The histology of ordinary urticarial weals is usually non-specific, with vascular and lymphatic dilatation, oedema and a variable perivascular cellular dermal infiltrate consisting of lymphocytes, monocytes, neutrophils and eosinophils. On electron microscopy, dermal mast cells show signs of degranulation. In one study, dermal mast cells in weals of chronic urticaria were increased by 10 times [1] compared with non-urticated skin, but this increase was not confirmed in a recent study using tryptase as a marker [2]. In the majority of ordinary weals, there is a sparse perivascular infiltrate, predominantly of helper T lymphocytes [3,4] with a TH_0 cytokine profile expressing mRNA for interleukin (IL)-4, IL-5 and interferon-γ (IFN-γ) [5]. In a minority of weals, neutrophils are a conspicuous feature, within the vessel walls or scattered in the dermis [6]. Eosinophils may play a more important role than their sparse numbers seen on light microscopy would suggest, as extracellular eosinophil major basic protein is frequently deposited in spontaneous weals [7] and they stain for activation markers [8]. The spectrum of cellular changes may depend on the age of weals and their underlying cause. Biopsies are generally performed if individual weals are persistent, and they may show features of delayed pressure urticaria or urticarial vasculitis. In delayed pressure urticaria, the infiltrate is denser, with neutrophils often present in early weals, and eosinophils extending deep into the fat in early and late weals. These cellular changes correlated with moderate up-regulation of the vascular endothelial adhesion molecules E-selectin, intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1) on perivascular cells [9]. Urticaria with histological evidence of vasculitis (venulitis) is defined as urticarial vasculitis.

Pathophysiology [1–3]

Mast cell mediators and activation

Urticaria is due to a local increase in permeability of capillaries and venules. These changes are dependent on activation of cutaneous mast cells, which contain a range of pro-inflammatory mediators, but predominantly histamine. Increased concentrations of histamine have been recovered in tissue fluid from lesions of chronic idiopathic urticaria [4] and from venous effluent draining the urticated areas in most physical urticarias. The clinical improvement on treatment with H_1 antihistamines underlines the role of mast cell-derived histamine as a major

mediator in urticarias. Activation of H_1 receptors in the skin induces itching, flare, erythema and wealing. Activation of H_2 receptors contributes to erythema and wealing, but not itch or flare. So far, H_3 receptors—identified in the nervous system as inhibitory autoreceptors, in that their activation leads to reduced biosynthesis and release of histamine—have not been identified in human skin. Other vasoactive and chemoattractant mast cell-derived mediators, and secondary release of non-mast cell mediators from inflammatory cells, may amplify and prolong the weal. Little is known of the process of weal resolution.

Mast cell activation may be non-immunological or immunological. Non-immunological mast cell activation occurs with a variety of substances including neuropeptides, such as substance P; drugs, including opiate derivatives, such as morphine and codeine, vancomycin and polymyxin; some radiocontrast media; and some foods, such as strawberries. Neuropeptides elicit histamine but not prostaglandin D_2 (PGD_2) or leukotriene C_4 (LTC_4) release.

Immunological mast cell activation (see Chapter 9) occurs as a result of linkage of two adjacent α-subunits of high-affinity IgE receptors (FcεRIα) of a mast cell. Preformed histamine, proteases and newly generated mediators, including PGD_2 and cytokines—IL-3, -4, -5, -6, -8, -13 and tumour necrosis factor-α (TNF-α)—are released from mast cells. In classic immediate allergic reactions, receptor cross-linking occurs indirectly when an allergen (such as latex) reacts with two or more antigen-specific IgE antibodies, each bound to FcεRIα. Activation also occurs by cross-linking autoantibodies directed against IgE bound to FcεRIα or against the α-subunit of FcεRI itself. Complement C3a and C5a can release histamine directly and appear to be a necessary co-factor for some autoantibody-induced degranulation [5]. Basophils also express FcεRIα and release histamine, IL-4, IL-13 and LTC_4 on activation.

Compared with normal controls, the cutaneous mast cells from chronic urticaria also release more histamine spontaneously and in response to non-specific degranulating agents such as codeine and morphine [6]. There is no evidence for decreased skin histamine metabolism in the skin of chronic urticaria subjects. However, their cutaneous vasculature is more responsive to histamine than skin of normal controls [7].

Tryptase and chymase are released in conjunction with histamine. Potentially, they could play a part in the pathogenesis of urticaria, as chymase can induce mast cell degranulation and tryptase and chymase cleave C3 to C3a and C3b. C3a can activate mast cells, and C3b can activate the alternative complement pathway. The example of hereditary angio-oedema has encouraged a search for other inhibitor deficiencies as a cause for other types of urticaria. A decrease of α_1-antitrypsin has been reported in cold urticaria [8]. Low levels have only sometimes been found in other types of urticaria, including chronic 'idiopathic' urticaria [9]. Usually there is a poor correlation between the levels found and the clinical activity.

There is no convincing evidence that the low levels of vasoactive PGD_2 and LTC_4 released from cutaneous mast cells play a significant role in urticaria. While TNF-α up-regulates vascular endothelial adhesion molecules, IL-8 causes neutrophil leukocyte accumulation. IL-4 also influences T-lymphocyte differentiation towards a cytotoxic phenotype and immunoglobulin production by plasma cells. However, a direct role for these interleukins in urticaria has not been substantiated.

Histamine-releasing autoantibodies

Sera of approximately 60% of patients with chronic 'idiopathic' (ordinary) urticaria have been shown to cause a pink weal, probably due to histamine, when injected intradermally into the patient's own skin (the autologous serum skin test) [10]. Approximately half of these patients' sera (30% of total chronic 'idiopathic' urticaria patients) released histamine *in vitro* from basophils and skin slices obtained from healthy people in one series [11]. The proportion of chronic urticaria sera releasing histamine has been up to 50% in others [5]. This activity is due to functional IgG autoantibodies directed against the α-subunit of FcεRI or less frequently against receptor-bound IgE [12,13]. These functional autoantibodies are predominantly of IgG1 and 3 subclass [14]. Complement dependence of autoantibody-induced mast cell degranulation has been shown [15]. In a few patients with a positive skin test, there was evidence of an unidentified non-IgG factor reacting with mast cells but not basophils [16]. Autoantibodies, of predominantly IgG2 and 4 subclasses, against FcεRIα have been detected by Western blot and enzyme-linked immunoassay (ELISA) in the sera of patients with other conditions, such as systemic lupus erythematosus (SLE), dermatomyositis, bullous pemphigoid and pemphigus vulgaris [14], and even in healthy subjects [17], but appear to be non-functional and therefore unlikely to be of pathogenic importance.

Immune-modulating treatment of severely affected chronic urticaria patients with a positive skin test, using plasmapheresis [18] and intravenous immunoglobulin [19], was associated with clinical remission in some. Thus, in some patients, chronic urticaria appears to be a manifestation of a specific autoimmune disorder. In the remaining 50% of patients, no histamine-releasing factor can be identified *in vitro* or *in vivo*. The role for histamine-releasing factors in the clinical behaviour and therapeutic response of chronic urticaria is still under investigation.

Neuropeptides

Some nerve endings are positioned close to mast cells. Histamine can stimulate sensory afferent nerves to release

substance P. Neuropeptides appear to be responsible for the neurogenic axon flare after intradermal histamine injection [20], but there is no direct evidence for neuropeptide involvement in weal formation.

Kinins and complement

Plasma-derived kinins do not appear to have a significant role in chronic urticaria, but it is thought that production of bradykinin by the action of kallikrein on kininogen and kinin-like peptides derived from the early components of complement are important in the pathogenesis of angio-oedema associated with C1 esterase inhibitor deficiency. The angio-oedema seen with ACEI is believed to be due to inhibition of breakdown of bradykinin by ACE, which also acts as a kininase. Complement activation, with production of the anaphylatoxins C3a and C5a, occurs in urticarial vasculitis.

Cellular involvement

The dermal leukocyte cellular infiltrate in chronic ordinary urticaria, consisting of lymphocytes, neutrophils and eosinophils, releases a variety of cytokines with pro-inflammatory properties that may enhance and perpetuate the wealing response. Blood basophils may be involved in the pathogenesis of chronic ordinary urticaria, as their numbers are substantially reduced in the presence of histamine-releasing factors in serum [21], and they also release less histamine in response to anti-IgE stimulation [22]. Recent evidence indicates that they may contribute to prolongation of urticarial weals by active recruitment from the circulation [23]. The observation that the cellular infiltrates in weals of patients with chronic autoimmune and non-autoimmune ordinary urticaria are similar [24] suggests that the inflammatory response is determined by the event of mast cell degranulation rather than its stimulus.

In physical urticarias, there is no evidence for increased mast cell numbers. Infiltrates tend to be mild and mixed in dermographism [25]. In addition to histamine release, ill-defined eosinophil and neutrophil chemotactic factors have been demonstrated in venous effluent from cold, cholinergic and solar urticarial lesions. The mode of activation of mast cells in physical urticaria is poorly understood, but in some patients with dermographism, cold and solar urticaria, a transferable IgE-like factor has been identified. It has been speculated that the physical stimulus in these patients may induce a neo-antigen that could stimulate IgE production directed specifically against it. On rechallenge, this neo-antigen would react with its specific IgE bound to mast cells and activate mediator release. Increased substance P and vasoactive intestinal peptide (VIP) have been recovered from dermographic and cold urticarial lesions, while clinical lesions of cold and localized heat urticaria were diminished by prior application of topical capsaicin, a depletor of neuropeptides.

Ordinary urticaria

Clinical features

Itching erythematous macules develop into weals consisting of pale to pink, oedematous, raised areas of the skin often with a surrounding red flare. They occur anywhere on the body, including scalp and palms and soles, in variable numbers and sizes, ranging from a few millimetres to lesions covering large areas and of varying shapes including rounded, annular, serpiginous and bizarre patterns due to confluence of adjacent lesions (Fig. 47.1). Occasionally, bullae may form in different types of urticaria. Weals generally last a few hours and resolve within 24 h, passing through a macular erythematous phase, but nearly always leaving the skin with a normal appearance. Weals are generally very itchy, especially superficial weals and particularly at night. Patients tend to rub rather than scratch, so excoriation marks are unusual, but occasionally bruising may result, which may be seen particularly on thighs. Weals may be more pronounced in the evenings or premenstrually.

In 50% of ordinary urticaria cases, there may be associated angio-oedema. These deep swellings, which may be the same colour as normal skin, occur most frequently on the face, affecting the eyelids and lips, but any other area of the body may be affected, such as ears, neck, hands, feet and genitalia. Mucosal swellings occur inside the oral cavity on the buccal mucosa, tongue, pharynx and larynx. Angio-oedema may be preceded by an itching or tingling sensation, but it is not always itchy and may be painful. The lesions may last for several days.

Urticaria may be preceded by vomiting [1] and be associated with systemic symptoms of malaise, loss of concentration, feeling hot and cold, headache, vomiting, abdominal pain, diarrhoea, arthralgia, dizziness and syncope and, in its most severe acute form, with anaphylaxis.

Urticaria in childhood

The same multiplicity of factors is found as in the adult [1], with a tendency to more cases of acute disease. Cow's-milk allergy is the commonest cause of urticaria in infants under 6 months old [2]. In infants, there may be less itching and a greater tendency for weals to become purpuric. A not uncommon pattern is one of bizarrely shaped weals, not seen as frequently in adults. No specific aetiology or natural history has emerged in such cases. Neonatal haemorrhagic urticaria (purpura en cocarde) occurs in very young children and is borderline between urticaria and vasculitis (Fig. 47.2).

