczema including photocontact allergy. (Courtesy of Dr J.D. Wilkinson, Amersham General Hospital, Amersham, UK.)

Fig. 20.27 Haemorrhagic blisters on the palm from *Primula* allergy.

transported to India in contaminated seed wheat [43]. Unfortunately, the weed has spread over much of the country, including urban areas [44]. It has become markedly allergenic in these environmental conditions, which also enhance the spread of dry plant dust and pollen. There is increased opportunity for skin exposure because many of the indigenous male population wear relatively scanty clothing. Severe incapacity and even fatalities have resulted from *Parthenium* dermatitis.

4 *Hand eczema* [12]. This pattern is seen particularly in gardeners after contact with weeds. A palmar distribution often predominates. Dermatitis of the hands is also associated with handling lettuce [45].

5 *Localized dermatitis*. Dermatitis may be confined to one or more localized areas [37], although this pattern is unusual in our experience.

6 *Oral*. Oral swelling and soreness after eating lettuce has been reported in sensitized persons [45].

Primulaceae

Primula obconica is the most important allergenic plant, although other *Primula* species may also cause allergic contact dermatitis [46]. *Primula obconica* is a decorative indoor plant. The major allergen is primin, a quinone found in the tiny breakable hairs on the leaves, stem and flowers of the plant [27]. Another potential allergen is miconidin [47].

Contact occurs particularly when dead leaves and plant heads are removed manually. Primin levels are at their highest between April and August [48]. The allergen content of the plant also varies with sun exposure, temperature and feeding [48]. The pattern of dermatitis is determined by both the allergen content of the plant and the patient's degree of sensitivity and exposure. Primin-free strains (*Primula obconica* 'Libre') have now been developed [49].

Clinical features. The classical appearance of *Primula* allergy is linear papulovesicles, oedema and blisters, which may be haemorrhagic, on the palms, dorsa of the hands and forearms (Figs 20.6 & 20.27). Transfer of the allergen via the fingers to the face, or more generally, is common. In some patients palpebral oedema is the presenting feature, but half of the cases have other patterns, and the diagnosis is easily missed unless the possibility of *Primula* dermatitis is kept in mind [11,50]. Misdiagnoses include constitutional pompholyx, urticaria or recurrent angio-oedema, and disseminated herpes simplex [51]. Erythema multiforme, a lichen planus-like eruption and toxic erythema as a result of *Primula* allergy can also cause diagnostic difficulty [52–54].

Alstroemeriaceae and Liliaceae

Alstroemeria (Peruvian lily) is a highly decorative plant commonly displayed as a spray with other flowers. The damaged plant's sap is allergenic to florists when the stems are wired and leaves stripped, in preparation for making the spray [55].

The allergen is tulipalin A, also known as α-methylene-γ-butyrolactone, released from the precursor tuliposide A [56]. This allergen is also found in tulips (especially the bulbs). Tulips are members of the Liliaceae family and dermatitis is a particular risk for bulb collectors, sorters and packers, as well as florists [57,58].

Clinical features. Dermatitis from tulip bulbs may cause a painful, dry, fissured and hyperkeratotic allergic dermatitis, at first underneath the free margins of the nails and then on the fingertip [59]. A similar pattern of dermatitis is

seen in florists sensitized to *Alstroemeria* [60], and it may be followed by depigmentation [61].

Alliaceae

Garlic and onion are both members of this family and may sensitize, but do not seem commonly to cross-sensitize mutually [62]. Diallyl disulphide is the major allergen in garlic [63]. The allergen(s) in onion has not been identified.

Clinical features. Classically there is fingertip involvement in those allergic to garlic (see Fig. 20.7) and onion. This may preferentially affect the non-dominant hand, as this is the one that holds the vegetable while it is being cut with an implement held by the dominant hand [64]. Systemic contact allergy, including pompholyx, caused by ingestion of garlic has been described [65,66].

Lichens and liverworts

Lichens consist of a fungus and an alga. They are found on trees, rocks, roofs and walls [4]. Oak moss (*Evernia prunastri*) is a perfume ingredient derived from lichens [67]. Allergenic components include atranornin, usnic acid and evernic acid [33,67]. Liverworts (*Frullania*) are small red/brown plants often growing with lichens and mosses. The allergens, in common with Compositae with which they commonly cross-react, are sesquiterpene lactones [32–34].

Clinical features. A pattern similar to pseudophotodermatitis from Compositae has been seen in woodcutters' dermatitis caused by sensitivity to lichens and liverworts [68,69]. Erythroderma may ensue in severe cases. Even walking through a forest may cause an exposed-site pattern of dermatitis in sensitized individuals [36].

Avoidance

Patients who know of their sensitivity may manage to avoid further contact if taught to recognize the plants to which they are allergic. This is fairly straightforward for *Primula obconica*, *Alstroemeria*, tulips, Alliaceae, lichens and liverworts. Tulipalin A, in tulips and *Alstroemeria*, penetrates vinyl gloves. Nitrile gloves are more satisfactory for handling bulbs and the plants [70]. Those sensitized to lichens may also be allergic to certain perfumes, particularly those containing oak moss (*Evernia prunastri*). Perfume avoidance advice (see p. 20.49) may also have to be followed.

The recognition of *Toxicodendron* spp. is particularly important. Although the classical three-lobed leaves are a helpful feature, clusters of five or more leaves can occur. As there is considerable regional variability in the morphology of these species [16,37], it is preferable that sensitized persons become familiar with the appearance of *Toxicodendron* spp. in their own region.

Toxicodendron oleoresin may remain under the fingernails and on the clothes, resulting in continuing problems [5]. Detergents, soap and water will inactivate the residual unreacted allergen. After exposure, thorough washing of the hands, fingers and the rest of the body should be carried out as soon as possible, ideally within 10 min. Clothes should be changed. Contaminated tools and clothing, including shoes, should be washed in detergent [5].

Specific creams, containing quaternium-18 bentonite and other barriers, have been developed and these may help prophylactically to a varying but incomplete extent [71,72]. Heavy-duty vinyl gloves afford better protection than rubber gloves [5].

Seasonal Compositae exposure may be difficult to avoid. Severe Compositae allergy may necessitate changing occupation (e.g. florists, gardeners) or avoiding pastimes such as flower arranging and gardening. It may be necessary to avoid handling lettuce, chicory, artichokes and endives in food preparation. Those with associated photosensitivity may have significant problems from this, especially over the summer months. A high protection broad-spectrum sunscreen is required for this subgroup. Where contact with *Toxicodendron* spp. and certain Compositae such as ragweed is unavoidable (e.g. outdoor workers), hyposensitization has been attempted, with limited success. There is a risk of unpleasant side effects, including extensive skin eruptions and perianal dermatitis [73–75]. This treatment does not have the approval of the Food and Drug Administration in the USA [5].

Patch tests

There are two plant allergens recommended for the standard series: primin is tested at 0.01% in petrolatum; sesquiterpene lactone mix contains alantolactone 0.033%, dehydrocostus lactone 0.033% and costunolide 0.033% emulsified with sorbitan sesquioleate [12].

Primin is the major allergen in *Primula obconica* but may fail to detect *Primula* allergy occasionally [76]. Other *Primula* species may contain this allergen [46,77].

Sesquiterpene lactone mix does not identify all persons with Compositae allergy [15,78–80]. An alternative screen consisting of a mix of arnica, yarrow, tansy, German chamomile and feverfew extracts has been developed [81]. In one study, it identified twice the number of sensitized persons detected by sesquiterpene lactone mix, and by testing with both allergens 76% of all allergic subjects were identified [82]. However, this Compositae mix gives frequent false-positive reactions and may be sensitizing [83–85]. A lower concentration than 6% has been suggested [85,86]. In the UK, dandelion allergy, in particular,

may be missed by the sesquiterpene lactone mix patch test [87].

Other commercially available plant allergens include a number of Compositae extracts, including dandelion. Diallyl disulphide, the main allergen in garlic, is tested at 1% in petrolatum, and α-methylene-γ-butyrolactone, the allergen in tulips and *Alstroemeria*, is tested at 0.01% in petrolatum. Lichen acid mix consists of atranornin, usnic acid and evernic acid, each at 0.1% in petrolatum.

Plant extracts, preferably of known concentration, can be used for patch testing. Dipping the plant in diethyl ether for 60–90 s, evaporating to dryness and resuspending in petrolatum (1–10%) is a suggested simple method, although there are many alternative approaches [4,5,88]. Patch testing for *Toxicodendron*, if considered necessary, can be undertaken by diluting the oleoresin 1 in 10 in acetone [5].

Patch testing with the plants themselves may be undertaken but carries the risk of false-positive irritant reactions and active sensitization. If multiple tests with plants and plant allergens are carried out, there is a possibility that many strong positives may occur leading to an 'angry back' and inducing false-positive reactions to other allergens. Ideally, before patch testing with a plant, it should be identified and if it is a known irritant then testing may not be advisable. A textbook on plant dermatitis is a useful reference source. Several parts of one plant may contain the same allergen, and if this is the case 1 cm^2 of leaf bruised gently with an orange stick is sufficient for patch testing. Sometimes, however, the allergen is concentrated in one organ of the plant (orange peel, cinnamon bark) or the concentration of the allergen varies from one part to another. When testing with unknown plants, several parts should be tested. For later botanical identification, half of the material should be kept in a refrigerator [1]. Any plant that has given positive allergic reactions should be properly identified by its Linnaean name.

In order to prevent registration of irritant tests, it is important to employ controls when testing with the plants and their extracts.

Woods, colophony and turpentine [1–4]

Woods are normally of two types, hard and soft. The same woods may have many different names, and sometimes an incorrect name is mistakenly or deliberately applied [4,5]. The situation is complicated further by the occasional introduction of 'rogue' timbers into batches of hardwoods [5–7]. The commonest allergenic woods are listed in Table 20.9 [4].

Occupational allergic contact dermatitis is more frequently associated with hardwoods, and is more commonly seen among cabinet-makers, instrument makers, and so on. Some tropical hardwoods are especially allergenic. In many instances the precise allergens are not known, but some have been identified. Chemically, these include quinones (including dalbergiones and lapachol), phenols, terpenes, stilbenes and anthothecol [1–4]. Softwoods, apart from pines and other conifers, are not commonly associated with contact allergy [4]. Jelutong (*Dyera*

* Lichens on the wood may also sensitize.
† There is no accepted international nomenclature.

costulata) is a South-East Asian tree whose timber has sensitized woodwork teachers [8].

Pine trees are the source of two significant allergenic materials, colophony and turpentine [4]. Turpentine is the balsam from species of *Pinus*. Oil of turpentine is the volatile oil distilled from this balsam. The term 'turpentine' is commonly used to designate oil of turpentine. Colophony is the non-volatile part of the balsam and is

known as gum rosin [9]. Swedish and Finnish turpentine is made in the processing of paper pulp from wood. Venice turpentine is the balsam from larch trees.

Colophony is also extracted as a distillate from pine tree stumps, when it is known as wood rosin, and as a by-product of pulping pine wood, when it is called tall oil rosin [9]. The chemical composition varies according to geographical source, production method and storage conditions. It is composed of approximately 90% resin acids and 10% neutral substances [10]. Auto-oxidation products of abietic and dehydroabietic acids, including peroxides, hydroperoxides, epoxides and ketones, have been proposed as allergens [11]. Colophony may be modified, thereby altering its allergenicity with the development of new allergens [12]. Maleopimaric acid and glyceryl monoabietate have been identified as allergens [13] in modified rosins [14]. Certain other resins are chemically related [15,16].

The major sensitizer in turpentine is hydroperoxide of Δ^3-carene [17], which is also an auto-oxidation product. Swedish and Finnish turpentine contains more of this substance than, for example, French and American turpentine. Limonene (D or L) and pinene (α or β) can also sensitize [18]. The term 'mineral turpentine' is used for the non-sensitizing, but irritant, white spirit, i.e. a petroleum product.

The sensitizer propolis used in bee glue is derived mainly from poplar resin. It may be found also in beeswax. The allergens include caffeates and benzyl isoferulate [19].

Lichens, liverworts and sensitizing plants may cause allergic sensitization by virtue of their coexistence with trees. Additives to wood such as varnishes, dyes, glues or preservatives may also sensitize at work.

Incidence and prevalence. The incidence and prevalence of occupational wood allergy are unknown. Colophony is a standard allergen, with a 2–6% prevalence of allergy in patch-tested populations [12].

Turpentine was removed from the ICDRG's recommended standard series because of infrequent allergy. It has been excluded from many industrial products, especially solvents, and replaced by petroleum products such as white spirit [20], although a high prevalence of sensitization continues to occur in Spain and Portugal [21,22]. Furthermore, there is now evidence of increasing sensitization to oil of turpentine, which will require further investigation [23].

In patch tests on 137 men and 2036 women, positive reactions to propolis occurred in 0.9 and 1.4% respectively [19].

Occurrence. Trees, wood and sawdusts are predictable sources. Colophony, however, is ubiquitous and not only found in pine and spruce trees and wood. The commoner sources of colophony and its modifications [10] are identified in Table 20.10, but this list is not all-inclusive. It is labelled in cosmetics by its INCI name Colophonium. Colophony derivatives (e.g. abietic acid, hydroabietic acid and hydraobietyl alcohol) may also be found in cosmetics.

Table 20.10 Sources of colophony.

Pine trees and wood	Spruce trees and wood
Rosin (grip/antislip materials)	Adhesive plasters and tapes
Adhesive dressings	Insulating and jointing tapes
Ostomy appliances	Dental dressings
Clear and brown soaps	Varnishes and coatings
Metalworking fluids (tall oils)	Solder flux
Glues, adhesives and sealants	Shoe adhesives and counters
Paper size	Flypaper
Shoe and floor polishes	Cosmetics (eye shadow, mascara)
Printing inks	Wood wool
Chewing gum	Linoleum
Balms and salves	Wart treatments

Turpentine is present in balsams and sawdust from pine and spruce. It was used as an industrial solvent but has now largely been replaced by petroleum derivatives and D-limonene [20]. It is still used by artists [20] and in ceramic decoration [24]. In certain producing countries such as Spain [21] and Portugal [22], turpentine is still more widely used than elsewhere, and it remains a common allergen there. In the USA it is still commonly used as a paint remover [25].

Propolis is encountered not only by beekeepers [26,27] but also in topically applied agents used in 'natural' products from health food stores and mainstream cosmetic outlets. Solid propolis can be chewed [28]. Increasing self-medication may mean increased contact allergy from this source. It may also be found in beeswax [27] used in cosmetics and topical medicaments [29].

Clinical features. Most cases of wood allergy present in the occupational setting and are related to contact with airborne sawdust. The pattern of dermatitis therefore affects the exposed sites, with the scalp of bald men being typically involved. Differentiation from a photosensitive eczema may be difficult, but light-protected sites (e.g. under the chin and behind the ears) are more likely to be equally affected in wood dermatitis. However, sawdust can gain access inside clothing to produce dermatitis predominating in the flexures. Genital involvement is a particular feature, in part from transfer of the allergen during urination [6]. Severe erythema multiforme-like eruptions have been described, particularly from *Machaerium scleroxylon* allergy [6,30,31].

Localized dermatitis may occur under exotic hardwoods, for example from a violin chin-rest, or wooden adornments and utensils [32–35].

Colophony allergy may present in many different ways because colophony is ubiquitous. Over 300 potential allergenic sources have been identified [25]. An exposed-site

pattern may be seen after machining pine and cutting down branches when gardening. Highly sensitive persons may suffer without having direct contact. Sensitivity to *X Cupressocyparis leylandii* trees has been associated with concomitant colophony allergy [36]. Allergy to colophony in solder fumes can give a similar distribution but dermatitis may be confined to the face [37,38]. Unsuspected sources for an exposed-site pattern have included linoleum flooring, paper dust and floor polish [39].

Facial and eye dermatitis can develop from contact with colophony-containing cosmetics, particularly mascara [39–42]. Reactions to sticky tapes and plasters, and colophony-containing medicaments, are often confined to the site of application. Adhesive plasters are often used to cover painful fissures on the hands and feet. These may have been caused by a pre-existing eczema or psoriasis, which may consequently be perpetuated or exacerbated by colophony allergy. Allergy to colophony derivatives (e.g. ester gum resin) used as adhesives for lower leg dressings may be confused with varicose eczema and secondary medicament sensitization [43,44]. A secondary-spread eruption may develop in such cases. A localized dermatitis may be induced by topical colophony-containing medicaments, including wart treatments [45–48].

Colophony may induce hand dermatitis due to contact with a diverse range of colophony-containing materials such as glues, polishes, paper, rosin, antislip powders, topical medicaments, waxes, and tall oils in metal machining coolants [10,12].

Perioral dermatitis and cheilitis have been related to colophony in chewing gum [48,49]. Dental materials, including floss, fluoride varnish, dressings and impression materials, may contain colophony, but rarely sensitize in the mouth [50–52]. A case of widespread dermatitis has been recorded after dental treatment in an allergic individual [53].

Colophony can also be present in adhesives in footwear [54,55]. It has also been incorporated, in modified form, in footwear in an impregnated cloth [56].

Turpentine allergy is usually associated with hand dermatitis or a localized pattern of dermatitis.

Allergy to propolis in medicaments is manifest at their sites of application. Allergy to chewed propolis may induce a perioral distribution of dermatitis [28].

Avoidance. Demonstration of allergy to a wood should be followed by anatomical confirmation of its botanical name and, ideally, by testing with the known allergen(s) for that wood [4]. Subsequent avoidance of the wood and related timbers may be necessary.

Detection of the origin of colophony allergy requires careful appraisal of potential sources. Use of traditional sticking plasters should be replaced by 'hypoallergenic' tapes. Insulating tapes may also contain colophony, as may certain adhesive leg ulcer dressings. Contact with pine and other coniferous trees, and probably *X Cupressocyparis leylandii*, should be avoided; in those with extreme sensitivity, felling and removing the offending trees may be necessary. Occupationally, it may be possible to change the allergenic product to an alternative.

Colophony and derivatives can be identified in fully ingredient-labelled cosmetics. The INCI term Colophonium is used. Derivatives that may be used in cosmetics include abietic acid, hydroabietic acid and hydroabietyl alcohol. Transparent colophony-containing soap should be avoided for washing. Wart paints incorporating collodion should also be avoided, along with colophony-containing topical medicaments and balms.

Colophony allergy from paper has been implicated in hand dermatitis, and the use of cotton gloves is suggested if this is a possibility [57].

However, the list of potential exposures is so extensive that it will often be a case of establishing whether any of the sources identified in Table 20.10 are relevant and tailoring avoidance advice accordingly. For a more comprehensive coverage of sources the reader is referred to *Fisher's Contact Dermatitis* [25].

Turpentine substitutes are now readily available for sensitized subjects. Propolis (and beeswax) found in topical applications can be avoided by using only fully ingredient-labelled cosmetics and medicaments.

Patch tests. Patch testing with freshly made, uncontaminated sawdust 10% in petrolatum is recommended but may carry the risk of false-positive and false-negative patch tests, and active sensitization [4]. Apparent allergic positive reactions should only be confirmed after testing on controls. It is advisable to ask the patient to bring a piece of unmachined wood at the same time as the sawdust. If a positive allergic reaction develops, the piece can be sent to a wood anatomist who will confirm the correct name for the wood. If the allergen for that wood is known, it is sometimes possible to patch test with it at the appropriate concentration. However, this may be difficult as most wood allergens are not commercially available.

Colophony is a standard allergen tested at 20% in petrolatum. A mixture of Chinese and Portuguese gum rosin is presently used in commercially available patch-test allergens [10]. As some modified colophony products may be allergenically different, they may also need to be tested separately [58].

Propolis is patch tested at 10% in petrolatum.

Patch testing [1,2]

Background

The diagnosis of allergic contact dermatitis is made by patch testing and of photoallergic contact dermatitis by photopatch testing. The techniques have evolved into a generally standardized methodology worldwide, although there are some variations, particularly with regard to reading times, test units and photopatch-test protocols [1,3].

Patch testing relies on the observation that primed antigen-specific T lymphocytes will be present throughout the body [4], and hence allergen in the patch test can be applied to normal skin, usually on the upper back where the tests are least likely to be disturbed. Other sites may be considered when this is not practicable, for example when

Table 20.11 Indications for patch testing. (From Bhushan & Beck [6].)

1 Eczematous disorders where contact allergy is suspected or is to be excluded
2 Eczematous disorders failing to respond to treatment as expected
3 Chronic hand and foot eczema
4 Persistent or intermittent eczema of the face, eyelids, ears and perineum
5 Varicose eczema

there is pre-existing inflammation or other skin changes on the back.

The test relies on the allergen being absorbed in sufficient quantity to induce a reproducible inflammation of the skin at the site of application in sensitized subjects. A positive reaction to a correctly prepared and applied patch test confirms the person has an allergic contact sensitivity, although this does not necessarily mean that the substance is the cause of the presenting clinical dermatitis, and its relevance should always be carefully considered.

Indications

It is well established that aimed patch testing with a few suspected allergens is suboptimal. The reason is that even experienced dermatologists are poor predictors of the outcome of patch tests; 17% of patients with allergies were missed on a prepatch-test assessment in one large clinic [5]. This parallels our own experience, with 20% of allergic patients regarded as definitely not allergic prior to patch tests and, conversely, 16% of patients thought to have contact allergy who were negative when patch tested.

A recent audit of patch testing has suggested that the investigation is underused, and consequently important opportunities to improve or resolve potentially disabling and undiagnosed allergic contact dermatitis are lost [6]. Facilities should be available to patch test at least 142 per 100 000 population annually and the categories of patient listed in Table 20.11 should be patch tested where practicable [6]. Dermatology-specific quality of life has been shown to improve significantly more in those patients who are patch tested because of more accurate diagnosis and earlier intervention [7,8]. Furthermore, the investigation has been shown to be cost-effective and to reduce the cost of therapy in patients with severe allergic contact dermatitis [7,9].

Methods

The basis of testing is to elicit an immune response by challenging already sensitized persons to defined amounts of allergen and assessing the degree of response. The amount of allergen is defined by its concentration in the vehicle and the amount applied. By testing the same allergens in parallel, the technique has been confirmed to be generally reproducible [10,11].

Chambers or discs are used to ensure occluded contact with the skin [1]. The fixing tape should be non-occlusive, non-allergenic and non-irritant. If the adhesive tapes peel off, the test should be repeated. Ideally, patch testing should not be carried out in patients with active eczema because it may reduce the threshold of activity and cause non-specific reactions, although in practice this is commonly not possible. The procedure should be delayed until the test site has been clear of eczema for at least a fortnight. Patch testing should not be performed following sunbathing, and the patches should not be exposed to the sun or other sources of UV light [12]. This information should be given to the patients before they book their appointments. Corticosteroids and other immunosuppressive drugs should be stopped (if this is feasible) before patch testing as they may reduce or extinguish positive patch tests in sensitized subjects. Nevertheless, this is unlikely at doses below 15 mg prednisolone daily [13,14], and we have identified relevant positive patch tests in patients who could only be investigated while they were taking other immunomodulators.

We prefer not to patch test pregnant patients in case an adverse event is blamed on the test, although we are unaware of any proven problem. Young children, even infants, can be patch tested when indicated, but the number of allergens tested may have to be reduced because of lack of space [15].

Test materials

The allergens are obtainable from the following manufacturers: Hermal, D-21462 Reinbeck, Germany (email: Hermalinfo@hermal.de), who market TROLAB allergens; and Chemotechnique Diagnostics AB, PO Box 80, Edvard Ols väg 2, S-230 42 Tygelsjö, Sweden (email: info@chemotechnique.se); or from their local distributors.

The commonest system used to apply allergens is the Finn chamber (Epitest Ltd, Oy., Rannankoukku 22, FIN-04300 Tuusula, Finland) on Scanpor tape (Norgesplaster, Vennesia, Norway). These are also available from local distributors. The chambers are supplied in strips of five or 10 (two rows of five) and consist of small occlusive aluminium discs. They are mounted on non-occlusive tape with an acrylic-based adhesive backing that has been chosen for its hypoallergenicity.

Other systems consist of square plastic chambers (Van der Bend chambers), oval plastic chambers (Epicheck) and the older AL Test system (a filter paper disc mounted on aluminized paper), which is available in rolls of chambers and is mounted on acrylic-based adhesive tape.

There is now also a new prepackaged ready-to-use patch-test system, TRUE (thin layer rapid use epicutaneous) test, based on a dispersion of allergen in a

hydrophilic polymer [16], although this is presently only available as a standard series of 23 allergens. It was developed by Torkil Fischer and Pharmacia, and is marketed in the UK by ALK-Abelló (UK) Ltd and in the USA by Allerderm. This system has been tested in parallel with the established Finn chamber system and there was close correlation of results [17,18]. It is a consistent, convenient, portable method for those wishing to test only the standard series.

Reactions to the adhesive tape may occur, but they are normally irritant not allergic. To reduce the incidence of such reactions, the strips must be applied without tension, with the patient in a relaxed posture. Folliculitis may occur due to occlusion, particularly in those with a tendency to seborrhoeic eczema.

Patch-test vehicles

Few substances can be applied to the skin as they are. In order to avoid an irritant effect, they must be mixed or dissolved in a vehicle to achieve a suitable test concentration. The test substance should, if possible, be soluble in the vehicle. If a dispersion of allergen in petrolatum is used, contact with the skin depends on the size of the particles and on their solubility or dispersion in petrolatum. Uniform dispersion and particle size are important [19]. Many substances can also be dissolved in water, alcohol, acetone, methylethylketone (MEK) or olive oil, as appropriate. Irritant solvents such as chloroform and benzene must not be employed. False-positive or false-negative reactions may occur when inappropriate vehicles are used. In addition, the concentration of allergen tends to increase as the solvent evaporates. Petrolatum is generally more reliable, and has the added advantage of being occlusive, which helps to prevent oxidation and prolongs shelf-life. Allergic reactions to petrolatum itself are very rare [20]. In hot climates, petrolatum may not be ideal, as it melts too quickly between preparation and application of the patch test, and a series in modified Plastibase has been devised for the Indian Contact Dermatitis Group.

Patch-test concentrations

Choice of a suitable concentration is of fundamental importance. Excessive concentrations result in false-positive reactions, because of their irritant effect, and may even sensitize patients; insufficient concentrations produce false-negative results. The concentration of allergen routinely employed for patch tests may, under some conditions and in some individuals, give rise to false-negative or false-positive reactions. The choice of concentration is thus a compromise, but most have been chosen by long experience with commonly used allergens. The concentrations used for patch testing are usually much higher than those encountered during development of dermatitis. To demonstrate the existence of nickel dermatitis produced by the minute amounts dissolved from nickel-plated objects, a 5% concentration of nickel sulphate in petrolatum is necessary. Chromate 0.25–0.5% is required to prove sensitivity to cement containing 0.0005–0.002% of chromate. Neomycin should be tested at 20% despite only being at 0.5% concentration in many topical medicaments [21].

Lists of suitable concentrations and vehicles are provided in a number of texts listed on p. 20.108. Metal salts in particular are tested at the margins of irritancy and may give false-positive, irritant patch-test reactions, especially in atopic individuals [22,23]. Weak reactions may not therefore be allergic, and the patient should be retested at a different site and with serial dilutions. Other standard allergens such as fragrance mix [24], parabens mix and wool alcohols may also be marginally irritant. On rare occasions, active sensitization may still occur even at the concentrations recommended. Irritant reactions are rarer with other substances used in standard series. They are potentially much more common with materials brought to the clinic for testing. Many industrial or domestic chemicals would give irritant false-positive reactions if undiluted, and no chemical or substance should be applied to the skin until full details of its composition and potential irritancy or toxicity are known.

If work or other materials are brought, a number of factors should be considered before they are used for patch testing. Is it appropriate to test with the material? Some materials are strong irritants and not allergens (e.g. strong acids and alkalis), and others may be contaminated or of uncertain or mixed composition (e.g. dust or grime from a working environment). The product may be intrinsically dangerous (e.g. explosive or produces toxic fumes) and require special handling. Some patients bring foods in the mistaken belief that the test will diagnose ingested food allergy.

The precise nature of the material should be ascertained by questioning the patient and examining the product label. In the UK, employers are required by law to have Health and Safety data sheets for all materials handled at work. These provide key information and a contact point with the manufacturing company. They must be scrutinized carefully, particularly with regard to irritancy, allergenicity, stability and solubility of the product and its components. Named chemical substances may be recognized as irritants or allergens, and their concentrations documented. Substances can be checked for pH, and neutralized if necessary [25].

An initial patch-test concentration can often be selected either by reference to standard texts or by contacting the manufacturer for details of toxicological testing data. It is advisable to start low (0.01% or less), and increase the concentration gradually if there is doubt about the optimum level for testing. It may be advisable to perform open tests

before proceeding to closed patch tests because the effect of irritants is enhanced by occlusion [26]. Materials intended to be left on the skin, such as medicaments and cosmetics, can be tested 'as is', 'rinse-off' products at 5%, and soaps, shampoos and detergents at 1%. However, the dermatologist administering a patch test will need to refer to standard references for guidance on dilutions and vehicles when testing finished products or specific chemicals. These are discussed on p. 20.108.

If a positive reaction to an unknown substance occurs, it should not be immediately accepted as allergic. Volunteers, who are not suffering from dermatitis related to the same agent, should be tested at the same concentration and using the same methods. If any reaction occurs among 50 controls, the substance should be regarded as a primary irritant at that concentration, and subsequent tests should be performed with decreasing concentrations.

Patch-test dose

If petrolatum is used as the vehicle and disposable syringes are the containers, a length of 5 mm of test substance in vehicle will suffice. If the vehicle is a fluid, a digital pipette should be used to deliver 15 µL to a filter paper in the chamber. Dropper bottles supplied by the allergen manufacturers tend to overfill the chambers. A surplus should be avoided, as it may contaminate neighbouring test sites. With TRUE test, the patches are preprepared. The risk of patch-test sensitization increases with the concentration and amount of test substance applied.

Storage of allergens

'Shelf-life' is prolonged if test substances not in daily use are stored in the dark in a refrigerator at 4°C. Many substances are unstable if exposed to light. Commercially available allergens are labelled with an expiry date.

Storage in small jars has the drawbacks of oxidation, drying and evaporation of volatile test substances [27]. Rubber pipette caps contaminate the solutions and may cause false-positive reactions in persons sensitive to rubber. Homogeneity of patch-test allergens may be lost, especially in hot climates, unless they are kept refrigerated [28].

Test site

Most dermatologists prefer to apply patch tests to the back [29]. The region used for testing is important with regard to the results of the investigation: both allergic and irritant reactions are most easily provoked on the upper back [30] (Table 20.12). Reactions on the lateral aspect of the upper arm are stronger than on the medial aspect. Sites other than the back and lateral aspect of the upper arm are generally less suitable as test areas, but when necessary we have used the abdomen or even the thighs rather than abandoning the investigation.

Table 20.12 Reactivity of various test sites. (From Magnusson & Hersle [30].)

	Type of reaction	
Test site	Irritant (%)	Allergic (%)
Upper back	100	100
Lower back	50	95
Upper arm	52	72
Forearm	38	74
Thigh	36	50

Marking

Test sites must be marked with indelible ink or stratum corneum stains (or fluorescent markers on dark skins). Marking materials can be obtained from allergen suppliers. It is necessary to repeat marking before removal of the patches, because their positions cannot be distinguished once the pressure effects have subsided. The patient should be instructed not to bathe or shower for the duration of the tests, and to avoid exercise or other activity likely to dislodge the patches.

Exposure time

The mere touch of a *Primula* leaf may provoke a subsequent bullous response in a sensitive person, but with some materials (e.g. textiles) even 5 days of occlusive patch tests may lead to false-negative reactions. Well-established allergens, however, are conventionally tested in such concentrations that a 48-h exposure under an occlusive patch will generally allow penetration of an amount sufficient to provoke a reaction. With low sensitivity, low concentration of allergen or poor absorption of a particular agent, there may be a long period of latency. The ideal regimen is a 48-h application time, with readings taken 1 h after removal and again 48 h later, i.e. at 2 days and 4 days [31], preferably with the same observer performing each reading. Others have suggested that a 3-day second reading is better [32]. A single 2-day reading is not advised as it may lead to the labelling of some marginal irritants as allergens, and positive reactions to more poorly absorbed allergens may be missed [31,33]. Variations to this schedule are made for expediency, to fit in with clinic times, and for the convenience of patients travelling long distances. If only one patch-test reading is possible, a 4-day reading has been recommended [34,35] although, according to some authors, a single 4-day reading is also associated with the risk of missing some significant positive reactions [36]. A third reading at 5–7 days seems to identify a small proportion of additional

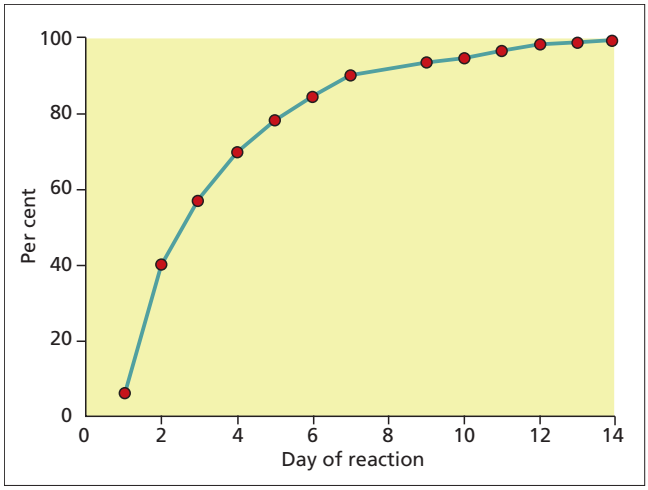

Fig. 20.28 Patch tests with neomycin 20% in petrolatum: positive reaction times after application.

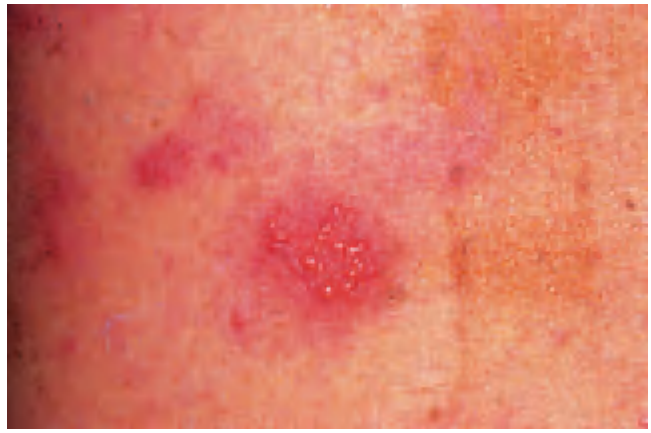

Fig. 20.29 A positive allergic (++) patch-test response in a patient sensitive to neomycin. (Courtesy of Dr J.D. Wilkinson, Amersham General Hospital, Amersham, UK.)

relevant positive allergies where sensitivity is weak or partially 'forgotten', or where there is poor absorption of the allergen [32,35,37,38]. Neomycin (Fig. 20.28) and corticosteroids are particularly liable to give late reactions.

Immediately after removal of the patch tests, there may be erythema from the stripping action of the tape, especially in dermographic subjects, and this must be allowed to settle. Furthermore, some reactions may take up to 1 h to develop once the pressure of the strips has been released and the infiltration allowed to swell the dermis.

Readings and interpretation

It is important that patch-test readings are scored according to the reactions seen and not according to the interpretation placed on the reaction by the reader. As the strength of a reaction is not always reproducible, an over-detailed quantification should be avoided. The scoring system devised by the ICDRG in 1970 is shown in Table 20.13 [39].

There are drawbacks to the ICDRG system in that it confuses morphology with interpretation. The ideal system is to record what is seen at 2 and 4 days, and then to decide if this represents an allergic or irritant response. This is done by assessing morphology and skin type, combined with knowledge and experience of the substance and the patient's history. Patch-test results should be recorded objectively, and the interpretation of the results should be recorded separately. In this way raw data remain available for re-examination.

Once they have developed, positive allergic reactions often persist for several days. The strength of the reaction depends on barrier function, the presence or absence of sweating, the atmospheric humidity, test material, technique and the reactivity of the individual.

Strong reactions of an allergic nature are erythematous and infiltrated, commonly with minute papules or vesicles (Fig. 20.29), which in severe reactions coalesce into bullae. The infiltration causes a thickening in the dermis, which is palpable and can be distinguished from surface changes in the epidermis. The reaction may extend beyond the margins of the patch, and there is often some itching. Nevertheless, sometimes true allergic reactions can be weaker than this, making interpretation more difficult.

In most instances there is little difficulty for the experienced clinician in identifying true positive allergic patch-test reactions. Nevertheless, there are occasions when distinguishing an allergic from a false-positive non-allergic irritant reaction can be difficult or even impossible. There may be clues—no infiltration, lack of itching, deep redness or a brown hue, and sharp delineation corresponding to the margins of the patch test (particularly around the edge with solid materials)—these all point to an irritant reaction. Some irritants provoke a 'soap effect', with a well-localized, glistening, finely wrinkled surface. Patch tests with nickel may cause pustular reactions that are often false positive (Fig. 20.30), although some progress to more typical allergic reactions. Cobalt also

–	Negative
?+	Doubtful reaction; faint erythema only
+	Weak positive reaction; palpable erythema, infiltration, possibly papules
++	Strong positive reaction; erythema, infiltration, papules, vesicles
+++	Extreme positive reaction; intense erythema and infiltration and coalescing vesicles
IR	Irritant reaction of different types
NT	Not tested

Fig. 20.30 Pustular patch-test reactions to metals are common in atopics and are often irritant in type.

produces a distinctive false-positive purpuric reaction. In our experience these tend to occur much more in atopic individuals, and need to be distinguished from allergic follicular reactions consisting of papules without pustules or purpura.

Patch tests positive at 2 days and negative at 3–4 days may be irritant. False-positive irritant reactions are liable to induce stronger reactions at 2 days than at 4 days, the so-called crescendo–decrescendo effect. However, this is not always the case and the reverse can happen in our experience. Difficulties in evaluation are particularly common with substances brought in by the patient for testing. It may be necessary to apply several concentrations at the first visit; controls should be performed with any substances giving positive reactions.

There is no substitute for a thorough knowledge and experience of the allergens used for patch testing. Even some standard allergens may be liable to induce weak false-positive reactions (e.g. metal salts, fragrance mix, parabens mix, wool alcohols and carba mix). Repeat patch testing may be helpful, especially with a breakdown of the mixes.

Non-invasive measurement techniques [40]

There are several non-invasive techniques that can be used to quantify and delineate the effects of patch tests, including measurements of changes in skin surface, epidermal hydration and water barrier function, and parameters of inflammation [40]. At present, these are more useful to the investigator than to the clinician [41]. They include replica techniques [42], transepidermal water loss [43], skin reflectance [44], laser Doppler flowmetry [45,46], thermography [47] and high-frequency ultrasound [48]. Attempts have been made to use some of these techniques to differentiate irritant from allergic patch-test reactions [49] but they have not superseded the combination of human brain, eye and hand in the assessments of patch tests.

Relevance of patch tests

It is important to try to relate the actual episode of dermatitis, with regard to both site and timing, to a history of exposure to the putative allergen. A positive reaction to a patch test commonly proves the cause of a dermatitis, i.e. the reaction is relevant. Other reactions may relate to previous attacks of dermatitis and are thus of past relevance. Some sensitivities cannot be interpreted within the limits of the knowledge available. Such unexplained positive reactions are quite common. However, many previous positive formaldehyde reactions were unexplained until it eventually became apparent that they indicated possible textile dermatitis. A similar situation occurred with balsam of Peru (*Myroxylon pereirae*) before its many associated allergens were recognized. Overall, approximately 75% of '++' and '+++' patch-test reactions are of current or past relevance. The relevance of '+' reactions is less certain [18].

A person may react to a patch test but still tolerate contact with the allergen. Dermatitis from face creams is uncommon in patients with dermatitis of the legs related to parabens sensitivity, known as the paraben paradox [50]. Clinically, latent sensitivity to occupational contactants is common in healthy workers who have never suffered any skin disease [51]. In a patient with dermatitis, a positive patch test must never be disregarded. If found in a healthy person, it may indicate a future risk of contact allergic dermatitis from that particular allergen.

Sources of error

False-positive reactions (Table 20.14). Irritant reactions occur if a chemical is tested at excessive concentration. Incorrectly interpreted false-positive reactions may lead to the wrong conclusions about the cause of a dermatitis, and this may result in inappropriate career or medicolegal advice. Recent or active dermatitis in the test area lowers the threshold for irritant reactions, as does dermatitis in other areas [52], and non-specific reactions can occur.

Table 20.14 Causes of false-positive reactions.

Excessive concentration
Impure substance (contaminants)
Irritant vehicle
Excess allergen applied
Uneven dispersion
Current or recent dermatitis at patch-test site
Current dermatitis at distant sites
Pressure effect of hard materials
Adhesive tape reactions
'Angry back' reaction causing intensification of weak irritants
Artefact

Table 20.15 Causes of false-negative reactions.

Insufficient concentration
Insufficient amount applied
Poor adhesion of patches
Patches applied at wrong site
Inappropriate vehicle
Readings performed too early
Substance degraded
Pretreatment of patch-test site with topical corticosteroids
UV irradiation of patch-test site
Systemic treatment with immunosuppressants

Secondary non-specific reactions close to genuine positive ones have been termed 'angry back' [53] or the 'excited skin syndrome' [54], and this may be an important cause of false-positive patch-test reactions. The phenomenon has been extensively investigated by Bruynzeel [55]. However, multiple positive reactions to nickel did not cause 'angry back' in a study by Andersen *et al*. [56].

If there is any doubt, the patch tests should be repeated some weeks later, preferably with individual agents and at various dilutions, as false-positive irritant reactions tend to stop abruptly below a certain concentration whereas allergic responses tend to persist, albeit proportionally weaker, at lower concentrations. Testing the same substance on a panel of controls, using the ROAT on the elbow flexure [57] or usage tests, may help to differentiate allergic from irritant responses. Controls should be tested at the lowest concentration of a positive test to avoid interpreting a false-positive irritant reaction as allergic.

False-negative reactions (Table 20.15). Sometimes a patch test fails to provoke a positive reaction in a person who is sensitive to the substance tested. The dermatitis therefore persists because of continued exposure to the allergen. The most common cause of false-negative reactions is insufficient penetration through the skin.

A low degree of sensitivity or poor penetration sometimes results in a long period of latency before a positive reaction develops, so that up to 7.5% of allergic positive patch tests do not become apparent until after 4 days, and may go unnoticed unless read 7–14 days after application [35]. This particularly applies to neomycin [21] and corticosteroids [58].

The apparent discrepancy between the concentration of allergen needed to elicit clinical dermatitis and the occasional failure of a patch test to elicit a reaction can be explained by many factors. In particular, a single exposure on normal skin is probably not representative of the accumulation of the allergen during repeated exposure conditions and chronic usage on already primed skin.

False-negative reactions are common when testing with textiles, cosmetics, medicaments, leather and rubber, as some ingredients are present in very low concentrations. False-negative reactions also occur when allergens are present in irritant products. Because of irritancy, a product may have to be diluted to such an extent before it can be safely tested that the allergen is present in insufficient concentration to elicit a response. Such products include cutting oils and washing materials. Sensitivity to finished products and topically applied preparations is best confirmed and revealed by testing with the individual components.

An allergy may be missed on patch testing if the test material has been wrongly diluted in a material in which it is immiscible or insoluble. Furthermore, an incorrect diluent may change the allergen into another substance altogether [59]. Partition coefficients are also important, because oil/water solubility may be a significant factor in skin penetration and allergenic potential.

Local treatment with topical corticosteroids [60], and systemic treatment with immunomodulators including ciclosporin, azathioprine and corticosteroids such as prednisolone (at a dose above 15–20 mg/day), may diminish or abolish reactions [13], as does prior sunbathing [12]. Negative reactions, in spite of clinical sensitivity, also occur in photocontact dermatitis if appropriate allergens are not photopatch tested.

Compound allergy [61,62]. Compound allergy occurs when a positive allergic patch-test reaction is seen to a finished product but tests with the ingredients are negative. Hence, the product and the constituents should be patch tested when allergy is suspected. This was a concept first proposed by Calnan [63] and considered in depth by Dooms-Goossens in her thesis [61].

New compounds may be formed within a product, and their presence can be confirmed by the finding of incongruous peaks on spectrometry. This was elegantly demonstrated in Hirudoid cream, where a new allergen was formed as a reaction product of two preservatives in the medicament [64]. The additive effect of multiple weak sensitizers [65], or the additive effect of weak allergens and irritants, should be considered [66]. Commonly, the reaction to the finished product is irritant [67]. A product's irritancy is not merely the sum of the irritancy of the ingredients, but an expression of the hydrophilic–hydrophobic balance of its ingredients. This can change with varying manufacturing techniques, for example changing the temperature or manipulating the proportion of one of the ingredients.

There are several possible alternative explanations. A constituent allergen may be an undeclared ingredient or there may be batch/source differences between the original compound and the subsequently provided components. The allergen may be in the container, for example a rubber stopper, and not in the product. The allergen may not have been tested in the correct vehicle or at the correct concentration, and testing it in its own base may reveal the allergy [61].

Quenching [68]. Theoretically, just as there may be potentiation of allergic and irritant responses, so a combination of chemicals may lead to a quenching effect [69]. This phenomenon has been investigated mostly in fragrance material aldehydes. It might be explained by the combined compounds changing available bonding sites for class II molecules or forming a compound that does not follow the same detoxification pathway. However, some authors have been unable to demonstrate any physicochemical interaction [70], and it remains questionable whether the phenomenon really exists [68].

Other observed quenching effects may be due to one of the compounds having anti-inflammatory properties [71,72], such as triclosan having a 'quenching' effect on nickel allergic contact dermatitis.

Other factors. The interpretation of patch-test reactions can be affected by the presence or absence of impurities or degradation products [73], hidden additives [74], batch differences [75] and the fact that some chemicals may undergo reactive metabolic changes in the skin. Natural products vary according to source [76,77], season [78] and method of extraction [79]. Storage or 'ageing' of a product may also affect its allergenicity [80] and irritancy [81]; D-limonene has been shown to be allergenic only in its old and oxidized state [82]. Patients should therefore always be tested with their own product. Season may also influence patch-test results, but whether this is due to UV radiation suppression of test reactions in summer or an enhancement of irritant-type reactions in winter remains uncertain [83,84].

Errors may occur in the registration of the relative sites of the tests. It is therefore advisable to repeat the test if in doubt.

Selection of test substances [1]

The decision about what to test is dependent on a sound knowledge of the common sensitizers, in conjunction with a thorough history of exposure. Fortunately, a high proportion of cases of contact dermatitis are caused by sensitivity to a small number of contactants, although there are potentially thousands. In relatively few cases of contact dermatitis are the clinical appearances and history so typical that an allergen can be incriminated readily [2,3].

It is therefore essential to test with a standard series of common contact allergens. Many investigation clinics have extra allergens and some of these may be grouped into additional special test series (e.g. for certain occupations or affected sites). Furthermore, it may be necessary to test with materials encountered in patients' working and domestic environments, and with any medicaments and cosmetics applied to affected areas.

Standard series [4]

The principle of screening all patients with a series of allergens commonly encountered in their environment is now well established. Aimed patch testing is ill-advised. The decision as to what should be in the standard series has now generally devolved from the ICDRG to other national and international groups. The standard series recommended by the EEC-DRG contains 25 allergens [5,6]. The BCDS has recently advised 35 allergens for their standard series [7]. Table 20.16 shows the standard series recommended in various parts of the world [5–9]. As some allergens disappear from a given environment and others attain significance, it is important that a standard series evolves. In the past, several common sources of contact dermatitis were overlooked until they were included in a standard series. Nowadays, fragrance materials are familiar contact allergens but were virtually unknown

Table 20.16 Comparative lists of allergens in four different standard series.

	EEC-DRG*	BCDS†¶	NACDG‡	JSCD§
Potassium dichromate	0.5	0.5	0.25	0.5
Neomycin sulphate	20	20	20	20 (fradiomycin)

IPPD, *N*-isopropyl-*N*′-phenyl-*p*-phenylenediamine; NT, not tested.

30 years ago [10]. Conversely, others (e.g. wood tars and turpentine) were removed from the standard series some years ago.

Newer standard allergens recommended for Europe include markers for corticosteroid allergy [6] (tixocortol pivalate and budesonide) and Compositae plant allergy (sesquiterpene lactone mix) [5]. The European standard series identified 75–80% of all allergies diagnosed in one multicentre study [11].

In some studies, as many as half of the relevant positive reactions were unexpected. Obviously, if patch testing is carried out for very wide indications, the percentage of negative reactions will increase, but at the same time unexpected positive reactions will correct misdiagnoses of constitutional or irritant dermatitis.

The selection of substances for a standard patch-test series must be based on local experience, but several substances are universally recognized allergens. Unless a permanent record is kept, a number of substances will continue to be included despite a low yield of positive reactions. In general, a substance should be included in the standard battery if it gives positive reactions in more than 1% of those tested, or if without it a significant number of unsuspected allergic reactions would be missed. This is true of ubiquitous allergens such as rubber chemicals, nickel and chromate, fragrance materials and common therapeutic and cosmetic allergens such as lanolin, neomycin and preservatives. However, less common allergens may be included if they are potentially easily overlooked and important. Such commonly unsuspected but infrequent standard allergens include primin and IPPD. The results of testing to a standard series of allergens vary from one part of a country to another, and from one country to another (Table 20.17) [7–9,12]. In most countries, additions to the international standards are required. In order to reduce the number of tests, defined groups of substances can be made up as ‘mixes’.

Additional series

There are many situations in which additional series of allergens are useful [1,13], for example in the investigation of dermatitis occurring in certain sites liable to medicament allergy (eyes, ears, perineum and venous ulcers/eczema) or sensitization from components of shoes or clothing. Some occupational groups, for example hairdressers, florists, dentists and metal machinists, are exposed at work to a variety of potential allergens not found in the standard series. Others may handle a specific group of allergenic chemicals, for example epoxy or acrylic resins. The main patch-test allergen producers now market extra series, although these may have to be further adapted to local habits or occupational exposures. Allergens provided by commercial allergen manufacturers tend to be of pharmaceutical grade, and may be negative when the actual sensitizer is an impurity in a commercial-grade product.

Other materials

Commercially produced patch-test allergens, either singly or in small numbers, may be applied where relevant. Patients may bring a wide variety of materials of their own from home or work for testing and, as mentioned previously, these must be thoroughly assessed and diluted appropriately before being tested.

Concentrations and vehicles for patch testing

Recommended patch-test concentrations and vehicles for many different materials, including specific chemicals, chemical groups and substances, and finished products, have been collated in a number of standard contact dermatitis references as outlined below. Most (but not necessarily all) of these lists are reliable, in that the stated concentrations do not usually give an irritant effect. Before patch testing with any unfamiliar material, the appropriate vehicle and concentration should be sought from one or more of these databases.

Photopatch testing [1]

Indications

The main clinical indication for photopatch tests is in the investigation of patients with eczematous eruptions predominantly affecting light-exposed sites, and from whom a history of worsening following sun exposure is obtained. Some patients have coexisting photosensitive disorders, causing practical problems in performing and interpreting the investigation.

Method

A British Photodermatology Group (BPG) workshop has achieved a consensus on the protocol for photopatch testing in the UK and Ireland [1], but the technique may vary slightly in other parts of the world. The BPG states that photopatch testing is an evolving technique with a need for further research.

A UVA source is required, which in most centres will be the UVA lamps used for PUVA therapy [1], commonly a hand/foot treatment unit. In photobiology centres, the more sophisticated irradiation monochromator may be used as an alternative. Other UVA sources include UVA blacklights, and filtered metal halide and xenon arc lamps [1]. In all cases irradiance should be measured with a calibrated UVA meter. The energy source must be monitored regularly, as the tubes deteriorate with time [2].

Historically, administered dosages of UVA to the photopatch-test site have generally ranged from 5 to 10 J/cm^2. However, the higher doses have the disadvantage of being more likely to induce false-positive phototoxic responses without increased detection of photoallergic subjects [3–5], and therefore a dose of 5 J/cm^2 is recommended. Modification of the dose may be necessary in UVA-photosensitive individuals, in which case 50% of the UVA minimal erythema dose is suggested. However, UVA phototesting to establish the minimal erythema dose is not always feasible or practicable, but is nevertheless advised before photopatch testing known photosensitive individuals.

Application of the allergens is performed in an identical fashion to conventional patch tests, except that they must be applied in duplicate—one set is irradiated and the other (the control) is not. Usually, the two sets of tests are applied on either side of the vertebral column at the same level. It is suggested that the patient's back is positioned 15 cm from the front panel of the lamps [1]. Steps must be taken to avoid any incidental irradiation by natural light of both the irradiated and the control set of allergens. The control site and the rest of the skin must be covered with opaque material during irradiation of the photopatch-test site. Three protocols have been used and these are described in Table 20.18. There is no evidence that any of these is superior to the others, although a recent study has failed to show an improved return with UVB irradiation or with a 7-day reading [6].

Test materials

A positive reaction on the irradiated side only is an indication of photoallergy. There are occasional difficulties distinguishing a false-positive phototoxic reaction from photoallergy but this is less likely with a dose of 5 J/cm^2. Readings are scored identically to conventional patch tests but the positive symbol is preceded by the prefix Ph, for example Ph++ is a strong positive photoallergic reaction. If the same allergen provokes an equally strong reaction on both sides, it is an indication of contact allergy alone; if it is significantly stronger on the irradiated side, then combined allergy and photocontact allergy may be occurring [7]. Doubtful and slight amplification of photoallergic reactions may be the result of phototoxicity.

The principle of a standard series also applies to photopatch tests. Having considered the available evidence, the BPG recommended just six compounds for a standard photopatch-test series, five UV filters and musk ambrette. The latter, although no longer incorporated into perfumed materials in the western world, was felt to be relevant to

Table 20.19 Photopatch-test standard series. (From British Photodermatology Group [1].)

Substance*	Concentration (%) in petrolatum
p-Aminobenzoic acid (PABA)	10.0
Octyl dimethyl PABA	10.0
Octyl methoxycinnamate	10.0
Benzophenone 3	10.0
Butyl methoxydibenzoylmethane	10.0
Musk ambrette†	5.0

* A more extensive series of UV filters and photosensitizers may now be appropriate for some centres.
† Musk ambrette is no longer thought to be a significant problem.

imported fragranced materials. This series is listed in Table 20.19. However, for some centres a more extensive series of UV filters and other photoallergens may be advisable according to the potential exposures in different populations [8].

Complications of patch and photopatch tests (Table 20.20)

Generally, the risks of patch testing when it is performed correctly are minimal, but there are a number of potential complications outlined below.

Positive reactions may spread locally and cause a flare of contact dermatitis at the original site or more generally. The long strips of adhesive semi-occlusive tape, which preclude bathing for several days, may lead to eczema, itching or folliculitis, especially with high temperature and humidity. In warm weather there may be leakage of the test materials on to clothing and patients should be advised to wear an old shirt or blouse during the test. Irritants at excessive concentrations may induce caustic burns and scarring, and even a strong allergic reaction might leave a scar on extremely rare occasions. Secondary infection of a positive reaction is virtually never a problem.

Table 20.20 Potential complications of patch testing.

Pruritus
Folliculitis
Leakage of materials on to clothing, especially dyes
Localized flare of dermatitis
Flare of dermatitis at previous contact sites
Generalized flare of dermatitis
Irritant reactions from patients' own inappropriately diluted products
Active sensitization
Pigmentation or depigmentation
Scarring
Anaphylaxis (very rare)

Fig. 20.31 Persistent hypopigmentation after patch tests.

Short-term post-inflammatory hypopigmentation does occur occasionally in positive patch tests, but more permanent hypopigmentation may develop from patch testing some quinones, phenols and dental acrylics, as well as by koebnerization of vitiligo (Fig. 20.31) [1–3]. Post-inflammatory hyperpigmentation may also develop, although this is usually temporary. Phototoxic substances may cause pigmentation if exposed to UV light, for example at photopatch tests or from natural sunlight [4].

Short-lived, non-immunological, urticarial reactions are common, particularly from cinnamates and sorbic acid. More importantly, anaphylactic reactions are a potential risk when patch testing with some materials, especially rubber latex [5] and penicillin [6]. A history of immediate hypersensitivity to rubber should be sought before patch testing with latex.

Active sensitization

Patch testing involves a small risk of sensitization. A reaction appearing 7 or more days after the application

may indicate either delayed expression of a pre-existing sensitivity or sensitization from the patch test. However, some late reactions, occurring up to 14 days after application of patch tests, are weak sensitivities from poorly penetrating allergens. Active sensitization usually presents as a strong positive patch test occurring at around 3 weeks [7]. Few clinics observe their patients long enough to note such reactions, but patients report them. The true incidence of sensitization is therefore difficult to establish, because even re-examination of a random sample of the patients tested [8] cannot differentiate between those sensitized by patch testing and those whose pre-existing subliminal sensitivity has been boosted by further exposure from patch testing. Patch-test sensitization from most routinely tested substances is very uncommon, and occurs more frequently when new substances are being investigated to ascertain the correct patch-test concentration [9]. Sensitization is also more common when testing with unrefined wood or plant extracts or with material provided by the patient.

Testing itself may cause a reawakening of sensitivity. However, the practical consequences of this are uncertain. Patients who can be resensitized by patch tests must also be easily resensitized by contact with the allergen under everyday conditions.

Such induced sensitivity tends to fade relatively quickly, and the patient's clinical course does not appear to be adversely affected. These rare adverse events are usually of no long-term consequence and must be balanced against the benefits of finding one or more relevant allergens.

Multiple patch-test reactions [1–6]

The finding of multiple positive patch tests is common, and it is important to consider the reasons for this so that the correct advice can be given to the patient. The main explanations are:

1 non-specific hyperreactivity;
2 multiple primary hypersensitivities;
3 cross-reactions (true and false).

Non-specific hyperreactivity [7,8]

Ideally, patch tests should be applied at a concentration that always identifies the allergen and never induces false-positive reactions. Unfortunately, some allergens have to be applied at a concentration that is marginally irritant in some subjects in order that allergic positive reactions are not missed. The threshold at which a false-positive irritant reaction develops differs from individual to individual and may even be variable in the same subject [9]. During active dermatitis, uninvolved skin, even at distant body sites, exhibits increased susceptibility to irritant reactions [7]. This 'status eczematicus' [2,7] may lead to false-positive patch-test results. It has become a well-established tenet that 'eczema creates eczema' [8], and that a strongly positive patch-test reaction [10] or four positive patch tests [11] may induce other non-specific false-positive patch-test reactions. When this affects adjacent patch-test sites it is often referred to as 'spillover' [12], 'excited skin' [13] or 'angry back' [6,7,10,14]. Rietschel [15] has proposed that 'stochastic resonance' may be involved. This suggests that there is signal amplification of immune-mediated events by neurological influence. False-positive reactions occur more readily with marginally irritant chemicals, and the incidence has been variously assessed as 8.6% [16] to 63.5% [10,14,17–20]. In view of this, it has been proposed that repeat patch tests should be undertaken in all individuals with three or more strong positive allergic reactions, with exclusion of the strongest reactants. However, other studies [21,22] have not found evidence to support a concept of non-specific hypersensitivity.

The occurrence of weak false-positive patch-test reactions can be reduced by delaying patch testing until all active eczema has settled [16]. As skin hyperirritability may persist for some weeks or months, even when a dermatitis has resolved [14,23,24], this is often impractical.

Multiple primary hypersensitivities

Multiple primary specific (or concomitant) sensitivities to substances that are unrelated chemically are frequent among patients with contact dermatitis. Among 5000 Scandinavian patients, they occurred in 20% of all persons tested. The reason why some patients develop multiple sensitivities and others do not is not clear. Patients with a long history of dermatitis are those most likely to accumulate several primary sensitivities, because of the opportunities to encounter new allergens under conditions favourable for sensitization [25]. Patients with leg ulcers [12,26] are especially prone to developing multiple allergies, as are patients with chronic actinic dermatitis [27].

One sensitivity may predispose to the acquisition of another, and there may be a genetic or constitutional predisposition to acquire sensitivities [19,28]. In one study of patients with leg ulcers, although multiple sensitivities occurred more commonly than might be predicted from their individual prevalence, it was suggested that this reflected duration of exposure rather than the theory of systemic ampliative allergy [12].

Sensitization is facilitated if an allergen is applied on injured (e.g. eczematous) skin [29], and such local factors may be sufficient to explain the frequency of sensitivity to topical medicaments and simultaneous sensitivity to several constituents. In dermatitis from applied medicaments, concomitant sensitivity to both an antibiotic and a component of the vehicle is quite common.

Different materials may contain more than one allergenic substance, and exposure therefore occurs simultaneously. In rubber dermatitis, sensitivity to unrelated vulcanizing agents is not unusual. Cobalt and nickel are difficult to separate, and thus cobalt commonly contains traces of nickel, and nickel traces of cobalt. Sensitivity may be caused by either or both. Patients sensitive only to cobalt often have dermatitis from nickel-plated objects and give positive reactions to patch tests with nickel of commercial quality [30]. Combined cobalt and chromate allergy is common among cement workers. However, closeness in the periodic table is a hypothesis put forward to explain the finding of palladium sensitivity in a high proportion of individuals with a strong positive reaction to nickel [31].

In dermatitis of the feet, concomitant sensitivity to chromate, rubber and dyes in shoes or stockings presents a particularly difficult clinical problem; one allergen may be primarily responsible but others are important in maintaining the eczematous state. The inflammatory response to allergens has been shown to be additive [32], as has the response to an allergen and an irritant [33].

Cross-reactions [4]

Cross-sensitization is defined as the phenomenon where sensitization engendered by one compound, the primary allergen, extends to one or more other compounds, the secondary allergens, as a result of structural similarity. The proposal is that the primary and secondary allergens are so closely related that sensitized T cells are unable to distinguish between them, and therefore react as if the compounds were identical. However, as we now assume that T-cell sensitivity is specific then the basis of the conclusions in many of the older publications [3,34,35] may be in doubt [1,36]. Contaminants may cause 'false' cross-sensitivity, and one substance may contain traces of another. In studies of cross-sensitivity, absolutely pure test substances must be used. Few investigations in the past have fulfilled these requirements and most should be repeated using modern methods of separation. Enantiospecificity or stereospecificity may lead to cross-reactivity with some isomers and not others [36]. Examples include usnic acid, 4-methoxydalbergiones and frullanolides. A computerized resource has been used for the systematic evaluation of structure–activity relationships [37].

However, poor solubility and other physical factors may prevent demonstration of cross-sensitization between substances with structural formulae which, to a dermatologist, might suggest a chemical similarity. Patients sensitive to both isoeugenol and cinnamic acid never react to ferulic acid, which might seem to be a hybrid of the two. The side-chain of isoeugenol is lipophilic and the phenolic ring hydrophilic; the side-chain of cinnamic acid is hydrophilic and the benzene ring lipophilic. Ferulic acid, with hydrophilic groups both in the ring and the side-chain, cannot imitate either of them if, somewhere in the development of the reaction, a distribution on a lipid–water interface is involved [25]. Similar physical properties are assumed to determine the nature of the secondary allergens in *Toxicodendron* spp. sensitization [38,39].

In simultaneous sensitivity to natural products such as perfumes, balsams and wood tars, it is impossible to decide whether reactions to several of the substances may be due to related or identical chemicals. Cinnamic aldehydes, for example, may occur in them all. The same applies to plants such as Compositae and *Frullania*, and to patients sensitive to *Toxicodendron* spp.

Other tests

Occlusive patch testing has stood the test of time. Although it is an artificial procedure, it has not been superseded. Nevertheless, alternatives continue to be sought and some of these may be useful adjunctive investigations.

Open tests

Patch testing is usually performed with the test site occluded, in order to increase percutaneous absorption. This is an artificial procedure, and clinical exposure might be more closely simulated by simple application of the sensitizer to uninvolved skin. However, few allergens provoke a dermatitis with a single exposure on normal skin. It is seen in *Primula* dermatitis, some patients having positive, even bullous, reactions to an open patch test to the leaf [1]. In most cases of clinical contact dermatitis, however, the allergen gradually accumulates in the epidermis, and irritants and mechanical injury promote its absorption. These conditions are not readily reproduced in a test procedure.

In highly sensitive individuals, allergens with good penetration can produce positive reactions in an open test, although the concentrations used for testing must be much higher than those used in a closed test. Thus, potassium dichromate 5% in water and nickel chloride 10–20% in alcohol [2] provoke a positive reaction in many chromate- or nickel-sensitive persons. Positive reactions often develop in a few hours [2].

The technique is simple [3]: the liquid test substance is dropped on an area of skin measuring about 1 cm in diameter and the solution is allowed to dry. The time for reading and the characteristics of the reaction are the same as for closed patch testing. The reaction can be followed from the start and may develop sooner than with a closed patch-test reaction [2]. It is often weaker, and a positive reaction, especially in the initial phase, may consist of isolated papules only.

One area where open testing has been widely used and advocated is prior to dyeing hair. Application of the dye to the retro-auricular area and examination of the site 2 days later has now been confirmed as an accurate method of detecting sensitized subjects [4]. However, hairdressers and individual users tend to do this only once and not each time the hair is tinted, and often they mistakenly undertake a 30-min reading. They may therefore miss the allergy if it develops subsequently.

With irritants, the reactions are also usually fewer and weaker in open than in closed patch testing because of reduced absorption [5]. Open tests are therefore sometimes used as a preliminary screening procedure with less well-known substances to reduce the risk of severe reactions. However, experience with open tests is limited and the risk of sensitization cannot always be estimated.

Usage tests

In cases of doubt, when either a closed patch test or open test is negative yet the history suggests a contact dermatitis, the patient can be asked to use the preparation again. This is especially helpful with cosmetic and clothing

dermatitis. Because it reproduces all the other factors associated with the original dermatitis, for example sweating, friction and application of allergen on damaged or presensitized skin, it is sometimes positive when conventional patch tests fail to reveal a sensitivity. However, it is not always possible to differentiate between an allergic and a non-specific or irritant response. With cosmetic preparations or medicaments, a repeat 'dab' test may be performed on previously affected skin.

Repeat open application tests [6]

In this test, substances are applied twice daily for 7 days and sometimes beyond, or until an eczematous reaction develops. The most appropriate site is the upper arm or flexor surface of the forearm, as patients can perform the test and observe any developing reaction. They should be told to discontinue the application if eczema occurs. An area of at least 5 cm^2 should be employed. The test may be used to determine the relevance of doubtful positive patch-test reactions to preparations in which the putative allergen is present in a low concentration, although false-negative results may occur [7]. It may also establish the clinical relevance of such products and confirm the source of the allergy [8–11]. A scale for recording ROAT reactions has been proposed and advocated [12].

Intradermal tests

Intracutaneous tests, as used in tuberculin sensitivity, have also been performed with simple chemicals, although mainly for investigative purposes. Within 1 day erythema and swelling appear at the site of injection. Later, usually after 2–4 days, papules or vesicles may develop. Sometimes, a flare may be seen shortly after the injection, and this lasts a few hours [13]. Over the next few days, erythema and infiltration are sometimes seen along the lymphatics leading from the test site.

Technical pitfalls with intracutaneous testing are numerous, as is known from extensive studies with tuberculin [14]. Too deep an injection will result in negative reactions. An immediate reaction, which is not a rarity with metal salts, may result in dilution and removal of the test substance. The concentrations employed should be at least 10–100 times lower than those used for epicutaneous testing [15,16]. In cases of extreme sensitivity, the concentration may need to be 1000–10 000 times lower.

The technique has proved reliable for nickel [2] and may identify corticosteroid allergy in patients with false-negative patch tests [17,18].

In vitro tests [1]

The principle of diagnosing contact allergy by *in vitro* testing is attractive, although the use of peripheral blood as a routine investigation for contact dermatitis may not be viable, not only from the budgetary point of view but also for logistical and practical reasons [2]. Nevertheless, attempts continue to be made to achieve this, albeit with single or small numbers of allergens. A number of different techniques have been tried and these are described below.

As yet, none of these tests is a substitute for the *in vivo* system of the challenge patch test. However, they may be helpful in elucidation of the immune cascade as they are based on measurements of products from T-cell activation. What is needed is a system to detect the presence of specific memory helper T-cell subsets within the skin or circulation.

Migration inhibition test

Migration inhibition factor is a soluble factor released by sensitized lymphocytes following stimulation. It inhibits the migration of monocytes and macrophages but not

polymorphonuclear leukocytes [3]. A direct and indirect assay is performed and the results expressed as a migration index. The test has been employed in nickel and chromate allergy, but is not completely reliable as there is overlap between sensitized and non-sensitized patients. Interference may be caused by a cytotoxic action of the allergens, and concentrations have to be optimum at just below non-toxic levels. The investigation was not reliable as an investigation for medicament contact allergy [4] but a capillary tube assay has been demonstrated to be of practical clinical value for diagnosing chromium allergy [5]. The method needs further investigation and refinement [6,7].

Lymphocyte transformation tests

Antigens are able to induce specific transformation of lymphocytes to large lymphoblasts, culminating in mitosis [8]. Most work has been carried out on nickel allergy [9,10], although there are conflicting accounts of the optimum stimulatory concentration of nickel and the method of preparation of cells following culture for radioactive thymidine uptake assays. Nickel may induce non-specific transformation in non-allergic subjects [11], but several groups of investigators have reported a significant difference between lymphocyte transformation in nickel-sensitive patients and controls [9,10,12,13]. Other standard-series allergens investigated, with potentially promising results, include chromate, PPD, neomycin sulphate and thiuram [14,15]. On the other hand, tests with a range of medicament allergens failed to reach statistical significance [4]. This investigation may be useful for investigating cross-reactivity patterns [16], although considerably more work is required before it can be regarded as a routine diagnostic test.

Leukocyte procoagulant activity

When stimulated by an antigen, leukocytes produce a significant level of procoagulant that activates the extrinsic cascade of blood clotting. The production of fibrin may explain the inhibition of macrophage migration. The activity is measured as a ratio of the clotting time of plasma incubated with cells, with and without antigen. It has been used in nickel-sensitive patients [17], when the procoagulant activity increased as the stimulatory nickel concentration increased. Interferon-γ (immune interferon; previously called macrophage activity factor) has modulatory effects on immune function, which are important in the transfer of antigenic information to T lymphocytes. It also has antiviral potential. It is employed in an assay to measure activity after incubating lymphocyte suspensions from hypersensitive patients, or controls, with the antigen. Conflicting results have been reported.

Spot tests [1]

Two spot tests are of particular practical value in the patch-test clinic as the materials are easy to handle and store.

Dimethylglyoxime test for nickel [1–3]

Dimethylglyoxime 1% (alcoholic solution) and ammonium hydroxide (aqueous solution) are stored in separate bottles. A few drops of each are put in separate clean white saucers, a cotton bud is then dipped in each of these and rubbed on the surface of the test object. A pink coloration on the cotton bud denotes the presence of nickel (Fig. 20.32). This test is accurate to 10 ppm of nickel, but the immune system may be able to detect lower levels

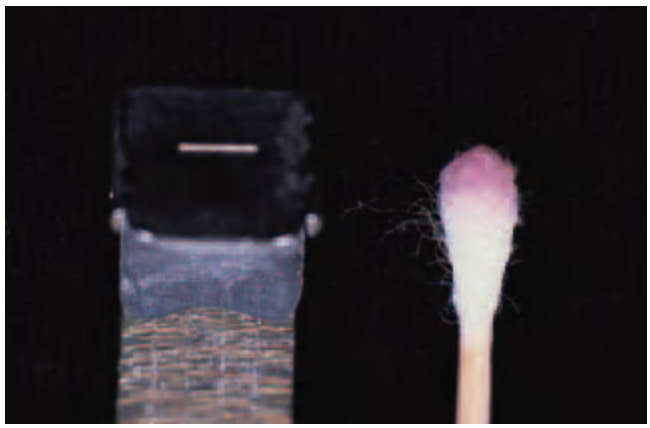

Fig. 20.32 Dimethylglyoxime test: a pink colour is detected when metals release a significant amount of nickel. (Courtesy of Dr J.D. Wilkinson, Amersham General Hospital, Amersham, UK.)

than this. It is a very useful test, and patients can be given kits to test items in the home and at work.

Acetylacetone method for formaldehyde [4]

The reagent is prepared by dissolving 15 g of ammonium acetate, 0.2 mL of acetylacetone and 0.3 mL of glacial acetic acid in 100 mL of distilled water. It can then be stored in a refrigerator. A sample (1 mL or 1 mg) of the product to be tested is put in a disposable glass test tube and 2.5 mL of the reagent is added. The mixture is shaken and stoppered and then placed in a water bath at 60°C for 10 min. A yellow colour is produced in the presence of formaldehyde, due to the formation of 3,5-diacetyl-1,4-dihydrolutidine. The alternative chromotropic acid method is less specific.

Other analyses

There are other spot tests for chromate [1] and epoxy resin [5] but these are not simple to perform during a clinic. More sophisticated tests such as chromatography, spectrophotometry, mass spectrometry and nuclear magnetic resonance spectroscopy require specialized equipment and expertise.

Prevention [1]

Many statutory bodies have a role in the prevention of contact dermatitis, including medical personnel, legislative bodies, central and local government, corporate industry, the media, surveillance and consumer bodies, and patient support groups. Principles of prevention can be related to two categories, individual and collective, and further divided into primary, secondary and tertiary. Primary prevention focuses on the induction of contact sensitization and control of exposure. Secondary prevention relates to elicitation, and tertiary to measures for established and continuing dermatitis. Some of the more important elements of prevention are discussed below; the reader is referred to Lachapelle's overview for more detailed coverage [1].

Allergen containment and replacement [2]

Potent allergens encountered in industry can be kept in closed systems, thereby avoiding the potential for direct skin contact [3]. In other instances products can be kept in special containers, which allow a no-touch technique when using the contents [4,5]. Replacement and elimination of potential allergenic hazards can be helpful in both the domestic and working environments, for example perfume-free cosmetics and medicaments, non-latex gloves, high-molecular-weight epoxy resins [6], and white spirit instead of turpentine.

Legal and other regulatory measures [7]

Regulatory measures can influence the incidence of dermatitis [8,9]. They may be legally or voluntarily enforced. The EU has passed a number of directives relating to contact dermatitis, particularly in relation to nickel and cosmetics.

As most consumers are primarily sensitized to nickel either following ear piercing [10] or by prolonged close contact with nickel-releasing alloys, it was proposed that such items should not release more than 0.5 μg/cm^2/week of nickel [11,12]. Ten per cent of the female population of Europe and the USA are sensitive to nickel [13], and this has significant implications with regard to hand eczema [14–16] and employment [17]; hence, nickel sensitivity is an issue where legal restraints could prove effective in improving the health of the population. Following the lead of Denmark and Sweden, the Nickel Directive was introduced with the aim of primary and secondary prevention of the presently high levels of nickel allergy in the EU [7]. The recommendations are summarized in Table 20.3. A Danish follow-up study comparing 1985–86 with 1997–98 patterns of nickel sensitization has already shown a decrease in allergy from 24.8% to 9.2% in the

tested populations aged 0–18 [9]. A debate continues over the wisdom of allowing certain recently introduced Euro coins to contain nickel [18–20].

The Cosmetics Directive lists materials allowed, not allowed and restricted. For instance, the preservative MCI/MI is not permitted above 15 ppm [7]. Enforced ingredient labelling on the packaging of cosmetics, which is also a requirement in the USA, has been a major factor in enabling avoidance of cosmetic allergens by sensitized customers [21]. Concern continues over the lack of labelling of components of fragrances, which are identified by the term 'parfum'. Natural ingredients, including plant extracts, must be denoted by their Linnaean name, which may confuse some individuals who are allergic to plant-derived components of cosmetics, including some perfumes.

The Directives on Dangerous Substances and Dangerous Preparations list 360 skin sensitizers and their concentration limits (e.g. formaldehyde 0.2%, acrylates 0.5–2%). A chemical product containing a classified skin sensitizer above 1% concentration must be labelled with the risk phrase 'R43—may cause sensitization by skin contact' [7]. For many substances 1% is above the level of sensitization and elicitation of contact dermatitis. The usefulness of labelling in this unselective quantitative way has been questioned [22].

Dermatitis accounts for a significant proportion of occupational disease [23]. Allergy to chromate in cement is a significant problem in the construction industry [24]. For over 10 years some Scandinavian countries have restricted hexavalent chromium in cement to below 2 ppm [7], which is achieved by adding ferrous sulphate. There is already evidence in these countries of a reduced prevalence of chromate allergy and hand dermatitis [8], which can be a cause of significant persistent disability [24].

Some legislation may apply only to one or a few countries. For instance, the use of PPD in hair dyes is forbidden in some countries and controlled in many others, bithionol in toiletries is forbidden in the USA, and dibromosalicylanilide in Germany. Formaldehyde in clothing is limited in Finland [7]. Prohibition of persulphate improvers in flour in Denmark (1938) and Germany (1956) led to a striking decline in bakers' dermatitis in both countries [25]. In Germany, the use of turpentine for paint is strictly limited [26,27].

In the UK, the assessment and monitoring of hazards and risks at work has improved following the introduction of Control of Substances Hazardous to Health (COSHH) legislation, but attention to dermatitis checks and risks is still suboptimal [28]. In addition, the HSE have a statutory right to investigate skin problems at work through the employment and medical advisory service (EMAS), provided they are reported [29].

Corporate responsibility

Although legal measures can influence the incidence of dermatitis, few have been introduced. In many instances governments will not intervene with legislation, relying on self-regulation, and this includes the cosmetic and pharmaceutical industries. The withdrawal of musk ambrette is an example of cosmetic industry self-regulation.

Manufacturers of all goods should ensure that their products are safe to use. Dermatologists and consumers have a role in reporting adverse events to the manufacturers, who should respond to any concerns. Surveillance systems, particularly of occupational dermatitis [30–32], and rapid computerized analysis of epidemiological information, with feedback to interested parties, can provide early warning of new allergens and sources of work-related dermatoses [33–35].

Risk assessments should be undertaken before a new product is placed on the market, including its potential for allergenicity. A product must be clearly labelled to ensure that it is handled safely.

Work

The preventative aspects of occupational contact dermatitis are discussed in detail in Chapter 21.

Domestic

The availability of modern domestic equipment should significantly reduce skin contact with irritants and potential sensitizers in the home; however, housewives are still one of the greatest 'at-risk' groups as far as the development of hand dermatitis is concerned. Cotton-lined gloves should be worn when the hands are in contact with irritants, including food, cleaning agents and polishes. Plastic gloves are less allergenic than rubber but are less pliable and malleable.

Education

Education of the community and workforces through the media, courses, lectures and wall charts in public places (including medical waiting areas) and at work will help to promote awareness of the problem of contact dermatitis. Patient support groups have played an increasing role in education of the public as well as those suffering from dermatitis.

Management [1,2]

Avoidance advice

A diagnosis of allergic contact dermatitis is reached on the basis of a detailed history and examination followed by patch tests, with an assessment of the relevance of any positive reactions. Once a diagnosis has been made, possible sources of exposure to the causative allergen(s) should be identified, and avoidance advice given. The first principle of management is to give advice on avoidance tailored to an individual. Examples of specific avoidance measures include plastic instead of rubber gloves, cosmetics and medicaments free of an identified allergen, and clothing free of nickel-containing studs, zips, etc. More general written information on the allergen sources may be helpful, but may also be confusing if many are not relevant to that person. In some instances, particularly of work-related problems, appropriate protective clothing or changes in handling technique may be advised. Materials used for protection, especially gloves, should not allow penetration of the allergen responsible for the dermatitis.

Ideally, the result of this advice will be resolution of dermatitis, but this does not always occur, and other factors, such as the possible contribution of irritant or constitutional eczemas to persistence of the problem, should be considered and discussed with the patient. Reassessment and reinforcement of avoidance measures is often required, sometimes repeatedly, in order that patients are fully aware of what action they should take. In some patients continued exposure is unavoidable but can be reduced to a sufficient degree to keep the dermatitis at an acceptable level. It is advisable to stress that allergy does not disappear when the dermatitis clears but that the risk of relapse after further contact with the allergen persists throughout life.

Active treatment

The mainstay of treatment of allergic contact dermatitis is avoidance of the causative factor(s), although topical corticosteroids will be required in most instances to control the disorder. The manner in which they are used will vary, and optimum regimens have yet to be established [3]. In acute, severe, localized allergic contact dermatitis a potent topical corticosteroid should be used. In more chronic or widespread contact allergies the potency may need to be reduced, and for long-term use in certain sites

(face, genitals and flexures) mild topical corticosteroids are indicated. On the palms and soles, the longer-term intermittent use of a potent corticosteroid preparation is usually beneficial and well tolerated [4].

General principles of eczema treatment should be followed, with regular and liberal use of hydrating emollients [5,6] and soap substitutes. Fissures of the fingers, palms and soles can be covered with hypoallergenic tape. Alternatively, zinc and salicylic acid paste BPC twice daily may be helpful, and cyanoacrylates (superglues) have been used with benefit by some dermatologists [2].

For acute weeping forms of allergic contact dermatitis, wet dressings with saline, aluminium acetate or silver nitrate (0.5%; stains black) may be of benefit. Potassium permanganate 1 in 8000 in warm water is helpful when used four times a day as a soak for vesiculobullous eruptions of the palms and soles. Brown staining of the skin and nails is a problem, and the treatment should be stopped when the affected areas become dry.

New topical ascomycin derivatives [7,8], which act as immunomodulating agents, are now being introduced for the treatment of atopic eczema, and there is also evidence of their benefit in allergic contact dermatitis in animal studies [7–9]. Topical tacrolimus was introduced in the UK in 2002 and is expected to be followed by pimecrolimus. These agents are considerably more expensive than topical corticosteroids.

Secondary infection will require antibiotics, and a sedative antihistamine is indicated for pruritus, particularly at night. In severe or widespread eruptions, systemic steroids may be necessary [10].

Recalcitrant disabling cases may require consideration of immunosuppressive therapy such as azathioprine [11–13] and ciclosporin. Assessment of thiopurine methyltransferase levels should be performed before undertaking treatment with azathioprine [14]. The investigation will identify a subset of patients potentially at high risk of myelotoxicity from this treatment. There is evidence in animals that ciclosporin [15] suppresses allergic contact dermatitis, but most reported clinical studies have been undertaken on chronic hand eczemas of mixed aetiology [16–18].

It has been reported that certain patterns, especially vesicular palmar eczema, have benefited from dietary avoidance or reduction in intake of allergen, most notably nickel and balsams, in sensitized subjects [19–23]. The effects of a low-nickel diet have been disappointing in our hands; nevertheless, there are strong advocates of these measures. Dietary chelation of nickel has also been attempted [24,25], but is not widely used in practice because of side effects [24].

Dietary manoeuvres have also been reported to be helpful for cheilitis and oral symptoms, particularly in those with positive patch tests to balsam of Peru, cinnamates, eugenol, colophony, flavours and antioxidants [26–30], although the relationship between 'burning mouth' and contact allergy is questionable [31,32].

Superficial X-rays and Grenz rays, which have been shown to suppress experimental contact dermatitis [33], can be safely used for localized dermatitis, although facilities for this treatment are gradually dwindling in the UK [34–36]. Phototherapy, both PUVA and UVB, is helpful in some subjects [37–39], including Compositae-allergic individuals with photosensitivity [40].

The use of barrier creams as preventatives in already sensitized persons is generally unsatisfactory. However, there is documented evidence of the value of products containing quaternium-18 bentonite in the prevention of *Toxicodendron* spp. dermatitis [2,41]. Other barrier creams containing active agents (e.g. chelating agents) against specific allergens may have future potential [42–44]. In one study clioquinol was the most effective agent at preventing nickel dermatitis [43].

Hyposensitization [45]

Many attempts have been made to down-regulate the immune response to allergens in an already sensitized individual. This has proved difficult to realize in practice. The degree of hyposensitization achieved by oral doses of allergens is limited and transient, for example DNCB and chromate in guinea pigs [46,47], and poison ivy in humans [48]. Although it has been attempted for *Toxicodendron* spp. allergy [49–51], oral hyposensitization is not routinely recommended [2,52]. Some success has nevertheless been claimed in India for hyposensitization against *Parthenium hysterophorus* [53].

Prognosis

The prognosis of allergic contact dermatitis depends on its cause and the feasibility of avoiding repeated or continued exposure to the causative allergen. Associated irritant dermatitis and constitutional factors are also important. Most studies suggest age of onset is not important prognostically for occupational dermatitis [1–3], although a recent UK study showed that older atopic individuals are less likely to improve, and those with allergic contact dermatitis are more likely to have time off work [4].