Acute urticaria

Most acute urticaria is ordinary and some will become chronic. Serum sickness due to injection of therapeutic animal antisera (e.g. to snake venoms) is now rare. Physical urticarias will go through an acute phase but most will last more than 6 weeks. Contact urticaria does not usually present as acute urticaria because it tends to be intermittent and short-lived. The incidence in the community is not well defined. Many cases will not present to secondary care. Although some cases can be ascribed to allergy, non-allergic causes or infections, many will be idiopathic after evaluation.

Idiopathic

This form of acute urticaria, in which no cause can be identified, was present in more than 50% of patients with acute urticaria presenting to a city 'walk-in' dermatology centre [1]. In the others, the most common preceding event was an upper respiratory tract infection, followed by drug ingestion, but allergy or intolerance to food was rare [1,2].

Allergic

This is commoner in the community than in dermatological practice, where it is rare. Allergic urticaria is due to interaction of an allergen with specific IgE bound to the mast cell. It is commoner in people who are atopic and have elevated IgE levels. Although it is unusual to find an allergic cause for acute urticaria [1], any drug, food, foreign substance from blood transfusion, injection, implant, contactant and inhalant should be considered as a potential allergen (Table 47.2). In an IgE-mediated reaction, there will have been a previous exposure and the reaction may occur in minutes and no longer than 60 min. Patients will usually recognize this and avoid the offending substance. Acute urticarial reactions from drugs are common (Tables 47.2 and 47.3), usually occurring within 36 h of drug administration. It is unusual to develop urticaria from a drug taken continuously for months. Sometimes, it is uncertain if a drug-induced urticaria is allergic, and if it is, whether the reaction is IgE-mediated or IgG-mediated via immune complexes [3]. Antibiotics, especially penicillins and cephalosporins, are common causes. Increased risk factors include previous exposure and reaction to the drug or a chemically related drug, intermittent and multiple drug therapy, and a familial predisposition [4].

Fig. 47.1 Different morphology of urticarial weals. (Courtesy of Addenbrooke's Hospital, Cambridge, UK (a); courtesy of St John's Institute of Dermatology, London, UK (b–d).)

Acute urticarial reactions to food are believed to be common and many go unreported [5]. Urticarial reactions may not be to the basic nutrient but to other ingredients, such as seeds or spices. Reactions occur within minutes, but occasionally allergic urticaria develops many hours after food ingestion, probably due to slow absorption or metabolism of food. Rarely, allergic reactions to food occur only if intake is followed by exercise, with neither food nor exercise alone inducing weals (food-dependent exercise-induced anaphylaxis) [6]. Substances reported to cause this include wheat, hazelnuts and shellfish.

Fig. 47.2 Idiopathic haemorrhagic oedema or cocarde purpura of childhood. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

Table 47.2 Some substances reported frequently to cause urticaria and anaphylaxis due to an immunoglobulin E-dependent mechanism, although other mechanisms may also be involved.

Latex
Hymenoptera (bee and wasp) stings
Penicillins
Cephalosporins
Insulin
Vaccines
Blood products
Crustaceans (lobsters, shrimp, crab)
Fish
Milk
Nuts, especially peanuts
Beans
Potatoes
Celery, parsley
Carrots
Spices
Rice
Bananas
Apples
Oranges

Table 47.3 Some substances implicated more frequently in causing non-immunological urticarial and anaphylactoid reactions.

Drugs
Acetylsalicylic acid (aspirin)
Other non-steroidal anti-inflammatory drugs
Polymyxin
Radiocontrast media
Plasma expanders
General anaesthetic agents

Stinging insects are members of the order Hymenoptera, and bees and wasps are representatives of its two major subgroups. Allergic reactions to injected sting venom are not uncommon and occasionally are fatal [7]. Development of bee-sting allergy usually requires multiple exposures, and is commonly seen in beekeepers. Development of allergy to wasp stings and the pattern of severity of reactions to any subsequent stings are unpredictable. Allergy to insect stings is not restricted to atopic individuals.

Reactions to some substances may be dramatically severe and may proceed rapidly to systemic anaphylaxis [8–10]. Here, prodromal symptoms include itching or tingling of the mouth, palms, soles and genital area. Subsequent signs include widespread erythema, urticaria, lacrimation, nasal stuffiness, bronchospasm, laryngeal oedema, nausea, diarrhoea, vomiting, hypotension or cardiac arrhythmias and can rarely lead to death. This is a medical emergency, and first-line treatment is with epinephrine (adrenaline) [10].

Some substances more readily evoking IgE-mediated anaphylactic reactions include penicillins, sesame seeds, peanuts, latex and Hymenoptera stings. The need to label food with individual constituents is increasingly recognized. In some patients, despite all efforts, no cause for anaphylactic symptoms can be identified [11].

Non-allergic

Acute urticarias from ingested substances may be non-allergic (see Table 47.3). They are then referred to as intolerance reactions. These may be due to direct histamine release from mast cells (histamine liberators) or due to other mechanisms (pseudoallergic). If they are very severe, resembling anaphylaxis, they are known as anaphylactoid [12].

Histamine liberators

Here, mast cell histamine release is not immunological and may occur after first exposure to a substance. Examples include morphine, codeine, tubocurarine and antibiotics, such as polymyxin, ciprofloxacin, rifampicin and vancomycin. Iodine-based radiocontrast dyes may cause anaphylactoid reactions. Exactly how radiocontrast media, low- and high-molecular dextran plasma expanders cause these reactions is not known. Complement activation is thought to play a role in serious dextran reactions.

Pseudoallergic reactions

The reaction is not substance-specific, and similar reactions may occur to unrelated compounds in the same individual. The severity of reaction is usually related to the dose of the offending substance. The mechanisms are unclear and may vary. Common offending substances include aspirin and other non-steroidal anti-inflammatory agents. These cause the reactions by pharmacological mechanisms thought to be related to their activity in inhibiting the cyclo-oxygenase pathway of arachidonic

acid metabolism, diverting it to pro-inflammatory lipoxygenase pathway products and by reducing PGE_2, which is inhibitory for immunological mast cell degranulation [13]. Although aspirin may exacerbate chronic urticaria, these reactions are usually not severe. While the exact role of food dyes and preservatives in exacerbating chronic urticaria is controversial, tartrazine and other dyes have been implicated in causing pseudoallergic reactions. Food preservatives are implicated less commonly.

Alcohol-induced urticaria is rare; the mechanism of causation is unknown, but appears not to be an allergic one [14]. Alcoholic beverages can aggravate urticaria non-specifically. White wines are often treated with sulphites, which have rarely been reported to cause urticaria and anaphylaxis [15,16]. Some red wines contain measurable concentrations of vasoactive amines including histamine [17] which could aggravate urticaria, but cutaneous symptoms relate poorly to histamine content [18].

Food may also contain vasoactive amines including histamine (such as cheese, fish, meat, tomatoes, pineapple and avocados) or histamine-releasing substances (such as in strawberries). Toxins in scombroid fish (under-processed tuna, mackerel) can cause acute urticaria by releasing histamine, and high levels of histamine can usually be found in affected fish [19].

Infections

Urticaria may follow non-specific infections [1,2], Epstein–Barr [20] or hepatitis B viral infections, anisakiasis (infection by a fish parasite) [21], streptococcal throat infections in children and, rarely, *Campylobacter jejuni* infections [22].

Chronic urticaria

Chronic urticaria of at least 6 weeks' duration may be ordinary, physical or vasculitic.

Chronic ordinary urticaria

There does not appear to be an increased incidence of atopy. Up to 37% of patients with chronic urticaria have associated delayed pressure urticaria and occasionally other physical urticarias. Most were considered to be 'idiopathic' [1] before autoimmunity was recognized as a cause [2]. Even now, the cause can rarely be identified with certainty, since there are no routinely available tests for histamine-releasing autoantibodies, although provoking factors should always be sought.

Potential provoking factors

Drugs

Many drugs can induce urticaria, but this is frequently of the acute type. The relationship between penicillin and chronic urticaria is a complex one, but the amount present in dairy products seems unlikely to perpetuate chronic urticaria except in people with extreme penicillin sensitivity, or if penicillin is present in food above permitted levels [3].

Salicylates and other related non-steroidal anti-inflammatory drugs such as diclofenac can aggravate urticaria and asthma by non-allergic mechanisms. Patients usually react with either urticaria or asthma, but not both [4]. The percentage of patients whose urticaria is exacerbated by aspirin (acetylsalicylic acid) varied from 20% to 30% in different studies [5,6]. Many medicines and proprietary preparations contain aspirin, but the small amounts of salicylates present in food are unlikely to be significant [7].

ACEIs can provoke angio-oedema and may aggravate urticaria.

Foods and food additives

Numerous foods have been blamed as a cause of urticaria [8]. However, an allergic cause for ordinary urticarias was found in fewer than 3.5% of cases [1,9]. The general population blamed foods for their adverse clinical reactions, including urticaria, more often than could be reproduced on double-blind challenge [10].

There are many reports that food additives aggravate chronic urticaria, but the high incidence of 33% [11] has not been confirmed in some double-blind studies [12]. The discrepancies in incidence in different studies could arise from the differing populations and test methods used. Food and food additives are blamed more frequently in reports emanating from allergy departments. There are various reasons for this, not least a different selection of patients. Other variables during testing include antihistamine therapy, basic diet, hospitalization and whether testing was placebo-controlled and double-blind, with confirmation of positive results on retesting [13]. The exact percentage of reactions to additives is not known, but is considered to be important in fewer than 10% of patients with chronic ordinary urticaria. The most frequently implicated food additives are tartrazine (E102), other azo dyes including amaranth (E123) and sunset yellow (E110). Reactions to benzoate preservatives (E210–219) and antioxidants, such as butylated hydroxytoluene (E321) and butylated hydroxyanisole (E320), are reported less often. In our enthusiasm to remove unnecessary additives from our environment, it must not be forgotten that food preservatives help prevent infections transmitted by food, which are overall a much more important problem than food allergy or intolerance [14]. Sulphites (E223–228), monosodium glutamate (E621) and aspartate are very rare causes of urticaria, which is usually of the acute type. The sensitivity to additives gradually lessens as the urticaria resolves. Dyes and preservatives can be found in medicinal products, but usually in smaller doses than in food [15]. Skin tests may at times be helpful, but cannot be relied on [16]. Oral challenge testing may be performed if desired by physician or patient, but in the authors' urticaria clinics (see St John's challenge test, Table 47.4) we find fewer than 10% reacting. However, food additives may be a more important problem in other populations. Full labelling of food products with their food ingredients and additive constituents is increasingly regarded as important.

Table 47.4 Substances used in blind-challenge testing of food additives at St John's Institute of Dermatology.

Tartrazine 10 mg*
Sodium benzoate 500 mg*
4-hydroxybenzoic acid 200 mg
Yeast extract 0.6 g
Penicillin 0.5 mg†
Aspirin 100 mg
Aspirin 500 mg‡
New coccine 10 mg
Canthaxanthine 100 mg
Sunset yellow 10 mg*
Annatto 10 mg
Butylhydroxytoluene 50 mg
Butylhydroxyanisole 50 mg
Sorbic acid 600 mg
Sodium nitrite 100 mg
Sodium nitrate 100 mg
Quinoline yellow 10 mg
Sodium glutamate 200 mg

* One-tenth of the dose to be given if a child is under 10 years or if there is a history of asthma.
† Not to be given if there is a history of severe penicillin reaction.
‡ Not to be given if there is a history of asthma or severe aspirin reactions.

Infections/infestations

Chronic urticaria is frequently flared by intercurrent viral infections. This may be a non-specific effect of circulating pro-inflammatory cytokines or chemokines, either acting on mast cells or leading to expression of adhesion molecules on endothelial cells.