The prognosis is relatively poor for those allergic to nickel [5] and chromate [1,6,7], probably as a result of their ubiquity in the environment, even though most chromate studies have involved those with occupational dermatitis, which is a selective group. It has been suggested that dietary nickel [8] and chromate [9] exposure might be responsible for the chronicity, but this is disputed [10]. There is a better outlook for those allergic to materials that are easy to identify and avoid, and often the dermatitis will resolve within a few weeks if conscientious avoidance measures are taken. This was exemplified by a European joint study where the sources of contact with allergens could be traced in only 35% of those who reacted to colophony but in 85% of those sensitive to tetramethylthiuram disulphide. The reason for the limited success with colophony was probably lack of knowledge of the sources of this sensitizer [11]. It is also clear from a number of studies that poor compliance and understanding results in a higher rate of ongoing exposure to the

causative allergen, and is associated with a worse prognosis [12–14].

As the skin integrity is compromised, there are enhanced opportunities for new sensitivities to medicaments or other substances to develop during the course of dermatitis. Sensitivity to rubber gloves may complicate pre-existing dermatitis of the hands. Such allergies are revealed only by repeat patch tests. During a long course of relapsing dermatitis, sensitivity to various allergens may accumulate, and this increases the risk of recurrence or persistence [15].

Contact dermatitis of the hands is often of mixed origin, with alternating or simultaneous exposure to allergens and irritants. In a study of the prevalence of dermatitis of the hands, half the patients had suffered from their dermatitis for more than 5 years. When 408 of them were followed up after 6–22 months, one-quarter had healed completely, half had improved and one-quarter were unchanged or worse. There was no difference in prognosis between irritant and allergic dermatitis [16]. A change of occupation does not necessarily alter the prognosis of occupational hand dermatitis [6,10,17–21].

Once acquired, contact sensitivity tends to persist [22]. The degree of sensitivity may decline unless boosted by repeated exposure, but with a high initial level of sensitivity it often remains demonstrable even several years later [23]. Sensitivity to ubiquitous allergens, such as nickel and chromate [24], and to strong allergens, such as primin and PPD [25], is reported to persist, whereas sensitivity to other weaker and avoidable allergens may disappear. Patterns of cross-sensitization tend to persist [26]. New sensitivities to additional allergens may be acquired subsequently.

Relapse or chronicity is due not only to unavoidable or unrecognized re-exposure to allergens and irritants but also to other contributory mechanisms [27,28].

1 The barrier function of the skin is impaired for months after an attack of dermatitis. Recovery is prevented by exposure to allergens or irritants in concentrations that might well be tolerated by normal skin.

2 Inappropriate treatment, including the overzealous use of cleansers and antiseptics, and the use of sensitizing popular or herbal remedies may also prolong the course of dermatitis.

3 Ingestion of allergens.

4 Secondary infection, especially with dermatitis of the hands. Microbial allergy may also be a factor in some eczemas [11].

5 Contact sensitivity has been thought in some cases to involve sensitization to the protein moiety ('protigen') of the hapten–protein conjugate. On this assumption, autosensitization might account for chronicity.

6 Stress is common in chronic dermatitis and may be both a consequence of and a trigger for eczema.

7 Constitutional factors predispose to chronicity.

8 There appears to be an 'inherent tendency' in almost any eczema to become continuous and chronic, but the factors causing this are unknown [28].

Immune contact urticaria

Contact urticaria may be non-immune or immune due to IgE antibodies against protein peptides. Immune contact

urticaria is commoner in, but not exclusive to, atopic individuals [1,2].

REFERENCES

1 Wakelin SH. Contact urticaria. *Clin Exp Dermatol* 2001; **26**: 132–6.

Pathogenesis

The pathogenesis of urticaria is discussed in more detail in Chapter 47. In a previously sensitized individual, the protein allergens react with IgE molecules on mast-cell membranes, releasing vasoactive substances, including histamine.

It has been reported that patients with atopic dermatitis and raised IgE levels have IgE on the surface of Langerhans' cells. This does not occur in atopic individuals with normal IgE levels or non-atopic controls [1,2]. This may explain why patients with atopic dermatitis have delayed hypersensitivity on patch testing to aeroallergens and develop a vesicular response to handling food proteins (protein contact dermatitis).

Clinical features

The symptoms usually occur within 1 h and fade by 3 h. The spectrum of associated symptoms is wide. Local symptoms are itching and burning, with the development of erythema and the characteristic weal and flare reaction. Early symptoms are commonly missed by physicians although well recognized by patients.

Exposure to allergens in those who are highly sensitized, topically or via the oral or respiratory route, may result in widespread urticaria [1] and swelling of mucous membranes, resulting in conjunctivitis, rhinitis, oropharyngeal swelling, bronchoconstriction and anaphylaxis.

Contact urticaria to foodstuffs

The commonest causes of contact urticaria are foodstuffs, which can provoke orolaryngeal symptoms from ingestion or hand symptoms in food handlers [2], such as fish processors [3] and slaughterhouse workers [2]. The diverse range of compounds includes fruit and vegetables [4], potato [5], eggs [6], fish [7], some medicaments [8,9], teak [10], *Myroxylon pereirae* [11], silk [12], animal saliva [13] and dander [14], and human sweat and semen [15]. In Scandinavia there is a strong association between the incidence of birch-pollen allergy and contact urticaria to fruit and vegetables, which is due to the presence of similar peptides [16]. Birch pollen is a common aeroallergen in Scandinavia, whereas in the UK the commonest aeroallergens are house-dust mite antigen and grass pollen, which may explain why there are fewer reports of contact urticaria in food handlers in the UK. If contact urticaria is confirmed there are recognized cross-reactions between various foodstuffs [17] (Table 20.21).

Contact urticaria to natural rubber latex [18]

Allergy to natural rubber latex was first recognized in 1979 by Nutter [19]. It has become a major health-care issue. The allergens are present in the water-soluble protein moiety of the sap collected from the rubber-bearing tree *Hevea braziliensis*, harvested mainly in Malaya and South-East Asia. The problem has been associated primarily with dipped rubber items [20–23], i.e. those made by dipping a mould or former into a latex solution, such as gloves, condoms, balloons, dummies and teats, catheters and medical tubing. These items are vulcanized at a lower temperature than solid rubber products such as tyres, seals and gaskets.

Since the advent of acquired immune deficiency syndrome (AIDS) and the huge increase in the use of latex examination gloves among health-care personnel, the production of inexpensive disposable natural rubber latex gloves has escalated. During the production process, the natural rubber latex is not left to stand in holding tanks as long, the process has been shortened by lower vulcanization temperatures and there is less thorough washing of the final product [24]. All these measures have led to an increase in the protein content of the gloves and this, coupled with their increasing use, has resulted

Table 20.21 Cross-reactions between foods causing contact urticaria. (From Sicherer [17].)

Food type	Risk (%)	Cross-reaction
Fish, e.g. salmon	5	Other fish, e.g. swordfish, sole
Grain, e.g. wheat	20	Other grains, e.g. barley, rye
Peach	55	Other Rosaceae fruit, e.g. apple, pear, cherry, plum
Melon (cantaloupe)	92	Watermelon, banana, avocado
Fruit (kiwi, avocado, banana)	11	Latex

in an increase in the incidence of allergy to natural rubber latex.

Natural rubber latex allergens are adsorbed on the maize starch powder on latex rubber gloves, and are released into the air when packets are opened or gloves are pulled out of multipack boxes. The allergens contaminate the air, and in operating theatres with recirculated air systems they can be spread to the whole theatre suite and cause unsuspected problems [25]. The use of powder-free gloves prevents contamination of the environment and the development of symptoms in already sensitized individuals [26].

Anaphylaxis can occur in any sensitized patients, and seems to be particularly prevalent when challenge is via mucosal surfaces, as in dental and vaginal examinations, intraperitoneal operations [27], catheter changing (especially in spina bifida patients who have frequent surgery and catheter changes [28]) and barium enemas [29].

The allergenic proteins are multiple. Many of the allergenic peptides in natural rubber latex cross-react with those found in other plants, such as banana [30], lychees [31], chestnuts [32] and avocado, and patients allergic to latex may exhibit sensitivity to such foods [33]. It is possible that some patients were first sensitized by the fruits and have a secondary allergy to latex.

Protein contact dermatitis [34,35]

Patients who have repeated exposure of the hands, especially the fingertips, to contact urticants, such as food proteins, may develop a vesicular eruption or protein contact dermatitis. Characteristically, the condition involves skin sites that have been affected previously by dermatitis. Damaged skin probably facilitates penetration of the allergens, and inflammatory cells already present in the dermis may explain the accelerated clinical response [36]. Many patients have no other signs of atopy. Protein dermatitis is common in dairy workers and veterinarians [37,38], slaughterhouse workers [39], chefs and sandwich makers [40], who become sensitized to the proteins they touch during work. A similar situation has also been reported with latex, both with and without contact urticaria [41,42].

Investigations

Testing is usually performed by a scratch patch test (or a prick test) to the food in question. A small piece of the substance is applied on a closed patch test to an area of skin. The skin may be lightly scarified with a needle or degreased with 96% alcohol [1]. After 20 min the area is examined for erythema or weal and flare. Sometimes, the patient will state that the symptoms are being reproduced well before the end of the test time. Occasionally, there is no reaction on normal skin and the substance has to be applied to previously affected skin, for example the fingertips. Skin testing should be performed with appropriate positive and negative controls. With an unknown allergen, exposure should be graded with initially an application test (open and subsequently occluded) followed by a prick test and, if appropriate, an intradermal test. Although commercial allergen extracts are available, it should be remembered that unless standardized they may not contain the relevant protein allergens, and the gold standard should always be test and challenge with a sample of fresh material. Skin tests should only be performed where resuscitation facilities are available.

If the patient has experienced an anaphylactic reaction and a specific IgE test is available, the blood test may confirm the diagnosis and thus avoid the risk of anaphylaxis as a result of skin tests.

In the case of latex, the specific IgE test is not sensitive and a negative test does not exclude the diagnosis. Although skin tests with glove extracts have been recommended, many gloves now contain low levels of latex protein and prick testing with home-made extracts frequently gives false-negative results. Prick test solutions for latex are commercially available, some of which claim greater than 98% sensitivity and 100% specificity. The final arbiter is a usage test in which a patient wears the suspect glove on a moistened hand and any reaction is observed.

Localized symptomatic dermographism is a common cause of urticaria to gloves in the absence of latex allergy [2]; contact urticaria to rubber chemicals is extremely rare [3].

Management

Management is by means of avoidance or the use of appropriate personal protective equipment, as desensitization for the majority of allergens concerned is not available. Avoidance measures are required for latex articles, especially rubber gloves, condoms, balloons, pacifiers, catheters and other medical tubing. Treatment of the acute episode includes the use of systemic antihistamines and epinephrine (adrenaline), depending on the severity of the attack.

In the case of latex, the use of a 'medic-alert' type bracelet will warn health-care workers should a patient be taken to casualty unconscious. The management of the latex-sensitized individual in the hospital environment can be a particular problem due to the widespread use of natural rubber latex products. Most hospitals are now aware of the problem and maintain a latex-free environment to treat such individuals. Examinations and interventional surgical and radiographic procedures should not be undertaken with latex gloves or equipment.

A change to low-protein gloves has been associated with a reduction in the prevalence of latex contact urticaria among health-care workers [1].

Chapter 21

Occupational Dermatoses

J.S.C. English

Eczematous dermatoses

The occupational aspects of dermatology have attracted increasing attention [1–13]. This has been reflected in the establishment in some countries of special departments of occupational dermatology [3,6]. Full-time and part-time appointments in occupational dermatology now exist in many countries [3]. Occupational dermatoses are common enough and sufficiently disabling to demand a wide knowledge from dermatologists of the noxious agents in various occupations, as well as an understanding of the workings of compensation systems.

Epidemiology

In many countries, loss of income due to occupational illness is compensated more fully than economic hardship from other diseases. Because of the public expenditure involved, governmental and legal definitions of an occupational dermatosis do not always agree with medical concepts.

A medical definition adopted by the Committee on Occupational Dermatoses of the American Medical Association (1939) was: 'An occupational dermatosis is a pathological condition of the skin for which occupational exposure can be shown to be a major causal or contributory factor.' This definition, although comprehensive, does not address the question of attributability to occupation rigorously enough for all purposes. Many dermatologists prefer to limit their concept of occupational dermatoses to 'a skin disease which would not have occurred if the patient had not been doing the work of that occupation' [4].

In practice, lack of knowledge and of diagnostic tests often makes the diagnosis of occupational dermatoses very difficult [4]. Evidence in favour of an occupational origin is [14–17]:

1 Occupational contact with an agent known to have caused similar skin changes in other individuals.
2 Occurrence of similar dermatoses in fellow workers or within the same occupation.
3 Correct time relationship between exposure and dermatitis.
4 Type and site of lesions consistent with information of exposure, and similar to other cases.
5 Attacks of dermatitis appearing after exposure, followed by improvement or clearing after exposure ceases.
6 History and examination corroborated by patch (or sometimes skin prick) test results.

The legal definitions of occupational dermatosis vary considerably from one country to another [18]. In the UK, the majority of occupational dermatoses are defined by Prescribed Disease D5 of the Department of Social Security as 'non-infective dermatitis of external origin (including chrome ulceration of the skin but excluding dermatitis due to ionizing particles or electromagnetic radiations other than radiant heat)'. The disadvantage of this type of definition is that it may exclude certain newly recognized occupational dermatoses, so that these require their own additional definitions. This was necessary in the UK in the case of occupationally acquired hypomelanosis (Prescribed Disease C25) (Chapter 39).

In the assessment of individual cases, the legal attitude revolves around whether the patient could reasonably have been expected to contract the disease if he or she had not been engaged in that particular occupation and type of work [19,20]. In the UK, the compensation that may be obtainable through a legal action is of a higher order of magnitude than that provided by the state system. Patients therefore will frequently seek both forms of compensation. In other European countries, the equivalent regulations vary [18]. Most include infections such as ringworm. Some traditionally reserve compensation for conditions and causative agents specifically listed. This practice is gradually being abandoned because in a period of rapid industrial progress, any list of substances proves too restrictive. In some countries, only some employees are covered by the compensation laws, and self-employed persons are excluded. In spite of its frequency and chronicity, housewives' dermatitis receives no legal compensation.

Outside the workplace, the worker is exposed to the same risk of contact dermatitis as anyone else in the community. Contact dermatitis is therefore not necessarily of occupational origin. Dermatologists demur at the popular terminological identification of 'dermatitis' with 'occupational dermatitis'. A dermatitis that primarily originates from occupational exposure is influenced by many other factors. A number of problems cause legal dispute:

1 Constitutional factors [21]. Most manufacturing processes cause dermatitis in certain workers only. If others similarly exposed remain healthy, those whose skin breaks down must have a lower resistance. Such a lowered resistance to contact irritants may be present in patients with previous atopic dermatitis [22] or in those with dry, seborrhoeic or fair skin [21]. Accordingly, any occupational contact dermatitis presupposes a certain constitutional predisposition and usually only occurs in a minority of the workforce. This has to be taken into account in deciding whether, in an attack of dermatitis, an occupational trauma is sufficient to be considered as a major causal factor or only as a contributory factor. A young person with previous atopic dermatitis may do office work with impunity, but if apprenticed as a hairdresser is likely to develop dermatitis. Similarly, a young atopic person runs a great risk of dermatitis if working in a coal mine [23]. It may be beyond dispute that dermatitis would not have developed in occupations suitable for the particular person, but medical and legal opinions are still divided over the justification of compensation to young people with constitutional eczema and occupational dermatitis. Similar constitutional factors may be implicated in the middle-aged group, but as they cannot yet be identified they do not disqualify.

2 Sensitization to medicaments prescribed or self-prescribed for occupational dermatitis inevitably occurs in some cases. This complication must be regarded as a sequel of disease, just as is secondary infection. Problems arise from late relapses due to repeated contact with the same medicaments.

3 Sensitization in private life, with relapse of dermatitis from occupational exposure (e.g. dermatitis of the hands from contact with nickel in patients sensitized by nickel in jewellery [17]; formaldehyde dermatitis in patients sensitized by textiles).

4 Primary occupational dermatitis, with chronicity maintained by private activity [24]. For example, to relieve the strain of inactivity, some workers resort to do-it-yourself work during sick leave (perhaps involving exposure to cement, paint, solvents, etc.), and housework is unavoidable.

5 The contributions of factors broadly grouped under the term 'stress' cannot be dismissed, but are usually difficult to assess [25]. It is accepted by many dermatologists that episodes of stress may be an aggravating factor in both irritant and allergic contact dermatitis and may even contribute to their initial onset.

Table 21.1 Occupations with the highest risk (rate/100 000 employed/year)–using labour force survey data as the denominator and cases of contact dermatitis reported to the UK EPIDERM survey as the numerator.

Occupation	Rate/100 000/year
Hairdressers	120
Printers	71
Machine tool operators	56
Chemical, gas and petroleum plant operatives	45
Car assemblers	35
Machine tool setters	34

Incidence

Most available incidence statistics are unsuitable for comparison. Some do not distinguish between occupational accidents and illnesses; others fail to separate dermatitis from other skin conditions. Few give information on short periods of absence from work or on dermatitis without disability, and most are based on compensation paid. However, the ongoing UK EPIDERM and the BKH-S surveillance schemes are addressing the epidemiology of occupational contact skin reactions [26,27]. Dermatitis was the predominant cutaneous reaction (79%), compared to urticaria (3.5%), infective conditions (2.5%) and neoplasia (12.8%) [26]. Recent findings show that skin diseases rank second (29%) to musculoskeletal conditions (57%) as causes of occupational disease [26]. The frequency of work-related skin reactions has been looked at in various occupational groups (Table 21.1).

The introduction of new chemicals may have increased the incidence of industrial dermatitis, but such a trend is counteracted by preventive and educational measures. The total number affected has increased, as the number of persons employed in industry has risen.

In a population sample from an industrial city, the overall 1-year period prevalence of hand eczema was 11.8% [28]. Hand eczema was significantly more common among those reporting potentially harmful skin exposures, cleaners for example having a corresponding prevalence rate of 21.3%.

In a joint European study of consecutive clinic patients with dermatitis, 30% of the men and 12% of the women had occupational dermatitis [29].

Of all occupational diseases, dermatoses comprise from 20 to 70% in different countries, and of the dermatoses between 20 and 90% are contact dermatitis. The relative proportions are determined by the extent and type of industrialization in an area, and certainly also by the skill and interest of dermatologists in contact dermatitis [29].

Age

Occupational dermatitis may occur at any age. The average age of onset varies from one occupation to another [7]. In some studies [30], two peaks appear, one at each end of working life. The young age group includes many patients with irritant and atopic dermatitis of the hands. Others find that the risk increases progressively with age [31].

Occupations

Certain industries and occupational groups contribute the majority of cases: in England and West Germany hairdressers [26,27] and in Italy bricklayers [32]. Agriculture, manufacturing and construction consistently head the list in the USA [33,34]. If the number of persons exposed is taken into account, certain subgroups or departments of large industries have a particularly high risk of dermatitis [12]. A high chromate content in local cement may place building workers at the top of the list. Among 1071 building workers, 6% had occupational cement dermatitis and half of them were sensitized to chromium [35].

Certain high-risk groups may not be identified because the number employed is low. Thus, tilers were found to have a much higher risk than bricklayers when the number of cases seen was correlated with the number employed. Self-employed persons are rarely compensated and are therefore not registered. A high risk of dermatitis among veterinary surgeons thus escaped notice. The most common occupational contact dermatitis is probably housewives' dermatitis. In a Swedish public health examination, this affected approximately 1% of adult women. Thirty-eight per cent of these had allergic contact dermatitis [36].

Period of exposure

Bakers get their dermatitis early, bricklayers later in life [7]. In one study, chromate in primers caused dermatitis after an average exposure of 5–7 months [37]. Hairdressers generally develop dermatitis early in their career [7], but the number who leave hairdressing before the age of 30 years is considerable and many leave for reasons other than dermatitis [38].

No comprehensive statistics have analysed the sum total of factors determining occupational risks. Wagner and Wezel [39] have suggested an approach. They base their calculations of occupational risk on three factors:

1 The number of cases related to the number employed.
2 The average age of onset of occupational dermatitis.
3 The average period of work before onset.

Ideally, the number employed should be divided into age groups. All three factors vary independently. Many workers start a job late in life (e.g. unskilled labour in manufacturing industries) and develop their dermatitis rapidly. Others get their dermatitis after decades of work.

Clinical features

Occupational contact dermatitis has the same morphology as any other contact dermatitis, i.e. cumulative irritant, allergic and photocontact dermatitis. The regional distribution, however, differs considerably because occupational contact dermatitis is mainly on exposed parts. The hands are affected, alone or together with other sites, in 80–90% of all cases of occupational contact dermatitis [29]. Irritant contact dermatitis started under finger rings in 12% of women and 2% of men [40]. The arms are also involved, especially if not covered by sleeves. Dusts and vapours affect the face and neck. Cement workers and miners often have dermatitis on the lower legs and feet. Those wearing rubber boots may have dermatitis from footwear.

Irritants and sensitizers

The most important irritants and sensitizers encountered in different occupations are detailed at the end of this chapter. The relative importance of occupational noxious agents varies considerably in different reports. Irritants such as detergents, alkalis and organic solvents head the list [39]. Schwartz *et al*. [41], in an extensive investigation, found petroleum products and alkalis to be the most important. The incidence of dermatitis from synthetic resins, such as epoxies and acrylates, has become increasingly frequent in the last few decades. In most reports, cumulative irritant dermatitis is more common than the allergic type. Most authorities agree that the most common sensitizer is chromium. Because a cumulative irritant contact dermatitis increases the penetration of allergens, it may predispose to the development of a superimposed allergic contact dermatitis. Likewise, an allergic contact dermatitis may render the skin more vulnerable to attack by irritants.

Diagnosis

The diagnostic approach to a suspected occupational dermatosis needs to be systematic. Most diagnostic difficulties arise from eczematous dermatoses [1]. Great care must be taken in the accurate distinction between contact dermatitis and endogenous eczema, and between irritant and allergic contact dermatitis. Skill is needed, not only in dermatology, but also in taking an occupational history [2,3], and in obtaining as detailed a picture as possible of what the patient actually does at work [4].

The clinical distinction on the hands, forearms or face between endogenous eczema, irritant contact dermatitis and allergic contact dermatitis is beset with pitfalls. Differences in distribution and morphology are useful guides, but dangerous to rely on uncritically. There is a tendency for irritant contact dermatitis to affect the dorsa of the hands (Fig. 21.1) and fingers (Fig. 21.2) and the finger webs, rather than the palms, and to be relatively devoid of vesicles. There is a tendency for vesicular eczema of the palms and sides of the fingers to be endogenous. However, certain irritants and allergens (Fig. 21.3) can produce a highly vesicular eczema of the palmar aspects of the hands and fingers, and both allergic contact dermatitis and endogenous eczema frequently involve the dorsal aspects of the hands, fingers and webs. Discs of eczema on the dorsa of the hands and forearms are frequently endogenous, but allergic contact dermatitis from chromium and cumulative irritant contact dermatitis can present in a very similar distribution (Fig. 21.1). Gross eyelid swelling usually indicates allergic contact dermatitis, but degrees of eyelid swelling can occur in both irritant contact dermatitis and endogenous eczema.

Fig. 21.1 Discoid pattern of irritant contact dermatitis from soluble oil.

Fig. 21.3 Allergic contact dermatitis from Compositae plants in a florist.

Fig. 21.2 Irritant contact dermatitis of the fingers in a printer.

It is difficult to overemphasize the importance of a sound working knowledge of occupational irritants, as well as allergens, and of patch testing, in overcoming these difficulties in clinical differentiation. It should be appreciated that hand eczemas, in particular, are often the joint outcome of endogenous, irritant, allergic and even general climatic factors, and may be partly occupational as well as wholly occupational or non-occupational. In identifying the primary and/or major cause of a contact dermatitis, antecedent and aggravating causes should not be neglected. Diagnosis of secondary bacterial infection in occupational contact dermatitis, for example, may allow significant improvement to be obtained with antibiotic therapy.

Occupational contact urticaria [1,2]

High-molecular-weight antigens such as proteins may induce specific immunoglobulin E (IgE) antibody production [3]. Many of these antigens can penetrate only thin skin or a defective skin surface. If the antigen and specific IgE antibodies bind to Fc receptors on the mast cells, these will release histamine and other mediators. The typical clinical picture is an urticarial reaction with erythema and oedema [1,2]. Contact urticaria can frequently be an occupational dermatosis [4,5]; immediate hypersensitivity to natural rubber latex in rubber gloves is an obvious example [6].

Veterinarians exposed to amniotic fluid, and kitchen staff who have contact with uncooked food items, may develop protein contact dermatitis, a variant of contact urticaria [7].

Occupational irritant contact dermatitis [1–9]

Dermatitis from the type of metalworking fluid or coolant most commonly known in the UK as 'soluble oil' is a prime example of occupational contact dermatitis that is usually primarily, and frequently totally, of cumulative irritant (Chapter 19) rather than allergic causation [9–14]. Soluble oils are oil-in-water emulsions used to cool and lubricate metalworking and certain other industrial manufacturing operations [15]. Synthetic coolants are aqueous chemical solutions and can have similar effects on the skin. Both types of product contain numerous additives, some of which are potential sensitizers (especially biocides [16,17]), but it is the substantial content of surface-active agents as emulsifiers or wetting agents in coolants that appears to underlie their potential for skin irritation [15,18]. Synthetic coolants also contain traces of nitrosamines, formed by triethanolamine or diethanolamine reacting with nitrites. Although currently under evaluation as carcinogens, there is no evidence that nitrosamines in coolants are irritant or sensitizing to the skin.

Soluble oil dermatitis is typical of occupational irritant contact dermatitis in that it is cumulative and has a multifactorial aetiology [11,12]. The degree of skin contact [19], individual susceptibility, machine type and control method [20], and biocide additions [21] are all important factors, in addition to the specification and condition of the metalworking fluid itself. Clinically, the dorsa of the hands, finger webs, wrists and forearms are predominantly affected [22] and the dermatitis can have a patchy distribution that mimics nummular eczema [12] (Fig. 21.1). This is also true of several other forms of occupational contact dermatitis, including cement dermatitis [23] and dermatitis from machine oil in hosiery workers [24]. There are two reports [25,26] of soluble oil dermatitis presenting as 'dyshidrotic' eczema; a similar pattern has been described from mechanical irritancy [27]. The prognosis is highly variable but may eventually be good even without a change of work [28].

Irritant contact dermatitis provoked by soluble oils and synthetic coolants is to be distinguished from oil acne, discussed later in relation to neat (or insoluble) non-aqueous cutting oils.

Occupational physical irritant contact dermatitis [1,2]

The skin can react in a variety of ways to excessive friction and microtrauma. The reaction depends upon constitutional factors, such as a tendency to develop psoriasis, or the type of trauma. Various types of reactions can occur: calluses, fissuring, lichenification, blistering, Koebner phenomena aggravating psoriasis and granulomas.

Fibreglass dermatitis is a well-known example of a physical irritant contact dermatitis and was first described in 1942 [3]. It consists of sharp glass spicules which are capable of penetrating the superficial part of the horny layer of the skin to cause immediate skin irritation. The acute irritation reaction results in a pruriginous dermatitis; as clothing may trap the fibreglass, this may occur on covered parts of the body.

Occupational allergic contact dermatitis [1–4]

Although probably less common than occupational irritant contact dermatitis, occupational allergic contact dermatitis still tends to be underdiagnosed [5]. Better history taking [3], more extensive patch testing, workplace visiting and greater use of chemical investigations [3] significantly increase the proportion of patients found to have contact sensitization relevant to their occupation. Allergic contact dermatitis also frequently complicates irritant contact dermatitis in occupational cases. A prime example of occupational allergic contact dermatitis is that from chromium [6,7] (Chapter 20).

Investigations

Skin prick test/RAST

Although testing for immediate hypersensitivity is not always a part of assessment of contact dermatitis, it can be important, particularly in the situation of hand dermatitis when type 1 hypersensitivity to natural rubber latex (NRL) is suspected [1]. The two tests in common use are the skin prick test and the radioallergosorbent test (RAST). The glove usage or challenge test requires a highly allergenic brand of glove and is potentially dangerous—emergency treatment facilities for the management of anaphylaxis are needed [2]. Skin prick testing involves an intradermal puncture through a drop of allergen or glove. A positive reaction consists of an urticarial weal, which is usually apparent after 15 min although it may take as long as 45 min to develop. A positive control test of histamine should also be performed to exclude a false-negative reaction due to oral antihistamine ingestion. A negative control prick test with saline should be also be performed to check if the patient is dermographic. There are occasional reports of anaphylaxis following prick testing with NRL extract [3]. With the advent of standardized commercially available NRL extracts, this risk is probably greatly reduced. Some clinicians may prefer to perform a RAST for NRL allergy, as they may not have adequate facilities or training to deal with anaphylaxis, however, the sensitivity and specificity may be less for RAST compared with prick testing. Skin prick and use tests are also useful when investigating protein contact dermatitis in occupations at risk, such as chefs or veterinarians [4].

Patch testing [1–5]

Four general problems of patch testing (Chapter 20) are particularly relevant in suspected occupational dermatitis:
1 False-positive reactions
2 False-negative reactions
3 Unexplained positive reactions
4 Missed allergens

False-positive reactions are commonly obtained if industrial chemicals are applied as patch tests undiluted [3]. Such reactions can be shown to be false-positive irritant

reactions if testing in control subjects also demonstrates positive reactions; applying serial dilutions of the chemical to the original patient will often demonstrate an abrupt loss of the reaction. The uncritical use of undiluted chemical samples as patch tests also increases the risk of active sensitization and other complications of patch testing (Chapter 20). When testing an unknown substance, a preliminary open test is often advisable [4].

False-negative reactions can also be obtained with samples acquired from the patient's workplace. This is because the concentration of an allergen in a sample—for example, rubber—may be too low to elicit a positive patch test reaction. This problem also arises when allergens are found in irritant products such as cutting fluids, solvents and soaps. Dilution of these to avoid a false-positive reaction from the irritancy of the sample may overdilute an allergen initially present in only low concentration (Chapter 20).

Unexplained positive reactions found on standard patch testing in suspected occupational cases should always be pursued for explanation [4,6]. This is particularly so when the allergens concerned are known to have a multiplicity of industrial uses, such as chromate, cobalt and colophony. A factory visit can be invaluable in the detection of previously unsuspected sources of allergens [7–9].

Missed allergens. When clinical assessment points strongly towards an occupational allergic contact dermatitis, the occurrence of negative patch test results should always raise the possibility of the responsible allergen having been omitted from testing [5,6]. Another major function of a factory visit is to detect such missed allergens.

Routine pre-employment testing with potential sensitizers to be used in the future job should not be carried out [4].

Chemical investigations

There is an array of qualitative chemical spot tests [1,2], of which four are likely to be of particular use in the investigation of occupational cases. These are the dimethylgloxime test for nickel [3], the diphenylcarbazide test for chromium [1], the lutidine test for formaldehyde [4] and the filter-paper test for epoxy resin [5]. These are all tests which can be carried out simply and reliably with minimum time and bench space.

Quantitative microanalysis of allergens and physicochemical techniques for the isolation of allergens [6] are likely to be beyond the scope of most dermatologists outside special departments, although they may be available within neighbouring departments. Thin-layer chromatography does, however, offer opportunities for relatively simple separation and identification, such as the detection of the sensitizing low-molecular-weight oligomers of epoxy resin [2,5].

Liquid and gas chromatography, which may be linked to mass spectrometry, colorimetric spectrophotometry, and atomic absorption and emission spectrophotometry all play important parts in current investigations [2].

Factory visiting

The diagnostic advantage to the dermatologist of seeing the way in which a patient carries out the work cannot be overestimated. Some general guidance is available [1–5], but it is the experience of making such visits that is the best instructor. The main types of information that are worth establishing during such visits, and recording subsequently, are as follows.

1 *Organizational*. Name, address (including postcode) and telephone number of workplace; names and status of all medical, nursing, employer and employee representatives met.

2 *Demographic*. Numbers employed overall and in patient's work area; current expansion, contraction, turnover; shift system and pay scheme.

3 *Technological*. Broad concept of production as a whole; detailed understanding of work carried out by patient and in patient's work area, including all potential irritants and allergens observed and their degree and extent of skin contact; names and addresses of suppliers of materials requiring further identification.

4 *Preventive*. Broad impression of working conditions (space, lighting, ventilation); more detailed review of protective installations, protective clothing, skin-care products and education; assessment of actual uptake and practical effectiveness of preventive methods.
5 *Miscellaneous*. Industrial relations, psychological, sociological or economic factors, any similar problem in sister factory, etc.
6 *Clinical*. Skin complaints in employees other than the patient, their clinical assessment, subdivision into occupational and non-occupational (often provisional).
7 *Epidemiological*. Prevalence of skin complaints as a proportion of the total exposed, estimate of prevalence of occupational dermatoses.
8 *Aetiological*. Opinions of others, with attribution as to source and estimate of reliability; own opinion, with grounds for it (may be inconclusive).
9 *Operational*. Summary of findings; recommendations for future investigation, management and review; follow-up.

Factory (or other workplace) visits can provide many major benefits [4].
1 Detection of relevance of previously unexplained positive standard patch test reactions.
2 Detection of missed allergen.
3 Substantiation of diagnosis of irritant contact dermatitis.
4 Diagnosis of mild or unfamiliar occupational dermatoses by their occurrence in several members of a workforce.
5 Substantiation that various non-occupational skin conditions have been grouped together as a pseudo-occupational dermatosis [6], and why.
6 Recognition of phenomenon of visible dermatoses, whether occupational or not, causing anxiety and subconsciously imitative symptoms in fellow employees [7].
7 Initiation of research on new occupational dermatoses.
8 Incidental effects, including improved dermatologist–occupational physician [8] and dermatologist–patient relationships.
9 Progressive increase in dermatologist's overall knowledge of the working contactants of his or her patients.

A second-best alternative that can still provide useful information if a factory visit is impossible is to communicate with medical, nursing, employer or employee representatives by letter or telephone.

Prognosis [1] (Chapters 19 and 20)

The most important aspect of prognosis in occupational dermatoses is that neither irritant or allergic contact dermatitis may be as beneficially affected by change of work as some believe [1–4]. This has a profound influence on the management of the established case [5], as well as underlining the importance of primary prevention.

Prevention [1–4] (Chapters 19 and 20)

Secondary preventive measures can reduce the risk of dermatitis in an established case, although success can be obtained only by close collaboration between the management of the factory and the dermatologist. Changes in the process, when practicable, are always likely to be more successful than personal protection [5]. Some preventive measures that are desirable from a dermatological point of view may be unsafe or impractical in an industrial environment. The wearing of gloves is often ruled out because of these strictures [6].

Materials selected for protective clothing may in practice allow many contactants to penetrate. Various sources provide practical guidance as to the choice of protective material [2,7–11]. There are now multilayered materials that show much greater resistance to allergens such as methyl methacrylate [12] and irritants such as organic solvents [7]. Even when protective clothing is practicable and competent to protect, the way in which it is taken off and put on again may lead to contamination of inside surfaces. Because occlusion increases penetration, wearing a glove that has been contaminated on the inside can be more harmful than wearing no glove at all [4]. Correct procedures must therefore be instituted and maintained.

Automated processes are often far from free of skin contact. Fregert [13] has listed many possible sources of skin contamination. Service engineers are particularly at risk [14].

Table 21.2 Basic workplace skin-care principles.

Luke-warm water for washing
Use correct gloves before exposure for the shortest time
Remove rings
Cotton liners underneath protective gloves
Avoid disinfectant hand cleansers
Apply emollient hand creams
Protect hands at home
Workforce education

Allergen replacement [1,14,15] is a useful concept. Extreme care must be taken to ensure as far as possible that the replacement is genuinely safer in all respects.

Some skin-care creams ('barrier' and moisturizing creams) have been demonstrated by various test methods [2,16–19] to have a protective effect against certain irritants. Their effectiveness in actual use remains less securely established [2]. Topical binding agents may have a role in the prevention of nickel dermatitis [20].

The basic principle of prevention of occupational contact dermatitis continues to be that of reduction of contact, or preferably avoidance. If chemicals remain on the skin for 24 h instead of 8 h, sensitization and irritation occur more readily [4]. Evidence-based skin care recommendations have been published [21] (summarized in Table 21.2). If improvements are made to the working conditions by intensified preventative measures, then this is likely to lead to a reduction in cases of occupational contact dermatitis [22].

Management of the established case [1,2]

As most workers naturally prefer to continue their work, a detailed analysis of causative factors is required. Minor changes of procedure may be helpful once guided by a precise diagnosis. A change of job may be considered in first-year apprentices, in those with uncomplicated allergic contact dermatitis from readily avoidable substances or in atopics who have unavoidable contact with irritants. This should only be decided after full dermatological investigation. In the majority of cases, continuation in the same occupation should be made possible [1,3–5].

Assessment of dermatitic potential

The potential of chemicals to act as contact irritants [1,2], contact allergens [3–7], photoirritants [8] and photoallergens [7,9,10] can be assessed by test methods in laboratory animals and, to a lesser extent, in human volunteer subjects. These methods assess potential; they do not in themselves predict the incidence of dermatitis. Actual risk depends not only on dermatitic potential but also on

other factors, the most important of which concern the conditions of exposure (concentration, frequency and duration) and the normality of skin. Also useful is background knowledge of the structure–activity relationships of chemical groups [11].

Modifications of widely accepted test procedures such as the guinea-pig maximization test [6] tend to occur with experience of their use [12–14], and sufficiently different tests have been developed to justify separate names [7,15–17]. Standardization of test procedures greatly reduces inter- and intralaboratory variation in results—but as this is never likely to cease to be a problem to some degree [18], the development of new tests that may offer greater ease of standardization (and economy) continues [19]. The use of mouse models for the prediction of sensitizing potential is now well established [20,21].

Alkali tests

The usefulness of alkali resistance and alkali neutralization tests as predictors of susceptibility to irritants remains controversial. Neither test is sufficiently simple and reliable to achieve widespread clinical use [1–3], and their diagnostic value has been overestimated.

More sophisticated tests with panels of irritants have been used to identify a 14% proportion of the general population with 'hyperirritable skin' [1]. Susceptibility to one irritant, however, does not necessarily imply susceptibility to another irritant in the same individual [1,4].

Transepidermal water loss

Measurement of the baseline transepidermal water loss (TEWL) may be a useful indicator of reactivity to irritants, although there is variation between studies [1].

Measurement of skin contamination

Methods of quantifying the degree of skin contamination by substances include skin wiping [1], skin rinsing [2], exposure pads [3,4], and the use of natural fluorescence (oils and tars) [5] or fluorescent tracers [6].

Non-eczematous occupational dermatoses

These constitute an important minority of occupational dermatoses. Particularly significant examples also described in other chapters are acquired hypomelanosis (see p. 21.15 in this chapter, and Chapter 39), scleroderma (Chapter 56) and carcinoma (Chapter 36). Many other dermatoses can be occupational, including some skin diseases caused by arthropods (Chapter 33), *Candida* paronychia (Chapter 31), onycholysis (Chapter 62) and exogenous pigmentations such as argyria (Chapter 39).

Chemical burns

Many chemicals used in industry and the home are capable not only of causing burns, but also of being absorbed and causing toxic effects leading to acute yellow atrophy of the liver or renal failure. Burns from acids and alkalis may cause acidosis or alkalosis, both requiring treatment.

Certain chemicals cause chemical burns, the first perceptible or visible changes of which can be delayed for several hours. Examples of these are mustard gas, podophyllin, dithranol, hydrofluoric acid, propane sultone, ethylene oxide and epichlorohydrin [1].

The primary—and essential—treatment of all chemical burns is copious washing (except for metallic potassium and sodium, which ignite in water). Specific remedies are available for only a few chemicals. Buffered phosphate solution, when readily available, is useful for acid and alkali burns, but is only practicable in large units likely to deal with more than the occasional case.

The depth of necrosis depends on the concentration, duration of contact and time before treatment is instituted.

Acids and alkalis

Sulphuric acid and potassium or sodium [2] hydroxide are the most common agents. Strong acids are hygroscopic and cause coagulative necrosis and discoloration of the tissues. Alkalis form proteinates and saponify fats. Copious washing may have to be continued for a long time. Sodium bicarbonate solution can be used for acid burns and vinegar and ammonium chloride for alkalis.

Cement (lime) [3–6]

Wet cement under occlusion (e.g. due to kneeling in cement, or contamination inside boots) can cause delayed full-skin-thickness burns. Soiled clothing should be removed immediately and the injury bathed copiously with water or, if available, phosphate buffer; excision and grafting of necrotic areas is frequently required [4].

Chromic acid [7]

This produces skin ulceration and necrosis. It may be absorbed and cause renal failure. Deeper burns may require excision and grafting. Superinfection with *Streptococcus pyogenes* may be a missed cause of delayed healing.

Phosphorus

This ignites on exposure to air. Burns should be kept moist until all particles are removed. Dry dressings should not be used. Small residual particles can be detected by phosphorescence in a dark room. Severe metabolic changes may occur, and patients who have suffered phosphorus burns should be carefully monitored. Copper sulphate solutions (in small amounts) have been advocated [8].

Hydrofluoric acid (HF) [9–12]

One of the strongest acids known, it is widely used in industry and research. It is ionized in solution and penetrates deeply. Burns are characterized by intense pain (often delayed) and deep tissue necrosis, which progresses for several days. Skin contact must be dealt with instantly with copious washing with water for at least 10–15 min. Repeated application of 2.5% calcium gluconate gel is then usually adequate for minor exposure of the skin to less than 20% HF. If this fails to reduce the pain within 30 min–1 h, repeated infiltration with 5–10% calcium gluconate (0.5 mL/cm^2 burned surface area) should be considered [10]. Regional intra-arterial calcium gluconate [10] or chloride [13] infusion also has its expert advocates, but hypercalcaemia is a significant risk. Surgical debridement may be required later, as in all chemical burns. Earlier surgical intervention has been successful in severe burns [14].

Phenol [15]

This is rapidly absorbed through the intact skin. Local necrosis is proportionate to concentration and small amounts of water or alcohol may increase the absorption. Toxic effects are numerous. 'Deluge' washing with large amounts of water or swabbing with polyethylene glycol [15] should be employed.

Acne of external chemical origin

SYN. ACNE VENENATA

Aetiology. A variety of chemicals possess, to some degree, the capacity to induce acne by external contact [1]. Many are occupational hazards, but some may be encountered in the home. The occupational chloracnes are of outstanding medical importance, for their development provides a valuable indicator of exposure to a toxic hazard. Many of the substances inducing chloracne are also hepatotoxic.

Halogenated aromatic hydrocarbons [2–7] are the most potent acnegenic agents. The chloronaphthalenes, chlorobiphenyls [8] and chlorobiphenyl oxides are used as dielectrics in conductors and insulators. Exposure occurs in those manufacturing these substances or making or handling cables [9,10]. A naphthalene wax used to 'feather proof' a counterpane caused acne on the face and arms of a child [11]. These substances will induce acne at any site [12] and at any age, usually after 1 or 2 months' exposure. The chlorophenols are used as insecticides, fungicides, herbicides and wood preservatives [13]. Their capacity to cause chloracne depends on the degree to which they are contaminated with chlorinated dioxins and the precise chemical structure of the latter, for example 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) (Fig. 21.4) is the most powerful chloracnegenic agent known [14–18].

Similarly, the toxicity of the polychlorinated biphenyls (PCBs) is largely due to contamination with polychlorinated dibenzofurans (PCDFs). Chloracne has been caused by a weedkiller containing 2,4-dichlorophenoxyacetic acid and 2,4,5-trichlorophenoxyacetic acid [19], by sodium tetrachlorophenate used as a wood preservative [2], by the herbicide 2,6-dichlorobenzonitrile [20], by a trifluoromethylpyrazole derivative being developed as an antirheumatic drug [21] and by an intermediate product found in the manufacture of tetrachloroazobenzene [4].

As a consequence of industrial or other accidents, large numbers of individuals may be heavily exposed to such

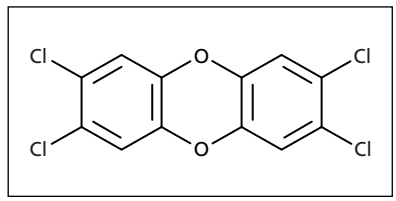

Fig. 21.4 2,3,7,8-tetrachlorodibenzo-*p*-dioxin—a halogenated aromatic compound—is highly toxic and causes chloracne.

chemicals [22]. In such circumstances, TCDD caused serious systemic symptoms and severe chloracne [23]. After another industrial accident the same chemical caused chloracne in members of the families of affected workers [24]. TCDD-induced chloracne, mainly in children, cleared well within a decade, and systemic effects were absent, following the more recent Seveso accident [25].

The induction of chloracne by the ingestion of PCBs has occurred in two large epidemics caused by the contamination of cooking oil [2,26]: the chloracnegen was shown to have caused transplacental, as well as direct, toxicity [27]. Polybrominated biphenyls became widely distributed in the state of Michigan, following a labelling error that resulted in their introduction into cattle feed [22].

Neat (insoluble) cutting oils, which are impure paraffin–oil mixtures, are the commonest chemical cause of acne, because they are so widely used in the engineering industry, but their acnegenic capacity is inconstant and not necessarily high. Men are more readily affected than women, and those with acne vulgaris are particularly susceptible. The use of moulding oil in the manufacture of precast concrete can cause oil acne [28]. Brilliantines containing impure paraffins may have a similar effect [29]. Comedones and cysts behind the ears have been attributed to paraffin products in shaving soap inadequately rinsed from this region [30].

Crude petroleum is acnegenic in oilfield and refinery workers [7]. Diesel oil can cause acne in motor mechanics [31].

Heavy coal-tar distillates, especially pitch and creosote, are also to some extent acnegenic. Conduit makers and road workers are affected. Under experimental conditions the lesions induced by crude coal tar are more inflammatory in white people than in black people [32].

Cosmetics [33]. Mild comedo acne with occasional papulopustules occurs in one-third of adult women in the USA. Of 25 facial cosmetic creams tested in rabbits, 50% were comedogenic; so were lanolin, petrolatum and some vegetable oils [34]. Pomades had an even more marked effect in black Americans [29]. Also acnegenic were indigenous vegetable oils in India [35]. The salts of fatty acids in conventional soaps are comedogenic if used excessively [36]. Fatty acid esters, especially isopropyl linoleate, acetylated lanolin alcohol, grape seed and sweet almond oils, have

Clinical features	Acne vulgaris	Halogen acne
Usual age	Teenage	Any
Comedones	Present	> 3 (if absent not chloracne)
Straw-coloured cysts	Rare	Pathognomonic
Temporal comedones	Rare	Diagnostic
Inflammatory papules and cysts	≥ 3	Present
Retroauricular involvement	Uncommon	Common
Nose involvement	Often spared	Often spared
Associated systemic findings	Rare	Common

Table 21.3 Clinical features of acne vulgaris vs. halogen acne.

been found to be particularly comedogenic in rabbits [37].

Asbestos. A large percentage of workers in a hardboard factory in Germany developed acne which was attributed to asbestos [38].

Topical corticosteroids. The continued application of topical corticosteroids under occlusive dressings may also induce comedo formation. It does not occur under the age of 10 years and is difficult to induce experimentally in subjects over 50 years of age [39].

Psoralen and UVA therapy. A predominantly perioral acne can appear during psoralen and UVA (PUVA) therapy [1].

Pathology [40]. In chloracne, squamous cell proliferation occurs in sebaceous gland acini and acanthosis in the upper part of the external root sheath. The wall of the comedo is at first acanthotic and tortuous, but later becomes thin.

Clinical features [3] (Table 21.3). Chloracne, or more correctly halogen acne, may be differentiated from chemical acne of other origins. The eruption involves the face predominantly, even if the chemical has been ingested. The nose tends to be spared, and skin of the malar regions, the angles of the jaw and behind the ears is often most severely affected. The typical lesions are small, skin-coloured cysts, 1 mm to 1 cm in diameter, associated with numerous comedones (Fig. 21.5). There may be some itching. If exposure to the causative agent ceases, the lesions very slowly resolve, leaving some scarring. Asymmetrical lesions in any region of the body may be seen when unusual sites are in direct contact with the acnegenic agent. When the poison has been ingested, constitutional symptoms are frequently present; hypertrophy of Meibomian glands of the eyelids, a predominantly sensory peripheral neuropathy, and patchy pigmentation of skin, nails and gums have been reported [26]. In acne caused by pitch or tar, comedones of the malar region predominate and there are few or no cysts. There may be a folliculitis of thighs and forearms. There is often some melanosis of exposed skin. Although it is doubtful that acne vulgaris predisposes to chloracne, its victims are more susceptible to oil acne. A highly inflammatory folliculitis of the forearms and thighs, with many comedones, is associated with aggravation of existing acne. Comedones induced by brilliantines or pomades [29] occur mainly around the frontal hair line.

Fig. 21.5 Chloracne. Profuse open comedones in malar crescent.

Diagnosis (Table 21.4). Acne in the 'wrong' sites and at the 'wrong' age, or with a predominance of comedones, should initiate an enquiry into possible external chemical factors. Mechanical trauma alone can aggravate or even induce acne in predisposed subjects [41], and its possible role as a contributory factor should always be taken into account.

Treatment. Even treatment with isotretinoin [21] or acitretin [19] may fail to prevent chloracne from persisting for many years, despite avoidance of further contact.

Chemical depigmentation [1,2]

Definition. Occupational leukoderma is defined as pigmentation or hypopigmentation of the skin due to industrial exposure to a chemical or chemicals known to have a destructive effect on epidermal melanocytes [1].

Aetiology. Certain chemicals, particularly the substituted phenols, are destructive to functional melanocytes [2]. Many of these compounds cause permanent depigmentation of the skin, resembling vitiligo. The most commonly implicated chemicals are *para*-tertiary butyl phenol, *para*-tertiary butyl catechol, monobenzyl ether of hydroquinone (Fig. 21.6), hydroquinone and related compounds [1,2]. A list of chemicals known to cause occupational leukoderma is shown in Table 21.5.

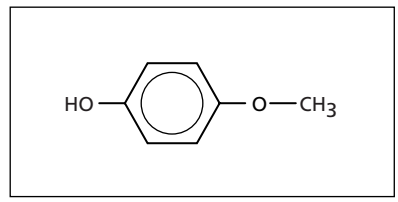

Fig. 21.6 Monomethylether of hydroquinone (4-hydroxyanisole or 4-methoxyphenol) is an intermediate in the manufacture of several chemicals.

Table 21.5 Chemicals capable of causing occupational leukoderma.

Hydroquinone

Lubricating and motor oils
Photographic chemicals
Antimicrobials and disinfectants
Detergents and deodorants
Inks

Diagnosis. The diagnosis of occupational vitiligo should be suspected if a worker who potentially has been exposed to depigmenting chemicals develops leukoderma on the dorsal aspects of the hands or in a more widespread distribution [3]. There should be particular suspicion if more than one worker is involved. The chemicals to which the worker is exposed should be identified and investigation made to see if it or they are known to cause depigmentation. Some occupations known to be at risk of exposure to depigmenting chemicals are shown in Table 21.6.

Treatment. There is no specific treatment for occupational vitiligo. Removal of the offending chemical may result in partial repigmentation, but this process may take years and may not occur at all. Treatment should be aimed at preventing further exposure. Camouflage cosmetics may be used and the depigmented skin protected from ultraviolet irradiation by sunscreens.

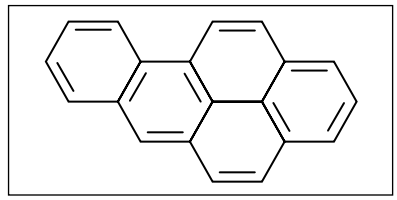

Fig. 21.7 Benzo[*a*]pyrene.

Occupationally induced skin tumours

Occupational skin cancers are rare and mainly of historical importance, apart from obvious examples such as epitheliomas developing in outdoor workers; however, some occupational exposures will predispose patients to develop skin tumours.

Historical review [1–4]

In 1775, the first cancer of any type to be linked with occupational exposure was scrotal squamous carcinomas in British chimney sweeps, reported by Percivall Pott [1]. In the rest of Europe, the disease was unknown because of wearing protective clothing and the reduced carcinogenicity of wood soot as opposed to coal predominantly burnt in Britain. Soot formed by burning wood has much lower levels of the polycyclic hydrocarbon, benzo[*a*]pyrene (Fig. 21.7), implicated in the aetiology of skin cancer compared to coal soot. Skin cancer was still reported in chimney sweeps in Britain in the 1950s. By 1945 in Britain, almost 50% of industrial skin cancer was attributable to exposure to pitch and tar in occupations such as mule spinners, jute workers and the engineering industry [2].

Definition. Occupational skin cancers are defined as those in which a person's occupation has played a major role in the aetiology of the tumour. Currently, multiple aetiological factors are thought to contribute to the development of skin cancer. In the past, however, there have been several virtual epidemics of skin cancer which were traceable to occupational exposures. The major occupational carcinogens recognized were polycyclic hydrocarbons, ionizing radiation and arsenic. Ultraviolet radiation is now the most important carcinogen in the aetiology of occupational skin cancer.

Aetiology and occupations (Tables 21.7 & 21.8). Polycyclic hydrocarbons are produced by incomplete combustion and distillation of coal, natural gas and oil shale. These chemicals are contained in tar, fuel oils, lubricating oils and greases, oil shale and bitumen.

Diagnosis. The diagnosis of skin cancer is similar to that of non-occupational skin cancers. Generally, the exposed

Ultraviolet light	Outdoor workers Welders Laser exposure Printers
Ionizing radiation	Nuclear power plant workers X-ray technicians Uranium mining

sites are involved. Previously, the scrotum was involved frequently, because of continuous exposure to carcinogens and the increased likelihood of skin absorption in that site. There may be coexisting signs of exposure prior to or in addition to evidence of skin cancer. These may include oil folliculitis and hyperkeratoses, described in people working with mineral oil, and pitch or tar warts. Oil hyperkeratoses were described as being flat, white, circular, hyperkeratotic smooth plaques, small in diameter and often clustered. In addition, there were verrucose pigmented round or oval irregular raised warts. Tar warts were pigmented small papules, which were often seen around the face on the eyes, eyelids, cheek, forearms and back of the hands.

Management. Prevention of the development of skin cancers is most important. In the workplace, it is important to consider substitution of carcinogens where possible; an example is the declining exposure to polycyclic hydrocarbons in recent decades. Protection of the skin, with either protective clothing or with engineering control such as machine guarding, is important. Daily washing is essential. Since most of the skin cancers are associated with a very long latency period, it is important to have continued surveillance of older or retired workers. Finally, the skin cancers need to be treated as appropriate.

Table 21.9 Scleroderma-like diseases related to occupational and environmental factors.

Inducing factors	Symptoms or disease
Occupational agents	
Vinyl chloride	Raynaud's phenomenon, sclerodactyly, acro-osteolysis, hepatic fibrosis, angiosarcoma, plaque-like fibrotic cutaneous lesions, leukocytopenia and thrombocytopenia
Organic solvents	Skin fibrosis, irritant dermatitis, hepatitis, neurological symptoms
bis(4-amino-3-methylcyclohexyl) methane (used in epoxy production)	Skin sclerosis, erythema, fatigue, myalgia, arthralgia
Quartz (silicon dioxide, SiO_2)	Systemic sclerosis
Iatrogenic agents	
Bleomycin	Pulmonary fibrosis, scleroderma-like lesions
Pentazocine	Pigmentary changes, panniculitis, ulcerations and sclerotic fibrosis on injection sites
L-tryptophan	Sclerodermatous induration, peripheral eosinophilia, myalgia, arthralgia
Silicon	Systemic sclerosis, Sjögren's syndrome, arthritis
Other substances	
Toxic oil syndrome	Scleroderma-like changes, neuromuscular atrophy, hypertension, sicca syndrome

Vibration white finger [1] (see also Chapter 22)

Definition. Vibration white finger (VWF) consists of the episodic appearance of white-finger skin patches (Raynaud's phenomenon [2]) in response to environmental cold and is accompanied by secondary loss of sensation caused by vascular ischaemia. It can be part of, but is not synonymous with, the hand–arm vibration syndrome [1].

Aetiology. The pathogenesis of VWF is poorly understood. Chronic vibration exposure may damage endothelial vasoregulatory mechanisms by disturbing the endothelial-derived relaxing factor-mediated vasodilatory function [3].

Clinical features. Operatives using vibrating tools, such as lumberjacks, coal miners and road and construction workers, are at risk of developing VWF. Affected individuals develop symptoms of Raynaud's phenomenon on exposure to cold or vibration, usually after many years of working with vibrating tools [1].

Diagnosis. The diagnosis is usually made by history alone; ice provocation tests are not always reliable in precipitating attacks of VWF [1].

Prevention. With widespread knowledge of the cause of VWF, controls over duration of use of relevant machinery and improved personal protective equipment has led to a reduction in the incidence of VWF [1].

Treatment. The treatment of VWF is the same as for Raynaud's phenomenon. It is generally believed that symptoms of VWF regress some time after cessation of exposure [1].

Medicolegal aspects of occupational dermatoses [1–4]

A report on a patient seen for compensation purposes should be prepared with much thought and care. Medical terms not of common currency should be explained as they occur. The following items of information should always be considered for inclusion:

1 Sources of information other than the patient (previous case notes; previous medical reports; workplace inspections).
2 Family history of atopy or any other allergies or skin disorders.
3 Previous personal history of atopy or any other allergies or skin disorders.
4 Previous occupations. Job titles, employers, types of contact, dates.
5 Present occupation. Job title, employer's name and full address, dates.
6 Time in contact with suspected causal factors. May be shorter (or longer) than time in present occupation.
7 Description of the working process. In sufficient detail to give accurate assessment of degree of skin contact, as well as the range of skin contactants.
8 Other cases of dermatitis, and standard of hygiene at the place of work. Types of skin cleanser, skin creams and protective clothing used at work.
9 Time and site of initial skin complaints. Previous injury at the initial site.
10 Progress, with approximate dates of gradual or sudden aggravation or improvement, and the influence of weekends, holidays, sickness absence.
11 Degree of incapacity during period of illness. Dates of absence from work. Level of earnings: previously, during illness, at present.
12 Changes in occupation since onset of skin complaint. Job titles, dates, details of changes in skin contactants.
13 Medical advice sought, treatment obtained and its effectiveness.
14 Clinical findings. Present state (have the lesions been suppressed by topical steroids?).
15 Special investigations; patch tests, prick or scratch tests, open tests, repeated open application tests (positive and negative tests, times of readings, vehicles, concentrations, application method, site). Exposure tests. Mycological/bacteriological examination.
16 Intercurrent diseases (fever, light eruptions, mycotic infection).
17 Diagnosis. With the Woolf reforms in the UK, it is necessary to give the full range of the opinions, including the reasons for the opinion given [5].
18 Common knowledge of risk at the occupation in question. Whether the employer could reasonably have been expected to have foreseen any risk to the skin.
19 Conclusions (in terms understandable to non-medical readers):

(a) Probable connection between occupational activity and the present pathological condition; balanced against predisposing factors and contributory factors in spare time.

(b) Possibility of continuing in previous occupation. If change of work is required, what are the chances of rehabilitation?
(c) Probable medical prognosis (state of the dermatitis), probable social prognosis (capacity for work).

Specific occupational hazards [1–4]

The following is offered as an *aide-mémoire*. Many causes of contact urticaria [4] have also been described as causing protein contact dermatitis.

Agriculture [5–15]

Irritants. Artificial fertilizers, disinfectants and cleansers for milking utensils, petrol, diesel oil.

Sensitizers. Rubber (boots, gloves, milking machines), cement, local remedies for veterinary use, wood preservatives, plants, pesticides, antibiotics in animal feeds, penicillin for mastitis, nickel and cobalt in fertilizers, cobalt and vitamin K_3 in animal feeds, ethoxyquin (preservative) in feed, quinoxaline and derivatives (growth factor), dinitolmide (anticoccidiosis), phenothiazine sedatives, soil disinfectants.

Contact urticaria. Animal hair and dander.

Artists [16,17]

Irritants. Solvents, clay, plaster.

Sensitizers. Turpentine, cobalt–nickel pigments and chromium pigments, azo and phthalocyanine dyes, colophony, epoxy, acrylic and formaldehyde resins.

Automobile and aerospace industries [18–20]

Irritants. Solvents, oils, cutting oils, paints, glass fibre, carbon fibre, hand cleansers.

Sensitizers. Chromate (primers, anticorrosives, oils and cutting oils), nickel, beryllium, cobalt, rubber, epoxy and acrylic resins, dipentene in thinners.

Baking and pastry making [21–25]

Irritants. Flour, detergents.

Sensitizers. Citrus fruits, flour improvers, thiamine, spices (cinnamon, cardamom), essential oils, azo dyes, fat preservatives (lauryl gallate), sodium carboxymethyl cellulose.

Contact urticaria. Flour, spices, essential oils, α-amylase.

Bartenders [26–28]

Irritants. Detergents, citrus fruits.

Sensitizers. Flavouring agents, citrus fruits, antibacterials in detergents, nickel.

Bathing attendants [29,30]

Irritants. Detergents, free or combined chlorine/bromine.

Sensitizers. Antimicrobial agents, sodium hypochlorite, formaldehyde, essential oils.

Contact urticaria. Sodium hypochlorite.

Bookbinders [31,32]

Irritants. Glues, solvents, paper.

Sensitizers. Glues, formaldehyde, plastic monomers, size (colophony, maleopimaric acid).

Building trade [33–36]

Irritants. Cement, chalk, fly ash, hydrochloric and hydrofluoric acids, glass wool, wood preservatives (also phototoxic), organic tin compounds.

Sensitizers. Cement and fly ash (chromate, cobalt), rubber and leather gloves, additives in shale oils, glues (phenol- or urea-formaldehyde resins), wood preservatives, teak, glass wool impregnated with phenol-formaldehyde resin, epoxy resin, polyurethanes, rubber strip seals, jointing materials.

Butchers [24,37–40]

Irritants. Detergents, meat, entrails.

Sensitizers. Nickel, colophony (sawdust), antiseptics, hardwood knife handles, meat.

Contact urticaria. Meat, blood.

Canning industry

Irritants. Brine, syrup, prawns and shrimps.

Sensitizers. Asparagus, carrots, preservatives (hexamethylenetetramine in fish canning), rubber gloves.

Contact urticaria. Fruit, vegetables, prawns, shrimps.

Carpenters, cabinet makers [41–45]

Irritants. French polish, solvents, glues, cleansers, wood preservatives (also phototoxic), glass fibre.

Sensitizers. Exotic woods (teak, mahogany, rosewood, etc.), glues, polishes, turpentine, nickel, rubber (handles), plastics, colophony, and epoxy, acrylic, formaldehyde and isocyanate resins.

Chemical and pharmaceutical industry [46–50]

Irritants and sensitizers are numerous and specific for each workplace. Halogenated chemical intermediates are frequent sensitizers.

Cleaning work [51,52]

Irritants. Detergents, solvents.

Sensitizers. Rubber gloves, nickel, formaldehyde, perfumes.

Contact urticaria. Rubber gloves, perfumes, alcohols.

Coal miners [53–56]

Irritants. Stone dust, coal dust, oil, grease, hydraulic fluid, wood preservatives, cement, powdered limestone and anhydrous calcium sulphate.

Sensitizers. Rubber (boots), face masks, explosives, chromate and cobalt in cement.

Cooks, catering industry [2,24,57–61]

Irritants. Detergents, dressings, vinegar, fish, meat, fruit and vegetable juices.

Sensitizers. Fruit and vegetables (onions, garlic, lemons, lettuce, artichokes), hardwood knife handles, spices, formaldehyde, rubber gloves.

Contact urticaria. Meat, fish, fruit, vegetables.

Dentists and dental technicians [51,62–64]

Irritants. Soap, detergents, plaster of Paris, acrylic monomer, fluxes.

Sensitizers. Local anaesthetics (tetracaine, procaine), mercury, rubber, UV-curing acrylates, aromatic epoxy acrylates, aliphatic acrylates, melamine-formaldehyde resin, BAC-esterchloride, disinfectants and sterilants (formaldehyde, glutaraldehyde, eugenol), nickel, epoxy resin (filling), periodontal dressing (balsam of Peru, colophony, eugenol), catalysts (methyl-*p*-toluenesulphonate and methyl-1,4-dichlorbenzenesulphonate) in impression and sealant materials.

Contact urticaria. Saliva, rubber gloves.

Dyers [3,34,65–68]

Irritants. Solvents, oxidizing and reducing agents, hypochlorite, hair removers.

Sensitizers. Dyes, chromate, formaldehyde.

Electricians [1,69]

Irritants. Soldering flux.

Sensitizers. Soldering flux, insulating tape (rubber, colophony, tar), rubber, nickel, bitumen, epoxy resins, glues (phenol-formaldehyde), polyurethanes.

Electronics industry [70–72]

Irritants. Soldering flux, organic solvents, HF, fibreglass, antistatic agents.

Allergens. Soldering flux, chromate, cobalt, nickel, epoxy resins, anaerobic acrylic sealants.

Contact urticaria. Soldering flux.

Enamel workers [73]

Irritants. Enamel powder.

Sensitizers. Chromate, nickel, cobalt.

Fishing [57,74–78]

Irritants. Wet work, friction, oils, petrol, redfeed from mackerel, fish juice (polypeptides).

Sensitizers. Tars, organic dyes in nets, rubber boots, rubber gloves, marine organisms (Dogger Bank itch) and plants.

Contact urticaria. Fish, marine organisms and plants.

Floor layers [1,79]

Irritants. Solvents, detergents, cement (can be ulcerative).

Sensitizers. Chromate (cement), epoxy resin, glues (phenol- and urea-formaldehyde), exotic woods, acrylates, varnish (urea-formaldehyde), polyurethanes.

Florists, gardeners, plant growers [80–84]

Irritants. Manure, bulbs, fertilizers, pesticides.

Sensitizers. Plants (*Primula obconica*, chrysanthemum, Asteraceae (Compositae), weeds, tulips, narcissus, daffodils, alstroemeria), formaldehyde, pesticides, lichens.

Food industry [24,25,57,59,61]

Irritants. Detergents, vegetables.

Sensitizers. Rubber gloves, spices, vegetables, fruits, preservatives.

Contact urticaria. Vegetables, fruits, meats, fish.

Foundry work [1,34,85]

Irritants. Oils, phenol-formaldehyde resins.

Sensitizers. Phenol- and urea-formaldehyde resins, furan and epoxy resins, chromate (cement, gloves, bricks).

Glaziers [1]

Sensitizers. Rubber, epoxy resin, hardwoods.

Hairdressers and barbers [2,51,86–90]

Irritants. Shampoos, soaps, permanent-wave liquids, bleaching agents.

Sensitizers. Hair dyes, rubber, nickel, perfumes, lanolin, thioglycolates, cocamidopropylbetaine.

Contact urticaria. Ammonium persulphate, henna, rubber gloves.

Histology technicians [1,91,92]

Irritants. Solvents, formaldehyde.

Sensitizers. Formaldehyde, glutaraldehyde, organic dyes, epoxy resin, acrylates, D-limonene.

Hospital workers [51,52,93–96]

Irritants. Disinfectants, quaternary ammonium compounds, hand creams, soaps, detergents.

Sensitizers. Rubber gloves, formaldehyde, chloroxylenol, penicillin, cephalosporins, streptomycin, neomycin, piperazine, phenothiazines, hand creams, nickel, glutaraldehyde, acrylic monomer, nitrogen mustard, local anaesthetics, propacetamol.

Contact urticaria. Rubber gloves, cisplatin.

Housework [59,61,97]

Irritants. Detergents, solvents, polishes, wet work, vegetables.

Sensitizers. Rubber (gloves), nickel, chromate, flowers and plants, hand creams and lotions, handles of knives and irons, oranges, balsams, spices, pyrethrum.

Contact urticaria. Vegetables, fruits, meats, fish, spices, rubber gloves.

Jewellers [1,98,99]

Irritants. Solvents, fluxes.

Sensitizers. Nickel, epoxy resins, enamels (chromate, nickel, cobalt), precious metals.

Masons [33,100]

Irritants. Cement, chalk, bricks, acids.

Sensitizers. Chromate and cobalt in cement, rubber and leather gloves, epoxy resin, hardwoods.

Mechanics [1,18,101,102]

Irritants. Solvents, detergents, degreasers, lubricants, oils, cooling system fluids, battery acid, soldering flux.

Sensitizers. Rubber, chromate, nickel, epoxy resin, polyester resin, D-limonene.

Metal workers [1,34,103,104]

Irritants. Cutting and drilling oils, hand cleansers, solvents.

Sensitizers. Nickel, chromate (antirust agents and dyes, welding fumes), cobalt, colophony (tall oil), antibacterial agents and antioxidants in cutting oils, and chromate, cobalt and nickel in used cutting oils.

Office workers [1,105–109]

Irritants. Photocopy paper, fibreglass, indoor climate.

Sensitizers. Rubber (erasing rubber, mats, cords, finger stalls), nickel (clips, scissors, typewriters), copying papers, glue, felt-tip pen dyes.

Painters and handymen [1,99,110–113]

Irritants. Solvents, turpentine, thinner, emulsion paints, wallpaper adhesive, organic tin compounds.

Sensitizers. Turpentine, dipentene, D-limonene, cobalt (dyes, driers), chromate (green, yellow), polyurethane, epoxy and acrylic resins, triglycidyl isocyanurate, glues (urea- and phenol-formaldehyde), varnish (colophony, urea-formaldehyde), preservatives in water-based paints and glues (methylol-chloroacetamide, chloroacetamide), polyester paint pigments.

Performing artists [114–117]

Irritants. Mechanical, sweating.

Sensitizers. Cosmetics, colophony, nickel, hardwoods.

Photography [1,118,119]

Irritants. Alkalis, reducing and oxidizing agents, solvents.

Sensitizers. Metol (*p*-aminophenol), colour developers (azo compounds), chromate, formaldehyde, PBA-1.

Plastics industry [120,121]

Irritants. Solvents, styrene, oxidizing agents, acids.

Sensitizers. Low-molecular-weight raw materials, hardeners, additives, dyes, styrene.

Plating–electroplating (and electroforming) [1,34,122–126]

Irritants. Metal cleaners, alkalis, acids, detergents, heat, dust from metal blasting.

Sensitizers. Nickel, chromate, cobalt, mercury, gold, rhodium, rubber gloves.

Plumbers [1,127,128]

Irritants. Oils, soldering flux, hand cleansers.

Sensitizers. Rubber (gloves, packing, hoses), nickel, chromate (cement, antirust paint), epoxy resin, hydrazine, epichloro-hydrin (solvent cement).

Printers [1,34,129,130]

Irritants. Solvents, acrylates in radiation-curing printing inks and lacquers.

Sensitizers. Nickel, chromate, cobalt, formaldehyde, isothiazolinones, colophony, paper finishes, glues, turpentine, azo dyes, acrylates, etc., in radiation-curing printing inks, lacquers and printing plates, rubber gloves.

Radio and television repair [1,34]

Irritants. Soldering flux, solvents.

Sensitizers. Soldering flux (hydrazine, colophony), epoxy resin, nickel, chromate.

Restaurant personnel [59,61]

Irritants. Detergents, vegetables, citrus fruits, shrimps, herring.

Sensitizers. Nickel, spices, vegetables, hardwoods (knife handles).

Contact urticaria. Vegetables, fruits, meats, fish.

Road workers [1]

Irritants. Sand–oil mix, asphalt (phototoxic), hand cleansers.

Sensitizers. Cement, gloves (leather, rubber), epoxy resin, tar, chromate in antirust paint.

Rubber workers [131–134]

Irritants. Talc, zinc stearate, solvents.

Sensitizers. Rubber chemicals, organic dyes, tars, colophony, chromate, cobalt, phenol-formaldehyde resin.

Sheet metal workers [34,135,136]

Irritants. Solvents, paints.

Sensitizers. Chromium in paints and on zinc-galvanized sheets, glues.

Shoemakers [1,137–139]

Irritants. Solvents.

Sensitizers. Glues (PTBPF resin), leather (formaldehyde, chloroacetamide, chromate, dyes), turpentine, rubber, colophony, bisphenol A.

Shop assistants [140]

Irritants. Detergents, vegetables, fruit, meats, fish.

Sensitizers. Nickel, colophony (price labels).

Contact urticaria. Vegetables, fruits.

Tanners [1,34,141–143]

Irritants. Acids, alkalis, reducing and oxidizing agents.

Sensitizers. Chromate, formaldehyde, glutaraldehyde, vegetable tanning agents, finishes, anti-mildew agents, dyes, resins.

Contact urticaria. Formaldehyde.

Textile workers [1,67,142,144,145]

Irritants. Solvents, bleaching agents, fibres, formaldehyde.

Sensitizers. Finishes (formaldehyde resins), dyes, mordants, caprolactam, nickel, diazo paper.

Contact urticaria. Formaldehyde.

Veterinarians [51,146–149]

Irritants. Hypochlorite, quaternary ammonium compounds, cresol, rectal and vaginal examinations of cattle.

Sensitizers. Rubber gloves, antibiotics (penicillin, streptomycin, neomycin, tylosin tartrate, virginiamycin), antimycotic agents, mercaptobenzothiazole (MBT) in medicaments, glutaraldehyde, preservatives in rectal lubricants.

Contact urticaria. Animal hair and dander, obstetric fluids, animal tissues, rubber gloves.

Welders [1,34]

Irritants. Oil.

Sensitizers. Chromium (welding fumes, gloves), nickel, cobalt.

Woodworkers [42,43,150–153]

Irritants. Woods, wood preservatives, solvents, detergents, fibreboard (urea-formaldehyde resin).

Sensitizers. Woods, wood preservatives, colophony, turpentine, balsams, tars, lacquers, glues (urea, phenol- and PTBP-formaldehyde resins), *Frullania*, lichens.

Contact urticaria. Woods.

Chapter 22

Mechanical and Thermal Injury

C.T.C. Kennedy & D.A.R. Burd

[C.T.C. Kennedy, pp. 22.1–22.66]

The skin is constantly subjected to both internal and external mechanical forces, so that for experimental purposes it may be impossible to determine what constitutes the normal resting state. These forces are likely to be as important in the maintenance of the structural integrity of the connective tissues of the skin [1,2] as they are with bone, which becomes demineralized during the protracted absence of normal gravitational force during space travel [3]. In contrast to events in the whole organism, isolated human dermal fibroblasts in culture make more collagen when subjected to reduced gravity [4]. Many normal biochemical functions of the skin are dependent on appropriate mechanical forces, and when these become excessive, as in lymphoedema, protease inhibitors are released with many deleterious consequences [5].

Healthy skin is well adapted to resist the adverse effects of a wide range of mechanical injuries [6]. These include friction, pressure, contusion, laceration, suction and vibration. The clinical consequence of injury will depend on characteristics of the noxious stimulus, such as its intensity and duration. Factors related to the skin also influence the response; thus, the same degree of friction may produce a blister in one person but no visible change in another. Time is required for adaptive responses, such as callus formation and lichenification, to occur.

Determinants of the response to injury

It is likely that racial and genetic factors have a major role in determining the responses to mechanical forces. At extremes of age, the skin has a reduced ability to withstand shear and other forces. Body site can determine how the skin responds, for example friction blisters do not occur on loose skin. The presence and degree of subcutaneous fat will influence the effect of pressure on the skin.

The physiological status of the skin that is being subjected to injury can have a major effect; for example, a moderate degree of sweating hydrates the stratum corneum and increases the coefficient of friction, whereas higher levels of sweating sufficient to produce free fluid on the surface markedly reduce the coefficient of friction. Environmental temperature is also important, as is humidity, the stratum corneum becoming brittle and inelastic when humidity is reduced. The withdrawal response to noxious stimuli is impaired by neurological disorders, such as syringomyelia, and as a result burns and other injuries are common in patients with neurological deficits. Some systemic diseases can result in a qualitatively different response to injury, for example the dermopathy of diabetes, and debilitating disease will increase susceptibility to pressure. The defective organization of the dermal–epidermal junction or of the superficial dermis seen in the mechanobullous disorders predisposes to blister formation with trivial trauma, and individuals with disorders of the connective tissue, such as Ehlers–Danlos syndrome and Marfan's syndrome, show abnormal fragility to mechanical injury. Some drugs, notably corticosteroids and d-penicillamine, can modify the structural integrity of the skin. Occasionally, structural changes in the skin protect patients from mechanical injury. In amyotrophic lateral sclerosis, pressure ulcers occur less than in comparably bedridden patients, probably because of more dense packing of collagen fibrils [7]. Finally, there seem to be reproducible differences in response between individuals that are poorly understood.

The discussion of mechanical and thermal injury to the skin in this chapter is limited to those effects that may concern the dermatologist. Some conditions are discussed elsewhere; for example, self-inflicted trauma (see Chapter 61) and the effects of cold (see Chapter 23). The therapeutic uses of pressure applied to the skin for venous hypertension (see Chapter 50), lymphoedema (see Chapter 51) and hypertrophic scars (see Chapter 46) are discussed in other chapters.

Isomorphic (Koebner) response

Definition. The development of lesions in previously normal skin that has been subjected to trauma [1,2]. The response should be reproducible and not limited to one type of trauma. The term Koebner response is best not used when a dermatosis occurs resulting from the spread of an infective agent (e.g. molluscum contagiosum or warts); for this phenomenon, the term *pseudo-Koebner* could be used. In the 'reverse' Koebner response, trauma to a lesion results in it resolving.

It differs from the *isotopic response* [3,4], in which a dermatosis occurs at the site of a previous healed and unrelated dermatosis; this is not within the scope of this chapter.

History. Koebner originally described the localization of psoriasis to skin injured by a wide range of stimuli [1] but the term has been used for a similar phenomenon in other diseases [2].

Aetiology. Many forms of physical trauma, including friction, pressure, incision and laceration, skin grafting, bites, vaccination skin tests, burns, freezing, and ultraviolet (UV) and ionizing radiation have been implicated; in addition, many infections of the skin and dermatoses have been associated with the Koebner response.

Pathogenesis. Underlying mechanisms have been most intensively studied in psoriasis (Fig. 22.1) [5] in which it seems that the epidermis and dermis both contribute [6], but epidermal damage is probably a critical event [7]. There is an increased influx of CD4 lymphocytes [8] and local production of cytokines and adhesion molecules are likely to be important. Little is known about the pathogenesis in other conditions in which the Koebner phenomenon occurs.

Clinical features. A dermatosis develops at a site of trauma. In psoriasis, the Koebner response occurs in about 20% of patients, but reported series vary widely [5]; the latency is about 10–14 days, and a Koebner response is more likely to occur when the disease is active. As well as in psoriasis [9], the Koebner response is often seen in lichen planus [2] and vitiligo [10–13]. It has been well

Table 22.1 Diseases showing the Koebner response.

Carcinomas	Fisher *et al*. [14]
Darier's disease	Penrod *et al*. [15]
Erythema multiforme	Huff and Weston [16]
Hailey–Hailey disease	Morales *et al*. [17]
Leukaemia	Koizumi *et al*. [18]
Lichen planus	(Chapter 42)
Lichen sclerosus	Todd *et al*. [19]
Scleromyxoedema	Durani *et al*. [23]
Multicentric reticulohistiocytosis	Aldridge *et al*. [26]
Necrobiosis lipoidica	Gebauer & Armstrong [21]
Perforating collagenosis and folliculitis	Jelinek [22]
Psoriasis	Farber *et al*. [9]
Myxoedema, pretibial	Missner *et al*. [20]
Vasculitis	Green & Narajan [24]
Vitiligo	Sweet [10]
Xanthoma	Miwa & Kanzaki [25]

recorded in many other diseases, some of which are shown in Table 22.1 [14–26].

It is controversial whether it is appropriate to use the term Koebner phenomenon for the pustular response to injury in Behçet's disease and pyoderma gangrenosum; this is usually termed pathergy (see Chapter 49). Kaposi's sarcoma is still sometimes included, although some cases could be an example of pseudo-Koebner response caused by Kaposi's sarcoma-related herpesvirus [27] and others are examples of the isotopic response [28].

Nikolsky sign

This well-known effect of shearing trauma was originally described as evoking lesions of pemphigus foliaceus but may be positive in other bullous diseases (see Chapter 41).

Utilization of mechanical stimuli [1]

Selective use may be made of mechanical stimuli to confirm the diagnosis or to allow for biopsy of early lesions in conditions in which dynamic changes and secondary effects occur rapidly. Simple frictional trauma, such as that caused by twisting a rubber-tipped pencil on the skin, can be used to facilitate accurate diagnosis of mechanobullous diseases.

The Nikolsky and Koebner phenomena may be used to study the early changes in diseases in which they are characteristic and can be of value in the diagnosis of pemphigus when patients are already on treatment and immunofluorescent techniques are not available [2]. The pustular reaction to skin puncture (including venesection) is evidence of an active stage of Behçet's syndrome. Suction [3,4] evokes bullous diseases and may produce petechiae in scurvy, etc. It has also been used to study vasculitis [5,6].

Firm stroking of the skin may elicit purpura in amyloidosis, is routinely used to diagnose dermographism, and has also been used to study the early lesions of vasculitis [7] and to confirm a diagnosis of delayed pressure urticaria [8].

Biomechanical considerations [1–3]

Resistance to various mechanical stimuli, both external and arising within the body, is a fundamental property of the skin. External forces include friction, stretching, compression, vibration and penetration. The major mechanical properties of skin are stiffness (resistance to change of shape), elasticity (ability to recover the initial shape after deformation) and viscoelasticity (see below). Quantification of the behaviour of skin subjected to mechanical forces is complicated by many factors. The skin is composed of not one but multiple and interrelated functional components, and its behaviour is subject to the confounding effects of physiological phenomena, such as the previous experience of the tissue, nutritional status, sweating and sebum excretion. Other variables of practical relevance [4] are related to body site, age, sex and disease—not only cutaneous disease but also systemic (e.g. diabetes). In addition, the mechanical properties of the skin may be profoundly influenced by environmental factors such as UV and heat radiation.

The generation of mechanical forces within the skin and subcutis has long been of interest to surgeons, with early contributions by Langer on the oval shapes produced when round punctures are made in the skin, and the recognition of relaxed skin tension lines [5]. The mechanical qualities of skin, especially creep, are critical to understanding expansion techniques used in dermatological surgery [6]. The effects of mechanical forces have also been studied extensively in relation to wound healing and the consequences of excess fluid in tissues [7].

In vitro studies have shown that application of mechanical stress results in increased DNA synthesis [8], production of collagen and proteoglycans [9], non-collagenous proteins [10] and cytoskeleton formation. Application of mechanical force intermittently results in more cellular activity than a constant force [11]. Wounds that heal under some stress have greater strength than those where there is no stress [12].

The importance of weight bearing on bones for their normal structural integrity was recognized long ago, and the stress imposed by gravitational forces is also important for the maintenance of dermal constituents [13].

A quantitative analysis of mechanical properties of skin and subjacent tissues must begin from engineering principles [1,14]. Most studies involve the measurement over time of deformation produced by a given constant force. The force is standardized as force per unit area or 'stress'. Stresses perpendicular to the surface are termed normal, whereas those in other directions are termed shearing stresses. The change in dimensions may be expressed as 'strain' and is the ratio between the deformation and the original length. Many elastic materials show a linear relationship between stress and strain, for example:

Stress = Young's modulus × strain.

Similarly, linear viscous liquids obey Newton's law in which stress is directly proportional to the rate of strain but independent of the strain itself. Many biological materials combine the characteristics of elastic solids and viscous liquids and are termed viscoelastic. Skin, in common with other viscoelastic materials, has non-linear stress–strain properties and has time-dependent behaviour even with low loads [15]. The best known of these are the properties of hysteresis (in which the stress–strain relationships are different between loading and unloading), stress relaxation (the stress resulting from a constant strain decreases with time) and 'creep' (increasing strain or length of the material when a constant stress is maintained). These time-dependent properties are thought in part to be a function of the ground substance. Furthermore, skin shows anisotropic properties; there is a systematic and regular directional variation in its mechanical and viscoelastic properties. The elastic component is broadly analogous to a linear spring and the viscous component to a dashpot shock absorber.

Much of the earlier work on the mechanical properties of the skin was carried out on tissues or their components (collagen, elastin, etc.) *in vitro* [1,16–18]. Strength-related values such as breaking strain, time-dependent creep and non-time-dependent parameters, such as elasticity and viscosity, have been measured, but these studies can be unhelpful in predicting the behaviour of whole skin *in vivo*.

The principal source of mechanical strength in the skin and subcutis is the reticular dermis; the papillary and periadnexal dermis (often known as adventitial dermis) and the connective tissue running between fat lobules to deeper structures have somewhat similar and lesser capacity to resist deformation [19], and it is likely that the epidermal components are only relevant in resisting relatively minor forces [2]. At a molecular level, it is the properties of collagen, usually of types I and III and its relationship with elastic fibres and ground substance, that determine the mechanical responses of skin.

Mechanical properties of the skin

Methods of evaluation [1–3]

Many methods have been used to derive information about mechanical properties of the skin. Most methods measure properties of the dermis, although some give information predominantly about the stratum corneum [4,5], and all have limitations.