The incidence of bacterial infections such as dental sepsis, sinusitis, urinary tract and gallbladder infections in chronic urticaria varies in different series. If present, treat-

ment of the infection usually does not improve urticaria [1] and, overall, infections are a rare cause of chronic urticaria. More recently, a possible role for *Helicobacter pylori* [2] has been suggested, but not confirmed by double-blind studies of eradication therapies. *Candida* infections, although described [3], are found extremely rarely to be a cause of urticaria. Intestinal parasites are a rare cause in developed and developing countries [4], but should be looked for if there is a blood eosinophilia or a history of recent travel to subtropical or tropical areas [5]. Rarely, protozoa or helminthic infection in the tissue may be a cause. Linear weals may follow migration of *Ancylostoma* and *Strongyloides* worms. Recently, *Toxocara canis* antibodies have been associated with chronic urticaria, but a causal relationship is not proven [6].

Inhalants

Grass pollens, mould spores, animal danders, house dust [1] and even tobacco smoke have been implicated as triggers of acute or chronic urticaria, with or without respiratory symptoms, but this must be very rare. If pollen allergy is proven, desensitization may exceptionally be successful [2].

Systemic disease

It is unusual to find a systemic cause that is not suggested in the history. Collagen vascular diseases, in particular lupus erythematosus and Sjögren's syndrome, have been described as possible causes of chronic ordinary urticaria, but these are usually associated with urticarial vasculitis. Chronic urticaria may be associated with IgM macroglobulinaemia (Schnitzler's syndrome).

Neither hypo- [1] nor hyperthyroidism [2] is commonly associated with chronic urticaria, but increased incidence of thyroid autoantibodies and disturbances of thyroid function have been reported [3]. Occasionally, appropriate treatment for an autoimmune thyroid disease [4] may help the urticaria but usually it has no influence.

Acquired C1 esterase inhibitor deficiency angio-oedema can be associated with collagen vascular disease and lymphoma. There is no convincing evidence of any association of chronic urticaria with malignancy [5].

Menstrual cycle and pregnancy

Urticaria may occur in pregnancy, but it is difficult to evaluate any causal relationship. Pruritic urticated papules and plaques of pregnancy (PUPPP, syn. polymorphic eruption of pregnancy) is the most common specific dermatosis of pregnancy and occurs during the third trimester. Urticaria may worsen premenstrually, but if urticaria occurs predominantly or only premenstrually, it has been attributed to progesterone sensitivity [1] or more rarely oestrogen sensitivity [2], usually on an autoimmune basis. More recently, a non-immune mechanism has been suggested for 'autoimmune' progesterone urticaria [3].

Implants

Urticaria has been linked anecdotally with a metal pin in the femur [1], a metal dental prosthesis [2] and with dental amalgams [3], but an apparent association in these cases may have been fortuitous.

Psychological causes

Psychological factors appear to play a contributory role in a proportion of patients, and flare-ups of urticaria do occur at times of psychological stress [1]. Psychological factors are often wrongly thought to contribute to angio-oedema because of the old name 'angioneurotic oedema', which implied something very different when it was first introduced. The importance of psychological factors is difficult to evaluate scientifically and can be over-emphasized. Depression and anxiety were found more frequently in chronic urticaria in two studies [2,3], but not in another [4]; however, depression may reduce the threshold for pruritus [5], and the effect of chronic urticaria on quality of life should not be underestimated [6].

Clinical history taking and diagnosis

The clinical diagnostic process is the same for all urticarias. A comprehensive history is essential for diagnosis and elucidation of any causative factors, as weals are often not present. Performing an extensive panel of investigations in addition to a standardized questionnaire added little to making a final diagnosis [1]. Information should be obtained regarding the onset, duration and course of the disease. The duration of individual weals and presence of purpura are important. Weals lasting more than 24–48 h, particularly if painful or tender, suggest the possibility of urticarial vasculitis or delayed pressure urticaria, but can occur in ordinary urticaria. Purpura, although rarely seen, suggests urticarial vasculitis, but can occur in ordinary urticaria. The location, numbers and shapes of weals vary and are usually not helpful in differentiating most urticarias, except for the typical small, monomorphic, short-lasting weals of cholinergic urticaria and the linear weals of dermographism. The presence of any angio-oedema, particularly if it has affected the oropharynx with difficulty in swallowing or breathing, should be noted. Enquiry should be made for systemic symptoms sometimes associated with cutaneous lesions, including malaise, headache, abdominal pain, arthralgia, wheezing and syncope. Possible precipitating or aggravating factors—including physical factors such as heat, cold, localized pressure on the skin, friction and sunlight—should be sought directly. It is important to enquire regarding any association with recent acute infection, drugs, non-prescription medicines and foods, although the latter are rarely a cause for chronic urticaria. A family history of atopy, autoimmunity or angio-oedema may be useful information.

Differential diagnosis

The diagnosis of urticaria and angio-oedema is rarely a problem. They are distinguished by their evanescent nature and normal overlying epidermis. Papular urticaria, erythema multiforme and prebullous eruptions must be distinguished from urticaria. Acute contact dermatitis, lymphoedema and collagen vascular disease (such as dermatomyositis) may mimic angio-oedema, but these conditions last longer than 24–48 h. The part played by urticarial reactions in atopic dermatitis is discussed in Chapter 18.

Investigation

Acute urticaria

In patients with potentially life-threatening reactions to an allergen, confirmation by a semiquantitative radioallergosorbent test (RAST) or fluoroimmunoassay (CAP FEIA®, Pharmacia) that measures serum antigen-specific IgE antibody to the allergen may be possible, for example for peanuts. In most cases of acute urticaria in which no cause is suggested in the history, investigation rarely provides an answer. For moderately severe acute reactions, skin-prick testing with suspected allergens may be helpful, for example for *Hymenoptera* venom and some foods, if the reaction is not a delayed one. Prick testing is potentially dangerous if there is a background of anaphylaxis. Epinephrine administration for severe reactions may be less effective in patients on β-blocking drugs. The clinical relevance of the results of prick and RAST tests needs careful evaluation. Routine prick testing in chronic urticaria is not helpful [1].

Chronic urticaria

A thorough history of the rash and any associated systemic symptoms is essential. Attention should be paid to

medication, especially non-steroidal anti-inflammatory drugs. It is important to identify a physical urticaria, as delayed pressure urticaria may be associated in 37% of these patients. If weals persist and are painful, with presence of systemic symptoms, urticarial vasculitis should be considered, and a biopsy performed. Patients frequently suspect allergy to foods, but this is rarely found in chronic ordinary urticaria. A food diary may be helpful, especially in episodic urticaria, but it should be remembered that the time interval may vary from a few seconds with allergy to 24 h or more with dietary pseudoallergens, and the substance may have been consumed regularly for years. If the patients suspect food additives, or if they have improved substantially on elimination of this substance or on a diet free of food additives, challenge testing can be carried out on a placebo-controlled basis. This is performed when the patient is in relative remission, and antihistamine therapy need not be stopped, although this is desirable. Coded test substances (see Table 47.4) are given orally in a gelatine capsule on a daily basis, with additives alternating with placebo capsules, the method being based on that devised by Warin and Smith [2]. The most important test substances are tartrazine, aspirin, sodium benzoate and 4-hydroxybenzoate. The patient records any urticarial response, and if present the suspected substance and placebos are re-administered on at least one occasion for confirmation of the results. When the provocation tests are positive, a regionally appropriate tartrazine-free, salicylate-free or other appropriate diet can be suggested and is usually only necessary for a few months [3]. It is usually not necessary to carry out these elaborate and time-consuming provocation tests in patients who respond well symptomatically to antihistamine therapy. A low-pseudoallergen diet may be helpful for some patients [4], especially if antihistamines have failed or are not accepted.

Skin-prick or intradermal tests are even less helpful, and there were no relevant unsuspected positive tests in a group of urticaria patients [1]. In addition, a positive skin test is difficult to interpret, as an atopic patient with urticaria will show many irrelevant positive results, and false-negative results may also occur. Although a few patients with chronic urticaria and a positive intradermal test to *Candida albicans* were helped by an anti-*Candida*/antiyeast regimen (nystatin orally and vaginal pessaries, amphotericin lozenges and a yeast-free diet for 2–4 weeks) [5], this has not been our experience.

Other investigations are aimed at finding any associated disease, but it is uncommon for a cause of urticaria to be found in the absence of some lead from the general history. Only a total and differential full blood count and erythrocyte count is performed routinely. An elevated erythrocyte sedimentation rate (ESR) suggests the possibility of an underlying systemic disease (lupus erythematosus, urticarial vasculitis, macroglobulinaemia), and an eosinophilia would prompt a search for parasitic disease. Screening tests for thyroid autoantibodies may be worthwhile, as up to 14% of patients with chronic urticaria may have thyroid autoimmunity [6] and initial reports suggest that treatment with thyroxine to suppress thyroid activity may resolve the urticaria [7]. Further tests depend on history, and routine biochemistry, complement levels, serum proteins and electrophoresis, serum immunoglobulins, non-organ-specific and organ-specific autoantibodies, total IgE and RASTs, skin tests and fastidious searching for evidence of infection are not indicated [8]. There is currently no simple clinical test for serum histamine-releasing autoantibodies, which remains a research investigation, although the autologous serum skin test (ASST) appears to be a reasonably sensitive and specific marker for them [9]. If angio-oedema is a major component of the disease, screening tests for hereditary or acquired C1 esterase inhibitor deficiency should be performed by measuring plasma complement C4. It is reduced and rarely, if ever, reaches normal values even between attacks of C1 esterase deficiency angio-oedema. Reduction of functional C1 esterase inhibitor confirms the diagnosis.

A skin biopsy may be helpful if the weals persist for more than 48 h and do not respond to antihistamines. Urticarial vasculitis or delayed pressure urticaria is then suspected.

Natural history

Acute attacks may last a few hours or days and be of great severity. There is no way of predicting the duration of an initial attack. Chronic cases where no diagnosis is established may last for weeks, months or even years. The severity is often greatest at the onset, with subsequent waning. New lesions appear daily or at irregular intervals, and there may be periodic exacerbations, sometimes

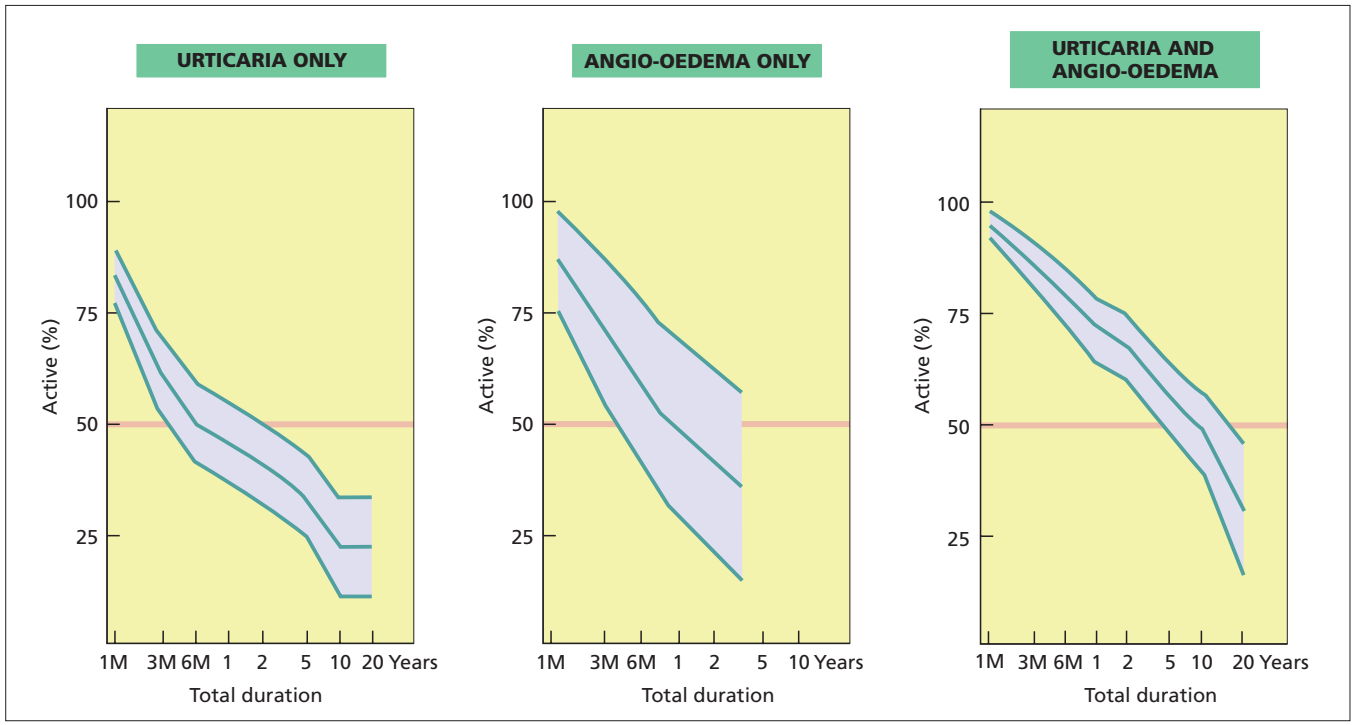

Fig. 47.3 The natural history of urticaria in 554 hospital patients. The expected percentage of patients with active urticaria, with 95% confidence limits, by the total duration of disease (log scale). M, months. (From Champion *et al*. [1].)