1 Tensile tests, in which the skin is extended by applying a force parallel to the surface [6–16]
2 Torsional tests, in which force is used to rotate a disc glued to the skin [3,17–22]
3 Vertical traction [4,23–25]
4 Indentation [5,24–29]
5 Suction within a cup pressed on the skin [30–37]
6 Vibration, for example using the hammer of a ballistometer [38–41]
7 Elastic wave propagation [42]
8 Hardness, using a durometer [43,44].

Because of problems with standardization of methods, results are usually not comparable between investigators. Details of methodology, such as the area of skin subjected to suction, are of great importance in understanding which zone of the skin is being evaluated. Results should always be standardized for skin thickness [45,46]. One of the few studies that has directly compared different methods concluded that the suction cup device mainly measures elasticity whereas the ballistometer predominantly measures stiffness [47].

Some of the measurements that can be derived from *in vivo* methods such as torsion [45] and suction [46] can be expressed as ratios, obviating the dependence on skin thickness, and give useful information about the elastic and viscoelastic properties of skin (Fig. 22.2). Despite their shortcomings, the various methods used have led to a general understanding of the mechanical properties of the skin, and quantification of some of these properties has proved useful in the recognition of pathological changes in connective tissues before they have become clinically apparent [1].

Determinants

Stratum corneum

The main function of the stratum corneum is to provide a limited barrier across which exchanges occur with the

environment. *In vivo* it is criss-crossed by a series of depressions outlining polygonal zones. This pattern is anisotropic and related to the anisotropy of the underlying dermis. When subjected to stretch it is only slightly extensible [1], deformation occurring by flattening out or redistribution of these depressions [2]. These changes cause secondary alterations in shape of the cells in the Malpighian layer and the underlying papillary dermis [2]. The elastic modulus of the individual corneocyte is far higher than of the complete stratum corneum, suggesting that the biomechanical properties of the latter are largely a function of the substances binding the cells to each other [3,4].

The extensibility of the stratum corneum is greatly influenced by the relative humidity and its state of hydration [4–9].

Frictional contact with the stratum corneum is an essential prerequisite for tactile sensation and many physical activities. It is also a cause of a variety of acute and chronic injuries to the skin. The stratum corneum behaves as a viscoelastic membrane when subjected to frictional force. The major component producing friction is a tendency to adhesion at the surface. In general, frictional resistance increases with the state of hydration, although free water or sebum on the surface reduces resistance. The contribution of the stratum corneum towards skin biomechanics can be seen in studies evaluating the effect of moisturizers and emollients. Extensibility and creep were both rapidly increased by water and paraffin oil, and glycerine more slowly; water only had a very short-term effect [10]. Chemical modification of stratum corneum proteins (e.g. by glutaraldehyde) can also reduce frictional resistance [11].

Basement-membrane region

This has been evaluated mainly by suction devices, which can split the skin in this region. It is likely that the basement-membrane region has a relatively minor role in the overall mechanical integrity of the skin [12], although abnormalities of structural components such as laminin 5 in the lamina lucida cause marked weakening of the skin in some types of junctional epidermolysis bullosa.

Dermis

The dermal collagen bundles are an intermeshing network of undulating fibres (see Chapter 3). Although electron-microscopic studies show the bundles running in all directions, in the reticular dermis the predominant direction is parallel with the skin surface, and in the adventitial dermis and subcutis the alignment is perpendicular to the surface. The initial response to deformation is a straightening of the collagen bundles and realignment of the straightened fibres in the direction of the applied force; beyond this, extension may occur through slip between fibrils, a process opposed by the closely associated glycosaminoglycans (see Chapter 3). Elastic fibres are responsible for returning the collagen to its predeformation state, particularly with low levels of load [13]. Elastin is the only mammalian protein with truly elastic properties. The interdependence of elastic tissue and collagen has been demonstrated in experiments using selective removal [14].

Physiological variation

Age

From about the age of 35 years in women and 45 years in men, the thickness of skin decreases with ageing on light-protected sites and the dermal–epidermal junction becomes flatter [1–4]. Many studies, using a variety of techniques, have evaluated the skin at different ages (reviewed in [5]). Although there are some conflicting results, overall there is agreement that there is a decrease in elastic properties with age. It seems likely that there is increasing resistance by the dermis to traction parallel to the skin surface, at least until the age of 60 years, but vertical resistances at the dermal–epidermal junction and within the dermis and subcutis progressively fall. Using a

device for propagation of low amplitude shear disturbances it has been shown that there is a progressive increase in viscosity of the skin with age [6].

Sex

Again, no clear answer emerges as to whether there is a difference between sexes, except for skin thickness after menopause. Some methods have shown that female skin is more extensible [7–9], although others have failed to confirm this [1,10,11]. The increase in extensibility from hydration of the stratum corneum may be greater in women than men [12]. Hormone replacement therapy appears to alleviate increased slackness of the skin associated with the menopause [13].

Body site

There are great differences between body sites, mainly because of differences in skin thickness [3,14]. When this is corrected for, skin distensibility and elasticity are lower in the acral areas than centrally, and are subject to diurnal variation, with elasticity increasing in the evening [15]. These properties contribute resistance to gravitational oedema formation, and are diminished in the elderly.

Using a small suction device, the ratio between viscous deformation and elastic deformation and the biological elasticity (i.e. the ratio between immediate recovery and total deformation) was lower in vulva than in forearm skin [16].

Light exposure

Chronic sun exposure produces a decrease in extensibility, elastic recovery and elastic modulus. The higher the melanin content, the lower the differences between sun-exposed compared with sun-protected sites [17]. Sun-exposed facial dermis has both increased thickness and decreased parameters of elasticity [18].

Pathological variation

Various *in vivo* techniques have been used to measure mechanical properties of the skin in disease states over a period of time. In some situations, the abnormalities have predated the clinical changes. Such measurements clearly have application for monitoring therapy [19]. Examples include scleroderma [20–23] and its treatment by d-penicillamine [24,25]; the decreased distensibility but unaltered elasticity of scleroderma of Buschke [26,27]; the consequences of corticosteroid atrophy [28,29]; the waxy skin of diabetics [30]; reduced extensibility (photosclerosis) resulting from psoralen and UVA (PUVA) therapy [31–33]; an acute increase in elasticity during radiotherapy [34] and the gravitational syndrome [35]. In lymphoedema there is reduced viscoelasticity [36]. Chronic haemodialysis produces some impairment of the viscous properties similar to those of ageing [37]. Useful correlations have emerged between biomechanical and genetic differences in diseases of connective tissue such as pseudoxanthoma elasticum [38] and Ehlers–Danlos syndrome [39–41]. Smoking can cause facial wrinkling [42] but the biomechanical correlates have not been defined.

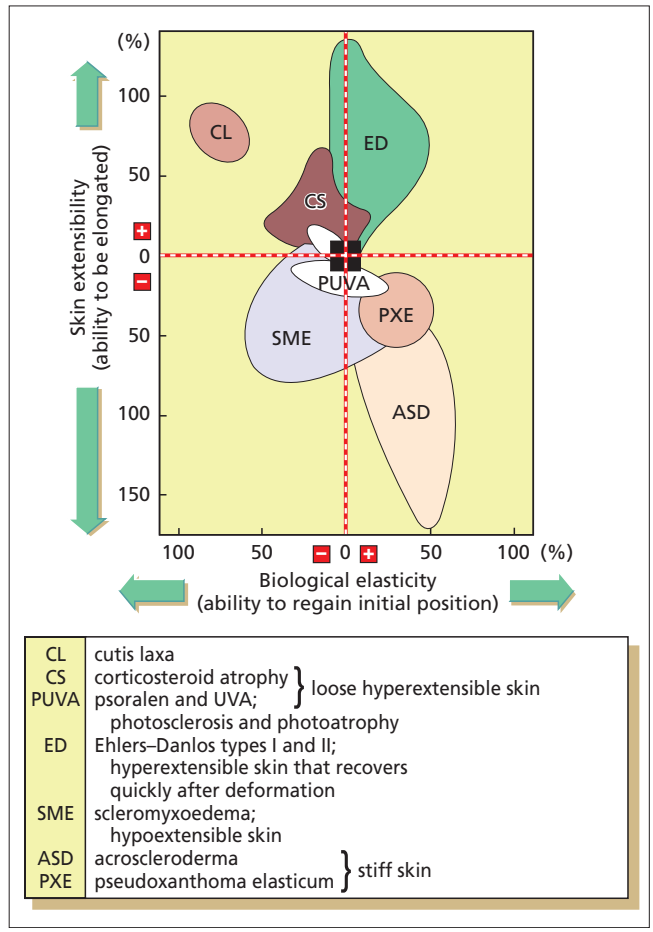

Fig. 22.3 Rheological properties of some conditions affecting the dermis. Each area represents data from several patients. (From Piérard *et al*. [33].)

Piérard *et al*. [31] have studied the ability of skin to be elongated (skin extensibility) and its capacity to regain the initial position after deformation (biological elasticity) in a number of disease states: their findings are used in Fig. 22.3 to illustrate the principles outlined in this section.

Effects of friction

Friction is defined as the resistance that any body meets in moving over another. Humans cannot function without friction between themselves and the environment, although even mild degrees of friction can cause distress, as in the unpleasant sensation that wool can induce for an atopic subject. Excessive frictional forces will cause injury, which may be acute, occurring in seconds or minutes, or chronic as a result of repeated, lesser degrees of friction. The response of the skin will depend on the magnitude and duration of the frictional force applied and properties of the skin itself. Abrasions and friction blisters are examples of acute frictional trauma, but blisters can only form if the stratum corneum is tough and thick enough to form a blister roof. Friction blisters are therefore difficult to produce except on the palms and soles [1]. The chronic effects of friction are dependent on adaptive responses, in particular a steady rate of increase in epidermal turnover, and perhaps the laying down of thickened, vertically orientated collagen bundles in the papillary dermis, as seen in lichenification. The best defined clinical consequences of chronic frictional injury are calluses and corns, but various forms of dermatitis are perpetuated and perhaps initiated by friction (see below).

The scientific study of friction-induced injury has largely been directed towards understanding friction blister formation. The laws of static friction state that frictional resistance is: (i) directly proportional to load; and (ii) independent of the area of contact between the surfaces [2]. The ratio between the force necessary to move one surface over the other and the load between the two surfaces is thus a constant, called the coefficient of friction. The static coefficient of friction is the force required to start one object in motion past another and the dynamic coefficient is the force required to sustain the motion of

one object past another. Because of its viscoelastic properties, skin deviates from Amonton's laws. Several different techniques have been used to measure friction [1–12]. Coefficients of static and dynamic friction have been determined for a number of materials in contact with human skin, with and without lubricants, but there is great individual variation [1,2,13,14]. Of the various anatomical sites measured, the palm of the hand has the highest coefficient of friction [15]. A number of machines to simulate repetitive rubbing have been devised, but there is no entirely satisfactory model for chronic frictional injury [6].

Physiological changes, such as the degree of hydration, have a large effect—very dry or wet skin having a much lower frictional resistance than moderately hydrated skin [16] for most sites but not for the dorsal forearm or lower back [17]. Skin surface lipids have relatively little effect [18]. Petrolatum initially decreases the coefficient of friction because of its lubricating property but then increases it because of its occluding effect on skin, causing increased hydration [14]. Age and sex have no significant effect on frictional properties of the skin, but body site is important; the forehead and behind the ear have the highest dynamic coefficient of friction and the abdomen the lowest [17]. The rough skin in atopics has a lower coefficient of friction than normal [10].

Callosities, corns and calluses

Definition [1]. A callosity is a plaque of hyperkeratosis caused by repeated friction and/or pressure. A corn is a sharply demarcated callosity occurring over a bony prominence, usually on the hand or foot, and is painful. A soft corn occurs between the toes. Podiatrists often refer to a corn as a heloma (Greek *helus*, a stone wedge). A callus is a broad-based diffuse area of hyperkeratosis of *relatively* even thickness, usually under the metatarsal heads.

Aetiology. Calluses (Fig. 22.4) and corns on the feet are usually the result of deformity, sometimes associated with dynamic changes in the function of the foot, and are often made worse or even caused by unsuitable footwear [2]. Perhaps the most extreme example of footwear causing gross abnormalities is the Chinese foot-binding syndrome, although some Western shoe fashions, such as 'winkle-pickers' and high-heeled shoes, can be similarly damaging albeit on a lesser scale [3]. Various intrinsic abnormalities of the foot predispose to callosities. These include bony prominences, a prominent condylar projection or malunion of a fracture. In some rheumatic diseases

Fig. 22.4 Calluses of the forefoot.

(e.g. rheumatoid arthritis) there are distinctive patterns of callosity formation which can be predicted from the joints involved [4]. Diabetic subjects, especially those with neuropathy, are prone to callus formation, and high pressure is strongly associated with ulceration [5]. Faulty foot mechanics can occur when there is a toe deformity (claw, hammer, mallet), a short first metatarsal or hallux rigidus. The dermatologist should be aware of the effects of deformity throughout the foot. In the hindfoot, a varus or valgus position of the heel as an anatomical abnormality will lead to a failure of the foot to absorb loads applied to it during the stance phase of gait. The net result is that excessive loads are applied to the plantar skin, leading to callosities. The pattern of these changes can be very distinctive. With the hindfoot anomaly, there is often an associated forefoot deformity with excessive pronation or supination of the metatarsals, hallux valgus and fixed deformities of the lesser toes. Calluses on the edges of the weight-bearing area of the sole are often caused by shoes that are too loose.

The biomechanics of the foot that lead to callosities have been investigated in detail [6–8]. A variety of measuring devices are available to document the abnormal forces and assist design of appropriate orthoses [9].

On the dorsum of the foot, factors provoking callosities include footwear and a habit of sitting with the foot tucked under the body [10,11], with or without a prominent underlying talus.

The soft corn usually occurs when tight shoes press the condyle of a metatarsal or phalanx against the base of a phalanx on the adjacent toe.

On the hand and at other sites, callosities generally reflect repeated frictional injury which will be apparent from the history.

An inherited disposition to callosities has been described, with an autosomal dominant inheritance [12,13].

Pathology. In a callus, there is epidermal hyperplasia. The stratum corneum is thickened and compact, sometimes with parakeratosis over the dermal papillae, and there may be expansion of the granular layer. The underlying dermis may show an increase in dermal collagen and fibrosis around neurovascular bundles.

A corn differs in that there is a thick parakeratotic plug set in a cup-shaped depression of the epidermis, usually with loss of the granular cell layer.

Clinical features. These are as follows.

Feet [1,5,10–12]. On the plantar surface, the most common site for corns and callosities is over the metatarsal heads (Fig. 22.4), although the sides of the arches and heel can be involved. A callus is an ill-defined area of waxy, often yellowish thickening over which the dermatoglyphic markings may become indistinct. A corn is smaller, usually very painful, and may have a glassy centre. Corns can occur within an area of callus. On the dorsum of the foot, corns and calluses are particularly found over the interphalangeal joints and tips of the toes. A distinctive variety of callus occurs over the talus, anteromedial to the lateral malleolus [12].

In the autosomal dominant 'hereditary callosities', blisters occur at the periphery of hyperkeratotic skin [12]. This is distinct from epidermolysis bullosa, epidermolytic hyperkeratosis and blistering sometimes associated with palmoplantar keratodermas (see Chapter 34).

The soft corn is usually between the fourth and fifth toes, is typically very painful and exhibits hyperkeratosis that becomes white from maceration. A small sinus may be present, and secondary bacterial infection can then present as cellulitis.

Hands. Callosities on the hands most commonly occur as distinctive occupational stigmata in many trades and professions [14,15]. Areas of thickening most commonly occur on the palmar surface and over the metacarpophalangeal joints. The site of the callosity may be highly specific [16]. They are rarely complained of, as was shown in a survey of solid-waste handlers in whom there was a 75% prevalence of palmar calluses [17]. Unless they become fissured or infected, they should be considered as an adaptation rather than a disability.

The habit of biting or chewing the side or knuckle of the finger is not uncommon in children ('gnaw warts'). Larger callosities are sometimes seen in the mentally retarded.

Callosities on the hands caused by frictional injury against the teeth have been described in patients with bulimia nervosa as a result of repeated manual stimulation of the gag reflex [18,19]. A distinctive hyperkeratosis on the side of the thumb can occur with use of a cigarette lighter [20].

Prayer nodules [21–23]. These are seen on the forehead of Shi'ite Muslims from repeatedly touching the forehead on a prayer stone. They may also occur on the knees and ankles from the squatting position adopted by worshippers. A similar pattern has been described on the ankles from sitting cross-legged [10].

Callosities from clothing and appliances. Trusses, especially if ill-fitting, may cause circumscribed patches of hyperkeratosis and pigmentation. Pressure from calipers or reinforced shoes may cause calluses in the disabled. The effects of friction and pressure on the amputee are discussed on p. 22.29.

Diagnosis. Corns on the feet can be difficult to distinguish from viral warts, particularly when the latter have a zone of reactive hyperkeratosis around them. Corns are generally more painful when pressed vertical to the skin

surface, whereas warts are more tender when squeezed laterally between the finger and thumb. Paring down a wart usually reveals the circumscribed abnormal surface markings. Granuloma annulare occasionally resembles callosity, but can be distinguished by biopsy. Various forms of keratoderma can resemble callosities, but do not occur selectively over sites of excessive compression.

Management. The major difficulties with diagnosis lie with foot callosities. The patient's footwear and any orthoses, the gait and the alignment of the feet should all be examined. Palpation may reveal abnormal bony prominences. There may be a past history of surgery. Radiography can be helpful. Pressure studies (pedobarographs) can be helpful in evaluating foot biomechanics (reviewed in [9,24]).

The aims of treatment are to:

1 Provide symptomatic relief
2 Determine the source of abnormal mechanical stress
3 Relieve the cause by conservative means
4 Consider surgery if these fail.

Relief of symptoms caused by corns and calluses can usually be achieved by careful and regular paring. Regular paring reduces the pressure induced by corns [25]. The initial procedure is often best done with a scalpel and subsequent treatment with an abrasive device. For soft corns, the use of a toe separator (felt, foam or silicone) can provide rapid relief. Salicylic acid (10–20%) keratolytic preparations can be of some help, but care is needed to avoid irritancy.

The role of the patient's shoes in producing callosities should be carefully assessed, and appropriate corrective steps taken. Extra width may be needed, especially with the toebox. A softer upper may be needed. With marginal calluses, the shoe is likely to be too loose. The shoe may need to be adapted to receive an orthosis—a cushioning device designed to redistribute the mechanical forces causing the callosity. Examples are the metatarsal pad for localized plantar callus, and a medial wedge for the cavovarus foot. Customized shoe inlays can be moved from shoe to shoe. Another useful orthosis is the silicone sleeve that can be used on deformed toes that have corns on them.

Sometimes, conservative measures are insufficient or fail. Surgical correction of toe deformities and resection of prominent condyles causing soft corns can be rewarding. Surgery for other bony causes should only be undertaken after careful study of radiographs and pedobarographs by an orthopaedic surgeon with expertise in the field [26,27]; results can be encouraging [28,29], but can also be disappointing [30].

The principles outlined above can be applied to symptomatic callosities elsewhere, for example at sites of abnormal pressure from a limb prosthesis. Occasionally, excision is justified on cosmetic grounds, for example for athlete's nodules [31].

Friction blisters

For friction blisters to occur, the stratum corneum must be strong enough not to be rubbed away. Usually, friction

Fig. 22.5 Friction blister on the palm mimicking a target lesion of erythema multiforme. This patient had generalized pruritus caused by biliary cirrhosis, and he repeatedly rubbed his thenar eminence on his skin to relieve the itch.

blisters do not form on lax or thin skin but are common on the palm (Fig. 22.5), sole, heel or dorsum of the fingers. Frictional force and the number of times an object moves across the skin determine the likelihood of blister development; the greater the force, the fewer the number of cycles of movement needed.

Pathology [1]. The blister usually forms in the spinous layer, just beneath the stratum granulosum. The keratinocytes in the base of the blister show variable oedema and perhaps degenerative changes. Mitotic activity commences in the base within 30 h [2].

Clinical features. These are usually self-evident and seldom present diagnostic problems when the cause is known. However, a patient may seek advice when a bulla appears unexpectedly or under inappropriate circumstances. It then becomes important for the dermatologist to consider whether the trauma was merely a localizing factor in a hitherto undiagnosed congenital or acquired disease (Fig. 22.5). As well as blister formation, there may be other consequences of the inciting trauma such as callus formation, petechiae, etc.

Prognosis. Uncomplicated blisters heal rapidly.

Diagnosis. A careful history of appropriate frictional trauma will usually enable the diagnosis to be made. There are often specific aspects of the circumstances in which blisters occur that are relevant to occupational causes [3] and other situations such as sporting activities. Trauma may induce lesions in both acquired and hereditary epidermolysis bullosa. Skin fragility can occasionally be a presenting feature of systemic amyloidosis, and the blisters seen in patients comatose from neurological lesions or drug overdose can clinically resemble those caused by friction; however, they differ histologically. Occasionally, bullous insect-bite reactions and other bullous diseases can be confused with friction blisters.

Management. Preventive measures include antiperspirants [4]; some case studies have shown that these may reduce blistering in epidermolysis bullosa simplex (Weber–Cockayne) [5] and in pachyonychia congenita [6]. Although most controlled trials have not shown convincing evidence of benefit [7,8], 20% aluminium chloride hexahydrate in anhydrous ethyl alcohol used for 3 days before hiking can reduce blistering [9]; but such preparations may cause irritant dermatitis. Foot powders with the aim of absorbing moisture are another traditional approach [10], but again controlled trials show lack of efficacy [11–13].

By contrast, certain types of synthetic insole can absorb frictional force and reduce blistering, for example Spenco, a closed-cell neoprene material [14,15], and the polyurethane product Poron [16]. Acrylic socks [17] and the use of a thin polyester sock under a thick, dense outer sock [18] can reduce blistering. It is likely that subthreshold exposure of the feet to friction reduces the likelihood of blistering [19].

When blistering has occurred, drainage so as to allow the roof to adhere to the base provides relief of symptoms and optimizes healing [20]. If the blister has burst and the roof has torn away, the wound should be treated with a non-adherent dressing and protective padding. Hydrocolloid dressings have been used with success [21,22].

Friction and dermatitis

The inflammatory changes that characterize eczematous dermatitis have been reported as a result of friction, and there are a number of eczematous conditions in which mild repetitive frictional injury has an important initiating, localizing or perpetuating role [1]. The importance of friction was recognized long ago [2], but has often been underestimated since. An experimental model has been devised [3].

Friction as a direct cause

Physical irritant contact dermatitis accounted for just over 1% of all patients attending a large contact dermatitis clinic in London, and of these about one-third were attributable to friction; low humidity was a common accompanying factor, especially for office workers [4].

Menné and Hjorth [5] described two workers repeatedly handling NCR (No Carbon Required) paper and a third whose contact was with bus tickets, who developed scaling, vesicles and occasional pustules on the areas of maximal contact; patch tests were negative. Three cases of nipple dermatitis were attributed to friction from poorly fitting brassieres [6].

Friction treatment for acne can lead to dermatitis [7].

Airbag dermatitis [8]

Although dermatitis was not proven in the histological sense, a symptomatic red rash has been described from injury from deployment of the airbag in automobiles. It is possible that talc used in the packaging plays a part as well as frictional injury. The bizarre shapes produced by the impact of the airbag can give the appearance of dermatitis artefacta [9].

Juvenile plantar dermatosis [10]

In this distinctive condition, there is a glazed, erythematous, hyperkeratotic and often fissured change on the contact areas of the anterior third of the plantar aspect of the feet (see Chapter 17).

Friction from footwear and barefoot sporting activities may be important causes, but are clearly not the only factors involved. In some series, there is a pronounced worsening in winter [11,12], whereas in others there is exacerbation in summer [13–15]. Certain types of occlusive footwear, such as the trainer shoe and rubber boots, often combined with relatively non-absorbent synthetic fibre socks, have been thought to contribute [15,16] and in some cases this may explain the seasonal effect. However, in a controlled study, children without juvenile plantar dermatosis had a similar use of trainer-type shoes as those with the disorder [17]. Up to 10% of cases have relevant contact allergy to shoe materials [10,17,18] and are clinically indistinguishable from the majority of cases, which are not caused by an allergic reaction.

Atopic dermatitis

Friction is probably one of many factors that account for the localization of atopic dermatitis, for example on the backs of the thighs in school children [19] and on the feet.

An eruption of follicular papules on the chin brought about by repeated contact with the knee has been described in Japanese children. It can resemble naevus sebaceous [20].

Contact dermatitis

Frictional injury presumably enhances percutaneous penetration of irritants and allergens. In the clinical setting, friction has been shown to have an adjuvant role in irritant dermatitis to soaps and detergents [21,22] and to cement [23], and is probably important in many other circumstances.

The induction of contact allergy is also more likely when there is concurrent mechanical trauma. In a series of 8230 patients patch tested for eczematous disorders, those who had sustained cuts, abrasions and other mechanical injuries had a much higher incidence of positive results than other groups [34]. In a number of industries, friction has been regarded as contributory to the high rate of allergic as well as irritant reactions, for example cobalt allergy in hard-metal workers [25].

Friction and nummular dermatitis

Patients sometimes attribute localization of nummular (discoid) dermatitis to repeated mild chronic frictional injury. An unusual example has been described as

shower-jet dermatitis, in which eczematous lesions were localized to an area on the front of the chest subjected to a high-pressure jet for 10–15 min/day [26].

Hyperkeratotic palmar and plantar dermatitis

Hyperkeratotic palmar dermatitis (see Chapter 17) has been described mainly in middle-aged or elderly men, and less commonly in women [27]. It may be difficult to distinguish from psoriasis, and some authors dispute its existence [28]. Chronic mechanical trauma and friction from hard manual work has been thought to be a contributory factor in some cases [1,27].

Frictional dermatitis of children

Although first described in 1956 [29], the exact status of this condition remains obscure and its prevalence undetermined. In a more recent series of cases, nearly half were atopic [30].

Aetiology. Friction from surfaces such as sand and rough carpets [31] and activities such as tobogganing [32] have been held responsible. Other authors have attributed the condition to sunlight [33] and similar cases have been described in which neither friction nor sunlight were considered to have a role [30].

Pathology. The histology shows mild non-specific changes with acanthosis, hyperkeratosis, small foci of spongiosis and a lymphohistiocytic infiltrate in the upper dermis [30].

Clinical features. An eruption of pinhead-sized pale or white papules or warty lesions occurs on the elbows, knees or backs of the hands, spreading to the adjacent areas, in children and occasionally in adolescence. Pruritus is mild. The condition may be more common in spring and summer.

Prognosis. The condition often recurs during childhood. Long-term studies have not been performed.

Treatment. A mild topical steroid or tar ointment is usually helpful.

Frictional sweat dermatitis

A spongiotic dermatitis occurring beneath undergarments during the hottest months of the year has been described from New Delhi and attributed to friction, heat and contact with sweat [34].

Friction and other dermatoses

Frictional trauma can localize skin diseases by means of the Koebner phenomenon (p. 22.2).

Psoriasis on the palms can be difficult to distinguish from hyperkeratotic eczema, and may be localized by

repetitive exposure to friction. A relationship to occupation is not always obvious [1].

Mechanical forces, including friction, are aetiological factors in acne mechanica (Chapter 43) and in dermographism and deep pressure urticaria (see Chapter 47).

Hyperpigmentation following repetitive rubbing occurs in predisposed, usually dark-skinned individuals and has been termed frictional melanosis. It is often localized over bony prominences of the trunk and limbs [2,3]. Frictional melanosis may occur *de novo*, or may accompany or follow dermatitis [4]. A distinctive rippled pattern, which overlaps with macular amyloidosis, has been described following the use of vigorous washing practices [5,6]. In some of these subjects, superficial amyloid deposits have been found on biopsy.

Pachydermodactyly, a distinctive digital fibromatosis (see Chapter 46), has been attributed to repetitive mechanical trauma such as repeated clasping of the hands and rubbing of crossed fingers [7]. Diffuse swelling of the digits, involving dermis as well as epidermis, clearly differs from calluses, knuckle pads, etc.

Bos and de Koning [8] described a distinctive frictional dermatosis on the upper gluteal region of elderly people, characterized by skin colour or slightly red patches with a rough surface and hyperkeratotic ridges running parallel to the natal cleft. These lesions occur particularly in those who spend most of the day sitting, and superficial ulceration may be a complication. Skin biopsies showed hyperkeratosis, psoriasiform hyperplasia, 'meandering' superficial vessels and some degenerative changes in the connective tissue.

Black heel and palm

SYN. TALON NOIR; CALCANEAL PETECHIAE

Definition. Pigmentation of the heel (or palm) secondary to extravasation of red blood cells.

Aetiology. The condition results from shear–stress rupture of the papillary capillaries, for example during violent sport, particularly where repeated jumping and sudden stopping or twisting of the heel occurs. Similar circumstances explain the occurrence on the palm.

Fig. 22.6 Black heel. Stippled pigmentation within the stratum corneum.

Pathology. Extravasated erythrocytes may be found in the dermal papillae [1], but often the histological changes are limited to the stratum corneum, where amorphous yellow–brown material may be found in rounded collections having undergone transepidermal elimination. This material is often negative with Perls' stain (which stains haemosiderin) but gives a positive benzidine reaction, showing that it is derived from haemoglobin [2,3].

Clinical features. Closely aggregated groups of bluish black specks occur suddenly at the back or side of the heel (Fig. 22.6), just above the hyperkeratotic edge of the foot. The metatarsal area has, rarely, been involved. The lesion may resemble a tattoo [4] or even a melanoma [2,5].

Either sex may be affected [2], but the condition is virtually confined to athletic adolescents [6]. Football, basketball, lacrosse and, less often, tennis and squash players are mainly affected. The condition can occur on the hands of weightlifters [7].

Diagnosis. When there is a history of sudden appearance of the pigmented lesions at a typical site, diagnosis is rarely in doubt. Viral wart can also produce a black stippled

appearance because of extravasation of red cells, but the skin surface is generally abnormal. Occasionally, melanoma or atypical melanocytic hyperplasia [8] will need to be excluded. With black heel, the patient and physician can usually be reassured by carefully paring the affected area, thereby completely removing the abnormality. By epiluminescence microscopy, black heel has highly specific features [9].

Treatment. The condition is usually asymptomatic, and its importance lies in its resemblance to malignant melanoma. When in doubt as to the diagnosis, carefully paring away the stratum corneum is generally sufficient to remove the pigment.

Pressure ulcer

SYN. DECUBITUS ULCER; BEDSORE; PRESSURE SORE

Definition. A localized area of necrosis caused by ischaemia, resulting from compression of soft tissue between a bony prominence and an external surface. Although formerly terms such as bedsore and decubitus ulcer (from the Latin 'to lie down') have been used, pressure ulcers can occur from prolonged pressure in any situation.

Epidemiology. The composition of populations studied for estimates of incidence and prevalence vary greatly, and even the definition of pressure ulcer (in particular whether erythema without ulceration is included), but nevertheless it is clear from the data that some groups are especially prone. Among hospital in-patients the prevalence varies between 3 and 14% [1–3].

The incidence for acquisiton of pressure ulcers in a UK district hospital was 4–10%, depending on case mix [4], and overall was about 10% in a US teaching hospital [5]. The elderly are especially susceptible [5,6] and the risk rises still further in some disease groups, for example those with fractured neck of femur in whom 66% developed pressure ulcers in one series [7]. The circumstances before, during and after major surgery are all important contributory factors to pressure ulcer formation [8]. The prevalence is usually higher in spinal injuries units than in general hospitals, despite optimal preventive measures being utilized. Others at particular risk include those in wheelchairs [9].

Many pressure ulcers develop at the patient's home and in nursing homes, with similar or higher prevalence and incidence figures to those derived from hospital-based studies [1,10,11]. At least in the hospital setting, various measures introduced during the 1990s appear to have reduced the prevalence of pressure ulcers [12–14].

Pathogenesis and pathophysiology

Although protracted pressure is a necessary component, there are usually additional factors that contribute to the occurrence of ischaemic injury.

Pressure. Compression of, or repeated trauma to, tissue over a bony prominence is usually a key factor in causation of a pressure ulcer. Kosiak showed a parabolic relationship between pressure and time, indicating that higher pressures require a shorter time period to cause ulceration than lower pressures [1–3]. Tissue damage is thought to occur when pressures over 9.3 kPa are sustained for more than 2–3 h. This is readily achieved when lying on a standard hospital mattress. Fat and muscle are more susceptible to pressure than skin and may show evidence of damage earlier [4,5].

Some areas of the body are more susceptible than others to the effects of pressure, notably the sacrum [6] and the heel [7].

Shearing forces. Shearing forces are exerted on a patient who is lying supine when the head of the bed is raised. The skin tends to adhere to the bedclothes, and the force exerted by gravity stretches and thus damages blood vessels, most markedly in the fat and fascia [8]. Shear can significantly decrease the amount of pressure needed to occlude blood flow [9]. Elderly patients develop higher shearing forces while sitting, further disposing them to pressure ulcers [10].

Friction. Friction to the skin can reduce the amount of pressure required to produce an ulcer [11], compromise skin barrier function and sometimes produce blisters. This easily occurs when patients are dragged across bed sheets rather than being lifted.

Increased temperature and moisture. Increased heat when patients are in bed or on cushions exacerbates the effects of ischaemia. Maceration of the skin, whether from increased sweating or resulting from contamination by urine, faeces, wound drainage, etc., is an important contributory factor by increasing frictional resistance and by rendering skin more susceptible to infection.

Microvascular damage. An early feature in the evolution of a pressure sore is endothelial cell damage. This is associated with accumulation of fibrin, both within and outside capillaries, venules and arterioles. Endothelial cell shedding is associated with deposition of microthrombi of fibrin, platelets and red cells, blocking the vessels [12]. There is defective fibrinolysis in and around pressure ulcers [13], which may well contribute to their very slow rate of healing compared with ulcers that are histologically similar but of different aetiology. Lymphatic drainage is also disrupted and this is likely to be a contributory factor [14].

Neural dysfunction. Spinal cord injury confers an increased susceptibility to pressure ulceration. This is in part caused by sensory and motor deficit and disuse atrophy, but other factors have been recognized. Following damage to the upper spinal cord, there is a large and immediate increase in the degradation of collagen in both skin and bone [15]. As a measure of defective collagen synthesis, it has been shown that the cross-linking enzyme lysyl hydroxylase is reduced in activity in the insensitive compared with the sensitive skin in paraplegics [16]. Spinal cord injury, particularly above the T6 level, is associated with a progressive decrease in α-adrenergic receptors after the injury and is therefore liable to impair autonomic control of the cutaneous vasculature [17]. Observations on patients with amyotrophic lateral sclerosis, a condition associated with not developing pressure ulcers, suggest a role for ciliary neurotrophic factor [18] as well as for alterations in connective tissue discussed earlier (p. 22.2).

Systemic factors. A number of factors relating to ageing changes in skin render elderly patients more susceptible to pressure ulceration. These include reduction of dermal–epidermal interface area, loss of subcutaneous tissue, diminished pain perception, reduction in skin vascularity, slower wound healing and reduced tissue elasticity. It is notable that a much lower external skin pressure was sufficient to stop the skin blood flow in the sacral area of elderly patients compared with younger volunteers [19].

The risk for pressure ulcers is increased by any circumstance that impairs the patient's mobility. Most severe illnesses can lower the degree and duration of pressure required to cause necrosis [20]. Malnutrition enhances the development of pressure ulcers [21]. Prolonged pyrexia, hypermetabolic states, hypoalbuminaemia and cancer have a similar effect [22]. Hypotension has been recognized as a risk factor in a controlled study [23], and significant arterial disease is also important. Patients undergoing procedures that involve extracorporeal circulation are notably at risk, whatever their age; pressure ulcers in such patients may occur at atypical sites, such as on the occiput of the scalp. Conditions that elevate whole-blood viscosity, uraemia, vitamin deficiency and uncontrolled diabetes are contributory factors in some cases. Even an otherwise healthy individual may develop a pressure sore if subjected to prolonged immobility, for example during operations or simply from sitting still for many hours.

Infection. There is a significantly greater likelihood of finding *Pseudomonas aeruginosa*, *Providencia* species and anaerobes in enlarging ulcers compared with those that are healing. It is likely that bacterial colonization of pressure ulcers can have an important perpetuating role [24].

In summary, the main clinical factors responsible for pressure necrosis are as follows:

1 Prolonged immobility and recumbency:
   (a) paraplegia
   (b) arthritis
   (c) severe physical disease
   (d) apathy
   (e) operation and post-operative states
   (f) plaster casts
   (g) intensive care

2 Loss or dulling of sensory stimuli:
   (a) coma, neurological diseases (especially multiple sclerosis)
   (b) drug-induced sleep

3 Vascular disease:
   (a) arteriosclerosis.

Risk factors [1]

Immobilization. Any circumstance that results in prolonged immobilization increases the risk for pressure ulceration. Examples include coma, debilitation, neurological and rheumatological illnesses, lying on a trolley in an accident department, a lengthy operation, post-surgical and other high dependency and critical care situations. Uncontrolled pain is an easily neglected reason for immobility.

Reduced oxygen profusion. Hypotension [2], whether caused by cardiac failure or drugs, anaemia, blood dyscrasias, arterial insufficiency and situations producing interstitial oedema such as nephrotic syndrome, can all increase the likelihood of pressure-induced ischaemia or may delay healing. Extracorporeal circulation is an important risk factor [3].

Malnutrition. Several studies have demonstrated a correlation between inadequate nutrition and pressure ulcers [4–8]. Postulated mechanisms include reduction of subcutaneous fat and delayed wound healing. Nutritional status can be gauged from the serum albumin, total lymphocyte count and body weight, provided there are no other reasons for these parameters being abnormal.

Age. Old age is associated with an increased risk, but it is unclear whether this is an independent variable. Neonates may also be at increased risk.

Other risk factors. Some surveys have suggested that diabetes mellitus, cancer, sepsis, prolonged pyrexia, prior corticosteroid therapy, dehydration and lifestyle parameters such as smoking and excessive alcohol intake are additional systemic risk factors.

Within the context of surgery, warming blankets have been identified as a risk factor [9].

Compression stockings to prevent venous thrombosis [10] and compression bandaging for venous leg ulceration can contribute to pressure ulcers [11].

Pathology. The most complete study of the histopathology of pressure ulcer and its antecedents in humans is given by Witkowski and Parish [1]. In the earliest clinically recognizable stage of blanchable erythema, there is dilatation of superficial dermal venules and papillary capillaries with a mild perivascular inflammatory infiltrate

and degenerative changes in occasional sweat coils and ducts. At the stage of non-blanchable erythema, there is marked red cell engorgement of superficial vessels, platelet thrombi in many of them, and extravasation of red cells. More eccrine units are degenerate and there is evident fat necrosis. Before ulceration occurs, various additional changes are recognized, including epidermal atrophy, subepidermal blister formation, tissue eosinophilia and necrosis of hair follicles. Some other studies have emphasized the presence of intra- and extravascular fibrin [2,3]. In early ulceration, there is loss of the epidermis, and at the stage of a black eschar there is full-thickness destruction of the skin. The antecedent for black eschar formation was not seen in the biopsies studied, but was presumed to be vascular disruption at a deeper plane. In a chronic ulcer, there was fibrosis with isolated collections of capillaries and no residual appendages.

Fig. 22.7 A grade 2 (Shea classification) pressure ulcer over the shoulder in an elderly bedridden female with rheumatoid arthritis. Note that there is also chondrodermatitis of the antihelix, indicative of pressure on the ear.

3 Vande Berg JS, Rudolph R. Pressure (decubitus) ulcer: variation in histopathology—a light and electron microscope study. *Hum Pathol* 1995; **26**: 195–200.

Clinical features and classification. Most pressure ulcers develop over bony prominences on the lower part of the body: 65% in the pelvic area (the sacral bone, ischial tuberosities and greater trochanters); and 30% on the lower limbs, usually the heels and lateral malleoli. On the upper part of the body the more common sites are the shoulder and elbow (Fig. 22.7).

Pressure-induced injury varies in appearance from blanchable erythema to necrosis of all tissues down to and including bone and joints. Assessment of erythema can be difficult in darkly pigmented skin and there may be extensive injury beneath eschar formation.

Based on clinicopathological correlations, clinical features have been classified to several somewhat different grading systems, three of which are contrasted in Table 22.2. The Shea classification [1] has been widely used, so is described here. In grade 1 there is erythema, sometimes accompanied by induration, warmth and pain. The erythema is reversible when pressure is relieved. Repeated pressure may result in brownish discoloration caused by extravasation of red blood cells and deposition of haemosiderin. Grade 2 is represented by blister formation and/or minor ulceration. In grade 3, there is a deeper degree of damage, involving the subcutaneous tissues, often producing a thick black eschar. Removal of this necrotic tissue may reveal tendons, ligaments and muscle. Grade 4 is represented by the appearance of deep fistulae, usually a consequence of progression to osteomyelitis. Grade 5 describes an ischaemic necrosis of subcutaneous fat, with or without deeper structures, with no or negligible skin ulceration. As skin is more resistant to ischaemia than the underlying fat and muscle, the subcutaneous

Table 22.2 Comparison of pressure ulcer classifications.

Shea [1]	Yarkony *et al*. [2]	National Pressure Ulcer Advisory Panel [3–5]
1 Limited to epidermis, exposing dermis; includes a red area	**1** Red area: (a) present longer than 30 min but less than 24 h (b) present longer than 24 h	**1** Non-blanchable erythema of intact skin
2 Full-thickness ulceration of dermis to junction with subcutaneous fat	**2** Epidermis and/or dermis ulcerated with no subcutaneous fat observed	**2** Loss of epidermis ± dermis
3 Fat obliterated, limited by the deep fascia; undermining of skin	**3** Subcutaneous fat observed, no muscle observed	**3** Ulceration into subcutaneous fat
4 Bone at the base of the ulceration	**4** Muscle/fascia observed, no bone	**4** Muscle/bone/joint exposed
5 Closed, large cavity communicating through a small sinus	**5** Bone observed but no involvement of joint space	
	6 Involvement of a joint space	

damage usually far exceeds the impression given by the surface changes. Deep sores typically have overhanging edges. With chronicity, calcification may occur.

The classification system of Yarkony *et al*. [2] has rather greater interrater reliability, and the National Pressure Ulcer Advisory Panel's system [3–5] is simple to use, but as none of the systems is universally accepted this can make comparison of studies difficult.

Complications

Infections. Colonization of pressure ulcers with one or more of a wide range of aerobic and anaerobic bacteria is very common, but wound healing is not necessarily impaired [1]. Extension of necrosis, bacteraemia and septicaemia can occur when there is invasion of adjacent healthy tissue. There may be obvious physical signs to indicate true infection, such as erythema, warmth, tenderness and increased purulent discharge. However, these signs may not occur in the debilitated; such so-called inapparent infection [2] may be difficult to distinguish from colonization. When taking a swab, surface contamination (pus, etc.) should be removed with a non-bacteriostatic liquid such as normal saline, and tissue fluid should be sampled; needle aspiration or even biopsy material are better for obtaining relevant microbiology [3]. In practice, inapparent infection may only be surmised when an ulcer does not heal despite pressure relief, correction of nutritional needs, etc. An empirical course of antibiotic therapy may be justified in such circumstances [4].

Osteomyelitis. This is more likely in the non-healing ulcer, and can be difficult to diagnose. All imaging techniques have shortcomings. A bone scan is usually abnormal and, if so, bone biopsy and culture will enable the appropriate antibiotic therapy to be determined [5].

Sinus tracts. These can extend deep into joint spaces, causing osteomyelitis, septic arthritis and, occasionally, communicate with viscera. A sinogram will assist surgical management [6].

Squamous carcinoma. Although rare, squamous carcinoma can arise in long-standing pressure ulcers. Such lesions have a high risk for metastasis [7].

Other complications. These include endocarditis, meningitis, amyloidosis and myiasis.

Prevention. Individuals likely to develop pressure ulcers can often be predicted and preventive measures are both cost-effective and avoid unnecessary patient suffering.

Recognition of the at-risk patient. A number of risk scales have been devised so that nursing staff and other carers can maximize their application of preventive measures. These risk scales vary in complexity, and consequently in the ease with which they can be used. The best known are those of Norton *et al*. [1] and Braden and Bergstrom [2,3] (Tables 22.3 & 22.4). With the Norton scale, a score of 14 or below indicates risk; with the Braden scale, 12 or less indicates high risk, 13–15 moderate risk and 16–17 mild risk.

Institutions should try to select the most appropriate at-risk scale for their needs [4,5].

Table 22.3 Norton scale.

Physical condition	Mental condition	Activity	Mobility	Incontinent
Good 4	Alert 4	Ambulant 4	Full 4	Not 4
Fair 3	Apathetic 3	Work/help 3	Slightly limited 3	Occasionally 3
Poor 2	Confused 2	Chairbound 2	Very limited 2	Usually/urine 2
Very bad 1	Stupor 1	Stupor 1	Immobile 1	Doubly 1
Name	Date			*Total score*

From [1].

Table 22.4 Braden scale for predicting pressure sore risk.

Patient's name _____ Evaluator's name _____ Date of assessment _____

SENSORY PERCEPTION (Ability to respond meaningfully to pressure-related discomfort)				Score
1 Completely limited Unresponsive to painful stimuli (does not moan, flinch, grasp) due to unconsciousness or sedation. *OR* Limited ability to feel pain over most of body surface.	**2** Very limited Responds only to painful stimuli. Cannot communicate discomfort except by moaning or restlessness. *OR* Has a sensory impairment that limits the ability to feel pain or discomfort over half the body.	**3** Slightly limited Responds to verbal commands, but can't always communicate discomfort or need to be turned. *OR* Has some sensory impairment that limits ability to feel pain or discomfort in 1 or 2 extremities.	**4** No impairment Responds to verbal commands. Has no sensory deficit that would limit ability to feel or voice pain or discomfort.	
ACTIVITY (Degree of physical activity)				
1 Bedfast Confined to bed.	**2** Chairfast Severely limited or non-existent ability to walk. Cannot bear own weight and/or must be helped into chair or wheelchair.	**3** Walks occasionally Walks sometimes but for very short distances, with or without assistance. Spends most of each shift in bed or chair.	**4** Walks often Walks outside the room at least once every 2 h during waking hours.	
MOBILITY (Ability to change and control body position)				
1 Completely immobile Does not make even slight changes in body or extremity position without assistance.	**2** Very limited Makes occasional slight changes in body or extremity position but cannot make frequent or significant changes independently.	**3** Slightly limited Makes frequent though slight changes in body or extremity position independently.	**4** No limitations Makes major and frequent changes in position with no assistance.	
MOISTURE (Degree to which skin is exposed to moisture)				
1 Constantly moist Skin is kept moist almost constantly by perspiration, urine, etc. Dampness is found every time the patient is moved or turned.	**2** Very moist Skin is often, but not always moist. Linen must be changed at least once a shift.	**3** Occasionally moist Skin is sometimes moist, requiring an extra linen change about once a day.	**4** Rarely moist Skin is usually dry, linen needs changing at routine intervals.	
NUTRITION (Usual food intake pattern)				
1 Very poor Never eats a complete meal. Rarely eats more than a third of any food offered. Eats 2 servings or less of protein (meat or dairy products) per day. Takes fluids poorly. Does not take a dietary supplement.	**2** Probably inadequate Rarely eats a complete meal and generally eats only about half of any food offered. Protein intake includes only 3 servings a day. Will occasionally take a dietary supplement. *OR* Receives less than optimum amount of liquid diet or tube feeding.	**3** Adequate Eats more than half of most meals. Eats 4 servings of protein each day. Will sometimes refuse a meal, but usually takes a supplement if offered. *OR* Is on a tube feeding or TPN regimen that probably meets most nutritional needs.	**4** Excellent Eats most of every meal. Never refuses a meal. Usually eats 4 or more servings of meat and dairy products. Sometimes eats between meals. Does not require supplementation.	
FRICTION AND SHEAR				
1 Problem Requires moderate to maximum assistance in moving. Complete lifting without sliding against sheets is impossible. Often slides down in bed or chair requiring repositioning with maximum assistance. Spasticity, agitation or contractions lead to almost constant friction.	**2** Potential problem Moves feebly or needs minimum assistance. During a move, skin probably slides to some extent against sheets, chair, restraints or other devices. Usually maintains relatively good position in chair or bed, but occasionally slides down.	**3** No apparent problem Moves in bed and in chair independently and has sufficient muscle strength to sit up completely during move. Maintains good position in bed or chair at all times.		Total score ☐

General nursing measures. Standard nursing practices to prevent pressure ulcer formation in those most at risk include:

- A skin inspection at least once daily, especially over bony prominences.
- Prevention of moisture accummulation from incontinence, wound drainage, etc. (e.g. by absorptive pads).
- Avoidance of friction and shear by lifting rather than dragging the patient, ensuring that the bed is kept free of food particles, etc.
- Avoidance of elevation of the head of the bed by greater than 30° as shearing forces increase beyond this angle.
- Pressure relief by turning the patient at least every 2 h. Patients should be turned successively from the back to the right side, then to the left side; when on the side, the patient should be positioned at an angle to avoid pressure on the trochanter and lateral malleolus.
- Soft pillows or foam wedges should be used to prevent sites such as the knees and ankles from direct contact with each other; the heels should be suspended away from contact with the bed (e.g. by pillows under the lower leg).
- Ensure that there is a shift of weight every 20–30 min for those in wheelchairs, to relieve pressure on the ischial tuberosities.

Specialized beds, mattresses and cushions. All at-risk patients being nursed in beds should have a pressure-relieving mattress in addition to frequent repositioning [6]. The support system can be subdivided as either static or dynamic in type. The former mould around the patient and distribute weight over a greater area. They are foam, water, gel or air-filled and may be suitable for patients who can assume a variety of positions. It is important that the material is not completely compressed. Dynamic systems (e.g. air-fluidized and low air-loss beds) change their support characteristics in a cyclical fashion and can successfully relieve pressure for patients unsuitable for a static system. They are generally more expensive.

There has been a systematic review of the randomized controlled trials evaluating most of the support systems currently available in the UK [7]. Although there are significant shortcomings in the trials evaluated, some valuable conclusions emerged. There is a useful reduction in incidence and severity of pressure ulcers when simple static supports (e.g. the foam type) are used, compared with standard hospital mattresses. There is no clear difference when the various types of static support are compared. Pressure-relieving overlays on the operating table are also of proven value and should be used more often than they are. Low air-loss beds are probably more effective in prevention than foam mattresses, but are much more expensive. For treatment, the air-fluidized type of support may improve healing rates.

Wheelchair cushions are rarely adequate for the job required of them, in that over 50% of the body weight is being supported on 8% of the sitting area, at or near the ischial tuberosities. However, air-filled cushions have been shown to be of value [8]. The most effective way of protecting the heel is to elevate it completely from the bed [9].

General medical measures. Any medical condition adding to the tally of risk factors (e.g. diabetes mellitus, cardiac failure or anaemia) should be controlled. Nutritional status should be assessed and appropriate measures taken if necessary.

Measures for patients with neurological disease. Spasticity should be relieved if possible by use of muscle relaxants, nerve block or surgery. In paraplegic patients, functional electrical stimulation has been shown to help, possibly by inducing shape changes in the buttocks and improving blood flow [10–12].

Overview—assessment and prevention. Those closely involved with the care of patients liable to pressure ulcer will find the assessments of available literature by the UK National Institute for Clinical Excellence (NICE) [13] and by the Royal College of Nursing [14] useful.

Management. The principles outlined above for prevention apply to management of the ulcer. Once the early reversible signs of pressure-induced injury are evident, action should be prompt.

Relief of pressure. The imperative consideration is the removal of the pressure. This must continue throughout the treatment of any pressure sore; all other forms of treatment are of secondary importance. Nursing in a prone position may be required and is acceptable for all patients except, perhaps, quadriplegics. The 90° lateral position must be avoided, as it frequently causes pressure sores over the greater trochanters and malleoli. Special nursing skills are required in positioning pillows to protect the knees and iliac spine. Pressure-relieving mattresses, beds and cushions are discussed above. If healing does not occur with use of a static device, a dynamic support system may prove more effective.

General treatment. It is essential to treat the whole patient. Pressure sores can be extremely painful and adequate analgesia is essential. Nutrition should receive special attention and a positive nitrogen balance should be achieved. For those with poor appetite, or unable to take sufficient solid food by mouth, frequent sip feeds of protein supplement or, occasionally, nasogastric tubal feeding may be required. Anaemia, zinc and ascorbic acid deficiency must be corrected. Blood transfusions may be required. Any serious underlying disease should be assessed and treated appropriately. The blood urea and serum albumin should be checked regularly. Whenever possible, the advice of a geriatrician conversant with the problem of pressure sores should be sought if early measures do not bring about restitution. The special problems of the paraplegic patient are not considered in detail here; these require the attention of a spinal physician or surgeon. Just as electrical stimulation may have a role in prevention, it may also assist healing in spinal cord-injured patients, although randomized control trials are needed.

Wound care. It is important to assess the nature and progress of a pressure ulcer, so there should be regular inspections—at a minimum weekly, with well-documented observations including a tracing and/or photographs. Signs of infection, sinus tract formation, offensive discharge, new necrotic tissue, undermining, etc. may determine the need for a change in management.

Irrigation with normal saline is generally sufficient to keep the ulcer clean [1]. Although it is desirable to minimize growth of bacteria, the many antiseptics and antibiotics used on pressure ulcers are mostly of unproven benefit; some can cause local and systemic toxicity, select resistant bacteria and/or result in contact allergic dermatitis. If used at all, a topical antimicrobial should not be applied for more than 2 weeks at a time.

When pressure is relieved, in many cases the necrotic tissue will separate naturally in 1–2 weeks but if there is eschar this is best removed by scalpel or scissors. If the patient cannot tolerate this, an enzyme preparation may be used (usually containing streptokinase, streptodornase, deoxyribonuclease, trypsin, papain, fibrinolysin and collagenase in various combinations), but these are of unproven value, can cause contact allergy and should not be used if there are exposed tendons.

Wounds generally heal best when moist. The choice of dressing for a pressure ulcer will be dictated in part by the stage. Thus, a superficial stage 2 ulcer will usually heal beneath a transparent semipermeable membrane such as Opsite®. For deeper ulcers with some necrotic debris, the choice is usually between a hydrocolloid, a hydrogel or an alginate. Hydrocolloids may be more effective at assisting autodébridement [2], but should not be used if muscle, tendon or bone are exposed and may be associated with overgranulation. Hydrogels are soothing to skin but are not adherent and dessicate easily. Alginates are useful in cavities and have a high absorption capacity. Dextranomer paste is also useful in reducing discharge [3].

Surgery. With some deep ulcers (e.g. when there is necrosis of bone) operative surgical débridement will be needed. Where spontaneous healing is not apparent within a reasonable period, surgical intervention may be necessary, provided circumstances are such that the ulcer is not likely to recur after surgery and that the patient's medical and nutritional status have been optimized. Most deep ulcers require radical excision and appropriate flap repair. Even when musculocutaneous flaps are used, recurrence is a significant problem [4,5]. Whenever possible, the flap should be sensate [6,7]. Tissue expansion may have a role in the surgical treatment of pressure ulcers [8,9]. Recurrence rates after surgery tend to be high [10].

When appropriate, vascular reconstructive surgery can improve wound healing.

Other measures

Electrical stimulation. The use of direct current has been shown to improve the healing of pressure ulcers [11]; possible mechanisms include an effect on wound repair processes and reduction of the bacterial population [12].

Hyperbaric oxygen. There are anecdotal reports of this modality being used as an adjunct to healing pressure ulcers [13,14].

Growth factors. Several growth factors have been evaluated for their effect on chronic wounds, but few have been assessed adequately. A placebo-controlled trial has shown that platelet-derived growth factor reduced ulcer volume [15], but its place is yet to be established. Anecdotal

reports such as the use of nerve growth factor [16] require further evaluation.

Vacuum-assisted closure. The application of negative pressure may facilitate healing of pressure ulcers [17–19].

Effects of suction

Localized suction to the skin usually produces either blisters, which can rupture to form erosions, or purpura. Early work evaluated the inverse relationship between the degree of negative pressure and time taken for blistering to occur [1,2] and demonstrated that the time taken to blister could be shortened if the temperature at the suction site was raised to 40°C [3]. Suction blisters are often used in experimental dermatology (e.g. to yield fluids for analysis of inflammatory mediators) and to generate pieces of epidermis for grafting as used in the treatment of vitiligo [4]. Blisters induced by suction are subepidermal in type, in contrast to friction blisters, which develop within the epidermis. The dermal papillae are usually well preserved, producing the effect known as festooning [5]. When the force of suction is sufficient to produce purpura, this may either take the form of petechiae or, if the injury is over a larger surface area, an ecchymosis will result. At the outset, such lesions are red, but they then undergo the usual changes associated with extravasation of red cells into the skin, producing purplish and then yellow staining.

Neonatal suction blisters

These present as one or a small number of blisters or erosions, typically on the fingers, lips or forearms. They heal quickly after birth [6]. (For further discussion see Chapter 14.)

Therapeutic cupping

This is a widespread folk medicine practice, particularly in Oriental countries [7] and in some parts of eastern Europe, although it has been used in the West and may increase because of migration of populations [8,9]. Cupping is performed on patients with various diseases, particularly febrile illnesses, by warming the edge of a cup and applying it to the patient's back. Suction is produced when the cup cools. The visible effect is a round area of ecchymosis often with petechiae at the border (Fig. 22.8). Cupping is often combined with acupuncture, and a number of complications have been associated (e.g. panniculitis) [10]. The skin changes caused by cupping can simulate child abuse [11,12].

Suction purpura in children

Vacuum extraction to assist in parturition can cause a characteristic rounded purpuric lesion on the forehead of the infant. Ecchymoses have been induced by suction cups attached to babies' rattles [13]. The habit of sucking on a cup and aspirating the air trapped within it can produce a distinctive zone of petechiae on a child's chin [14]. As a habit or neurotic activity, children sometimes suck on their arms, and this can produce small areas of purpura, typically arranged in lines [14]. The sucker-shaped rubber ends on toy arrows have also been recorded as producing purpura by a suction effect [14]. Distinctive rounded purpuric lesions on the forehead (purpura cyclops) from the rubber suckers on their children's toys can occur on fathers—the 'sucker-daddy' syndrome [15,16].

Penile suction injuries

Penile injuries resulting from sexual experimentation may be bizarre. Vacuum cleaner injuries can cause ecchymosis

Fig. 22.8 Purpura caused by therapeutic cupping. (Courtesy of Dr M. Rustin, Royal Free Hospital, London, UK, and the Editor of the *British Medical Journal*.)

if the suction is mild, and extensive lacerations when severe [17].

Other examples of suction purpura

Other recorded examples include the so-called 'love bite', a consequence of sucking while kissing; the use of suction devices on electrocardiograph leads; and gas masks, for example used during the Gulf War [14]; suction from cup-shaped indentations on a bath mat [18] and from getting stuck in the bath [19].

Suction pads

Hyperkeratotic lesions on the thumbs of a child attributed to repetitive suction have been described, but chewing was also taking place and may have been a contributory factor [20].

Miscellaneous reactions to mechanical trauma

Coin-rubbing injuries

Coin rubbing or *kua'sha* originated in China and has spread to many other countries in South East Asia. It is often known by the Portugese term *cao gio*. As a form of folk medicine, it is used to treat many complaints. The coin (usually copper or silver), or sometimes a silver spoon or other object, is dipped in wine, water or an aromatic oil and then scraped over the skin surface until a visible change—redness or purpura—is observed. The technique is often accompanied by pinch-pulling (*t'i-sha* or various synonyms) in which the index and middle fingers are used to pluck the skin. Common sites include the intercostal spaces, bridge of the nose, the space between the eyebrows, the occipital depression over the neck, either side of the larynx, and the elbow and knee flexures.

Clinical features. There are symmetrical bands and ovoid patterns of bruising. Occasionally, the lesions can be misinterpreted as representing foul play [1].

Reactions to musical instruments

These have been reviewed by type of instrument [1,2], and by type of causative injury [3,4]. Mechanical injuries can

Fig. 22.9 'Fiddler's neck'. Lichenification and cysts on the neck of a violinist. (Courtesy of Dr R.D.G. Peachey, Bristol Royal Infirmary, Bristol, UK.)

be acute (e.g. friction, blisters and erosions) but are more commonly chronic resulting from repetitive friction and/or pressure between the musician and the instrument, in some situations aggravated by sweating, faulty techniques or excessive hours of playing. Not only the skin but also bony and soft tissues can be affected, and in younger wind instrument players there can be permanent distortion of dentition and palatal morphology. Trauma to fingers can also quite often damage nails and associated tissues. Contact allergies in musicians are usually to rosin (various string instruments), exotic woods (e.g. used for chin rests), nickel, cane reeds (saxophones and clarinets) or to propolis (violin varnish) [3].

Violin and viola players may develop 'fiddler's neck' [5], characterized by localized plaques of lichenification, often with hyperpigmentation, erythema, inflammatory papules and pustules and sometimes cysts. Marked oedema may be associated in some cases [6]. The condition occurs at the site where the chin rest of the instrument presses against the skin over the angle of the jaw (Fig. 22.9). The mode of grip on the instrument and the fitting of the chin rest are likely causative factors and a soft cloth may ameliorate a poor fit in the short term [7]. Violinists are also subject to developing thickened pads over the interphalangeal joints (Garrod's pads or fiddler's fingers). These are areas of thickening over the dorsal aspect of the left second and third proximal interphalangeal joints. They may result from the intermittent relaxation and contraction of the extensor tendon over an interphalangeal joint that is held in extreme flexion [8]. Thrombosis of the axillary and subclavian veins has occurred from pressure from a viola [9]. Pizzicato paronychia is another hazard for string players.

Finger callosities occur on the pulps of the fingers of many musical instrument players. A typical example is 'harpist's fingers', which usually show paronychia and calluses on the sides and tips of the fingers, often together with onycholysis and subungual haemorrhage [10].

Piano paronychia is associated with long hours of piano playing, and nails can be loosened by repetitive glissando (gliding of fingers over the keys).

'Guitar nipple' is usually found in young girls and presents as an inflamed cystic swelling at the base of the nipple [11]. Deep-vein thrombosis has been described in guitarists as a result of a combination of flexion of the left leg with pressure from the belly of the guitar on the medial aspect of the thigh [12]. Acro-osteolysis has been described in the digits of the left hand, the only symptom being tenderness in relation to pressure on the nails [13].

Cellists can develop a lesion known as 'cellist's chest' [14] from pressure, producing erythema, oedema and pigmentation over the sternal area. There may be changes similar to those of 'fiddler's neck'. 'Cellist's knee' and even 'cello scrotum' have been described, although the validity of the latter has been questioned [15].

'Clarinettist's cheilitis' [16,17] is an eczematous condition, not caused by contact allergy, that affects the middle of the lower lip (see Chapter 66).

'Flautist's chin' [18] is probably similar to fiddler's neck.

Wind instrument players can develop permanent laxity of the cheeks, and forceful blowing of the trumpet can rupture the orbicularis oris (Satchmo's syndrome) [19].

'Drummer's digit' is an erosion or blister on the left ring finger [20].

Black dermographism of the lip has been described in a flute player using a lotion containing zinc oxide, titanium dioxide, iron oxides and talc [21] (for further details on black dermographism see p. 22.84).

Treatment. Modification of technique can usually result in resolution of trauma-related problems in musicians. Callosities can be helped by keratolytics and a pumice.

Hypothenar hammer syndrome

This condition is brought about by the effects on the ulnar artery and associated soft tissues of repetitive trauma to the hypothenar eminence [1]. It is typically associated with actions that use the hand to hammer, push or squeeze. It is mainly found among individuals in certain craft occupations, such as mechanics and carpenters, but can also occur as a sporting injury (e.g. in golf and badminton) [2] and may present in those using a vibrating tool [3].

The proposed pathogenesis is that the superficial palmar branch of the ulnar artery is compressed against the hook of the hamate and this can lead to stenosis, occlusion or aneurysm, with thrombosis or emboli ensuing. Although the condition typically presents unilaterally, the presence of bilateral abnormalities when patients are investigated suggests that there is an underlying predisposition [4].

Among manual workers, most patients are middle-aged men and present with pain or paraesthesia and variable degrees of ischaemic change including blackened eschar formation on the ends of the second, third, fourth or fifth digits of the dominant hand. There may be surrounding hyperkeratotic changes [5]. Fingers affected by the underlying vascular pathology are cooler, and may show other signs of chronic ischaemia. Allen's test is often positive. Some patients have comorbidity factors such as smoking and cold exposure.

The condition is often misdiagnosed as collagen vascular disease, or some other vaso-occlusive disorder.

Investigations should include arteriography, which can demonstrate stenosis, occlusion, aneurysm, etc. and provide essential information for vascular surgical repair. Magnetic resonance angiography is proving to be a highly informative minimally invasive method of evaluation [6].

Management includes counselling to avoid repetitive trauma, minimize exposure to the cold and stop smoking. Aspirin and calcium-channel blockers may be helpful. Vascular surgical expertise will generally be required for thrombolytic measures or resection of the abnormal vasculature and appropriate reconstruction.

Achenbach's syndrome

This disorder is characterized by sudden painful blue discoloration and swelling of a finger or fingers (or sometimes the palm of the hand), often after physical effort of gripping or twisting. It is probably caused by rupture of a small vein. Its importance is that it may be confused with Raynaud's phenomenon (discussed further in Chapter 23).

Trauma and subcutaneous fat

Acute panniculitis is considered in detail in Chapter 55. It should be noted here that mechanical injury to the subcutaneous fat, especially on the lower legs, can be a primary cause of fat injury, although more often it is a localizing factor [1,2]. It is often followed by atrophic changes.

Semicircular lipoatrophy

This distinctive condition, also known as lipoatrophia semicircularis, is characterized by one or more partial horizontal band-like depressions, usually on the anterolateral thigh or thighs. It mainly occurs in women. Since the initial report [3], relatively few cases have been reported, but it is asymptomatic so may be underreported; several authors have commented that it may well not be rare [4].

Repetitive mild trauma has been suggested as causative in most cases. In one series, seven women of different heights and body mass index working in the same office all developed the condition at the same vertical distance from the floor, corresponding to the height of the edge of their desks; pressure against this edge was postulated to have caused the semicircular lipoatrophy [5].

When a cause is identified and remedial action taken, spontaneous resolution generally occurs [5], in most cases after 9 months to 4 years.

Semicircular lipoatrophy is considered further in Chapter 55.

Computer palms and mouse fingers

It has long been recognized that manual occupations can leave characteristic changes on the skin, some of which are discussed elsewhere in this chapter.

Computer palms

Two cases of a distinctive non-blanchable erythema with telangiectasia on the ulnar side of the palms has been described in two healthy computer programmers who had spent 10 or more hours a day, 7 days a week, leaning forward and thereby putting pressure on the hands [1]. The authors speculated that there were similar causative factors to those producing pressure ulcers (pressure, shear, moisture and friction).

The differential diagnosis includes liver disease, connective tissue disease, exposure to chemotherapeutic agents, internal neoplasia and erythema ab igne.

Mouse fingers

A single case has been described of erythema, scaling and peeling of the thumb and fifth finger tip of the right hand, attributed to friction, pressure and sheer exerted on these digits while holding a computer mouse for long periods at a time [2].

Dermatological problems of the amputee [1–3]

Skin problems arising from amputation are seen much more on the weight-bearing lower limb than the upper limb. The main factors are pressure, shear friction and overhydration of the stratum corneum. Lesions that might be trivial elsewhere on the skin, such as minor calluses or fissures, can have a major impact when they occur on a weight-bearing amputation stump. Factors relating to the stump, the prosthesis and other systemic or cutaneous disease all contribute to the likelihood of dermatological complications.

Ideally, the skin on the stump should be well vascularized, freely mobile and with no redundant folds, tension or adhesions to the bone. Scars should be away from weight-bearing areas and bony prominences. The muscles should be fixed so that movements are balanced and no muscle groups are left free to undergo atrophy. Sockets should be designed to provide a close but comfortable fit, with weight-bearing areas designed onto the inner wall and outer rim, and the greatest pressure should be exerted onto those regions most able to receive it. These ideal circumstances may be impossible to achieve, for example after a traumatic amputation the stump may be too short, and often in cases of vascular disease there is reduced blood supply.

Above-knee amputation prostheses are of two basic types: the conventional prosthesis, which is suspended from a belt; and the suction-socket type, which is held in place by negative pressure and therefore must be a very accurate fit to the stump. Because of the dearth of soft tissues, the prostheses for below-knee stumps are usually suspended, although recently suction-socket types have begun to appear. Nowadays there is usually a socket liner made of silicone gel between the stump and the socket, and this is tethered to the socket by a quick-release shuttle lock [4]. The silicone gel roll-on liner is advantageous for some amputees but creates additional problems for others, notably skin problems resulting from heat retention and friction injury from the edge of the liner [5,6]. Dermatological problems in the first weeks after an amputation are unusual; if they occur, they are usually the consequence of secondary infection of the wound or of reaction to topical medicaments.

Management of the conditions that present in the amputee requires a multidisciplinary approach [2,7].

Common mechanical injuries

Constant rubbing over pressure points readily produces a burning sensation, associated initially with erythema and desquamation. If there are folds in the stump skin, intertrigo can occur, particularly in hot humid weather. With chronicity, painful fissures and secondary eczematization can occur. Friction blisters and erosions usually occur around the brim of the socket and the distal end of amputation stumps. On below-knee stumps, the pretibial area is also a common site for friction blisters. Friction-related injuries, including blistering, can be a problem with the cut edge of silicone gel sleeves. Erosions can progress to ulceration (Fig. 22.10), especially when there is underlying arterial insufficiency, oedema, scars adherent to bone or neurological impairment. Sometimes, quite

Fig. 22.10 Pressure-induced lichenification, inflammation and ulceration on an amputation stump. (Courtesy of Dr N. Purry, Disablement Services, Southmead Hospital, Bristol, UK.)

soon after the prosthesis has been fitted, there is some reduction in size of the stump, such that the limb wedges into the prosthesis. This can cause oedema and also ulceration.

Skin thickening can also occur in response to injury. Lichenification, often with hyperpigmentation [8] may be seen, sometimes as part of an eczematous response. Callosities and corns may occur at focal pressure points, especially in below-knee amputees. The 'lenticular button' hyperkeratosis [9] is often painful. Pressure and friction can induce follicular hyperkeratoses [10], sometimes containing entrapped hairs, which can then develop into sterile abscesses. Acne mechanica has been described, responding to isotretinoin [11]. Trauma to the stump can occasionally produce purpura.

Treatment. It is important to recognize injuries resulting from mechanical factors, as they are likely to require adjustments to the prosthesis.

Epidermoid cysts

These are common, usually occurring a few months or more after the prosthesis has been in use. In one series of 67 amputees with epidermoid cysts, the cysts interfered with the wearing of a prosthesis in 23 [12]. Predisposing factors include the previous occurrence of acne, hairy skin and a poor prosthetic fit so as to cause a roll of flesh above the socket brim. Common sites are the adductor, ischial, inguinal and popliteal areas. It seems likely that the cysts originate from shearing forces invaginating fragments of the epidermis into the dermis. Cysts can rupture to produce granulomatous inflammation and discharging sinuses.

Treatment. Adjustment of the prosthesis is necessary, but is sometimes not sufficient to cure the difficult problem of cyst formation. This may require incision and drainage, or excision. It is often necessary for the patient to do without the prosthesis if such measures are undertaken. For the inflammation associated with rupture of the cysts, intralesional steroid may be helpful. If there is true secondary infection, this will require appropriate treatment.

Circulatory disorders

Both venous and lymphatic return are readily impaired by unsatisfactory pressure gradients and inadequate muscle activity in the amputation stump, and these problems are aggravated if there was a pre-existing venous disorder in the limb. The clinical features are oedema, often accompanied by eczema, and sometimes with purpura leading to haemosiderin staining. Stump oedema is very common and can occur even without circulatory insufficiency. Obesity, lack of exercise and poor fit are among the most common contributory factors. As well as correcting underlying causes, application of a graduated pressure bandage at night is useful, and counter-pressure can be produced by modifications to the prosthesis.

A distinctive verrucous hyperplasia can occur with the combination of venous impairment and poor fit [13] and is associated with below-knee amputation [14]. Kaposi-like acroangiodermatitis can present as bluish plaques [15,16].

Treatment. It is important to exclude abnormal pressure or lack of support as a cause of oedema, and to make appropriate adjustments. The garment worn over the prosthesis can provide some useful support, as can wind-on elasticated bandaging when the prosthesis is not in use.

Other problems

Infection. Bacterial colonization and both primary and secondary infections are more common on amputation stumps than on normal skin, probably because of the increased humidity and tendency to frictional injury of the stratum corneum. Folliculitis is one of the more common problems that occur with the silicone gel socket liner. Antiseptic cleansers, such as chlorhexidine, have an important role in prevention.

Miliaria. In warm weather, miliaria of the stump is often seen. The papules, papulovesicles or pustules may cause no symptoms, but can be intensely irritating. Problems resulting from heat retention with silicone gel socket liners can sometimes be relieved by careful, more frequent washing [6].

Contact dermatitis. This can be caused by a metal, plastic or leather component of the prosthesis, or to medicaments, talcs, oils, etc., and may be overlooked or may be falsely attributed to infection or friction. In a cross-sectional study of 210 amputees, 71 had a related skin disorder and, of these, 12 had relevant patch-test reactions [3]. Patch tests [17,18] should include azo dyes, methacrylates and acrylates, epoxy resins, polyester resin, chrome, nickel, paraphenylenediamine (PPD), *para*-tertiary butylphenol, formaldehyde resin, *para*-tertiary butyl catechol and when suction-socket prostheses are used, appropriate rubber additives and neoprene [3,17–20].

Bullous pemphigoid. This has been reported localized to the amputation stump [21,22].

Neoplasms. Most tumours occurring in stump skin are coincidental or related to the disease necessitating the amputation. A traumatic neuroma can result from amputation, usually appearing on the end of a nerve that has been cut and, when painful, excision may be needed. Squamous carcinoma can rarely arise from a persistent stump ulcer [23] or from verrucous hyperplasia [24].

Incidental reactions

Dermatoses localized by trauma (Koebner response; p. 22.2) are liable to occur on the amputation stump, especially psoriasis or lichen planus. Troublesome psoriasis has also been noted on the palms through the use of crutches as a result of amputation. Patients with atopic dermatitis often have exacerbations on prosthesis-bearing stumps because of the effects of increased temperature, humidity, friction and, perhaps, oedema and bacterial infection. Mechanical forces and increased hydration in amputees can localize acne vulgaris and can aggravate hidradenitis suppurativa. Particularly when sympathy or compensation are sought, the amputation stump may become the site for dermatitis artefacta.

Spectacle-frame acanthoma

This is the preferred term for a condition initially described as *granuloma fissuratum of the ear* [1] and also known as *acanthoma fissuratum*.

Factors that contribute to the pathogenesis include the weight of the spectacles, minor derangement in local anatomy and maceration.

Histology shows acanthosis and hyperkeratosis of the epidermis, with a central depression and occasionally ulceration. In the dermis, there is often hyalinization of the collagen and a mild mixed inflammatory infiltrate [2]. Granulomatous change is not usually present.

The typical lesion occurs behind the ear or on the side of the nose [3–5] as a soft flesh-coloured papule, nodule or plaque, often with a groove at the site where there is contact with the spectacle frame (Fig. 22.11). In a review of 27 published cases, males predominated [2]. Cases with bilateral involvement are uncommon [6].

Spectacle-frame acanthoma usually resolves after a few weeks or months if the patient discontinues wearing spectacles or changes are made to obviate the mechanical trauma.

The main importance of the condition is that it can mimic basal cell carcinoma, which can also be bilateral behind the ears. If necessary, the condition can be treated by surgical excision, electrosurgery and curettage, or intralesional corticosteroids.

Fig. 22.11 Acanthoma fissuratum. A soft plaque, which may mimic basal cell carcinoma, caused by pressure and friction from the spectacle frame.

Acne mechanica [1]

Pressure of tight clothing or friction, often with heat and increased humidity causing maceration, may exacerbate acne vulgaris or cause its appearance in unusual sites in susceptible subjects. Right-handed students may have predominantly left-handed facial acne from pressure of the left hand. High-necked jerseys, shoulder pads, seat backs in trucks or even adhesive plasters may produce the required mechanical stress. Some athletes are prone to this condition [2]. Acne mechanica has also been described in other circumstances (e.g. on the backs of young patients lying in hospital beds for several weeks, and on the face following jaw splinting [3] and with the use of orthopaedic crutches [4]). The resultant acne can be severe (e.g. acne conglobata occurred on the buttocks in a transatlantic rower) [5].

Traumatic effects of sports [1]

Skin conditions related to sport include mechanical injuries and other direct consequences of the sporting activity, conditions initiated by the environment and infections [1,2]. While the professional sportsperson and trainer may be well aware of these, the amateur may not recognize any connection and even the dermatologist may at times be puzzled. Some of the clinical entities are highly characteristic [3]. The skin adapts to training, developing a higher degree of 'elastic efficiency', but this requires time and continuity in the chosen sport. Many traumatic effects occur in the 'weekend jogger' or the summer holiday activist. The wheelchair athlete is particularly prone to blisters and pressure injury [4,5].

Many conditions affecting those engaged in sports are an indirect consequence of trauma. These include infections commonly transmitted by contact [6,7], such as herpes simplex [8], molluscum contagiosum [9] and tinea corporis [10,11]. Other infections that appear to be more common include viral warts [12], impetigo and furunculosis [13]. The sport of mud-wrestling has been associated with Gram-negative folliculitis [14]. Tinea pedis, often in a mixed infection with Gram-negative bacteria, is a common problem particularly in those using swimming pools. Otitis externa is also an important problem for the swimmer (see Chapter 65). Trauma to nails and trauma-related paronychia is considered in Chapter 62. The sports enthusiast is often at significant risk from sunburn or cold injury. In hot conditions, miliaria and hyperhidrosis can be problems. There are many circumstances in which contact dermatitis can occur; from sports equipment [3], environmental allergens, etc. Sporting activities can exacerbate pre-existing skin disease, such as atopic dermatitis, psoriasis, acne and other skin diseases. The spectrum of sports-related skin disorders also includes the consequences of anabolic steroid misuse, the physical urticarias, exercise-induced anaphylaxis [15] and leukocytoclastic vasculitis [16].

Blisters

These usually result from violent or unaccustomed local-

ized friction, and are most common on weight-bearing surfaces; in the wheelchair athlete, this includes the back [5]. Heat and humidity favours the development of blisters. Preventive measures and the management of friction blisters are discussed above (p. 22.13).

Haemorrhagic effects

Calcaneal petechiae ('black heel') [17] is described above (p. 22.16). It is particularly common after sports where there are sudden stops such as basketball. A similar condition, 'black palm', can occur in weightlifters [18] and is occasionally seen in golf and tennis players. Petechiae around the ankle in a long-distance runner have been described [19]. Annular purpura can occur when the skin is struck by a table tennis ball ('ping-pong patch') [20]. Annular purpura of a different type has been described in association with step aerobics; annular purpuric lesions developed on the legs [21]. Subungual haematoma, sometimes preceded by erythema, oedema and a throbbing pain, is common among racket-sport enthusiasts ('tennis toe') [22] and runners ('jogger's toe') [23]. Splinter haemorrhages have been seen in golfers [24]. Tennis toe most often affects the first or second toe, whichever is the longer, and the symptoms and signs may mimic a fracture. Jogger's toe tends to involve the third, fourth or fifth toe. Hyperpigmentation resulting from small ecchymoses of the skin on either side of the upper portion of the gluteal cleft is a distinctive finding in long-distance runners, and has been called 'runner's rump'. It is caused by contact between the buttocks while running [1].

Abrasions

These are common in many sports but are particularly associated with contact with wrestling mats [25,26] and artificial turf, which can also produce 'turf toe' (see below). Abrasions from use of skateboards are also common [27].

Acute inflammation

'Turf toe', a painful condition in which there is oedema and erythema over the dorsal aspect of the great toe with acute tendonitis of the flexor and extensor tendons, frequently occurs in athletes playing on artificial turf [28,29]. 'Jogger's nipples' was described in women who run without brassieres [30], but also occurs in men who wear shirts consisting of coarse fibres. It may be more prevalent when ambient conditions are cool, making the nipples erect, and when the skin is moist from sweating, increasing frictional resistance. A similar condition can be seen in competitive cyclists, but it has been suggested that the injury is thermal rather than the result of friction [31].

Corns and calluses

Many sporting activities result in calluses and corns. Some special examples include 'pulling boat hands' [32] in which there is an additional effect of cold injury, and 'rower's rump' [33]. When calluses or corns are a problem on the feet in runners, it is important to consider basic biomechanical principles of the foot, which may require specialist orthopaedic intervention.

Athlete's nodules

An entity sometimes known as surfer's or athlete's nodules can present on the anterior tibial prominence [34], dorsa of the feet or knuckles [35]. These asymptomatic nodules show dermal fibrosis as well as epidermal hyperplasia. A similar ovoid, largely dermal nodule occurring in the sacrococcygeal area of Japanese students has been attributed to pressure from the bicycle saddle over a distinctive abnormally posteriorly projecting sacrum [36,37].

Other frictional effects

Acne mechanica is common in many participants in sports [38] and may precede acne keloidalis nuchae in football players [39].

'Swimmer's shoulder' is a transient erythematous plaque caused by friction from an unshaven face during freestyle swimming [40].

Intertrigo of the groins is a frequent problem in the heavily muscled athlete. 'Judo jogger's itch' [41] occurred while jogging following vigorous judo but may be a manifestation of a dry skin subjected to abnormal physical and climatic trauma. A distinctive eruption of symmetrical erythematous linear plaques on the palms has been described in children, resulting from grabbing the floor and walls of the pool while swimming underwater [42].

'Mogul skier's palm' consists of hypothenar ecchymoses from repetitive planting of ski poles [43]. 'Hooking thumb' is unique to competitive weightlifters and consists of abrasions, haematomas and calluses on the distal third of the thumb [44].

Miscellaneous

Striae distensae have been associated with weightlifting [45,46]. The areas of skin most frequently involved are the anterior shoulders, lower back and thighs. Painful piezogenic pedal papules have also been ascribed to sporting activities [47]. 'Bicyclist's vulva' is a unilateral lymphoedema resulting from repeated chafing and folliculitis; investigations showed previously unrecognized abdominopelvic lymphatic abnormalities [48].

Skin signs of torture

Definition. In its Tokyo declaration, the World Medical Association in 1975 defined torture thus: 'Deliberate, systematic or wanton infliction of physical or mental suffering by one or more persons acting alone or on the orders of any authority, to force another person to yield information, to make a confession, or for any other reason'.

Prevalence. Amnesty International has listed 144 countries known for some form of human rights violation [1].

Clinical features. Dermatologists may be involved in caring for victims of torture immediately after it has been inflicted, but are far more likely to see individuals as patients or for legal purposes when the acute injury has settled and the signs are those of previous tissue damage [2,3]. The immediate signs of torture (e.g. abrasions, skin defects and haematomas) are dealt with in depth by Rasmussen [4].

It is important to recognize that, in some societies, the torturer takes great effort to minimize or avoid visible external signs from the injuries inflicted. Another characteristic is that beneath the normal or near-normal skin, there may be long-term or permanent injury (e.g. fractured bones, fibrosis of muscles, damage to nerves and tendons).

Examination of the victim of torture should take account of the potential legal implications as well as the emotional welfare of the victim [5]. The wider aspects of the psychological consequences for the victim, and aspects of rehabilitation, should also be considered by the physician caring for the victim of torture [6].

Specific injuries

Acute injuries in the form of bruising, oedema, abrasions and lacerations may be evident from their pattern as being consistent with some form of assault. As with child abuse, the weapon may have left a distinctive imprint, such as petechial haemorrhages produced by a hand, or parallel lines from a truncheon or stick. Usually, the dermatologist will be presented with scars, and it is important that a careful history is taken to support the diagnosis. There are a number of close mimics of the sequelae of torture.

Beating or whipping

These often produce parallel or criss-cross lines on the back or buttocks. Over bony points the residual marks tend to be circular. If the victim has been able to use his or her arms to protect the face, scars may be found on the backs of the forearms and hands rather than the face.

Beating on the soles of the feet

SYN. FALANGA; BASTINADO

This form of torture is used throughout the Middle East, in India and Sri Lanka. As well as damage to the skin and soft tissues, falanga can produce alterations in the plantar aponeurosis, tendons and joints in the feet. Immediately after the beating has been carried out, there is gross swelling and exquisite pain on walking. Late falanga symptoms include pain in the legs and feet, which tends to increase during the day and with exercise. The springiness of the subcutaneous tissue of the forefoot area and heels can be permanently damaged, producing so-called 'smashed' balls of the feet [7,8]. The loss of elastic resistance in the soft tissue of the balls of the feet is best tested when the patient is standing. Not all observers of falanga victims have found these characteristic changes [5]. Magnetic resonance imaging shows a distinctive thickening of the plantar aponeurosis in most cases [9].