associated with intercurrent infections or non-steroidal anti-inflammatory drug intake. In general, spontaneous improvement occurs even in the absence of diagnosis or treatment. Fifty per cent of cases of those with weals alone attending a specialist clinic can be expected to clear within 6 months of onset, but 50% of those with associated angio-oedema can still be expected to have their condition 10 years later [1] (Fig. 47.3). A recent survey of the prognosis of patients attending a tertiary referral clinic in the Netherlands confirms the poor outlook for many patients with chronic urticaria, especially those with cold urticaria [2].

Management

Explanation and non-specific measures may be helpful. Patients should minimize overheating, stress and alcohol. Aspirin and aspirin-containing compounds, and if possible other non-steroidal anti-inflammatory agents and also opiates, should be avoided. Paracetamol is usually a satisfactory alternative. If food additives, colourings or preservatives have been proven to be a problem, diets excluding these substances may be of value to a limited number of patients. Drug therapies can be first-, second-, or third-line, the choice of treatment depending upon the response to previous measures [1] and the impairment of quality of life for the patient.

First-line therapies

Histamine is the main mediator of urticaria, with H_1-receptor activation causing itch, wealing and flare, while H_2 activation plays a smaller role in weal formation. Thus, H_1 antihistamines are the first-line treatment of urticaria. They are usually modifications of the histamine molecule with which they compete and block the H_1 receptor. Generally H_1 antihistamines are rapidly absorbed, reaching peak serum concentrations in 2 h. However, many are metabolized in the liver, and some active metabolites have a longer half-life than the parent compound and determine the activity profile of the medication.

The use of traditional classic antihistamines has been limited by their side effects, including sedation, anticholinergic properties and paradoxical excitation in children. However, they are useful if night-time sedation is required. Hydroxyzine is the most potent of the classic antihistamines. Doxepin, a tricyclic antidepressant with potent antihistaminic activity, in a starting dose of 10–

30 mg, is useful for the anxious patient at night, but as it also reacts with α-adrenergic receptors it should not be taken with monoamine oxidase inhibitors.

The second generation of potent, specific, low-sedation H_1 antihistamines is now the treatment of choice [2], as well as their newly introduced derivatives, sometimes known as third-generation antihistamines. Their main advantage is low sedation at doses recommended by the manufacturer, and minimal anticholinergic side effects. They are at least as effective as hydroxyzine and generally as effective as each other. There is no clear evidence that tolerance occurs after continued use.

Terfenadine, the first available low-sedation antihistamine, is now little used due to concern about prolongation of the cardiac Q–Tc interval at normal doses, especially in circumstances where cytochrome P-450 is inhibited (liver disease, in conjunction with macrolide antibiotics, such as erythromycin, or imidazole antifungals, such as ketoconazole, itraconazole). Astemizole has been withdrawn for the same reason. Although this side effect is rare, serious irregular ventricular tachycardias with Q–Tc prolongation (*torsade de pointes*) have occurred, with fatalities. Recent elucidation of the *HERG1* gene encoding the major K^+ cardiac repolarization channels offers a molecular understanding of the cardiotoxic properties of terfenadine and astemizole, which block the channels at clinically relevant concentrations [3]. Mizolastine, which also undergoes limited conversion by hepatic CYP 3A4, is able to block *HERG1* channels to some degree. Its use with drugs that prolong the Q–Tc interval—such as amiodarone, quinidine and neuroleptic drugs and tricyclic antidepressants—and with electrolyte disturbance should be avoided. The classical antihistamines hydroxyzine and diphenhydramine also have the ability to induce Q–T prolongation [3], emphasizing that higher than recommended doses of these antihistamines should be used only with caution. The active metabolite of terfenadine, fexofenadine, appears to be ineffective at blocking K^+ channels.

Loratadine (adult dose 10 mg daily) is a derivative of azatadine. Although loratadine is also metabolized in the liver by cytochrome P-450 to some extent, the parent compound has not been reported to have an effect on the cardiac Q–Tc interval, and so far no clinically proven relevant drug interactions have been reported. It too has a recently launched metabolite, desloratadine, which has more potent antihistaminic properties than its parent compound. It is not yet clear whether it offers a clinical advantage in urticaria or any subsets of it.

Cetirizine (adult dose 10 mg/day) is poorly metabolized in the liver and is excreted, predominantly in the urine, unchanged. It is more sedative than placebo in some studies and is best taken at night. Cetirizine reduces dermal eosinophil cell accumulation *in vitro* and *in vivo*. However, the clinical importance of this effect in the treatment of delayed pressure urticaria and urticarial vasculitis, where eosinophils may be an important component of the inflammatory cell infiltrate, is uncertain. The active enantiomer, levocetirizine, has recently been launched.

Acrivastine (adult dose 8 mg three times a day) has a rapid onset and duration of action and is excreted predominantly in the urine.

Antihistamines cross the placenta. There is no reliable evidence that they are teratogenic, but they should be avoided in pregnancy and particularly in the first trimester if possible. If it is not possible, then chlorpheniramine appears to be the least risky to use.

Low-sedation antihistamines are used to reduce urticarial activity, with minimal side effects. Individual response is variable, but adequate dose and timing in relationship to maximal urticarial activity is important. Alternative low-sedation antihistamines can be tried, and sedating ones added at night. A combination of an H_1 antagonist with an H_2 antagonist may be more effective than H_1 antihistamines alone in an unpredictable subgroup of patients. Use of ranitidine (adults 150 mg twice a day) is preferable to cimetidine, which has more antiandrogenic side effects and drug interactions.

Second-line therapies

Oral systemic corticosteroids are effective in severe urticaria when given in higher doses such as 0.5–1.0 mg prednisolone/kg/day. Although short courses are useful for acute exacerbations, prolonged use should be avoided because of the risk of side effects. Oral corticosteroids are often required for disease control in severe delayed pressure urticaria and urticarial vasculitis, but every attempt should be made to minimize the dose and duration. In uncontrolled studies, anabolic steroids have been reported to benefit patients with refractory urticaria [4].

The emergency treatment for non-hereditary angio-oedema causing respiratory embarrassment from oropharyngeal–laryngeal angio-oedema is epinephrine. It acts rapidly by vasoconstriction and stabilizing mast cells through β-adrenoceptor stimulation. For moderately severe reactions it can be inhaled for its local effect, but for severe reactions particularly of the anaphylactic type, epinephrine must be injected intramuscularly or subcutaneously. Treatment should be repeated if there is no improvement after 10–15 min. Patients who have had a severe reaction should be shown how to self-administer epinephrine and should keep two unexpired ampoules or 'pens' available. Details of treatment of anaphylaxis can be obtained elsewhere.

The choice of other second-line therapies will be influenced by the clinical presentation. Perhaps the most promising new class of drugs is the leukotriene receptor antagonists, which have been shown to benefit aspirin-sensitive urticaria [5]. Mast cell stabilizers such as the

β-agonist terbutaline [6] and the calcium-channel antagonist nifedipine [7] also have been combined with H_1 antagonists in small numbers of patients, and any additional benefit remains to be confirmed. Narrow-band phototherapy may help some patients [8], although controlled studies are needed.

Third-line therapies

For patients with severe, unremitting urticaria not responding to conventional therapy, immunomodulatory strategies have been tested in small, uncontrolled trials. Plasmapheresis improved six out of eight such patients with autoimmune urticaria for 3–8 weeks only [8]. Intravenous immunoglobulin (IVIG) infusions, at 0.4 g/kg/day for 5 days, improved nine out of 10 patients, two of whom remained clear for 2 years [9]. Ciclosporin A at 2.5–3.5 mg/kg/day for 1–3 months improved or temporarily cleared the majority of patients with severe urticaria [10,11] and its efficacy has been confirmed in a randomized placebo-controlled study at 4 mg/kg/day for 4 weeks [12].

Physical and cholinergic urticarias [1,2]

The physical urticarias are a distinct subgroup of urticarias in which a specific physical stimulus induces reproducible wealing (Table 47.5), and this feature is the basis of diagnosis. Cholinergic urticaria occurs in response to sweating caused by heat, so it is frequently included in the physical urticaria group, but it may also be triggered by emotional and gustatory sweating.

Table 47.5 A classification of physical urticarias and their prevalence.

	Prevalence
Due to mechanical force	
Dermographism	
Immediate symptomatic	+++
Red	+–
Cholinergic	+
Delayed	+–
Associated with mastocytosis	+
Delayed pressure urticaria	++
Vibratory angio-oedema	+–
Due to heat	
Generalized	
Cholinergic urticaria	++
Variants:	
Cholinergic pruritus	+
Persistent cholinergic erythema	+
Cholinergic dermographism	+
Exercise-induced anaphylaxis	+
Localized contact heat urticaria	+–
Due to cold	
Idiopathic	
Inherited	+–
Acquired	
Contact	
Cold erythema	+
Immediate cold contact	+++
Delayed cold contact	+–
Localized	+–
Systemic	
Generalized reflex cold urticaria	+–
Cold-dependent cholinergic urticaria	+–
Secondary to serum cryoproteins (cryoglobulins)	+
Solar urticaria	+
Aquagenic urticaria	+

Combinations of different types are common.
+–, rare; +, uncommon; ++, moderately common; +++, very common.

The frequency of physical urticarias in the general population is unknown, but they account for 19% of urticaria cases in a dermatology clinic [3], with dermographism making up 9% and cholinergic urticaria 4%. However, mixtures of various types of physical urticaria or of a physical urticaria with ordinary urticaria are common—for example, delayed pressure urticaria occurs in 37% of people with ordinary chronic urticaria.

Wealing caused by physical stimuli usually occurs in minutes at the site of contact with the skin and persists for less than 2 h (immediate contact type—for example, dermographism and most cold urticaria). However, sometimes a generalized stimulus affecting the whole body is

necessary (reflex type—for example, cooling body core temperature to induce reflex cold urticaria and a rise in core temperature to induce cholinergic urticaria). In a few forms of physical urticaria, a delay of several hours from the physical stimulus occurs before weals appear—for example, delayed dermographism, delayed pressure urticaria and the rare delayed cold urticarial reaction.

In many forms of physical urticaria, if the stimulus is sufficiently great or the patient is very sensitive, angioedema and systemic reactions may occur from mediator release.

Urticaria due to mechanical forces

Dermographism

Immediate symptomatic dermographism (factitious urticaria)

This involves the triple response which may arise from firm stroking of the skin [4]. This response consists of *local erythema* due to capillary vasodilatation, followed by *oedema* and a *surrounding flare* due to axon reflex-induced dilatation of arterioles. This reaction is normal, but in 5% of normal people this physiological response is sufficiently exaggerated to warrant the term dermographism [5,6]. In a minority of these people, it is accompanied by itching (symptomatic dermographism). Symptomatic dermographism may have an immunological basis. Dermographism has been successfully transferred when IgE (and occasionally IgM) in patients' sera has been injected into normal recipients [7,8]. It is postulated that mast cells sensitized with immunoglobulins (especially IgE) react to a neoantigen induced by mechanical stimulation of the skin and release their mediators. Neuropeptides may contribute to the reaction [9,10].

Symptomatic dermographism can occur at any age, but the greatest incidence is in young adults. Patients complain of wealing and itching at sites of trauma, friction with clothing, or scratching the skin. The itching is often disproportionately severe compared with wealing and is often most severe at night. The eliciting stimulus determines the shape of the weals (Fig. 47.4), but they are often linear from scratching or stroking (Fig. 47.5). Dermographism is not increased in chronic idiopathic urticaria, nor is there any correlation with systemic disease or food allergy [9]. Dermographism is usually idiopathic, but sometimes may follow a drug reaction—for example, penicillin reaction [10] or an infestation, including scabies. Dermographism may last for months or years, or be present intermittently.

Symptomatic dermographism is most easily diagnosed by using a calibrated instrument, the dermographometer [11], which has a spring-loaded stylus, the pressure of which can be adjusted to a predetermined setting.

Fig. 47.4 Dermographism, meaning 'skin writing'. (Courtesy of St John's Institute of Dermatology, London, UK.)

Fig. 47.5 Linear lesions of immediate dermographism induced by stroking back skin with a calibrated dermographometer. (Courtesy of St John's Institute of Dermatology, London, UK.)

Stroking the skin at a pressure on the skin of less than 36 g/mm^2 [9] induces a linear itching weal within 10 min.

Other forms of dermographism

Rarer forms of dermographism exist including *red dermographism*, where repeated rubbing is necessary to induce small, punctate weals [12]. *Cholinergic dermographism* is seen in some patients with cholinergic urticaria, whose dermographic response consists of an erythematous line

studded with punctate weals characteristic of cholinergic weals [13]. *Delayed dermographism* is rare. After a normal fading of the triple response or an immediate dermographic response, a weal returns in the same site, but is usually tender and persists up to 48 h [14]. The mechanism is unknown, but it is closely related to pressure urticaria [15], in which a delayed dermographic response is not unusual.

The presence of wealing following friction (Darier's sign) is characteristic of the lesions of urticaria pigmentosa and of systemic mastocytosis, in which the number of skin mast cells is increased.

Treatment of symptomatic immediate dermographism with low-sedating H_1 antihistamines is often effective, sometimes in low doses. For the more severely affected, there is no clinical benefit in combining H_2 antagonists with H_1 antagonists [16]. However, some improvement may be obtained with ultraviolet B (UVB) or psoralen and ultraviolet A (PUVA) therapy [17].

It should be noted that not all forms of dermographism are urticarial. *White dermographism* (due to capillary vasoconstriction following light stroking of the skin) occurs normally and is particularly pronounced in atopic subjects. *Black dermographism* is discoloration of the skin after pressure from a metallic object.

Delayed pressure urticaria

Delayed pressure urticaria [18–20] in its predominant form is uncommon (2% of urticarias) but it occurs to some degree in about a third of patients with chronic ordinary urticaria, although they may be unaware of this unless directly questioned [21]. Patients with predominantly delayed pressure urticaria nearly always have a component of chronic ordinary urticaria. Wealing occurs at sites of sustained pressure applied to the skin after a delay of 30 min to 9 h, but usually 4–8 h, and lasts 12–72 h [20].

The underlying mechanism for delayed pressure urticaria is unclear. On histological examination, there are decreased numbers of stainable mast cells [22], suggesting previous activation. Release of chemoattractant factors could account for the leukocyte infiltrate, which has been likened to a late-phase cutaneous reaction [23], but no allergen can usually be identified. Neutrophils are present in the majority of early lesions (less than 9 h) and the minority of late lesions (over 24 h). Eosinophils are found in early, and especially in late, weals (Fig. 47.6) with evidence of eosinophil major basic protein deposition [24]. These cellular changes correlated with up-regulation of vascular adhesion molecules, E-selectin and VCAM-1. IL-6 and fibrin present in lesions may amplify and perpetuate the process.

Weals occur frequently under tight clothing, on the hands after manual work, on the buttocks and lower back after sitting (Fig. 47.7) and on the feet after walking.

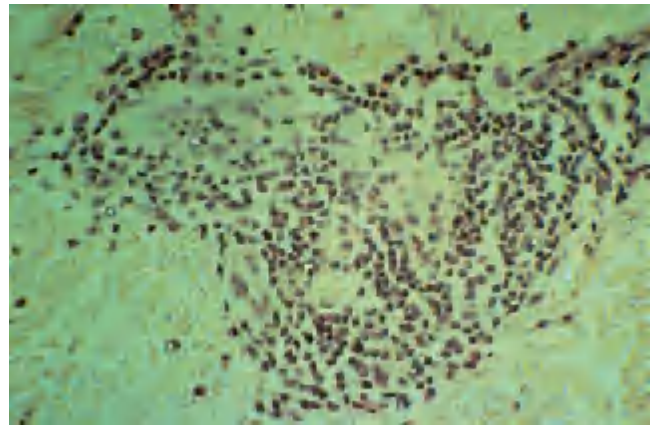

Fig. 47.6 Histology of 24-h lesion of delayed pressure urticaria, showing a profuse dermal inflammatory infiltrate of lymphocytes, neutrophils and eosinophils without vasculitis. (Courtesy of St John's Institute of Dermatology, London, UK.)

Fig. 47.7 Extensive delayed pressure urticaria over the back after sitting against a hard surface. Induced delayed dermographism is also seen on the upper back. (Courtesy of St John's Institute of Dermatology, London, UK.)

Lesions may be itchy, but are often tender or painful, particularly on the soles and scalp. The severity is variable, but it may be accompanied by systemic symptoms of malaise, flu-like symptoms, arthralgia, myalgia and leukocytosis. The condition may be mistaken for urticarial vasculitis.

The diagnosis can usually be made by careful questioning and confirmed by testing. Objective testing is performed by using a dermographometer set at 100 g/mm^2

pressed perpendicularly on the back for 70 s [25], or rods with a convex end diameter of 1.5 cm weighted with 2.5 kg for 20 min or 4.5 kg for 15 min on the back or thighs [21]. A positive response is when indurated lesions are present at test sites at 6 h. Weights (15 lb, 7 kg) applied for 15 min over the shoulder with a wide strap induce indurated lesions after a few hours [18,19]. Strapping a marble onto the forearm for 5 min has been described as an empirical test [26]. Areas of delayed pressure urticaria may be refractory to further pressure-induced lesions for up to 48 h [27].

Delayed pressure urticaria responds poorly to antihistamine therapy, which, however, may help the ordinary urticarial component. Cetirizine in high doses (10 mg three times a day) has been advocated as being more specific, as it also inhibits eosinophils. Although non-steroidal anti-inflammatory drugs may be helpful for the pressure-induced weals, they may exacerbate ordinary urticaria. Drugs that inhibit granulocyte infiltration such as montelukast, colchicine, dapsone and sulphasalazine have been tried, but are not of proven value.

Systemic steroids can provide symptomatic relief, but in doses that are usually unjustifiable for long-term therapy—although they can be used short term for exacerbations.

The prognosis is variable. The symptoms fluctuate in severity; they may show spontaneous improvement, or last for many years.

Vibratory angio-oedema

Vibratory urticaria is a very rare form of urticaria, which was first described in its familial form [28]. Any vibratory stimulus such as jogging, vigorous towelling or using lawnmowers induces a localized, red, itchy swelling within minutes and lasting less than a few hours, but if the stimulus is severe, generalized erythema and headache may occur. Avoidance of the precipitating stimuli enables patients to lead normal lives. Occasionally, vibratory angio-oedema may occur in an acquired form [29,30].

Temperature-dependent urticaria

Heat urticaria

Cholinergic urticaria

Cholinergic urticaria is a very distinctive type in which characteristic small weals appear in association with sweating. It accounts for about 5% of urticaria, and lesser degrees are common in adolescents. Wealing occurs on stimulation of sweating, whether induced by a rise in core temperature, emotion or gustatory stimuli.

The pathogenesis is still not clear. It is thought to be related to stimulation of the cholinergic postganglionic sympathetic nerve supply to the sweat glands. Increased histamine levels have been detected in the blood of patients with cholinergic urticaria. It was originally postulated that acetyl choline can release histamine, perhaps in an indirect way, but such a mechanism is conjectural [31]. Passive transfer tests with serum of affected individuals are sometimes positive, probably due to an immunoglobulin [32]. Such an antibody may prime the mast cell for activation. An allergy to sweat itself has been postulated [33]. Decreased levels of the protease inhibitor antichymotrypsin have been detected in the serum of some patients [34]. There is no generalized disturbance of autonomic function [35].

Fig. 47.8 Close-up of small monomorphic lesions of cholinergic urticaria on the trunk. (Courtesy of Norfolk and Norwich University Hospital, UK.)

The disease typically occurs in adolescents of either sex and may be worse in the winter months [36]. It has been reported to occur in families [37]. The patient complains of itching weals that appear within minutes of exertion, when hot, or after emotional disturbances or even eating spicy food. The weals characteristically are small, 1–3 mm across, with or without a well-marked flare (Fig. 47.8). Sometimes, the erythematous component is more pronounced, especially in the blush areas, and is confluent and studded with weals. Oblique lighting is helpful for observing the weals, especially in dark skin. The lesions persist for a few minutes to an hour or two. Ordinary urticaria not precipitated by heat may be associated with cholinergic urticaria in some patients. Although

micropapular weals resembling those of cholinergic urticaria can occur in ordinary urticaria, these usually last for hours. Cholinergic angio-oedema has been recorded [38,39]. In *persistent cholinergic erythema*, multiple small erythematous macules are distributed symmetrically on trunk and limbs, increasing in number after exercise. Individual macules are short-lived, but appear at different sites over a prolonged period, giving the overall impression of a persisting rash [40]. *Cholinergic itching* without weals has been described [41].

In some patients with cholinergic urticaria, systemic symptoms of flushing, faintness or asthma may occur [42,43]. Exercise-induced anaphylaxis may occur as part of the cholinergic urticaria spectrum after severe exercise [44]. However, exercise-induced anaphylaxis in others does not appear to be associated with cholinergic urticaria and often occurs in patients sporadically and unpredictably, and appears to be a distinct entity [45]. It is possible that some are examples of unrecognized food and exercise-induced anaphylaxis.

Rarely, a generalized eruption resembling cholinergic urticaria may be provoked by systemic chilling [46].

The diagnosis of cholinergic urticaria is best confirmed by provocation, with the appearance of typical weals after warming—for example in a hot bath at 42°C for 15 min, to raise the core temperature by 0.7–1°C—or exercise in a hot environment [47]. Intradermal injections of cholinergic drugs such as methacholine produce local axon reflex sweating and sometimes the appearance of satellite weals. However, this test is unreliable and not specific enough to be useful [47].

Some patients get partial relief from antihistamines used either regularly or before they forecast attacks, but most have to modify their lifestyle by reducing exercise. Ketotifen, which also has mast cell stabilizing properties, may be more helpful in some patients than conventional antihistamines [48] but is sedating. A few patients find that if they can bring on a severe attack by suitable exertion they can achieve freedom for up to 24 h afterwards. For selected severely affected patients not responding to antihistamines, the attenuated androgen danazol improved wealing [34]. Usefulness is limited by its side effects and, due to potential abuse in sport, restrictions in prescribing.