The after-effects of falanga can be greatly helped by appropriate physiotherapy and supportive footwear.

Kicks

Injury from kicking tends to produce more or less circular scars over areas where there is bone close to the skin such as the patellae, shins and ankles.

Electrical burns

Electrical burns rarely leave permanent scars, but there may be fine, white, linear or puckered circular scars or groups of red punctate marks. If electricity is passed through clips applied to the skin, there is a greater likelihood of scarring. If seen early after electrical torture, there may be brown scales at the site of application of electrodes [4]; there are vesicular changes in the nuclei of cells in the epidermis, vessel walls and sweat glands [10], and a distinctive pattern of calcification is seen [11]. These changes can be helpful in distinguishing electrical and thermal injury. Scars may be grouped around a target area such as the nipples, lips, ear lobes or helices [12]. In a type of electrical torture known as Picona, an electrically charged needle is used repeatedly on a sensitive site, and may leave clusters of scars [13,14]. Scars on the genitalia, a frequent site of electrical torture, are rare because the skin of the penis or vulva does not scar easily. The pubic skin nearby, however, is very easily scarred.

Fig. 22.12 Torture. Circular lesions on the dorsum of the left hand presenting a thin, atrophic and wrinkled centre (thin arrow) and a narrow hyperpigmented zone in the periphery (thick arrow). (Courtesy of Amnesty International.)

Cigarette burns

Burns from cigarettes or heated circular instruments tend to be distinctive (Fig. 22.12). Brief contact with a cigarette tends to leave little scarring, but if there has been prolonged contact, there may be a deep puckered circular scar with a thin silvery surface. Deliberately inflicted cigarette burns are often applied to a part of the body that is readily accessible to the interrogator, for example the front of the thigh, or back of the forearm or hand, if the victim was seated. Such injuries are often inflicted in a regular pattern.

Stab wounds

Stabbing with a knife usually leaves a regular 1–2 cm linear scar. A bayonet, however, has one sharp edge and one blunt one and this may leave a teardrop-shaped scar. If a metal implement sharpened to a point is used to prod the victim it leaves a circular scar somewhat like a deep cigarette burn.

Inflicted injury to finger- and toenails

Finger- and toenails may be crushed or removed, or implements pushed beneath them. The end result is usually thickening and distortion of nail growth, but this can be difficult to distinguish from other forms of trauma.

Mimics of torture

Scars may have an innocent origin, for example from accidents, sporting injuries, etc. These are often on the most exposed parts of the body. Common dermatoses, such as acne and insect bites, particularly if the latter are infected, can leave prominent scarring. Tribal markings and traditional healing practices, involving injuries inflicted by knives, burning, etc., can be problematic in differential diagnosis. Scars from such practices are often parallel and in groups. Some Islamic fundamental sects ritually flog themselves with whips or chains and this can also result in parallel linear scarring. Vaccination may be a cause of prominent scarring, but the site is usually characteristic. Occasionally, operation scars can cause confusion.

Skin signs of child abuse

Child abuse is usually a clandestine activity denied by the perpetrator. The diagnosis can be very difficult to establish and may require the analytical observational skills of a dermatologist. There is often a differential diagnosis—physical abuse, accidental injury and various naturally occurring conditions can closely resemble one another and may coexist. Four circumstances may arouse suspicion of child abuse: suggestive physical findings, the past and present medical history, behavioural abnormalities exhibited by the child and the psychosocial conditions that are unearthed during the consultation. Suspected child abuse is best managed by a team including a paediatrician and social worker, following a framework of guidelines. Over the past two decades several reviews have detailed the features that should be understood by the dermatologist [1–7].

Definition. Child abuse is treatment of a child by an adult in a way that is unacceptable in a given culture at a given time [8]. Commonly, there is subdivision into four categories:

1 *Physical abuse* (syn. non-accidental injury): bodily injury is deliberately inflicted or the child is forced to engage in a harmful activity
2 *Sexual abuse*: inappropriate exposure to sexual acts or materials
3 *Emotional abuse*: coercive, demeaning or overly distant behaviour so as to interfere with normal psychological or social development
4 *Neglect*: the failure to provide the basic needs of life [9].

There are many difficulties with these definitions. For example, physicians (and others) do not agree among themselves as to what constitutes an 'acceptable' level of physical punishment for a child [10]. Society itself may have a high level of violence, and may tolerate widespread use of corporal punishment in its schools [11]. It can be difficult to categorize physical damage caused by healing practices used by some cultures and faiths, for example coin-rubbing (p. 22.26) and moxibustion, although members of satanic cults who subject children to physical and sexual abuse are generally regarded as transgressing the law.

Epidemiology. In the USA, a national survey indicated a prevalence of 16 in 1000 for child abuse [12]. The actual prevalence may be much higher—in the UK, 4% of children up to the age of 12 years are brought to the notice of professional agencies because of suspicions about possible abuse, and approximately 1 in 1000 children under 4 years suffer severe physical abuse [8]. In the USA, at least 4000 children die each year as a result of child abuse and neglect [13]; Meadow gives an estimate of 1 in 10 000 for the UK [8]. There is evidence that child abuse is becoming more common [8,11]. Although child sexual abuse occurs across the social strata, physical abuse and neglect are correlated with poverty [13].

Most child abuse is perpetrated by a family member, usually a parent or a cohabitant, for example the mother's boyfriend. Abuse is about 20 times more likely if one of the parents was abused as a child. Young parents seem more prone to abusing than older ones.

The different forms of child abuse may be concurrent, so the dermatologist must be vigilant to examine for forms of injury beyond that presenting in the skin (e.g. fractures, ruptured viscera, brain damage) and to evaluate for emotional abuse and neglect.

Fig. 22.14 Non-accidental injury. Superficial burns.

Physical abuse

Clinical features. The many manifestations of deliberate harm to children are illustrated in great depth in the monograph by Hobbs and Wynne [6]. The most common lesions that may present to a dermatologist are bruises and abrasions, followed by lacerations, scratches (Fig. 22.13), soft-tissue swellings, strap marks, haematomas, burns and bites [11]. Bites can be recognized as human by measuring the intercanine distance (greater than 3 cm implicates a perpetrator with secondary dentition) and recording the pattern of the puncture marks. Cigarette burns can often be suspected when there are one or multiple rounded crater-like ulcers or erosions. Acutely, there may be singed vellus hairs. Immersion burns tend to be sharply demarcated and uniform in degree [14] and there are often no splash marks (for further discussion of deliberately inflicted burns see p. 22.83). Needle injuries are a rare cause [15].

In general, one or more of several clues may point towards physical abuse:

1 Unconvincing delay in seeking medical help. With genuine injury there is a speedy request for help in most cases.

2 Details of the history appear implausible, change over time and/or are inconsistent with the developmental capabilities of the child.

3 Lack of concern by the person bringing the child.

4 Abnormal reactions, for example hostility to medical staff.

5 Abnormal demeanour by the child.

6 Disclosure by the child that the injury was inflicted.

7 Lesions have a shape or pattern recognizable as being caused by the means that inflicted them. Examples include bruises in the shape of a hand or pressure from fingers, linear lesions from being struck by a cord or coat hanger, the imprint from the buckle of a belt, and burns from metal utensils such as spoons (Fig. 22.14).

8 Location of lesions. Bruises from accidental trauma are usually over the bony prominences [16], such as knees, forearms, elbows, shins and forehead. Those resulting from abuse are often on the soft parts of the thighs, abdomen, buttocks, cheeks, neck and anogenital regions. Bruising in the mouth, and tears of the frenulum of the tongue, should arouse suspicion.

9 Multiple injuries over many body sites in different stages of healing.

10 The presence of other signs that suggest physical abuse. These may include bilateral periorbital ecchymoses,

retinal haemorrhages, rib fractures and traumatic hair loss. The latter may be suspected when the scalp is bruised or tender.

Management. It is essential that the child is examined in a comfortable supportive environment and that meticulous details are recorded in any case of suspected child abuse. It is important that the examination includes the mouth and anogenital areas. It is often necessary for permission to be granted. If possible, photographs should be taken. There is usually a statutory procedure to be followed when child abuse is suspected, which will necessitate the involvement of those with expertise in paediatric examination and assessment of the social setting of the child.

When bruising is present, the colour and location of each lesion should be documented. Bruises can be aged according to colour: red, 0–1 day; blue/purple, 1–4 days; green/yellow, 5–7 days; yellow/brown, 8–10 days; cleared 1–3 weeks [17], although more recent work has cast doubt on the reliability of these conclusions [18–20].

Investigations may be needed. When bruising is present, it is prudent to request a full blood count and clotting screen. Swabs should be taken from fresh bite marks. If there are reasons to suspect bony injury, a skeletal survey may be appropriate, as may an abdominal ultrasound for evaluation of the viscera.

Differential diagnosis. As well as being called on to recognize the varied physical signs of deliberate damage to the skin, the dermatologist may have to diagnose a wide variety of simulants of inflicted injury. These include purpuric and vascular disorders, some other causes of hyperpigmentation, blisters that can mimic burns and unusual scars. Establishing the dermatological diagnosis will require a full and careful history with all appropriate investigations. Animal bites can usually be distinguished by the narrower punctures and different spacings. Some examples of physical and sexual child abuse are summarized in Table 22.5 [1–34].

Table 22.5 Some dermatological mimics of physical abuse.

Mimics of bruising caused by physical abuse
Purpura, vascular and pigmentary problems
Disorders of coagulation [1,2]
Valsalva petechiae (vomiting and coughing) [3]
Sports injuries
Vasculitis [4]
Acute haemorrhagic oedema [5,6]
Erythema multiforme [7]
Perniosis [8]
Vascular malformations [9]
Haematoma from hair combing [10]
Ehlers–Danlos syndrome [11]
Topical steroid misuse
Incontinentia pigmenti [12]
Phytophoto dermatitis [13,14]
Medication-induced hyperpigmentation (e.g. fixed drug eruption)
Maculae cerulae (pediculosis) [15]
Coin rubbing (*cao gio*) [16] and spooning [17]
Cupping [18]
Hair-thread tourniquet syndrome [19]
Mongolian spots [20]
Urticaria pigmentosa [21]
Subcutaneous fat necrosis
Morphoea
Neuroblastoma [22]
Ink or dye stains [23]
Mimics of burns caused by physical abuse
'Therapeutic' burn [24]
Moxibustion [25]
Car seat burns [26]
Impetigo [27]
Immunobullous diseases
Photodermatoses, phytophotodermatitis
Enuresis blanket [28]
Chemicals [29]
Mimics of scarring caused by physical abuse
Ehlers–Danlos syndrome [30]
Striae [31–33]
Miscellaneous disorders that have mimicked physical abuse
Congenital indifference to pain [34]
Angio-oedema [1]

Sexual abuse

Sexual abuse has been defined as: 'Each and every sexual act that injures the self-determination of any person, who has either not reached a certain age, or who stands in a particular relation to the perpetrator, or who is unable to defend him/herself as a result of their physical or mental condition' [1]. It may occasionally have to be considered when there are physical signs suggestive of acute injury to the vulva, penis, anus and oral cavity in adults with learning difficulties, but the dermatologist is much more likely to see cases suspected of child abuse.

Child sexual abuse

Child sexual abuse has been defined as: 'Any use of children for the sexual gratification of adults' [1]. The dermatological features have been reviewed [2,3] and are illustrated extensively in Hobbs and Wynne's monograph [4].

Acutely, child sexual abuse presents with one or more of four types of complaint:

1 Symptoms caused by local trauma or infection, such as perineal soreness, bleeding, vaginal discharge and anal pain
2 Those caused by emotional effects of the abuse (e.g. enuresis, encopresis and anorexia)
3 Sexualized conduct
4 Sexually transmitted disease.

When a child presents with perianal warts or molluscum contagiosum, the possibility of sexual abuse will need to be considered even though there may be an innocent explanation.

As with the examination for physical abuse, it is important that the conditions for the examination are conducive and that appropriately skilled personnel are involved [1,5]. For anal and genital examination, colposcopy is very useful [4]. An assessment of the vulva should include the size, shape and any irregularities of the hymenal orifice, especially tears, and whether there are any swellings within the hymenal membrane; any erythema, swelling or bruising of the labia; and any vaginal discharge. Digital penetration tends to produce tears anteriorly, whereas penile penetration is associated with tears of the posterior fourchette. The examiner should be aware of normal variants of paediatric genital anatomy [4,6]. Bruises or scratching in areas adjacent to the anogenital region should raise suspicion. Perianal signs that may cause concern include multiple fissures, swelling or thickening, and

purpura. It is important to examine the mouth for signs of oral sex (e.g. palatal petechiae). There are specialized techniques for detection of semen [7].

With the exception of finding semen, lubricants or hairs, or genital infection with *Neisseria gonorrhoeae*, it can be impossible to prove sexual abuse on the basis of physical signs and investigations alone. Nevertheless, appropriate swabs should be taken to culture the full range of sexually transmitted pathogens and other likely infective agents.

For most cases where there is some suspicion (e.g. from sexually precocious conduct by the child), evident emotional disturbance or a disclosure of sexual abuse, it is essential for the dermatologist to involve the appropriate paediatrician and support team. The dermatologist should be aware that child sexual abuse often has long-term psychological consequences that can underlie dermatitis artefacta, 'neurotic excoriations', various manifestations of body dysmorphic disorder, compulsive washing practices and vulvodynia [8]. If previous child sexual abuse is recognized as a causative factor, psychotherapy can prove helpful.

Differential diagnosis. Almost any condition that can cause inflammation or bruising in the anogenital region may cause concern if there are social or other circumstances pointing towards sexual abuse, as may infection that is not inevitably sexually transmitted. Accidental trauma can also present difficulties [1]. Probably the most common dermatosis mistaken for child sexual abuse is lichen sclerosus, especially when there is subepidermal haemorrhage or when fissures are present [2,3]. If necessary, a biopsy can confirm the diagnosis. The dermatologist should, however, be aware that lichen sclerosus and sexual abuse are not mutually exclusive, not uncommonly coexist, and it has been suggested that trauma is a contributory factor in the aetiology [4].

As with physical abuse, other causes of bruising may need to be considered. These include idiopathic thrombocytopenic purpura, other bleeding diatheses and Ehlers–Danlos syndrome [5]. Haemolytic uraemia syndrome has presented with rectal bleeding thought to be caused by sexual abuse [6]. Conditions that mimic bruising include Mongolian spot, phytophoto-dermatitis (e.g. from prior handling of psoralen-containing plants or innocent transfer of lime juice onto the buttocks and thighs followed by sun exposure) [7,8] and dyes on the skin from clothing. Bleeding from vulvar haemangioma has been mistaken for sexual abuse [9], as have various congenital anomalies of the genitalia, such as hymenal tags and clefts [10]. Urethral disorders, particularly those that bleed, have led to suspicion of abuse (e.g. caruncle [5] and urethral prolapse [11]). Many blistering disorders have been mistaken for child sexual abuse (e.g. vulvar pemphigoid) [12] and chronic bullous disease of childhood [13].

Perianal Crohn's disease [14], abscesses and fistulae may resemble the fissures and scarring that can occur from anal abuse. Strangulation of the penis or clitoris is usually accidental [15–17].

The reliability of anal dilatation as a sign of abuse has been questioned [18,19]. However, gross examples are more likely to be significant. It is worth noting therefore that severe constipation [20] and neurological disorders [21] can cause marked anal dilatation. Accidental trauma (e.g. from the crossbar of a bicycle) can cause contusion of the external genitalia, including the clitoris and anterior parts of the labia, but is not likely to damage the hymen; in contrast, penetrative vulval abuse tends to damage the posterior parts of the vulva [15,16,22].

Much trauma is done by the act of female circumcision, which may not be admitted. Infectious diseases that may be wrongly attributed to sexual abuse include yaws, in which syphilis serology will be positive [23], and streptococcal infection of the anus, vagina, urethra and penis.

Some infections that can be sexually transmitted, but are not necessarily so, include herpesvirus type 2, anogenital warts (even the human papillomavirus types most associated with the genital tract) [24] and molluscum contagiosum.

Occasionally, common dermatoses that produce erythema, such as irritant dermatitis, seborrhoeic dermatitis, atopic dermatitis, napkin dermatitis, psoriasis, candidal infection or threadworm infestation, may require correct diagnosis in the context of suspicion of abuse.

Some of the conditions discussed above are included in Table 22.5.

Traumatic lesions during intensive care

The complex technology now involved in intensive care includes a number of invasive procedures and other devices that can cause cutaneous lesions [1–3], and for convenience these are summarized here. Continuous arterial catheterization may lead to bruising, haematomas and even local or peripheral skin necrosis [4–6]. Other sites of necrosis may be caused by pressure of headbands or other attachments. Phlebitis may occur from infection or irritant intravenous agents. Blisters can arise resulting from heat generated beneath oxygen transducers, perhaps more so in children than in adults [7]. When conducting gel is smeared across the chest wall, electrical burns can result from arcing between the paddle electrodes used for defibrillation or cardioversion; in most centres this is avoided nowadays by using prepackaged conducting gel pads [7]. Erythema ab igne has been described following malfunction of an adjustable temperature blanket [8]. Even though preventive measures are widely used, pressure ulcers do occur (p. 22.17).

Cutaneous injuries in the newborn

In the neonatal period, iatrogenic injury can be caused by trauma before, during or after delivery [1]. The skin of the newborn, especially if premature, is especially vulnerable to various noxious insults. Examples of prenatal injury include amniocentesis or fetal skin biopsy, leaving a dimpled scar. Common intrapartum injuries include that caused by the heart-monitoring scalp electrode, laceration from episiotomy or amniotomy, ecchymosis and variable oedema from vacuum extraction or delayed delivery. Post-natal mechanical trauma can be caused by the identification tag, blood sampling by heel prick, intravenous cannulae, and pressure from the prone position to the nose, toes and knees. Heating pads and monitoring devices can cause second- or even third-degree burns.

Neonatal injuries are considered further in Chapter 14.

Penile injuries

A variety of constrictive bands at the base of the penis are used by some individuals to increase sexual gratification. Sometimes these can become incarcerated and cause secondary ischaemic injury [1].

Human hair accidentally wrapped round the penis has caused penile oedema [2].

Petechiae may result from squeezing the glans to prevent premature ejaculation [3]. Zip-fastener tears are less common than previously, possibly because of the popularity of Y-front briefs. Lesions resulting from sexual experimentation may be bizarre. Vacuum cleaners can cause various injuries to the skin and urethra [4,5] and a meatal stricture may result.

Signs of emotional abuse and neglect

Neglect may be evident from malnutrition, an uncared-for dirty appearance, exaggerations of common dermatoses or lack of appropriate immunizations for the child's age [1]. Some examples of burn and scald are a result of neglect rather than deliberate physical abuse [2]. Both physical neglect and 'emotional abuse' can result in failure to thrive with depressed gain in height and weight. Cold swollen blue or red hands and feet have been described in cases of emotional neglect [3,4]. Some would consider the failure to administer treatments (e.g. to a child with eczema) as a form of child abuse.

Munchausen syndrome by proxy

This term is used to denote the situation in which the parent or caretaker falsely attributes symptoms in order to gain medical care or some other benefit. Such behaviour can result in multiple unnecessary surgical interventions [1].

REFERENCE

1 Weston WL, Morelli JG. 'Painful and disabling granuloma annulare': a case of Munchausen by proxy. *Pediatr Dermatol* 1997; **14**: 363–4.

Foreign bodies

Definition. Some extraneous materials (e.g. silica and zirconium) incite a characteristic pattern of granulomatous reaction in which a distinctive type of multinucleate giant cell, the foreign-body giant cell, is prominent. The term foreign-body reaction is used for this tissue response but may also be used for other patterns of pathological response to extraneous materials that become deposited in the skin or deeper tissues, usually as a result of direct penetration of the skin by the material itself, during surgery or by injection. Epidermis, hair and nail can induce a 'foreign-body' response if implanted in or beneath the dermis. Cutaneous reactions to medicaments introduced at a distant site (e.g. the pigmentation caused by minocycline) and some local adverse reactions to drugs are considered in Chapter 73.

Aetiology. Some examples of the types of foreign body and routes of entry are shown in Table 22.6 [1–48].

Pathogenesis. The biological response to a foreign body will depend on its composition, how it enters the body, the body site, the quantity of material and its physical form. In some instances (e.g. mercury and some animal and vegetable matter), a toxic or allergic reaction can occur as well as a later foreign-body reaction. Some reactions are complicated by infection, especially traumatic inoculation of wooden splinters and vegetation spines, which can introduce sporotrichosis and deep mycotic organisms as well as more common pyogenic infections. Infection may also localize to sites of inert foreign bodies during bacteraemia [1].

Pathology. When material has penetrated the skin there is usually a phase of acute inflammation in response to the injury. This may be necrotizing if there is significant trauma, toxin release or bacterial infection. Persistence of foreign material results in accumulation of monocytes, evolution of these into tissue macrophages, epithelioid histiocytes and giant cells (Langhans' and foreign-body type) and a fibroblastic reaction with laying down of new connective tissue around the area of foreign-body deposition.

Penetration injury can also result in implantation cysts mixed with granulomatous response.

Polarizable foreign bodies can be seen in biopsies of otherwise typical sarcoidosis, and if adequate criteria are met for a diagnosis of sarcoidosis, such foreign body material does not alter the diagnosis [2].

Clinical features. The clinical presentation will depend on the mode of entry and nature of the foreign body, the tissue response to it and whether there is associated infection. In some instances, there may be characteristic toxic effects (e.g. absorption of mercury from a broken thermometer) [3]; pharmacological effects (e.g. resulting from alkaloids in blackthorn) [4]; or allergic responses (e.g. to oils and resins in some woods).

Retained foreign bodies are commonly associated with bacterial infection, which tends to be resistant to antibiotic therapy. Vegetative foreign bodies may be associated with fungal infection. Soft-tissue infections may manifest as cellulitis, an abscess or a draining sinus. A wound that fails to heal or continues to cause pain with movement may conceal a foreign body, as can the persistence of a purulent discharge.

Many types of foreign body elicit a granulomatous response, seen clinically as erythematous brown or purple papules, nodules or plaques. The lesions often become harder over time because of fibrosis. Some materials result in discharge even when there is no infection (e.g. paraffins and other oils).

The implanted material may produce pigmentary change (e.g. carbon and metals result in a tattoo-like, black or bluish-black colour). Occasionally melanoma is simulated.

Clinical presentation can be modified by epidermal cyst formation, resulting from pieces of epidermis being carried in by a penetrating foreign body. It is important to recognize that even small external signs of entry of a foreign body can denote significant damage to deeper structures, such as tendons, joints and bones. This is especially true of high-pressure injection (grease, paint, water and some firearm injuries).

Diagnosis. Lacerations should be carefully examined for foreign bodies, using instruments rather than the gloved finger if there might be a sharp object in the wound. Palpation of a mass may justify extending the wound so as to explore it adequately.

When there is strong suspicion that all or part of a foreign body is in or beneath the skin, imaging techniques should be considered.

Plain radiography. A plain X-ray will often detect a foreign body, but visualization depends on the object's density, configuration, size and orientation. Metal, bone, teeth, pencil graphite, some plastics, glass and gravel are radio-opaque but may not be visible if located over a radiologically dense background such as bone. Some materials that are less dense than tissue can be seen as filling defects (e.g. white pine) [5], but very often organic foreign bodies are not visible on plain radiographs, especially 48 h or more after entry [6]. Plain films, using multiple projections, can enhance localization.

Ultrasonography. Ultrasound imaging is often helpful for vegetative foreign bodies that are not visible on plain X-ray, but there are a number of pitfalls in interpretation, especially in the hand [7,8]. Wooden splinters can be obscured by surrounding granulomatous tissue [9], and old scar tissue, small bones, fresh bleeding and sutures can produce false-positive reactions [10].

Computed tomography. Computed tomography (CT) scanning, which can visualize wooden material, has the advantage of producing images in multiple planes, which can aid localization and can relate a foreign body accurately to nearby structures. However, there is a greater radiation dose than plain radiography, so CT is best avoided as a screening procedure.

Magnetic resonance imaging. Magnetic resonance imaging (MRI) is comparable to CT for materials of similar density to soft tissue (Fig. 22.15) and may be superior for the detection of plastics [11], but must not be used for metal fragments. Gravel produces a severe artefact.

Histopathological techniques [12]. For foreign bodies below the limits of detectability by imaging techniques, it may be possible to make a diagnosis on material taken at biopsy by microscopic or ultrastructural techniques.

Some foreign materials have a distinctive microscopic structure, for example the regular arrays of plant cells in some vegetative material, such as wooden splinters and thorns. The presence of particulate material in phagocytic cells can often be seen on routine haematoxylin and eosin-stained sections. The periodic acid–Schiff (PAS) stain often shows up splinters, talc, starch and fungi. Dark-field illumination can help visualize some metallic materials. Polarization microscopy can demonstrate silica, talc, suture material, wood and plant matter [13]. In suitably processed material, the elements present can be ascertained by electron dispersive X-ray analysis (EDXA) and for lower-molecular-weight substances electron energy loss spectroscopy (EELS) may be appropriate [14].

The application of different methods is indicated in Table 22.6.

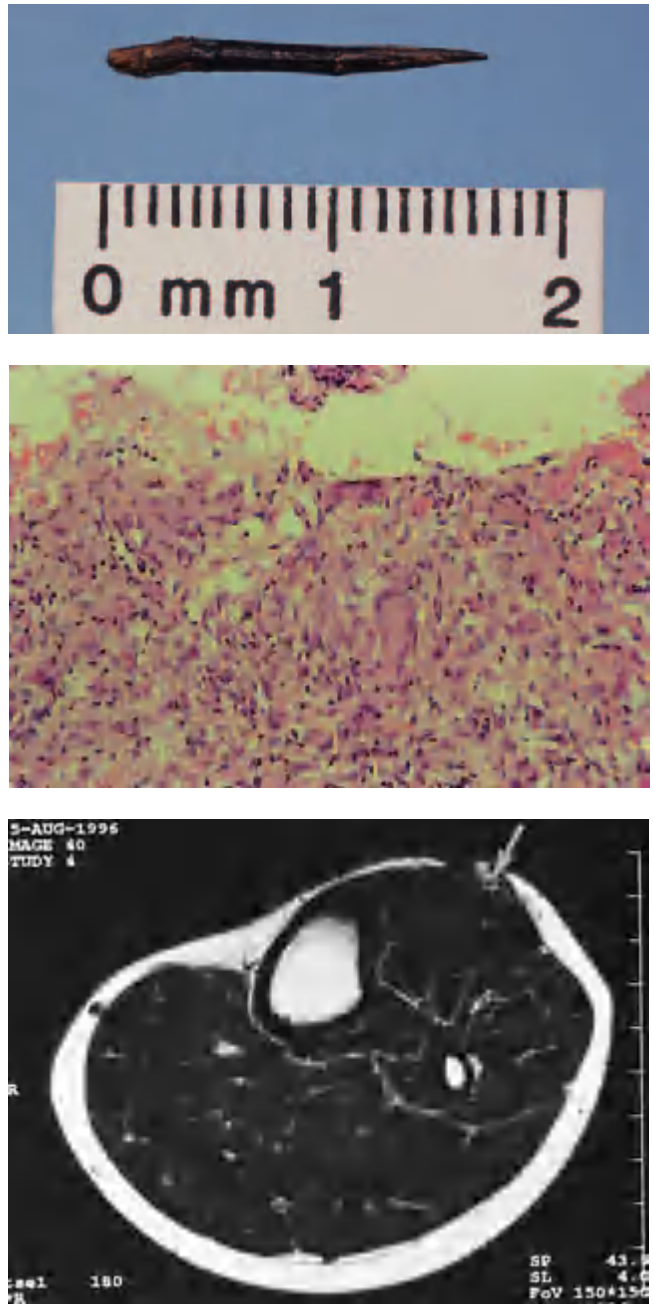

Fig. 22.15 Foreign-body reaction caused by deeply embedded thorn. The patient presented with a chronic leg ulcer. (a) Thorn that eventually emerged spontaneously. (b) Mixed inflammatory and granulomatous reaction from the ulcer bed. (c) Magnetic resonance imaging scan showing sinus tract containing the thorn (in cross-section, at tip of arrow).

Treatment [15]. It can be a difficult judgement as to whether or not to remove a foreign body. Some indications for removal of a foreign body are shown in Table 22.7. Non-reactivity, small size and inaccessibility may weigh in favour of leaving a foreign body. Vegetable material is often best removed. All wounds should be clean and tetanus immunization provided if necessary.

Table 22.7 Indications for removal of a foreign body. (Adapted from Lammers and Magill [15].)

Reactivity of the material (e.g. thorns, spines, clothing)
Heavy bacterial contamination (e.g. teeth, soil)
Toxicity (e.g. spines with venom, heavy metals)
Proximity to tendons, vessels, nerves or fractured bone
Impairment of mechanical function (e.g. abnormal gait from foreign body in foot)
Intra-articular location
Potential for migration towards an important anatomical structure
Intravascular location
Persistent pain
Established infection or inflammation
Allergic reaction
Cosmetic or psychological considerations

The best approach to remove a foreign body will depend on the size, location and nature of the material, and length of time it has been there. A simple method for locating a radio-opaque foreign body is to insert two or three needles of different sizes angled at 90° to each other. Using radiographs in multiple projections, ultrasound or CT, the needle closest to the foreign body is identified, and tissue dissected along its path [16]. It may be possible to pull out the foreign body intact, or slide out a long pointed object along the axis it entered. Material likely to be dealt with by the dermatologist may often be excised as a block of tissue.

After removal, the wound should be irrigated and débrided if necessary. If the foreign body was radio-opaque, and there is any doubt about completeness of removal, a post-operative film can be carried out.

Some distinctive foreign-body reactions

Paraffinoma

SYN. SCLEROSING LIPOGRANULOMA

Some vegetable oils containing triglyceride can be digested by lipases, but others, and mineral oils, greases and wax, cannot be broken down, and elicit a foreign-body reaction. Most instances of paraffinoma nowadays are caused by misguided attempts at tissue augmentation, often self-administered. The male genitalia is the most common site [1]; other sites include the male breast [2], gluteal regions and extremities. Paraffin gauze that was used to pack the nasal passages and sinuses has caused chronic inflammatory paraffinoma of the periorbital tissues [3,4].

The pathology of paraffinoma shows rounded clear spaces of varying sizes surrounded by fibrous tissue and a mixed inflammatory reaction, including foamy macrophages and multinucleated giant cells—the 'Swiss cheese' appearance.

Treatment is by excision.

Polyvinyl pyrrolidone

This hydrophilic polymer, formerly used as a plasma expander, is still used as a slow-release agent in a few injectable medications. Occasionally, it can produce a soft-tissue mass, often after a long latent period [1]. The material appears as a distinctive blue-grey deposit in macrophages with little or no inflammation or fibrosis. By Congo red, polyvinyl pyrrolidone (PVP) stains a cherry-red colour [2].

Hydroxyethyl starch pruritus

Hydroxyethyl starch (HES) is a plasma expander. It is widely used in intensive care units, and to improve the microcirculation in some otological and peripheral vascular diseases. Pruritus is a well-recognized complication, with a frequency of more than 30% in some European retrospective series [1,2] and 13% in a UK questionnaire survery [3]—although in a large prospective study the incidence was only 1% [4]. HES is deposited in the skin.

The pruritus usually begins between a few days and several months (typically within a few weeks) after the infusion. It is usually generalized, although can be localized (e.g. to the trunk or anogenital regions). Bouts of itching can be triggered by friction, bathing in warm water and physical exertions. HES pruritus is often severe and can last years. Usually there are no visible signs, but a single case has been described of diffuse erythematous skin infiltration [5].

HES is degraded in the plasma, taken up by histiocytes in many tissues including skin, and cleared through the kidneys. In the skin, HES accumulates in vacuoles within macrophages, which if abundant can resemble a storage disorder [5]. The vacuoles may also be seen in endothelial cells and basal epithelial cells. The identity of HES can be confirmed using specific immunostaining [6]. Only in patients who develop pruritus, the characteristic vacuoles are also seen in the various components of peripheral nerve cells, and resolution of itching is associated with eventual loss of the vacuoles [7].

It is not clear why only some patients given HES develop pruritus. In several series there is a threshold cumulative dose of approximately 200 g, although there is no close relationship to the volume given [3]. Patients with otological disease may be more susceptible than other groups [4]. Tissue storage is greater in those who develop pruritus [8].

The mechanism for pruritus is uncertain, although direct stimulation of cutaneous nerves by the deposits of HES has been proposed [9].

Treatment is unsatisfactory. The pruritus is unresponsive to oral antihistamines, topical or systemic corticosteroids and phototherapy, although topical capsaicin has some therapeutic value [9]. In most cases the pruritus resolves after 6–18 months.

Sclerodermiform reaction to vitamin K

The intramuscular injection of preparations of vitamin K has been followed by an erythematous plaque in the lumbosacral area, which takes on a dusky colour and becomes infiltrated and itchy after 10–15 days. After some months, it resembles a patch of scleroderma, ivory-white in colour with a surrounding lilac ring. Confluence of plaques in the trochanteric and lumbosacral area produces the so-called 'cowboy's belt' appearance, complete with holsters. All the nine cases studied by Texier [1] had received other vitamins, liver extract or iron injections and no case resulted from vitamin K alone, but this ingredient was a common factor. Occasional cases have been described subsequently [2]. A case resembling eosinophilic fasciitis has also been described [3].

Pentazocine ulcers (Fig. 22.16)

A distinctive woody induration with overlying ulceration is characteristic of repeated intramuscular or subcutaneous use of the analgesic pentazocine (Table 22.6). Such reactions are usually found in narcotic abusers.

Immunization granulomas

Temporary nodule formation at the site of immunization procedures may occur and usually subsides quickly. A more persistent granulomatous reaction resulting from the aluminium hydroxide component has been described [1] and may have an allergic basis in some cases [2,3]. This reaction has been found after administration of tetanus–diphtheria–pertussis [2,3], influenza [4] or hepatitis B [5] vaccines and after desensitization therapy with allergen extracts. A pure histiocytic foreign-body reaction is often

Fig. 22.16 Pentazocine ulcers.

observed in early lesions, whereas a delayed hypersensitivity granulomatous reaction is seen in older lesions. Although patch tests may be positive to aluminium [2], there is no relationship between patch-test results and the histopathological pattern [6]. X-ray microanalysis has shown the presence of abundant aluminium in the histiocytes [7]. In a series of 21 cases followed for up to 8 years, five cleared, improvement occurred in 11 and five were unchanged [3]. Patients known to have such reactions should in future receive non-adsorbed vaccines or toxoids [8].

Angiolymphoid hyperplasia with eosinophilia
(see Chapter 53)

This has also been associated with tetanus toxoid inoculation [1].

REFERENCE

1 Akosa AB, Ali MH, Khoo CTK, Evans DM. Angiolymphoid hyperplasia with eosinophilia associated with tetanus toxoid vaccination. *Histopathology* 1990; **16**: 589–93.

Zinc-induced insulin granuloma

A distinctive granulomatous response to zinc-insulin has been described [1] in which there is an acute neutrophilic response before granuloma formation. Other cutaneous and subcutaneous adverse effects of insulin preparations are discussed in Chapter 73. Use of a non-zinc insulin usually results in resolution.

REFERENCE

1 Jordaan HF, Sandler M. Zinc-induced granuloma: a unique complication of insulin therapy. *Clin Exp Dermatol* 1989; **14**: 227–9.

Intralesional corticosteroids

Occasionally, deposits of injected insoluble corticosteroids have been associated with a granulomatous response [1,2] and in one instance a reaction resembling rheumatoid nodule has been described [2]. Other adverse effects of intralesional corticosteroids are discussed in Chapter 46.

Silicone

Silicone (polydimethyl siloxane) is used medically in three forms: liquid for soft-tissue augmentation; bag-gel implants for augmentation mammoplasty; and as a solid elastomer in joint prostheses. In tissues, it has a characteristic of tending to migrate both locally and via lymphatics. Many of the reported adverse effects are likely to have been a result of adulterants, although even medical grade silicone can produce a granulomatous reaction [1,2]. The possible role of silicones in the aetiology of scleroderma and other connective tissue diseases is discussed in Chapter 56.

When silicone bag-gel material ruptures, it can migrate along fascial planes and gravitate into the skin, producing indurated inflammatory subcutaneous masses [3].

Following liquid or gel silicone injections, the histological appearance is of varying sized vacuoles similar to paraffinoma, but with less fibrosis and usually an absence of granulomatous response if medical grade silicone was used [4]. Sometimes, however, granulomatous reactions do occur [5].

Recently, cases have been described of multiple silicone-containing granulomas at the site of entry of acupuncture needles that had been coated in silicone oil [6,7].

If adulterants are present, a more inflammatory reaction is described. Particles of rubbery silicone elastomer

can elicit a vigorous foreign-body granulomatous response.

The Si–C chemical bond, characteristic of silicone and not found in nature, can be detected by infrared spectroscopy, and silicon can be demonstrated by EDXA.

Silicone reactions can only be eliminated by appropriate surgery, although amelioration of the inflammatory response by treatment with minocycline has been reported [8].

Collagen implants

Injectable collagen for tissue augmentation has traditionally been of bovine origin; it is produced by selective hydrolysis of telopeptide regions, and is mainly type 1 collagen. A more durable form is cross-linked with glutaraldehyde (Zyplast®). Although bovine collagen implant is non-toxic and in general produces little irritation, transient erythema lasting 2–4 days is very common following its use. Before substantive treatment using this material is undertaken, patients receive a skin test. Of those who do not react to the test site, 1–3% will subsequently develop induration, which may progress to nodule formation. These nodules may last several months [1]. The glutaraldehyde cross-linked material is associated with fewer reactions [2]. Rarer reactions include intermittent swelling at the same site, which can last up to 3 years, sterile abscesses [3] and local necrosis [3,4].

When deposited in the dermis, bovine collagen implant appears microscopically as an amorphous eosinophilic material, less birefringent than normal collagen. When hypersensitivity reactions occur, there is a diffuse granulomatous reaction in the early stages [4] and later the response tends to be a palisaded granuloma, with an admixture of lymphocytes, plasma cells, eosinophils and neutrophils [5]. This can produce a superficial similarity to necrobiotic granulomas such as granuloma annulare. Special stains can be useful, for example colloidal iron, which stains the bovine collagen a strong magenta colour compared with the pink of normal collagen [1,6].

In most instances, bovine collagen injection reactions can be treated symptomatically or left to involute.

Although reactions to human-derived collagen implants are less likely they have been reported [7].

Fibreglass dermatitis

Reactions to glass fibre are usually caused by physical injury, although allergic contact dermatitis resulting from residual epoxy resin on the fibres has been described [1]. The fibres that cause reactions are generally greater than 4 μm in diameter [2].

Pruritus is very common and may occur with or without skin lesions, which, if present, usually consist of transient erythematous papules that are often follicular. The forearms, hands, face, neck and flexural folds are common sites. Covered sites can be affected because the fibres can penetrate clothing. Fair-skinned blue-eyed individuals seem to be more susceptible [3]. The fibres only penetrate the more superficial epidermis, yet the histopathological changes include subcorneal pustules, spongiosis and a mixed upper dermal infiltrate [4]. The mechanisms underlying these changes remain speculative. Glass fibres are often difficult to see in biopsy specimens but can be recovered by Scotch tape stripping and this may be of use in diagnosis [5].

With prolonged exposure, a form of hardening can occur, with the pruritus, but not the visible signs of dermatitis, reducing in intensity [3].

Complications of tattoos

The term tattoo, derived from the Tahitian *tatau* [1], has been used for both the deliberate introduction of permanent colours into the skin through punctures, and for accidental entry of pigmented material [2]. The latter is common after abrasion injuries, for instance in cyclists and coal miners. Cases have been described of tattooing from close exposure to black gunpowder, as used in replica firearms [3]. Accidental tattooing from Monsel's solution or ferric chloride [4,5] provides rare iatrogenic causes. Tattooing can occur from contact with jewellery (e.g. earrings) [6].

Complications of decorative tattoos are relatively rare in Western countries. More sophisticated techniques have lowered although not abolished the risk of transmission of syphilis, tuberculosis and hepatitis [7–9], molluscum contagiosum [10] and viral warts [11]. Pyogenic infection is uncommon. An acute inflammatory reaction may last for days or weeks but is of no serious import. The complications of tattoos can have forensic implications [9].

The most commonly used pigments are carmine, indigo, vermilion, India ink, chrome green, cobalt blue, cinnabar (red), cadmium sulphide (yellow) and manganese (purple). Hypersensitivity reactions [12–14] are most commonly seen to cinnabar (mercuric sulphide), but are also seen with cobalt, chrome and manganese [15] and aluminium (purple) [16]. A photosensitivity reaction to cadmium yellow occurs occasionally [17]. When photosensitive reactions to red tattoos are investigated, the cause is sometimes a cadmium salt [18]. New non-metallic dyes are now being used increasingly and may produce reactions. The compound responsible can sometimes be identified by nuclear magnetic resonance and mass spectroscopy. Even carbon, long thought to be inert, may be capable of eliciting a granulomatous response [19].

Permanent pigmentation of the eyebrow area by injections of a ferrous oxide preparation has become popular since its introduction in 1984 [20] and a granulomatous dermatitis has been described [21]. A similar reaction has been recognized resulting from chromium salts [22] and mixed pigments [23].

Histological findings may resemble contact dermatitis with or without a granulomatous infiltrate, lichen planus or 'pseudolymphoma' [24,25]. B-cell lymphoma has been recorded as evolving from a tattoo-induced pseudolymphoma [26]. Perforating granuloma annulare can follow tattooing [27].

A sarcoidal reaction occasionally occurs. This is often non-specific, although it may obviously be a manifestation of sarcoidosis in some patients [28,29] and has been associated with uveitis as an isolated finding [30,31].

Psoriasis and lichen planus may occur in tattoos as examples of the Koebner phenomenon in patients with the active disease.

Traumatic tattooing (e.g. from an explosion) is amenable to laser treatment (e.g. with the erbium-YAG) [32].

The treatment of decorative tattoos is discussed in Chapters 77 and 78.

Hair as a foreign body

Fragments of hair may penetrate the skin and cause a variety of reactions, according to the site and depth of penetration, ranging from slight erythema to the formation of abscesses and sinuses. Chronic reactions take the form of foreign-body granulomas, which may present as subcutaneous nodules or with hypertrophy of the overlying epidermis. The clinical syndromes encountered are very diverse and their cause is often unsuspected.

Barbers' hair sinus

Interdigital sinuses are common in men's barbers, presumably because of the short sharp hair fragments generated from cutting men's hair [1,2]. They also occur in female hairdressers [3] and those who cut animal hair [1]. The sinuses usually affect the first or third left or second right finger web. The lesions—tender nodules with a central sinus or intermittently discharging papules—are relatively inconspicuous and are often disregarded. Hair can also cause inflammation when implanted into the finger pulp [4] and beneath fingernails [5], probably when there is an abnormality of the nail or a pre-existing dermatosis [6].

Hair sinuses of the feet

Hair fragments may penetrate the skin of the feet. Long curved hairs embedded in the toes or ankles have been recorded in ladies' hairdressers; one case resembled larva migrans [7]. Deeper penetration may provoke tender nodules or abscesses.

A distinctive syndrome, seldom recognized, may follow the penetration by a hair of the toe-cleft skin, usually the fourth. The patient complains of pain and tenderness, which is usually attributed to other causes. There is oedema of the dorsum of the foot above the involved cleft. A pinhole sinus is found beneath the accumulated interdigital debris. Surgical excision may be necessary. The hair-thread tourniquet syndrome may also involve the feet (see below).

Milker's sinuses

Milker's sinuses are now uncommon but are more disabling. Fragments of cow hair may penetrate deeply, involving even the tendon sheaths. Secondary infection often follows, sometimes by dermatophytes [8]. Most lesions involve the second or third web of the right hand, forming tender nodules and discharging sinuses [9]. Recurrent episodes of cellulitis follow. Spontaneous cure may eventually take place, but may be so long delayed that surgical intervention is advisable.

Fig. 22.17 Pilonidal sinus.

Anogenital pilonidal sinus

Anogenital pilonidal sinus is discussed more fully in Chapter 68. Some cases are of developmental origin but many follow the penetration of the skin by hair(s) by the root-end, through the action of the cuticular cells. The sinus itself does not have hair follicles. The penetrating hair(s) may cause a foreign-body giant cell reaction, sometimes with secondary bacterial infection, which can cause a sudden onset of pilonidal abscess. In addition to the primary track resulting from the initiating hair(s), there may be secondary tracks opening from the cavity. Presentation is usually as a midline opening or series of openings in the natal cleft about 5 cm from the anus. Pilonidal disease usually starts at the onset of puberty. Males are affected much more commonly than females, but three cases have been described in young women under the title of 'jazz-ballet bottom', in which secondarily infected natal cleft abscesses were associated with the presence of hair shafts [10]. Frictional trauma from the dancer's movement of the sacrococcygeal region against the floor was thought to have driven the hair into the skin.

Half of affected patients present as emergencies with an acute pilonidal abscess; the remainder have chronic fluctuating discomfort associated with a foul-smelling discharge from one or more sinus openings [11]. Examination reveals the characteristic opening in the natal cleft (Fig. 22.17) through which a tuft of hair is often seen emerging.

There is no uniform approach to management. A small sinus can sometimes be treated by removal of the hairs and regular shaving of the surrounding skin. A phenol injection technique has been used, either alone, with curettage or combined with excision [11]. Most patients are treated either by excision and primary closure, or by laying open and healing by secondary intention or repair with skin flaps. Primary closure or flap repair produces more rapid healing and shorter time off work [12,13];

wound breakdown after suturing may be lessened by prophylactic use of clindamycin [14]. Modifications of direct closure can be used to flatten the natal cleft and thereby reduce the risk of recurrence [15], but there may be greater morbidity if such techniques fail [11].

A pilonidal abscess is probably best treated by incision, drainage, curettage of hair and granulation tissue, and leaving open for secondary intention healing.

Squamous cell carcinoma has been described as a rare complication of pilonidal sinus [16,17].

Miscellaneous hair-filled sinuses

The penis can occasionally be the site for a pilonidal sinus-like lesion [18]. Pain, tenderness and discharge in the umbilicus has been associated with the presence of hair, perhaps in association with a hirsute abdomen and poor umbilical hygiene [19]. A hair sinus originating on the chin has resulted in loss of a tooth resulting from penetration of the sinus through into the incisor tooth socket [20]. Trauma was reported to account for a hair sinus over the mandible [21]. Hair sinuses of the areola of the breast [22–24] are discussed further in Chapter 67.

Hair-thread tourniquet syndrome

A foreign-body reaction to hair and hair-like fibres has been described following the encirclement of fingers, toes and the penis, usually as an accidental event [25] but also as an instance of child abuse. The affected area presents as a dusky swelling, sometimes with focal discharge, and the hair may be completely buried and only evident after surgery [26]. Removal of the constricting fibre is usually sufficient [25,27].

Pseudofolliculitis barbae

This foreign-body reaction to the ingrowth of obliquely cut, often tightly curled hair causes an eruption of erythematous papules in the beard area [28,29]. It is especially common in dark-skinned races. Stretching of the skin and shaving against the 'lie' of the hair increases the tendency. The pubic hair has also been involved. A similar condition has been described in Iraqi women who pluck the hairs of their legs, leaving some broken stumps which curl back into the follicle [30]; 'pseudofolliculitis vibrissae' [31] represents a variant caused by close cutting of nasal hairs, that may be confused with perforating folliculitis of the nose.

Preventive measures include discontinuing shaving, use of a clipper to maintain a beard hair length of 1 mm, and use of specialized single blade razors and depilatories.

Treatment is generally unsatisfactory; many symptomatic remedies have been reported (e.g. topical retinoids, α-hydroxyacids and antibiotics) but laser hair removal techniques may offer the best approach thus far [29,32].

Complications of artificial hair implantation

Although the use of synthetic fibres implanted in the scalp has been known for many years to produce severe foreign-body reactions [33–35], baldness sufferers continue to undergo implantation procedures with synthetic materials. Although some fibres, such as polyester, have been promoted as less liable to produce reactions [36], chronic purulent foreign-body reactions remain a typical consequence [37,38].

Other penetrating injuries

Reactions to ornamental metal piercing [1]

Piercing of body parts with metal ornaments is a tradition in many societies, and may have originated in the Hindu religion. Piercing of sites in addition to the earlobe have become increasingly fashionable in Western societies over the past three decades.

Non-traditional facial sites include high ear piercing and nose boring, in which cartilage is penetrated, and piercing of the eyebrow, lip, cheek and tongue. The navel (periumbilical skin) and nipple are common sites on the trunk. A variety of genital piercings are encountered, some specific to particular cultures, for example the 'Prince Albert' or 'dressing ring' which penetrates the urethra and was said to be used to secure the penis inside tight fitting trousers in Victorian times [1]. The use of non-traditional body piercings extends far beyond the young, adventurous and sado-masochistic [2].

In general, complications are frequent [3] but, unless serious, do not come to the attention of specialists. They include redness and swelling, exudation, minor infection, bleeding and, less often, cyst formation, significant tears and scars. Allergic contact dermatitis, usually to nickel, is also common.

Much of the data on complications from piercing in relation to ears is discussed in Chapter 65. Serious infections can occur, for example a tongue piercing leading to intraoral cellulitis requiring associated ventilation and surgical intervention [4], endocarditis was reported from a nose piercing [5] and a breast abscess from a nipple ring [6]. There is increased risk for local infection if the ring is placed through tissue with potentially pathogenic resident flora (e.g. eczematous skin) and for cardiac complications if there is a pre-existing cardiac susceptibility [7]. As with ear piercings, lack of attention to sterility can lead to transmission of viral infections such as hepatitis and human immunodeficiency virus (HIV) [8].

Unlike ear piercing, nose boring does not seem to be particularly associated with hypertrophic scar or keloid formation but is often followed by a self-limiting type of pyogenic granuloma-like capillary proliferation [9]. The nose piercing clasp can become embedded in a mass of granulation tissue, necessitating surgical intervention [10].

Significant trauma is particularly a feature of body piercing through genitalia (e.g. urethral rupture after insertion of a Prince Albert ring) [11].

It is sometimes necessary to remove a body piercing, for example because of infection, local tissue damage or the need for a radiological investigation. Removal depends on the design of the piercing. There are three basic designs: the barbell stud in which a straight bar has a threaded ball on each end; the labret stud in which the threaded ball is on one end only, and the captive bead ring, which consists of a bead held 'captive' by tension from both sides of an incomplete ring. Removal is usually straightforward once the design is appreciated [12].

Titanium implants

Bone-anchored skin-penetrating titanium implants are now a well-established method for securing auricular and other facial prostheses and hearing aids. There can be secondary infection with *Staphylococcus aureus* [1] and occasionally untreated reactions at the skin interface can lead to loss of osteo-integration [2]. Although most patients have no adverse cutaneous reaction to this procedure, inflammation does occur in about 10% [3]. Even in clinically normal skin around such implants, there is an increase in B lymphocytes, presumably because of the

breach of skin barrier function by virtue of the passage through it of the titanium to the bone beneath [4], and the cellular components for a T-cell-mediated hypersensitivity response may be present to the same degree as happens with stainless steel implants, even though a clinically evident allergic event does not take place [5].

Skin lesions in drug addicts [1,2]

The skin in an injecting drug addict can manifest lesions as a direct result of injection into veins or arteries, from subcutaneous deposition of the drug, and as a consequence of dissemination of the drug or contaminants in the injection fluid. Skin changes have also been described when addictive drugs have been taken by routes other than an injection. The skin manifestations of alcohol abuse [3] are outside the remit of this chapter.

The drug addict will seldom disclose his or her addiction during a routine examination for a skin disease. In view of their increasing incidence, the dermatologist should be aware of the nature of the more commonly found stigmata of addiction. Puncture scars in a linear distribution over a vein (or running parallel on each side of it) were seen in all of 54 addicts examined [4]. An extraordinary number of veins may be used—often those on the hands or fingers and even the dorsal vein of the penis [5]. The granulation tissue of chronic ulcers may be used when no more veins are available [6].

Serious infection is the most common manifestation of drug abuse. Abscesses, ulcerating nodules [7] or necrotizing lesions [8] occurring in unusual sites, particularly a painless ulcer on the dorsal penile shaft [9], should arouse suspicion; a past history of similar abscesses even more so (although these patients are likely to be unreliable witnesses). Abscesses caused by the drugs themselves or resulting from infection are more common when drugs are injected subcutaneously or intramuscularly (often called 'skin popping'), and the damage to deeper structures can be severe [10,11]. Ulcers can be very slow to heal [12]. Potentially fatal necrotizing soft-tissue infections can present like simple abscesses in illicit drug users [13]. The use of a cocaine and heroin mixture (colloquially known as 'speedball') is a risk factor for abscess formation, probably by the enhanced vasoconstrictive effect [14]. Wound botulism in the USA is now almost always caused by skin popping of black tar heroin [15,16] and is also seen in Europe [17]; even anthrax has occurred [18]. In the injecting addict, HIV infection is a risk factor for both abscesses and endocarditis [19].

Injections of the analgesic drug pentazocine may cause marked ulceration, sclerosis and hyperpigmentation (Fig. 22.16). Panniculitis is also a feature. Seventeen cases, of whom six were physicians, were recorded at the Mayo Clinic in 11 years. Psychiatric illness was almost always present and a personal family history of diabetes was common [20]. Two patients have been described who developed a systemic disease with pulmonary granulomatosis secondary to pentazocine abuse [21]. Benzodiazepine by injection can also cause skin necrosis with scarring [22].

A syndrome brought about by systemic candidiasis, presenting with purulent nodules in the scalp and follicular pustules in other hair-bearing areas, tenderness over various bones and cartilages and distinctive eye lesions, has been described in intravenous heroin addicts [23]. This unusual candidal infection has been attributed to the use of lemon juice as a solvent for the drug [24–26] and has also occurred with buprenorphine dissolved in juice from a 'plastic lemon' [27]. The skin itself may, however, be the source of *Candida albicans*, the profuse sweating associated with heroin usage and drug-related immunosuppression contributing to the follicular localization of the skin lesions and the pattern of dissemination that occurs [28]. The condition is typically seen in users of brown heroin [29], although it has been described in an white heroin addict in whom the *Candida* was thought to originate in the mouth [30].

Post-inflammatory pigmentation is a very common feature in intravenous drug abusers. More specific 'soot tattooing' may occur from flamed needles [31]. Other signs include thrombosis of, or bruising over veins; local urticaria from leakage of heroin or methadone; painful necrotic ulceration from barbiturates; and, rarely, keloids. Thrombosed subcutaneous veins can be felt as fibrous cords, and oedema is a common occurrence when most of the vessels in an extremity have been damaged. Circular scars are characteristic of skin popping.

Leukocytoclastic vasculitis occurring in one extremity has been described as a complication of intravenous drug abuse and was probably a result of intra-arterial injection [32].

Systemic amyloidosis is emerging as a serious complication of heroin abuse [33–35].

Free-base cocaine ('crack') by inhalation has been associated with acrocyanosis, severe necrotizing livedo

reticularis and muscle infarction [36–38]. The vasoconstrictive effects of cocaine have been implicated as a cause of scleroderma in a man addicted to the drug for 9 years [38], and a localizing factor for vasculitic lesions [39].

Itching at the site of the injection or in the centre of the face is a common initial effect of heroin, but passes off after 2–3 weeks on the drug. Paraesthesiae from cocaine or methyl amphetamine may lead to excoriation and scarring. Such findings would be significant in a young patient in whom scabies has been excluded. Piloerection is a well-known feature of the opiate abstinence syndrome.

Decorative and sometimes cryptically informative tattoos are sometimes found over injection sites in intravenous drug abusers [2].

In South Africa, a distinctive brown staining of the palmar surface of the first web space is associated with smoking cannabis by means of a broken-off bottle neck [40].

The anabolic and androgenic steroids are liable to abuse in athletes and bodybuilders, and should be considered in cases of seborrhoea, acne, hirsutism and striae distensae when appropriate [41].

A papular and pustular facial eruption has been attributed to *N*-methyl-3,4-methylenedioxyamphetamine (MDMA)—'ecstasy pimples' [42].

Frostbite has been described with recreational use of nitrous oxide [43].

Skin hazards of swimming and diving

The increasing popularity of aquatic leisure activities has brought into prominence a wide variety of water-related dermatoses [1,2] (Table 22.8). Amateurs in underwater swimming and scuba diving are not always conversant with the hazards, particularly if these activities are carried out in unaccustomed waters on holiday.

Table 22.8 Some water-related dermatoses.

General
Sunburn
Cold urticaria
Aquagenic pruritus
Dry skin (swimmer's xerosis)
Swimmer's ear (external otitis)
Contact reactions
Bathing costumes
Wet suits
Snorkel masks, goggles, etc.
Fresh water
Swimming pools
Fungal infection, verrucae
Chlorine and bromine irritation
Chapping in atopics
Aquagenic acne
Green and blond discoloration of hair
Swimming pool granuloma
Jacuzzi/hot tubs
Pseudomonas folliculitis
Sauna
Miliaria
Tinea versicolor
Rivers, lakes
Cercarial itch
Trench foot
Streams
Onchocerciasis
Showers
Aquagenic pruritus
Sea water
Immersion syndrome
Algae dermatitis
Jellyfish and other venomous stings
'Sea-bather's eruption'
Coral abrasions and sea-urchin injuries
Surfer's nodules
Deep-sea diving
Otitis externa
Intertrigo
Staphylococcal infections
Scalds, flash burns
Abrasions from wetsuit folds
Pruritus, erythema (decompression)
Tropical (e.g. sponge divers)
Venomous bites and stings
Coral, sea urchin injuries

General hazards

The hazards of UV radiation associated with swimming and aquatic sports are discussed in Chapter 24. People falling from boats into very cold water can die within minutes unless specially protected from heat loss. Prolonged immersion in warmer sea water can cause electrolyte imbalance by percutaneous absorption (immersion imbalance). Dry skin after swimming ('swimmer's xerosis') may in part be brought about by an osmotic gradient; other factors include dilution of sebum and use of soap afterwards [1]. The relationship of external otitis ('swimmer's ear') to water sports is discussed in Chapter 65. Cold urticaria and aquagenic urticaria and pruritus are discussed in Chapter 47.

Bacterial contamination from sewage disposal accounts for many cases of gastrointestinal disorders in swimmers using coastal resorts, even in the UK [3], and in those bathing in recreational rivers [4]. Skin infections resulting from faecal organisms may also be more common in contaminated rivers [3], and skin irritation can occur from toxins released by blue–green algae in inland waters [3]. 'Bikini bottom' is a nodular folliculitis of the inferior buttocks, probably caused more by poral occlusion from not changing out of a damp swimming costume than by specific pathogens [5].

Allergic contact dermatitis can occur, for example to bathing costume elastic or dyes, goggles, snorkel masks or mouthpieces [6]. Rarely, toxic leukoderma from use of goggles has been reported [7].

Traumatic conditions include 'surfer's knees', waterslap injuries on the anterior thighs of speed swimmers, rope burns on the extremities of water skiers [8], 'purpura gogglorum' caused by the effects of pressure and suction [9] and 'swimmer's shoulder'—an erythematous rough plaque caused by friction from the unshaven chin while swimming freestyle [10].

Swimming pools and whirlpools [11,12]

Chlorine causes irritation in subjects with dry skin or atopic dermatitis. Contact urticaria from exposure to chlorinated pool water has also been described [13]. 'Aquagenic acne' is attributed to rebound hyperactivity of the sebaceous glands, an irritating effect of chlorine on pilosebaceous duct orifices and poral obstruction by overhydration [1]. A bromochlorine pool antiseptic (1-bromo-3-chloro-5-dimethyl-hydantoin) resulted in several outbreaks of pruritus and irritant dermatitis [14]. Chemical conjunctivitis may occur if the subject swims with the eyes open. The use of communal changing room facilities may increase the risk of spread of verrucae and tinea pedis. *Mycobacterium marinum* infections are discussed in Chapter 28. The bleaching effect of chlorine may lighten the colour of hair if bathing and sun exposure are excessive. In competitive swimmers even black hair can become golden; mechanisms involved include damage to the cuticle, entry of hypochlorous acid and resultant damage to melanosomes [15]. Green tinting of hair may occur in blondes from frequent swimming in pools, probably because of exposure to copper-based algicides. Regular shampooing and 3% hydrogen peroxide lotion may decrease this effect [16,17].

Pseudomonas folliculitis

Pseudomonas aeruginosa has been associated with outbreaks of folliculitis, mainly in those using whirlpools (jacuzzis)

Fig. 22.18 Sea-urchin granulomas. The nail discoloration is caused by potassium permanganate. (Courtesy of Bristol Royal Infirmary, Bristol, UK.)

and hot tubs, although in some cases the source has been indoor swimming pools [18–20]. *Pseudomonas aeruginosa* is able to withstand relatively high temperatures and high chlorine levels. The organism colonizes the overhydrated stratum corneum of the follicular ostia. Symptoms usually appear 8–48 h after exposure, quite often with multiple members of a family being affected [21]. The rash is usually itchy and polymorphous, with erythematous macules, papules, vesicles and pustules. The areas most affected tend to be those covered by the bathing suit. The head and neck are rarely affected. There may be associated conjunctivitis, pharyngitis and, occasionally, swollen and painful breasts, abdominal symptoms and lymphadenopathy. 'Hot-tub dermatitis' is discussed further in Chapter 27. Acute external otitis, also usually caused by *Pseudomonas* infection, may occur concurrently.

Treatment is symptomatic. The problem usually clears spontaneously over 7–10 days.

Outdoor swimming

Sea bathing

Many hazards ranging from the trivial to the fatal can occur in seabathers [6]. These include the distinctive stings and other lesions inflicted by members of the phylum *Cnidaria*, which includes jellyfish, sea anemones, corals and hydroids [22]; 'seabather's eruption'; irritant and toxic contact reactions to seaweed, bryozoa (e.g. Dogger Bank itch), sponges, bristle worms, sea cucumbers and some fishes; physical injury from the scales of elasmobranch fish, such as dog fish and skate, lacerations from coral; suction injury by some ray fish; puncture wounds from sea urchins (Fig. 22.18) and some molluscs; and octopus bites and fish stings [23]. These aquatic injuries are all considered in detail in Chapter 33.

Two distinct pruritic papular dermatoses are associated with microscopic cercarial larvae in contaminated water, namely swimmer's itch, discussed here, and seabather's eruption (see Chapter 33).

Swimmer's itch [2,24–26]

This is an allergic response to the larvae of animal schistosomes for which humans are not the primary host. The biology is discussed further in Chapter 33. Swimmer's itch occurs at 12–24 h after exposure to the larvae of animal schistosomes, usually in fresh water, although less often in salt water. Outbreaks are more common in the summer.

The initial symptom may be a prickling sensation soon after leaving the water, corresponding to when the larvae penetrate the skin, and can last an hour or so. Erythematous macules appear 10–15 min after penetration, mainly on areas not protected by the swimming costume. If the individual is not sensitized to the cercariae, symptoms and signs subside in less then 12 h. In the sensitized, lesions evolve over 10–20 h into intensely itchy papules, which can coalesce into plaques. Itching and the papular eruption can last 1–2 weeks. In severe cases, usually those repeatedly exposed to cercariae, lesions may evolve into vesicles and pustules, and systemic symptoms such as headache and fever can occur.

The epidermis shows spongiosis with collections of neutrophils and eosinophils. Occasionally, biopsies taken within 48 h of the exposure may show cercariae in the outer epidermis [26,27].

Seabather's eruption, caused by cnidarians (see Chapter 33) may be similar, with pruritic papular lesions, but tends to maximally affect the skin covered by the swimsuit and only occurs in salt water. Other possibilities may include arthropod bites of various types and seaweed dermatitis.

Covering the skin, for example with a wetsuit, may be protective. Vigorous towelling down after swimming is said to reduce cercarial penetration. Topical steroid creams, and topical antipruritics such as 0.5% menthol or calamine lotion, may improve the pruritus.

Professional deep-sea diving [28]

A considerable experience has accumulated over the past two to three decades as a result of marine oil drilling, where divers may spend up to 90 days at considerable depths. They are exposed to high temperature and sometimes humidity exceeding 90%, conditions that favour *Pseudomonas* external otitis [29]. This may be preventable by good prophylactic hygiene and by the use of aluminium acetate eardrops. Staphylococcal infections of the skin may become troublesome within diving suits and are less amenable to antibiotic therapy than usual (perhaps because of the high temperature and humidity). Scalds may occur from overheating of the diving suit and flash burns from welding procedures are an occasional hazard.

Skin squeezing at the folds of the suits may cause linear abrasions. During decompression, the diver may suffer from pruritus and erythema: a more severe lymphoedematous peau d'orange occasionally occurs. Furthermore, if the diver is underwater for a long time, the equivalent of a 'napkin eruption' can develop from micturition within the clothing.

Vibration

Vibration is defined as a repetitive movement about a point of equilibrium. Transmission of vibration energy to the skin has been associated with a number of chronic biological consequences, the best defined of which is the hand–arm vibration syndrome (HAVS) (see below and Table 22.9). It is also recognized that vibration can induce localized hyperhidrosis, callus formation, vibratory angio-oedema and a condition characterized by pain, swelling and erythrocyanosis [1]. Vibration may be a contributory factor to the hypothenar hammer syndrome (p. 22.28). Potentially beneficial effects have been ascribed to short-term exposure to vibration, such as elevation of skin temperature and increased lymphatic clearance [2]. The monographs by Griffin [3] and Pelmear *et al*. [4] deal comprehensively with the study of vibration and its medical consequences.

Hand–arm vibration syndrome

SYN. VIBRATION WHITE FINGER; VIBRATION SYNDROME

The term 'vibration white finger' has long been used for Raynaud's phenomenon resulting from the use of hand-held vibratory tools. Recognition that there are also neurological and musculoskeletal consequences of vibration exposure in the exposed limb led to the now-preferred

Table 22.9 Vibration injury: Stockholm Workshop Scales.

	Stages	Grade	Description
Vascular component	0V		No attacks
	1V	Mild	Occasional attacks affecting only the tips of one or more fingers
	2V	Moderate	Occasional attacks affecting distal or middle (rarely also proximal) phalanges of one or more fingers
	3V	Severe	Frequent attacks affecting all phalanges of most fingers
	4V	Very severe	As in stage 3, with trophic changes in the fingertips
Sensorineural component	0 SN		Vibration-exposed but no symptoms
	1 SN		Intermittent numbness with or without tingling
	2 SN		Intermittent or persistent numbness, reduced to sensory perception
	3 SN		Intermittent or persistent numbness, reduced tactile descrimination and/or manipulative dexterity

term HAVS [5–8]. Because there is an associated generalized disorder of the autonomic nervous system, the terms vibration syndrome [9] and vibration disease [10,11] are also used. Vibration-related changes can also occur in the feet [12].

Aetiology. Almost any vibratory source within the range 4–5000 Hz can produce HAVS if sufficiently intense. The time of exposure may be as little as 1 month to more than 30 years. There are numerous variables that determine whether or not the condition occurs [13]. Some relate to the equipment, some to the environment and others to the individual [14]. Thus, low ambient temperature, lower frequencies of vibration, firm gripping of the equipment, smoking [15,16] and stress are risk factors. Existing vascular disease and vasoconstrictive medications may be risk factors in some cases [17]. HAVS tends not to occur in hot climates.

The most common tools causing HAVS are percussive metal-working machines, such as rivetting and fettling tools, drills, impact wrenches, jack hammers, road-breaking tools and chainsaws. In many other occupations there is some risk, albeit less well studied [18]. In high-risk occupations, the incidence and prevalence can be 90% or more [10,19]. The condition has even been described in a teenager making prolonged use of a hand-held vibrating computer game [20].

Prevalence. In the UK approximately 500 000 workers are exposed to vibration and of these about 20 000 suffer moderate to severe HAVS [7].

Pathophysiology and pathology. There are vascular and neurological changes. There may also be changes in connective tissues and in the blood, the latter probably occurring secondary to endothelial damage.

The initial events are not well understood [21]. The following documented changes are likely to be important: mechanoreceptor nerve endings and non-medullated fibres become damaged [22], there is a more generalized loss of neuronal activity than in primary Raynaud's phenomenon [23] and there is selective damage to α_1-adrenergic receptors in vessels causing an excessive vasoconstrictor response from the predominant α_2-receptors [15,24,25]. Other structural changes noted include loss of myelin, increased numbers of Schwann cells and fibrosis [26].

Vascular lumina are reduced, probably by both internal thickening and smooth muscle hypertrophy [22,27–29]. There is an increase in fibrous tissue within and around blood vessels [30] and arterial thrombosis can occur [31]. Soluble intercellular adhesion molecule 1 (ICAM-1) levels are increased, as in scleroderma, suggesting that neutrophils may adhere and contribute to the microvascular damage [32]. Whole-blood viscosity may be elevated [33], although the importance of this is uncertain.

A generalized abnormality in the autonomic nervous system [34] may cause orthostatic hypotension [35], vasoconstriction of limbs not directly exposed to vibration [36] and an impairment of hearing, possibly caused by ischaemia in the inner ear [37]. A site of putative damage in the central nervous system has been suggested [38].

As well as damage to nerves, there is evidence of damage to muscles, especially the intrinsic muscles of the hand [39].

Bone cysts have been described in HAVS but may be a coincidental finding and not purely a result of vibration injury [40].

Clinical features. There are three possible major components to the HAVS: circulatory, neural and musculoskeletal [41].

After a highly variable latent period, the initial symptom is usually tingling and/or numbness in one finger. This often occurs directly after using the vibrating tool and also at night. This sensory change is followed by episodes of blanching, initially of the tip of the finger most exposed to the vibration source, with progression towards the base, and then increasing numbers of digits are affected. The thumb below the tip is usually spared. The pattern of digits affected reflects the subject's grip on the tool. Attacks are usually precipitated by cold and sometimes damp conditions, most common early in the morning and during rest periods rather than work. The attacks may last 15–120 min followed by painful reactive hyperaemia. With progression of the disease there is reduction in touch sensation, and difficulty doing fine manual work. Muscle fatigue and weakness are common, probably because of incomplete muscle contraction.

Late in the disease, attacks of pallor wane but there is persistent dusky cyanosis, swelling and stiffness of the digits and focal areas of necrosis of the fingertips. When the latent period is short, the symptoms and signs of HAVS tend to be more severe and more rapidly progressive.

The toes can be affected, either directly (e.g. from exposure to a vibrating platform) or by reflex sympathetic spasm.

Other changes attributed to vibration injury include carpal tunnel syndrome [42,43]. Although this may be more a result of mechanical and ischaemic factors [44], noise-induced hearing loss is exacerbated by the effects of the autonomic nervous system [45,46].

Patients with HAVS should be staged as part of the assessment of their disability, for each hand separately. The Stockholm Workshop Scales [5,47] are most widely used (Table 22.9).

Diagnostic tests. The diagnosis of HAVS is based on a history of vibration exposure before the onset of symptoms, and exclusion of other causes of Raynaud's phenomenon, such as primary Raynaud's disease, thoracic

outlet syndrome, syringomyelia, spinal cord compression, collagen vascular disease, peripheral vascular disease and vasoconstrictive drugs [6,48,49].

A variety of tests have been used in diagnosis and assessment of vascular, neurological and musculoskeletal abnormalities [49,50]. For the purposes of assessing a claim for an industrial injury compensation, certain tests may be regarded as the most reliable [51]. Thus, in the UK the following are recommended: finger systolic blood pressure following cooling, to assess vascular abnormalities; either vibrometry or aesthesiometry, for neurological dysfunction; and grip strength [52,53]. These tests are likely to be available only in centres specializing in evaluation of HAVS.

Even with a battery of tests it may be difficult to determine which patients will benefit from carpal tunnel release [54].

Prognosis. Early stages of HAVS are reversible, but advanced stages in patients over 45 years are irreversible and may progress despite withdrawal from vibration [2,55]. If measures are taken early in the course of disease, improvement is possible [56].

Treatment. It is important to maintain central body temperature and to avoid allowing the hands to become cold. Mittens are preferable to gloves. Smoking should be strongly discouraged. If possible, further vibration exposure should be avoided; if this is not feasible, frequent work breaks should be allowed.

Calcium-channel antagonists such as nifedipine can help the vascular symptoms. Other drugs that may be useful include α-adrenoreceptor antagonists such as thymoxamine and some prostanoids. Other remedies used in Raynaud's syndrome are given in Chapter 56. Sympathectomy is not generally effective.

Prevention. Because the more advanced stages of HAVS are irreversible, preventive measures and surveillance of at-risk workers are widely regarded as essential. Various steps can be taken to reduce exposure, for example automation [57], shorter shifts, antivibration gloves and pads on the tools. Much effort has been made to redesign equipment so as to reduce vibration [58,59] and the need for excessive grip strength. Workers should be informed of the hazards of their occupation, and should wear warm antivibratory gloves, avoid smoking and undergo regular medical surveillance. It is best for those at risk to avoid medications that can cause vasoconstriction (e.g. β-blockers).

Current industry standards in the USA and Europe are reviewed [60].

Other vasomotor symptoms

A condition in which pain, swelling and erythrocyanosis is induced by high-speed electrical tools (frequency 166–833 Hz) was described many years ago [1]; this syndrome is not provoked by exposure to cold.

Vibratory angio-oedema

Unlike the other dermatological phenomena induced by vibration, vibratory angio-oedema tends to occur at low frequencies (approximately 10 Hz) [61], such as are produced by handling a power lawnmower, or by rubbing or towelling the skin. The condition may be quite common among mountain bikers [62]. Vibratory angio-oedema is considered in more detail in Chapter 47, together with other physical urticarias.

Reactions to internal mechanical stress

Tissue expansion [1]

Skin and subcutaneous tissues clearly expand during pregnancy and morbid obesity. The recognition that skin can be expanded artificially by certain African tribal customs involving the upper lip and ear led surgeons to develop methods of tissue expansion [2–5].

The standard method is to carry out the expansion over a 2–8-week period by inflating sacs inserted beneath the skin. Other techniques include external traction systems [6,7] and intraoperative techniques to produce expansion rapidly [8–11].

The response of skin and soft tissue to progressive expansion has mainly been studied in relation to progressively inflated silicone implants [12]. The main changes [13] are seen in the dermis, where there is reduction in thickness. The rate of thinning is maximal in the first few weeks of expansion and then decreases because of compensatory mechanisms. Within a few days of implantation, a dense fibrous capsule forms around the expander. The number of fibroblasts and their metabolic activity increase, and there is also evidence for increased metabolic activity in the myofibroblasts [14]. Collagen fibres are morphologically normal, but elastic fibres become thickened and appear more compact [14]. The epidermis

undergoes increased mitotic activity and maintains its thickness [4,15]. The appendages become separated with expansion of skin but probably are otherwise normal. There is a proliferation of blood vessels, particularly at the junction between the expansion chamber and the tissue around it. This increased vascularity is clearly of value when expanded skin is used in plastic surgical manoeuvres [16]. At a molecular level, various cellular mechanisms seem to be involved, including the cytoskeleton, extracellular matrix and several interrelated signal transduction pathways, with protein kinase C having a central role [17].

In intraoperative tissue expansion, the skin is stretched beyond its inherent extensibility by a device, usually for 30 min, allowing direct closure under much reduced tension. In such rapidly expanded skin, the collagen fibres become aligned in the direction of the stretching force, and elongated; the epidermal thickness remains unaltered [18].

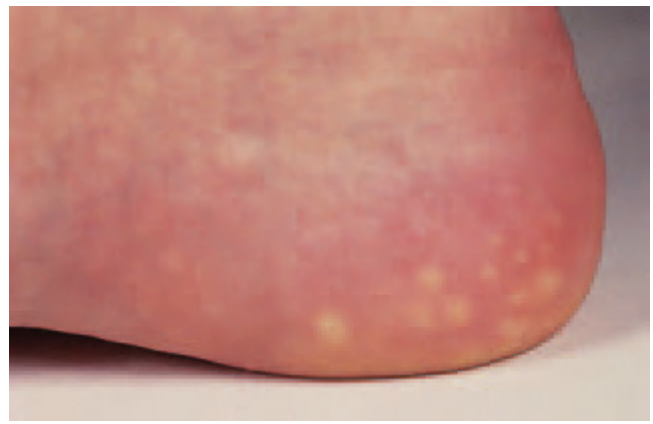

Fig. 22.19 Piezogenic pedal papules.

Piezogenic pedal papules

This rather cumbersome title, derived from 'piesis' (pressure), has been given to soft skin-coloured papules and nodules that appear on the side of the heel, usually the medial aspect (Fig. 22.19), when the subject is standing, and disappear when weight is taken off the foot [1]. Observation of healthy subjects has shown that such papules are common, although painless and indeed often unnoticed [2–6]. The frequency of the condition makes it difficult to assess the assertion that piezogenic pedal papules can be familial [7] and also that there is an increased frequency in Ehlers–Danlos syndrome [8]. In a population study there was no association with hypermobile joints [5].

Pain on standing is usually the reason for presentation, although some patients do express curiosity about the papules even when they are symptomless.

Similar papules have also been noticed on the lateral edge of the hand [9] and wrist [10].

Pathogenesis. Painless papules consist of normal fat tissue [3], but when pain occurs it has been attributed to herniation of the fat into the dermis with a resultant reduction in dermal thickness [9,11]. Postulated reasons for this pain include a defect in septation of the adipose tissue [11] and ischaemia resulting from extrusion of fat within its vascular supply and associated nerves [12].

Treatment. When piezogenic pedal papules of the feet are painful, improvement of the symptom can sometimes be achieved by avoidance of prolonged standing and, when relevant, loss of weight. Compression hosiery [13] and electro-acupuncture [14] have been reported to relieve symptoms. Supportive rubber footpads and heel cups can also be helpful. If conservative measures fail, small excisions of the papules can be curative [15].

Muscle herniation of the lower legs [1,2]

Small asymptomatic herniations of the tibialis anticus are probably common in those whose legs are exposed to continual muscle stress. Discomfort occasionally prompts referral [2]. They are usually easily distinguished from varicosities.

Mechanical trauma and skin neoplasia

Patients often describe an injury preceding the appearance of a cutaneous malignancy. However, the role of trauma in such cases is complicated by fallibility of the memory and uncertainty of the nature of the skin prior to the injury. Also, in many instances the injury is multifactorial, possibly involving a foreign body, heat, a chemical carcinogen such as tar or soot, as well as mechanical trauma [1,2].

When a single episode of mechanical injury to normal skin has been followed by carcinoma, the wound has often healed slowly, broken down repeatedly or failed to heal, and the neoplasm is nearly always a basal cell carcinoma [3–6]. On circumstantial evidence, basal cell carcinoma of the sole has been attributed to trauma in some cases [7].

Occasional instances of squamous carcinoma have been reported [8,9] but these have not followed simple mechanical trauma and have been complicated by other factors, such as foreign material left in the skin. Bowen's disease has been reported arising in a scar [10]. Basal cell carcinoma and squamous cell carcinoma have been recorded at sites of vaccination to smallpox [11–15], tattoos [16,17] and bacillus Calmette–Guérin (BCG) immunization [18]. Basal cell carcinoma has been reported at a skin graft recipient site [19]. The role of trauma in the genesis of malignant melanoma has been considered, but there is no strong supportive evidence [20,21]. Occasional instances of melanoma have been recorded in relation to immunization sites [22,23] as have sarcomas [24,25]. Lymphoma has rarely been associated with preceding trauma [26].

The development of a malignant neoplasm can be divided into at least three stages: initiation, promotion and progression. Environmental factors may be relevant for any of these stages [27]. Using a mouse model in which the initiator was the chemical carcinogen dimethylbenzanthracene, it has been shown that repeated abrasion is an effective promoter of both papillomas and carcinomas of the skin [28,29]. It has not proved possible to initiate carcinogenesis with surgically induced ulceration [30].

In the clinical context, however, the role of repeated mechanical trauma in the genesis of skin malignancy remains speculative [31]. For medicolegal purposes, the association of trauma with ensuing skin cancer should fulfil criteria that were laid down long ago, but remain valid [32]: authenticity and sufficient severity of the injury, previous integrity of the wounded part, tumour originating within the boundaries of the injury, histological variety of cancer compatible with an origin from local tissue, and a latent period.

Effects of heat and infrared radiation

The physical and biochemical effects of infrared (IR) radiation, comprising approximately 40% of solar irradiation, have been relatively neglected [1], but are the subject of a comprehensive review [2].

IR is the segment of the electromagnetic spectrum that extends between red visible light and microwaves and radiowaves. The wavelengths range from 0.75 µm (750 nm) to 100 µm. As with UV radiation, there is an arbitrary subdivision into near IR (0.75–3 µm), middle IR (3–30 µm) and far IR (30–100 µm). Energy is inversely proportional to wavelength, therefore most biological effects are seen at shorter wavelengths. IR causes molecular vibration, the most obvious effect of which is to raise temperature. Radiation from 0.75 to 0.8 µm can cause photochemical reactions. Some wavelengths of IR are strongly absorbed by water—both in the atmosphere and in the hydrated stratum corneum. Transmitted IR can penetrate up to 30 mm [3]. The major sources of IR radiation are the sun and IR lamps.

Most experimental work into the effects of IR radiation on skin have used sources that emit UV and/or visible radiation as well, and the data are conflicting.

Experimental effects

Acute effects

IR alone produces erythema, which disappears by 6 h [4]. Histological studies have shown vasodilatation and mast cell degranulation [5]. The mediators have been studied in suction blisters and are essentially similar to those found in UVB erythema: free arachidonic acid, prostaglandins PGD_2, PGE_2, PGF_2 and 6 oxo-$PGF_{1\alpha}$. The free arachidonic acid level is still high after 72 h [6]. Epidermal proliferation is reduced by IR and does not become normal until after 7 days [7].

Prior heating with IR reduces the phototoxic response to methoxypsoralen and UVA [8]. The interaction between UV and IR radiation has been evaluated but with conflicting results [8–10] and further studies are needed.

Chronic effects

In a mouse model, over a 45-week period, the histological effects of radiation were studied, using a visible plus IR source—alone, in combination with UVA and UVB, and with UV followed by IR [11]. There was deposition of fibres with the staining properties of elastin in animals receiving only visible plus IR radiation, and an augmentation of the elastosis was attributable to UV. As with clinical solar elastosis, there was also an increase in ground substance.

Carcinogenesis

IR radiation can coagulate protein and nucleic acid and is synergistic with UV radiation in denaturing DNA. The production of UVB-induced cyclobutane dimers is temperature dependent [12], therefore this tumour-initiating event is likely to be augmented by IR. DNA repair after UV- and X-ray-induced damage is slower at 41–43°C than at 37°C, as occurs with heating resulting from IR [13]. It has been shown that mice heated to 35–38°C had a shorter latent period for UVR-induced tumours than controls [14,15]. Heat, wind and humidity have been shown to enhance UV carcinogenesis [16].

Erythema ab igne

Definition. A characteristic reticular telangiectatic and pigmented dermatosis, resulting from repeated or prolonged exposure to IR radiation, insufficient to produce a burn. It most commonly affects the legs of women.

Aetiology. The condition, once common in the UK, has become rare since the introduction of central heating, although it is still sometimes seen in rural areas among elderly people who stand or sit closely over fires, or who are habituated to the use of hot water bottles. It may be a valuable sign of hypothyroidism. A resurgence of the condition in the USA affects not only the elderly but also impecunious students [1], because of the high cost of central heating.

Sources other than domestic heating may be responsible for erythema ab igne at other body sites. Examples include the repeated application of hot water bottles or heated pads for chronic backache, recliner chairs with built-in heaters [17], occupations such as foundrymen and bakers, and the various customs of carrying heated coals (see below). It has been reported as a useful marker of chronic pancreatitis because local heat relieves the abdominal pain [18] but also occurs when heat is applied for other real and imagined pains [19]. The car heater may be a cause [20]. In mentally disturbed patients with thermophilia, bizarre areas of erythema ab igne are sometimes encountered.

Histopathology [21–23]. In the early stages, epidermal atrophy, dermal pigmentation and vasodilatation are evident. Basophilic degeneration of the connective tissue, focal hyperkeratosis and epithelial cellular atypia occur later, closely resembling the changes induced by actinic damage [24]. Electron microscopy shows similar changes in the elastic fibres as found in chronic sun exposure [25]. There can be loss of type IV collagen from the basement membrane zone [26]. Keratoses and eventually squamous cell carcinomas may form (see below).

Clinical features. Any surface of the body is susceptible [27] and the condition can occur at all ages including children [28]. Following a single exposure to IR radiation of a subthreshold intensity, a mild and transient reticular erythema occurs. Further or repeated exposure causes a more marked erythema with noticeable hyperpigmentation and, sometimes, superficial epidermal atrophy. Subepidermal blistering [29] can occur in the affected skin (Fig. 22.20). The cumulative effects of small and repeated thermal exposures often clear during the summer months but involution gradually becomes less complete. The changes caused by repeated and prolonged exposure to IR radiation eventually resemble those of poikiloderma, with reticulate telangiectasia, atrophy, melanosis and diffuse hyperkeratosis.

Fig. 22.20 Erythema ab igne with subepidermal bulla formation.

The distribution of the dermatosis depends not only on the direction of the incident radiation, but also on the contour of the skin and the interposition of clothing. When erythema ab igne results from sitting in front of the fire, people may sit sideways, causing the outer aspect of one leg and the inner aspect of the other to be particularly affected. Others habitually sit directly in front, and a strictly symmetrical eruption is seen. In severely affected individuals the reticular pattern is lost, a wide area of skin becoming pigmented and atrophic, with only the periphery showing the characteristic pattern.

An unusual variant has been described in elderly immobile females with lymphoedema in which there are reticulate ridges of tissue that can be compressed [30].

Rarely, lichen planus, psoriasis or chilblain lupus may appear as a Koebner phenomenon in the affected area.

Diagnosis. Although diagnosis is usually straightforward, there may be confusion with livedo reticularis, in which changes are strictly symmetrical and telangiectatic rather than pigmented. When large vessels are involved, nodules and ulcers may coexist with livedo reticularis, a triad diagnostic of a severe vasculitis (see Chapter 49).

Management. Hypothyroidism should be excluded. In elderly women living alone, erythema ab igne may be a sign of hypothermia. The help of ancillary social services may be needed. Advice should be given on clothing and efforts made to improve the microvascular circulation. 5-fluorouracil cream has been used to eliminate the dyskeratotic keratinocytes [31].

Heat-associated carcinomas

Squamous carcinomas of the skin occurring in areas of

heat damage have been known from ancient times, often regarded as exotic curios and their significance has been overlooked [32]. They include the Kang cancer of northern China [33] and Japan [34] from sleeping on beds of hot bricks, the Kangri cancer of Kashmir [35,36] from wearing pots of hot coals and the Kairo cancer of Japan caused by carrying metallic benzene-burning flasks—all devices to counteract cold. 'Turf' cancer of the legs of rural Irish women has been associated with standing for long periods of time over peat fires [37]. Simultaneous occurrence of Merkel cell carcinoma with squamous carcinoma has been recorded [38,39]. Basal cell carcinomas and actinic keratoses have been reported at a site on the cheeks of those wearing rimless glasses, where the temperature is higher than the surrounding skin because of focusing of the sun's rays [40,41].

Skin cancer following burns is discussed on p. 22.82.

Burns

[D.A.R. Burd, pp. 22.66–22.84]

A burn is an injury caused by a pathological flux of energy within a tissue resulting in a disruption of functional integrity [1]. The source of the energy may be thermal, chemical, electrical or radiation. The spectrum of burn injury is the greatest of any form of trauma, ranging from an inconsequential superficial burn to the fatal destruction of the entire body surface, depending on the severity of the burn. What is remarkable is that with the advances in the understanding of the pathophysiology of the burn injury and the more aggressive approach to management, the prospect of surviving a complex major burn is better now than ever before.

Burns may be of industrial, domestic or environmental origin. In developed countries where there is a strict adherence to health and safety issues, the incidence of industrial burns has shown a gratifying decrease [2,3]. There have also been changes in the pattern of domestic injuries. Major flame burns from house fires have

decreased but there are still a large number of scalds in the second year of life when children are developing independent mobility but have not yet learnt fear. The true incidence of burns in any population is difficult to determine because of the wide spectrum of the injury. Serious burns will be treated in specialist units. In the UK, there are 5000–6000 admissions to such units annually. An equal number of patients are seen and treated as outpatients in specialist clinics, and for each such patient approximately a further five are treated in accident and emergency departments without referral to a specialist clinic. An additional unknown number of burns are self-treated in the general population or treated in general practice.

Pathophysiology. The pathophysiological reaction to a burn injury is complex and varies with the cause. In thermal injuries, the changes in the burn wound are mainly caused by the direct effects of heat but superimposed on these are changes associated with an acute inflammatory process. It is these latter changes that account for the widespread and devastating effects of major burns on the entire range of homoeostatic functions of the body.

The initial local response to a sudden increase in body surface temperature is the dilatation of blood vessels in an attempt to dissipate heat. A further increase in tissue temperature triggers an inflammatory response, mediated by peptides and low-molecular-weight substances that regulate the cellular function and microenvironment of the tissues. The key cells in the post-burn inflammatory response are the polymorphonuclear leukocyte, mast cell and endothelial cells. These, together with platelets, are the prime components responsible for the mediation, progression and resolution of the inflammatory response. A very simplified account of this process is given here, more detailed accounts are given elsewhere [4,5]. Activation of complement and coagulation cascades with the release of histamine from mast cells results in a short phase of vasodilatation and plasma protein leakage from post-capillary venules, resulting in local oedema formation. Intracellular proteases released as a result of cell damage activate kallikrein, which is responsible for transforming kininogen to kinin. Kinins have several effects, including vasodilatation, pain stimulation and leukocyte migration. A delayed phase of leukocyte and platelet margination then results in the release of prostaglandins, prostacyclins, thromboxanes, leukotrienes and lipoxins, which is accompanied by a substantial increase in microvascular permeability and changes in vasomotor control. The prolonged post-traumatic phase of vasodilatation and anti-platelet aggregation is regulated through endothelial cells via two different mediators: prostaglandin I_2 (PGI_2) and nitric oxide. Hypercoagulability of the lymph and the plasma has been observed 2–3 h after injury and correlates with the finding of increased levels of kinins in lymph.

Disseminated intravascular coagulation may also accompany a severe burn. As the tissues are infiltrated by leukocytes, the efficient elimination and destruction of injured tissue is effected. Neurotransmitters are also involved, especially substance P, which evokes vasodilatation and plasma protein leakage, and calcitonin gene-related peptide, which is a potent vasodilator.

Histopathology [6,7]**.** An accurate determination of the depth of injury is an important consideration when formulating a management plan for a burn patient. Theoretically, wound biopsy with histopathological examination would seem to be a very precise method for achieving this determination. Clinically, however, it is necessary to accept that burn wounds are rarely homogenous in nature and partial thickness burns may well be of mixed depth. Biopsies will leave permanent scars in partial thickness wounds; they are also expensive and time-consuming to process. In addition, the burn wound is a dynamic entity and it may take up to a week for a stable state to be achieved. Nevertheless, histological studies of the response of the skin to graded burn injuries have contributed to the knowledge of the mechanism of bullae formation.

In the most superficial injuries, only the upper epidermis shows changes. Nuclei appear either pyknotic and possess a perinuclear halo or, with greater damage, stain only faintly eosinophilic or not at all. In superficial partial thickness burns, subepidermal blisters are often seen. There is necrosis of the epidermis together with the coagulation of collagen in the papillary dermis. As the burn becomes progressively deeper, a good indicator of the depth of irreversible damage to the collagen is apparent in the appendageal structures where there is generally a fairly sharp demarcation between heat-coagulated and relatively normal epithelium. With full thickness burns there will be complete dermal necrosis with loss of all appendageal structures, and coagulation necrosis may extend into the subcutaneous fat and underlying muscles.

Clinical aspects

The rationalization of the care of burns patients requires effective prehospital management, transportation and

assessment, and triage in a hospital emergency department. The importance of education and communication at this level cannot be overestimated. Subsequent, safe transfer of a stable patient to a specialized burns unit initiates the next phase of treatment. Several texts give excellent comprehensive accounts of total burn care [1,2]. The account that follows is an overview of the immediate assessment and management of a burn, and is aimed at the non-burns specialist who may be faced with the emergency care and short-term treatment of such patients.

First aid and prehospital management

Stop the burning process

The patient must be removed from the source of injury and the ongoing damage halted. Obviously care must be taken to ensure that rescuers and helpers do not themselves become injured but this can and does happen. This is a particular problem with electrical and chemical injuries. Patients sustaining chemical injuries should have clothing removed as quickly as possible and copious irrigation with water is the key to first aid. In chemical burns, the tissue damage is very much a function of the concentration of the agent and the duration of exposure, therefore in the otherwise fit patient, copious irrigation at the scene of the accident is preferable rather than immediate transfer to an emergency centre. It is essential to be aware of the possible dangers of handling contaminated clothing; and appropriate protective clothing, including gloves and eye protection, should be available for the emergency services.

With electrical injuries, the source of electrical current should be identified and switched off, if possible, and the victim moved from the source of the current using non-conductive materials.

In flame burns, the first priority is to extinguish the source of the burn, which can be accomplished by rolling the patient on the ground, by application of a smothering blanket or coat or by the use of water or extinguishing foams. The next priority, as with scald burns, is to promote cooling. This is best performed with water or water-soaked towels. Early cooling can reduce the depth of the burn and reduce pain, but caution must be exercised as a significant drop in body temperature can result in hypothermia.

Primary survey

The primary survey is the rapid assessment of the patient to ensure immediate survival. Attention is focused on airway, breathing, circulation and cervical spine immobilization. The most immediate threat is to the airway. This is always a problem when there has been significant smoke inhalation, but also when there have been burns of the face or neck. Upper airway oedema can develop rapidly, compromising the patency of the airway. Oxygen 100% should be available and administered. The patency of the airway should be assured using customary techniques. The neck is extended and, if the victim is unconscious and the tongue appears to be obstructing the airway, an oropharyngeal airway should be inserted. If upper airway obstruction appears to be developing, for example if there is severe and progressive hoarseness after severe smoke inhalation, the insertion of an endotracheal tube may be necessary. It should be noted, however, that it is rare for oedema to develop in under 30–40 min from the time of removal from the fire. It is far better for correct placement of an oro-endotracheal tube to be performed by an anaesthetist in controlled circumstances than for the blind nasal intubation by an inexperienced paramedic or emergency physician.

It is important to establish that there is a pulse. In a large burn, this may be more meaningful than blood pressure measurement in establishing that there is a circulation.

Sometimes, the incident that has resulted in the burn may have caused other injuries, for example in automobile accidents, explosions and house fires. In these situations, it is very important to be aware of the possibility of spinal cord injury. Cervical spine immobilization must be accomplished using an appropriate cervical collar until the patient can be appropriately evaluated.

Secondary assessment

The secondary assessment involves a thorough head to toe examination of the patient. A rapid check is made of the patient's head, neck, thorax, abdomen, upper and lower limbs to ensure that no other life-threatening injuries are present and that, if they are, the appropriate measures may be taken. It is also appropriate at this time to ascertain, if possible, any relevant past medical history, medications or allergies and to establish the mechanism and time of injury.

It may be appropriate to establish an intravenous line but it must be recognized that in a major burn access is going to be a significant problem and it is essential not to damage possible sites for cannulation. If it is possible to get a patient to hospital within 60 min of injury, an intravenous line is not essential and may be deferred.

With regard to the burn wound, the patient should be wrapped in clean dressings. Sterility is not important. No topical antimicrobial dressings should be applied. The priority is to transport the patient to hospital, and unnecessary delay should be avoided. Covering the wound may diminish the pain, and small aliquots of intravenous analgesia may be given.

During the process of transport, the receiving accident department should be notified of the incoming patient and the severity of the problem so that appropriate receiving

Fig. 22.22 A deep partial thickness burn of the back sustained in an explosion. The scorched skin has been débrided. The burns healed within 3 weeks with conservative therapy.

staff and facilities can be mobilized. The determination of the severity of the injury is, however, particularly difficult for those who do not have regular experience of assessing burns patients.

2 Sex
3 Type of injury
4 Brief details of incident
5 Time of injury
6 Extent of injury
7 Associated injuries
8 General status of patient.

Assessment in the hospital accident department

The assessment of the patient in the accident department is essentially the same as for any trauma patient, with treatment priorities based on the stability of the vital signs and the mechanism of injury [3]. The logical sequence of treatment priorities can be quickly established using the same overview as briefly described in the prehospital treatment. Two unique aspects of burns are critical determinants of severity: the depth of the burn and the area of the burn.

Depth of burn [4]

Burns can be simply classified as being partial (Figs 22.21 & 22.22) or full thickness (Fig. 22.23); partial thickness burns are then subdivided into superficial partial thickness and deep partial thickness (Fig. 22.24). This classification is very important in subsequent decisions regarding surgical management of the burn, but in the initial assessment other factors will determine the more immediate aspects of treatment, including whether to refer the patient to a specialized burns centre. It is possible to make an estimate of the depth of the burn from the clinical appearance (Table 22.10).

Fig. 22.23 A full thickness fatal burn in an elderly woman whose nightdress caught fire on a gas cooker.

Area of burn

The assessment of area of the burn is important as it directly affects the fluid resuscitation of the patient together with the disposition of the patient. Various methods are available to determine the percentage of the body surface that is burnt. The simplest method is the

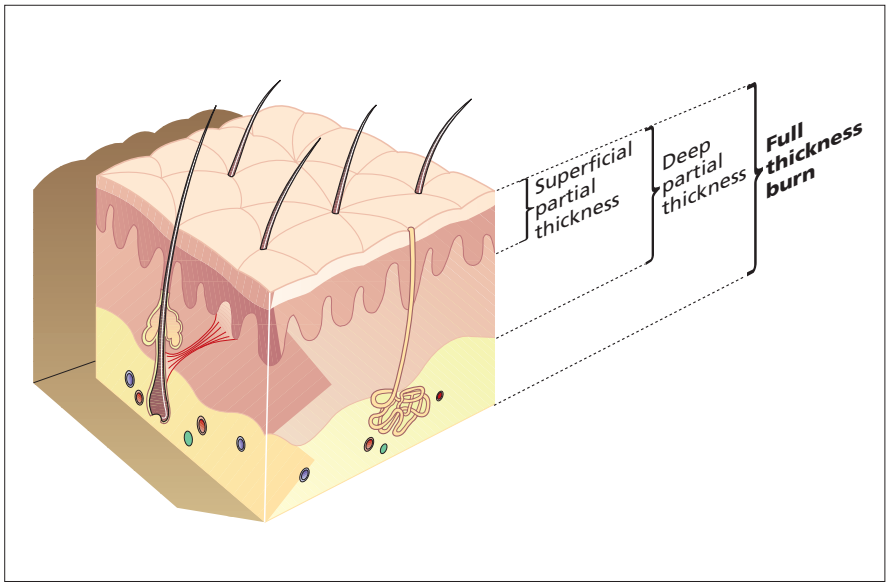

Fig. 22.24 Burns are classified according to their thickness.

Table 22.10 Clinical features of partial and full thickness burns.

Depth	Colour	Blisters	Capillary refill	Sensation
Superficial partial thickness	Pink	±	Present	Painful
Deep partial thickness	Red/pale	±	No	±
Full thickness	White	No	No	No

'Rule of Nines', which divides the body surface into areas of 9% or multiples of 9% (Fig. 22.25).

In the infant or child, a more accurate assessment can be made using the Lund and Browder chart, which takes into account the relative changes in proportions of head and legs in the growing child (Fig. 22.26).

A further guide to estimating the area of the burn is to realize that the closed palm of the patient is equal to approximately 1% of the body surface. This can be useful for assessing the total area of scattered burns. It is important not to include simple erythema in the estimation of the burn injury. Erythema is a reversible hyperaemia, which is not associated with tissue damage. As such it will not give rise to the pathophysiological changes that occur with tissue destruction, which may require intravenous fluid replacement.

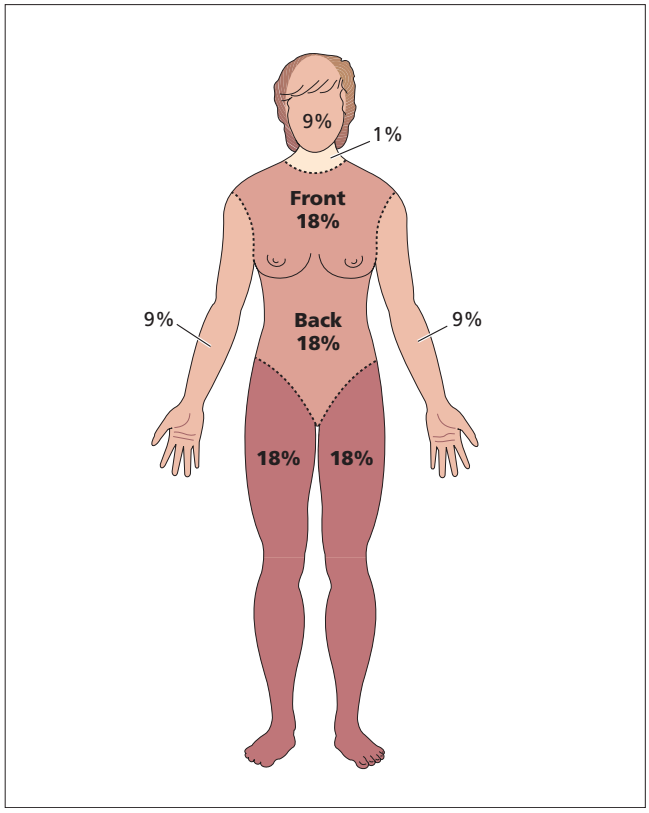

Fig. 22.25 The Rule of Nines.

Fluid resuscitation

The hypovolaemic shock that follows burn injury is caused by a shift of fluid from the vascular to the extravascular compartment. The more extensive the burn, the more extensive the shift of fluid. This fluid shift is a progressive phenomenon, which is maximal within hours of the burn and can persist for several days after the burn. As a simple guide, all patients who have burns in excess of 10% body surface area (BSA) should be commenced on

	Relative percentage of body surface area affected by growth					
Area	**Age 0**	**1**	**5**	**10**	**15**	**Adult**
A = ½ of Head	9½	8½	6½	5½	4½	3½
B = ½ of one Thigh	2¾	3¼	4	4½	4½	4¾
C = ½ of one Leg	2½	2½	2¾	3	3¼	3½

Fig. 22.26 Lund and Browder chart.

intravenous resuscitation. Intravenous fluid resuscitation is also indicated for all patients with inhalation injury and other associated injuries. A minimum of two large-bore intravenous cannulae should be inserted, preferably through unburned tissue. After insertion, blood should be taken for blood grouping and cross-matching, and baseline laboratory studies that include a complete blood count, serum electrolytes, glucose, blood urea nitrogen and creatinine. As soon as feasible, the patient should be weighed, as resuscitation formulae are based on a combination of body weight and area of burn.

The intravenous fluid infusion has to be regulated to give in the first 24 h:

- *Adults*: 2–4 mL Hartmann's solution/kg body weight/% BSA burn
- *Children*: 3–4 mL Hartmann's solution/kg body weight/% BSA burn

The intravenous fluid rate is adjusted to give half of the estimated volume in the first 8 h post-burn. The remaining half of the estimated resuscitation volume should be administered over the subsequent 16 h of the first day post-burn.

In children, there should be an additional element given for maintenance fluids because of the increased evaporative fluid losses. Maintenance requirements for the first 24 h are 1000 mL for the first year of life, plus 100 mL for each subsequent year of life up to 5 years of age. A 5-year-old child would thus require the following maintenance fluids in the first 24 h:

$$1000\ \text{mL} + (4 \times 100) = 1400\ \text{mL}.$$

The formula is only a guide, and clinical and laboratory monitoring are essential to tailor the fluid requirements to the individual patient.

The goal of resuscitation is to maintain vital organ function while avoiding the complications of inadequate or excessive fluid infusion. Excessive volumes of intravenous fluid can increase tissue oedema formation and compromise tissue oxygenation. This is particularly a problem with pulmonary and/or cerebral oedema. Inadequate

fluid resuscitation can cause diminished perfusion of the renal and mesenteric vascular beds, which can lead to organ failure [5].

Urine output

Urine output is the single best indicator of fluid resuscitation in the uncomplicated burn. Accurate measurement of urinary output requires the insertion of an indwelling Foley catheter. Acceptable hydration is indicated by a urine output of more than 0.5 mL/kg/h in an adult and 1.0 mL/kg/h in a child. In the initial stage of resuscitation, diuretics are not usually indicated. Patients with high-voltage electrical injuries or crush injuries may have myoglobin and/or haemoglobin in the urine. This predisposes to renal tubular obstruction. In this situation, an osmotic diuresis should be promoted by giving intravenous mannitol 1 g/kg (20% solution), and urinary alkalinization should be considered. The urine can be alkalinized using isotonic sodium bicarbonate intravenously at a rate sufficient to maintain urinary pH > 6.5 without the plasma pH exceeding 7.45. The urine pH should be monitored 4-hourly, and acid–base balance and serum electrolytes 6-hourly. This is continued until the myoglobinuria and/or haemoglobinuria disappears.

Gastrointestinal tract decompression

In the immediate and early stages of management of the major burn, it is important to be aware that the patient may require surgery and general anaesthesia. The patient should be given nil by mouth until seen and assessed by a burns physician. It is appropriate to insert a nasogastric tube. This can decompress the stomach, which may become distended from the combination of the stress response to trauma together with diminished peristalsis in the gastrointestinal tract associated with use of narcotic analgesia.

Immediate wound care

Very little needs to be done to the burn wound itself prior to assessment by the burns physician. Frequent reassessment is necessary to look for harmful effects of the wound on ventilatory and circulatory function with a view to undertaking escharotomies to relieve the splinting effect of the wound.

The patient must be kept warm and dry. It is essential to prevent the traumatized patient from becoming hypothermic, and wet dressings should be avoided on the burns. Appropriate dressings will depend upon local conditions and duration of transport. Clean surgical drapes can be used to cover the patient. Clingfilm can be used if there is no danger of hyperthermia; in cold climates 'space blankets' may be useful.

Pain relief

There are two aspects to the pain experienced by the burn victim: one is the physical pain from the injury, but another major component is the psychological trauma that the victim suffers. Morphine is indicated for both pain relief and as a powerful anxiolytic. It should be given only by the intravenous route, as changes in peripheral perfusion make the subcutaneous or intramuscular route unpredictable. In adults, a dosage of 1–4 mg i.v. every 2–4 h is indicated for severe pain. For children, the dosage of morphine should be modified according to the weight of the child, using 0.2 mg/kg i.v. in the first instance, and subsequently titrating the dose according to the response.

Additional medication

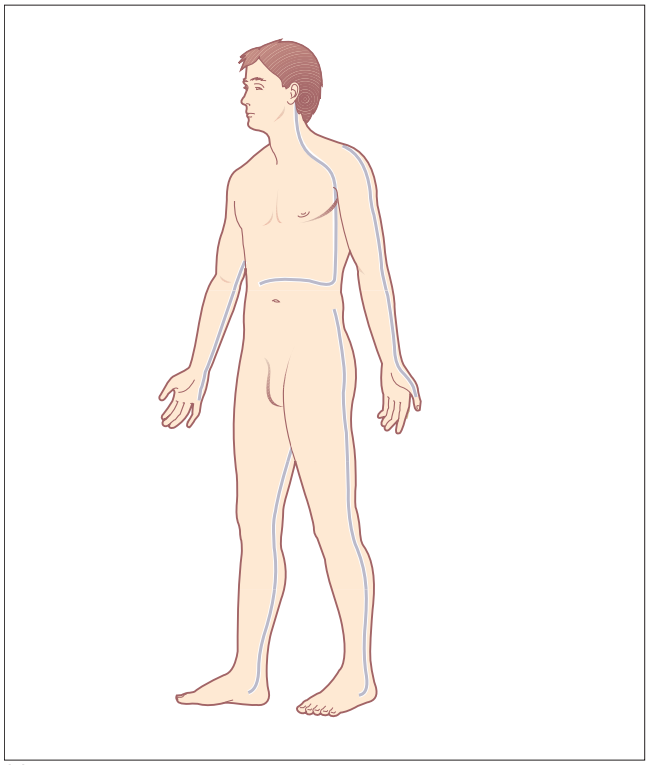
The need for tetanus prophylaxis is based on the patient's immunization status and the nature of the wound. All patients with burns in excess of 10% BSA should receive 0.5 mL tetanus toxoid. If prior immunization is unclear or unknown, 250 units of tetanus immunoglobulin are also given.

Escharotomy

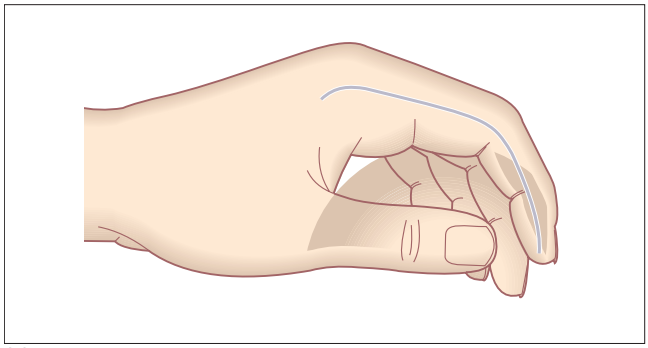
When there has been a circumferential deep dermal or full thickness burn affecting the limbs or the chest or neck, the skin will lose its normal plasticity. On the trunk, this may cause sufficient rigidity of the chest wall to compromise respiratory excursions and ventilatory function. When it occurs in a limb, oedema forming within the inelastic envelope will result in an increase in pressure within the limb, which may be sufficient to compromise the arterial inflow. Peripheral pulses and capillary refilling should be checked regularly, and if there is concern that perfusion of the limb is failing, escharotomies should be considered. Escharotomies are preferably made with electrocautery using mid-axial incisions in the limbs (Fig. 22.27). These incisions are made through the eschar and into the level of the superficial fascia of the limb. The wounds so made will gape open (Fig. 22.28) and the adequacy of the procedure can be assessed by the return of peripheral pulses and capillary refilling. It must be emphasized that escharotomies are not without morbidity, and care must be taken to avoid damage to underlying nerves. Escharotomies should ideally be undertaken under anaesthetic within an operating room environment.

Triage

When the burn patient has been evaluated and stabilized, a decision has to made about further treatment. There are recognized criteria for those burns that should be referred to a specialized burns unit (Table 22.11). Local conditions



(a)



(b)

Fig. 22.27 Escharotomy lines.

may dictate modifications to this list, but if there is any doubt about a patient's suitability of transfer, there should be direct consultation with the burns unit physician.

Transfer of the patient

The decision to transfer a patient becomes more difficult when there are associated injuries. The treatment of these may take precedence over the treatment of the burn, for example an intra-abdominal injury, major long-bone fracture, open-chest injury or intracranial bleed. A senior clinician should be involved in the referring hospital and a decision should be made jointly with a senior specialist in the burns unit. Once a decision has been made to transfer a patient to the burns unit, it is essential that he or she is properly stabilized before transfer. Essential prerequisites are listed in Table 22.12.

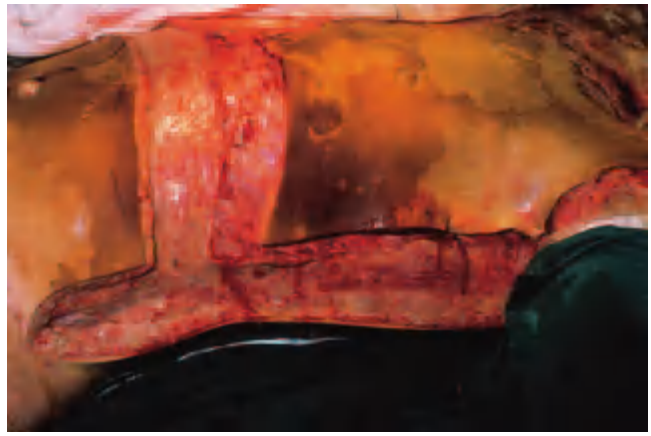


Fig. 22.28 An escharotomy performed transversely across the lower chest and in the mid-axillary line for a full thickness burn of the trunk. Note that this is purely an incision of the skin and subcutaneous tissue, and no tissue has been excised. The massive gaping results entirely from swelling of the incised burnt tissues and the escharotomy allows the chest to expand.

Table 22.11 Criteria for referral to a burn centre.

Burns greater than 10% BSA
Burns that involve and threaten functional or cosmetic impairment of the face, hands, feet, genitalia, perineum and major joints
Full thickness burns greater than 5% BSA
Electrical burns
Chemical burns
Burns associated with inhalational injury
Circumferential burns of limbs or chest
Burns at the extremes of age (children and elderly)
Burn injury in patients with pre-existing medical disorders which could complicate management, prolong recovery, or affect mortality
Any burn patient with concomitant trauma

BSA, body surface area.

1 Respiratory support
• 100% oxygen with or without intubation
2 Circulatory support
• Intravenous access + infusion + urethral catheter
3 Gastrointestinal decompression
4 Wound care
5 Pain medication
6 Tetanus immunization

Documentation

It is essential to include all available information about the nature of the injury as well as the physical findings and

extent of the burns. In addition, there should be a clear flow chart documenting resuscitation measures, drugs given and blood results. Doctor-to-doctor contact is essential to ensure the safe transfer of the patient. This is particularly the case where a patient has been intubated in the referring hospital. The communication should be a two-way process, and the burns unit should inform the referring hospital of the outcome of treatment of the burn patient, not only as a matter of professional courtesy but also from the point of view of continuing medical education.

Overview of continued fluid resuscitation

In most situations, the continued resuscitation of the burns patient will take place in a specialized centre. There will be occasions, however, as a result of associated injuries or problems with transport, where a non-burns specialist may have to supervise the management of the patient through the critical period of fluid resuscitation.

The patient who has been managed in the orderly manner as described above is in the best condition to move into the next critical phase of proper fluid management. Mortality in the first 24–48 h post-burn has decreased considerably with increasing understanding of the massive fluid shifts from the intravascular to the extravascular (intracellular and interstitial) spaces that occur during the burns shock phase. The primary goal of fluid therapy is to replace the fluid sequestered as a result of the thermal injury. It is obvious from the many formulae that have been proposed over the years that there is no universally accepted burns resuscitation formula. It must be emphasized that whatever formula is used, it is only a guideline and the actual amounts of fluid given should be varied according to clinical response.

In principle, the least amount of fluid should be given to maintain adequate organ perfusion, and the infused fluid must contain sodium to replace the extracellular salt lost into the burned tissue and into the cell. In the past, there has been great debate over the relative merits of crystalloid versus colloid resuscitation regimens. In the absence of convincing clinical evidence to support either, the burns physician should take into account local practices, availability and cost of solutions, and should develop a protocol that can be safely and effectively adhered to but that will provide the flexibility to take into account individual patient requirements.

In this overview, the fluid to be infused in the first 24 h is derived from a consensus formula recommended by the Advanced Burn Life Support Course in the USA and the Emergency Management of Severe Burns Course from Australia and New Zealand. The figures are based on the Parkland formula.

However, it must be recognized that plasma proteins are extremely important in the circulation, as they generate the inward oncotic force that counteracts the outward capillary hydrostatic force. It has been demonstrated experimentally that restoration and maintenance of plasma protein concentrations are not effective until 8 h post-burn, at which time normal levels can be maintained with infusion. With this in mind, it is recommended that colloid should be introduced into the resuscitation regimen once the initial phase of massive fluid shift has begun to stabilize [5]. While this may occur as early as 12 h post-burn, a consensus recommendation is to introduce the colloid in the second 24 h using 0.3–0.5 mL of colloid/kg body weight/% BSA burned. The colloid should be 5% normal serum albumin (50 g/L).

Monitoring response to resuscitation

There is no single parameter of perfusion in the burn patient that can be considered to be a completely reliable indicator of tissue oxygenation. Therefore, a combination of observations should be made. As the severity of the burn increases so does the need for more complex and invasive monitoring [6].

Continuous monitoring

Cardiac monitoring. Arrhythmias are not worrying in the young patient so long as oxygenation is adequate, but are a major concern in the patient over 45 years of age in whom they may be the first indicator of hypoxia or of electrolyte and acid–base abnormalities.

Arterial blood pressure *per se* is an insensitive measure of volume status because of the increased sympathetic tone in the early stage of resuscitation. However, a minimal level of perfusion pressure must be maintained and therefore blood-pressure monitoring must be established. An arterial line may be required if the patient is haemodynamically unstable and if frequent blood gases are required.

Pulse oximetry can provide continuous information on the oxygen-haemoglobin saturation and is non-invasive.

Body temperature. The core and peripheral temperature should be recorded. The burn patient is very prone to hypothermia with the infusion of cool fluids, and it must be recognized that thermoregulation is abnormal in burns. The damage to the skin interferes with normal mechanisms of heat conservation and dissipation; in children, there is also a disturbance of hypothalamic control. This has two important consequences:

1 Pyrexia in children in the first 36 h post-burn is most probably not related to infection

2 Core–peripheral temperature gradients become unreliable indicators of haemodynamic status.

Fig. 22.29 Total burning of the legs in a patient who fell asleep smoking and woke up with the bed on fire. Skin, fat, muscle, tendon and bone were all burnt.

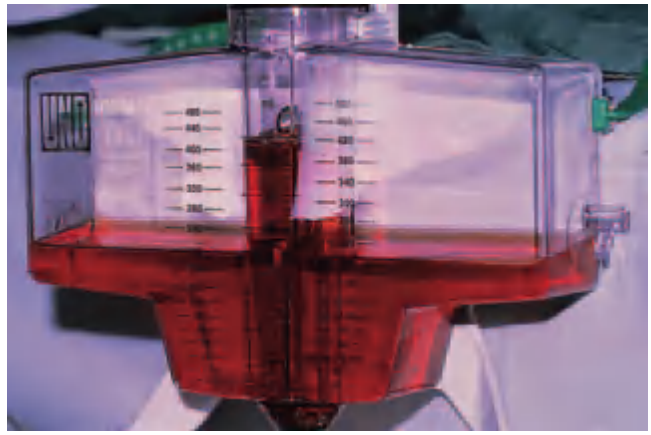

Fig. 22.30 The urine in the same patient showing the bright-red colour of myoglobinuria.

Fluid balance. During the first 24 h post-burn, in the absence of an abnormal solute load (e.g. glucose, mannitol or alcohol, which may falsely increase urine output in the presence of hypoperfusion), urine output should reflect the glomerular filtration rate and therefore renal perfusion. A urine output of 0.5–1.0 mL/kg/h normally reflects adequate renal blood flow. The rate of fluid administration should be increased if urine output is below 0.5 mL/kg/h but this should not be too rapid as boluses will cause marked transient increases in venous pressure and thus will significantly increase oedema. A urine output of more than 1.0 mL/kg/h usually means too much fluid is being given, with the possibility of excess oedema formation. Myoglobinuria will cause red discoloration of the urine (Figs 22.29 & 22.30).

Monitoring central venous pressure (CVP) or pulmonary artery wedge pressure may be necessary. In the early stage of resuscitation of a patient with a large burn, the CVP is usually low, in the region of 0–5 cmH_2O even with adequate fluid resuscitation, but can be used to follow trends. The majority of young patients, even with massive burns, do not require pulmonary artery wedge pressure monitoring for initial resuscitation, and the morbidity associated with pulmonary artery lines may outweigh the benefits. As with the CVP, the pulmonary artery wedge is usually normal to low (6–10 mmHg) after a burn even when adequate perfusion is present. Hypoperfusion is almost always caused by hypovolaemia.

The interpretation of the values obtained by this level of intensive monitoring is the domain of the intensive care specialist. In patients with severe burns, unlike other forms of trauma, the ideal values for more complex cardiorespiratory variables such as measurements of oxygen delivery and consumption are at present unknown, and aggressive attempts to optimize microcirculatory blood flow by the use of volume loading, inotropes or vasodilators may be inappropriate [7]. This is because generation of high intravascular pressures in the presence of a generalized capillary leak may only serve to increase the rate of fluid loss and to exacerbate the oedema-related complications of increased tissue pressure and decreased tissue oxygen tension.

Intermittent monitoring

Haemoglobin and haematocrit. Baseline values are useful but thereafter changes in values may not accurately reflect changes in blood volume because of the selective loss of plasma from the blood. Haemoconcentration invariably occurs after large burns, and normalization of blood volume will take some 24–48 h. Blood loss during this time can be underestimated, for example from escharotomies, internal bleeding or associated with fractures, because the rate of plasma loss may exceed the rate of whole-blood loss resulting in a normal haematocrit despite severe volume depletion.

Electrolytes. As the initial losses are primarily from plasma, the sodium, chloride and potassium values remain relatively constant despite hypovolaemia and vary mainly as a result of the type of resuscitation fluid used. Osmotic hyponatraemia occurs in the presence of a solute such as glucose or mannitol to which cells, including osmoreceptors, are incompletely permeable (solutes to which cells are readily permeable such as ethanol or urea do not exert the osmotic effect to expand extracellular volume and lower the plasma sodium concentration).

Water intoxication occurs when sodium losses are replaced by hypo-osmolar solution or if hyponatraemia is corrected too rapidly.

The term *sick-cell syndrome* is used by some to describe clinical states of hyponatraemia associated with profound systemic disease such as renal and hepatic failure. It is

also described in burns where it is thought to result from hypovolaemia, infection, anaemia or undernutrition. Dysfunction of the cellular sodium-potassium adenosine triphosphatase pump is thought to be the cause. If other causes of hyponatraemia have been excluded, this diagnosis should be considered if there is reversal of the sodium : potassium ratio (normally > 1) to < 1. Treatment is directed at the primary cause [8].

Elevated potassium levels occur if there is marked haemolysis or rhabodomyolysis, or if renal disease is present. It is important to note, however, that potassium-sparing drugs have prolonged effects, and that actual hyperkalaemia may occur in the absence of significant renal dysfunction. Emergency management should be given if serum potassium exceeds 7.0 mmol/L, or if there is widening of the QRS complexes, heart block or dysrhythmia.

Creatinine and blood urea nitrogen. It is useful to establish baseline values to rule out intrinsic renal disease. Thereafter, changing figures indicate trends in resuscitation.

Coagulation screen. Initial values of prothrombin time, partial thromboplastin time and platelet count are useful in the resuscitation phase to establish baseline values. It is not common to replace clotting factors and platelets during the first 36 h, although this may become a critical issue in the later stages of burn management.

Chest X-ray. If the patient is ventilated, a daily chest X-ray should be obtained. The development of pulmonary problems following smoke inhalation is a progressive phenomenon and requires intensive and specialized care.

Burn wound management [9]

The management of the burn wound is in a continuous state of evolution and is not without controversy. The principle is to achieve healing as quickly as possible with the minimum of scarring. One of the problems concerning burn wound management relates to the phenomenon alluded to earlier, the 'burns spectrum'. There are two critical aspects that determine the severity of burn injury: the depth of the burn and its extent.

The vast majority of burns are small and superficial and may be self-treated, or treated in emergency rooms or by general practitioners. These burns are best treated by deroofing blisters, gentle cleansing with saline and the application of a non-adherent dressing overlain with an absorbent layer.

When the depth of burn is greater, the role for conservative treatment becomes more controversial. Surgery is definitely indicated for full thickness burns unless there are overriding clinical considerations to the contrary.

The major controversy surrounds the management of the deep partial thickness burn [10]. These burns can and will heal if allowed to do so in an environment that protects the wound from infection. Healing can take several weeks, however, and there is a high incidence of hypertrophic scarring in deep partial thickness burns that have been allowed to heal spontaneously. The decision will depend on the experience of the burn surgeon because there have been no extensive randomized controlled trials to indicate the 'best' approach. The controversy is of particular relevance to the vast majority of children's burns, which are scalds, and which are often of 'indeterminate' depth. Some burn surgeons advocate waiting until the depth of burn declares itself at approximately 48 h; if it is assessed that the burn will not heal within 7–10 days, the patient will be taken to the operating room and the dead tissue tangentially excised until there is a wound bed of viable tissue on which a split-thickness autograft can be placed. The arguments for this approach include rapid wound closure with less likelihood of infection, shorter hospital stay and improved cosmetic result. This approach will mean that certain patients might have unnecessary surgery, with the risks of general anaesthesia and an additional wound at the donor site. Other surgeons advocate waiting for 10–14 days before making the assessment, and then grafting only those areas that look unlikely to heal by 3 weeks. This approach reduces the likelihood of unnecessary or extensive surgery, but does require a longer time to complete healing with an increased time of exposure to the risk of infection and a greater chance of hypertrophic scarring.

A third approach, which is particularly suitable for children in whom scalds predominate, is to perform an examination under anaesthetic at 3–5 days post-burn. At this stage the depth of burn is assessed clinically by assessing turgor in the tissues, as well as the presence or absence of blanching or 'fixed' staining of the burned skin. Even in the presence of fixed staining, indicating a deeper dermal burn, if there is absence of maceration of the wound, a biological dressing can be applied after thorough cleansing. Figure 22.31 shows the progression of healing after the application of glycerolized human cadaver skin [11]. While the surgical management of the burn wound is not within the remit of the dermatologist, advice may be sought regarding management of the burn wound in the acute stage. It is very important that the preferences of the local specialist centre are known as the application of different dressing materials may radically alter the appearance of the burn wound and thus affect the surgical decision-making process.

The critical determinant regarding whether to treat surgically or conservatively is the depth of burn. While there have been many attempts to develop techniques to achieve this objectively, the most common and practical clinical approach remains the assessment by an

Fig. 22.31 (a) An 11-month-old child with a deep dermal scald exhibiting fixed staining in the wound; (b) covered with closed meshed glycerolized human allograft; (c) 2 weeks later the allograft is dry and spontaneously separating; (d) allogenic skin all removed, healed burn that did not develop hypertrophy. (Reprinted from [11], © 2002, with permission from Elsevier Science.)

experienced burn surgeon who will use visual and tactile cues. Such clinical subjective assessment is only 70–80% accurate as compared to the use of laser Doppler imaging [12,13]; although this technique remains in the research domain at present, its incorporation into routine clinical practice would give a more predictable outcome to the management of the burn wound.

Use of topical antimicrobial treatment, as with dressings, should not interfere with the wound appearance, and has to be balanced with the very real risks of infection developing within the burn wound. Early colonization of the burn wound is likely to be associated with Gram-positive cocci. Patterns of microbial activity vary between units and within time; *Streptococcus pyogenes* group A used to be regarded as the most serious pathogen but there is now far more concern about staphylococcal toxaemia, particularly in children with small burns [14,15]. For this reason, certain centres in the UK advocate using mupirocin as a topical agent on burns in children when the total burn surface area (TBSA) is less than 10%. This is covered with a dressing that combines a non-adherent layer and an absorbent layer, which will not affect the appearance of the burn wound. For more extensive burns where early surgery may be considered, dressing with paraffin gauze and dressing gauze soaked with povidine-iodine will not affect the appearance of the burn.

Where early surgery is not the practice or is not indicated for some other reason, topical antibacterial creams are commonly used. Silver sulfadiazine 1% cream, with or without chlorhexidine, is active against Gram-negative bacteria, including *Pseudomonas* spp. Typically, the cream is spread liberally on to dressings and applied to large areas. There is now also increasing use of silver sulfadiazine cream with cerium nitrate [16,17]. The advantage of this combined preparation concerns the effect on the burn wound. Topical creams produce a macerated wound that renders surgery less precise. The combination of silver sulfadiazine and cerium nitrate produce a calcium-rich layer on the surface of the dermal burns. The resultant

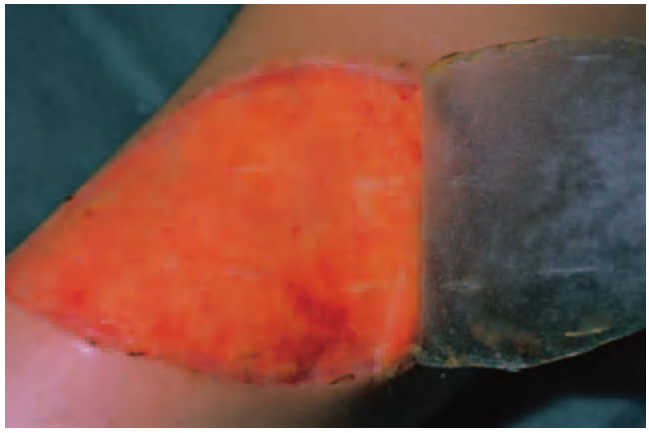

Fig. 22.32 A full thickness skin defect that has been treated with Integra® for 3 weeks. The outer silicone layer is here being removed. New dermis has been formed, and is now ready for a thin graft.

Fig. 22.33 Six years after applying Integra® to resurface a full thickness burn on the left hand the skin shows multiple fine wrinkles. The patient was aged 19 years.

shell-like layer acts as a bacterial barrier and, coupled with a dry wound, minimizes infection. This combined preparation is also associated with a lesser infiltration of polymorphonuclear neutrophils (PMN) into the burn wound. This may account for the drier nature of the burn eschar as opposed to the macerated wound associated with silver sulfadiazine, where PMN infiltration is prevalent.

While formulations containing silver remain the most widely used topical antimicrobials in burns care, the delivery of silver continues to be the focus for new developments. Sustained release of silver from dressing materials has distinct advantages over the cream formulations and will become more a feature of topical burns wound care in the next decade [18].

Surgical intervention

Surgery essentially involves removing the irreversibly damaged burned tissue and closing the wound. Surgery can involve tangential shaving of partial thickness burns or excision of full thickness burns. The surgeon now has an increasing number of options for closing the burn wound. When the wound is small, an autograft is the method of choice. The larger the burn area, the smaller the available donor sites for obtaining autografts. It is in these larger burns that great advances in terms of survival have been made with the trend towards early surgery and burn wound closure. Wound closure has been achieved using a wide range of materials including human allografts, fresh, frozen and glycerolized porcine xenografts, *in vitro* cultured keratinocytes used as both allo- and autografts, together with a variety of synthetic materials used as temporary dressings. Continuing interest is focused on burn wound closure using a dermal regeneration template, Integra® [19–21]. This synthetic bilaminate membrane is manufactured using biological raw materials (Fig. 22.32). The dermal analogue is an open lattice of fibres made of bovine collagen covalently linked to chondroitin-5-sulphate. The temporary outer layer, the epidermal analogue, is medical grade silicon, which is subsequently replaced with an ultrathin epidermal autograft. The collagen-GAG dermal analogue has a three-dimensional architecture similar to that of normal dermis and completely biodegrades after 30 days. It thus serves as a scaffold for the ingrowth of fibroblasts and endothelial cells, facilitating the formation of a neodermis. This functions like a human dermis in terms of biomechanical performance and response to growth. Six-year follow-up of Integra® used in reconstruction after burn scar revision does show the phenomenon of 'premature aging' in some cases (Fig. 22.33) and the search for new biomaterials continues [22–25].

General care

Small and minor burns require little care other than the specific treatment of the burn wound. Larger burns, however, require more specialized and extensive care. After the period of fluid resuscitation and early stabilization, with or without surgery, there will be a prolonged period of treatment and rehabilitation, which can be physically and psychologically demanding [26,27]. Constant attention must be paid in the earlier phases to reducing the risks of infection; early feeding with high-protein high-calorie diets with added vitamin and minerals is important to counteract the hypercatabolic response to the burn injury. While there have been considerable improvements in survival, major burns are still associated with a significant mortality and morbidity. It is important to balance encouragement and hope for recovery with realism that survival is not always certain and recovery is a long process. It must also be appreciated, particularly in children, that the magnitude of the physical trauma is mirrored by

the magnitude of the psychological trauma to the parents and relatives. Great sensitivity is required by those caring for these patients, and professional counselling should be available for the relatives.

Cutaneous sequelae of burns

Superficial partial thickness burns will heal without scarring, although there may be some loss of pigment, which is usually temporary. Deeper burns are associated with scarring and there is a high incidence of hypertrophic scarring, especially in the deeper partial thickness burns that have been allowed to heal conservatively (Fig. 22.34). Hypertrophic scars go through a phase of many months when they can be intensely pruritic and this can be a significant problem for children. Pressure garments (Fig. 22.35) and silicone gel and elastomers are used in the management of hypertrophic scars [1]. Occasionally, the scarring can result in functional problems that require surgical intervention (Fig. 22.36). Aesthetic problems related to scarring and contracture with deformity also require combined approaches of splinting and surgical intervention, which may need to be repeated over a considerable period of time. Late neoplastic change in burn scars is discussed below.

Fig. 22.34 Hypertrophic scarring in a burn in a dark-skinned person. Areas on the back were grafted and the burn scars between the grafts became hypertrophic.

Electrical burns

These occur from environmental, domestic and industrial sources and present a unique form of trauma, which may affect multiple organ systems and present challenging problems for clinical management. Electrical burns are arbitrarily classified as high- or low-tension injuries, with

Fig. 22.35 Commercially available pressure garments made by Biersdorf.

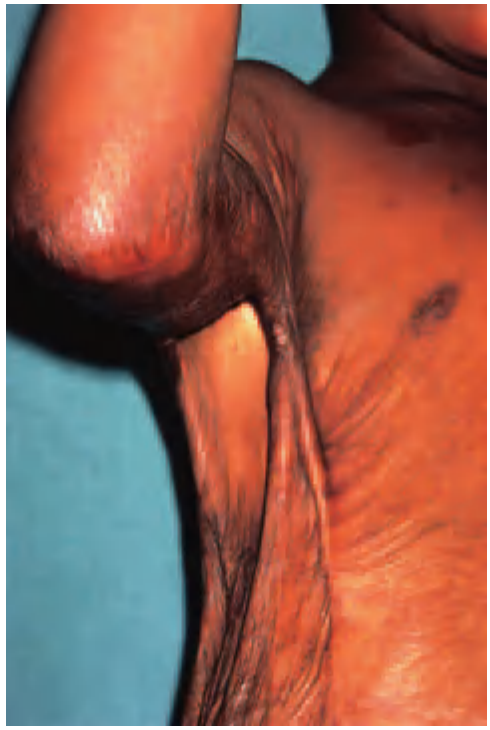

Fig. 22.36 Contracture of the shoulder resulting from scarring of the axilla.

low-tension burns being less than 1000 V and high-tension burns greater than 1000 V. Electrical injuries account for approximately 3% of burn patients admitted to specialized centres, and the majority come from contact with the domestic 240 V alternating current at 50 Hz single phase. Other sources of current are the high-voltage power lines that pose a threat not only to workers but to sports enthusiasts involved in pursuits such as fishing, hang-gliding, parachuting and kite flying [1,2]. Other injuries are associated with electrification in rail transport, both the overhead lines and the 'third' rail. Finally, car batteries cause a significant number of injuries to car mechanics (usually in amateurs).

The pathophysiology of the electrical injury is complex [3] and not completely understood. Historically, the mechanism was thought to be heat, as the passage of electric current through a solid conductor results in the conversion of electric energy to heat (the joule effect). However, it is probable that significant damage is also produced directly by the effect of the electric current inducing cell membrane breakdown, a phenomenon called electroporation. Clinically, the severity of injury relates to the voltage, the thickness and wetness of the skin and the duration of contact. The location of the entry and exit points determine the areas that will have been potentially damaged. High-voltage injuries may result in extensive muscle damage with subsequent risk of renal failure. All organs between the entry and exit points are liable to injury, and cardiac standstill can occur.

Electrical burns show distinct histological features. The nuclei of the basal cells, and sometimes of the more superficial epidermal cells, appear stretched vertically. There may be dermal–epidermal separation, with elongated degenerated cytoplasmic processes from the basal cells protruding into this space.

Management of the patient with electrical injury involves general supportive treatment as well as specific wound treatment [4]. If there are electrocardiogram (ECG) abnormalities then continuous cardiac monitoring is necessary together with pharmacological treatment of any dysrhythmia. Fluid resuscitation may be indicated. It must be appreciated that the extent of the injury is often 'hidden' with deep muscle damage. Because of this, fluid requirements may considerably exceed those predicted by the cutaneous burn alone. A particular concern is myoglobinuria with the risk of renal failure, in which case a brisk urine output should be encouraged with the use of mannitol (see above).

Historically, the teaching on wound management was that there was delayed muscle necrosis and therefore that early wound débridement and wound closure was contraindicated. Current thinking is that débridement of obviously necrotic tissue should be performed as early as possible, preferably soon after admission at the same time as escharotomies, fasciotomies and nerve decompression

are undertaken [5]. Wound closure should, however, be delayed for a short period to allow progressive tissue damage to declare itself [6]. This damage is thought to result from the effects of the electroporation. The tissue damage resulting from this would be recognized several days after injury when arachadonic acid metabolites have caused microvascular ischaemic cell death.

Lightning burns are not infrequent and can produce a variety of injuries. Characteristically, there are arborescent lesions (Lichtenberg figures), which are erythematous, mottled or charred, and small linear burns at the site of metal objects held in the hands or in clothing pockets. However, the skin lesions are overshadowed by the general effects of respiratory arrest, gastric dilatation, ileus, cerebral oedema and fractures.

Electrical flash burns can occur with both low- and high-tension injuries. These involve the exposed areas, typically hands and face. Superficial flash burns can be treated conservatively but deeper ones will require surgery in specialist units. Extensive flash burns will require intravenous fluid resuscitation.

Miscellaneous electrical burns

There are a number of electrical burns that can give rise to medicolegal issues because they can mimic torture or child abuse. For example, burns that were actually caused by a defective enuresis alarm system were similar to cigarette burns, which, because of their shape and multiplicity, were thought unlikely to have been caused accidentally (Fig. 22.37).

Fig. 22.37 These lesions raised the suspicion of child abuse because they were initially thought to be caused by multiple cigarette burns but in fact they were caused by repeated accidental burns from an enuresis alarm.

Laser burns [1,2]

When laser energy is absorbed by skin, it is converted into heat. The principal chromophores are melanin and haemoglobin. The effects on the skin are determined by a number of variables, such as wavelength of the laser emission, power, duration of exposure, direction of the beam and skin colour. The carbon dioxide laser produces non-specific destruction, often vaporizing the skin with a narrow zone of coagulative necrosis adjacent to the healthy tissues. In contrast, the wavelength of the tuneable dye laser can be chosen for maximal absorption by one component of the skin, and with very brief duration pulses the damage can be restricted. Laser light of 577 nm, delivered in impulses of nanoseconds' duration, is used to treat port-wine stains without scarring. Histologically, damage is limited to the superficial dermal vessels. When thermal damage is more extensive, hypertrophic scarring can occur; this is a more significant risk with the argon laser.

Microwave radiation burns [1]

Microwave radiation is non-ionizing high-frequency short-wavelength radiation, which generates heat by its effects on water molecules. Accidental exposure to microwave radiation has caused burns sufficient to result in amputation [2]. Lesser injuries have been followed by paraesthesia. Two cases of children deliberately injured

by microwave ovens have been described in which the injuries were sharply demarcated [3]. Subsequent studies of the effects of microwave radiation on piglet skin and the underlying tissues indicated that, when sufficient microwave energy was given to burn the skin and muscles or viscera, there was relatively little injury to the subcutaneous fat [4]. This sparing of the fat appears to be a unique property of the microwave burn.

Burns and skin neoplasia

Malignant transformation in burn scars was described by Marjolin in 1828. Clinical features to suggest the development of malignancy include induration and persistence of ulceration after a burn; the appearance of an elevated border at the edge of a post-burn ulcer; breakdown of a burn scar with an indurated base; and nodule formation within a burn scar.

Most malignancies arising in burns scars derive from epithelial keratinocytes, although malignant melanoma, sarcoma and schwannoma have also been described [1–5]. The frequency with which burn scars develop a neoplasm is unknown, but in a previous generation it was estimated that approximately 2% of squamous carcinoma and 0.5% of basal cell carcinomas arose in burn scars. Most carcinomas that develop in burns scars are squamous in type [6,7]. Neoplastic change is more likely when there is delayed healing or repeated ulceration (Fig. 22.38), and the incidence of carcinoma is reduced if such wounds are grafted at an early stage [8]. Burn scar carcinoma is most common in the lower limb and in limb flexures. Most squamous carcinomas occur after a long latent period, sometimes several decades, although it is shorter in the elderly. Uncommonly, a carcinoma may arise within weeks or months of a burn: this short latent period neoplasm is more commonly basal than squamous cell in type. Metastasis to regional nodes is much more common in the squamous carcinomas arising in burn scars than those associated with actinic damage. It occurred in 16 of 44 cases, of whom 15 died [9]. Metastases occurred in 20% in one series [8] and 36% of another [10]. The prognosis is worse for lower limb lesions [9].

Basal cell carcinomas occurring in burns scars are more common on the head and neck, in actinically damaged skin and in older patients [8]. Carcinoma following exposure to hot metal fragments, as occurs in welders, is more likely to be basal than squamous cell type [11].

It is not known how burns result in carcinogenesis. When the latent period is short, and a neoplasm develops in sun-damaged skin, it is likely that the burn is acting as a promoter. When the latent period is long, other mechanisms are more likely. Burning itself may act as an initiator of carcinogenesis [12]. When the burn results in chronic ulceration or repeated cycles of healing and ulceration, this in itself may act as a promoter. Because squamous carcinoma can occur even when the damaged area is grafted, the carcinogenic stimulus may arise in the dermis in some situations. It is also possible that locally impaired immune function contributes to the development of malignancy.

For medicolegal purposes, the criteria established long ago [13] for associating a carcinoma with a previous burn are still valid.

Abuse by burning

Regrettably, human beings sometimes cause serious injury to others, including members of their family circle and especially those who are helpless, such as young children or elderly parents. Abuse may be willful and malicious but in many cases it is caused by thoughtless neglect. The problem of deliberate injury to children by burning has been identified for over 20 years [1,2]. Similar aggressive acts towards dependent elderly are not widely recognized but it is highly probable that there is a much higher frequency of this type of injury than is reported in the literature [3,4] and that, as with child abuse, the more burn-care professionals become sensitive to the possibility of abuse of the elderly, then the more the observed incidence will rise. Burning has been the mechanism of abuse in about 10% of cases of child abuse. The incidence of abuse associated with childhood burns varies considerably from 1% to 25% of burn admissions to specialized centres.

It can be very difficult to diagnose a non-accidental injury but there are a few features that should give cause for concern (see also p. 22.36):

1 A child is brought for treatment by an unrelated adult
2 There is an unexplained delay in seeking treatment
3 The parents seem to be responding inappropriately to the injured child (e.g. they are inattentive or unconcerned)
4 Blame for the injury is placed on another person (usually not present)
5 The injury is not consistent with the history.

Inflicted burns can have characteristic patterns of injury (Fig. 22.39) [5]. The majority of non-accidental burns in children are scalds; these may be spill injuries or immersion burns. Immersion burns are very rare as accidental injuries in children under 1 year of age. Suspicious features are burns of glove and stocking distribution or the classical 'doughnut' of spared skin on the buttock on a child who has been forced to sit in a bath of hot water. Flame burns are less common. Contact burns may occur with the placing of a child against a hot object or by branding the child with cigarettes or a domestic iron.

Fig. 22.39 This pattern of a heating grill on the buttocks of a child was a result of child abuse.

Fig. 22.40 This child with 'staphylococcal scalded skin syndrome' and no history of burns was originally admitted to a burns unit as a case of suspected child abuse.

While the diagnosis of child abuse is very important, the misdiagnosis of abuse can be a tragedy that can destroy family groups. It is very important therefore to be aware of injuries that may simulate abuse. Cutaneous infections can mimic deliberate injury, for example impetigo, severe napkin rash and scalded skin syndrome (Fig. 22.40). Hypersensitivity can sometimes be mistaken for intentional burns. Photodermatitis can be caused when substances in certain fruits come into contact with skin exposed to sunlight. A pattern of erythema and blistering can develop that simulates a splash burn. Without a history of injury, abuse may be suspected. Cigarette burns can be accidental but multiple cigarette burns are pathognomonic for child abuse.

The patterns of abuse of the elderly are less well documented, but the author has knowledge of cases of immersion of physically dependent elderly people in hot baths resulting in burns. While this may not come into the category of malicious abuse, it is indicative of negligence on the part of the carer. Another distressing injury comes from contact burns against hot water pipes or radiators. These can be sustained by elderly people collapsing in the night and not being able to move away from the source of heat. There may be no conscious abuse but the exposure of at-risk individuals to preventable environmental hazards, together with the lack of supervision, may constitute negligence. While there is legislation that protects children (e.g. fireguards are a legal requirement when there are children under a specified age in a room), the same degree

of legislation does not yet apply to dependent elderly people. This situation will probably change, particularly as the at-risk elderly population increases.

Abuse by burning is a very disturbing and emotive injury. It is essential that, while a high index of suspicion should be maintained with burns patients at the extremes of age, these suspicions should be thoroughly and sensitively pursued. Multidisciplinary teams should be established to undertake this investigation. Experienced and trained professionals will then have to confront the suspected abuser if appropriate.

Blackening of the skin by metals

SYN. BLACK DERMOGRAPHISM

The black discoloration produced when the skin is stroked against certain metals is called black dermographism [1]. Unlike other forms of dermographism it has a purely physical, not a physiological basis. It is caused by the abrasive effect of powders on the skin, which rub against a relatively soft metal, generating particles that are so small that they absorb but cannot reflect light [2]. Any powder harder than a metal in contact with it can abrade the metal and produce skin blackening. Calamine lotion (zinc and ferric oxide), face powders (zinc oxide, titanium dioxide and ferric oxide) and some dentifrices containing pumice readily produced the phenomenon from gold, silver or platinum jewellery. In some individuals who exhibit black dermographism, the powder originates from the workplace.

Pure gold (24 carat) does not seem to have the property of skin blackening, possibly because the surface has more plasticity and deforms rather than fragments when friction is applied [3].

In addition to the presence of powders on the skin, factors that increase the likelihood of blackening include dryness and roughness of the skin, and amino acids in sweat (especially those containing sulphur, which can produce black complexes with gold). Sodium chloride (e.g. from sweat and sea water), which may promote corrosion, and tarnishing of the base metal in gold alloys can both contribute to the phenomenon.

Black dermographism can mask a contact allergic dermatitis to gold [4].

Blackening of the skin can be treated by simply washing with soap and water, and it can be prevented if the skin that will be in contact with the metal is carefully cleansed free of powder.

Rusting

Certain individuals have the ability to corrode metal. This comes to light in apprentices in the precision engineering industry and makes them unable to pursue their career. Such individuals are known as 'rusters' [1].

Rusters tend to have hyperhidrosis [2] and the mechanism of the electrolytic corrosion has been investigated in detail [1]. 'Rusters' have an increased secretion of salt in their sweat [3].

The composition of the steel being handled is important; with increasing amounts of copper, the phenomenon is less likely to occur [2].

Treatment is difficult. Measures to reduce hyperhidrosis such as aluminium chloride hexahydrate under occlusion may help, as can hand washing and protective gloves [2].

Finger wrinkling

Early and excessive wrinkling of the skin of the fingers after immersion in hot water was thought to be a useful sign of cystic fibrosis [1,2] or a test of sympathetic nerve function [3,4], but false-positive results limit its value, and nearly one-third of normal subjects showed no wrinkling at all [5]. The factors influencing wrinkling include hydration of keratin and patency of sweat pores [6,7].

Carbon monoxide poisoning [1]

Symptoms and signs become increasingly apparent with circulating levels of carboxyhaemoglobin above 30%, and coma, convulsions and cardiorespiratory arrest are likely to occur with concentrations of 60% or more.

A burning sensation may be the earliest symptom in mild cases [2]. The distinctive vivid erythematous or oedematous plaques may appear, especially at pressure sites, within hours after carbon monoxide poisoning [3] but this often-quoted 'cherry red' change only occurs in about 1% of cases of carbon monoxide poisoning [4].

Vesicles and bullae may develop, often in a geographical pattern [5,6]. The lesions simulate those seen in barbiturate poisoning or after cerebral vascular accidents or drug-induced coma.

Histologically, the bullae show epidermal necrosis, intraepidermal vesiculation and necrosis of the secreting portions of the sweat glands [3,5]. Spontaneous resolution occurs, in those who survive, in about 15 days [3,7]. Pressure and hypoxia are probably the main factors in the pathogenesis.

Complications include haemolytic anaemia, renal insufficiency from rhabdomyositis, and peripheral neuropathies.

Treatment. This is with 100% oxygen, administered by a tightly fitted face mask or, if necessary, endotracheal intubation and mechanical ventilation. General supportive measures may also be required.

Chapter 23

Reactions to Cold

P.M. Dowd

Introduction

The stimulus of an adverse environment, if not too extreme, is one of the factors which encouraged humans and other animals towards civilization. Humans and animals have adapted to cold by several mechanisms [1–4]. They include tolerance of changes in body temperature, increased production of heat and increased insulation. In humans, increased insulation is achieved by an increase in fat, vascular changes and especially by social changes related to housing and clothing.

Physiological reactions to cold [1–9]

The cutaneous changes induced by cold depend on many variables other than the actual temperature achieved and the duration of chilling. These include the rate of chilling and the rate of rewarming. These variables are of importance when considering clinical damage caused by accidental exposure to cold as well as when cold injury is deliberately inflicted therapeutically (see Chapter 77). Extreme cold, sufficient to freeze tissues, causes gross damage to cells. There is disorganization of the macromolecular structure, perhaps due to the formation of ice crystals outside or inside the cell, leading to hypertonicity and denaturation of protein. Lesser degrees of cold also cause pronounced changes in normal physiology. All enzymes and vital processes are depressed by lowering the temperature, but to a differing extent. Some of the most obvious effects are those on the vascular system. Exposure to cold causes constriction of the arterioles and veins by a direct mechanism mediated, at least in part, via endothelial synthesis of the vasoconstrictor peptide endothelin-1 (ET-1). There is also a reflex increase in sympathetic tone arising from cold receptors in the skin and, moreover, if the blood temperature falls, from the heat-regulating centre in the hypothalamus. The direct effect of cold on the veins tends to be greater than on the arteries, and both rewarming and local metabolites have a greater dilator effect on the arterial side, so that resumption of arterial flow after exposure to cold tends to lead to oedema [5].

Moderate exposure of fingers to cold leads to the 'hunting reaction' of Lewis [10]. Normally, cold-induced vasoconstriction is a protective device to prevent loss of heat from the body. With more severe exposure to cold, this may jeopardize the integrity of the skin tissues. A local vasodilatation mediated by the sensorimotor peptidergic nervous system then comes into play, and there is a resultant phasic increase and decrease in blood flow through the cutaneous microvasculature [10].

An important effect of cold is to increase the viscosity of blood. This plays a part in some abnormal reactions to cold. Other physiological effects of cold include changes in platelet adhesiveness, diminished conduction velocity in cutaneous nerves and slowing of the dissociation of oxyhaemoglobin to haemoglobin.

The interplay of these numerous factors with the general depression of metabolism determines the varied colours which may occur in normal or pathological skin in response to cold.

Diseases caused or aggravated by cold

The severity of cold injury to the skin depends on several factors, not solely the absolute ambient temperature and duration of exposure to cold, which determine the type of cold injury sustained by all normal individuals on adverse exposure to cold. Perhaps the greatest variable determining the cutaneous manifestations of cold exposure is the individual's susceptibility to cold injury. Individuals who have an endogenous susceptibility to cold suffer clinical cold-related disorders on exposure to modest degrees of cold that would be tolerated without ill effect by other normal individuals. Hence, diseases caused or clinically revealed as a result of cold injury to skin are perhaps best divided into two groups: (i) diseases of cold exposure, and (ii) diseases of abnormal susceptibility to cold (Table 23.1).

Table 23.1 Diseases caused or aggravated by cold.

Diseases of cold exposure

Cold urticaria
Perniosis
Acrocyanosis
Erythrocyanosis
Cold erythema
Cold panniculitis
Neonatal cold injury
Prurigo hiemalis

Diseases of cold exposure

Frostbite

Aetiology and pathology. Frostbite is the result of acute freezing of the tissues on exposure to extreme degrees of cold. Exposure of only a few seconds' duration may be sufficient to cause it. Factors which increase the rate of loss of heat from the skin, for example contact with good conductors such as metals, result in greater severity of injury for the same duration of exposure. Traditionally it has been accepted that wind chill increases the severity of frostbite, but a recent survey in Antarctica demonstrated that although the frequency of frostbite tended to follow the frequency of wind-chill values, except at higher wind-chill values, neither temperature nor wind chill was found to significantly influence the severity of frostbite. Prior cold injury was shown to be significantly associated with further cold injury [1].

The pathological changes are dependent upon the duration and severity of the exposure to cold, and vary from mild perivascular inflammatory changes to severe bulla formation and tissue necrosis extending as far as bone. The acute response to cold leads to actual freezing of, and ice crystal formation in, the affected part, with destruction of superficial tissues in milder cases and of deeper tissue, including larger blood vessels, nerves and bone, in the most severe cases.

The diagnosis is made on the history and clinical appearances and the exclusion of other causes of cold-related erythema, blister formation and gangrene [2].

Clinical features. The parts of the body that can be least protected from cold are affected—toes, feet, fingers, ears, nose and cheeks (Fig. 23.1). After the initial pain or feeling of burning on exposure, the affected part becomes pain-free and the sensation of cold in the affected part disappears. The affected zone of skin becomes waxy and white, and these appearances persist until the time of thawing. Depending on the severity of the cold exposure, muscles and nerves may be damaged, leading to paralysis, and arteries and subcutaneous tissue and even bone may be injured [3].

The extent and severity of tissue damage become really apparent on rewarming. Erythema, mild pain and soreness, lasting for a few hours, may be the only sequelae in mild cases. Blistering and destruction of the epidermis, dermis and deeper tissues occur in more severely affected individuals, and gangrene may then ensue [3].

Damage to the nerves and blood vessels may result in persistent paraesthesiae, abnormal sensitivity to cold and compromised nutrition to the tissues, even where loss of tissue does not occur. Hyperhidrosis may also occur. These effects, which are considered to result from damage causing functional abnormality of the sympathetic and

Fig. 23.1 (a,b) Frostbite.

non-adrenergic non-cholinergic nervous systems, may last for months or even years. Squamous cell carcinoma in the resultant scars may occur many years after the injury [4].

Treatment. Rapid rewarming by immersion in water at 40–42°C for 20 min is now recommended, in the light of experimental and clinical studies [5,6]. Exposure to higher temperatures is contraindicated. Treatment of frostbite in field conditions must invariably be on an ad hoc basis, and it cannot be too strongly stressed that further trauma must be avoided. In particular, rubbing the affected part with snow, a technique which has enjoyed some popularity in the mistaken belief that it hastens rewarming, is absolutely contraindicated as it has adverse effects of considerable magnitude. The prompt and early administration of heparin, and also infusion of low-molecular-weight dextran, appear to have proved beneficial [5,7].

Sympathectomy has little or no effect in the early stages. It used to be considered helpful in the later stages but now the indications for this operation are rarely encountered. Vasodilator and thrombolytic agents may be useful as adjuvant therapy, but randomized multicentre trials are still required to prove their efficacy [8,9].

Surgical removal of gangrenous tissue should be delayed for weeks or even months to allow tissue regeneration after maximum vasodilator therapy.

Trench foot

SYN. IMMERSION FOOT

Aetiology and pathology. Trench foot and immersion foot are now regarded as more or less identical processes [5]. Prolonged exposure to cold, usually above freezing, accompanied by damp and windy conditions, together with prolonged immobility and dependency of the limbs, results in the production of this clinical picture, either by tissue damage involving vessels or occlusion of vessels and resultant tissue damage. Smoking and vascular disease are considered to contribute to the severity of the tissue damage [10].

The pathological changes are those of dependent oedema and stasis, with perivascular inflammation, or in more severe cases actual occlusion of vessels and ischaemic necrosis of tissues. Both myelinated and unmyelinated nerve fibres are damaged, resulting in a decreased density of terminal cutaneous nerve fibres within the plantar skin [11].

The diagnosis is based upon the history and the clinical findings of cold, anaesthetic limbs and possibly limited superficial gangrene. The differential diagnosis includes other causes of arterial occlusion [12].

Clinical features. The limb feels cold, and is anaesthetic. On rewarming, it initially becomes oedematous. The ability to sweat is lost, and anaesthesia persists. Subsequently, hyperaemia and painful paraesthesiae occur. In severe cases, limited superficial gangrene may occur, but this is not severe enough to necessitate extensive surgery. Cold sensitivity, vasomotor instability and hyperhidrosis may persist for many months. This syndrome is now being seen with increasing frequency among the homeless population [13].

Treatment. The best approach is prevention, but once the condition has occurred bedrest, analgesics and antibiotics should be given initially. Adjuvant vasodilator therapy is still of unproven long-term benefit.

Conservative surgical excision of non-repairable tissue together with appropriate plastic reconstruction may be necessary, but this should not be undertaken until medical measures have had a chance to exert maximum effect over several weeks.

Diseases of abnormal sensitivity to cold

Perniosis

SYN. CHILBLAINS

Aetiology and pathology. Chilblains are localized, usually tender, inflammatory, erythematous, often itchy lesions, which may blister or ulcerate. They occur as an abnormal reaction to a cold ambient temperature [1]. Why cold causes chilblains in some individuals and not in others is uncertain. A genetic factor is often apparent in perniosis, several generations not infrequently being affected, and the lesions are often superimposed on a background of acrocyanosis and/or erythrocyanosis. Other factors include nutrition, focal sepsis, hormonal changes and systemic disease, especially dysproteinaemias, myelodysplastic disease and anorexia [1–3]. Pregnancy may have a beneficial effect on chilblains [4].

In contrast with normal individuals, in whom moderate cold exposure induces cutaneous vasoconstriction succeeded by vasodilatation in an attempt to maintain reperfusion, a persistent cold-induced constriction of the large cutaneous arterioles and persistent dilatation of the smaller, more superficial vessels occurs in individuals who are afflicted by perniosis.

Histologically, classical acral lesions exhibit intense oedema of the papillary dermis, a marked perivascular mononuclear cell infiltrate in the upper dermis sparing the oedematous papillary dermis, and oedema and vacuolation of thickened blood vessel walls ('fluffy oedema') [5]. The dermal infiltrate characteristically shows peri-eccrine as well as angiocentric concentration [6,7]. Epidermal changes in chilblains consist mainly of necrotic keratinocytes and spongiosis. Immunohistochemically, the dermal infiltrate is composed of a majority of T cells with macrophages and a few B lymphocytes [6,7]. The term 'superficial perniosis' distinguishes this group of clinical and histological changes as a discrete entity.

In contrast with acral perniosis, the majority of lesions from thigh perniosis exhibit a histological pattern referred to as 'deep perniosis' [5]. They are characterized by an intense mononuclear cell perivascular infiltrate extending throughout the dermis and into the subcutaneous fat, with 'fluffy oedema' of blood vessel walls. Dermal oedema is not a persistent feature. A minority of thigh perniosis lesions have a mixture of superficial and deep patterns of perniosis. No pathophysiological mechanism has been proposed for these histologically different patterns. It is possible that thigh perniosis is due to a combination of external cooling and insulation from internal warming, whereas acral perniosis involves only outside cooling, as there is little or no adipose tissue at acral sites.

There does not appear to be a primary neurological deficit in idiopathic acral perniosis [8]: immunohistochemical staining of the cutaneous nerves by the panneuronal marker PGP 9.5 and of the peptidergic nerves with antibodies to calcitonin gene-related peptide (CGRP), substance P, neuropeptide Y and vasoactive intestinal peptide is not qualitatively or quantitatively different from normal controls matched for site, age and sex. However, in the affected skin of patients with acral perniosis and acrocyanosis associated with a past history of very low body weight, immunohistochemistry revealed a great increase in nerve bundles in the papillary dermis, some with an abnormal morphology. A generalized increase in CGRP-, substance P-, neuropeptide Y- and vasoactive intestinal peptide-containing fibres was also demonstrated in this group of patients by immunohistochemistry [8]. The pathophysiological significance of these findings in the different groups of patients with perniosis remains to be elucidated, but does indicate that at least in uncomplicated acral perniosis the primary pathophysiology does not reside, at least structurally, in the nerves supplying the cutaneous microvasculature, and that idiopathic perniosis is probably primarily a disease of the microvasculature. Further evidence in support of this comes from the hyporesponsiveness of the microvasculature to a variety of vasoactive agents injected intradermally [9]. The abnormal nerve bundles in perniosis associated with low body weight may develop as a compensatory mechanism in response to loss of insulating fat, although the pathophysiological mechanism resulting in the increase in nerve bundles is, as yet, not understood.

The diagnosis is based on the history and clinical picture. Histological confirmation may be obtained, and can be useful in the differential diagnosis. Perniosis must be distinguished from acrocyanosis, chilblain lupus erythematosus and cryofibrinogenaemia. If blistering is present, bullous lupus erythematosus should also be excluded. In the presence of ulceration, organic peripheral vascular insufficiency should also be included in the differential diagnosis.

Fig. 23.2 Chilblains.

Fig. 23.3 Ulcerated chilblains associated with senile arterial disease.

Clinical features. The onset of perniosis is in the autumn or early winter, when humidity is high. Individual lesions are tender, pruritic, red or purple lesions, which may blister or ulcerate. They occur especially on the fingers and toes (Fig. 23.2), heels, lower legs, thighs, nose and ears. Individual lesions usually run a self-limiting course over about 3 weeks. The condition in severely affected individuals may persist throughout the winter, and may be unremitting even in the summer months.

Chilblains occur frequently in children in northern Europe, but can develop at any age. They are more rarely seen in North America, except in northern New England, British Columbia and northern California (P.M. Dowd, personal communications), than in north-western Europe, probably because of warmer living and working conditions and the more prolific use of clothing with a high insulation factor. In childhood perniosis in North America, a high incidence of cryoglobulins and cold agglutinins was found [10].

A particular type of perniosis occurs in young, mainly female patients who are horse-riding enthusiasts and wear tight-fitting breeches [11]. This type of perniosis is also encountered in North America, and may also occur after wading across mountain rivers [12]. Infiltrated erythrocyanotic plaques are distributed symmetrically on the outer aspects of obese thighs; occasionally there is ulceration and follicular plugging. High titres of cold agglutinins may occur in equestrian perniosis [13].

A subgroup of patients with acral perniosis, often with acrocyanosis, have had anorexia nervosa or bulimia and have often indulged in a sustained vigorous exercise programme in order to maintain a low body weight. The perniosis and acrocyanosis may persist for many years after a return to an acceptable body weight and the resumption of regular menstruation [14,15].

Other variants of chilblains. In the presence of arterial disease, systemic disease or prolonged exposure to cold or friction, irreversible changes of fibrosis, hyperkeratosis and lymphoedema may occur, and the lesions persist for many weeks or even months. Senile chilblains are an example (Fig. 23.3).

There are less common forms of chilblains. Papular perniosis may closely mimic erythema multiforme [2]. The lesions appear in crops and favour the sides of the fingers, often superimposed on a background of acrocyanosis. They may last for many days. The histology shows subcutaneous oedema, but not the changes of erythema multiforme. Some such cases may later develop more typical recurrent erythema multiforme [5].

Pustular chilblains have also been called 'acrodermatitis pustulosa hiemalis' [1] and have to be distinguished from tuberculides. Chilblains are sometimes annular. Perniotic lesions, sometimes with necrosis, on the fingers, toes, nose and ears may occur in elderly men in association with monocytic leukaemia [3].

Chilblains have to be distinguished from chilblain lupus erythematosus (see Chapter 56) and, especially on the nose, from the variant of sarcoidosis called lupus pernio (see Chapter 58).

Treatment. The importance of, and the benefit which can be obtained from, the prophylactic wearing of warm clothing and living in warm housing conditions should not be underestimated [16]. Recently, the vasodilator calcium channel blocker nifedipine has been demonstrated to be an effective therapy and prophylaxis for acral idiopathic perniosis [17,18]. It is also effective in acral perniosis associated with low body weight. The author finds the calcium channel blocker diltiazem also effective, but to a lesser degree than nifedipine (P.M. Dowd, unpublished observations). It is, however, also less prone to undesirable adverse effects than nifedipine. Tamoxifen, and the vasolidator nicotinic acid derivatives and minoxidil topically applied are also effective in some patients (P.M. Dowd, unpublished observations), and are alternatives to

systemic therapy with nifedipine in those individuals who find the adverse effects of this drug intolerable. UV radiation has been a time-honoured remedy [19], and has been used in prophylaxis, but a more recent study of its efficacy concluded that phototherapy was of no value in the prophylaxis of chilblains [20].

Acrocyanosis

Aetiology and pathology. Acrocyanosis is a persistent cyanotic or erythrocyanotic discoloration of the skin, usually with a mottled pattern. It chiefly affects the hands; less commonly the feet and face are also involved. It may be idiopathic or secondary, occurring in association with a number of diseases and after drug administration (Table 23.2).

The peripheral arterioles are said to react unduly to the cold, and the smaller vessels, especially those of the subpapillary venous plexus, are dilated. The mechanism resulting in the changes is not understood, but has been said to involve the veins [1]. Changes in blood viscosity have been reported [2]. As in cases of uncomplicated perniosis, no neuronal deficit can be demonstrated by conventional light microscopy and immunohistochemistry of the neuronal supply to the cutaneous vasculature, including that of the vasoactive peptidergic nerves [3], indicating a primary vascular pathology.

Table 23.2 Aetiology of acrocyanosis.

Idiopathic
Secondary
Autoimmune
Connective tissue disorders
Primary and secondary antiphospholipid antibody syndrome
Neoplastic
Benign and malignant paraproteinaemias
Paraneoplastic syndrome
Cold agglutinin disease
Cryoglobulinaemia
Eating disorders
Anorexia nervosa
Bulimia nervosa
Orthostatic disorders
Chronic orthostatic intolerance
Postural orthostatic tachycardia syndrome of adolescents
Adolescent chronic fatigue syndrome
Neurological disorders
Brachial plexus neuropathy
Chronic arsenic poisoning
Drugs
Butyl nitrate
Interferon-α (2a)
Metabolic diseases
Fucidosis
Ethyl-malonic aciduria
Psychiatric
Mental retardation
Schizophrenia
Essential thrombocythaemia

In acrocyanosis and oedema of the lower limbs accompanied by light-headedness and fatigue, and occurring within 10 min of assuming upright posture (postural orthostatic tachycardia syndrome), blunted arterial vasoconstriction in the presence of normal venous compliance produces massive redistribution of blood within the peripheral venous capacitance beds [4].

Clinical features. In idiopathic acrocyanosis, the changes may be transient after cold exposure, but frequently persist during the winter and even throughout the summer months. The face may be involved as well as the hands. There is often a family history, indicating a genetic basis for this condition. The disorder usually starts in adolescence and persists into adult life. In some individuals it spontaneously remits. Large-vessel disorders are not usually associated with this disease except when it begins much later in life. Perniosis, erythrocyanosis and livedo reticularis may occur simultaneously with acrocyanosis.

The diagnosis is based on the clinical finding of persistent cyanotic discoloration in the presence of normal

Fig. 23.4 Acrocyanosis/erythrocyanosis due to neurotic immobility.

peripheral pulses and absence of venous occlusion. Acrocyanosis must be distinguished from severe Raynaud's phenomenon and perniosis. In cases developing for the first time in adult life, a secondary cause should be sought.

Acrocyanosis in mentally retarded and schizophrenic patients is said to be due to immobility, but the real reason why the incidence of acrocyanosis is increased in these disorders is unknown (Fig. 23.4).

Treatment. There is no medical cure for this condition. Synthetic vasodilator therapy, including the calcium channel blocking agents nifedipine and diltiazem that are effective in episodic peripheral vascular insufficiency and perniosis, is not usually effective [5], although topically applied nicotinic acid derivatives and minoxidil can be beneficial (P.M. Dowd, unpublished observations).

In acrocyanosis secondary to drugs, marked improvement follows cessation of drug administration. Therapy of associated diseases may result in clinical improvement in acrocyanosis but this is by no means a universal occurrence.

Erythrocyanosis [1]

Aetiology and pathology. Erythrocyanosis is persistent dusky erythema, and often deep cyanosis, occurring usually over areas with a thick layer of subcutaneous fat, such as the thighs and lower legs, and less commonly the buttocks and forearms. It is exacerbated in the winter months. It is thought that the thick layer of subcutaneous fat insulates the cutaneous vessels from the warmth of the underlying blood supply and renders them susceptible to the effects of environmental cold exposure, but the precise aetiology is unknown.

Areas of erythrocyanotic skin may be preferentially affected by diseases that characteristically involve areas of slow circulation, including tuberculosis, leprosy, sarcoidosis and lupus erythematosus.

Clinical features. Erythrocyanosis may occur together with or independently from acrocyanosis. Dusky, frequently deeply red–purple discoloration of the skin occurs most commonly on the lower legs in adolescent girls, and on the thighs and buttocks of obese prepubescent boys. Very occasionally, it can occur on the forearms of infants and on the thighs and lower legs of middle-aged women. It may be accompanied by ulceration, erythema, and also keratosis pilaris and more diffuse desquamation. Nodular lesions resembling chilblains or Bazin's disease may occur after acute cold exposure, and oedema and fibrosis may occur as late manifestations.

The diagnosis is based on the clinical picture, in the absence of any history of localized cold exposure. The differential diagnosis includes deep perniosis, superficial thrombophlebitis, Bazin's disease (erythema induratum) and varicose eczema, depending on the anatomical site.

The disease may persist indefinitely and be accompanied by progressive thickening and fibrosis. Fortunately, spontaneous improvement can occur in adolescent patients, usually after a few years.