Localized heat urticaria [49,50]

This is one of the rarest forms of physical urticaria. Localized warming of skin at temperatures varying from 38 to 50°C for 2–5 min induces wealing at the test site lasting 1 h. The pathomechanism is variable, with histamine release being described in some reports [51] and complement activation in others [52]. Treatment with antihistamines or induction of tolerance by repeated heat exposure may be helpful [51,53,54].

Cold urticaria [55–57]

Cold urticaria encompasses a variety of syndromes in which cold induces urticaria (see Table 47.5).

Idiopathic cold contact urticaria is the most common, comprising 96% of a series of cold urticaria patients [57], while others are rare. In some patients with idiopathic cold contact urticaria, the serum can passively transfer the cold urticarial response to normal recipients. This autoantibody is usually IgE-like [58], but IgM has been recorded. *In vitro* histamine release occurred from skin challenged with cold [59]. The antigen may be either a protein produced normally by cold exposure or, less likely, an abnormal protein. Histamine is an important mediator [59–61]. The contribution of other mediators detected, such as PGD_2 [62], leukotrienes [63], platelet-activating factor [64] and TNF-α [65], remains to be elucidated.

It is important to warn against cold-water bathing due to the risk of anaphylaxis and drowning. Treatment with low-sedation antihistamine is helpful. Induction of tolerance by repeated graduated exposures to cold can be helpful for selected patients [60,66], but it is time-consuming and not always effective.

Idiopathic cold urticaria

Immediate cold contact urticaria

This is by far the commonest form, occurring at any age but most frequently in young adults. It may be preceded by non-specific upper respiratory viral infections, infectious mononucleosis or insect bites. Itching and wealing of the skin occur on cold exposure within minutes and last up to 1 h. Cold winds and cold rain are particularly effective stimuli. Sometimes, the mouth and pharynx may swell after drinking cold liquids. Systemic symptoms include flushing, palpitations, headache, wheezing and loss of consciousness, and drowning has occurred after cold-water bathing.

Dermographism and cholinergic urticaria are frequently associated. The average duration of cold urticaria was 6 years in one series [57], but it may persist for many years.

Diagnosis is made by application of an ice cube in a thin plastic bag for up to 20 min onto the skin, and wealing occurs within 15 min, usually during rewarming [57] (Fig. 47.9). Sometimes, a more extensive local challenge such as immersion of a forearm in iced cold water is necessary [57].

Delayed cold contact urticaria

This form, where wealing occurs after a delay of hours after cold contact, is very rare [67]. A familial form has been reported [68].

Fig. 47.9 Wealing following an ice-pack application for 20 min. (Courtesy of St John's Institute of Dermatology, London, UK.)

Localized cold contact urticaria

This is very rare [69].

Familial cold urticaria

This rare form is inherited as an autosomal-dominant trait and is now known to be caused by the same gene mutation as Muckle–Wells syndrome [70] (p. 47.29).

Acquired cold contact erythema

Painful erythema without wealing occurs in response to cold [71], but in other patients it may be a forme fruste of immediate cold contact urticaria.

Cold urticaria secondary to serum cryoproteins

This is rare and was found in only 1% of one series [57]. It is usually associated with other manifestations such as Raynaud's phenomenon, purpura or skin necrosis. Cryogobulinaemia may be idiopathic or occur in collagen vascular disease, chronic lymphatic leukaemia, myeloma and in infectious disease, including infectious mononucleosis. Cold urticaria is said to occur in only 3% of people with cryoglobulinaemia [72]. Blood samples for cryoprotein estimation must be kept warm until laboratory testing. Treatment is directed against the underlying condition. Cryofibrinogen occurred in the blood of 3.4% of a large hospital population [73], and in 3% of patients in cold urticaria [74]. Its significance in relationship to cold urticaria remains to be determined. Cold agglutinins are not usually associated with cold urticaria [75]. Cold haemolysins have not been detected in recent series.

Systemic cold urticaria

In generalized reflex cold urticaria, widespread wealing occurs in response to cooling of core body temperature, but a local ice-cube test is negative [76,77]. Testing is performed by placing the patient in a cold room at 4°C for 30 min in light clothes. In cold-induced cholinergic urticaria, additional exercise is necessary in the cold room to induce weals.

Solar urticaria [78]

Weals develop at the site of exposure within minutes of visible, long- or short-wave ultraviolet radiation [79] and usually fade within 2 h, in contrast to polymorphic light eruption, in which urticated lesions appear hours later and last days. The pathogenesis is discussed in Chapter 24.

Aquagenic urticaria [80–82]

Contact with water at any temperature induces an eruption resembling cholinergic urticaria, although the weals are few in number and are surrounded by a wide flare (Fig. 47.10). Other urticarias that can also be induced by water, such as cold urticaria, cholinergic urticaria and dermographism, must be excluded. It has been proposed that water carries an epidermal antigen to the sensitized mast cell [83]. This is a different entity from aquagenic pruritus, in which there is water-induced itching but no wealing [84,85].

Urticarial vasculitis [1–3]

Some urticarias are considered to be due to a type III hypersensitivity immune reaction, with deposition of immune complexes in blood vessels and other tissues and are often associated with systemic symptoms. The archetypal reaction is serum sickness. Some acute drug allergies give rise to a serum-sickness response.

Serum sickness [4]

Classically, serum sickness follows parenteral injections of therapeutic sera, the immune complexes consisting of antigen and IgG, usually with antigen excess (type III reaction). The immune complexes activate complement and are deposited in tissues including skin. It was a prevalent illness in the pre-antibiotic era—when heterologous antisera were used extensively to treat diphtheria, scarlet fever and pneumococcal pneumonia—but is now uncommon. Other causes of serum sickness-like syndrome include drugs, especially penicillin, radiocontrast media, hepatitis B infections and rarely foods. Onset is after 1–3 weeks, or more quickly if there has been previous exposure. Urticarial lesions are persistent, lasting a few days, and are sometimes tender or painful with bruising. Systemic features include fever, arthropathy, lymphadenopathy, cough, gastrointestinal disturbances and nephritis. The illness usually lasts for 5–28 days.

Urticarial vasculitis is essentially the same condition, but is frequently chronic, although it may be intermittent. The cutaneous lesions resemble urticaria in appearance, but histologically demonstrate vasculitis (venulitis). Characteristic histological changes include endothelial swelling, extravasation of red cells and a perivenular cellular infiltrate rich in neutrophils, with leukocytoclasis and fibrinoid deposits in and around blood vessels [5]. Occasionally, a lymphocytic infiltrate may be prominent. However, urticarial lesions demonstrate a gradation of histological changes from a sparse perivascular infiltrate, through an intermediate stage of a dense cellular infiltrate, to a frank vasculitis [6]. Thus, the distinction between ordinary urticaria and urticarial vasculitis may not be clear-cut. If the minimum criteria for vasculitis is evidence of vessel damage and/or leukocytoclasis, this histological change has been reported in 2–20% of chronic urticarial weals, but a realistic figure is about 5% [7].

That urticarial vasculitis can be considered as a type III hypersensitivity reaction was suggested by the presence of circulating immune complexes, deposition of immunoglobulin and complement in vessel walls, and consumption of complement in a significant proportion of cases. Serum hypocomplementaemia may be present in a minority of patients. When it is, serum $C1_q$ levels are reduced and $C1_q$ precipitins, which are IgG autoantibodies against the collagen-like region of $C1_q$, are increased. These anti-$C1_q$ autoantibodies are also present in SLE, suggesting a relationship between the two conditions. However, no cause can be found in most cases of urticarial vasculitis.

Fig. 47.11 Lesions of urticarial vasculitis which had been present for 2 days. (Courtesy of St John's Institute of Dermatology, London, UK.)

Only a minority are associated with infections (from hepatitis B and C, Epstein–Barr virus and *Borrelia burgdorferi*), serum sickness, collagen vascular disease (including lupus erythematosus and Sjögren's syndrome) or hypergammaglobulinaemia (including Schnitzler's syndrome, where IgM gammopathy is associated with fever and bone pain) [8]. Drugs such as cimetidine and diltiazem, haematological diseases [1] and cold and solar urticaria are very rare causes.

Compared with lesions of ordinary urticaria, lesions of urticarial vasculitis usually persist for more than 24 h and may burn as well as itch, be tender or painful and sometimes resolve with residual bruising or staining (Fig. 47.11). Rarely, bullae may occur. Angio-oedema is present in up to 40% [1] of cases. However, it is often not possible to distinguish urticarial vasculitis from urticaria by the clinical appearance of the lesions. Systemic involvement is common; the most frequent symptom, affecting more than 50% of cases, is arthralgia, which is usually flitting and migratory, but frank arthritis is rare. Gastrointestinal involvement, with abdominal pain, nausea and vomiting, occurs in approximately 20%. A similar percentage is affected with pulmonary disease, characteristically pulmonary obstructive disease found in smokers, especially in hypocomplementaemic urticarial vasculitis (HUVS). Microscopic proteinuria and haematuria occur in 5–10% of patients, but in the absence of connective tissue disease, progression to severe renal disease is unlikely. Rarer manifestations include Raynaud's phenomenon, lymphadenopathy and splenomegaly, conjunctivitis, episcleritis, uveitis, pseudotumour cerebri, myositis, pericardial and pleural involvement.

The diagnosis is established on lesional skin biopsy. Laboratory abnormalities are common, with a raised ESR being the most frequent. Hypocomplementaemia probably occurs in fewer than 50% of cases, but often correlates with the severity of systemic involvement. Other abnormalities sometimes found include circulating immune complexes, a positive antinuclear and rheumatoid factor (usually in low titre) and presence of cryoglobulins and $C1_q$ precipitins.

Investigations should include a search for the occasional associated disease, and for any systemic involvement. They should include a full blood count and ESR, urinalysis, renal and liver function, serum complement and immunoglobulins and chest radiograph. Further testing depends on other suspected clinical involvement.

Overall, the disease has a relatively benign course lasting an average of 3 years [1], although it can persist for many years.

Contact urticaria [1]

Contact urticaria is quite common, but is not usually a cause of hospital referral unless there is an occupational problem, for instance latex allergy due to glove use. The term simply means urticaria resulting from skin or mucosal contact with the provoking substance. It may be allergic or non-allergic (also called immunological and non-immunological). The range of chemical, plant, animal and food exposures causing contact urticaria is very wide [2] (Table 47.6).

Allergic

Percutaneous or mucosal penetration of an allergen to which the individual has already developed specific IgE will result in a type I hypersensitivity response involving mast cell degranulation with histamine release. This may

Table 47.6 Some causes of contact urticaria.

Allergic (immunological)
Cow's milk
Cod
Kiwi fruit
Peanuts
Sesame seeds
Spices
Celery
Non-allergic (non-immunological)
Balsam of Peru
Cinnamic aldehyde
Methyl salicylate
Benzoic acid
Sorbic acid
Witch hazel
Jellyfish
Nettles

result in an immediate localized weal and flare resolving within 2 h, an acute episode of generalized urticaria, or even anaphylaxis if the individual is extremely hypersensitive. It is easily missed when it is responsible for exacerbations of a pre-existing eczema, for example in atopic children. Weals occur at sites of contact with the allergen, usually therefore on the hands and face. The commonest causes are foods (for example, nuts, fish, fruits) or latex. Diagnosis can be confirmed by RAST if there is a history of anaphylaxis, or by skin-prick testing. Management is largely directed at avoidance of the allergen, although taking an antihistamine prophylactically reduced the number of episodes of urticaria in atopic children [3].

Oral allergy syndrome

This is a form of allergic contact urticaria involving the mouth, characterized by immediate itching, swelling and burning after eating a wide range of fresh fruits and nuts, including apple, pears, cherries, plums and hazelnuts. Eating cooked fruit often does not cause symptoms. The wide range of cross-reactions is probably due to a natural panallergen in silver birch pollen [4]. Diagnosis is by skin-prick testing to the fresh fruit. RAST testing may be negative. Fortunately, the condition only rarely progresses to angio-oedema, and treatment with antihistamines is not usually necessary.

Non-allergic

This form of contact urticaria may be caused by direct injection of vasoactive chemicals by plants (e.g. nettles) or animals (e.g. caterpillars, jellyfish). A more common form, though, is from exposure to cosmetics (e.g. cinnamic aldehyde, balsam of Peru) or food additives (e.g. sorbic acid or benzoic acid). Occupational exposures include ammonium persulphate in hairdressers. The reaction may take up to 45 min to develop and is thought to be due to PGD_2 formation rather than histamine release, since it can be blocked by non-steroidal drugs. The relevant investigation is either a prick test or patch test, read at 15–45 min rather than 48 h.

Angio-oedema (without weals) [1]

It is useful to separate angio-oedema without weals from angio-oedema with weals, as may occur in ordinary, physical and vasculitic urticarias since the aetiology, investigation and management may be different.

Ordinary angio-oedema

SYN. ANGIONEUROTIC OEDEMA; QUINCKE'S OEDEMA

This is a variant of urticaria in which the subcutaneous tissues, rather than the dermis, are mainly involved. The term 'angioneurotic oedema' is somewhat misleading. It was originally considered to be an abnormality of the nerve supply of the small blood vessels, without the implication of emotional disturbance that the word now suggests. The same multiple aetiology and frequent lack of precise diagnosis are found as in chronic ordinary urticaria [2,3]. However, both hereditary angio-oedema and the angio-oedema associated with ACEIs cause swellings without weals, suggesting that the mechanisms may not be identical for ordinary urticaria with angio-oedema and angio-oedema without weals. Almost any part of the body may be involved, but the commonest sites are the lips (Fig. 47.12), eyelids and genitalia. The tongue and pharynx may also be affected. Individual lesions may be single or multiple and may appear with dramatic suddenness. Itching is usually absent. The lesions last for a few hours, or occasionally persist for 2–3 days. Differential diagnosis includes eczema especially of the eyelids, cellulitis, lymphoedema, idiopathic oedema, idiopathic scrotal oedema and the Melkersson–Rosenthal syndrome.

The management of angio-oedema is essentially the same as that for acute urticaria, except that mucosal lesions may occur and cause great distress. Emergency treatment of mucosal lesions is discussed along with anaphylaxis in Chapter 71. However, in contrast to hereditary angio-oedema, described below, life-threatening

(a)

(b)

Fig. 47.12 Angio-oedema of the lip (a) during and (b) 3 days after an attack. (Courtesy of St John's Institute of Dermatology, London, UK.)

swellings are very rare. An association with epilepsy has been reported [4].

ACEI-induced angio-oedema [1–4]

ACEIs have a special ability to cause angio-oedema, usually without associated urticaria [1]. The mechanism is thought to relate to the ability of ACEIs to prolong bradykinin survival and potentiate its effects by inhibiting kininase. Over 1000 cases had been reported by 1992 [2]. Most cases develop within 3 weeks of commencing treatment, but can occur at any time during treatment, even a year or two after starting. Angio-oedema affects the face and oral mucosa predominantly. Symptoms may be severe, and laryngeal involvement may be life-threatening. Intravenous antihistamines and corticosteroids are needed, sometimes repeatedly, and epinephrine injections should be given if swelling involves the airway [1]. Reactions are more likely to occur if the patient has had previous episodes of angio-oedema [3]. If such reactions do occur, it is not safe to change to one of the other ACEIs, which should be used with great care (or avoided) with angio-oedema of any cause.

Hereditary angio-oedema [1–5]

This is a rare disorder, accounting for only 5% of all cases of angio-oedema without weals and only about 1% of all cases of angio-oedema. It is transmitted as an autosomal-dominant trait on chromosome 11. At a molecular level, several different mutations have been identified. A family history is usually but not invariably apparent. However, it must be remembered that a family history is not infrequent in the ordinary type of urticaria and angio-oedema. The clinical picture usually allows the diagnosis to be made before laboratory confirmation. Over 50% of cases present before puberty [3], but the onset may be delayed even into late adult life. There are recurrent swellings of the skin and mucous membranes throughout life, often associated with nausea, vomiting, colic and urinary symptoms. These attacks may occur regularly every few weeks, or may be less frequent. Between the attacks, the patient is well. Abdominal symptoms may occur in the absence of skin changes and cause great diagnostic difficulty. In one large series [3], 34% of patients had undergone abdominal surgery. Pharyngeal, laryngeal and even bronchial involvement are especially significant and dominate the prognosis. The skin and mucosal lesions are often solitary and may be painful. They seldom itch. They may appear spontaneously or after trauma, dental trauma, being especially hazardous. Ordinary urticaria does not occur, but there may be a rather distinctive reticulate erythema, perhaps with minimal oedema, which occurs prodromally [6] (Fig. 47.13). Some patients have a relatively minor disability and may improve over many years. In other families, before the advent of modern therapy, over 20% of cases used to die of respiratory obstruction before early middle age, and fatalities are still at risk of occurring.

The blood of these patients is deficient in a natural inhibitor of C1 esterase, which is made in the liver under genetic control [7]. It seems to require the activity of both alleles to maintain normal levels. The inhibitor is present either in reduced amounts (type I) or, in 15% of affected families, in an inactive form, although it can be detected in normal amounts immunologically (type II). A third type of hereditary angio-oedema has been proposed recently (type III), limited to women with a family history of recurrent angio-oedema, including swellings of the upper airway, but with normal levels of plasma C1 esterase inhibitor and C_4 [8], although this remains controversial. The protein is a natural inhibitor of the activated first component of complement and of kininogenase (kallikrein) and other enzymes. It may be that attacks are triggered off

Fig. 47.13 The prodromal eruption of hereditary angio-oedema. 'Chicken-wire' reticulate erythema/urticaria, non-pruritic, on the trunk of a woman aged 38 years who had had numerous episodes over many years, each one lasting many hours or even days. Many attacks, but not all, were followed within 24 h by classical attacks of hereditary angio-oedema, confirmed by history and laboratory confirmation of C1 esterase deficiency. (Courtesy of Dr A.P. Warin, Royal Devon and Exeter Hospital, UK.)

by stimuli that normally activate Hageman factor and hence consume the deficient inhibitor. This C1 esterase inhibitor deficiency may be detected antigenically, but functional assays are necessary to detect type II hereditary angio-oedema. The components of complement (C_2, C_4 and CH50) are low during, after and to some extent even between attacks, or in symptomless carriers. Complement C_4 is nearly always low, and its measurement may be used as an initial screening test. There is no clear correlation between the clinical severity and laboratory abnormalities. There is a weak association with autoimmune diseases, including Sjögren's syndrome and SLE [9].

The response of hereditary angio-oedema to conventional treatment for urticaria is generally poor. Antihistamines, steroids and even epinephrine are said to be of little or no help. Not all patients need any treatment. Treatment may be considered as long-term prophylaxis, short-term prophylaxis and the emergency management of an established attack. Oestrogen therapies, such as the oral contraceptive pill, may induce or exacerbate hereditary angio-oedema and should be avoided if possible.

Androgens have been used prophylactically for many years with some success, but more recently the lives of many of these patients have been revolutionized by the use of attenuated androgen/anabolic drugs such as danazol and stanozolol. They stimulate the production of the deficient inhibitor. Long-term treatment is often required and may cause androgenic problems in women and children. The usual starting doses are danazol 200–600 mg daily or stanozolol 1.0–5.0 mg daily. However, considerably smaller doses given intermittently on several days of a week may suffice. The dose is assessed on the clinical response, rather than any changes in the laboratory tests, as improvement may occur even when the C1 esterase inhibitor levels remain low. Liver function tests should be monitored during long-term treatment, and benign hepatic adenomas have been reported. Such therapy may also be used for short-term prophylaxis, for example 6 days before and 3 days after dental surgery at the higher dose ranges [3]. Some, but not all, cases of the acquired variant of the disease (see below) also respond to this therapy. Epsilon amino caproic acid (not available in the UK), 12–18 g daily, or the related tranexamic acid 2.0–4.5 g daily, has been found to help some patients, but these drugs are contraindicated with thrombosis. They are less effective than danazol or stanozolol, but are useful where androgens are contraindicated, especially for short-term prophylaxis. Replacement therapy with fresh frozen plasma has been used for short-term prophylaxis. As well as providing the deficient inhibitor, it also provides more substrate; theoretically, therefore, it could worsen the angio-oedema, but in practice this does not seem to be a problem. However, a partly purified preparation of the inhibitor is now quite widely available. It is the treatment of choice for severe attacks, especially laryngeal oedema and abdominal colic, or it can be used for short-term prophylaxis [10] prior to procedures placing the patient at risk of laryngeal swelling, including dental extraction, endoscopy or intubation. Symptoms subside in 30–90 min [3].

Acquired C1 esterase inhibitor deficiency angio-oedema [11–15]

An acquired deficiency of the inhibitor may also give rise to a picture very similar to the hereditary form but with later onset. This may be associated with:

1 A B-cell lymphoma in which anti-idiotypic antibodies against the monoclonal antibody expressed on the surface of the abnormal cells allow complement activation and consumption of $C1_q$ and of the inhibitor.

2 SLE [16].

3 An antibody directed against the inhibitor, but without any evident lymphoma.

The laboratory changes are similar to those of hereditary angio-oedema, except that the C1 levels are also decreased. Danazol is helpful in some cases, but not the autoantibody type, which also fails to respond to replacement therapy but may be helped by corticosteroids.

Episodic angio-oedema with eosinophilia [1]

Recurrent episodes of angio-oedema and urticaria associated with pyrexia, blood eosinophilia and infiltration of the dermis with eosinophils have been described. There is no evidence of systemic involvement or progression to a cardiomyopathy. Each episode resolves with prednisolone treatment. During an attack, elevated serum levels of IL-5 have been demonstrated in some cases [2], IL-6 in others [3] and a subsequent increase in TNF-α in others with a more transient variant [4].

Other syndromes resembling urticaria or angio-oedema, or with urticaria as one component

Papular urticaria [1]

Injection of foreign protein by biting insects into skin of the most sensitive subjects may cause an immediate IgE-mediated reaction consisting of weals. A punctum is often visible on the weal, which may blister. This reaction sometimes evolves into a delayed hypersensitivity reaction leading to intensely itchy, indurated papules lasting weeks or months. It is most commonly seen on the legs of children after flea and mosquito bites.

Cyclical oedema [1]

SYN. PERIODIC OEDEMA; PERIODIC DISEASE

These terms are used in different ways by different clinicians to describe several different entities. These include hereditary angio-oedema, some cases of familial Mediterranean fever, idiopathic oedema, the capillary leak syndrome and autoimmune progesterone urticaria. They are all characterized by oedema of the skin and perhaps other tissues, often with striking periodicity for which there may be no simple explanation.

REFERENCE

1 Reimann HM. Cutaneous manifestations of periodic diseases. *Int J Dermatol* 1979; **18**: 824–7.

Idiopathic oedema [1–4]

This is known as the fluid-retention syndrome and is often described under the conditions listed above. The syndrome (or syndromes) is not a variant of angio-oedema, but can conveniently be considered in this chapter. It is quite separate from the premenstrual tension syndrome, which may also be associated with fluid retention. As the name implies, the aetiology of idiopathic oedema is obscure, but it involves an increase in capillary permeability. Other causes of oedema, such as cardiac, renal, hepatic, hypoproteinaemic, allergic, or those due to venous or lymphatic obstructions, are excluded by definition. Obesity is often a major factor, especially with recent weight gain; misuse of diuretics is common and other drugs may also contribute. Psychiatric disturbances are very often found.