Treatment. Warm clothing, exercise, weight reduction and elastic support hose may all be helpful. Systemic vasodilators are largely ineffective, and local vasodilators of limited value. UV light, previously regarded as beneficial, has not, in the author's clinical experience, been of any value.

Livedo reticularis

SYN. LIVEDO RACEMOSA; LIVEDO ANNULARIS; INFLAMMATIO CUTIS RACEMOSA; ASPHYXIA RETICULARIS MULTIPLEX; DERMATOPATHIA PIGMENTOSA RETICULARIS

Definition. Livedo reticularis is a mottled cyanotic discoloration of the skin, with a characteristic network pattern, which is accentuated by cold.

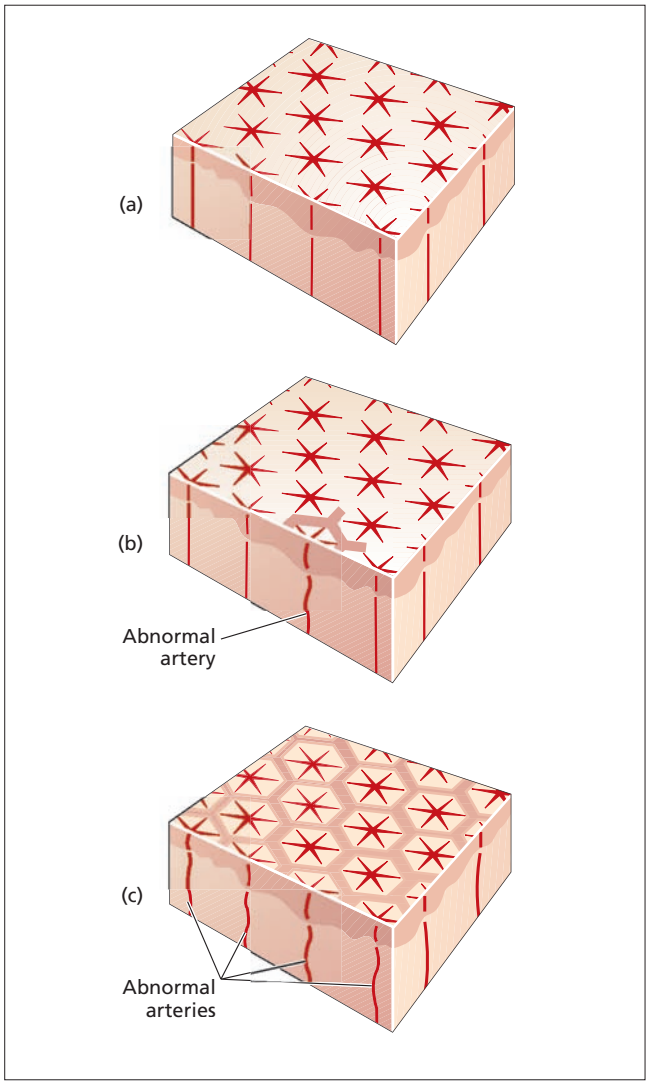

Fig. 23.5 Diagrammatic representation of (a) normal vasculature; (b) livedo racemosa due to patchy arterial pathology; (c) livedo reticularis due to diffuse arterial pathology.

Aetiology and pathology. Unna [1] postulated that the blood supply of the normal skin is arranged in cones, their bases 1–4 cm across on the surface of the skin, and each supplied by an arteriole. Such an arrangement may be presumed to exist. The mottling of livedo reticularis follows this pattern, the abnormal dark area of the network corresponding to the areas of anastomosis between two cones where the blood supply is relatively diminished (Fig. 23.5).

Livedo reticularis may be physiological, idiopathic or secondary to intravascular obstruction or vessel wall disease (Table 23.3).

The aetiology of the physiological and idiopathic varieties of this disease is unknown, but the histological changes of endarteritis are found in the small arterioles and venules of livedo reticularis of any degree of severity.

Table 23.3 Classification of livedo reticularis.

1 Physiological livedo reticularis
Cutis marmorata

2 Idiopathic or primary livedo reticularis
Congenital
Cutis marmorata telangiectatica congenita

Acquired idiopathic
Uncomplicated
With winter ulceration
With summer ulceration
With systemic vascular involvement

3 Secondary livedo reticularis
Intravascular obstruction
Stasis
- Paralysis
- Cardiac failure
- Amantadine therapy

Occlusive disease

- Syphilis
- Hepatitis C
- Brucellosis
- *Coxiella burnetii*

Hyperparathyroidism and hypercalcaemia [9]
- Calciphylaxis [10] (see Fig. 23.10)

The colour changes of livedo reticularis are believed to be due to the dilatation of, and stagnation of blood within, the capillaries and minute vessels in areas of anastomosis between two cones of vessels, each supplied by an arteriole —it is at this anastomotic point that the blood supply is relatively diminished and hence particularly vulnerable to a variety of adverse intravascular and vessel wall events.

The inherent pattern of livedo reticularis may be brought about by two quite separate mechanisms.

1 A change in the wall or within the lumen of the vessels. Although the visible changes are due to superficial small-vessel dilatation, the basic pathology affects the larger arterioles.

2 Some other pathological process that selectively picks out the area of slightly diminished vitality.

Clinical features. The diverse causes of livedo reticularis are reflected in localized and more diffuse visible changes in the skin of varying degrees of severity. The mottled cyanotic discoloration of livedo reticularis most commonly occurs on the legs, but the arms and trunk may also be affected. Tingling and numbness of the skin commonly occur on exposure to cold, which also intensifies the severity of the cyanotic discoloration. Diffuse arterial disease and viscosity changes give rise to diffuse mottling of the skin; patchy arterial disease to patchy mottling. Sometimes, this mottling takes the form of a complete network; sometimes, apparently a branching configuration (livedo racemosa). Dilatation of the small vessels is usually the only visible change, although there may be slight oedema.

Ulceration, starting in the dark area, occurs in some cases. Pigmentary change, scaling, etc. strongly suggest that external heat is concerned or that there is some other dermatosis localized to the dark areas. Cold will intensify the cyanosis whatever its cause. The changes are initially reversible if the cause can be removed, or on warming, but after a time the vessels become permanently dilated and telangiectatic.

Physiological livedo reticularis

SYN. CUTIS MARMORATA

This physiological, mottled, cyanotic, transient reaction to cold may be seen in up to 50% of normal children and in some adults. The mottling is diffuse, mild and usually symptomless. It is more prominent in association with a wide variety of systemic diseases leading to debility, or any disorder which causes stasis of blood within vessels, for example paralysis. It is accentuated in several disorders in the neonate. Chilblains, acrocyanosis and erythrocyanosis may be associated. The diagnostic dividing line between this condition and idiopathic livedo reticularis can be fine, and the two conditions may represent a spectrum of disease.

Congenital livedo reticularis

SYN. CUTIS MARMORATA TELANGIECTATICA CONGENITA

This is a rare developmental defect of the skin, which is present at birth [11–13]. It is usually asymmetrical and severe; atrophy of the skin may coexist (Fig. 23.6). Commonly, it is not associated with any other disorder, but occasionally a variety of other congenital lesions may be associated. Rarely, it may be familial. No treatment is effective, but the condition usually improves spontaneously with age.

Acquired idiopathic livedo reticularis

This occurs predominantly in young adult and middle-aged females. Mild degrees appear to be common and harmless, and merge with physiological cutis marmorata. In the more severe cases it is associated with ulceration, usually in winter, although sudden ulceration in summer can occur (Fig. 23.7). The mottling usually has its onset in the third or fourth decade, and is at first transient on exposure to cold; subsequently, permanent discoloration can occur. Tingling and numbness of the skin, and sometimes oedema, may be present. The disease may be progressive or remain stationary. Its aetiology is unknown.

Fig. 23.7 Idiopathic livedo reticularis with summer ulceration.

The diagnosis is based upon the presence of the persistent cyanotic discoloration of the skin in a characteristic network pattern. The differential diagnosis includes erythema ab igne, capillary naevi and angioma serpiginosum, and rarely drug rashes occurring in a livedo pattern. Underlying causes and associated diseases (Table 23.3) must be excluded before making a diagnosis of idiopathic livedo reticularis.

Livedo reticularis occurs in 20–25% of migraine sufferers and in this subset stroke is more frequent, raising the possibility that livedo reticularis can be used as a clinical marker to identify those migraine sufferers with an increased risk of stroke [14].

Idiopathic livedo reticularis with systemic involvement

SYN. SNEDDON'S SYNDROME

In a rare group of apparently idiopathic livedo reticularis, which should now be regarded as a separate pathological entity [15–19], widespread and severe patchy livedo reticularis (syn. livedo racemosa) is associated with arterial disease in peripheral, cerebral, coronary and sometimes renal vessels (Fig. 23.8). There is a progressively worsening course over several years, with intermittent cerebral and other vascular occlusive episodes, and a poor prognosis [19]. Histologically, the arteries show an endarteritis obliterans.

In about 40% of patients with Sneddon's syndrome (SNS), anticardiolipin or antiphospholipid (APL) antibodies are found in the circulation. This group are diagnosed as having the APS or lupus anticoagulant syndrome [20–22]. Approximately 35% of APS patients have systemic lupus erythematosus (SLE). The fishnet of the livedo is larger in APL-negative patients and these do not develop thrombocytopenia. Seizures and clinically audible mitral valve regurgitation are more frequently encountered in APL-positive patients. Patients with primary APS and SNS do not differ from those with livedo reticularis, ischaemic cerebral events and APS within SLE. Whether SNS covers a continuum of diverse clinicobiological entities ranging from APL-negative to SLE-related cases with primary APS–SNS in the middle, or whether SNS should be regarded as a nearly similar clinical expression of two distinct disorders remains a subject for debate and investigation [23–25]. Recent studies suggest specificity of APL antibodies for different phospholipid-binding plasma proteins, including β_2-glycoprotein 1, prothrombin, protein C and protein S [26].

Fig. 23.8 Idiopathic livedo reticularis with systemic involvement (Sneddon's syndrome). Male aged 45 years; 10 years' progressive livedo with coronary, renal and eventually fatal cerebrovascular disease.

Treatment. Uncomplicated idiopathic livedo reticularis does not require active therapy other than the prophylactic measure of protection from cold by warm clothing and avoidance of cold exposure. Severe cases, including those with ulceration, may be helped by prolonged anticoagulant and antithrombotic therapy [22]. Corticosteroids are disappointing, although azathioprine has been successfully used [27]. Sympathectomy is not beneficial. Prostacyclin can be very valuable in the management of the ulceration (P.M. Dowd, unpublished observations). Corticosteroids and antithrombotic therapy have been

Fig. 23.9 Patchy livedo reticularis due to idiopathic thrombocythaemia.

Fig. 23.10 Patchy livedo reticularis due to calcification of blood vessels secondary to chronic renal failure. A fatal *Pseudomonas* septicaemia followed skin ulceration. (Courtesy of West Suffolk Hospital, UK.)

recommended in the management of the APL syndrome, but not usually until the advent of a thrombotic episode [22]. Whether these drugs should be given prophylactically in this condition is still a matter of debate.

Secondary livedo reticularis

Secondary livedo reticularis, of which there are many causes (Table 23.3), tends not to be widespread or symmetrical but patchy and asymmetrical, reflecting patchy arterial change (Figs 23.9 & 23.10). Full investigation is required to exclude polyarteritis nodosa, and the estimation of antineutrophil cytoplasmic antibodies (ANCA) is now mandatory. Patchy livedo, sometimes with ulceration, occurs in the syndrome of benign cutaneous polyarteritis nodosa [28,29]. This is not associated with the severe systemic involvement of polyarteritis nodosa. The other causes of secondary livedo reticularis should be systematically sought.

Fig. 23.11 Erythema ab igne. A local burn which also accentuates the livedo pattern.

Treatment. The treatment of secondary livedo reticularis is that of the underlying condition.

Eruptions localized in livedo pattern

A wide variety of eruptions, which can at times demonstrate the Koebner phenomenon, may selectively involve the outer zones of the livedo network. This does not necessarily indicate any significant vascular abnormality in the skin. Psoriasis, lichen planus, discoid and systemic lupus erythematosus, tuberculides, secondary syphilis and drug eruptions may all occur in this pattern. Vascular naevi of the port-wine type may be reticulate; it is necessary to exclude a deep-seated change involving the larger vessels, but often the process seems to be quite superficial.

Erythema ab igne (see Chapter 22)

This is due to the prolonged effect of heat on the skin and is, in effect, a low-grade burn selectively involving the more vulnerable areas at the periphery of the livedo network. Commonest sites are the legs just below the knee, but a variety of different, sometimes quite bizarre, patterns occur when heat is applied to the skin either for warmth, relief of pain or at work [30] (Fig. 23.11). The earliest change is erythema, which may be associated with quite marked inflammatory changes and be followed by pigmentation. Bulla formation sometimes occurs. The

pigmentary changes may persist for many months or even years. Squamous carcinomas and other malignancies have been recorded in very chronic cases.

Raynaud's phenomenon

Definition. Raynaud's phenomenon is defined as episodic digital ischaemia occurring in response to cold or emotional stimuli. It is characterized by sequential colour changes (white, blue and red). Pallor is essential for the diagnosis. However, in severe recalcitrant Raynaud's phenomenon, with attacks of long duration occurring in association with connective tissue diseases, the initial pallor may be short-lived and succeeded by prolonged cyanosis, with or without discrete foci of tissue necrosis. Raynaud's phenomenon may be primary, or secondary to other causes. In recent years there has been a vogue, chiefly in the non-dermatological literature, to refer to Raynaud's phenomenon as Raynaud's syndrome. The two terms are often now used synonymously. Primary Raynaud's phenomenon is idiopathic, and occurs as an isolated innocuous disorder. This type of Raynaud's phenomenon is also called Raynaud's disease. Secondary Raynaud's phenomenon occurs in association with identifiable underlying diseases, or is either environmentally or drug induced.

Aetiology and pathology. The sequential changes of pallor, cyanosis and rubor were first described and delineated by Maurice Raynaud in 1862 [1]. In 1900, Jonathan Hutchinson [2] had realized that there were several causes of the clinical phenomenon, and by 1926 Allen and Brown [3] had established clinical criteria to delineate innocent Raynaud's phenomenon from Raynaud's phenomenon associated with underlying diseases. The modified criteria of Allen and Brown [3] still provide a sound clinical basis for differentiating primary from secondary Raynaud's phenomenon. The advent of immunological tests for the connective tissue diseases has enabled further refinement of the criteria for the diagnosis of primary Raynaud's phenomenon (Table 23.4).

Table 23.4 Criteria for the diagnosis of primary Raynaud's phenomenon.

Intermittent attacks of discoloration of extremities
Absence of evidence of organic peripheral arterial occlusion
Symmetrical or bilateral distribution
Exclusion of any disease, occupation, trauma or drug ingestion that could give rise to vasospastic abnormalities
Absence of immunological abnormalities
Female sex, age under 25 years
History of cold intolerance since childhood
Normal nail fold capillaries

Raynaud's phenomenon other than of occupational origin is more common in women. The prevalence is variously quoted as 5–30%: the marked statistical disparity appears to be due to the size and origin of the populations studied and the clinical diagnostic criteria used by the researchers, particularly with regard to colour changes. Rigorous investigation to differentiate primary from secondary Raynaud's phenomenon in general practice is probably not cost-effective. Application of the criteria listed in Table 23.4 is sufficient in most cases to make the differentiation. Female patients with age of onset over 25 years, no pre-existing cold intolerance even of mild degree, no occupational, traumatic or drug-related aetiological factors, and no history of a low body weight should be regarded as being at high risk of developing connective tissue disease and merit rigorous investigation, including screening for the presence of antinuclear, anti-Scl 70 and anticentromere antibodies. The presence of abnormal capillaries on nail fold microscopy, or structural defects on angiography (now, however, rarely indicated), is incompatible with a diagnosis of primary Raynaud's phenomenon, and merits a search for an underlying cause. Cutaneous nail fold blood vessels may be abnormal clinically and on microscopy in the connective tissue diseases. Lewis and Pickering [4] found atherosclerotic changes in the digital arteries of patients who had underlying disease but not in patients with primary Raynaud's phenomenon. Digital arteries in post-mortem biopsies from patients who had died of systemic sclerosis exhibited severe intimal hyperplasia, consisting predominantly of deposits of collagen. This was sometimes accompanied by luminal narrowing and thrombosis. Diminution in the number of blood vessels, fibrosis and replacement of the dermis with collagen have also been demonstrated in systemic sclerosis. In addition, digital vasculitis has been reported in some patients with connective tissue diseases. Electron microscopy of finger-pulp biopsies from patients with a variety of underlying causes of Raynaud's phenomenon showed luminal narrowing associated with endothelial cell swelling and thickening of the basement membrane in the dermal capillaries [5]. The basement membranes of unmyelinated nerves were similarly affected, and there was marked degeneration of myelinated nerves. In nail fold biopsy specimens there was a decreased number of cutaneous nerve bundles and deposition of globular eosinophilic PAS (periodic acid–Schiff)-positive material in systemic sclerosis and mixed connective tissue disease [6]. The causes of Raynaud's phenomenon are listed in Table 23.5.

By immunohistochemistry, it has now been shown that patients with primary Raynaud's phenomenon and Raynaud's phenomenon secondary to systemic sclerosis and vibration white finger have a deficiency of sensorimotor CGRP-containing vasodilator neurones [7–9]. This is reflected in a decreased ability of these patients to produce a neurogenically mediated flare upon intradermal injection of ET-1 (intradermal injection of ET-1 induces pallor, i.e. vasoconstriction, immediately around the injection site and this is surrounded by an area of spreading flare, i.e. neurogenic vasodilatation).

In patients with vibration white finger there is a more profound neuronal loss than in primary or secondary Raynaud's phenomenon (systemic sclerosis), and this loss

Table 23.5 Causes of Raynaud's phenomenon.

Primary Raynaud's phenomenon (Raynaud's disease)
Secondary Raynaud's phenomenon
Trauma or vibration

Vinyl chloride
Nitroglycerin withdrawal
Heavy metals
Miscellaneous
Paraneoplastic syndrome
Chronic renal failure
Primary pulmonary hypertension
Hypothyroidism
Anorexia nervosa

is not confined to CGRP-containing nerves [9]. *In vivo* pharmacological studies in these patients have demonstrated decreased flare responses to intradermal injections of both ET-1 and histamine, findings consistent with the more widespread neuronal loss demonstrated by immunohistochemistry [10]. Immunostaining for ET-1 and endothelial nitric oxide synthase in the cutaneous blood vessels has not revealed any significant differences from normal in any of these patient groups. However, in patients with Raynaud's phenomenon, circulating ET-1 levels are elevated independently of vasospastic attacks, and are further increased in these patients and in patients with vibration white finger following cold challenge. The raised levels of ET-1 could be explained by the consideration that ET-1 is the product of a 'stressed' endothelium [11,12]. Raised circulating levels of von Willebrand factor protein (vWF, factor VIII-related antigen) have also been reported in patients with Raynaud's phenomenon, pointing to the 'stress' effect of cold on endothelium. The deficit of CGRP-containing vasodilator nerves means that the cold-induced vasoconstriction mediated by the direct action of ET-1 on the blood vessels is unopposed. Current evidence indicates that the CGRP-containing sensorimotor nerve fibres are concerned with cold nociception, controlling both reflex local (through antidromic release of peptides from perivascular fibres) and systemic (through their central sensory connections and projections) neurovascular responses. The precise quantitative contributions of the peptidergic and autonomic nervous systems to the production of the clinical features of Raynaud's phenomenon awaits further elucidation [10].

Previously, attention has also been focused on the blood. Changes have been found in circulating catecholamines [13], red cell deformability [14], blood viscosity, platelet aggregation and fibrinolysis [15]. These abnormal findings are chiefly encountered in patients with Raynaud's phenomenon secondary to connective tissue disease, and their relevance to the aetiopathology of Raynaud's phenomenon is uncertain.

Clinical features. Raynaud's disease (or Raynaud's phenomenon without apparent cause) is much commoner in women, in the proportion of at least 5 : 1. The age of onset is usually under 40 years, but it may occur over this age. The age and sex distribution of secondary cases is that of the underlying disease, and is not therefore so restricted to the female sex. Raynaud's disease affects the hands and, less often, the feet; changes elsewhere are exceptional, although the tongue can be involved [16], and primary pulmonary hypertension has been reported.

A typical attack consists of sudden pallor of one or more digits, followed after a few minutes by cyanosis or sometimes by erythema. In Raynaud's disease the condition is usually symmetrical and affects several digits. In Raynaud's phenomenon secondary to other vascular disease, only one or more digits may be involved, and asymmetry is not unusual. Such asymmetry can occur in primary Raynaud's disease. Attacks are usually precipitated by cold, either local or of the whole body, by pressure or by psychological stimuli. They may be very mild, and occur infrequently or many times each day. In severe cases, almost invariably of the secondary type of Raynaud's phenomenon, secondary changes may occur in the skin. These include telangiectases of the nail fold, thinning and ridging of the nail, and atrophy or sclerosis of the fingers (sclerodactyly). Gangrene is extremely rare in true Raynaud's disease, but not uncommon in the presence of organic arterial diseases or systemic sclerosis. The disease runs a variable course. In Raynaud's phenomenon secondary to vascular disease, the prognosis is that of the underlying disease, and extensive destruction of the digits may occur. In Raynaud's disease, the prognosis is good in 80% of cases, but progressive disability occurs in the remainder.

Diagnosis. The diagnosis of Raynaud's phenomenon can usually be made with ease on the basis of the history. Acrocyanosis is distinguished by the absence of the characteristic paroxysmal pallor.

Establishing the cause of Raynaud's phenomenon is less easy, but application of the modified criteria of Allen and Brown provides a good basis for the diagnosis of primary Raynaud's phenomenon. The history should exclude those cases due to vibration [17] and heavy metal or ergot intoxication. Buerger's disease and other organic arterial diseases are very rare causes of Raynaud's phenomenon. The secondary cases tend to show asymmetrical changes of later onset. In difficult cases, prolonged observation and arteriography may be needed. Neurovascular disorders around the thoracic outlet must be excluded in atypical cases and where asymmetry occurs. Such disorders require full neurological examination, observation of the effect on the pulse of movement at the shoulder girdle, and radiological investigation. However, the thoracic outlet syndrome and cervical rib are rare causes of Raynaud's phenomenon. An underlying neoplasm must be sought in any case with sudden onset in adult life, especially in men, and if gangrene supervenes [18].

The distinction between Raynaud's disease and the early onset of systemic sclerosis is sometimes difficult. Sclerodactyly may occur secondarily to vascular disease in the absence of systemic sclerosis, and histology does not distinguish between them. Raynaud's phenomenon is frequently the presenting symptom of systemic sclerosis, but if there are no other signs within 2 years of onset, systemic sclerosis is less likely to develop [19], although it is possible [20]. The presence of circulating autoantibodies (antinuclear, anticentromere and anti-Scl 70 antibodies) should be regarded as indicating the presence of a connective tissue disease until proven otherwise. Radiology of the oesophagus may provide evidence of systemic

sclerosis, in the form of aperistalsis. However, this may also occur in uncomplicated Raynaud's disease or in Raynaud's phenomenon secondary to lupus erythematosus, mixed connective tissue disease or dermatomyositis, in which Raynaud's phenomenon may be the presenting symptom. A search for cryoglobulins and cold agglutinins should be made (see below).

Treatment. Patients with primary Raynaud's phenomenon often respond to conservative measures, including the wearing of woollen gloves and sheepskin mittens (two layers are recommended rather than one), and avoidance of draughts and exposure to cold, wet and windy ambient climatic conditions. Battery-powered, electrically operated gloves are available but tend to be cumbersome. Smoking should be prohibited. When these measures are ineffective, the medications of choice are the calcium channel blockers nifedipine [21] (10–80 mg slow-release orally daily) or diltiazem (60–120 mg orally three times daily). When the adverse effects of these drugs are intolerable, topical vasodilators, such as 1–2% hexyl nicotinate [22] in aqueous cream, may be beneficial.

Therapy of more severe cases is far from satisfactory, although a large number of treatments have been used successfully in some cases. Conventional vasodilators are often tried. However, calcium channel blockers, such as nifedipine and diltiazem, are more satisfactory. The topical vasodilators glyceryl trinitrate [23] and hexyl nicotinate [22] have been used. Other drugs have included methyldopa [24], the serotonin antagonist ketanserin [25], fibrinolysis enhancement therapy with stanozolol [26] and even griseofulvin [27]. Oral administration or infusions of reserpine have been used for some years [28], and also low-molecular-weight dextran [29]. More recently, these have been superseded by infusions of prostaglandin E_1 [30,31], prostacyclin [32,33] and CGRP [34], or plasma exchange [35]. Fluoxetine may be useful in some patients [36].

Sympathectomy provides only moderate benefit in cases severe enough to warrant it, and only in those in which organic arterial disease or scleroderma can be excluded and in which changes secondary to long-standing spasm have not occurred. Cases with a pronounced neurogenic factor are helped, but the improvement is only temporary. Thoracoscopic sympathectomy has given encouraging results in a small series [37].

Treatment of secondary Raynaud's phenomenon is that of the underlying disease whenever possible.

The most important aspect of the management of occupationally induced Raynaud's phenomenon, such as vibration white finger, is prevention by reducing occupational exposure to vibration. In a small study to assess the efficacy of calcium channel blockers in the treatment of vibration white finger, patients who were treated with diltiazem for 18 months showed significant improvement in both vascular and neurological symptoms, and in objective *in vivo* pharmacological tests [38].

Cryoglobulinaemia [1–7]

Cryoglobulins are globulins precipitated from plasma or serum on cooling. Single-component cryoglobulins are composed of an immunoglobulin (IgG, IgM, IgA), and may be associated with myeloma, macroglobulinaemia and lymphoma, or occur as a primary or idiopathic form.

Mixed cryoglobulins are immune complexes of an IgG immunoglobulin with an antiglobulin, usually IgM, less often IgA or IgG. Small amounts may be found in normal persons and in many different diseases, sometimes only temporarily. These include the following.

1 Infections
  (a) Glandular fever
  (b) Hepatitis B
  (c) Syphilis
  (d) Borreliosis
  (e) Subacute bacterial endocarditis
  (f) Leprosy
  (g) Kala-azar
  (h) Hepatitis C
  (i) Human immunodeficiency virus (HIV)-1 infection
2 Autoimmune diseases
  (a) SLE
  (b) Rheumatoid arthritis
  (c) Sjögren's syndrome
  (d) Vasculitis
3 Lymphoproliferative diseases
  (a) Myeloma
  (b) Lymphoma
  (c) Macroglobulinaemia
4 Liver disease
5 Sarcoidosis.

Mixed cryoglobulins are found not infrequently in patients with vasculitis and in some patients with chronic urticaria; in such patients there is little indication that the cryoglobulins are responsible for the lesions (although they may activate complement), and aggravation by cold is usually not apparent [3].

Demonstration is relatively simple. Venous blood is drawn into a warm syringe and allowed to clot at 37°C. The serum (or plasma if cryofibrinogen is suspected) is cooled to 4–5°C and any precipitate noted. This should redissolve on warming. Rheumatoid factor is usually positive. More elaborate methods are required for quantitative studies and to determine the nature of the protein.

The amounts of cryoglobulin reported to cause symptoms are very variable: less than 25 mg/dL may rarely be associated with symptoms; much higher levels may be symptomless. Levels as high as 80 g/L have been recorded. Symptoms are most easily explained in terms of intravascular precipitation of cryoglobulins. They include purpura on exposed parts after cooling, patchy livedo reticularis, cold urticaria, Raynaud's phenomenon and atypical ulceration of the legs, even resembling a dermatitis artefacta. Haemorrhages from the nose, eyes and retinal vessels are not uncommon. Systemic symptoms include those of the underlying disease. Glomerulonephritis, arthralgia and fatigue are among the many manifestations. A search for all the known causes of cryoglobulinaemia is indicated, together with characterization of the nature of the cryoglobulin, before regarding the disease as primary or idiopathic. Treatment is unsatisfactory where the cause cannot be removed. Anticoagulants and corticosteroids have provided symptomatic relief in some cases. Plasmapheresis may be helpful.

Cryofibrinogenaemia [8,9]

Cryofibrinogenaemia occurs in a variety of different diseases, but has not often been associated with cold sensitivity. In idiopathic cryofibrinogenaemia, vascular lesions, purpura and even frank gangrene may occur. The cold-precipitated protein is found in plasma but not in serum.

Cold agglutinins [5,10]

Cold agglutinins are found in low titres in 95% of normal persons. They are increased in many diseases: virus infections, especially viral pneumonia and glandular fever; trypanosomiasis; lymphomas; disseminated lupus erythematosus; and haemolytic anaemias. They may also be elevated in the absence of any other disease. Abnormal titres range from 1 : 128 to 1 : 168 million. Symptoms, which most frequently occur in elderly people, include Raynaud's phenomenon, acrocyanosis and even gangrene. Cold urticaria is not usually part of the syndrome. Treatment is not satisfactory. Corticosteroids and anticoagulants have been reported as helping a proportion of cases.

Cold haemolysins [5,11]

SYN. PAROXYSMAL COLD HAEMOGLOBINURIA

Haemolysis after exposure to cold is typically associated with syphilis. However, cold haemolysis may occur in the absence of syphilis and may even be associated with a false-positive Wassermann reaction. Symptoms occur on rewarming, and include haemoglobinuria, fever and general systemic symptoms. Cold urticaria and Raynaud's phenomenon may also occur, and be the presenting symptoms. Antisyphilitic treatment helps some cases where syphilis is the cause, although the haemolysin itself usually persists. Treatment in other cases is unsatisfactory.

Cold urticaria

This disease is described in Chapter 47.

Cold erythema

This is one of the rarest of the diseases of hypersensitivity to the cold. Areas of erythema and pain occur after cold exposure. The lesions are transient, with a time course very similar to that of primary acquired cold urticarias. Cold erythema is considered to be a disorder related to cold urticaria but characterized only by erythema rather than erythema and wealing [1].

Treatment. The rarity of this condition has precluded controlled studies of potentially novel therapies, and prophylaxis remains the mainstay of therapy.

Other syndromes caused by cold

Neonatal cold injury

SYN. SCLEREMA NEONATORUM

This condition is discussed in Chapter 14.

Cold panniculitis

SYN. ADIPONECROSIS E FRIGORE

This term may be loosely used to describe a variety of clinical syndromes, notably perniosis. It has also been applied in a much stricter sense to a rare panniculitis with a much more clear-cut and reproducible reaction to cold exposure [1]. Firm plaques of fat necrosis on the chubby cheeks of young children have been described after exposure to cold. The lesions cleared up spontaneously without scarring [2].

Hypothermia

This may cause changes in the subcutaneous tissues (see Chapter 55) or may be induced by extensive inflammatory skin conditions (see Chapter 17).

Chapter 24

Cutaneous Photobiology

J.L.M. Hawk, A.R. Young & J. Ferguson

Basic principles of cutaneous photobiology

[A.R. Young, pp. 24.1–24.10]

Definition. Photobiology is the study of the effects of UV and visible radiation on living matter. Cutaneous (dermatological) photobiology is concerned with those effects on skin.

Ultraviolet radiation (UVR), its production and measurement

The nature of UVR [1]

UV and visible radiation, which comprises a very small part of the electromagnetic radiation spectrum (Fig. 24.1), is energy released during the transition of a molecular electron from a higher energy outer molecular orbital to a less energetic inner one. Each such emission, known as a photon, is a discrete oscillating electromagnetic pulse of energy E (joules, J), wavelength λ (nanometres, nm, 10^{-9} m) and velocity through space c (3×10^8 m/s), such that $E = hc/\lambda$, where $h = 6.63 \times 10^{-34}$ J/s (Planck's constant) (Fig. 24.2). Thus, a 300-nm photon has energy 6.63×10^{-19} J, where 1 J is defined as the work required to accelerate 1 kg over 1 m in 1 s to a velocity of 1 m/s in a frictionless environment. Repeated molecular emissions from a point source lead to multiple spherical radiation wavefronts, each of total energy equal to the sum of the individual photon energies, but diverging with gradually diminishing intensity per unit surface area. The amount of such energy incident on a surface is known as the radiant exposure, exposure dose or fluence (J/m^2, formerly mJ/cm^2), and the rate of incidence as the irradiance, dose rate or intensity (W/m^2, formerly mW/cm^2), where 1 W = 1 Watt = 1 J/s.

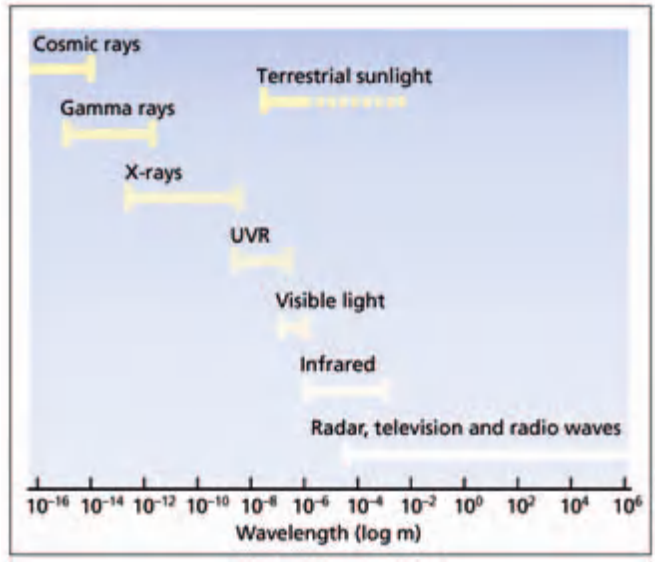

Fig. 24.1 The electromagnetic spectrum.

The UVR spectrum, 100–400 nm, comprises three wavebands: UVC (100–280, commonly but less precisely, 200–290 nm), UVB (280–315 nm, 290–320 nm) and UVA (315–400 nm or 320–400 nm); visible light is 400–700 nm.

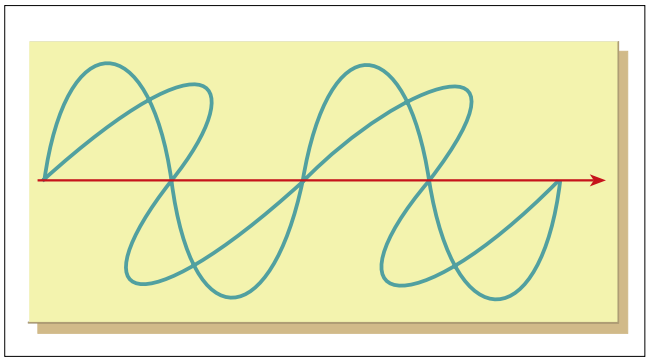

Fig. 24.2 Schematic representation of electromagnetic wave.

UVA has recently been subdivided into UVA-I (340–400 nm) and UVA-II (320–340 nm) because, biologically speaking, the effects of UVA-II are more like those of UVB.

Sources of UVR [2–4] (Fig. 24.3)

UVR is emitted spontaneously in large amounts by the sun and other stars. Terrestrial sunlight, modified by the Earth's atmosphere, contains both UVB and UVA. At noon, when the sun is high in the sky, the UVB content is approximately 5% and UVA accounts for the remaining 95%. However, when the sun is lower, early or late in the day, the UVA content is even higher. UVR is also produced by artificial sources, the most common in dermatological photobiology being gas discharge lamps, glass or quartz columns containing molecules of mercury vapour or xenon gas; these are excited to emit UVR by constant collisions with electrons passed through them between electrodes. The simplest are low-pressure mercury arc lamps emitting 254 nm UVC radiation, which are useful in limited fashion for research and germicidal purposes. Alternatively, alkaline earth phosphor coatings may convert these into reliable broad-spectrum UVB or UVA fluorescent tubes, commonly used for phototherapy or basic cutaneous phototesting.

More compact and of higher output, however, are medium-pressure mercury lamps, which emit a discrete spectrum of wavelengths ranging from the UVC to the infrared; but these require cumbersome power supplies and are relatively inefficient. Hence, they are now rarely used except for occasional localized UVB phototherapy (Alpine and Hanovia sunlamps), contact UVB and UVC phototherapy (Kromayer lamp) and fluorescence diagnosis (Wood's lamp).

The powerful high-pressure xenon arc lamp, although also bulky, when appropriately filtered has a smooth, broad, approximately solar-simulating emission throughout the whole UVR, visible and infrared wavebands, and is thus increasingly used in solar simulators for clinical investigation and research. Outside photobiology, fluorescent visible tubes, regularly used for room lighting, emit moderate amounts of UVA but minimal UVB, whereas incandescent tungsten light bulbs produce only trivial quantities of each, apart from the brighter quartz halogen type, which can produce considerably more.

Optical components for the modification of UVR [5]

The intensity, spectral content and direction of propagation of a UVR beam may be modified for photobiological purposes by systems of lenses, mirrors, filters and radiation-dispersing elements. The most complex of these, used particularly for precise cutaneous phototesting, is the irradiation monochromator, comprising a high-pressure xenon arc source, radiation focusing lens or

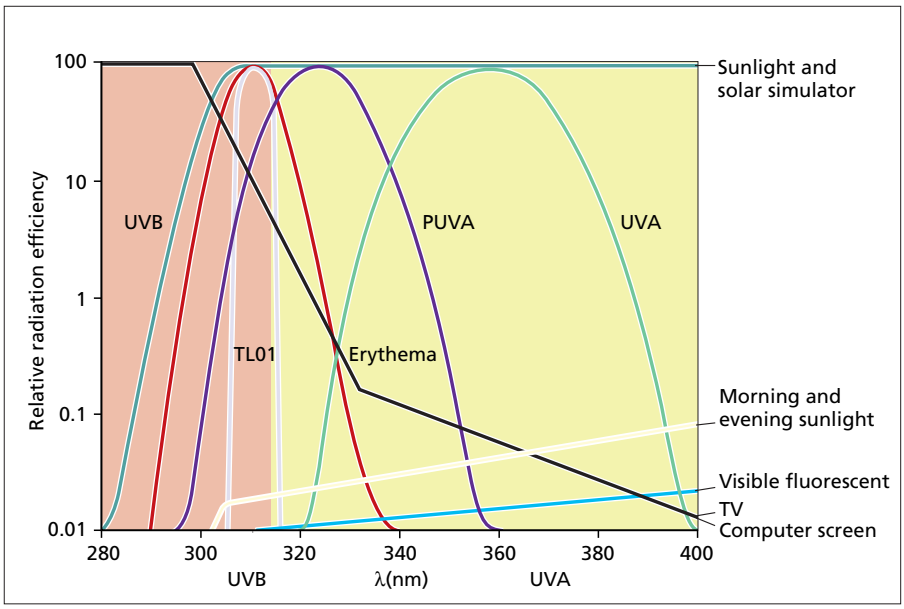

Fig. 24.3 Approximate emission spectra of typical sources encountered in dermatological photobiology and elsewhere, with action spectrum for human cutaneous erythema for comparison.

mirror, entrance aperture, collimating mirror, dispersing prism or grating, telescope mirror and exit aperture, from which emerges a selected narrow adjustable radiation waveband onto the skin.

Dosimetry (radiometry) of UVR [6,7]

For measurement purposes, radiation energy from a particular spectral region of interest, such as that for erythema or photochemotherapy with psoralen and UVA (PUVA) for treatment of psoriasis, is converted into electrical energy for meter readout. The total irradiance over such a waveband is assessed by means of an instrument known as a radiometer, made up of a radiation filter, input optics and a detector, whereas that at specific wavelengths, known as the spectral irradiance, is measured with the much more complex spectroradiometer, which includes a monochromator instead of a filter; the radiation dose is then calculated as the product of the measured irradiance and the exposure time in seconds. Spectroradiometric measurements are necessary to characterize emission spectra used for research purposes. These instruments have a dynamic range over several orders of magnitude, which can identify 'contaminating' radiation (e.g. UVB in a supposedly UVA source) that may be biologically important. There are a number of different types of radiation detector—four employed in dermatological photobiology are the variable spectral response photomultiplier tube, the vacuum phototube and the solid-state photodiode (all converting photon energy directly into electrical energy), and the uniformly responsive thermopile (which transforms it into heat first). Photomultiplier tubes are very sensitive but fragile, and therefore useful in spectroradiometers for accurate work, whereas the less responsive vacuum phototubes and solid-state photodiodes are more robust, small and suitable for rapid portable radiometry, for example of phototherapy equipment; thermopiles, on the other hand, which are also small and robust but have flat spectral responses, are best for the quick accurate measurement of monochromatic irradiances, or of serial broad-band irradiances of fixed spectral content.

UVR interactions with matter

General [1–5]

Radiation incident on a surface is either reflected, or transmitted and scattered within the medium beneath, particularly at short wavelengths, by collision with the contained particles. It then eventually exits, unless it first collides with and is absorbed by an appropriately structured molecular moiety, known as a chromophore (Fig. 24.4). Any of a broad range of contiguous wavelengths, each representing equivalent photon energies, the so-called absorption spectrum, may be absorbed, with slightly differing probabilities (Fig. 24.5), leading to electronic excitation to an outer, higher energy molecular orbital (Fig. 24.6), enabling chemical reactions to occur and leading to possible clinical consequences such as skin sunburning, photoageing or cancer. More usually, however, the electron rapidly returns to its resting state, accompanied by harmless, longer wavelength radiation re-emission.

UVR interaction with atmosphere [6,7]

Solar radiation incident upon the Earth's atmospheric envelope is either reflected, or transmitted and attenuated, principally by gas molecule and water droplet scattering at wavelengths above 330 nm, by stratospheric ozone absorption between 200 and 330 nm, and by oxygen absorption below 200 nm. Extraterrestrial sunlight intensity is thereby reduced to about 1350–900 W/m^2 at the Earth's surface, comprising around 450 W/m^2 for visible

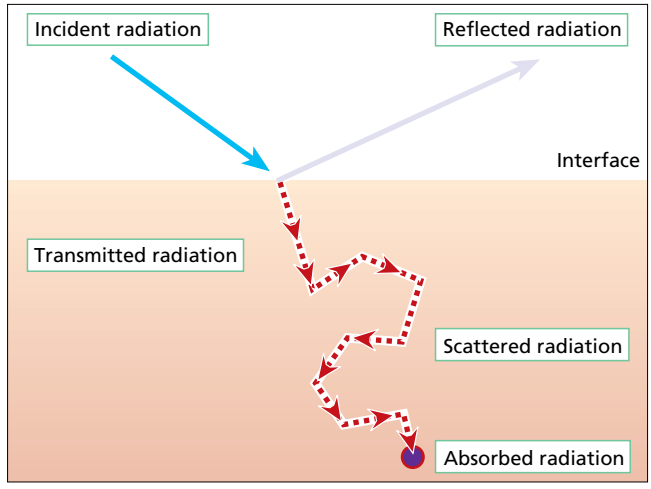

Fig. 24.4 Interaction of UV radiation (UVR) with physical matter.

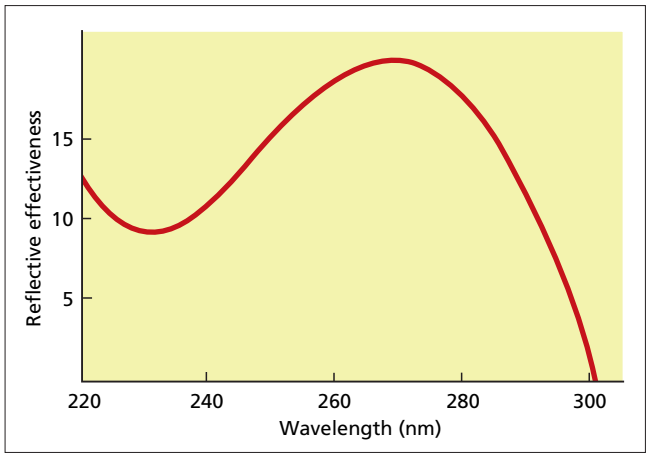

Fig. 24.5 Typical appearance of wavelength probability curve for excitation of orbiting electron to outer electronic orbital (absorption spectrum).

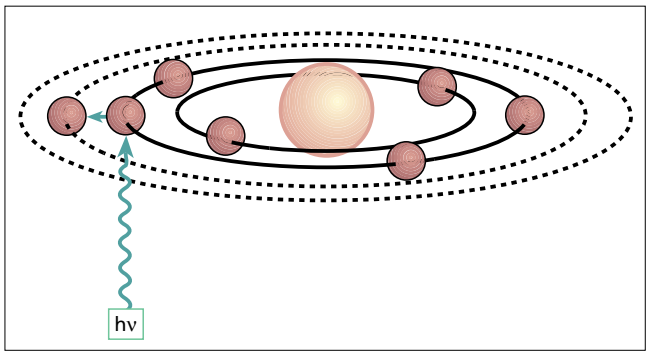

Fig. 24.6 Schematic representation of photon absorption, leading to excitation of orbiting electron to outer electronic orbital.

light, up to about 40–50 W/m^2 for UVA and 2 W/m^2 for UVB, and the remainder for infrared.

UVR interaction with sunscreens [8–10]

Sunscreens are topical preparations that attenuate UVR intensity by reflecting or absorbing it, or both. Reflectant sunscreens remit both UVB and UVA from a film of inert mineral oxide particles, usually zinc oxide or titanium dioxide in a suitable vehicle, whereas absorbent products absorb it into specific chemicals and re-emit it as harmless quantities of visible light or heat; combination preparations are a mixture of the two.

UVR interaction with skin [1–3,11–14]

Approximately 5% of the UVR incident on skin is diffusely reflected, the remainder being transmitted, scattered and absorbed, or passed out of the medium (Fig. 24.4) [2,8]. Thus, transmitted radiation below approximately 300 nm is largely attenuated within the epidermis by chromophores such as urocanic acid, DNA, RNA, tryptophan, tyrosine and melanin, whereas dermal DNA, RNA and the amino acids in elastin and collagen presumably absorb any radiation that passes through the epidermis. At approximately 300 nm and above, UVR is more readily transmitted to the dermis, after initial variable absorption by epidermal chromophores, followed by reflection back from dermal collagen bundles to the environment; in addition, minor absorption by intravascular haemoglobin, tissue bilirubin and β-carotene in fat is possible.

DNA is almost certainly the most important skin chromophore, UVR-induced lesions potentially severely inhibiting cellular metabolism or leading to mutation or cell death by apoptosis or necrosis. DNA photoproducts include cyclobutane pyrimidine dimers (CPD), pyrimidine (6–4) pyrimidone and Dewar photoproducts, DNA hydration products, DNA–protein and DNA–DNA cross-links, and thymine glycols, all of which are largely but not necessarily completely repaired by specific enzymatic processes. DNA photolesions in the epidermis, such as CPD, can be readily detected *in vivo* after suberythemal and erythemal UVR exposures.

Environmental exposure to UVR [1–3]

The sun is the principal source of environmental UVR. Recently, the standard erythema dose (SED) has been advocated as the best means of quantifying UVR exposure. A SED is equivalent to an erythemally effective exposure of 100 J/m^2 and is independent of individual sensitivity to UVR and the specific UVR spectrum. An exposure of 2–4 SEDs would be expected to produce a mild sunburn on previously unexposed skin. Indoor workers in northern Europe receive about 200 SEDs/year, which is approximately 5% of the total available ambient radiation. Of this annual dose, 50% is received in just 33 days of the year. Outdoor workers would be exposed to 400–600 SEDs/year. Children spend more time out of doors and it is estimated that those in the UK receive an annual dose of about 300 SEDs. Behaviour is a major determinant of UVR exposure such that it is possible for children in the UK to have higher solar exposure levels than in Queensland, Australia [3]. Various studies have shown that approximately 10% of the UK population has had UVR exposure from sunbeds and other tanning devices. Other artificial sources may also be important; some indoor workers are significantly irradiated by, for example, arc welding devices and hospital phototherapy equipment. Office workers and home dwellers may be at risk from low-intensity UVR from fluorescent or, more importantly, quartz halogen lamps used for indoor lighting.

Prophylactic measures to minimize human cutaneous UVR exposure [1]

Restriction of skin exposure to direct sunlight is advisable when UVR intensity is high, such as following short atmospheric radiation transit at times around the solar zenith, particularly at high altitudes, low latitudes and in summer (Fig. 24.7); furthermore, because much of this UVR is incident from areas of blue sky as a result of normal atmospheric molecular and aerosol scattering, exposure to sky light should also be minimized at such times. Finally, as UVR intensity is increased by reflection from snow by up to 85%, sand by 25% and rippling water by perhaps 5%, but decreased by only 20–90% by cloud cover and 60% for every 50 cm travelled through water, extra care should also be taken when these factors apply, particularly in alpine areas or near the sea. Radiation intensity is not, however, significantly altered by any accompanying heat, cold, wind or visible light.

Clothing consisting of close-weave, loose-fitting material covering as much of the skin as fashionably acceptable is further invaluable protection against UVR exposure and if opaque to visible light is generally protective against UVR as well; in particular, broad-brimmed headwear is useful for the face and scalp.

In addition to these measures, the regular adequate prophylactic application of high-protection, absorbent, reflectant or combination sunscreens is helpful in minimizing the short- and possibly long-term effects of cutaneous UVR exposure [2–8]. Absorbent products have traditionally been the most popular; they act well against UVB and are also cosmetically satisfactory, although cutaneous irritation and contact or photocontact dermatitis are possible hazards [3,4]. For the UVA-induced photodermatoses and very photosensitive normal subjects, however, the relatively inert, mineral oxide-containing reflectant preparations, although less cosmetically appealing, have been preferred, as they are less irritating and less liable to cause contact sensitivity, as well as being very effective against both UVB and UVA. Recently, new, increasingly effective UVA absorbers such as the dibenzoylmethanes and terephthalylidene dicamphor sulphonic acid have significantly improved absorbent screen efficacy [9], and micronized reflectant particles, although recently giving rise to temporary minor concerns about possible photodegradation and cutaneous absorption, have increased reflectant preparation acceptability, thus improving choice. Combination preparations have also become more common, and appear to

provide optimal cover in all circumstances except severe UVA photosensitivity.

The efficacy of a sunscreen is determined by its ability to afford protection against erythema, which is primarily caused by solar UVB but with some contribution (15–20%) by UVA. The measure of protection, assessed under controlled laboratory conditions, is known as the sun protection factor (SPF) [3,4] and is the multiple by which UVR exposure may be increased, after sunscreen application, before burning begins. One requirement of SPF assessment is the application of 2 mg/cm^2 skin. However, several studies have shown that people typically apply less than half this concentration and so will receive a much lower level of protection than indicated by the SPF on the label [2]. Attempts have also been made formally to assess UVA protection alone, as these wavelengths are important at high doses and in many photodermatoses, but no internationally agreed method has yet been found [3]; however, many UK sunscreens display a rough guide [10], denoted as an approximate proportion of the protection offered against UVB. High SPF (15–25) products providing substantial UVA protection are suitable for all purposes, particularly the photodermatoses, but many have a mild propensity to induce contact sensitization and appear white on the skin [3,4], so that lower levels of protection (10–15) may sometimes be more satisfactory for normal, particularly darker, skins and moderate exposures. Sunscreen resistance to removal by water, known as 'substantivity', may also be quantified in terms of its rate of loss of efficacy on submerged skin [3]. Highly substantive preparations are clearly preferable in circumstances where they may be washed or rubbed off.

In the UK, certain highly protective sunscreens may be prescribed as so-called 'borderline substances' for the treatment of abnormal photosensitivity, the exact choice depending on the circumstances in which the preparation is to be used (Table 24.1).

Systemic effects of UVR exposure in humans

Solar radiation is essential for life and the provision of human well-being, offering warmth, illumination and nourishment from plant photosynthesis. However, the UV component of such radiation does not appear necessary. Thus, various past claims of reduced minor illness and improved work rates following UVR exposure have not been substantiated [1–3] and, although UVR exposure is known to induce some systemic change, for example increasing circulating vitamin D concentration [4] and modifying blood immunological function [5], the widely claimed mood-enhancing and health-giving properties of sunlight [6], if they exist at all, seem more likely to be mediated through visible irradiation effects on the eye.

Normal cutaneous effects of UVR exposure

Early effects

Inflammation

UVR absorption by skin chromophores leads to widespread epidermal and dermal cellular damage, which is associated with inflammation [1]. DNA is probably the primary molecular target of injury [2], as a result of both direct UVB absorption and also secondary UVA-induced photosensitization reactions. Nuclear transcription factors and cytokine production are also induced at this stage [3,4], very likely by the same DNA damage [5], leading to increased production of serum and epidermal interleukins [3], with consequent cellular adhesion molecule activation [6], mild neutrophil and moderate mononuclear cell infiltration [7], and the release of various inflammatory mediators, such as prostaglandin E_2 and nitric oxide

Table 24.1 Sunscreens currently available in the UK for prescription as borderline substances; note, however, that formulations may be regularly altered.

Sunscreen*	Active ingredients	Spectral efficacy
Delph Lotion SPF15	Ethylhexyl *p*-methoxycinnamate 7.5% Oxybenzone 3.0% Titanium dioxide 0.6%	Moderate UVB, moderate UVA
Delph Lotion SPF20	Ethylhexyl *p*-methoxycinnamate 7.5% Oxybenzone 3.0% Titanium dioxide 1.6%	Moderate UVB, moderate UVA
Delph Lotion SPF25	Ethylhexyl *p*-methoxycinnamate 3.5% Oxybenzone 1.3% Avobenzone 4.0% Titanium dioxide 2.1%	Good UVB, good UVA
Delph Lotion SPF30	Ethylhexyl *p*-methoxycinnamate 4.8% Oxybenzone 1.5% Avobenzone 4.0% Titanium dioxide 2.5%	Good UVB, good UVA
E45 Sun Block lotion SPF25	Zinc oxide 13.9% Titanium dioxide 3.6%	Good UVB, good UVA
E45 Sun Block lotion SPF50	Zinc oxide 16.0% Titanium dioxide 6.4%	Very good UVB, very good UVA
RoC Total Sunblock cream SPF25	Octyl methoxycinnamate 7.5% Butyl methoxydibenzoylmethane 2.0% Titanium dioxide 5.5%	Good UVB, good UVA
SpectraBan Alcoholic solution SPF25	Octyldimethyl *p*-aminobenzoic acid 3.2% *p*-aminobenzoic acid 5.0%	Good UVB, minimal UVA
SpectraBan Ultra lotion SPF28	Butyl methoxydibenzoylmethane 2% Oxybenzone 3% Octyldimethyl *p*-aminobenzoic acid 8% Titanium dioxide 2.0%	Good UVB, good UVA
Sunsense Ultra lotion SPF60	Octyl methoxycinnamate 7.5% Oxybenzone 3.0% Titanium dioxide 3.0%	Very good UVB, good UVA
Uvistat Cream SPF20	Ethylhexyl *p*-methoxycinnamate 7.0% Butyl methoxydibenzoylmethane 4% Titanium dioxide 4.5%	Good UVB, good UVA
Uvistat Cream SPF30	Ethylhexyl *p*-methoxycinnamate 7.5% Butyl methoxydibenzoylmethane 4% Titanium dioxide 6.5%	Good UVB, very good UVA

* Trade names.

[8]. Clinically, erythema, pain, warmth and, in severe cases, swelling and loss of function, develop over hours to days. These changes are accompanied histologically by epidermal spongiosis and, except after UVA, the formation of sunburn cells (apoptotic cells) [9], along with dermal vasodilatation, oedema and neutrophil and mononuclear cell infiltration [7]. UVR wavelengths around 300 nm are the most DNA damaging and erythemogenic [2]. The lowest dose to induce erythema is known as the minimal erythema dose (MED), and is around 500 J/m^2 for the UVC–UVB boundary (280 nm), 250 J/m^2 for UVB (300 nm) and 320 kJ/m^2 for UVA (360 nm) (Fig. 24.8).

Avoidance of sunburn requires restriction of UVR exposure, covering up with appropriate clothing and the use of high-SPF sunscreens. If burning occurs in spite of these precautions, treatment is largely symptomatic, and involves the administration of oral fluids, particularly in severe cases, the application of soothing topical emollient creams or evaporating lotions and, more actively, the use of topical or oral non-steroidal (or perhaps occasionally steroidal) anti-inflammatory agents from the earliest onset of symptoms. On rare occasions, sunburning may be severe or life-threatening and then requires treatment as for thermal burns.

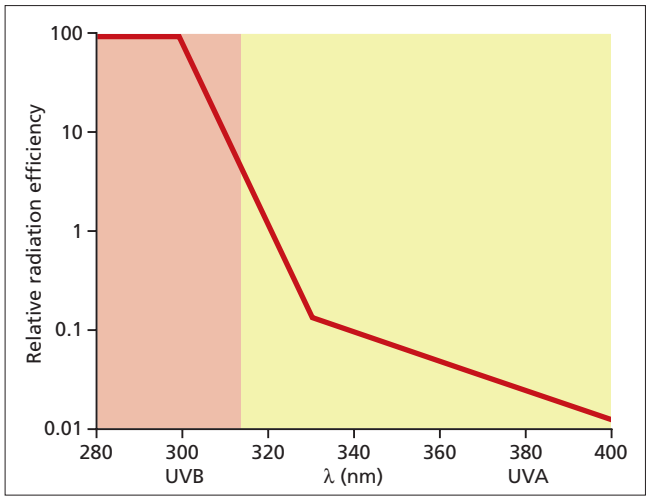

Fig. 24.8 Action spectrum for induction of erythema in human skin.

Tanning

Immediate

Immediate, often greyish, tanning of irradiated skin, lasting for a minute or so up to hours, may occur within seconds of exposure to 20–120 kJ/m^2 of UVA, and perhaps also short-wavelength visible radiation, particularly in more pigmented subjects. This probably results from photo-oxidative darkening and cellular redistribution of epidermal melanocytic melanin, although sunburning sensitivity is not apparently decreased by this response; however, supranuclear melanin caps present in strategically important basal layer cells may protect vulnerable genetic sites.

Delayed

Delayed (facultative) tanning of irradiated skin, persisting for weeks to months, gradually appears over hours to days after cutaneous exposure to around 400 J/m^2 of broad-band UVB (somewhat greater than the MED, particularly in fair-skinned subjects), 150–200 kJ/m^2 of broad-band UVA (somewhat less than the MED) or 100 J/m^2 of UVC (about equal to the MED). The mechanism of such tanning is uncertain, but tyrosinase activation by nucleotide residues from sites of UVR-induced melanocytic DNA damage appears likely to initiate the process [10], thus leading to new melanin production and its transfer from melanocyte dendrites to adjacent keratinocytes. Melanocyte size, dendritic arborization and enzyme activity are also increased during this process and, in addition, quiescent melanocytes are activated and new melanocytes recruited by cell division. Sunburning sensitivity in white subjects is thereby moderately decreased by about two- to fourfold [11].

Hyperplasia

Skin hyperplasia persisting for a month or two develops over hours to days following UVB or UVC (but generally not UVA) exposure, and results from a marked increase in cell mitosis, DNA, RNA and protein synthesis rates, after some hours of early inactivity. The stimulus for this is unknown but, as for tanning, may conceivably be UVR-induced cellular DNA damage. The epidermis and dermis, particularly the inert stratum corneum, thicken as a result by up to two to four times, thereby apparently giving some protection against subsequent UVR-induced inflammation, an effect that combines with and may perhaps supersede the concomitant protection from tanning, particularly in fair-skinned races.

Immunological changes

The skin is a major immunological organ in which the dendritic Langerhans' cells in the epidermis normally present antigens to naïve T cells. It is now well established that UVR has profound effects on skin immunity that are mediated by alterations to the antigen-presenting capacity of Langerhans' cells and the stimulation of abnormal antigen presentation by CD11b macrophages [12]. These alterations are the result of UVR-induced changes to the chemical microenvironment of the skin, in particular the cytokine profile [4].

UVR has been shown to inhibit the induction and elicitation phases of the contact hypersensitivity response in mice and in humans. Mouse studies have shown that UVR-induced immunosuppression has a major role in skin cancer and susceptibility to infectious agents, and a similar role is suspected in humans. Recent studies have shown that a single suberythemal exposure of solar simulated radiation (SSR) suppresses the induction phase of the contact hypersensitivity response in sun-sensitive skin types I/II (Table 24.2). An erythemal exposure was necessary to give a comparable level of immunosuppression in sun-tolerant skin types III/IV and this difference may be a factor in the differing susceptibilities of skin types I/II and III/IV to skin cancer [13]. The most likely chromophores for the immunomodulatory effects of UVR are DNA and stratum corneum-bound urocanic acid which undergoes a *trans* to *cis* isomerization in the presence of UVR. The ability of sunscreens to prevent UVR-induced immunosuppression is a controversial issue that is in the process of being resolved [14].

Vitamin D synthesis

UVB irradiation, most efficiently in moderate doses, rapidly converts epidermal 7-dehydrocholesterol into previtamin D_3, which is then isomerized over several days to vitamin D_3, and transported by plasma vitamin D-binding protein into the circulation [15].

Table 24.2 Acute and long-term characteristics of different skin phototypes.

Skin type	Susceptibility to sunburn	Constitutive skin colour	Facultative tanning ability	Susceptibility to skin cancer
I	High	White	Very poor	High
II	High	White	Poor	High
III	Moderate	White	Good	Moderate
IV	Low	Olive	Very good	Low
V	Very low	Brown	Very good	Very low
VI	Very low	Black	Very good	Very low

Photo-onycholysis

A few subjects develop recurrent, probably UVA-induced, photo-onycholysis of nails exposed to strong sunlight, conceivably from photosensitization by endogenous photoactive cutaneous substances such as porphyrin in the presence of high-intensity UVA exposure, a process probably similar to those operating in drug- or porphyria-associated photo-onycholysis [16].

Late effects

Pseudoporphyria

Regular skin exposure to the predominantly UVA radiation from sunbeds, or perhaps also to strong sunlight during the use of high-protection UVB sunscreens, may lead over weeks or months to largely reversible cutaneous blistering and fragility, as well as to superficial atrophic scarring, as occurs in the hepatic porphyrias, particularly in fair-skinned subjects [17]. This may conceivably be the result of photosensitization by endogenous photoactive cutaneous substances such as porphyrin in the presence of high-intensity UVA exposure, a process probably similar to those operating in drug-associated pseudoporphyria and the hepatic porphyrias.

Photoageing

Skin photoageing is the gradual deterioration of cutaneous structure and function following long-term recurrent exposure to sunlight or artificial UVR sources. These events are superimposed on intrinsic chronological skin ageing [18]. The epidermis and dermis are both affected, probably principally by UVB, but the dermis may be affected to some extent by UVA. Cutaneous fine and coarse wrinkling, dryness, coarseness, telangiectasia, yellowness, mottled pigmentation, laxity, loss of tensile strength and comedones are characteristic. Histologically, there is a mild inflammatory infiltrate and profuse upper dermal accumulation of a form of amorphous degenerate elastic tissue, known as elastosis. *In vivo* studies provide evidence for an important role for UVR-induced matrix metalloproteinases, which degrade collagen, the major structural protein of the dermis [19]. Restriction of UVR exposure and the use of high-SPF broad-spectrum sunscreens may slow progression of this process [18], and long-term use of the topical retinoid all-*trans* retinoic acid [18,19], and to a lesser extent of α-hydroxyacid preparations, may improve any changes already present.

Photocarcinogenesis

Human epidemiological and animal studies strongly suggest that chronic cutaneous UVB and, to a lesser extent, UVA exposure are responsible for the induction of most non-melanoma skin cancers, and probably of melanomas as well, although it has been suggested that UVA may play a relatively more important part in the latter [20]. A number of UVR-induced cutaneous events appear to be important, including the mutation of the *p53* tumour suppressor gene [21], and possible alterations in immune surveillance (as apparently occur in exaggerated fashion in the skin cancer-prone disorder xeroderma pigmentosum), appear aetiologically important. Restriction of UVR exposure, the use of appropriate clothing and the application of high-SPF sunscreens prevent actinic keratoses [22] although, overall, the evidence that sunscreen use prevents skin cancer is not impressive [23,24], perhaps because of less than assiduous use or excessive UVR exposure. In addition, long-term topical use of the retinoid tretinoin may perhaps very slowly improve actinic keratoses, and topical 5-fluorouracil cream and liquid nitrogen cryotherapy are very effective in the rapid treatment of these lesions. However, for fully developed skin cancers treatment with surgery or radiotherapy is required (see Chapters 76–78).

Skin phototypes

An individual's genetically determined cutaneous sunburning and tanning tendency following UVR exposure may be roughly graded by self-assessed skin phototype (Table 24.2) [25,26]. This assists in the determination of safe but effective regimens for phototherapy and photochemotherapy, as well as an individual's susceptibility to sunburn and skin cancer, and thus the degree of photoprotection required. In general, MED increases with skin type, but there is considerable overlap between skin types, such that a skin type I may have the same MED as a skin

type IV [27]. Thus, although broadly useful, skin type assessment is only a guide.

Abnormal cutaneous effects of UVR exposure: the photodermatoses

Acquired disorders with a probable immunological basis (Table 24.3)

Polymorphic light eruption

[J.L.M. Hawk, pp. 24.10–24.14]

Definition. Polymorphic light eruption (PLE) is a common intermittent sunlight or artificial UVR-induced eruption, particularly of temperate regions, affecting subjects of any race within hours or rarely days of exposure. The rash is non-scarring, itchy, erythematous and usually papular, although it is sometimes plaque-like, vesicular, bullous or mixed. It usually affects exposed skin, but may occur on covered areas, and lasts for days to a week or two after exposure has ceased. It is most common in young women, is often worse in spring, and is probably a delayed-type hypersensitivity reaction against endogenous cutaneous photoantigen as a result of a genetically determined reduction in UVR-induced cutaneous immunosuppression.

Aetiology. The eruption of PLE is induced by UVR [1], and perhaps also rarely by visible irradiation [2], whether from sunlight or artificial sources, including sunbeds [3]. However, bright summer sunlight in temperate climates is generally the trigger. Artificial induction is difficult, although not infrequently achievable through solar-simulated exposures [4,5]. The evoking action spectra have not been precisely determined, apparently varying between patients, but typical lesions have followed broadband UVB [6–8], UVA [9,10] and, very rarely, visible [2] irradiation. Monochromatic induction is more difficult, but lower than normal MEDs or abnormal papular responses occur in rather more than half of exposed patients [1], and evaluation of the literature suggests around one-quarter of patients overall may be sensitive to just UVB, one-quarter to both UVB and UVA, and half to just UVA.

PLE appears to have a largely genetic basis, affecting the families of patients some three times more commonly than the general population, and both of some 70% of identical but only 30% of non-identical twins [11]. As only up to approximately 20% of the population express the disorder, however, environmental factors [11] and penetrance of the affected allele [12] are also apparently important.

It was long thought that PLE was a delayed-type hypersensitivity (DTH) reaction against UVR-induced cutaneous antigen. Sequential skin biopsies following

Table 24.3 Distinguishing features of some acquired photodermatoses.

Disease	Clinical features	Specific investigations (in all cases estimation of circulating antinuclear antibodies and extractable nuclear antigen and screening for blood, urine and stool porphyrins is advisable)	Differential diagnosis	Treatment (in all cases restriction of UVR exposure, wearing of protective clothing and use of high-protection broad-spectrum sunscreens is advisable)
Polymorphic light eruption	Very common, affects mostly young women in temperate climates. Intermittent, summer sun-induced, non-scarring, erythematous, itchy, symmetrical, papular eruption of usually only some exposed areas. Onset in hours, resolution in days. Examination in remission normal	History most important in diagnosis. Histology useful in uncertain cases. Direct immunofluorescence negative. Solar or solar-simulated irradiation may induce rash. Broad-band UVB and UVA, or monochromatic, irradiation tests may also help, but only sometimes abnormal. Lupus must be excluded by serology	Persistent lymphocytic infiltrations, e.g. Jessner's; solar urticaria; lupus erythematosus and other light-exacerbated dermatoses; erythropoietic protoporphyria	Prophylactic, low-dose broad- or narrow-band UVB or PUVA; short-course, topical, oral or injected steroids; ciclosporin or azathioprine in intractable disease
Actinic prurigo	Rare, affects mostly girls and adult females, may persist indefinitely. Chronic UVR-induced, papular or nodular eruption, itchy, symmetrical, excoriated, most severe on exposed areas; fades towards covered sites, may affect buttocks a little. Worse in summer, may flare after sun exposure. Superficial scarring of face possible. PLE may accompany. Probable persistent variant of PLE	Clinical features most important. Broad-band UVB and UVA, or monochromatic, irradiation tests sometimes abnormal. HLA tissue typing for DRBI *04(07) helpful if positive	PLE; nodular prurigo; atopic prurigo; insect bites; atopic eczema; scabies; erythropoietic protoporphyria	Topical steroids or occasionally intermittent oral steroids and emollients; low-dose UVB or PUVA; intermittent oral thalidomide, with care to avoid pregnancy and peripheral neuropathy, in severe, unresponsive cases
Hydroa vacciniforme	Very rare. Affects mostly children, often remits in adolescence. Intermittent, summer sun-induced, painful, scattered or confluent, symmetrical, vesicular eruption of some or all exposed areas. Onset in hours, crusting in days, disfiguring pock scars in weeks	Clinical features most important. Histology usually characteristic. Solar simulated, broad-band UVB or especially UVA irradiation may induce rash, monochromatic irradiation a UVA erythema. Viral and porphyrin studies negative	Xeroderma pigmentosum; erythropoietic protoporphyria; PLE; actinic prurigo; herpes simplex	Largely intractable; high-protection, broad-spectrum sunscreens most often useful; prophylactic, low-dose UVB or PUVA may help; hydroxychloroquine reported effective, but questionable
Solar urticaria	Rare. Affects all ages, both sexes. Intermittent, UVR- or visible light-induced, non-scarring, wealing eruption of some or usually all exposed areas. Onset in 5–10 min, resolution in 1–2 h. Often perennial. Very rarely associated with lupus erythematosus, drug or chemical use, erythropoietic protoporphyria. Examination in remission normal	Clinical features important. Broad-band UVB, UVA or visible, or monochromatic, irradiation usually elicits rash, defines action spectrum	PLE; drug- or chemical-induced photosensitivity; erythropoietic protoporphyria; other urticarias	High-dose, non-sedating antihistamines; prophylactic PUVA; induction of tolerance by recurrent exposure to action spectrum wavelengths; plasmapheresis
Chronic actinic dermatitis	Rare. Affects mostly elderly men, often outdoor enthusiasts. Chronic, UVR- and sometimes also visible light-induced, itchy, excoriated, lichenified or pseudolymphomatous, eczematous eruption, especially of exposed areas, sometimes generalized. Worse in summer, may flare after sun exposure. Allergic, especially airborne, contact dermatitis and endogenous eczema may coexist	Broad-band UVB, UVA or visible, or monochromatic, irradiation elicits eruption, defines action spectrum, necessary for diagnosis. Histology often characteristic. Patch and photopatch tests frequently positive to exacerbating allergens. $CD4^+$: $CD8^+$ T-cell ratio reduced in skin and circulating blood, particularly in florid cases	Atopic eczema; seborrhoeic eczema; other forms of endogenous eczema; allergic, especially airborne, contact dermatitis; cutaneous T-cell lymphoma; other forms of erythroderma	Topical steroids and emollients; high-protection, broad-spectrum, non-irritating sunscreens; intermittent oral steroids; intermittent immunosuppressive therapy with azathioprine, ciclosporin or mycophenolate; PUVA may also help

PLE, polymorphic light eruption; PUVA, psoralen and UVA.

low-dose solar-simulated irradiation then supported this experimentally by demonstrating a perivascular infiltrate with a predominance of $CD4^+$ T cells in lesions up to 72 h post-induction, and in later lesions an infiltrate dominated by $CD8^+$ cells [4]. This clearly differs from the immunosuppressive response seen in normal subjects [13], as does the associated release of interleukin-6 (IL-6), IL-8 and possibly IL-1 [14], rather than the IL-10 and tumour necrosis factor-α (TNF-α) of unaffected individuals [14]. Further, the characteristic adhesion molecule activation patterns for E-selectin, vascular cell adhesion molecule-1 (VCAM-1) and intercellular adhesion molecule-1 (ICAM-1) [15] further support a DTH response [16], and the stimulation of autologous peripheral blood lymphocytes *in vitro* by UVR-irradiated PLE but not normal keratinocytes [17], through presumed UVR-induced antigen production in the former, provides even more supportive evidence.

The genetic abnormality in PLE leading to apparently enhanced UVR-induced cutaneous antigen recognition may well be a reduced capacity for normal UVR-induced cutaneous immunosuppression [18]. This suggestion is supported by the finding of increased patient susceptibility to dinitrochlorobenzene skin sensitization following solar-simulated irradiation, compared with normal controls [18]. Further, specific features permitting this abnormality may well include a marked Langerhans' cell resistance to depletion by even very intense UVR exposure [19], and a conceivably reduced capacity to handle free radical insult through genetically determined glutathione depletion [20].

Cutaneous UVR molecular absorbers initiating the PLE rash have not yet been identified, but may at least sometimes be a variety of heat-shock protein found in PLE-affected, but not unaffected or UVB-irradiated normal skin [21]. Perhaps more likely, however, is that a variety of absorbers may be responsible, possibly by becoming antigenic themselves or leading to putative antigen production through secondary free radical activity [20].

Pathology [22]. There is variable epidermal spongiosis and dermal, perivascular, predominantly mononuclear cell infiltration with oedema, often extending to the deeper dermis in more long-standing lesions. The cells are generally T lymphocytes, but eosinophils and neutrophils may also be present.

Clinical features (Fig. 24.9) [1]. PLE is most common in temperate regions, affecting up to 20% of subjects in such areas [23–25], particularly women under 30 years of age. Far fewer suffer in tropical regions [24,26], although all ethnic groups appear susceptible, and dark skin does not apparently confer significant protection. Familial occurrence is also common [11,25]. PLE attacks are most common in spring and summer following sun exposure, the first episode sometimes occurring after solar overexposure, and then often diminishing gradually in severity or ceasing as summer progresses. Reflected solar UVR from snow in winter and sunbed radiation [3] may also provoke outbreaks. Several minutes' to hours' irradiation is generally needed for rash induction, sometimes days, particularly after periods of sunlight abstinence. Pruritus almost always occurs, often within minutes, and a rash within minutes to hours. The rash lasts hours, days, or rarely weeks, particularly if exposure continues. It may be localized or widespread. Variable areas of exposed or lightly clad skin may be affected, generally symmetrically but often patchily. The eruption distribution in any patient is generally characteristic, although sometimes varying with time or exposure intensity. Typically affected sites are the bridge of nose, malar areas of cheeks, front of chin, sides and back of neck, upper chest, dorsa of hands, dorsolateral aspects of arms, fronts and backs of legs, and dorsa of feet. Lesions vary greatly both between and within patients, but are generally itchy, clustered, erythematous or skin-coloured, large or small papules, sometimes coalescing into smooth or irregularly surfaced confluent plaques. Vesicles, papulovesicles and, rarely, bullae, or generalized oedematous swelling, the last especially affecting the face, may also occur. Rarely, there may be pruritus alone [27], but erythema alone, with or without itch, is extremely rare. Mild papular PLE sparing the face is sometimes known as benign summer light eruption

Fig. 24.9 Polymorphic light eruption, showing variably sized, erythematous papules.

in continental Europe [28], and that of the light-exposed helices of boys' ears, which is often vesicular and was initially reported as a springtime epidemic, is sometimes called juvenile spring eruption [29–31]. Systemic malaise, chills, headache, fever and nausea may rarely accompany PLE. The condition may persist indefinitely, but often gradually improves, and occasionally remits [32].

Diagnosis. This is suggested by the history, clinical findings, absent circulating antinuclear antibodies and extractable nuclear antigen, and normal blood, urinary and stool porphyrin concentrations. In doubtful cases, lesional histology may be helpful but not diagnostic; immunofluorescence findings are negative. If uncertainty persists, skin irradiation monochromator testing may demonstrate reduced minimal erythemal or abnormal papular responses, and broad-spectrum testing, or solar exposure if available, may elicit the eruption itself. Solar urticaria is differentiated from PLE by its rapid (5–10 min) onset delay after exposure, short (1–2 h) total time course, and different lesional morphology; from erythropoietic protoporphyria by its painful nature, usual lack of rash and raised red blood cell protoporphyrin concentration; from light-exacerbated atopic eczema by its eczematous clinical and histological features; from lupus erythematosus (LE), which may also precede or coexist with PLE [33,34], by its characteristic circulating and cutaneous immunological abnormalities; and from erythema multiforme by its clinical features, distinctive histology and not infrequent association with a precipitating agent.

Treatment. Mild PLE may be managed by the restriction of UVR exposure, covering up with appropriate protective clothing, and the application of high-protection broad-spectrum sunscreens [35], although these last agents may perhaps exacerbate the condition on occasion by transmitting the often inducing UVA but not the relatively immunosuppressive UVB wavelengths [13]. In more severely and frequently affected patients, prophylactic broad- or more reliably narrow-band UVB phototherapy, or the slightly more efficient but less convenient PUVA, is regularly helpful for many months [36,37], almost certainly through immunosuppressive activity [13,38]; follow-up courses annually are then usually necessary for at least some years [39]. Suitable protocols include administering approximately 30–70% of the predetermined broad- or narrow-band UVB MED with subsequent increments of approximately 10–40% two to three times weekly for 4–6 weeks, or UVA 0.5 J/cm^2 and psoralen 0.6 mg/kg with increments of approximately 10–40% twice weekly for a month; for treatment-induced PLE flares, oral steroids may be given as below.

Oral antimalarial therapy has long been advocated for prophylactic use, but probably provides at best mild protection [40,41], and beta-carotene probably less or none [40]. More recently, oral omega-3 fatty acids have been reported as moderately helpful [42]. For occasional PLE attacks, however, or if rash develops in spite of the above measures, brief oral steroid courses, perhaps prednisolone 25–30 mg at earliest disease onset and then each morning until clear, are almost always effective [43]. Steroid by injection is probably similarly useful, but topically less so. Oral azathioprine [44] or ciclosporin [45] may also rarely be required for unremitting disabling disease.

Actinic prurigo

[J.L.M. Hawk, pp. 24.14–24.16]

Definition. Actinic prurigo (AP) is a rare, sunlight-induced, papular or nodular, extremely itchy and therefore usually excoriated eruption of light-exposed and, to a lesser extent, covered skin, sometimes associated also with acute PLE-like attacks. It is usually worse in summer. It may begin at any age and often persists indefinitely. A similar condition, also called hereditary or familial polymorphous light eruption, may afflict North, Central and South Americans of native or mixed extraction. AP is probably a persistent variant of PLE, but is usually clinically distinct.

Aetiology. A causal role for UVR in AP is suggested by the condition's usually greater severity in summer along with abnormal monochromatic skin responses in about two-thirds of exposed patients [1–3], perhaps about half to UVB alone, and half to both UVB and UVA; a few are sensitive to just UVA, the rest normal. Broad-spectrum responses have not been formally reported, but solar-simulated irradiation appears on occasion to induce an acute PLE-like eruption that can progress to the AP rash. Further, the regular association of AP with PLE in patient or family [4], and the fact that some AP patients later develop PLE or vice versa [3], again suggests a relationship between the two conditions. In addition, the perivascular mononuclear cell infiltrate of early AP, not yet immunohistochemically characterized, resembles that of PLE [5,6], and the reported possible AP erythemal enhancement by the topical prostaglandin inhibitor indometacin [7] further supports an immunological basis for the disease [8]. AP may thus be a persistent PLE variant, and very likely a DTH response against endogenous cutaneous photoantigen. Hereditary factors appear predominant in determining the AP phenotype. Over 80% of white British patients demonstrate human leukocyte antigen (HLA) type DRB1*04 (DR4), which is present in only 30% of normal and PLE subjects, and 60% have the rare subtype DRB1*0407 [3,9], which is relatively common in native Americans [10]. This feature may very likely be the determinant transforming PLE into AP, a contention further supported by the fact that some genetic AP patients have clinical PLE but atypical lesional persistence [3]. The cutaneous UVR molecular absorbers initiating the AP eruption have not been identified, but may well be as postulated for PLE.

Pathology [5,6,11]. There is early variable epidermal acanthosis and spongiosis along with dermal perivascular mononuclear cell infiltration and oedema, as may also occur in PLE. Later, however, non-specific excoriations, increasing acanthosis, variable lichenification and an increasingly heavy mononuclear cell infiltrate tend to supervene. Rarely, a more bizarre picture reminiscent of cutaneous T-cell lymphoma may be present.

Clinical features (Fig. 24.10) [1,2,12]. AP may begin at any age in children or adults (most commonly female) and persist indefinitely [13]. A family history of AP, or more often PLE, is common [4], but personal and family atopy, previously considered a likely AP association, is probably no more frequent than in normal subjects. The eruption is seasonal, if often not clearly related to specific sun exposure, and generally worse in summer; rarely, however, it

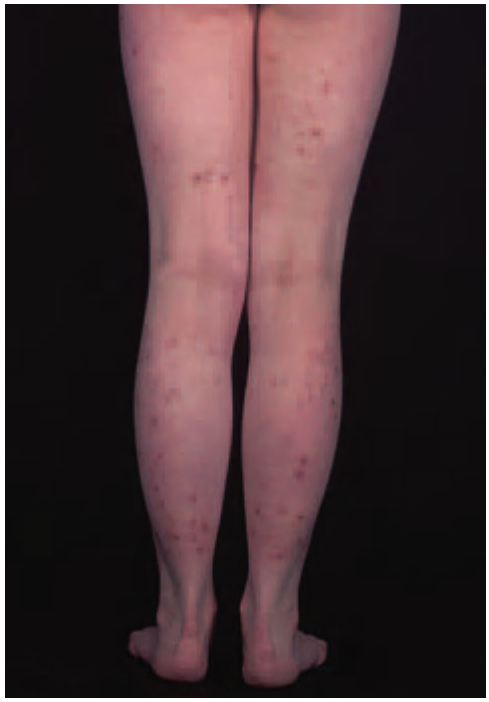

Fig. 24.10 Actinic prurigo, showing excoriated papules, more profuse distally.

may be more severe in both spring and autumn, or winter. The condition generally demonstrates very pruritic erythematous papules or nodules early on, and later these are often excoriated, crusted or scabbed, sometimes with eczematization or lichenification. The face and distal limbs are most affected, whereas the proximal limbs and the forehead under the fringe are relatively spared. The rash generally gradually fades towards more frequently covered sites, but even the sacral area and buttocks may be involved in severe cases. The limbs may also demonstrate hypo- or hyperpigmented healing lesions or flat white scars, and the face minute linear or pitted scars. Cheilitis and conjunctivitis may also occasionally be present, particularly in native American patients [14,15]. Attacks of an eruption indistinguishable from PLE may also sometimes occur, at times fading thereafter into AP.

Diagnosis. This is suggested mainly by a carefully taken history supported by appropriate examination findings, along with absent circulating antinuclear antibodies and extractable nuclear antigen, and blood, urine and stool porphyrins. In doubtful cases, early lesional histology may also help; immunofluorescence findings are nonspecific. If there is continuing diagnostic difficulty, irradiation monochromator skin testing may confirm light sensitivity in up to two-thirds of patients, and broad-spectrum irradiation may sometimes induce an acute PLE-like rash. HLA typing is diagnostically supportive if HLA-DRB1*04 (DR4) is demonstrated, much more so if there is the rare DRB1*0407 subtype [3,9]. Atopic eczema, particularly light-exacerbated, may be distinguished by its history, appearance and distribution; insect bites by their shorter time course and often asymmetrical distribution; scabies by its lack of seasonality and presence of the mite; prurigo nodularis by its lack of seasonality, usual adult onset and generally more widespread lesions; and erythropoietic protoporphyria by its abnormal red blood cell protoporphyrin concentration. Nevertheless, AP diagnosis may often remain uncertain in the early stages, and depends on disease evolution for confirmation.

Treatment. Mild AP may be managed by the restriction of sun exposure, use of appropriate protective clothing, regular application of high-protection broad-spectrum sunscreens and topical steroids and emollients. As in PLE [16], sunscreens may perhaps, on occasion, exacerbate the disorder by permitting inducing UVA but not immunosuppressive UVB transmission. Poorly responsive patients may sometimes do well with occasional oral steroid courses for flares [13]. For more persistent disease, however, prophylactic low-dose broad- or narrow-band UVB phototherapy or PUVA, given as for PLE, may be helpful [13,17,18], the latter preferably in bath form in children, and perhaps best after initial rash clearance with steroids or as below. Resistant cases, however, usually require oral thalidomide 50–100 mg nightly until clearance, adjusted thereafter to as low a dose as possible [13,19], although a high risk of teratogenicity and moderate risk of peripheral neuropathy necessitate extreme care in its use; 3–6-monthly nerve conduction studies generally preempt the latter [20]. Conjunctival manifestations may respond to topical ciclosporin [21], and preliminary work suggests topical tacrolimus or pimecrolimus may inhibit early skin lesions; severe disease in patients unsuitable for thalidomide may perhaps respond instead to oral ciclosporin or other immunosuppressive agent, an approach, nevertheless, not yet apparently reported.

Hydroa vacciniforme

[J. Ferguson, pp. 24.16–24.17]

Definition. Hydroa vacciniforme (HV) is a rare acquired photodermatosis, usually with onset in childhood, and characterized by vesicle, crust and scar formation that follow exposure to sunlight.

Aetiology. The origin of this condition is unknown. Spring and summer exposure, particularly to UVA wavelengths [1], appears responsible. Recently, an association between HV and latent Epstein–Barr virus (EBV) infection has been proposed [2].

Pathology. Acute lesion histology is non-specific, showing a reticulate keratinocyte degeneration with spongiosis and a perivascular mononuclear cell infiltrate. Lesion biopsy days later shows ulceration, necrosis and capillary oedema followed by scarring [3]. Although monochromator testing is usually within normal limits, repetitive high-dose skin irradiation with a UVA source can induce papulovesicles [4] (Fig. 24.11).

Clinical features. Although the incidence is unknown, HV is a rare, usually sporadic, but occasionally familial [5] condition occurring equally in both sexes [6]. Presentation is usually during the first decade, but there is a late-onset variety [7]. Twelve to 24 h after exposure to direct or window glass-transmitted sunlight, pruritic, sometimes haemorrhagic vesicles and papules arise on an erythematous background, typically affecting the cheeks, ears, nose and hands (Fig. 24.12). As the lesions resolve, they enter a dry crusting phase followed by permanent scars, which can be disfiguring [8] (Fig. 24.13). In some children, acute episodes are accompanied by systemic malaise [3]. Rarely, eye involvement may take the form of anterior uveitis with corneal clouding and visual impairment [9]. HV-like lesions have been reported in association with T-cell lymphoma, and as EBV has been shown to be associated

Fig. 24.11 Papulovesicles following 10 J/cm^{-2} three times daily to mid-upper back skin.

Fig. 24.12 Hydroa vacciniforme, showing vesiculation and crusting. (Courtesy of Dr M. Price, Brighton General Hospital, Brighton, UK.)

Fig. 24.13 Post-hydroa vacciniforme scarring.

with T-cell lymphoma there is interest in the relationship between EBV, HV and lymphoma [10].

In most cases, HV resolves spontaneously by adulthood, with a typical disease duration of 9 years [6]. In a few cases, disease activity persists undiminished, even into middle age [11].

Treatment. Photoprotection with appropriate clothing and a broad-spectrum sunscreen form the standard approach. If there is no response to photoprotection, springtime prophylactic therapy using broad-band UVB, narrow-band UVB or PUVA can be beneficial [6,12,13]. Although some anecdotal evidence exists to support the use of beta-carotene/canthaxanthin [14], azathioprine and antimalarial therapy, their true benefit is uncertain. Prophylactic fish oil may also be of help, although poor tolerance limits its use [15].

Chronic actinic dermatitis

SYN. PHOTOSENSITIVITY DERMATITIS AND ACTINIC RETICULOID (PD/AR) SYNDROME

[J.L.M. Hawk, pp. 24.17–24.19]

Definition. Chronic actinic dermatitis (CAD) is a rare UVR- and rarely visible light-induced eczema of the exposed and, to a lesser extent, covered skin. There is often an associated, frequently airborne, contact dermatitis. It most commonly affects older men, but sometimes occurs in younger individuals with atopic eczema or human immunodeficiency virus (HIV)-infected patients. It is usually persistent, may be incapacitating, and is generally worse in summer. It may represent a contact dermatitis-like DTH reaction against endogenous photoinduced allergen.

Aetiology. CAD is an eczematous eruption clinically [1] and histologically [2], and is reproducible at all skin sites, in the absence of exogenous photosensitizer, by UVB, UVB and UVA, or rarely UVB, UVA and short visible irradiation [3]; UVA alone may also occasionally be responsible. Broad-spectrum and monochromatic exposures appear similarly effective, frequently at considerably lower than minimal sunburning doses. Furthermore, the often pseudolymphomatous clinical and histological appearances of severe forms of the condition [4,5], and the dermal infiltrate containing a predominance of CD8$^+$ T cells [5], resemble persistent allergic contact dermatitis [6,7], suggesting that CAD is similar, but by inference a response directed against cutaneous photoinduced endogenous antigen. This may presumably be the result of either direct UVR molecular absorption and change, or endogenous secondary photosensitization [8], a suggestion supported by the fact that albumin, for example, may become antigenic *in vitro* through photo-oxidation of its component histidine [9]. In addition, CAD often occurs in association with pre-existing widespread, often airborne, contact dermatitis to exogenous sensitizer or photosensitizer [10–13], or perhaps occasionally drug-induced photosensitivity [14]. Such reactions arguably enhance cutaneous immune function sufficiently during light exposure to enable putative endogenous photoantigen recognition. Alternatively, or in addition, chronic photodamage may conceivably impair UVR-induced cutaneous

immunosuppression such that endogenous UVR-induced skin photoantigen is more easily recognized, as apparently also occurs genetically in PLE [15]. Elderly outdoor workers or leisure enthusiasts [16] are most often affected, and their photo-aged skin may engender slower putative antigen removal, as well as easier associated contact allergen penetration, such that immune antigen recognition is further facilitated. Finally, CAD may occasionally develop in patients with long-standing PLE or endogenous eczema, and also in previously normal skin. As the disorder gradually develops [12], so too do the characteristic irradiation abnormalities of CAD. UVR molecular absorbers initiating the CAD rash have not been definitively identified, but DNA, RNA or a similar or related molecule may conceivably be involved in at least some instances; the CAD action spectrum in one patient series resembled that for sunburn inflammation [17], for which DNA is now considered a prime target [18].

Pathology [3,19]. There is epidermal spongiosis and acanthosis, sometimes with hyperplasia. A mononuclear cell infiltrate, predominantly perivascular and frequently dense, is present in the dermis. These cells sometimes have large hyperchromatic convoluted nuclei or show mitotic figures. In addition, there may be macrophages, eosinophils and plasma cells. In florid cases the appearances may be indistinguishable from those of cutaneous T-cell lymphoma.

Clinical features (Fig. 24.14) [3,20]. CAD occurs most commonly in temperate climates, and affects mostly elderly men of any race. Familial incidence does not occur. The condition may develop in previously normal skin, or following endogenous eczema, photo-allergic or allergic contact dermatitis, perhaps oral drug photosensitivity, occasionally PLE or, rarely, HIV infection [20]. In addition, allergic contact sensitivity to ubiquitous, often airborne, substances such as plant antigens, fragrances and topical medications often coexists. The eruption generally worsens in summer or after sun exposure, a relationship not always recognized by the patient, especially as marked or continuing irradiation may sometimes temporarily improve it. It is eczematous, patchy or confluent, markedly itchy, often lichenified, and in severe cases there are scattered or widespread, erythematous, shiny, infiltrated, pseudolymphomatous papules or plaques arising on a background of erythema, eczema or normal skin [7]. Exposed sites are predominantly affected, particularly the face, scalp, back and sides of neck, upper chest and dorsal aspects of forearms and hands. There are often sharp demarcations at lines of clothing, and sparing of skin creases, upper eyelids, finger webs and areas under the ear lobes, and sometimes too of geographically shaped, variable sites on the face or elsewhere. In addition, palmar and plantar eczema is not uncommon, eyebrow and scalp hair may be stubbly or lost, and erythroderma may occasionally supervene.

Fig. 24.14 Chronic actinic dermatitis, showing pseudolymphomatous infiltration of the face but sparing of the scalp.

Once established, CAD tends to persist over many years before not infrequent gradual resolution [21]. Malignant lymphomatous transformation has also been claimed [3], conceivably following chronic antigenic stimulation in long-standing untreated CAD, but this seems extraordinarily rare [21]. However, it does seem possible that very occasional malignant lymphomas may be markedly light-sensitive of themselves [22]. Pseudolymphomatous CAD induced by combined UVB, UVA and, occasionally, visible wavelengths has been known as 'actinic reticuloid' [4], eczematous CAD induced by UVB and UVA as 'photosensitivity dermatitis' [1], and by UVB alone as 'photosensitivity dermatitis' or 'photosensitive eczema' [23]. CAD arising in association with photoallergic contact dermatitis has also been known as 'persistent light reaction'.

Diagnosis. This is suggested by the typical clinical findings in conjunction with absent antinuclear antibodies and extractable nuclear antigen, and normal blood, urine and stool porphyrin concentrations. In addition, there are abnormal erythematous or eczematous responses on clinically normal skin to broad-band or monochromatic irradiation, generally at doses much lower than the normal sunburning MED. The provoking wavelengths are UVB in virtually all patients, UVA also in most, and visible light in addition in some. A small proportion, however, appear to react to UVA alone, although drug photosensitivity

must be carefully excluded in such instances. In cases of uncertainty, the histological findings, sometimes florid in severe cases, are generally helpful in confirming an eczematous response. Other eczemas of light-exposed areas, even those exacerbated by UVR exposure, are generally distinguished by their normal cutaneous irradiation responses, along with other evidence of the underlying disorder. In drug or chemical photosensitivity, there is often clear evidence of exposure to an inducing substance, and the eruption is generally not eczematous, unless the agent is topical and the rash therefore usually localized; in addition, cutaneous irradiation testing is usually normal or positive only to the UVA wavelengths. In cutaneous T-cell lymphoma, also reported as occasionally photosensitive, the clinical picture, histology and T-cell receptor gene rearrangement studies are generally definitive. Any light sensitivity and irradiation test abnormalities, usually principally in the UVA range, are also generally mild [24], except possibly in very occasional, markedly photosensitive cases [22]. Erythrodermic CAD must be distinguished from other erythrodermas, if necessary by irradiation skin testing after the eruption has resolved in a darkened room. Significant circulating Sézary cell numbers may also occur in such cases [25], but with a $CD4^+$: $CD8^+$ ratio generally much lower than in the malignant Sézary syndrome [26].

Treatment. It is essential to minimize exposure to UVR and, if necessary, visible light, even from fluorescent room lighting. Relevant contact allergens should also be avoided. However, computer and television screens are safe. Appropriate clothing cover and the use of non-irritating broad-spectrum high-protection sunscreens of low allergenic potential are also often helpful. However, these measures are rarely effective alone, and topical or intermittent oral steroid therapy are usually also necessary. For resistant disease, prolonged very low-dose PUVA or perhaps narrow-band UVB phototherapy may be needed in addition, or oral immunosuppressive therapy [27,28], as phototherapy is often poorly tolerated, especially initially, except under high-dose systemic and topical steroid cover. Thus, ciclosporin 3.5–5 mg/kg is usually effective within weeks [29], or azathioprine 1.0–2.5 mg/kg [30] or mycophenolate mofetil 25–40 mg/kg. In addition, topical tacrolimus has recently been reported as helpful [31].

Solar urticaria
[J. Ferguson, pp. 24.20–24.21]

Solar urticaria (SU) may be primary (idiopathic) or secondary to porphyrias, phototoxic drugs and chemicals. Idiopathic SU is an uncommon wealing disorder induced by UVB, UVA and visible wavelengths.

Aetiology. SU is considered to be an allergic type 1 hypersensitivity response [1] mediated by histamine [2,3] and other agents. Some patients have a circulating factor (putative photoallergen), which has been reported to passively transfer the disease to normal individuals. Isolation of the transfer factor suggests it behaves like a globulin and has a molecular weight in the range of 25–1000 kDa. Provocation wavelengths, which vary between patients, may change during the disease course [4], and this suggests a range of photoallergens activated by UVB, UVA and visible light, separately or in combination. The finding of SU provoked by visible light should raise the possibility of a porphyria. In some cases, augmentation [5] by a different part of the spectrum is seen [6]; in others, visible wavelengths can inhibit provocation of urticaria [7]. The explanation of these phenomena is unknown.

Phototesting using monochromator or broad-band sources reveals immediate urticaria with a 24-h delayed erythema component. Knowledge of the wavelength dependency is important for management. If the condition is severe and unresponsive to treatment, intradermal testing with irradiated autologous serum and/or plasma may help indicate whether there might be a beneficial response to plasmapheresis. Where secondary SU is suspected, a careful drug history and tests to exclude porphyria are required.

Pathology. The histopathology of SU in provoked lesions shows at 5 min and 2 h a predominantly perivascular neutrophilic and eosinophilic infiltrate, with dermal oedema separating the collagen bundles. At 24 h, mononuclear cells predominate. In some, features of a vasculitis are seen [8–10].

Clinical features (Fig. 24.15) [11–14]. The incidence of idiopathic SU is unknown. It occurs in both sexes, with a slight female preponderance. It occurs at any age, but has a peak onset between 20 and 30 years [15]. It affects all races, although whether equally is unknown. Typically, the onset of disease is sudden, with most patients aware of tingling of sunlight-exposed skin, erythema and flare within minutes of visible radiation exposure. As with other urticarias, the symptoms and signs subside within a few hours, although rarely they may persist for 24 h [16], and they may be localized to fixed sites [17]. A minority of patients may only describe symptomatic erythema [18], with urticaria only evident on high irradiation dose testing. Sensitivity to the provoking wavelengths varies between patients, some requiring as little as 2–3 min of light exposure whereas others require an hour or more. When the condition is severe, it can pose great problems for the patient, particularly if visible wavelengths are involved, and if unresponsive to treatment it may induce a hermit-like existence.

Fig. 24.15 Solar urticaria provoked by window glass-transmitted sunlight. The white tracksuit stripe has failed to prevent visible wavelength penetration.

The weal (and often the flare) reaction is typically confined to sunlight-exposed skin with a cut-off at the edges of clothing. Occasionally, patients may experience erythema, weal and flare under thin light-coloured clothing that allows the penetration of visible wavelengths. Lesions typically fade over the following hour or two, leaving an erythema that may persist for 24 h or more, and representing a delayed component. Following each episode, the skin may be refractory to further provocation for a number of hours. If the skin reaction is severe and extensive it may be associated with nausea, bronchospasm, light-headedness and syncope [19].

Idiopathic SU resolves spontaneously in approximately 50% of cases within 5 years [15]. The disease severity may run a fluctuating course, with periods of improvement and remission.

Treatment [20]. Although some mildly affected patients only require simple light-avoidance measures, which include advice on use of dark clothing and a broad-spectrum sun barrier, others may require regular antihistamines taken early in the morning prior to sunlight exposure. Approximately one-third respond completely to non-sedative H_1 blockade [21], with a further one-third having partial relief. The addition of an H_2 antagonist may provide further benefit [22]. It is curious that the response to antihistamine [21] may be drug- and dose-dependent.

Successful desensitization with photochemotherapy (PUVA) [23], UVA [24] and UVB (TL-01) [25,26] has been

reported, although benefit may be short-lived. Limited treatment to normally photoexposed sites can be combined with antihistamines, and should be preceded by a minimal urticarial dose (MUD) determination.

In the severely affected patient who is unresponsive to standard therapy, plasmapheresis should be considered, particularly if the intradermal test is positive [27,28], and this can be combined with PUVA [29]. Some, but not all, have had lasting benefit from this approach. Alternatively, ciclosporin [30] or intravenous immunoglobulin [31] may be of value. Other treatments that have been reported, but which probably are not of benefit, include beta-carotene [32] and antimalarials [33].

DNA repair-defective diseases (see Chapter 12)

Drug- and chemical-induced photosensitivity: exogenous [1,2]

[J. Ferguson, pp. 24.21–24.23]

Abnormal skin reactions to sunlight and artificial sources of UV and visible radiation induced by photosensitizing drugs and other chemicals are often labelled as exaggerated sunburn and therefore underdiagnosed. Such reactions are subdivided, according to route of administration, into systemic and topical.

Aetiology. Most photosensitivity reactions involve oxygen in a variety of ways to produce toxic photosensitizer and substrate radicals.

Most systemic photosensitizers are phototoxic (non-immunologically mediated) in mechanism. The subcellular targets vary for each drug and photoactive metabolite, and the resulting clinical spectrum of reactions may mislead the unwary. For the drug prescribing pattern in the UK and Europe, the agents most commonly responsible for photosensitivity are listed in Table 24.4 [3]. Although phototoxicity is said to occur in any individual providing there is enough phototoxin and appropriate irradiation, there is an idiosyncratic variant in which a few individuals taking the drug develop the problem whereas the great majority are unaffected. This unexplained phenomenon may account for the frequent sporadic reports of reactions attributed to a surprisingly large range of drugs. Other less common mechanisms include drug-induced lupus, pellagra and photoallergy [4]. Photoallergy is usually associated with topical exposure to agents such as non-steroidal anti-inflammatory drugs (NSAIDs), fragrances and sunscreens. Topical phototoxicity has been reported with dyestuffs and psoralen-containing plants (phytophotodermatitis). Contact with the sap of members of the Umbelliferae and Rutaceae plant families followed by sunlight exposure will produce typical clinical features

Table 24.4 A general classification of photosensitizers.

Exogenous
Drugs: antibiotics; major tranquillizers; antidepressants; anti-inflammatories; diuretics; antiarrhythmics/antihypertensives
Plant materials: psoralens
Dyestuffs: methylene blue, toluidine blue xanthenes, fluorescein, eosin, anthraquinones
Polycyclic hydrocarbons: pitch, coal tars, anthracene, acridine, fluoranthrene
Perfumes and cosmetics: musk ambrette, 6-methylcoumarin
Sunscreens: benzophenones, dibenzoylmethanes, cinnamates, PABA* esters
Miscellaneous: fabric whiteners; quinoxaline-*N*-dioxide
Endogenous
Porphyrins

* Para-aminobenzoic acid.

of linear blistering and late onset pigmentation as seen in the phytophotodermatitis termed 'strimmer's dermatitis'. Our knowledge of photoactive drugs is obtained from anecdotal case reports, post-marketing surveillance and, more recently, controlled trials required by regulatory authorities.

Clinical features. Acute phototoxic reactions to drugs and chemicals can present with an immediate burning sensation in light-exposed sites, accompanied by erythema and, on some occasions, urticaria. Usually, these agents (Table 24.5) also produce a delayed erythema component, which may blister. Some follow the sunburn time-course, with painful erythema and blistering at 24–48 h, whereas the newest reported group, the calcium-channel antagonists, produce an exposed-site telangiectasia following years of therapy. Psoralens, whether by the topical or oral route, produce erythema delayed by 72–96 h. Pseudoporphyria, which clinically mimics porphyria cutanea tarda or variegate porphyria, is caused by a group of agents that damage the dermal–epidermal junction, probably by recurrent low-grade phototoxicity. Porphyrin levels are normal. Most photoactive drugs are UVA-dependent. With some, such as quinine and thiazides, responsible wavelengths extend into the UVB and visible regions, and the most recent intravenous anticancer photodynamic therapy agents (Photofrin and Foscan) have a UVA and visible wavelength dependency.

Post-phototoxic pigmentation, which can persist for years, is a particular feature of amiodarone, chlorpromazine and tetracyclines. With photomutagenic psoralens, multiple phototoxic episodes can result in skin malignancy [5]. Persistent photosensitivity (persistent light reactor) is a rare and little studied complication.

Topical drug usage varies between countries. Photoallergic dermatitis caused by NSAIDs, although rare in the UK, is much more common in Spain and Portugal. Drug-induced LE, although uncommon, can occur. Major topical photoallergens are listed in Table 24.6.

Pellagra rarely can be precipitated by isoniazid, phenytoin and other drugs.

Prognosis. The duration of photosensitivity after stopping a photoactive drug also varies. With most psoralens it is a matter of hours, whereas photosensitivity resulting from fluoroquinolones lasts 2–3 days. It may last for up to a year with amiodarone, thiazides and quinine, and the postphototoxic pigmentation can last even longer.

Investigation. Suspected drug-induced photosensitivity is best investigated with phototesting 'on' and after a

Table 24.5 Major patterns of cutaneous phototoxicity.

Skin reactions	Photosensitizers or diseases
Prickling or burning during exposure; immediate erythema; oedema/urticaria with higher doses; sometimes delayed erythema/hyperpigmentation	Coal tar; pitch; anthraquinone-based dyestuffs; amiodarone; chlorpromazine; erythropoeitic protoporphyria; Photofrin; Foscan
Exaggerated sunburn	Chlorothiazides; quinine; demethylchlortetracycline
Telangiectasia and angiomas	Calcium-channel antagonists
Late-onset erythema; blisters with slightly higher doses; low exposures—hyperpigmentation only	Psoralens; phytophotodermatitis
Increased skin fragility giving blisters with trauma	Nalidixic acid, furosemide, tetracycline, NSAIDs, amiodarone

Table 24.6 Major reported topical photoallergens.

Sulfonamides/sulfonylureas	Sulfanilamide; tolbutamide; chlorpropamide
Phenothiazines	Promethazine; chlorpromazine
Furocoumarins	5- and 8-methoxypsoralen
Fragrances	6-methylcoumarin; musk ambrette
Sunscreens	Benzophenones; PABA esters; dibenzoylmethanes; cinnamates
NSAIDs	Piroxicam; ibuprofen; naproxen

period 'off' the drug. Clinical and phototest improvement support the diagnosis. If drug-induced lupus is suspected, lupus serology and histology will help establish that diagnosis. Photopatch testing for photoallergy should be conducted when a topical photosensitizer is suspected.

Treatment. The simplest and most effective measure is to replace the offending drug with a non-phototoxic alternative. Although this is usually straightforward, with some, such as amiodarone, it may not be possible. Reduction in drug dosage and use of an appropriate broad-spectrum sunblock and, on occasions, UVB or PUVA desensitization may be required.

Dermatoses exacerbated by UVR

[J.L.M. Hawk]

Certain dermatoses not initiated by UVR exposure may be exacerbated by it (Table 24.7) [1,2]. Immunological events associated with their underlying pathogeneses are perhaps modified in some cases, and pre-existing inflammation exacerbated in others. Precise mechanisms, however, have only rarely been addressed [1]. The underlying disease may on occasion be significantly worsened, even if only mild to begin with, and this is particularly the case in seborrhoeic [2] or atopic eczema, which in some countries represent a relatively high proportion of all photodermatoses [3]. More usually, however, the disorder may be unaffected or more likely improved by irradiation. If light exacerbation does occur, the eruption most commonly develops or worsens at all exposed sites, less often only at those typical of the disorder. Treatment is by restriction of UVR exposure, use of appropriate clothing cover, application of high-protection sunscreens and assiduous therapy of the underlying disorder, even if mild [1,2]. The last measure alone can frequently result in resolution of the light sensitivity [2]. If such measures are insufficient, courses of low-dose UVB or PUVA therapy (as for PLE) may be carefully tried in conditions that usually respond to such treatment—for example, seborrhoeic or atopic eczema and psoriasis—but not in disorders such as cutaneous LE or dermatomyositis, in which the aggravation of systemic features is a potential severe hazard.

Table 24.7 Dermatoses sometimes aggravated by sunlight exposure.

Acne
Atopic eczema
Bullous pemphigoid
Carcinoid syndrome
Cutaneous T-cell lymphoma

Clinical evaluation of the patient with suspected cutaneous photosensitivity

[J.L.M. Hawk, pp. 24.23–24.24]

Patients with photosensitivity usually present with intermittent or persistent abnormalities of light-exposed areas, or rarely with generalized erythroderma. Those with inter-mittent problems are more likely to attribute the eruption to sunlight. If they do not, as is often the case in individuals with a persistent abnormality or erythroderma, careful history taking is essential, first to identify light as the likely cause, and then to determine the probable specific diagnosis. Patient details generally relevant for this process are age at disease onset, gender, family history, prior sunlight sensitivity, occupation, leisure activities and systemic or topical substance use, and

information on the eruption required includes its seasonal behaviour, exposure duration for elicitation, latent interval between exposure and onset, duration, occurrence through window glass or clothing, associated systemic symptoms, patient-described morphology and distribution. Thus, young women most commonly suffer PLE, women or girls AP, children of either sex HV, xeroderma pigmentosum (XP) or erythropoietic protoporphyria (EPP), and elderly men or individuals with atopic eczema CAD. A family history of photosensitivity is often present in PLE, AP, XP and the porphyrias. CAD is more usual in outdoor leisure enthusiasts exposed simultaneously to sunlight and airborne contact allergens. Disease deterioration despite sunscreen use suggests possible sunscreen contact dermatitis, although this may also occur not infrequently in PLE. Development of an eruption within minutes with resolution in approximately an hour suggests SU or photosensitivity to drugs such as amiodarone, and occurrence within 20 min to several hours with resolution over days suggests PLE, HV, EPP, XP, subacute cutaneous lupus, other light-exacerbated dermatoses, or other drug photosensitivity such as thiazide diuretics. Systemic malaise occasionally occurs in PLE, HV, SU or cutaneous lupus. Reactions through window glass or clothing suggest a disease action spectrum including the UVA wavelengths, which is possible in most photodermatoses except normal sunburn and XP.

The morphology of lesions described by PLE patients is of variable-sized, raised, itchy, red or skin-coloured, often clustered, spots or blisters, affecting exposed areas, and in HV, blistering with scarring is reported. SU features raised itchy weals. In EPP and amiodarone drug photosensitivity, a severe burning sensation without visible signs is usual, although with prolonged exposure, firm, colourless or pink diffuse swelling, rarely with scattered blisters, may occur in the former. In most other drug-induced photosensitivity and some cases of XP, exaggerated sunburning responses are described, often peaking in XP later than normal at 2–3 days. In light-exacerbated dermatoses, the morphology reported generally suggests the underlying disorder; in subacute cutaneous LE, however, concomitant PLE is also rarely possible [1,2].

Any eruption generally affects some, rarely all of the forehead, nose, upper cheeks, point of chin, ear rims, back and sides of neck, upper chest, dorsa of hands and feet, and limb extensor surfaces; covered sites may also be affected to a lesser extent. However, the light-protected hair fringe area, upper eyelids, finger webs, skin creases and sites beneath the nose, lower lip, chin and earlobes are often spared, except potentially with concomitant airborne contact dermatitis. Persistent excoriated papules are suggestive of AP, an eczematous eruption suggests CAD, especially with associated airborne allergen exposure, or light-exacerbated atopic or seborrhoeic eczema, and skin fragility, blistering and superficial scarring a hepatic porphyria or pseudoporphyria, particularly following drug, excessive alcohol or frequent sunbed exposure. Light-associated erythroderma suggests CAD.

Following such assessment, a specific diagnosis is generally already strongly suspected, but absolute certainty usually requires at least some further investigation, as described below.

Further investigation of the patient with cutaneous photosensitivity

[J. Ferguson]

Patients suspected of photosensitivity should have their antinuclear factor and extractable nuclear antigen (anti-SSA [Ro] and -SSB [La]) assessed. When appropriate, the cutaneous porphyrias can be excluded by spectrofluorimetry and, if necessary, by quantitative assessment of blood, urine and stool porphyrins. Histological examination of lesional or provoked skin lesions may be helpful, but is rarely diagnostic.

After taking a standard photodermatology history, investigation is to some extent disease-specific. Photobiology units often use a structured investigational referral form identifying phototest procedures such as monochromator, solar simulator and broad-spectrum larger area provocation testing [1]. As with all optical test equipment, quality control with calibrated metering and spectroradiometry is essential. Use of such devices is followed by immediate and delayed readings, and abnormality is detected by comparison with normal data. Provocation testing of larger skin areas is particularly useful in PLE and AP.

If the morphology is eczematous and an exogenous chemical is suspected, patch and photopatch testing will help identify the responsible allergen or photoallergen. Recently, photopatch testing has been standardized within the UK [2], where the most common photoallergens are the organic sunscreens. In the genophotodermatoses, assessment of DNA repair, DNA and RNA synthesis rates, cell survival post-UVA irradiation, sister chromatid exchange frequencies and, more recently, cell mutation studies, may establish the diagnosis.

Chapter 25

Virus Infections

J.C. Sterling

Introduction

A virus particle, or virion, consists of a length of nucleic acid, either RNA or DNA, within a protein shell, the capsid. The genetic information is sufficient to encode proteins involved in viral replication and production of the protective coat, but requires host cell ribosomes for translation. This absolute dependence on the host is the distinguishing feature of viruses.

A simple classification of viruses that cause illness in humans and their relationship to the skin is given in Table 25.1. This classification is followed throughout the chapter. Other viral-associated skin diseases, including Gianotti–Crosti syndrome and pityriasis rosea, a condition of unknown but possible viral aetiology, are also discussed.

General pathology of viral infections

Pathogenesis of viral disease

For a virus to produce infection, it must gain entry into a susceptible cell within an appropriate host. Many viruses, particularly those producing systemic infection, enter the body via mucous membranes after inhalation, ingestion or contact. The skin can act as a portal of entry, although this usually depends on some breach of the barrier function of the integument, for instance a scratch or fissure or by direct inoculation. Attachment to the cell surface by means of a receptor is followed by entry of the virion into the cell, by pinocytosis or phagocytosis. Viruses differ in the range and type of cells which they can infect; host specificity and tissue tropism are hallmarks of viral infections. For example, poliovirus can infect neurones and is called a neurotropic virus, while human papillomaviruses have a tropism for epithelial cells. A cell in which a particular virus can replicate is described as permissive for that virus. After entry into the cell, pre-existing cell enzymes

remove or damage the capsid sufficiently for the nucleic acid to emerge.

The next stage depends on the nature of the virus. In relatively simple ones, like enteroviruses, the RNA acts as a messenger, is infectious on its own and is immediately translatable by host ribosomes into viral proteins. More complex RNA viruses, such as influenza, have non-infectious RNA, sometimes called 'negative-strand' RNA, which has to be transcribed into messenger RNA (mRNA) by a polymerase enzyme carried in the virus itself. RNA tumour viruses contain a 'reverse transcriptase' enzyme which synthesizes DNA from the viral RNA template. DNA viruses are generally more complex and are able to transcribe mRNA from their DNA using either cell polymerase (e.g. adenoviruses) or viral polymerase (e.g. vaccinia). At the same time, replication of the viral nucleic acid also occurs.

A variety of proteins—regulatory, enzymic and structural—are produced and these, together with the products of cell damage, probably contribute to the local and general response to the infection. The time required for new virus production in acute infections is measured in hours and the number of new virions in thousands per cell. Newly produced virions can invade adjacent cells or be carried via the bloodstream and so the infection spreads. During this process the cell itself may be destroyed by a *lytic infection* (e.g. enterovirus and herpes simplex) or damaged transiently (e.g. myxovirus). With time, an immune response develops against the virus particles and processed viral proteins, which can lead to containment and clearance of the infection.

Not all virus infections end in this fashion. Some viruses infect cells that apparently remain normal and may multiply while virus replication continues within, i.e. *persistent infection*. When persistently infected cells produce no infectious virus because the replication cycle is arrested, the virus is said to be *latent*. From time to time, a latent virus can become active—*reactivation*—new virions are produced and other cells are infected. This process can result in clinical signs and symptoms as in the case of cold

sores (reactivated herpes simplex) and shingles (reactivated varicella-zoster). Other viruses cause cell proliferation, for example poxviruses and human papillomaviruses. Viruses can also be implicated in the process of carcinogenesis as in the development of cervical cancer and hepatoma.

Exanthems of viral infections

Widespread exanthems may be a manifestation of viral infections that cause a viraemia. An attempt to explain the different types of viral exanthem (Table 25.2) can be made by tracing the sequence of events which follows the arrival of blood-borne virus particles in the skin, where they lodge in dermal capillary loops. Some microorganisms (e.g. some togaviruses, poxviruses and rickettsiae) can replicate in capillary endothelium, causing damage directly or by a type 3 (Arthus) reaction that results in infarcts and haemorrhages. The great majority of viruses, however, act as inert foreign particles, reacting with circulating antibodies and sensitized lymphocytes to produce inflammation. Circulating immune complexes of antibody and viral antigens also localize in dermal blood vessels and are responsible for the rashes in many virus infections, for example human parvovirus. The complex cascade of inflammation in the dermis results in erythematous macules and papules.

In the case of most RNA viruses there is no replication, these are the only reactions and the intruding particle is removed (e.g. echoviruses, coxsackie A, most togaviruses and rubella). A few RNA viruses are, on occasion, able to enter actively metabolizing epidermal cells and replicate for a limited time, with cytolysis and production of a vesicular lesion (e.g. the vesicular exanthem of coxsackie A and some rarer vesicular exanthems).

Replicative ability in epidermal cells is mainly a feature of the DNA viruses, which may explain why this group contains those viruses capable of replication after direct inoculation of the epidermis. Vesicles and pustules result from viral replication in the epidermis, where the focal necrosis is followed by an immune response and

Table 25.2 Viral exanthems.

Type of rash	Pathogen associated
Macular	Rubella Echovirus (esp. 2, 4, 6, 9, 11, 16, 18) Coxsackie A (esp. 4, 5, 6, 9, 16) and B (esp. 5) EBV (infectious mononucleosis) Human herpesvirus 6 (roseola) Human herpesvirus 7
Maculopapular	Togavirus Echovirus (esp. 6, 9) Measles Human parvovirus (B19) (erythema infectiosum)
Maculopapular–vesicular	Coxsackie A (occasional 5, 9, 10, 16) Echovirus (occasional 4, 9, 11) Marburg
Maculopapular–petechial	Togavirus (esp. Chikungunya) and bunyavirus haemorrhagic fevers (including Lassa)
Urticarial	Coxsackie A9 (occasional) Hepatitis B (occasional)
Vesicular	Herpes simplex virus Hand, foot and mouth disease (Coxsackie 16, 5) Vesicular stomatitis virus
Vesiculopapular	Varicella-zoster
Papulovesiculopustular	Vaccinia Variola Cowpox
Papulovesicular	Orf Milker's nodule
Papular	Molluscum contagiosum Warts Gianotti–Crosti

The type of rash given is the most common clinical association but it may in some patients overlap with the next category.
EBV, Epstein–Barr virus.

infiltration with leukocytes. Vesicular lesions are caused by poxviruses, herpes simplex, varicella-zoster and some coxsackievirus infections. The cell proliferation caused by human papillomaviruses and molluscum results in localized tumours.

The antibody production that produces local inflammatory lesions may serve to prevent further dispersal of infection by the bloodstream. However, the cell-mediated immune response is probably the major local inflammatory factor, the means of containment and healing of the infection. When it is not competent, as in immunosuppression or immunodeficiency, there may be serious spread of the lesions, as seen in vaccinia and varicella. The factors which influence the areas of distribution of the rash and the sequence of affected regions are imperfectly understood [1]. Where there is an area of capillary trauma, caused for example by intermittent pressure or a pre-existing area of inflammation, viruses will localize, but the caudal progression in rubella and the centripetal distribution in varicella are unexplained.

Laboratory diagnosis [1–6]

The extent to which laboratory procedures are helpful depends on the nature of the infection and locally available resources. The general condition of the patient should always be considered and it is stressed that in early pregnancy any rash should be investigated to establish the possible risk to the fetus from rubella, parvovirus or other congenital infections. A considerable expansion of technical methods is taking place and clinicians are urged to discuss current local facilities with their microbiologists.

Some rapid methods are now feasible, using fluorescence microscopy, electron microscopy and immunological techniques, so that laboratory confirmation for such diverse conditions as orf and hepatitis B is possible on the day of receipt of specimens. Tissue culture can give an answer in 24 h in herpes simplex. At the other end of the time scale, especially where animal inoculations are required, a diagnosis may take weeks. When a particular infection is suspected, guidance on the most useful laboratory tests can be obtained from the section on diagnosis given for each infection. Broadly, the following groups of tests are available.

1 Virus isolation, usually done in cell cultures but occasionally in fertile eggs or laboratory animals.
2 Examination of histological specimens for features typical of a virus infection, for example inclusion bodies, koilocytes.
3 Visualization of virus by electron microscopy.
4 Detection of viral antigens by immunological techniques, for example fluorescent antibodies, radioimmunoassays.
5 Detection of viral nucleic acid by molecular techniques such as hybridization or polymerase chain reaction (PCR).
6 Serological tests to detect seroconversion, rising antibody titres or specific antibodies, for example IgM, low-avidity IgG.

Specimens for virus isolation are most likely to be positive if taken early in the illness. After the onset, the amount of live virus declines, especially when accessible to circulating antibody.

Specimens should be sent to the laboratory with the minimum of delay. Throat swabs should mop up the maximum nasopharyngeal material and the broken-off swab head should be immersed in a virus-transport medium, kept cool if in transit for more than 1 h.

Cerebrospinal fluid should be transported rapidly, preferably chilled.

Vesicle fluid is best collected in a glass capillary, which can have one end sealed but not so as to heat the fluid. An alternative is to use a sterile disposable hypodermic needle and transport it in its plastic container. A swab of vesicle fluid transported as for a throat swab is also valuable. Small biopsies from proliferative skin lesions are best transported in medium. Crusts are sent dry in a sterile bottle.

Urine is of limited value; as a special transport medium may be needed, arrangements should be made with the laboratory. Faeces should be sent as a few grams in a sterile container.

The fraction of blood—white cells, plasma or serum—most suitable for PCR varies according to the viral nucleic acid to be detected. Blood for togavirus isolation must be chilled and reach the laboratory quickly. It is best processed without delay or rapidly frozen below −40°C because of inactivation of virus by antibody.

If smallpox, Lassa fever, Marburg disease or haemorrhagic fevers are suspected, consult both the laboratory director and the local community physician before any specimens are taken.

Serological tests

Two specimens of clotted blood (5–10 mL each) should always be taken to achieve an unequivocal diagnosis in infections for which serology is available. The first must be taken as soon after the onset of symptoms as possible in order to have serum before appreciable antibody production has taken place. The second should be taken after a considered interval, depending on the type of infection. In general, 10 days is optimal, but when the antibody response immediately follows the rash as in rubella, 5 days may suffice, provided the first blood was taken on the day of eruption of the rash.

It is a long-established convention that a fourfold or greater rise in titre between acute and convalescent sera is

diagnostic. Because of technical variations it is customary to titrate both sera in parallel so that comparison of titres is accurate. Interpretation has to take into account possible anamnestic rises caused by organisms with some antigenic similarity.

Examination of a single serum may provide strong presumptive evidence of infection when it demonstrates a high relevant antibody titre, but this can be quite misleading at times as the particular antibody level may antedate the infection under consideration. The demonstration of specific IgM or IgA antibody in a single acute serum is also of diagnostic value in rubella and other infections. Unfortunately, in human immunodeficiency virus (HIV) infections and many immunodeficient or immunosuppressed people, serological responses to infection are unpredictable and cannot be relied upon for diagnosis.

Poxviruses

The poxviruses are the largest animal viruses and are just visible by light microscopy. They are complex double-stranded DNA viruses that replicate in the cytoplasm where they produce eosinophilic inclusion bodies (*Guanieri bodies*). They are generally resistant to physical damage; some, for example variola, have remarkable resistance to drying and can remain viable for months in crusts. Spread is mainly by direct-contact inoculation, with droplet spread in some, for example variola, which can produce respiratory tract lesions. Some grow readily in eggs and tissue culture, others not at all.

The human is host for four genera.

1 Orthopoxvirus: variola (smallpox), vaccinia, monkeypox and cowpox, which are ovoid, 300 × 250 nm.
2 Parapoxvirus: orf and milker's nodule viruses, which are cylindrical, 260 × 160 nm.
3 Molluscipoxvirus: molluscum contagiosum, intermediate in structure, 275 × 200 nm.
4 Yatapoxvirus: tanapox virus.

Smallpox

Smallpox infection is now eliminated from the world and routine vaccination against it has been abandoned. Eradication of smallpox was accepted at the 23rd World Health Assembly in May 1980. A review of this historic development is provided elsewhere [1]. The last case of smallpox in the UK occurred in Birmingham in 1978 as a result of a laboratory accident. The last case in an endemic area was in October 1977 in Somalia.

Fig. 25.1 Scarring of face following smallpox infection. (Courtesy of Dr S.B. Verma, Baroda Skin Clinic, Baroda, India.)

The recent global terrorism has reawakened concerns that the virus could be released as a biological weapon. This has led to a rapid increase in the number of medical and military personnel receiving vaccinia vaccination and an awareness of the clinical features of smallpox infection.

Clinical features [2,3]. After an incubation period of 10–14 days, a high fever with malaise, headache and backache are the first symptoms of smallpox. Within 1–3 days a macular eruption develops, which evolves over about 3 days into a rash of tense vesicles and then pustules. The eruption usually starts on the face and spreads caudally, usually affecting the extremities more than the trunk. The palms and soles are frequently affected. Lesions within an area are at the same stage. After about a week, the lesions dry, scab over and finally heal. There is frequently skin scarring following recovery, which can be marked and is still recognized in areas of the world where the infection was last evident (Fig. 25.1).

The severity of smallpox is variable. Over one-third have severe disease and mortality is between 25 and 40% of those affected.

Diagnosis. The most likely differential diagnoses are chickenpox and Kaposi's varicelliform eruption. Laboratory identification of smallpox from blister fluid is made only by designated laboratories. The virus is recognizable as an orthopoxvirus by electron microscopy and can be definitively identified by PCR amplification.

Treatment. There is no specific antiviral agent of proven efficacy for smallpox. Treatment is supportive. Strict isolation procedures must be observed and contacts of any infected individual traced as quickly as possible.

Vaccinia

Vaccinia virus, a distinct entity now named poxvirus officinalis, is unique in that it does not occur naturally but is the first stable virus to have resulted directly from human activity in the serial propagation of viruses for human inoculation. Antigenically it closely resembles variola and is invaluable for vaccination against smallpox; culturally it resembles cowpox. It could be a mutant of either, but as adaptation of variola to growth on calf skin has not succeeded, opinion in general favours a mutant of cowpox. Buffalopox is considered to be a strain of vaccinia virus that has spread to these animals by farmers and has since evolved, necessitating classification as a subspecies. It is found in buffalo herds in certain areas in India and may cause bullous or crusted lesions in buffalo farmers [1]. Several severe infections have been reported from India in people handling buffaloes.

Vaccinia virus can potentially be used as a carrier of genes for protective antigens of other pathogenic microorganisms (recombinant vaccinia viruses), and it is used in some specialized laboratory research. It is recommended that vaccination should cease except for investigators at special risk [2]. Vaccination of military and some medical personnel continues because variola could be used in biological warfare. It is worth remembering that vaccination is not without risk. Reported complications of vaccination characterized by abnormal skin lesions are described below.

1 Generalized vaccinia (Fig. 25.2): after 6–9 days a generalized rash develops as a result of the brief viraemia following successful vaccination. Recovery is the rule.

2 Accidental infection: the result of autoinoculation from the site of vaccination to another part of the body (e.g. eye), or inoculation of another person.

3 Eczema vaccinatum: this occurs in people with atopic eczema or a history of past eczema. Lesions occur on eczematous areas of skin about 5 days after exposure to the virus. Apparently healthy skin may also be involved. The condition is associated with high fever, lymphadenopathy and about 5% mortality rate.

4 Progressive vaccinia: the lesion at the site of vaccination fails to heal in immunodeficient people. Instead it enlarges progressively. Secondary lesions develop and they also enlarge. Without antiviral treatment there is usually a fatal outcome. The incidence of progressive vaccinia was about one per million vaccinations in 1968 in the USA [3].

Fig. 25.2 Vaccinia: vaccination site with generalized spread. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

5 Encephalomyelitis can also rarely complicate vaccination.

Monkeypox

Human monkeypox is an emerging viral infection in tropical Central Africa. Apart from variola, it is the only other member of the Orthopoxvirus genus to cause significant infection in humans. Monkeypox in humans was not recognized until 1970 and since then cases have been described in the tropical rainforest areas of Central and West African countries, mainly the Democratic Republic of Congo.

The animal reservoir of the virus is not yet known but is not thought to be a monkey. The disease in monkeys is similar to that in humans but subclinical infection is more common. There is, however, a 3–4% mortality rate in monkeys, depending on the species infected. A variety of African rodents, especially squirrels, are found to harbour the virus. In a recent outbreak of 81 cases in the southern

USA it was thought that small rodents transported from Ghana were the source of the infection [1].

Clinical features. The majority of cases occur in children under 10 years old, and the case fatality rate in African cases is of the order of 17%. The infection is clinically indistinguishable from smallpox, although there is a more marked lymphadenopathy [2]. At the onset of the disease, there is general malaise with fever, upper respiratory tract symptoms and a rapidly spreading pustular eruption mainly on the limbs and head. There is frequently lymphadenopathy. The rash is generally monomorphic, with individual lesions evolving together over the course of a few days from pustules to scabs. It can be confused with chickenpox.

Human-to-human spread in close contacts may occur, and the disease in such secondary cases is often milder [3]. Vaccination with vaccinia gives partial protection against monkeypox.

Diagnosis. The electron microscopic appearance of the virus is similar to variola and vaccinia. Cultural characteristics of monkeypox not shared with variola are good growth in RK13 cells and the development of pocks on the chorioallantoic membrane of fertile eggs at 39°C. PCR can distinguish monkeypox DNA from other orthopoxviruses.

Treatment. Supportive treatment is usually all that is necessary. It has been suggested that cidofovir would be a useful treatment [4].

Cowpox

Aetiology. Since before Jenner used cowpox virus inoculation in the 18th century to protect against smallpox infection, it has been accepted that cowpox is primarily a disease of cattle, yet despite the name it appears that cattle are only infected by chance, as are the cat and human. Evidence is increasing that a small wild rodent (possibly a vole or wood mouse) is the natural host [1]. Most recognized infections in the UK now are in feral or domestic cats [2] and there is a seasonal increase in the late summer and autumn. Humans usually acquire cowpox from cats by implantation of virus into broken skin [3].

Cowpox appears to occur only in Europe [2], Russia or Mediterranean Asia, where human infection is uncommon and usually sporadic.

Pathology [4]. The histological appearance is very similar to vaccinia but epithelial necrosis is less rapid and there is more inflammation, erythema and haemorrhage. Hypertrophy and proliferation are seen in the basal layer of the epidermis and there are large cytoplasmic inclusions in the lower epidermal cells.

Clinical features [4,5]. After an incubation period of 5–7 days (range 2–14 days) a papule appears and rapidly becomes vesicular. This passes through a haemorrhagic stage before becoming pustular and then ulcerating during the second week. This crusts over with a hard black eschar 1–3 cm in diameter. The pustule, which is often umbilicated, is surrounded by a zone of erythema and oedema. Lymphangitis and lymphadenitis are usual, and fever, myalgia and constitutional symptoms are frequent. Healing takes place in 3 or 4 weeks. Post-vaccinial encephalitis is a rare complication [6]. The lesions, which are usually on exposed skin of the hands, arms or face, are often multiple, and may spread centrally from the periphery [7]. Conjunctivitis has also been reported [3].

Widespread cowpox infection mimicking eczema herpeticum has been reported in a patient with atopic eczema [8] and may rarely be fatal [9]. An extensive but self-limiting eruption of probable cowpox occurred in the previously healthy anogenital skin of a woman with Darier's disease [10].

Diagnosis. A history of contact with cats or cows is suggestive but half the cases will have no such history [4]. Milker's nodules and orf should be excluded. Primary tuberculosis, foreign-body granuloma, anthrax and sporotrichosis should not cause difficulty.

Rapid diagnosis of a poxvirus can be made by electron microscopy of a scraping or crust. Should this prove negative, growth in tissue culture or on the egg chorioallantoic membrane, where characteristic haemorrhagic pocks develop, is advised because a negative result may be due to the small amount of virus in clinical samples. Diagnosis of the virus type can be made by analysis of PCR-amplified DNA [5].

Treatment. None is required, other than control of secondary infection should this develop. In immunocompomised individuals, post-exposure immune globulin may be considered but is not readily available.

Orf

SYN. ECTHYMA CONTAGIOSUM; CONTAGIOUS PUSTULAR DERMATITIS

Aetiology. Orf is caused by a parapoxvirus. The characteristic woven appearance of the virus is seen with negative staining on electron microscopy (Fig. 25.3). The disease is widespread in sheep and goats. It affects mainly young lambs, who contract the infection from one another, or possibly from persistence of the virus in pasturelands. Human lesions are caused by direct inoculation of infected material and are not uncommon among shepherds, veterinary surgeons and farmers who bottle-feed lambs. A child has been infected by falling in a contaminated pasture [1]. Butchers, meat handlers and housewives are sometimes infected from carcasses, especially sheep heads [2]. Two small outbreaks in Turkey were due to close contact with infected sacrificial animals [3]. One attack normally confers immunity, and human-to-human spread has not been recorded. Vaccination with vaccinia does not give protective immunity against orf.

Fig. 25.3 Orf virus: phosphotungstate preparation, × 230 000. (Courtesy of Dr J. Nagington, Cambridge, UK.)

Fig. 25.4 Orf. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

Orf is common among sheep handlers [4], and is readily recognized by them and their local physicians so that secondary referral is infrequent.

Similar parapoxvirus lesions in humans have followed contact with infected reindeer and musk ox calves [5].

Pathology [6–8]. The epidermal cells show gross intercellular and intracellular oedema, vacuolization and ballooning degeneration. A dense cellular infiltrate in the dermis consists in the centre mainly of histiocytes and macrophages and peripherally of lymphocytes and plasma cells. There are very few polymorphonuclear leukocytes. Throughout the lesion there is an increased number of small blood vessels, many of which show swelling and proliferation of endothelial cells. Ultrastructural studies show viral particles only in the cytoplasm of degenerating epidermal cells [9].

Clinical features [2,4,7,10,11]. After an incubation period of 5 or 6 days, a small, firm, red or reddish-blue papule enlarges to form a flat-topped haemorrhagic pustule or bulla (Fig. 25.4), often crusted in its umbilicated centre. In the fully developed lesion, which is usually 2 or 3 cm in diameter but may be as large as 5 cm, the central crust is surrounded by a rather characteristic greyish-white or violaceous ring, which is in turn encircled by a zone of erythema. It is sometimes irritable during the early stages and is often tender. The lesions are solitary or few in number and are common on the fingers, hands or forearms, but may be on the face. Lymphangitis and regional adenitis are not uncommon but are slight and there may be mild fever and malaise. Spontaneous recovery, usually without scarring, occurs in 3–6 weeks. Second attacks are quite common.

Fig. 25.5 Orf with erythema multiforme. The orf lesion on the dorsum of the forefinger has been present for 14 days, the secondary erythema multiforme for 4 days. (Courtesy of Dr A.S. Highet, York District Hospital, York, UK.)

Large fungating lesions are occasionally reported, and may resemble large pyogenic granulomas or malignant tumours. One such patient was immunosuppressed during treatment for lymphoma [12] and the lesion was refractory to treatment; another had chronic lymphatic leukaemia but appeared to be in remission at the time of the orf infection [13]. A similar lesion developed in the facial abrasions of a frictional 'rope burn' in an otherwise healthy boy [14]. A 16-month-old girl with widespread atopic dermatitis developed a pyogenic granuloma-like lesion with satellites [15].

Rare, widespread, papulovesicular or bullous lesions, which resolve after a few weeks, suggest the possibility of viraemic dissemination [16,17].

Erythema multiforme occasionally develops, typically 10–14 days after the onset of orf (Fig. 25.5), and less distinctive 'toxic erythemas' are also seen.

Diagnosis. The diagnosis is easy if the possibility of orf is suspected. Confirmation is best made by electron microscopy of the crust or a small biopsy [18]. Vesicle fluid should not be used as it contains very little virus and is usually negative. Growth of the virus in tissue culture is slow and inconstant. Serological tests are not available routinely, but a detectable antibody response does occur [19]. Molecular viral DNA analysis by PCR is possible but not routine [20].

Treatment. Any secondary infection should be treated while spontaneous recovery is awaited. Large exophytic lesions can be treated surgically [13,14] or with cryotherapy, although recurrence may occur in the immunosuppressed [21]. The use of 40% idoxuridine has been claimed to shorten the duration of the lesions [13,22], but its effect has not been rigorously assessed. The antiviral agent cidofovir has recently been reported to induce regression [23].

Milker's nodule

SYN. PSEUDOCOWPOX; PARAVACCINIA

Aetiology. Milker's nodule virus is a parapoxvirus with the same cylindrical morphology as orf virus. In the UK it produces mild infections of the teats of cows, i.e. 'ring sores', and ulcers in the mouths of calves. Bovine papular stomatitis virus affects the same sites in cattle in Europe and North America, sometimes without obvious lesions and sometimes with greater severity. The two viruses are variants. Both can produce lesions on the hands of milkers or veterinarians who examine the mouths of animals [1,2]. Human infection is accidental and human-to-human spread does not appear to have been recorded. The

Fig. 25.6 Pseudocowpox. (Courtesy of Dr J.B. Kurtz, Oxford, UK.)

infection may be transmitted by contaminated fomites in burns [3] or scalds [4].

Pathology [5,6]. Histologically there is multilocular vesicle formation in the acanthotic epidermis. Parakeratosis is often conspicuous. Cytoplasmic, or more rarely intranuclear, inclusions may be detectable. There is a granulomatous reaction in the upper dermis.

Clinical features [6–9] (Fig. 25.6). After an incubation period, which is usually about 5 days but may be as long as 2 weeks, flat red papules are formed. Within a week they appear as reddish-blue, firm, slightly tender nodules. The tense and shining epidermis becomes opaque and grey and forms a small crust over the depressed centre of the nodule. A zone of erythema usually surrounds the nodules. Many cases develop lymphangitis but there are rarely any constitutional symptoms, and resolution without scarring takes 4–6 weeks. Between two and five nodules are usually present, but they may be solitary or more numerous. They commonly occur on the hands, particularly the fingers, but are occasionally seen on the face.

One or two weeks after the appearance of the nodules some patients develop a papular or papulovesicular eruption on the hands, forearms and arms, and sometimes on the legs and neck [10]. It fades in 1 or 2 weeks.

Diagnosis. The nodules may be very vascular, and have been confused with pyogenic granulomas. Differential diagnosis from orf on morphological grounds is not possible. The history is more helpful.

Isolation of the virus is slow and unreliable. Electron microscopy of biopsy fragments of the scab is most useful if facilities are available.

Tanapox

This is an acute febrile illness associated with a localized nodular skin lesion. It is caused by tanapox virus, classified as a yatapoxvirus.

The infection was first seen as epidemics in 1957 and 1962 around the Tana River in Kenya. It has subsequently been seen in the Congo again in close proximity to the river Congo and is probably more widely distributed in tropical Africa. The virus is known to affect monkeys and humans, but its natural reservoir and mode of spread are not known. It may be acquired by inoculation through abraded skin or via mosquitoes.

Clinical features. There is mild pre-eruptive fever accompanied by headache and backache. The lesion begins as erythema surrounding a central thickening, which slowly develops as a nodule to reach a maximum diameter of 15 mm by the end of the second week. Local lymph nodes are enlarged and tender. The nodule ulcerates in the third week and is followed by gradual healing, leaving a scar after about 6 weeks. Occasionally there is more than one lesion, the maximum recorded being 10 [1] and they are usually on the limbs.

Diagnosis. The slow evolution and lack of a pustular stage are characteristic of tanapox infections. The diagnosis can be confirmed by electron microscopy, which shows enveloped poxviruses. The virus does not grow on the chick chorioallantoic membrane but some strains will give a typical appearance in tissue culture.

Molluscum contagiosum [1,2]

Aetiology. Molluscum contagiosum virus (MCV) causes characteristic skin nodules, and is largely if not exclusively

a human disease. It is classified within the Poxviridae in a specific genus, Molluscipox, and has features intermediate between the orthopox and parapox groups. It cannot be grown in tissue culture or eggs and although not readily transmissible to laboratory animals, has recently been shown to produce typical changes on human skin cultured on immuno-incompetent mice [3]. Two types have been identified, MCV-1 and MCV-2, distinguished by restriction endonuclease analysis or PCR [4,5]. Type 1 causes the majority of infections (76–97%), but there is no relationship between virus type and lesional morphology or anatomical distribution [6,7].

Epidemiology. The virus occurs throughout the world. The disease is common, although its incidence in most areas is not reliably known. Infection follows contact with infected persons or contaminated objects, but the importance of epidermal injury is unknown.

The disease is rare under the age of 1 year, perhaps due to maternally transmitted immunity and a long incubation period [8]. Otherwise the incidence seems to reflect exposure to others. In hot countries where children are lightly dressed and in close contact with one another and where personal hygiene may be poor, spread within households is not uncommon: the age of peak incidence is reported as 2–3 years in Fiji [8], and 1–4 years in the Congo (Zaire) [9]. In New Guinea the annual attack rate for children under 10 years of age has been reported to be 6% [10]. In cooler climates, however, spread within households is rare and infection is more common at a later age.

Use of swimming pools has been correlated with childhood infections, with a peak incidence at age 10–12 years in Scotland [8] and 8 years in Japan [11]. In these and other studies, boys were affected more often than girls, perhaps due to more frequent use of swimming pools and communal bathing facilities and participation in contact sports. A later incidence peak in young adults is attributable to sexual transmission. Infection of children through sexual abuse is presumably possible [12]. However, to a greater extent than warts, molluscum contagiosum is seen quite commonly on the genital, perineal and surrounding skin of children, and abuse should not be regarded as likely unless there are other suspicious features.

There is a clinical impression that molluscum contagiosum is commoner in patients with atopic eczema, and occasional reports describe widespread infections, possibly based on impaired immunity [13,14]. Topical steroids and, more recently, other topical immunomodulatory therapy have been suspected as a contributing factor in patients with eczema and in other patients [15].

Unusually widespread lesions have been reported in patients with sarcoidosis [16], those taking immunosuppressive therapy [17–20] or those with HIV disease (see Chapter 26), suggesting that cell-mediated immunity is significant in control and elimination of the infection.

Pathogenesis and pathology [21–24]. The pathogenesis of the lesions is uncertain. The virus seems first to enter the basal keratinocytes, causing an increase in cell turnover that extends into the suprabasal layer. In the prickle cell layer, mitosis declines as viral DNA synthesis increases. The cellular proliferation produces lobulated epidermal growths that compress the papillae until they appear as fibrous septa between the lobules, which are pear-shaped with the apex upwards. The basal layer remains intact. Cells at the core of the lesion show the greatest distortion and are ultimately destroyed, and appear as large hyaline bodies (molluscum bodies) some 25 μm in diameter, containing cytoplasmic masses of virus material [25]. These bodies are present in large numbers in the cavity, which appears near the surface at the centre of the fully developed lesion. Inflammatory changes in the dermis are absent or slight [26], but in lesions of long duration there may be a chronic granulomatous infiltrate. It has been suggested that the inflammatory reaction may be induced by the discharge into the dermis of the contents of a papule [27].

Specific antibodies have been found in 60–80% of patients with molluscum contagiosum and, perhaps due to unrecognized infection, in about 5–15% of controls [28,29], but a role for humoral immunity in regression of lesions has not been established. Genes encoding proteins with immune-evasion properties have been identified within the MCV genome [30].

Clinical features (Fig. 25.7). The incubation period is variously estimated at 14 days to 6 months. The individual lesion is a shiny, pearly white, hemispherical, umbilicated papule which may show a central pore. It may be identified with a hand lens when less than 1 mm in diameter. Enlarging slowly it may reach a diameter of 5–10 mm in 6–12 weeks. Rarely, and usually when one or very few are present, a lesion may become considerably larger. Plaques composed of many small lesions ('agminate' form) occur rarely [31]. Lesions frequently spread and the number of lesions ultimately present is sometimes very large. After trauma, or spontaneously after several months, inflammatory changes result in suppuration, crusting and eventual destruction of the lesion. There is healing without scarring, but occasionally, especially at sites with more subcutaneous fat, depressed scars may remain [32] (Fig. 25.7b).

The duration of both the individual lesion and the attack is very variable and although most cases are self-limiting within 6–9 months, some persist for 3 or 4 years. Follow-up studies in children in Fiji [33] confirmed these figures but showed that individual lesions were unlikely to persist for more than 2 months. However, solitary lesions may persist for up to 5 years [34]. Temporary remissions of up to 2 months may occur.

The distribution of the lesions is influenced by the mode of infection, and by the type of clothing worn, and hence

Fig. 25.7 Molluscum contagiosum: (a) typical umbilicated lesions; (b) depressed scars following infection. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

by the climate. In temperate regions they are commonly seen on the neck or the trunk, particularly around the axillae, except in sexually transmitted infection, when the anogenital region is usually involved. In children in the tropics lesions are more common on the limbs. The widespread and refractory mollusca of HIV disease occur especially on the face [35]. In otherwise healthy subjects occasional facial lesions are seen, particularly on the eyelids. Molluscum may affect the scalp, and has occurred on the lips [36], tongue and buccal mucous membrane, and indeed on any part of the body surface, including the soles where the appearance is atypical [37]. Molluscum has occurred in scars [38] and in tattoos, apparently transmitted in the pigment [39].

In at least 10% of cases, particularly in atopic subjects, a patchy eczema, often very irritable, develops around one or more of the lesions a month or more after their onset [40] and erythema annulare centrifugum has also been reported [41]. Chronic conjunctivitis and superficial punctate keratitis may similarly complicate lesions on or near the eyelids [42]. The delayed papular response observed in some of the subjects of unsuccessful inoculation experiments [43] is probably a comparable hypersensitivity to the virus. The eczema and the conjunctivitis subside spontaneously when the lesion is removed.

Follicular molluscum contagiosum in four adults produced atypical, less protuberant pale papules [44]. Squeezing of comedo-like follicular lesions in a 9-year-old boy led to large abscesses that were attributed to the dispersion of virus into the dermis [45].

Diagnosis. The diagnosis of molluscum contagiosum is usually obvious when multiple lesions are present, and the identity of an indeterminate suppurating lesion is revealed by other, often very small, lesions at an earlier stage of their evolution. Rapid freezing with ethyl chloride or liquid nitrogen may accentuate their distinctive umbilication. Direct microscopical examination of unstained or stained expressed core or a curetted lesion crushed on a slide can establish the diagnosis [46]. The solitary molluscum may resemble pyogenic granuloma, keratoacanthoma or epithelioma and may be difficult to identify. The diagnosis is often not made until the lesion is examined histologically, but it can be carried out rapidly by electron microscopy [47]. Molecular analysis of DNA from specimens confirms molluscum contagiosum using hybridization or PCR techniques [4,5]. In HIV disease, molluscum contagiosum may resemble cutaneous cryptococcosis (see Chapter 26).

Treatment [48]. To avoid spread of infection, patients should be advised to avoid swimming pools, communal baths, contact sports, shared towels, etc. until clear.

In many instances, therapy is not necessary and natural resolution can be awaited. If this is slow, lesions are symptomatic or associated eczema is troublesome, treatment may be desirable. The choice of treatment will depend on the age of the patient and the number and position of the lesions. Destruction of lesions or production of an inflammatory response can hasten clearance.

Cryotherapy is effective, but needs to be repeated at 3–4 weekly intervals. Curettage and diathermy are appropriate for large lesions, especially when histology is required. Other simple mechanical methods, like expression of the contents of the papule by squeezing it with forceps held parallel to the skin surface, superficial curettage or shaving off the lesions with a sharpened wooden spatula, may each suffice. In children, however, prior application of local anaesthetic cream for an hour under plastic film occlusion may permit treatment to be performed painlessly in most cases [49]. Destruction by laser may also be considered [50], although, as with some of the other methods of surgical removal, scarring may result [51].

Topical preparations can be used to produce an inflammatory response. Liquified phenol applied precisely to lesions will certainly result in inflammation but is painful. Dilution of the phenol to 10 or 20% will be better tolerated

and hardly less efficaceous. Cantharidin, also used to produce a local irritant inflammation, has been used extensively in North America with success [52]. Topical wart paints of 15–20% salicylic acid in collodion or acrylate base applied carefully to lesions once or twice weekly will also speed clearance. The combination of salicylic acid plaster with povidone-iodine has been reported to be more effective than either alone [53].

The antiviral agent cidofovir has been shown to effectively resolve molluscum lesions [54] and has been used topically as a 1–3% ointment or cream or intravenously. It should be considered for treating extensive lesions in, for example, immuno-incompetent patients where eradication has proved difficult with standard treatment regimens or in immunosuppressed patients.

Local immune stimulation with imiquimod cream has produced clearance in both immunocompetent and immunosuppressed children and adults. Treatment regimens have used various application protocols, from one to three times daily for 3–7 days per week for 4–16 weeks, resulting in clearance in about 80% of patients [55,56]. The immunomodulatory effects of cimetidine may be able to induce remission of molluscum contagiosum. A 2-month course of oral cimetidine at a dose of 40 mg/kg daily was associated with clearance of lesions in 10 of 13 children [57].

Other possible topical preparations include tretinoin [58], potassium hydroxide solution [59], nitric oxide cream [60], silver nitrate paste [61] and podophyllotoxin cream [62].

The eczema that can arise in association with molluscum lesions is best treated without topical steroids or other topical cytokine inhibitors.

Herpesviruses

The herpesvirus group consists of relatively large DNA viruses. Their replication is intranuclear and produces typical intranuclear inclusions detectable in stained preparations. They are subgrouped according to genome similarities into the α, β and γ herpesviruses.

The eight human members of the group are herpesvirus hominis (herpes simplex virus, HSV) types 1 and 2 (α), herpesvirus varicellae (varicella-zoster virus, β), human cytomegalovirus (β), Epstein–Barr virus (γ), human herpesvirus 6 (β), human herpesvirus 7 (β) and human herpesvirus 8 (γ).

A feature of infection by members of the herpesvirus group is the absence of virus elimination following clinical recovery. Virus persists throughout the person's life as a latent infection in the cells for which the strain is specific. Under certain conditions, especially immune suppression, the virus may become reactivated and produce an acute infective episode with cellular damage.

Herpes simplex

Aetiology [1–6]. Herpes simplex, caused by HSV, is one of the commonest infections of humans worldwide. There are two major antigenic types: type 1, which is classically associated with facial infections; and type 2, which is typically genital, although there is considerable overlap in disease manifestations.

Both HSV-1 and HSV-2 persist in sensory nerve ganglia after primary infection. The virus produces no viral proteins while latent and can therefore remain undetected by host defence mechanisms. From this condition of latency, the virus may travel peripherally along the nerve fibre and, if it replicates in the skin or mucous membrane, may cause recurrent disease. The virus can be shed in saliva and genital secretions from asymptomatic individuals, especially in the months following the first episode of disease, although the amount shed from active lesions is 100–1000 times greater.

Spread is by direct contact with, or droplets from, infected secretions. Primary type 1 infections occur mainly in infants and young children, when they are usually minimal and often subclinical. Primary infections may rarely produce a painful vesicular stomatitis. In crowded areas of the developing world, up to 100% of children have antibody by the age of 5 years, but in higher socioeconomic groups the incidence is lower, for example less than half of university entrants in the UK have been infected. Type 2 infections occur mainly after puberty and are often transmitted sexually. About one-third of young adults are seropositive for type 2 and this rises to half the population by later life. The primary HSV-2 infection is more commonly symptomatic. In one sample of women, overall transmission rates between couples, from infected to uninfected partner, averaged 4–30% annually [7]. Transmission was most frequent during periods of asymptomatic shedding, which ranged from 0.5 to 4% of days sampled. The apparent increase over the last few decades in the proportion of genital infections involving HSV-1, about 20–40% in some recent studies, may be attributable to orogenital contact. Four of six children with genital herpes (three with HSV-1 and one with HSV-2) were identified as having been sexually abused [8].

Trauma facilitates transfer of the virus to fully keratinized skin. The virus can be inoculated into any body site to cause a new infection, whether or not there has been previous infection with either type. The source may be endogenous (autoinoculation), for example to the finger especially in nail-biters or thumb-suckers. Examples of exogenous inoculation are lesions of the hand in health care workers (Fig. 25.8) and others [9,10], facial lesions contracted during contact sports, and infection of a breast-feeding mother's nipples from the infected mouth of her baby [11].

Following primary infection, humoral and cell-mediated immune responses take place, the latter probably being

Fig. 25.8 Herpes simplex: inoculation lesion on thumb of dermatologist. (Courtesy of Dr A.S. Highet, York District Hospital, York, UK.)

more important [12]. They do not fully protect against reinfection or recurrent disease. The acquisition of HSV at a new site in a patient previously infected at a different site is referred to as a non-primary, first-episode infection. Initial (non-primary) genital herpes tends to be less severe in patients who have had previous oral infection. Where immunity is deficient (either congenitally or due to disease or drugs), both primary and recurrent herpetic infections may be increased in incidence and severity, and may run a prolonged and atypical course. Examples include patients immunosuppressed following organ or marrow transplantation, patients receiving cytotoxic therapy for malignancy [13] including cutaneous T-cell lymphoma [14–16], and patients with HIV infection and acquired immune deficiency syndrome (AIDS) (see Chapter 26).

Immunological abnormalities, in addition to possible local cutaneous factors, may explain the increased incidence in atopic eczema of recurrent herpes simplex [17] and the evolution in some individuals of erythema multiforme, as well as the occasional more severe infections [12,18,19], including eczema herpeticum.

Maternal primary genital infection at the time of birth, before the maternal immune response has taken place, is transmitted to the infant in about 50% of cases and the neonatal infection may be severe and fatal. Primary infection earlier in the third trimester may cause fetal growth retardation and prematurity. However, serious morbidity is rare if non-primary, first-episode or recurrent genital infection occurs during pregnancy or at delivery, presumably because the fetus in these situations is protected by maternal antibody [20–22].

In the otherwise healthy patient, herpetic recurrences are associated with temporary depression of cell-mediated immunity [22]. Peripheral trauma, including sunburn, may also stimulate reactivation of the virus.

Herpes simplex may occur in certain bullous disorders, complicating the oral presentation of pemphigus [23,24], infecting the erosions of familial benign chronic pemphigus [25], and occurring as severe infections in patients receiving immunosuppressive treatment for pemphigus [26]. It has also complicated pyoderma gangrenosum in a case of chronic lymphatic leukaemia [27].

Pathology. In the cutaneous lesions, the cytoplasm of the infected epithelial cells becomes oedematous and the cells swell, producing the so-called 'ballooning degeneration'. Thick-walled vesicles are formed by the combination of intracellular and intercellular oedema. The dermis, and later the epidermis, are infiltrated with polymorphonuclear leukocytes. Specific changes occur in the cell nuclei and different stages in the process of the development of the intranuclear inclusions can usually be seen in a single section. In addition, giant cells containing two to 15 or more nuclei are almost invariably present in cutaneous and corneal epithelium. The cytological changes are essentially the same in all organs and foci of necrosis surrounded by a zone of inflammation are characteristically found in brain and liver when these organs are involved [1].

Viral particles can be identified ultrastructurally, mainly in the cell nucleus, and with detailed examination HSV-1 and HSV-2 can be distinguished [2].

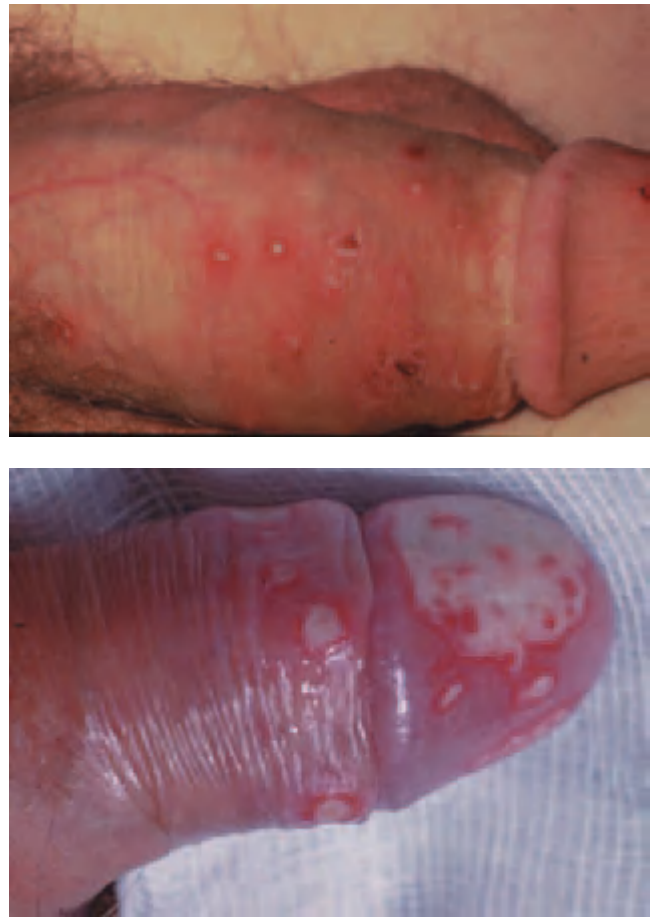
Clinical features [3–7]

Primary infection. Primary infection occurs in a previously seronegative individual and is often subclinical. When clinical lesions develop, the severity is generally greater than in recurrences. Genital primary disease is more commonly symptomatic than oral.

Herpetic gingivostomatitis. This is the most common clinical manifestation of primary infection by HSV-1, although the sites infected by the two HSV types are not mutually exclusive. Most cases occur in children between 1 and 5 years of age. After an incubation period of approximately 5 days, the stomatitis begins with fever, which may be high, malaise, restlessness and excessive dribbling. Drinking and eating are very painful and the breath is foul. The gums are swollen, inflamed and bleed easily. Vesicles presenting as white plaques are present on the tongue, pharynx, palate and buccal mucous membranes. The plaques develop into ulcers with a yellowish pseudomembrane. The regional lymph nodes are enlarged and tender. The fever subsides after 3–5 days and recovery is usually complete in 2 weeks.

In differential diagnosis, streptococcal infections, diphtheria, thrush, aphthosis, coxsackievirus infections including herpangina, Behçet's syndrome and Stevens–Johnson syndrome must be considered.

Herpes genitalis. Infection in the genital area is usually sexually transmitted. HSV-2 is the most common type in this area, although there is an increasing frequency of HSV-1 herpes genitalis [8]. Penile ulceration from herpetic infection (Fig. 25.9) is the most frequent type of genital ulceration seen in genitourinary medical clinics in the UK. The ulcers, which may be preceded by a general malaise, are most frequent on the glans, prepuce and shaft of the penis. They are sore or painful and last for 2–3 weeks if untreated. In male homosexuals, herpes simplex is common in the perianal area and may extend into the rectum. In HIV-infected individuals, ulceration may become chronic.



(a) (b)

Fig. 25.9 Herpes genitalis: (a) scattered lesions on penile shaft; (b) confluent lesions resulting in large erosions. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

In the female, similar lesions occur on the external genitalia and mucosae of the vulva, vagina and cervix. Pain and dysuria are common. Infection of the cervix may progress to a severe ulcerative cervicitis.

Recurrences may be rare, but two-thirds of those affected have recurrences two to six times per year. Where a person has had past HSV-1 infection, this is likely to decrease the severity of a primary HSV-2 infection, shortening the clinical course and reducing systemic symptoms.

Keratoconjunctivitis. Primary herpes infection of the eye causes a severe and often purulent conjunctivitis with opacity and superficial ulceration of the cornea. The eyelids are grossly oedematous and there may be vesicles on the surrounding skin. The pre-auricular gland is enlarged and tender.

Inoculation herpes simplex [9] (see Fig. 25.8). Direct inoculation of the virus into an abrasion or into normal skin gives rise to indurated papules, large bullae or irregularly scattered vesicles after an incubation period of 5–7 days. The regional nodes are enlarged but fever and constitutional symptoms are usually mild. Inoculation of the fingertips results in a 'herpetic whitlow' [10], in which painful deep vesicles coalesce to produce a honeycombed appearance or a large bulla. The condition is easily confused with pyogenic infections. Recurrences of herpetic whitlow may arise; the majority are reported to be due to HSV-2 and occur in women with recurrent genital herpes [11].

Multiple crops of vesicles and pustules on plaques or erythema and oedema on the face, scalp and upper trunk, simulating impetigo and lasting some 10–12 days have occurred in wrestlers. On the face of the adult male the appearance of herpes may be deceptive; it may take the form of a folliculitis, but satellite umbilicated vesicles soon suggest the correct diagnosis [12]. Facial contact during rugby is another recognized means of acquiring HSV infection [13], commonly called 'scrumpox'.

Complications. Eczema herpeticum is discussed on p. 25.35 and in Chapter 18. Pharyngitis may accompany primary orofacial herpes, but also occurs in 10% of primary and 1% of recurrent episodes of genital herpes.

Headache and meningism affected 36% of women and 11% of men in a series of 268 patients with primary genital herpes simplex [3]. All recovered fully. In such patients, HSV DNA can be found by PCR in the cerebrospinal fluid.

Radiculoneuropathy is seen occasionally in primary anogenital infection in women, and especially in perianal disease in homosexual men [3,7,14]. There may be sacral paraesthesia, urinary retention, constipation and, in men, impotence. Recovery takes a few days to a few weeks.

Disseminated or systemic infection may occur in the immunodeficient and in those neonates not protected by maternally acquired antibody, but rarely in otherwise healthy patients. Systemic infection may develop with or without widespread cutaneous lesions. At any age, encephalitis, untreated, has a high mortality and a high incidence of disability in survivors [15,16]; in neonates HSV-2 gave a worse prognosis than HSV-1, even with antiviral therapy [17]. HSV hepatitis is rare in adults; when severe, it is often fatal [18,19], but mild disturbances of liver function are not uncommon [20]. Lower respiratory tract infection has occurred in immunosuppressed, burned or intubated patients [21], and in neonates [22].

Monoarticular arthritis complicated a case of widespread herpes simplex [23].

Recurrent infection. After the first infection, whether symptomatic or inapparent, there may be no further clinical manifestations throughout life. Recurrences arise in 30–50% of cases of oral herpes, but are more frequent after genital herpes infection, developing in 95% of individuals with HSV-2 compared with 50% of those with HSV-1 infection [6,24].

Recurrences may be triggered by minor trauma; other infections including febrile illnesses but also trivial, non-febrile, upper respiratory tract infections; ultraviolet radiation [25]; trigeminal neuralgia and especially after intracranial operations for that disease [26]; other neural surgery [27]; dental surgery [28]; or dermabrasion [29]. Some women have more recurrences in the premenstrual period. Emotional stress is blamed in some cases [30], possibly related to the effect on immune function [31]. However, in many cases no reason for the eruption is evident.

Recurrent infections differ from primary infections in the smaller size of the vesicles and their close grouping, and in the usual absence of constitutional symptoms. In the immunocompetent, they do not as a rule affect the buccal mucosa, although inapparent oral shedding occurs in about 12% of the UK population.

Itching or burning precedes by an hour or two the development of small, closely grouped vesicles on an inflamed base. They usually become pustular and crusted before healing in 7–10 days without scarring. The eruption may be painful just at the onset or pain may last for a few days. They occur most frequently on the face, particularly around the mouth (Fig. 25.10), but can be situated anywhere on the body. Larger vesicles are not uncommon, especially in children. Recurrences tend to be in the same region but not always on the identical site. Although the vesicles usually form an irregular cluster, they may be arranged in a line or in zosteriform distribution, particularly in the lower thoracic or lumbar region [32,33]. In such cases there may be considerable deep pain and regional lymphadenopathy. Fever, pain and lymphangitis may also be associated with herpes of the hand or forearm. Recurrent herpetic lesions are most commonly vesicular and ulcerative, but occasionally they are atypical with the appearance, for example, of folliculitis, candidal fissures or minor 'frictional ulcers'. Laboratory confirmation is needed for the accurate diagnosis of atypical lesions.

Herpes genitalis. Recurrences are fairly common, with clusters of small vesicles that produce non-indurated ulcers on the glans or shaft of the penis (see Fig. 26.9). They are of shorter duration than the initial infection. Similar lesions may occur on the labia, vagina or cervix and can cause distressingly painful symptoms. In other individuals the lesions can be unnoticed.

Subclinical viral shedding. Asymptomatic shedding of HSV-2 is more frequent than of HSV-1 and correlates with the frequency of symptomatic recurrences. In the first year following acquisition of HSV-2, asymptomatic shedding is more common than in subsequent years.

Complications. Constitutional symptoms rarely occur with recurrent herpes of the face or lips, although fever and an organic psychosis accompanied each attack in one child [34]. Cranial nerve palsies may occur [35], sometimes with each eruption [36]. Rarely neuralgic pain may precede each recurrence of herpes by 1 or 2 days, a syndrome often associated with the name of Maurice [37]. An association with cluster headaches has also been reported [38].

Eczema herpeticum (see p. 25.35 and Chapter 18) can be associated with recurrent as well as primary HSV. In the immunocompromised, persistent ulcerative or verruciform lesions may occur (see Chapter 26).

If recurrent herpes simplex involves the eye, keratoconjunctivitis, dendritic ulcers, disciform or hypopyon keratitis and iridocyclitis may occur. An ophthalmological opinion should be sought.

Lymphoedema has followed recurrent attacks on a limb, but probably only in the presence of developmental lymphatic hypoplasia [39]. Secondary leukoderma may develop in pigmented skin, and accompanying granulomatous changes have been recorded [40].

1 *Inoculation herpes*. This may recur with or without further exposure to infection. Recurrent crops of grouped vesicles have been reported from birth, continuing throughout infancy, without systemic involvement [41].
2 *Erythema multiforme* [42,43]. In 65% of patients with recurrent erythema multiforme there is a history of herpes labialis, usually preceding the erythema multiforme by several days to 2 weeks, but occasionally seeming to coincide with it. Although virus cannot be seen by electron microscopy or isolated, HSV antigen gB has been detected around keratinocytes in the epidermis in erythema multiforme skin lesions [44], and HSV DNA has been demonstrated by PCR in lesions, probably in the epidermis [45,46]. This evidence is not confined to cases with clinically apparent preceding herpetic lesions. All of 15 patients with recurrent post-herpetic erythema multiforme expressed the human leukocyte antigen (HLA) DQw3 [47]. Treatment of HSV-associated recurrent erythema multiforme, if started by the patient in the prodrome stage (with a 5-day course of aciclovir), will often prevent development of erythema multiforme. If this is not effective and attacks are frequent, a 6-month course of prophylactic aciclovir should be tried even in patients in whom HSV is not obviously a precipitating factor. Dapsone or azathioprine may be effective in cases resistant to aciclovir or not associated with HSV [48].
3 *Bell's palsy*. The suggestion that Bell's palsy is due to reactivation of HSV has been strengthened by the detection of the HSV-1 genome in facial nerve endoneurial fluid and posterior auricular muscle in patients with this condition. The use of an appropriate antiviral should therefore be considered in the early management of Bell's palsy [49].
4 *Recurrent lymphocytic meningitis*. A benign form of aseptic meningitis that lasts 3–14 days and may recur at intervals of months or years is associated with HSV [50]. In a study of cerebrospinal fluid from 13 patients, 12 had HSV-2 antibodies (of whom 10 also had HSV DNA detectable by PCR), while one had both HSV-1 DNA and antibodies. Among 27 people who had primary HSV-2 meningitis, five had recurrence of symptoms [51]. Prophylactic or pre-eruptive aciclovir has been reported to prevent recurrences [52].
5 *Encephalitis*. This severe disease can occur after the virus has established latent infection. Rapid diagnosis [53] and treatment are essential to minimize the mortality and morbidity of the condition.

Diagnosis. Diagnosis of infection by culture of the virus from vesicle fluid usually requires only 1–5 days. Primary infections can be distinguished by seroconversion or a rise in antibody titre. Recurrences tend to produce little change in antibody titre; measurement of antibody is therefore not helpful in the diagnosis of recurrent HSV. For a more rapid diagnosis, viral antigen may be detectable by immunofluorescence in scrapings from lesions

[54] or the virus seen by electron microscopy in vesicle fluid. The detection of HSV DNA in the cerebrospinal fluid by PCR has become the diagnostic method of choice for herpes encephalitis and aseptic meningitis and can also be used to identify the virus and the type at other sites [55].

Treatment [1,2]. Mild uncomplicated eruptions of herpes simplex require no treatment. The use of a topical antiseptic agent on affected skin may help to reduce the risk of

secondary bacterial infection. In severe primary infection or troublesome recurrent disease, antiviral therapy should be instigated.

Aciclovir (acyclovir). After triple phosphorylation, this drug is incorporated into DNA where it interferes with the action of DNA polymerase and acts as a chain terminator. The first phosphorylation step is catalysed by a specific viral thymidine kinase so that the effect of the drug is confined to virus-infected cells. Aciclovir is of proven clinical value against herpes simplex and varicella-zoster viruses, although the latter is somewhat less sensitive.

Valaciclovir and famciclovir are chemically related to aciclovir and have the same mechanism of action. They are precursor drugs; valaciclovir is converted to aciclovir and famciclovir is converted to penciclovir. They are absorbed from an oral dose better than aciclovir and have improved bioavailability.

Primary infection. Aciclovir systemically is the treatment of choice for severe or potentially severe primary herpes simplex infection, but there is no effect on establishment of virus latency and rates of recurrence after therapy. Treatment should be started as soon as possible. The usual dose is 5 mg/kg i.v. 8-hourly, though twice that dose has been used for neonatal herpes [3] and encephalitis [4]. As the drug is excreted via the kidneys the dose must be scaled down in renal failure. Transient rises in blood urea and creatinine may occur with bolus injections; slow infusion over 1 h in an adequately hydrated patient is recommended. The usual oral dose is 200 mg five times daily, although 800 mg twice daily has been used with success [5]. The drug is given for 5 or more days.

Recurrent infection. Recurrent herpes labialis may need no treatment if attacks are mild or infrequent [6]. Oral aciclovir started as soon as possible after onset of symptoms can shorten the duration and decrease the intensity of an episode [7]. If recurrences are frequent, long-term prophylactic aciclovir at a dose of 200–400 mg twice daily for 4–6 months may increase the time between episodes [8,9].

In the immunocompromised patient, mucocutaneous herpes simplex responds well to intravenous aciclovir [10,11]. After exposure, the infection can be prevented by intravenous [12] or oral [13] aciclovir, which should be started several days before the anticipated immunosuppression and continued throughout the period of greatest risk. Longer-term prophylaxis where indicated is also effective [14].

Prophylaxis against reactivation or spread of HSV may be useful before cosmetic laser treatment of the face, as widespread herpes has been reported following such procedures [15].

Aciclovir is effective in eczema herpeticum [16,17] and neonatal herpes [3] and reduces the mortality and morbidity of herpes simplex encephalitis [4].

Initial eruptions of genital herpes [18] improve significantly with oral aciclovir [19,20] but recurrent infections respond less well [21]. However, treatment of the more severe recurrences may be worthwhile; in such cases it is important to minimize delay before starting treatment, and patients should have a supply of tablets to be started on their own initiative [5]. Frequent recurrences, and also any associated erythema multiforme [22], can be suppressed by long-term treatment [23,24], although cessation of therapy, even after several years, may allow resumption of recurrences [25]. Prophylactic doses vary between 200 and 1000 mg daily; a typical regimen is 400 mg twice daily, gradually reduced to find the minimum effective dose for the individual patient. Valaciclovir 250 mg twice daily or 1 g once daily [26] or famciclovir 125 mg three times daily or 250 mg twice daily [27] are also effective in suppression of recurrent episodes.

Topical aciclovir is of established value for herpetic keratitis. In the treatment of recurrent eruptions of herpes labialis [28], and of first-episode and recurrent herpes genitalis [29], improvement has been demonstrated [30] but seems less impressive than that obtained by oral administration and in some studies has been ineffective [31]. Similarly, there is no strong evidence that topical aciclovir influences the disease course in recurrent cutaneous herpes simplex. Topical penciclovir compares favourably with aciclovir [32], and reduces the duration of pain and the eruption in comparison with placebo [33].

Resistance of herpes simplex to aciclovir has not emerged as a significant problem in immunocompetent patients [34]. However, in the immunocompromised, resistant strains that cause intractable lesions have emerged following long-term or frequently repeated treatment. Resistance is usually due to a change in, or loss of, viral thymidine kinase [35] or more rarely to alteration of viral DNA polymerase [36]. The former strains may respond to antivirals that have a different mode of action (e.g. phosphonoformate, also known as foscarnet, or cidofovir; see below).

The risk to the infant from primary herpetic vulvovaginitis in the mother at the time of delivery is so great that caesarean section is indicated [37], and prophylactic aciclovir should be considered for the neonate [3].

Other treatments. In the treatment of severe herpes simplex infection resistant to aciclovir, systemic phosphonoformate (foscarnet) may be considered [38]. An alternative antiviral is cidofovir, which acts by blocking DNA replication. This can be administered systemically but is also active topically. A small number of individuals with severe HSV infection resistant to conventional treatment have responded to cidofovir [39].

Enhancement of the immune response to HSV could reduce recurrences. Vaccines against the virus are under development but not yet in clinical use. Topical imiquimod and resiquimod, which cause local release of cytokines and enhancement of antigen presentation, have shown some promise in treatment of recurrent genital herpes [40].

Zinc ions inhibit the activity of HSV-specific DNA polymerase. A 10-min application of zinc sulphate 0.025–0.05% in water to the expected site of the herpes, repeated two to four times per month, has been reported to prevent recurrent eruptions and previously associated erythema multiforme [41], although a small controlled trial of the same regimen could not confirm this effect [42]. Topical zinc sulphate in a gel formulation has also been reported to be of benefit in episodes of reactivated infection [43].

Recurrences of herpes labialis may be prevented or reduced in intensity by the use of a topical sunscreen [44].

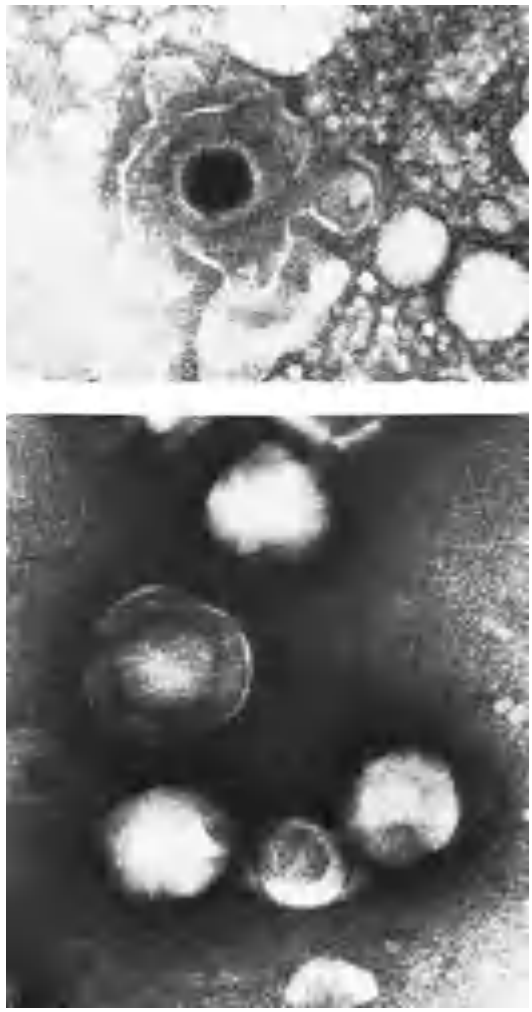
Varicella (chickenpox) and zoster (shingles)

Aetiology [1]. Varicella and zoster are caused by the same virus, herpesvirus varicellae, sometimes referred to as varicella-zoster virus (VZV) (Fig. 25.11). Varicella is the primary infection with a viraemic stage, after which the



(a)

(b)

Fig. 25.11 Herpesvirus varicellae. Phosphotungstate preparations from vesicle fluid: (a) the dark centre is due to penetration of the capsid by phosphotungstate (× 72 000); (b) the envelope encloses the nucleocapsid and obscures detail (× 116 250). (Courtesy of Dr J. Nagington, Cambridge, UK.)

virus persists in nerve ganglion cells, usually sensory. Zoster is the result of reactivation of this residual latent virus.

Varicella occurs throughout the world and is transmitted by droplet infection from the nasopharynx. Patients are infectious to others from about 2 days before to 5 days after the onset of the rash. Vesicle fluid contains a large amount of virus, but its importance in transmission is not known. Dry scabs are not infectious. In cities, epidemics occur at irregular intervals, with the highest incidence in children aged 2–10 years. Subclinical infections may occur.

Zoster (from the Greek word meaning a girdle, a reference to its segmental distribution) is a sporadic affliction of individuals. The average annual incidence in the UK has been estimated at 3.4 per 1000 [2]. It is uncommon in childhood and the incidence increases with age. The sexes are equally affected. Zoster patients are infectious, from virus in the lesions and, in some instances, the nasopharynx. In susceptible contacts of zoster, chickenpox can occur.

Varicella confers lasting immunity and second attacks are uncommon, especially in immunologically healthy subjects, but clinical reinfection with a mild varicella-like illness occurs occasionally [3].

In varicella, IgG, IgM and IgA antibodies appear 2–5 days after the onset of the rash, and their levels peak during the second and third weeks. Thereafter, the titres gradually fall although IgG persists at low levels. If zoster occurs later, the levels of IgG antibody increase rapidly and become much greater than during the primary infection. Antibodies seem to have an incomplete protective effect; maternal or administered antibody reduces the severity of infection but does not prevent it.

Cell-mediated immunity is more important. If the primary infection occurs when cell-mediated immunity is impaired, as in organ-transplant patients, varicella may be severe and occasionally fatal. In patients with impaired immunity, both the incidence and severity of zoster are increased, and it is frequently complicated by disseminated cutaneous disease and systemic involvement, usually pneumonia, hepatitis or encephalitis. This is seen in malignancy, especially lymphomas, so that the incidence of zoster in Hodgkin's disease has been estimated to be 9%; of 221 patients in the USA with cutaneous T-cell lymphoma [4], 10% developed zoster. Also at risk are patients receiving cytotoxic or immunosuppressive therapy, especially the more profound suppression required for bone marrow transplantation; in one series of over 1300 marrow recipients, 30% of those surviving 1 year developed zoster [5]. In patients infected with HIV, zoster is 10 times more common than in the normal population and may become disseminated and chronic (see Chapter 26).

Maternal varicella in the first 20 weeks of pregnancy is associated with an approximate 2% risk of fetal damage, including central nervous system and ocular defects, and limb hypoplasia; neonatal death has been reported [6]. Maternal zoster in pregnancy is not associated with intrauterine infection [7,8]. Zoster in infancy has followed maternal varicella, the baby's primary infection having occurred *in utero* [9–11]. If the mother has varicella within 4 days before to 2 days after term, the neonate would have no maternal antibody and is at risk of severe varicella, with a mortality rate of up to 30% in the absence of treatment [12,13].

Varicella may be more severe at sites of cutaneous inflammation [14]. The factors determining the site of an eruption of zoster are often not clear, but it may be precipitated by pressure from neoplastic deposits on the nerve roots; by radiotherapy, usually at the level of the affected nerve root [15]; by spinal [16] and other surgery; and by other, often trivial, traumas [17,18].

Frontal sinusitis preceded 16% of all cases of ophthalmic zoster [18].

Occasional clusters of cases of shingles are reported, and it is suggested that, uncommonly, exposure to exogenous VZV may trigger reactivation of latent virus [19]. A possible mechanism is blocking of cell-mediated defences by specific antibody whose level rises following subclinical reinfection [20].

Pathology [1]. Following an initial period of replication in the oropharynx, a viraemia causes widespread dissemination. In varicella, cells of the Malpighian layer of the skin show ballooning of their cytoplasm due to intracellular oedema, and distinctive nuclear changes comprising eosinophilic inclusions and marginated chromatin. Some nuclei develop additional nuclear membranes that divide the nucleus into small compartments. The multinucleate giant cells, with up to 15 nuclei, are a characteristic feature of infections with VZV and HSV, and are produced mainly by cell fusion [2]. Intracellular oedema combined with intercellular oedema forms the vesicle, the roof of which consists of the upper Malpighian and horny layers. A mild inflammatory reaction in the dermis later extends to the epidermis and the proportion of polymorphonuclear cells increases with ulceration.

In fatal cases of varicella [3] essentially similar cytological changes with areas of focal necrosis are found in the liver, kidney and other organs. The lungs show interstitial pneumonia with focal consolidation and haemorrhage.

In zoster, as well as skin lesions, there are inflammatory changes in the posterior nerve roots and ganglia and sometimes these involve the anterior horn. Virus particles have been seen in ganglion cells and Schwann cells in the affected nerve bundles [4]. More extensive changes are sometimes reported: leptomeningitis, encephalitis with local demyelination [5], and myelitis. Disseminated lesions in other organs may occur as in varicella.

Zoster can cause some destruction of nerve fibres in the middle and lower dermis, detectable with silver-impregnation techniques [6]. Partial denervation may persist for over a year and characteristically does so in patients with post-herpetic neuralgia [7]. Corresponding fibres in the spinal cord degenerate and there may be scarring in the region of the ganglion.

Clinical features

Varicella (Fig. 25.12). The incubation period is usually 14–17 days (range 9–23 days). After a day or two of fever and malaise, often slight or absent in children, an inconstant and fleeting scarlatiniform or morbilliform erythema is followed by the development of papules which very rapidly become tense, clear, unilocular vesicles. Within a few hours the contents become turbid and the pustules are surrounded by red areolae. In 2–4 days a dry crust forms and soon separates, to leave a shallow pink depression which, in the absence of secondary infection, heals without scarring. The vesicles appear in three to five crops over 2–4 days. They are most numerous on the trunk, then on the face and scalp and on the limbs. Their distribution is centripetal, and on the limbs the eruption is more profuse on thighs and upper arms than on lower legs and forearms. A characteristic feature is the presence of lesions at different stages in each site. The total number of lesions is very variable: they may be few or profuse. The distribu-

Fig. 25.12 Varicella. (Courtesy of York District Hospital, York, UK.)

tion may be modified by pre-existing inflammatory changes, at the sites of which lesions may appear in increased density [1]. The vesicles in such areas tend to be at the same stage and are often small, but may occasionally be bullous [2]. In exceptional cases of normal distribution the lesions are larger and umbilicated or varioloid. Vesicles are common in the mouth, especially on the palate, and are occasionally seen on other mucous membranes, including the conjunctiva. On the anal mucosa they may be followed by painful ulcers.

Fever is variable in severity and duration and roughly parallels the extent of the eruption. It may be trivial or may reach 40 or 41°C for 4 or 5 days. Constitutional symptoms tend to be proportionate to the fever. In some patients pruritus is troublesome. Haemorrhagic varicella, in which a very extensive eruption of haemorrhagic vesicles is accompanied by high fever and severe constitutional symptoms, is rare in the previously healthy patient. It is relatively more common in some tropical regions in which malnutrition may be a factor, but most cases now seen in temperate regions occur in immunocompromised patients.

The fetal and neonatal consequences of varicella in pregnancy are discussed on p. 25.23.

Complications. These are rare in otherwise healthy children, are less infrequent in neonates and adults and are common in the immunosuppressed. Relatively short courses of oral steroid treatment in children and adults may permit the development of severe and potentially fatal chickenpox [3].

Encephalitis [4] in the otherwise healthy patient occurs in less than 1 per 1000 cases and complete recovery occurs in 80%. Other neurological complications are very rare. The other main systemic complications are varicella pneumonia and hepatitis. Varicella pneumonitis is more likely to occur in adults and is 15 times more common in smokers than in non-smokers [5].

Secondary infection is seldom a serious problem in temperate climates, but under tropical conditions may be severe [6] and may be complicated by septicaemia. Cutaneous gangrene ('varicella gangrenosa') may follow secondary infection, but rarely extensive local gangrene may occur in the absence of bacterial involvement, and sometimes during a mild attack of varicella [7]. The mechanism is unknown.

Thrombocytopenic purpura, beginning on the fifth to tenth day and usually recovering spontaneously after 3 or 4 months, occasionally follows otherwise benign varicella.

Rhabdomyolysis has been reported in association with varicella [8]. Viral arthritis during varicella has been reported, although bacterial arthritis also occurs [9]. Reye's syndrome has been associated with preceding varicella [10].

Stevens–Johnson syndrome occurring as a consequence of varicella infection has been reported [11], and should be considered if bullae develop in addition to the typical vesicles of chickenpox. Treatment with systemic corticosteroids, in addition to aciclovir, may be necessary. Erythema multiforme has been reported immediately prior to the eruption of chickenpox or zoster [12].

Varicella in immunocompromised people may be severe and progressive, with a mortality of 7–10%. Features associated with a progressive varicella include haemorrhagic varicella, pneumonitis, hepatitis and encephalitis; chronic varicella is associated with hyperkeratotic lesions and acute retinal necrosis syndrome. Repeated attacks of varicella have also been observed.

Zoster. The first manifestation of zoster is usually pain, which may be severe and may be accompanied by fever, headache, malaise and tenderness localized to areas of one or more dorsal roots. The pain may be sharply localized to the same area, but may be more diffuse. The time between the start of the pain and the onset of the eruption averages 1.4 days in trigeminal zoster and 3.2 days in thoracic disease. Closely grouped red papules, rapidly becoming vesicular and then pustular, develop in a continuous or interrupted band in the area of one, occasionally two and, rarely, more contiguous dermatomes. Mucous membranes within the affected dermatomes are also involved. New vesicles continue to appear for several days. Often in children, and occasionally in adults, the eruption is the first indication of the attack. The lymph nodes draining the affected area are enlarged and tender. The pain and the constitutional symptoms subside gradually as the eruption disappears. In uncomplicated cases recovery is complete in 2–3 weeks in children and young adults, and 3–4 weeks in older patients.

Occasionally, the pain is not followed by the eruption ('zoster sine eruptione') [13].

The thoracic (53%), cervical (usually C2,3,4, 20%), trigeminal including ophthalmic (15%), and lumbosacral

Fig. 25.13 Zoster of trunk. (Courtesy of York District Hospital, York, UK.)

Fig. 25.14 Ophthalmic zoster. (Courtesy of York District Hospital, York, UK.)

(11%) (Fig. 25.13) dermatomes are most commonly involved at all ages, but the relative frequency of ophthalmic zoster increases in old age. Rarely, the eruption may be bilateral.

In some 16% of patients with zoster, vesicles develop beyond the dermatome involved within a few days of the local eruption. This is more common in the elderly but in most cases only a few lesions appear and the course of the zoster is unchanged. In patients with lymphomas or who are otherwise immunocompromised, generalized varicella ('disseminated zoster') develops and may be haemorrhagic. Rarely in such cases the zoster may successively involve further dermatomes. Systemic involvement may follow and can be fatal [14].

In the elderly and undernourished the local eruption often becomes necrotic, and healing, which may require many weeks, may be followed by severe scarring. In the otherwise healthy child, zoster usually runs a benign course.

In immunosuppressed individuals, especially due to HIV infection, zoster may run a protracted course, with a small number of lesions developing into verrucous or crusted nodules (see Chapter 26).

Variations in the zoster syndrome depend on which dorsal root is involved, on the intensity of its involvement and on the extension of the inflammatory changes into the motor root and anterior horn cells. Visceral involvement may be responsible for abdominal pain, pleural pain or temporary electrocardiographic abnormalities with or without precordial pain [15,16].

Motor involvement [17]. This occurs overall in 5% of cases and is commoner in older patients and those with malignancy, and in cranial compared with spinal nerve involvement. The motor weakness usually follows the pain and the eruption, by a few days to a few weeks, but occasionally precedes or accompanies them. The affected segment is usually but not always the same. Complete recovery is expected in 55% and significant improvement in a further 30%. Facial palsy in herpes zoster oticus is discussed below. In ophthalmic zoster, ocular palsies occur in 13% and facial palsies in 7% [18]. An abdominal hernia followed zoster involving the thoracic 10th and 11th motor roots [19]. Zoster of the anogenital area may be associated with disturbances of defecation or urination [20–22].

Trigeminal nerve zoster. In ophthalmic nerve zoster (Fig. 25.14) [23], the eye is affected in two-thirds of cases, especially when vesicles on the side of the nose indicate involvement of the nasociliary nerve (Hutchinson's sign). Ocular complications include uveitis, keratitis, conjunctivitis, conjunctival oedema (chemosis), ocular muscle palsies, proptosis, scleritis (which may be acute or delayed for 2–3 months), retinal vascular occlusion, and ulceration, scarring and even necrosis of the lid. Involvement of the ciliary ganglia may give rise to Argyll Robertson pupil.

Zoster of the maxillary division of the trigeminal nerve produces vesicles on the uvula and tonsillar area, while with involvement of the mandibular division, the vesicles appear on the anterior part of the tongue, floor of the mouth and buccal mucous membrane. In orofacial zoster, toothache may be the presenting symptom [24].

Herpes zoster oticus. The facial nerve, mainly a motor nerve, has vestigial sensory fibres supplying the external ear (including pinna and meatus) and the tonsillar fossa and adjacent soft palate. Classical sensory nerve zoster in these fibres causes pain and vesicles in part or all of that distribution, though the skin involvement may be minimal and limited to the external auditory meatus. To what extent other neural elements are actually infected is debated, but swelling of the infected sensory fibres in their course through the confined spaces of the facial canal and the internal auditory meatus, leading to compression of adjacent neural structures, explains the commonly associated features [25–27]. Thus, pressure on the facial nerve motor fibres adds facial palsy, which with the ear pain and associated vesicles completes the classic triad of Ramsay Hunt syndrome; compression of the vestibulocochlear nerve may cause sensorineural hearing loss, dizziness and vertigo; and involvement of the nervus intermedius or its geniculate ganglion would impair taste sensation from the anterior two-thirds of the tongue and alter lacrimation.

Herpes zoster oticus accounts for about 10% of cases of facial palsy. The paralysis is usually complete and full recovery occurs in only about 20% of untreated cases.

Post-herpetic neuralgia [28]. The commonest and most intractable sequel of zoster is post-herpetic neuralgia, generally defined as persistence or recurrence of pain more than a month after the onset of zoster, but better considered after 3 months. It is unusual in childhood and increases in incidence and severity with age. It occurs in about 30% of patients over 40 years of age and is most frequent when the trigeminal nerve is involved. It is more likely to develop if there was dermatomal pain prior to the eruption, if the acute pain of zoster was severe and if the zoster rash was prolonged. The pain has two main forms, a continuous burning pain with hyperaesthesia and a spasmodic shooting type, although a pruritic 'crawling' paraesthesia may also occur. Allodynia, pain caused by normally innocuous stimuli, is often the most distressing symptom and occurs in 90% of people with post-herpetic neuralgia. The neuralgia varies in intensity from inconvenient to profoundly disabling.

Other complications

1 Scar sarcoid [29] and other granulomas [30] have been reported in healed zoster scars.

2 Bacterial infection of damaged skin.

3 Encephalitis or meningoencephalitis. This is more common in the elderly, the immunosuppressed and in association with disseminated zoster.

4 Acute retinal necrosis syndrome. This rare complication follows an attack of shingles affecting the ophthalmic nerve or an unrelated dermatome [31].

5 Guillain–Barré syndrome and transverse myelitis have also been noted occasionally following zoster.

Diagnosis. The distinctive features of varicella are the centripetal distribution, the polymorphism in each affected site and the rapid progression of the individual lesion from

vesicle to crust. Typical zoster presents few difficulties once the eruption has developed and can be confused only with zosteriform herpes simplex (see p. 25.18). This diagnosis should be excluded virologically in apparently recurrent zoster.

The virus is readily identified by electron microscopy of vesicle fluid and can be grown in tissue culture but this takes longer and is less reliable than for HSV. Detection of VZV antigen by direct fluorescent antibody staining of a smear or of VZV DNA by PCR in a scraping from the base of a vesicle offers an alternative method. Titration of complement-fixing antibody in acute and convalescent sera may be a useful test in atypical infections. PCR analysis permits detection of VZV and is particularly useful in patients with suspected encephalomyelitis, in whom examination of the cerebrospinal fluid can lead to rapid diagnosis.

Prevention of varicella

This can be by pre-exposure, post-exposure and antiviral prophylaxis.

Pre-exposure prophylaxis. A live attenuated vaccine is effective in preventing varicella in healthy children [1] and in children with leukaemia in remission; in the latter patients, vaccination reduces the incidence and severity of varicella [2] but does not affect the incidence of zoster [3]. Two doses of vaccine, 3 months apart, result in approximately 90% seroconversion and 75% of responding recipients continue to have detectable antibody for up to 10 years [4].

Post-exposure prophylaxis. Specific zoster immune globulin (ZIG) administered within 10 days of contact reduces the severity of varicella but does not prevent it [5,6]. It should be given to neonates whose mothers develop varicella within the period from 7 days before to 7 days after delivery [7]. Some advocate additional prophylactic intravenous aciclovir, for the mother before delivery [8] and the baby after delivery [9–11]. ZIG is indicated for immunocompromised children and adults, for example organ-transplant recipients and patients who have taken oral steroids for at least 14 days within the previous 3 months who have not had previous chickenpox, if exposed to varicella or zoster [12]. It should also be given to exposed non-immune pregnant women not only to reduce the severity of chickenpox but also to reduce the risk of fetal transmission in those women who develop disease despite ZIG prophylaxis [13].

Vaccination in later life, when immunity against VZV is waning, may help to reduce the occurrence or severity of zoster.

Antiviral prophylaxis. In the immunocompetent person, aciclovir given from about 9 days after exposure for 1 week appears to be effective in aborting or reducing the severity of chickenpox and allows immunity to develop. In the immunocompromised, such prophylaxis only delays the onset of the disease. Prophylaxis with aciclovir has also been effective in preventing zoster in the early months following bone marrow transplantation [14].

Treatment [15,16]. Varicella in the otherwise healthy child requires only symptomatic treatment [16]. Some advocate the use of aciclovir in childhood chickenpox to reduce the severity and duration of the eruption [17]. Rest and analgesics are sufficient for mild attacks of zoster. Soothing antiseptic applications may be helpful and secondary bacterial infection will require antibiotics.

An antiviral [18] is indicated for varicella in adults and for severe varicella or zoster infections at any age in the immunocompromised. Treatment should be started as early as possible, preferably within the first 1 or 2 days. The virus is less sensitive to aciclovir *in vitro* than HSV and higher doses are usually recommended, typically 10 mg/kg or 500 mg/m^2 i.v. 8-hourly. Courses of 5, 7 and 10 days have been used and some advocate a change from intravenous to oral drug after 48 h. In general practice, zoster is often treated with aciclovir 800 mg five times a day for 7–10 days [19] or with valaciclovir 1 g or famciclovir 250 or 500 mg three times a day for 7 days. Such treatment prevents progression of the eruption, reduces the systemic complications of varicella and zoster, lessens zoster pain during treatment and can reduce the risk of development of post-herpetic neuralgia [20]. In patients over 50 years old, famciclovir (500–750 mg three times a day for 7 days) started within 72 h of the onset of shingles has also been shown to decrease the duration of post-herpetic neuralgia by approximately 2 months (2.6 times faster resolution than in the placebo group) [21].

If the first division of the trigeminal nerve is involved, there is a risk of damage to the eye, and antiviral therapy and ophthalmological advice are indicated.

Studies of the benefits of corticosteroid therapy together with aciclovir in the treatment of shingles have given conflicting results. One study in immunologically normal patients found that, in conjunction with aciclovir, prednisolone 40 mg daily tailed off over the following 3 weeks hastened the return to normal activity, better sleep and reduced the time analgesia was required [22]. Another study [23] concluded that the addition of prednisolone conferred only a slight benefit on the rate of healing and reduction of acute pain but at the expense of an increase in adverse effects. Without antiviral cover, serious dissemination of infection due to systemic steroids is a risk.

In the treatment of herpes zoster oticus (Ramsay Hunt syndrome), steroid therapy is better established, probably because of the central importance of inflammatory swelling in its pathogenesis. The prognosis is improved by prednisone 60 mg daily for 2 weeks tailed off over the third week [24], or by aciclovir 10 mg/kg i.v. 8-hourly for

7 days [25]. A combination of the two drugs may give better results [26].

For post-herpetic neuralgia the use of opiates should be avoided if possible. A tricyclic antidepressant such as amitriptyline [27] or nortriptyline (or clomipramine or doxepin) is useful, especially for hyperaesthesia and constant burning pain, an effect independent of any antidepressant activity. For best results, it should be given early in a dose of 25 mg daily and continued for 3–6 months. These adrenergically active antidepressants may be most effective if antiviral treatment is given during the acute attack of shingles [28]. For stabbing pain, sodium valproate (or another anticonvulsant such as clonazepam or carbamazepine) is of value. Especially in the elderly, doses should be initially low and increased every few days as required. Gabapentin is a useful analgesic for the pain. The application of aspirin (a suspension of two tablets crushed in 15–30 mL chloroform) has been reported to give substantial relief within half an hour [29]. Topical capsaicin 0.025%, a substance P depleter, may relieve pain in some patients, though its usefulness in some is limited by a burning sensation following application [30].

Cytomegalovirus

Aetiology and epidemiology. Cytomegalovirus (CMV) infections are common throughout the world and are usually inapparent. Primary infection is followed by lifelong carriage of the virus with intermittent shedding in various secretions. This may be increased by physiological stimuli such as pregnancy, and by immune suppression due to disease or therapy as in AIDS and transplant recipients respectively.

Depending on socio-economic conditions, between 40 and 100% of adults in a community are infected as shown by the prevalence of antibodies against CMV. There are several ways of transmitting CMV, which are to some extent age dependent. Intrauterine transmission occurs in 0.1–1.0% of births. Perinatal and neonatal infections arise as a result of exposure to infectious cervical secretions in the birth canal or from infected breast milk. Pre-school children may acquire CMV from oral secretions or urine of other infected infants. At an older age, sexual transmission is important. Blood transfusion is also a source of CMV, the virus being associated mainly with neutrophils. CMV may be transmitted in transplanted organs from CMV-seropositive donors.

Clinical features [1,2]

Congenital CMV infection. In its most severe form, hepatosplenomegaly, jaundice and purpura are present. Most cases die within 2 months and survivors usually have severe neurological damage. There may be erythropoietic

tissue in the dermis derived from undifferentiated dermal mesenchyme; this presents as purple or red papules or nodules lasting 4–6 weeks ('blueberry muffin' lesions). Vesicles very rarely occur in congenital CMV disease [3]. In a case of acute graft-versus-host disease in a young infant, CMV was suspected as the cause of the underlying immunodeficiency [4]. About 15% of congenitally infected infants will have long-term neurological sequelae, especially deafness.

CMV mononucleosis. In the otherwise healthy child or adult there is usually no clinical disturbance. When symptoms do appear they resemble infectious mononucleosis, with fever and lymphocytosis, although lymphadenopathy and splenomegaly are not usually striking. In up to one-third of cases, there is a follicular, maculopapular [5] or rubelliform eruption, often affecting the legs and lasting up to 2 days. Urticaria may occur [6]. As in Epstein–Barr virus infectious mononucleosis, ampicillin commonly triggers a widespread eruption. Lymphocytic vasculitis manifesting as papules and plaques in a partly annular configuration, with livedo reticularis, has been described in a 7-year-old girl with CMV mononucleosis [7]. Guillain–Barré syndrome is a not uncommon complication of CMV mononucleosis.

Other dermatological features in childhood. CMV was suggested as the precipitating factor in a case of scleroedema in a young infant [8], and may be one of several viral infections that can cause Gianotti–Crosti syndrome [9,10] (see p. 25.78). CMV may also play an aetiological role in an acral eruption termed the papular purpuric gloves-and-socks syndrome [11].

CMV in the immunosuppressed [12]. CMV infection in the immunocompromised can be severe and even fatal, with pneumonitis, hepatitis, gastrointestinal ulceration, retinitis and superinfection with other opportunistic pathogens. Neurological complications include encephalitis, myelitis and especially myeloradiculitis when the peripheral nerve roots are infiltrated with lymphocytes in AIDS [13].

Skin lesions may occur in disseminated CMV infection, a characteristic histological feature of which is the presence of cytomegalic cells in vascular endothelium. This may progress in some cases to vasculitis. The dermatological features include a widespread eruption that may become papular and purpuric, with vesiculobullous or pustular lesions and indurated pigmented nodules or plaques. Sharply demarcated ulceration may occur, mostly around the genitalia, perineum, buttocks and thighs. In AIDS, keratotic skin lesions [14] and severe oral [15] and skin ulceration [16] have been reported.

Following a course of antiviral treatment of CMV in immunosuppressed or immunocompromised people, relapsing infection and progression of organ involvement may occur.

Diagnosis. Classically the infection is diagnosed histologically by finding typical intranuclear inclusions surrounded by a clear halo in enlarged cells. This method is relatively insensitive, but with the addition of immunohistochemistry, cytomegalic inclusions are more readily demonstrable. Virus isolation from throat washings, urine, bronchoalveolar lavage fluid, blood or biopsy material is carried out in human embryo fibroblast cells, but it takes 5–28 days to produce a cytopathic effect seen as 'owl eye' nuclear inclusions. This can be accelerated by looking for CMV early antigen (pp65) after 24–48 h culture [17]. Rapid methods with greater sensitivity include direct detection of CMV antigenaemia and PCR. Primary infection can be diagnosed serologically by the appearance of CMV IgM and IgG antibodies. Congenital CMV can only be diagnosed confidently by virus isolation or the presence of CMV IgM antibody within 3 weeks of birth.

Treatment. Most CMV infections do not require specific therapy, but in life-threatening situations or when CMV retinitis threatens sight, two antiviral agents—ganciclovir and foscarnet—have been used with some success.

Epstein–Barr virus

Epstein–Barr virus (EBV) selectively infects B lymphocytes and occasionally certain squamous epithelial cells. This tropism depends on the expression on the cell surface of the CD21 molecule (the receptor for complement C3d), to which the virus must bind before gaining entry to the cell [1].

Primary infection is often asymptomatic but may be symptomatic and present as infectious mononucleosis. Following infection, the virus persists for life in a latent state in long-lived resting B cells, of which 0.1–5 are infected per millilitre of blood. Under certain conditions, these cells are activated when a range of viral and cellular proteins are expressed. In those EBV-infected B cells that undergo terminal differentiation or apoptosis, viral replication occurs and the cells die. No latent infection takes place in epithelial cells, although persistent infection with viral shedding may occur. In the oropharynx, liberation of virus into the saliva from localized differentiated B cells explains the spread of infection between individuals.

EBV is associated with nasopharyngeal carcinoma and with various B-lymphoproliferative lesions.

1 B-cell tumours, histologically characterized as large cell lymphomas, occur in immunocompromised people and especially immunosuppressed transplant recipients.

2 EBV-associated post-transplant lymphoproliferative disease occurs in 0.5–1.5% of the recipients of solid organs. Primary EBV infection is an important risk factor that explains the three- to four-fold increased frequency of post-transplant lymphoproliferative disease in the paediatric transplant population. Unchecked B-cell proliferation may cause a glandular fever-like illness or progress to polyclonal and monoclonal lymphomas.

3 Burkitt's lymphoma, found in equatorial Africa and New Guinea.

4 A rare X-linked recessive lymphoproliferative syndrome.

5 Both large cell lymphomas, which are frequently cerebral, and Burkitt's lymphoma are seen in patients with HIV.

Epidemiology. In all populations, the great majority of people are infected with EBV by middle age; infection, once acquired, is lifelong. In early childhood the virus is probably spread by contact with saliva on fingers or fomites, and in economically disadvantaged societies most infection is acquired at this stage. In more developed communities, early childhood infection is less frequent (e.g. about 40% of college entrants in the USA have been infected) and primary infection occurs most commonly in early adult life, when kissing is the usual route of infection, though occasional droplet spread may occur. Most primary infection, especially in childhood, is asymptomatic or mild, but when it is delayed to adolescence or adulthood, clinical illness is more frequent, i.e. infectious mononucleosis [2].

Infectious mononucleosis

SYN. GLANDULAR FEVER

Infectious mononucleosis is characterized by fever, sore throat with exudative pharyngotonsillitis and lymphadenopathy. Enlargement of the spleen has been recorded in about half of those acutely infected. There is a lymphocytosis with at least 10% atypical cells, and usually some abnormalities in liver function tests indicating hepatocellular damage, which results in jaundice in about 4% of those infected. Petechiae at the junction of the hard and soft palate are a distinctive feature of the disease and usually appear on the second or third day of fever.

An exanthem occurs in about 10% of cases, usually between the fourth and sixth days. Most common is a macular or maculopapular eruption of trunk or upper arms, involving face and forearms in some cases and thighs and legs occasionally. Morbilliform and scarlatiniform eruptions are sometimes seen. Acute urticaria is a presenting manifestation in some cases [3]. The lesions fade after a few days. If ampicillin is taken during the course of the illness, an extensive maculopapular or morbilliform eruption develops in over 90% of cases, 7–10 days after the start of treatment. A similar effect is occasionally seen with penicillin and tetracyclines.

Cold agglutinins are common in infectious mononucleosis, usually without clinical manifestations, but they might explain occasional cases of transient cold urticaria [4]; one case had, in addition, cutis marmorata and ulcerating bullae [5].

Thrombocytopenic purpura is common but platelet counts below $1000/mm^3$ are fortunately rare. Splenic rupture and encephalitis are life-threatening complications.

Diagnosis. Diagnosis can be made by examination of a blood film for abnormal lymphocytes. Tests for heterophile antibodies that agglutinate sheep or horse red blood cells and which can be adsorbed with ox red blood cells but not by a guinea-pig kidney suspension become positive in 90% of patients after 1–2 weeks. This (the Paul–Bunnell) test occasionally gives false positives and is less reliable in childhood. During the infection, antibody to EBV viral capsid antigen is produced: IgM class antibody persists for a few months and IgG antibody for life. Virus isolation is a specialized technique not performed by most diagnostic laboratories.

Other cutaneous manifestations of EBV

Oral hairy leukoplakia. This is an AIDS-associated lesion presenting as white plaques on the sides of the tongue (see Chapter 26). EBV replicates in maturing epithelial cells

but is not present in basal and parabasal keratinocytes. Oral hairy leukoplakia is also reported to occur in patients receiving immunosuppressive therapy [6–10] and occasionally in immunocompetent individuals [11,12].

Gianotti–Crosti syndrome (see p. 25.78). EBV has been reported in association with this eruption, which is believed to be a reaction to viral infection in childhood [13,14].

Lipschütz ulcers. Painful genital ulceration occurring in adolescents without venereal infection [15] can be due to primary EBV infection [16]. The sloughy ulcers are often multiple and develop in association with malaise, fever and inguinal lymphadenopathy. They heal spontaneously but somewhat slowly.

Kikuchi's histiocytic necrotizing lymphadenitis. This may occur in association with EBV infection.

Subcutaneous NK-cell ($CD56^+$) lymphoma. Presenting initially as a panniculitis, this has been reported to contain EBV DNA [17].

Hydroa vacciniforme-like lesions. These have been reported as a presentation of cutaneous angiocentric T-cell lymphoma with EBV present in the lymphoid cells of the lesions [18].

Other associations. There are reports of cases of EBV infection associated with a variety of reactive dermatoses: erythema multiforme [19], erythema nodosum [20], erythema annulare centrifugum [21], acute pityriasis lichenoides [22], and a predominantly facial eruption resembling inflammatory granuloma annulare [23].

Human herpesvirus 6 [1]

Human herpesvirus 6 (HHV-6) was originally isolated in 1986 from peripheral blood leukocytes (B cells) of patients with HIV infection or lymphoproliferative disorders [2]. In culture, infected cells (B and especially T cells) are large and refractile and frequently contain intranuclear and/or intracytoplasmic inclusions. The virus is serologically and genomically distinct from other human herpesviruses, although it is closest to CMV and its genome has some regions that cross-hybridize with CMV under stringent conditions. There are two distinct groups: group A and group B. Although there is a high degree of antigen cross-reactivity between group A and group B strains, only HHV-6 B strains appear to be associated with human disease.

This virus causes roseola infantum (exanthem subitum), the most common exanthematic fever in children under the age of 2 years, with a peak incidence between 6 and 9 months, reported to account for 24% of acute febrile illness presenting at a paediatric emergency department [3]. In the acute stage of the disease there is HHV-6 viraemia, which is followed by the appearance of antibodies to the virus [4]. Seroprevalence studies have shown that by the age of 1 year, 75% of infants have antibodies to HHV-6 [5] and 90% of adults are seropositive [5]. Subclinical infection is common and it is estimated that only about one-third develop clinical disease. After the initial infection, the virus persists and can be detected in saliva

from a high percentage of healthy subjects, the likely mode of spread [6].

Clinical features

Roseola infantum (exanthem subitum) [7,8]. The incubation period is 10–15 days. Fever, sometimes ranging between 39.5 and 40°C, begins abruptly, persists for 3–5 days and is usually accompanied by few or no symptoms. Irritability, inflamed tympanic membranes and, occasionally, periorbital oedema and haematuria are early manifestations. As the temperature falls, an eruption of discrete rose-pink maculopapules develops on the neck and trunk; it may later spread to the arms, face and legs. The lesions may rarely become vesicular [9]. After 1 or 2 days the rash fades, leaving no scaling or pigmentation. The patient's cervical and occipital lymph nodes are usually enlarged.

Febrile convulsions are not uncommon, occurring in 13% in one series [2]. HHV-6 DNA has been demonstrated in the cerebrospinal fluid of children with primary HHV-6 infection and also at times of recurrent seizures following exanthem subitum [10], which suggests that HHV-6 is a direct cause of the associated encephalitides. Fatal encephalitis is rare but has been reported in primary infection [11]. Other complications reported are fatal hepatitis and haemophagocytic syndrome [12]. During the first 2 days there may be leukocytosis but as the rash develops, leukopenia with a relative lymphopenia is usual.

The eruption of primary HHV-6 infection is almost restricted to the first 3 years of life. If primary infection occurs in adults, there may be a mononucleosis-like illness, with variable fever or rash and with mainly cervical lymphadenopathy that may persist for up to 3 months, or an acute but self-limiting hepatitis [13–15].

Reactivation of HHV-6. In immunosuppression, latent HHV-6 may reactivate and cause a variety of symptoms [16]. Fever, rash, hepatitis and pneumonitis are recognized.

Other manifestations. HHV-6 infection has been associated with multiple sclerosis, Guillain–Barré syndrome, chronic fatigue syndrome, lymphoproliferative disorders, pityriasis rosea and Kikuchi–Hashimoto disease, although the importance of the associations are not clear.

Diagnosis. The lack of symptoms during the febrile phase and the appearance of the eruption as the fever subsides should suggest the diagnosis, although clinical confusion with rubella or measles is not uncommon [17] and the picture of roseola infantum can also be caused by HHV-7 infection. Confirmation is by demonstrating seroconversion or rise in antibody titre to HHV-6, typically by indirect immunofluorescence using cells infected with HHV-6 as antigen. IgM antibody is usually present 5–7 days after the rash, maximal 2 weeks after infection and persisting for about 2 months. Virus isolation requires specialized techniques not available in most diagnostic laboratories. Molecular detection of viral RNA by reverse transcriptase (RT)-PCR or DNA by PCR is possible but may need to be qualitative to distinguish primary from latent infection. HHV-6 DNA has been detected by PCR in peripheral blood mononuclear cells during the acute illness and was still positive in 78% of samples taken within 2 months and in 66% of samples taken 2 months to 2 years after the primary infection [2].

Treatment. Only symptomatic measures are usually required. Antiviral therapy with ganciclovir, cidofovir or foscarnet would be appropriate in individuals with severe disease.

Human herpesvirus 7

Frenkel *et al*. [1] isolated a new herpesvirus from human $CD4^+$ T lymphocytes in 1990. Now named HHV-7, this virus is distinct from, but related to, HHV-6. The virus has been subsequently isolated from the peripheral blood of healthy people and a patient with chronic fatigue

syndrome. It has been found to be very prevalent, infecting children at a similar age to HHV-6 [2]. At present it is not known if HHV-7 is specifically related to any disease but, like HHV-6, it has been reported in illness with clinical features of exanthem subitum (roseola infantum) [3–5]. HHV-7 viral DNA has been detected in the blood and lesional skin of patients with pityriasis rosea, sometimes together with HHV-6, although the pathogenetic relationship is debated (see p. 25.79).

Human herpesvirus 8

SYN. KAPOSI'S SARCOMA-ASSOCIATED HERPESVIRUS

Epidemiological evidence suggests that Kaposi's sarcoma (see Chapter 26) is caused by an infectious agent. In 1994, Chang *et al*. [1], using molecular techniques, identified two novel DNA fragments in AIDS-associated Kaposi's sarcoma tissue. This DNA had partial homology to two γ herpesviruses, herpesvirus saimiri and EBV. Subsequently, this new lymphotropic human herpesvirus has also been found in association with classic Kaposi's sarcoma in immunocompetent people [2]. Kaposi's sarcoma-associated herpesvirus (KSHV) DNA has been detected in 95% of Kaposi's sarcoma lesions and is present in the monocytes, endothelial cells and spindle cells. The same DNA sequences have been found in AIDS-related lymphomas of the body cavity [3] and in Castleman's disease [4]. The association between Kaposi's sarcoma and HHV-8 is strengthened by the observation that most AIDS patients with Kaposi's sarcoma develop antibodies against KSHV-related nuclear antigens 6–75 months before the sarcoma appears [5]. The mechanism by which KSHV produces tumours is different to most other malignancies. Many of the proteins expressed by the virus influence cell proliferation, angiogenesis and apoptosis and down-regulate local immunity. Early lesions of Kaposi's sarcoma are polyclonal [6], although clonal growth may develop as a late event.

Herpes B virus

Herpes B virus, or cercopithecine herpesvirus 1, is a benign enzootic infection of Asiatic monkeys (the *Macaca* genus), and readily spreads among other monkeys in captivity. The virus remains latent in infected monkeys and may reactivate spontaneously or at times of stress. The virus is highly pathogenic to humans, in whom it typically causes fatal encephalitis. However, the frequency of mild or asymptomatic infection is not known. Human infections have occurred in attendants and research workers, most frequently following monkey bites, but occasionally in those who have handled monkeys or monkey tissues and have not been bitten. Guidelines to prevent B virus infections in monkey handlers have been published [1]. Person-to-person transmission is rare [2].

Clinical features [1,3]. In humans, lesions resembling herpes simplex develop after 5–21 days at the site of the bite or scratch. There may be symptoms of tingling, itching, numbness or pain before the vesicular eruption appears. The eruption may remain localized or show some extension, with regional lymphangitis and lymphadenopathy. Fever, malaise, headache and abdominal pain indicate a systemic illness. Encephalitis, usually fatal, develops after 10–35 days in a high proportion of cases.

Diagnosis. There is usually a history of contact with monkeys or monkey tissue. Culture of the virus from vesicle fluid or brain biopsy material will confirm the diagnosis but must be performed in a specialized laboratory. Specific primers for PCR are available for the direct detection of B virus DNA. Serological tests of paired samples can also be helpful.

Treatment. Monkey-inflicted wounds should be vigorously cleaned with soap and water, followed by iodine or alcohol. An acute serum sample should be collected. Aciclovir has been successful in the treatment of experimental B virus infections [4]. Two people, treated early in the course of their infection with aciclovir, developed only a mild illness from which they recovered, although two others, treated late, died [2]. Valaciclovir orally is now the

recommended treatment given as soon as possible following exposure. The dose is 1 g three times a day for 14 days. Intravenous ganciclovir is more potent than aciclovir *in vitro* [5] and has also been used clinically.

If symptoms of B virus disease develop, treatment is with aciclovir 12.5–15 mg/kg i.v. three times daily or ganciclovir 5 mg/kg i.v. twice daily; if there are signs of encephalitis, ganciclovir is the treatment of choice.

Kaposi's varicelliform eruption including eczema herpeticum

Aetiology. Kaposi's varicelliform eruption refers to a widespread cutaneous infection with a virus that normally causes localized or mild vesicular eruptions, occurring in a patient with pre-existing skin disease. The great majority of such cases are infections with HSV-1, for which the term *eczema herpeticum* is now preferred, especially for the more localized infections. The more general eponymous title may be used to encompass similar widespread infections with other viruses, including coxsackie A16 [1] and vaccinia [2] (eczema vaccinatum), rarely seen now that smallpox vaccination is limited to selected groups. Atopic eczema is by far the commonest predisposing condition, although the term 'eczema herpeticum' has not been restricted to cases with a background of eczema. Other susceptible dermatoses include Darier's disease [3,4], pemphigus foliaceus [5,6], benign familial pemphigus [6], ichthyosis vulgaris [7], including a case complicated by allergic contact dermatitis [8], congenital ichthyosiform erythroderma [9], mycosis fungoides [10], Sézary syndrome [11] and other inflammatory dermatoses [12]. Extensive spread of herpetic infection has followed trauma or cosmetic procedures to the face such as burns [13], dermabrasion [14] and laser therapy [15].

Most herpes simplex infections in patients with atopic eczema are not unusually severe or widespread, although an increased frequency of recurrent cold sores has been reported [16]. In 179 consecutive children with severe atopic eczema, eczema herpeticum was diagnosed in 10 and was judged severe in six [17]. Less severe, localized eczema herpeticum is not rare among patients with atopic eczema [18,19].

Of eczema herpeticum cases, the majority are primary infections. There may be a history of herpes simplex infections in family members or other close contacts. However, in one study of 75 cases, 20% followed ordinary recurrent herpes labialis, so that eczema herpeticum may result from endogenous recurrent infection [18]. Eczema herpeticum may be worse in patients with severe, especially erythrodermic, atopic eczema [19] but frequently occurs in mild or quiescent cases [17,18]. Recurrences of eczema herpeticum were noted in five of 10 [17] and eight of 75 [18] cases.

Cases are seen at all ages, most commonly in the second and third decades [18]. In localized cases, local spread seems likely, but widespread dissemination is haematogenous.

Patients who develop eczema herpeticum usually have intact cell-mediated immunity to HSV and have antibodies against the virus [20]. There are reports of eczema herpeticum developing in patients without HSV-specific cell-mediated immunity and one child with severe recurrences of eczema herpeticum had IgG2 deficiency [18]. Whether other immunological abnormalities are involved is unknown. An association with systemic [18] or topical steroid treatment has not been consistently found [17]; whether heavy steroid use predisposes to herpetic infection or simply reflects the severity of the eczema is not known. Other topical and systemic immunosuppression has also been associated with eczema herpeticum, namely topical tacrolimus [21].

Clinical features [1,17,22,23] (Fig. 25.15). In severe cases, after an incubation period of about 10 days (range 5–19 days), vesicles that rapidly become pustular erupt in massive crops. They may be confined to abnormal skin but are often widely disseminated and may generalize, simulating smallpox [2]. They may be haemorrhagic and the face may become grossly oedematous. New crops of vesicles may appear for 5–7 days. Fever, which may be high, commonly develops 2 or 3 days after the onset of the eruption and constitutional symptoms may be severe. The regional lymph nodes are enlarged. The fever subsides after 4 or 5 days and the pustules become crusted and slowly heal, leaving little permanent scarring. Rarely, there may be progression to potentially fatal systemic infection [18,24].

In localized infections, the diagnosis may be confused by secondary bacterial infection, but typical vesicles or subsequent erosions, generally confined to eczematous areas, should be sought, especially if there is a poor response to antibacterial therapy [3]. Low-grade fever and lymphadenopathy are common. These milder infections are usually self-limiting [19].

Recurrences of eczema herpeticum may commonly be milder than the initial episode, but are sometimes of comparable severity [17].

Fig. 25.15 Eczema herpeticum: (a) perioral; (b) periocular; (c) front of neck of 20-year-old man; (d) resolving lesions. (c, Courtesy of York District Hospital, York, UK; d, courtesy of Addenbrooke's Hospital, Cambridge, UK.)

Treatment and prevention. Awareness of the possibility of widespread herpetic infection should be encouraged in atopic eczema patients or their parents. Patients with atopic eczema, especially those with a history of eczema herpeticum, should avoid close contact with relatives and friends with active herpes simplex.

Severe cases should receive intravenous aciclovir [25,26] as early as possible. Less ill patients respond well to oral aciclovir [27,28] or one of the newer antiherpes agents.

Bacterial infection and the underlying eczema or other dermatosis should be treated in the usual way, except that if aciclovir is being withheld, more cautious use of steroid therapy may be advisable until the viral lesions have healed.

Human papillomaviruses

Papillomaviruses are small (50–55 nm diameter) DNA viruses that infect squamous epithelia, causing cell proliferation. The commonest effect of human papillomavirus (HPV) infection is the development of warts (verrucae). These virus-induced tumours are pleomorphic and can affect a wide variety of sites, principally skin of extremities, genital skin and mucosa, larynx and oral mucosa. The virus infects the basal layer of the epithelium, possibly the stem cells, but viral replication takes place only in fully differentiated keratinocytes, i.e. cells of the upper stratum spinosum and stratum granulosum. The viral DNA is functionally divided into early (E) and late (L) regions; the early genes are responsible for DNA replication, transcriptional regulation and transformation while the late genes code for the structural proteins of the viral capsid. Expression of the late genes depends on differentiation of the host cell. Propagation of papillomaviruses in tissue culture *in vitro* is therefore extremely demanding, as it is difficult to mimic all the necessary requirements for completion of the virus life cycle [1,2].

HPVs form a large group of closely related viruses that can be distinguished on the basis of their DNA. Originally, types were distinguished by DNA homology in liquid hybridization under defined conditions [3]. The ease of PCR and DNA sequencing now permits a different definition of typing: a distinct genotype has greater than 10% difference in nucleotide homology within the *L1* gene compared with other papillomavirus types [4]. If the homology is greater than 90%, the strain is regarded as of that subtype. The number of HPV types is continuously increasing. To date, about 80 types have been cloned and fully characterized. However, new methods of HPV detection have revealed a large number of potential new types, which are yet to be completely evaluated.

The main clinical associations of the different HPV types are shown in Table 25.3. All papillomavirus types have a tropism for stratified squamous epithelial cells, but they vary in their specificity for different anatomical sites [8]. For example, HPV-1 replicates in heavily keratinized skin of palms and soles, whereas HPV-16 has a preference for genital areas and HPV-11 replicates in genital and laryngeal epithelium.

Papillomas caused by HPVs are initially benign. In these lesions, viral genomes replicate as extrachromosomal episomes. A small percentage can progress to dysplasia or neoplasia. This occurs only with certain so-called 'high-risk' or 'cancer-associated' types of HPV, and under certain genetic and environmental circumstances, some of which are incompletely understood. In the majority of malignantly transformed cells (i.e. those affected by high-risk genital HPVs), the viral DNA is integrated into the cellular chromosomes, usually with the loss of large sections of the viral genome. Viral replication does not occur, but the viral regulatory genes *E6* and *E7* are always retained. The oncogenic potential of the high-risk HPV types depends on the expression of these early genes, whose products play a role in cell transformation and immortalization: the E6 protein inactivates the cellular tumour-suppressor protein p53 and the E7 protein inhibits the cellular pRb protein, which normally functions as a negative regulator of the cell cycle.

The clinically evident infections due to HPVs are described on subsequent pages, although there is also evidence that after initial infection, HPV may persist in a latent form and may be subsequently reactivated.

Subclinical and latent HPV infection. Evidence is accumulating, mainly from studies of genital skin and mucosa, for subclinical and latent HPV infection. It has been estimated that up to 70% of genital HPV infections may be subclinical, i.e. unnoticed by the patient but detectable by full clinical examination, histology, cytology or molecular analysis. In a latent infection, there may be no morphological changes but the viral DNA is present.

Of 545 students attending an annual gynaecological examination in an American university, 1% were aware that they had signs of genital warts, but a further 16% had evidence of HPV infection from colposcopy, cytology or detection of HPV antigen or HPV DNA assessed by hybridization [9]. Among female adolescents in an urban population, 24% had clinical, cytological or DNA evidence of HPV infection, although of these, infection was clinically evident in only 15% [10]. Of over 9000 women routinely screened by cervical cytology in Germany, 2.1% had simple HPV infection (koilocytosis) and 3.7% had signs of dysplasia or neoplasia; of the other (cytologically normal) cases, HPV DNA was detected by hybridization in 9% [11]. The same method demonstrated HPV DNA (including type 16) in penile smears from apparently healthy men [12], in neonatal foreskins obtained at routine

Table 25.3 The main clinical lesions caused by different human papillomavirus (HPV) types. (Data from Cobb [5], de Villiers [6] and Meyers *et al*. [7].)

HPV type	Associated clinical conditions
1	Deep plantar and palmar warts
2	Common warts, filiform warts, plantar warts, mosaic plantar warts
3	Plane warts
4	Common warts, plantar warts
5	EV, SCC in EV
6	Anogenital warts, laryngeal papillomas
7	Butchers' warts
8	EV, SCC in EV

circumcision [13] and in the majority of a series of Panamanian prostitutes [14].

The highly sensitive PCR has revealed apparently very high rates of HPV cervical infection in the general population [11]. In both the Panamanian [14] and Taiwanese [15] studies, when individual women were assessed serially, results were not always consistently either positive or negative, suggesting either an uneven distribution of HPV in affected epithelium or intermittent reactivation of HPV.

Diagnosis. Clinical diagnosis of warts is often sufficient, but atypical, subclinical or dysplastic lesions may need laboratory confirmation of HPV infection. Methods available include:

1 histology;
2 detection of virus particles by electron microscopy—this method would not be helpful for those types of wart which have few virus particles, for example genital warts;
3 immunohistochemistry or immunocytochemistry using type-common or type-specific antibodies;
4 DNA hybridization on tissue extracts or *in situ*;
5 PCR.

Warts

HPVs can infect and cause disease at any site in stratified squamous epithelium, either keratinizing (skin) or non-keratinizing (mucosa). The clinical problems encountered with such infections can be broadly divided into cutaneous warts, genital warts, oral warts and laryngeal warts.

Epidemiology. Warts occur at any age, but are unusual in infancy and early childhood. The incidence increases during the school years to reach a peak in adolescence and early adulthood [1–3], then declines rapidly through the twenties and more gradually thereafter. In various studies, it has been estimated that 3–20% of school-age children have warts. Of 1000 children under 16 with warts referred to hospital clinics in Cambridge, UK in the 1950s, 70% had common warts, 24% plantar warts, 3.5% plane warts, 2.0% filiform warts and 0.5% anogenital warts [4].

In countries with highly developed medical services, referral rates of warts to dermatology clinics have greatly increased in the last 50 years; however, for common and plantar warts, there are insufficient data to assess whether this reflects a true increase in incidence rather than increased demand for treatment. Over the same time frame, there has been a steady increase in the incidence of anogenital warts (condylomata acuminata) [5]. A study in the UK in 1994 estimated the incidence in young adults aged 16–24 to be 500 per 100 000, with an overall population incidence of 300 per 100 000 [6]. A large study in Rochester, Minnesota, in the 1980s [7] recorded an annual incidence of 106.5 per 100 000, or about 0.1% (0.5% in young adults). This latter study found an adjusted male/female incidence ratio of 1 : 1.4 for anogenital warts, with median ages of 22 for women and 26 for men.

An increase in the incidence of anogenital warts in childhood has also been claimed [8], although numbers of reported cases are small and the purported increase has not been substantiated by epidemiological data; in particular, the Rochester study showed no such trend between 1950 and 1978 [7].

Incubation period. The time of acquisition of the infection can seldom be ascertained for common and plantar warts, but the incubation period has been estimated to range between a few weeks and more than a year [9], and experimental infections have taken as long as 20 months to produce clinical warts [10].

A prospective study of sexual contacts of patients with genital warts indicated an incubation period of 3 weeks to 8 months (average 2.8 months) [11]. It is believed that perinatally acquired HPV infection may not manifest as genital warts for up to 2 years [12]. Only 57% of cases of laryngeal papilloma in children are diagnosed by 2 years of age [13].

Infectivity. Two-thirds of 97 sexual contacts of patients with genital warts themselves developed lesions within 9 months; infectivity seemed highest early in the course of the disease [11]. Studies of male sexual contacts of women with genital HPV disease have shown that use of the hand lens or colposcope on penile skin treated with 3% acetic acid (as in standard gynaecological colposcopy), with biopsy in cases of doubt, can reveal previously unsuspected (subclinical) HPV lesions. The percentage of male contacts ultimately diagnosed as infected was given as 69% [14] and 88% [15]. Thus, it should probably be assumed that any sexual contact of a patient with genital warts is likely also to be infected.

There is no reliable information on the infectivity of common and plantar warts, but experience suggests that it is substantially less. The infectivity of maternal genital HPV as regards laryngeal papilloma in the child seems low; of 51 cases of pregnancy in women with genital warts in the Rochester study, no cases of childhood laryngeal papilloma were seen [7]. The risk of transmission from mother to child with subsequent development of disease in the child has been estimated to be between 1 in 80 and 1 in 1500 [16].

Modes of transmission. Warts are spread by direct or indirect contact. Impairment of the epithelial barrier function, by trauma (including mild abrasions), maceration or both, greatly predisposes to inoculation of virus, and is generally assumed to be required for infection at least in fully keratinized skin [9], as in the following examples.

1 Plantar warts are commonly acquired from swimming pool or shower-room floors, whose rough surfaces abrade moistened keratin from infected feet and help to inoculate virus into the softened skin of others.

2 Common hand warts may spread widely round the nails in those who bite their nails or periungual skin, over habitually sucked fingers in young children, and to the lips and surrounding skin in both cases.

3 Shaving may spread wart infection over the beard area.

4 Occupational handlers of meat, fish and poultry have high incidences of hand warts, attributed to cutaneous injury and prolonged contact with wet flesh and water.

5 Genital warts have a high infectivity. The thinner mucosal surface is presumably more susceptible to inoculation of virus than is thicker keratinized skin; in addition, lesions were noted to be commonest in sites subject to greatest coital friction in both sexes [11].

Iatrogenic transmission. Because of the long incubation period, iatrogenic spread would be difficult to establish and seems not to have been reported, though the possibility exists. HPV DNA has been detected on instruments used for the examination of women with clinical or subclinical HPV infection [17,18]. The virus was still detectable after rinsing in aqueous chlorhexidine and therefore heat sterilization is recommended. HPV DNA was found in the smoke plume from warts treated with laser or electrocautery [19]. The common practice of dipping cotton-wool swabs for a series of patients into the same flask of liquid nitrogen could transfer herpes simplex virus (used as a model, and by implication HPV) between patients [20].

Transmission of anogenital warts in adults. HPV transmission has been most closely studied in the case of anogenital warts. The fact that Oriel's study [11] of 332 patients took place in venereology clinics may involve some selection bias, but his conclusion is generally accepted that anogenital warts in adults are usually but not always transmitted sexually. He observed prospectively 97 people who had had intercourse with patients known to have anogenital warts; 64% developed lesions within 9 months. There are also epidemiological parallels between anogenital warts and other sexually transmitted diseases.

Perianal warts may accompany genital warts, presumably often due to local spread of infection in both sexes, but especially in women. In Oriel's venereologically based study [21], 60 of 72 men and four of eight women, with exclusively perianal warts, reported anal coitus within the preceding year. However, it was not suggested that this was the only possible route. A Danish study of surgical treatment in patients with perianal warts found that 58% of the men were homosexual and 33% of the women regularly practised anal intercourse, but numbers were small and patients with exclusively perianal lesions were not differentiated, genital warts being associated in 38% [22].

Occasional non-sexual acquisition of anogenital warts in adults is assumed to be possible. HPV-1 and HPV-2 may occur in genital warts [23,24]. Warts on the penile shaft in three men in Oriel's series [11] were clinically and histologically similar to common warts which they had in other sites. The sensitivity of PCR analysis has shown that HPV DNA may be present on underwear and the fingers of patients with genital warts [25,26], suggesting that transmission could occur by a number of routes.

Transmission of anogenital warts in children [8,12,27]. Anogenital warts are uncommon in children, although their occurrence frequently stimulates discussion of the possibility of sexual transmission. With the lack of large-scale prospective studies, the possibility of bias in referral or in reporting should be considered, and there remains insufficient information to offer a reliable estimate of the relative frequency of sexual abuse in such cases.

Infection from the mother's genital tract at delivery [28–30] is regarded as a frequent source of childhood anogenital warts, probably including those presenting up to 2 years of age. Genital papillomaviruses transmitted from mother to baby at birth may persist in childhood [31,32] as shown by the retention of the DNA and/or a

humoral response against the viral proteins. Postnatally, transmission from adults with genital warts may occur non-sexually [33], such as by sharing a bath with an infected adult. A review of reports published between 1976 and 1983 [34] found that, of the total of 21 cases, the probable route of infection was believed to be sexual in 11, prepartum or intrapartum in three, and unknown in seven. Studies involving HPV typing of childhood anogenital warts have produced somewhat varying conclusions. Rock *et al*. [29] found genital HPV types (6, 6/11 or 16) in all of five cases and suspected sexual abuse in three. Benton *et al*. [35] found types 6/11 and/or 16/18 in six of 10 cases, and none was positive for HPV-1, HPV-2 or HPV-4; one or both parents of seven of the 10 cases had genital warts, but sexual abuse was considered unlikely in all cases. Venning *et al*. [36] typed nine of 11 cases; three had HPV-2, one HPV-3, two HPV-6, one HPV-11 and two were negative. Of the 11 children, five had coexisting extragenital warts and one of these had HPV-2 in both sites, supporting the possibility of autoinoculation from common warts. The clinical types included classical condyloma acuminatum, fleshly pedunculated lesions, verucca vulgaris and plane warts, but morphology did not correlate fully with HPV type.

Thus, on present incomplete information, both sexual and non-sexual routes are significant in transmission of childhood anogenital warts. The long and variable incubation period, the possibility of latent or subclinical infection in the source and the problems in eliciting an accurate account of sexual contact from the child and of confirming it from the perpetrator all make it difficult to decide which applies in an individual case. Absence of other physical evidence of molestation, location of the warts on fully keratinized skin as opposed to genital or anal mucosa, a clinical resemblance to common warts and young age of the child, perhaps up to 1–2 years at the onset of the warts, would tend to support non-sexual transmission. Where sexual abuse is suspected, the case should be referred to a child-abuse specialist. In addition, HPV typing, if available, may be forensically useful; the same type in child and in suspected abuser would be consistent with, but not proof of, sexual transmission, while different types would be strong evidence against the possibility.

Pathology. The characteristic histological feature of viral warts is vacuolation in cells in and below the granular layer, often with basophilic inclusion bodies composed of viral particles, and eosinophilic inclusions representing abnormal keratohyaline granules. This cytopathic effect may show detailed features typical of the HPV type involved [1,2] and is almost always accompanied by epidermal acanthosis and often papillomatosis.

Common and plantar warts. These are characterized by hyperplasia of all layers of the epidermis. There is gross hyperkeratosis with areas of parakeratosis especially in plantar warts, and both Malpighian and granular layers are conspicuously thickened. Elongated and flattened dermal papillae are bent inwards towards the centre of the wart. The granular layer may be disordered and vacuolated cells are carried up with the parakeratotic stratum corneum.

Plane warts [3]. The hyperkeratosis is of a loose lamellar type and there is acanthosis without papillomatosis. Vacuolated epidermal cells are more numerous and some are very large.

Genital warts. Genital warts show extreme acanthosis and papillomatosis, although the horny layer is parakeratotic and not much thickened. There may be many vacuolated cells in the upper Malpighian layer, but they may be limited in distribution and not found in all sections. The epidermal processes are wide and rounded, with a well-defined lower border. The connective tissue is frequently very oedematous and the capillaries tortuous and increased. Benign giant condylomas may be difficult to differentiate from malignant condylomas [4]. In the latter the processes are narrower, multiple and often irregular, and mitoses are frequent. Repeated biopsies from a giant condyloma may fail to reveal the malignancy established by its subsequent course [5].

The histology and cytology of cervical epithelium with regard to HPV infection, dysplasia and neoplasia have been widely discussed in the literature and different classifications have developed.

Immunity to HPV [1–3]. The relative sequestration of the virus in the upper reaches of the epidermis, the difficulty of finding control subjects who have never been infected and the large number of HPV types have delayed research and our understanding of the immune mechanisms in relation to this virus. Recently, however, the ability to clone the viral genes and to produce recombinant capsid proteins and early (E) gene peptides has led to many advances. For example, beagle dogs immunized with virus-like particles of major capsid protein of the canine oral papillomavirus developed neutralizing antibodies and were completely protected from developing mucosal papillomas [4]. Also, cell-mediated immune responses have been produced in mice by injecting an HPV-16 E7 peptide. This protected them against subsequent challenge with HPV-16 transformed tumour cells which would otherwise have caused a lethal tumour [5]. These and other studies have led to the development of both prophylactic and therapeutic vaccines. The recent report of 100% protection afforded by vaccination with HPV-16 virus-like particles is dramatic evidence that protective immunity against HPV disease may be possible in the future [6].

HPV lesions are under immunological surveillance. A humoral immune response is mounted against papillomavirus products [7], but the importance of this in modulation of the disease process or prevention against reinfection is yet to be determined. Cell-mediated immunity appears to be the principal mechanism for the rejection of warts. Warts can disappear when the immune response is stimulated. In contrast, in persistent disorders of cell-mediated immunity, the prevalence and severity of warts and the incidence of HPV-related malignancy are increased. In addition, the histological changes in regressing warts are consistent with cell-mediated attack; a study of resolving plane warts showed lymphocytic and phagocytic infiltrates including helper and suppressor T cells, Langerhans' cells and satellite-cell necrosis [8]. A more detailed dissection of the immunological events occurring in resolving genital warts has shown that the lymphocytic infiltrate comprises predominantly $CD8^+$ cells [9].

The apparent failure of the immune system in otherwise healthy individuals to clear warts for months or years remains incompletely understood. A subdued local immune response is suggested by the observations that Langerhans' cell numbers are reduced within warts [10] and ICAM-1 expression is reduced in the proliferating epidermis [11]. In non-regressing warts, T lymphocytes are rare within the epidermal compartment, although they are relatively plentiful in the dermis beneath warts. Some early studies of non-specific measures of lymphocyte function in otherwise healthy patients with warts showed reductions compared with controls, the significance of which was uncertain. In patients who harbour high-risk genital HPVs with the development of cancer, it is possible that the immune system may be unable to

target certain HPV proteins, possibly due to the development of tolerance. The initial success of the virus in establishing infection may depend in part on avoidance of detection by the innate immune response and certain immunomodulatory effects of the viral proteins. These are as yet not fully characterized but involve altered regulation of interferon-response gene effects.

Clinical features

Common warts (Fig. 25.16). Common warts (excluding plantar warts) are due mainly to HPV-2, but also to the closely related HPV-57 and to HPV-1 and HPV-4. Firm papules with a rough horny surface, they range in size from less than 1 mm to over 1 cm in diameter, and by confluence can form large masses. They are most commonly situated on the dorsa of the hands and fingers and, in children under 12 years of age, on the knees, but may

occur anywhere on the skin. A single wart may persist unchanged for months or years, or large numbers may develop rapidly or after an interval. New warts may form at sites of trauma, although this Koebner isomorphic phenomenon is usually less marked than in plane warts. However, multiple warts around the nail folds are often seen in nail-biters.

Common warts are usually symptomless, but may be tender on the palmar aspects of the fingers, when fissured or when growing beneath the nail plate. Warts around the nail folds or beneath the nail may disturb nail growth, and warts on the eyelids may be associated with conjunctivitis or keratitis. Common warts account for only 1 or 2% of warts on or around the genitalia; in the male they are almost always confined to the shaft of the penis. They often retain their usual morphological characteristics with dry hyperkeratosis and frequently do not resemble soft acuminate (genital) warts.

It is impossible to offer a reliable prognosis in the individual patient. About 65% of warts disappear spontaneously within 2 years [1–3] and tend to do so earlier in boys [2]. Neither the patient's age nor the number of warts present influences the course. Regression of common warts is asymptomatic and occurs gradually over several weeks, usually without blackening [3,4].

Malignant change in common warts is extremely rare but has been reported.

Plantar warts [5]. Plantar warts involve HPV-1, HPV-2, HPV-4 or HPV-57. The deep 'myrmecia' form is due to HPV-1. Smaller lesions may contain HPV-2, HPV-4 or HPV-57, while mosaic warts are commonly caused by HPV-2.

A plantar wart at first appears as a small, shining, 'sago-grain' papule but soon assumes the typical appearance of a sharply defined rounded lesion, with a rough keratotic surface surrounded by a smooth collar of thickened horn. If the surface is gently pared with a scalpel, the abrupt separation between the wart tissue and the protective horny ring becomes more obvious, as the epithelial ridges of the plantar skin are not continued over the surface of the wart. If the paring is continued, small bleeding points, the tips of the elongated dermal papillae, are evident.

Most plantar warts are beneath pressure points, the heel or the metatarsal heads. In older girls and women they occur predominantly beneath the forefoot and toes. Individuals may be affected by single or numerous lesions. Sometimes, a cluster of small satellite warts, the smallest of pinhead size, having at first an almost vesicular appearance, may develop around a large wart. Mosaic warts are so described from the appearance presented by a plaque of closely grouped warts (Fig. 25.17). The angular outlines of the tightly compressed individual warts are seen when the surface is pared. Groups of warts on the plantar aspect of the heel may in fact be connected under the surface [6].

Fig. 25.17 Mosaic plantar wart. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

Pain is a common but variable symptom. It may be severe and disabling but may be absent, and many warts are discovered only on routine inspection. Mosaic warts are often painless.

The duration of plantar warts is very variable. Spontaneous regression occurs sooner in children than in adults and is delayed if hyperhidrosis or orthopaedic defects are present. In children before puberty the average duration is probably less than a year and some 30–50% disappear spontaneously over a 6-month period of observation. In older children and adults a longer duration is not uncommon and persistence for several years is not exceptional. The number of warts present does not influence the prognosis, although mosaic warts tend to be persistent. Regression is occasionally clinically inflammatory, and often culminates in blackening from thrombosed blood before the lesion separates [3], but in many cases simply takes the form of apparent drying and gradual separation.

Plantar warts are often confused with callosities or corns, with which they may indeed be associated. Callosities have a uniformly smooth surface across which the epidermal ridges continue without interruption. In cases of doubt the horny layer should be gently pared. Corns occur on pressure points on the toes, soles or interdigital skin.

Plantar warts may rarely be confused with the discrete horny papules of punctate keratoderma of genetic origin (see Chapter 34), which develop during childhood or early adult life, are irregularly scattered over the palms and soles, and are often largest in pressure areas.

Plane warts (flat warts) (Fig. 25.18). Plane warts, due mainly to HPV-3 and HPV-10, are smooth, flat or slightly elevated and are usually skin-coloured or greyish-yellow but may be pigmented. They are round or polygonal in shape and vary in size from 1 to 5 mm or more in diameter. The face and the dorsa of the hands and the shins are the sites of

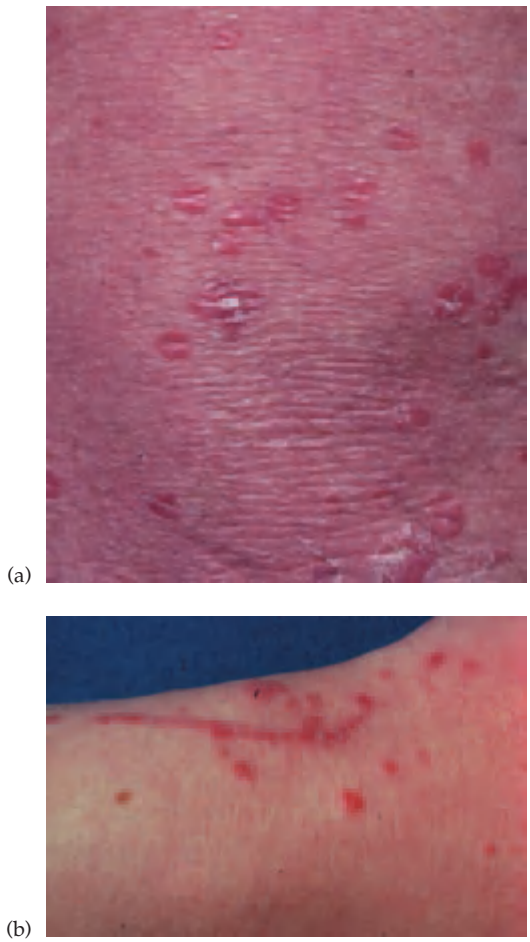

Fig. 25.18 Plane warts: (a) warts on knee; (b) warts on arm with spread into a scratch. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

predilection and the number present ranges from two or three to many hundreds. Contiguous warts may coalesce and a linear arrangement in scratch marks is a characteristic feature (Fig. 25.18b). Although all warts present are usually of the same type, a few common warts may be associated, especially on the dorsa of the hands. Laryngeal papillomas have sometimes been associated with plane warts on the face.

Regression of plane warts is usually heralded by inflammation in the lesions, causing itch, erythema and swelling, such that previously unnoticed warts may become evident. Depigmented haloes may appear around the lesions. Resolution is usually complete within a month, and appears to be HPV-type specific as it generally occurs in all plane warts at all body sites, though not in any coexisting warts of other types [7,8].

In differential diagnosis, lichen planus causes most difficulty. It is relatively less common in children, favours the flexor aspects of the forearms, is unusual on the face and is often itchy. The mucous membranes may be

Fig. 25.19 Filiform wart on forearm. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

involved. The flat polygonal papules are lilac-pink and smooth and may show Wickham's striae. In contrast, the surface of plane warts has a stippled appearance under the hand lens.

In acrokeratosis verruciformis, numerous warty papules are symmetrically distributed on the dorsa of the hands.

Filiform and digitate warts (Fig. 25.19). Filiform and digitate warts occur commonly in the male, on the face and neck, and are irregularly distributed and often clustered. Digitate warts, often in small groups, also occur on the scalp in both sexes, where they are occasionally confused with epidermal naevi. Isolated warts on the limbs often assume a filiform shape.

Anogenital warts (Figs 25.20 & 25.21). The term 'condyloma acuminatum' (*condyloma*, knuckle; *acuminatum*, pointed; plural condylomata acuminata) was originally used to emphasize the difference between anogenital warts, which are usually protuberant, and the flatter syphilitic lesions called condylomata lata. It became an accepted term, mostly in the American literature, for viral anogenital warts. With developments in the understanding of HPV disease, it is clear that the term is used variously to denote (i) the classical protuberant type of anogenital wart only; (ii) all clinically identifiable HPV disease of the anogenital region, including flat warts on the external genitalia and cervical 'flat condylomas'; and (iii) all clinical lesions due to the HPV types usually associated with genital warts, including those in extragenital sites, for example the mouth.

Anogenital warts are common, with an estimated 1.3 million new cases per year in the USA. They are often asymptomatic, but may cause discomfort, discharge or bleeding. The typical anogenital wart is soft, pink, elongated and sometimes filiform or pedunculated. The lesions are usually multiple especially on moist surfaces, and

(a)

(b)

(c)

their growth can be enhanced during pregnancy [9] or in the presence of other local infections [10,11]. Large malodorous masses may form on vulvar and perianal skin. This classical 'acuminate' (sometimes called papillomatous or hyperplastic) form constitutes about two-thirds of anogenital warts. The commonest sites, the area of frenulum, corona and glans in men, and the posterior fourchette in women, correspond to the likely sites of greatest coital friction [9]. Most other lesions are flat, though more conspicuous than plane warts elsewhere, and some of these, generally on non-mucosal surfaces such as the penile shaft, pubic skin, perianal skin and groins, may be sufficiently pigmented to resemble seborrhoeic keratoses. Both acuminate and flat types may coexist. Occasionally only lesions resembling common warts are seen, in men usually on the penile shaft, and these may be the result of contact with common warts elsewhere on the patient or on the sexual partner [9,12].

In children, warts in the anogenital area are often more hyperkeratotic than in adults and may be caused by HPV types associated with cutaneous disease as well as by HPV-6 and HPV-11 (see p. 25.40).

The duration of anogenital warts varies from a few weeks to many years. Recurrences can be expected in about 25% of cases, the interval varying from 2 months to 23 years [13]. HPV DNA has been demonstrated in clinically and histologically normal skin adjacent to warts and intraepithelial neoplasia, and this latency correlated well with recurrence after clinical cure [14].

Of 59 examples of the classical acuminate form, 75% contained HPV-6 and 25% HPV-11. These virus types were also found in flat lesions of low epidermal atypia, but clinically indistinguishable flat lesions containing HPV-16 showed severe epidermal atypia (anogenital intraepithelial neoplasia, Bowenoid papulosis) [12].

Patients with genital warts frequently have other genital infections. These are mainly minor conditions such as candidiasis, trichomoniasis and non-specific genital infection with occasional major venereal infections (syphilis or gonorrhoea) [15,16], although in some series based in venereology departments the incidence of these associated infections has been as high as 10–20% [9,10].

Vulval papillomatosis, with a diffuse velvety or granular appearance, has been associated with HPV infection [17], although more recent studies have refuted a causal link [18,19].

The development of large protuberant masses, induration, pain or serosanguineous discharge should arouse suspicion of malignant change (including Buschke–Löwenstein tumour), requiring prompt excision or biopsy.

Human papillomavirus and warts in special situations

Butcher's warts. Occupational handlers of meat, poultry or fish have a high incidence of warts on skin that is in prolonged contact with animal flesh, usually the hands. Among 1480 New York meat-trade workers, 23% of those directly handling meat had warts compared with 10% of those employed in other tasks [1]. In a Polish study, warts affected 49% of slaughterhouse workers who had direct contact with flesh, but only 9% of those working in a slaughterhouse automated so that little handling of meat took place [2].

These lesions affect the hands, are often larger than common warts and recur after successful treatment in 50% of cases. HPV-2 (the cause of common warts) is frequently found in butcher's warts, but HPV-7 is present in up to one-third of lesions [2–4]. Of 11 fish handlers with hand warts [5], HPV-7 occurred in seven and multiple types in four. HPV-7 initially seemed specific to meat handlers, although there is no evidence that it is an animal papillomavirus which has crossed the species barrier. It has, however, been reported occasionally in warts of non-meat handlers [4,6], and in facial and oral warts of patients with HIV disease [7].

Epidermoid plantar cysts. Epidermoid cysts of weight-bearing areas of the sole have been found to contain papillomavirus (HPV-60 and in one case HPV-57) in several Japanese patients [8,9]. The cysts, which may arise by implantation, show histological features of HPV infection in the stratifying squamous wall. The upper epidermal cells produce large cytoplasmic granules and abundant viral particles.

Pigmented warts. Warts with pigmentation have been reported mainly on palms and soles in Japanese patients [10]. Melanosomes are increased within the lesions, which are associated with HPV-65 (64%), HPV-4 (23%) and HPV-60 (13%).

Respiratory papillomatosis [11,12]. This condition is most commonly due to HPV-11 but is also associated with other common genital types, HPV-6, HPV-16 and HPV-18. Childhood cases are believed to result from maternal infection, probably at birth during vaginal delivery. Latent virus in the laryngeal mucosa [13] presumably explains recurrences after successful treatment, and might explain adult-onset cases, although some of these might be due to sexual transmission [14,15].

Oral warts and HPV [16]. Oral warts, including some which appear to have been sexually transmitted [17], usually contain HPV-6 or HPV-11 [18]. HPV-13 and HPV-32 seem to be almost specific for lesions of the rare, benign, familial disorder focal epithelial hyperplasia (Heck's disease) [19]. HPV-16 has been detected in over 80% of cases of oral leukoplakia, and in some cases of oral squamous carcinoma.

Conjunctival papillomas and HPV. HPV antigen is frequently identified in conjunctival papillomas [20]. Two childhood cases, presenting at about 1 year of age, had genital HPV types suggesting intrapartum infection [21,22].

Nasal inverting papillomas. HPV-11 and HPV-57 have been detected in nasal inverting papilloma and in an inverting papilloma of the maxillary sinus [23–25].

Psoriasis. The use of sensitive PCR amplification has revealed HPV sequences in patients with psoriasis and it is speculated that the virus may have a role in the disease process. DNA of the epidermodysplasia verruciformis HPV types has been demonstrated in over 80% of psoriatic skin lesions compared with nearer 20% of normal skin of non-psoriatic individuals [26,27].

Treatment [1,2]. The routine treatment of every wart is unnecessary and undesirable. Before specific treatment is given, it is helpful to explain to the patient or parent that warts can be expected to resolve spontaneously without trace, and that the common, more radical measures, such as cryotherapy or cautery, have their disadvantages. Patients may need encouragement to persevere with long-term daily use of the simpler preparations. Whatever method is used there will be failures and recurrences. The best clinical guide to cure is the restoration of normal epidermal texture including the epidermal ridge pattern where appropriate.

Advice on simple measures to limit the spread of the infection will be appreciated. Plantar warts should be covered with adequate plaster strapping or the foot with close-fitting rubber 'verruca socks'; pool-side sandals should be worn at swimming pools or communal baths or showers. The spread of periungual and perioral warts is often due to biting of nails or periungual skin, and this practice must be strongly discouraged if attempted treatment is to be worthwhile; the use of adhesive strapping

after the application of a 'wart paint' helps to break the habit. In addition, simple domestic hygiene, such as cleaning of baths after use and avoidance of shared towels, may be advised.

Below are additional points regarding anogenital warts.
1 The full extent of subclinical and latent genital HPV infection in both sexes is not yet clear. It is generally assumed that treatment of clinical lesions, and probably also subclinical infection, reduces infectivity, although the extent to which this may be confounded by latent virus is unknown. Considering the high sexual infectivity of anogenital warts and the high incidence of latent genital HPV, it may be prudent to assume that the sexual partner is very likely to be infected and that virus is likely to persist, perhaps indefinitely, even after clinical cure. It is usual to advise abstention from intercourse or use of condoms until visible lesions are clear or, some suggest, for 6 months or more thereafter [3]. However, it might be supposed, in stable relationships, that infection of the partner will already have taken place, and it is not known whether the patient can ever be deemed free of infectivity.
2 Occasionally, vulvar warts may be so large in pregnancy as to obstruct vaginal delivery and require caesarean section.
3 The main long-term concern is the risk of cervical dysplasia and neoplasia, so that cervical smear examinations, perhaps at annual intervals, should be advised both for female patients with anogenital warts and for female partners of male patients. This would be especially important if an HPV type known to be associated with neoplasia has been identified. Viral typing can be done by PCR or DNA hybridization techniques on cervical smears or brushings.
4 In children with anogenital warts, consideration should be given to the possibility of sexual transmission and the advisability of referral to a child abuse specialist.