The disease nearly always affects adult women, who are often overweight and labile in mood. The main changes are related to a periodic, often diurnal weight gain of more than 1.4 kg, sometimes more than 5 kg. This causes a bloated feeling in the abdomen, breasts, face and limbs. Pitting ankle oedema is not a feature. Symptoms suggestive of irritable bowel syndrome or frequency of micturition are common. Management includes sympathetic support, weight loss and only minimal use of diuretics. Psychotropic drugs are usually not needed.

Systemic capillary leak syndrome [1–3]

SYN. CLARKSON'S SYNDROME

This is a rare syndrome in which there are dramatic recurrent attacks of exudation of fluid into various organs and may involve the skin. Attacks of angio-oedema have been reported. A severe shock-like state may ensue and the eventual mortality is high. There is an IgG paraproteinaemia. The response to treatment has been poor, although patients have been helped by a combination of aminophylline and terbutaline [4]. A similar syndrome may follow therapy for metastatic cancer with IL-2 [3].

Schnitzler's syndrome [1–6]

SYN. URTICARIAL VASCULITIS WITH MONOCLONAL GAMMOPATHY

This syndrome was first reported in 1974 [1]. There is chronic urticaria, often with rather persistent non-itchy weals suggesting an urticarial vasculitis, which is sometimes confirmed by histology but more usually shows a neutrophilic urticaria [7]. Bone pains, with associated radiological bone changes, are present in half the cases. Malaise, fever and lymphadenopathy may occur. The characteristic finding is a monoclonal gammopathy—usually IgM, but perhaps IgG [5]. An IgG autoantibody against IL-1α was found in the sera of patients with Schnitzler's syndrome more frequently than controls [8], although the significance of this in the pathogenesis is not certain. The overall prognosis is often, but not always, benign. Long-term follow-up is required, because evolution to Waldenström's disease may occur [9]. Symptomatic treatment has included non-steroidal anti-inflammatory drugs, colchicine and dapsone, but sometimes prednisolone is required. IFN-α-2b was reported to relieve urticaria and bone pain in one patient [10].

Periodic fever syndromes

Muckle–Wells/familial cold urticaria syndrome

These two rare autosomal-dominant periodic fever syndromes are due to mutations in a common gene called *CIAS1* on chromosome 1q.44, encoding a protein with a pyrin domain [1], but nevertheless have distinctive phenotypes.

Muckle–Wells syndrome [2–4]

During childhood and adolescence, patients with this rare disease suffer recurrent bouts of urticaria with chills, fever and malaise, each lasting 24–48 h. Nine separate families are known in the UK. The urticaria may start from birth and may occur daily throughout life. There may be actual weals or sometimes only macular erythema (Fig. 47.14). Conjunctival erythema may occur. Over the next two to four decades, sensory deafness appears, and in some cases progressive nephropathy due to amyloidosis. Amyloidosis is present in other parts of the body in the prereticulin pattern of deposition.

The condition, which is inherited as an autosomal-dominant trait, must be distinguished from familial Mediterranean fever, which has autosomal-recessive inheritance, and other forms of renal amyloidosis.

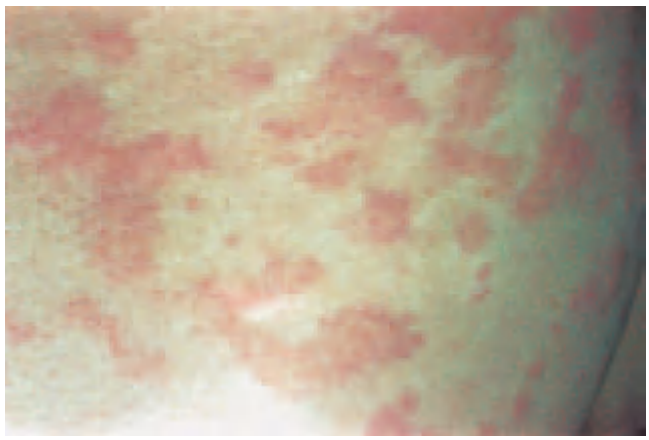

Fig. 47.14 Muckle–Wells syndrome. The characteristic, often rather faint, transient, sometimes erythematous, sometimes urticarial eruption. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

Familial cold urticaria [5–7]

The onset is noted in infancy and persists for life. Weals, which are often painful, occur in response to a drop in body temperature and can persist for 48 h. Fever, headache and a leukocytosis may accompany the rash. An ice-cube test is negative. Treatment is difficult but there has been a good response to stanozolol in one family [8].

Familial Mediterranean fever [1,2]

Familial Mediterranean fever usually has autosomal-recessive inheritance and a striking predilection for Sephardic Jews, Armenians and Arabs. The gene responsible is carried on the short arm of chromosome 16. Many patients present with recurrent self-limiting attacks of fever and a tendency to peritonitis, pleurisy and synovitis. Skin lesions include rather distinctive erysipelas-like lesions on the lower leg, but urticaria and vasculitic lesions may occur [3,4]. About one-quarter of patients develop or even present with renal amyloidosis, which is often fatal. Some symptoms are controlled by colchicine.

Hyper-IgD syndrome [1–4]

A few cases have been recognized since its first description in 1984 [1]. It has some features in common with familial Mediterranean fever and Muckle–Wells syndrome, but appears to be a distinct entity. The clinical features include periodic fever and skin lesions, among which are erythematous macules, urticaria, annular erythema and nodules. Other findings include joint pains, abdominal pain, cervical lymphadenopathy, leukocytosis and raised ESR. The special finding is a raised IgD level in the blood, although it is uncertain how this is related to the other findings. There is no tendency to amyloid deposition. The response to treatment is unsatisfactory.

TNF-receptor-associated periodic syndrome (TRAPS)
SYN. FAMILIAL HIBERNIAN FEVER [1,2]

This multisystem disorder comprises a recurrent migratory erythematous rash, fever, arthralgia, synovitis, conjunctivitis, pleurisy and amyloidosis of the kidneys and liver due to mutations in the TNF receptor I gene on chromosome 12. Levels of soluble TNF receptor are reduced in the blood during disease activity because the receptor is not shed from monocytes and neutrophils. Although the rash is typically migratory and macular rather than urticarial, oedematous plaques lasting up to 21 days may occur [2]. The condition should be considered in the differential diagnosis of the periodic fever syndromes.

Mastocytosis

Introduction

Mastocytosis is a rare condition characterized by too many mast cells that are functionally normal, in contradistinction to urticaria, in which normal numbers of mast cells appear to be too releasable. It usually presents in the skin, but may affect other tissues, especially the bone marrow and gastrointestinal tract. The distinction between cutaneous mastocytosis and systemic mastocytosis (as defined by demonstrating excess mast cells outside the skin) will depend to an extent on how hard they are sought, and it is therefore of less value to the practising clinician than some classifications would suggest. The first description of mastocytosis was made by Nettleship and Tay in 1869 [1]. The term urticaria pigmentosa was used by Sangster to describe the skin lesions in 1878 [2], but it was not until 1939 that the term 'mastocytosis' was offered by Sézary to describe skin and systemic involvement occurring together [3].

There have been considerable gains in the understanding of its aetiopathogenesis and classification over the last decade, with the recognition of specific gene mutations in the proto-oncogene c-*kit*, which encodes a tyrosine kinase receptor on mast cells that is the binding site for stem cell factor (SCF, syn. Steel factor, mast cell growth factor, c-*kit* ligand). The relationship between mastocytosis presenting primarily in the skin and primarily as a haematological disorder continues to be clarified. Two recent in-depth reviews are recommended reading [4,5].

Classification

A modification of the clinical classification embracing dermatological and haematological presentations of mastocytosis by Metcalfe [1] is shown in Table 47.7. It should be emphasized, though, that the great majority of cases presenting to dermatology clinics will have indolent (type I) mastocytosis (either cutaneous or systemic) and that progression to an associated haematological disorder (type II) is uncommon. Both type III (aggressive mastocytosis with lymphadenopathy) and type IV (mast cell leukaemia) are rare. Classifications based on aetiopathogenesis encompassing c-*kit* mutational analysis are currently of no practical value in the clinic, although it is possible that identifying subsets of disease using molecular genetics may lead to more accurate prognosis and better management in the future.

Table 47.7 Clinical classification of mastocytosis.

I	*Indolent mastocytosis*
	A Cutaneous
	Urticaria pigmentosa
	Mastocytoma
	Telangiectasia macularis eruptiva perstans (TMEP)
	Diffuse (erythrodermic) cutaneous mastocytosis
	B Systemic (extracutaneous mast cells in at least one organ)
II	*Mastocytosis with an associated haematological disorder*
	A Myeloproliferative disorders
	B Myelodysplastic disorders
III	*Aggressive mastocytosis with lymphadenopathy and eosinophilia*
IV	*Mast cell leukaemia*

Modified from Metcalfe's 1991 classification (Metcalfe DD. Classification and diagnosis of mastocytosis: current status. *J Invest Dermatol* 1991; **96**: 2S–4S).

REFERENCE

1 Metcalfe DD. Classification and diagnosis of mastocytosis: current status. *J Invest Dermatol* 1991; **96**: 2S–4S.

Aetiopathogenesis

That the release of mast cell mediators causes symptoms of flushing, itching and gastrointestinal disturbance in mastocytosis is not in doubt, but the reason for mast cell accumulation in tissues in the first place is not yet clear. Interest has been focused on activating mutations of c-*kit* which were first found on a growth factor-independent mast cell line from a patient with mast cell leukaemia (HMC-1) and subsequently on adults with mastocytosis [1]. Two amino acid substitution mutations have been described in codons 816 and 560, leading to autoactivation of the receptor. However, the story is not straightforward, because the activating mutations have not been found in children with typical disease. Three of six children were found to have a novel dominant *in*activating mutation in codon 839 [2]. Furthermore, mutations in c-*kit* have not been identified in familial mastocytosis or in the germ line of affected adults, indicating that they are somatic. The *kit* receptor is also expressed on haemopoietic stem cells and melanocytes, which might be relevant to the occasional occurrence of myeloproliferative and myelodysplastic disorders in mastocytosis and the hyperpigmentation usually seen in urticaria pigmentosa lesions.

A report that soluble SCF was present in the epidermis of patients with cutaneous mastocytosis but not healthy individuals initially appeared to offer another potential mechanism for stimulation of *kit*, leading to hyperplasia of the skin mast cell population [3], but this has not been confirmed in later studies. Soluble SCF is not increased in the sera of patients with urticaria pigmentosa [4].

Clinical presentation

Nearly all mastocytosis with bone marrow abnormalities will show skin lesions, but few patients with skin lesions will have clinically significant haematological disease.

Prevalence

Mastocytosis is uncommon. Reliable population-based prevalence data are not available, but only two new patients were seen each year in one dermatology centre from a catchment population of 300 000 [5]. There is no sex difference or increase in atopy [6].

Genetics

Over 50 families with familial mastocytosis have been reported to date. Most of these had urticaria pigmentosa, but four cases of telangiectasia macularis eruptiva perstans (TMEP) occurred in three generations of one family, with an autosomal-dominant pattern of inheritance [7].

Cutaneous mastocytosis

Urticaria pigmentosa

This is the commonest pattern of cutaneous mastocytosis. Urticaria pigmentosa developed in the first year of life in 84% of 67 children [8]. The most common age of onset for adult urticaria pigmentosa is 20–40 years [9]. Numerous reddish-brown or pale, monomorphic maculopapules, plaques or nodules appear in a symmetrical distribution anywhere on the body except the face, head, palms and soles with the highest concentration usually being on the trunk (Fig. 47.15) and thighs (Fig. 47.16). The edges of the lesions are not completely sharp. They urticate within a few minutes of gentle rubbing (Darier's sign) (Fig. 47.17) causing localized itch, redness and wealing, which subsides within an hour. Stroking may also produce wealing in clinically unaffected skin. Darier's sign is not always demonstrable, especially in those with a long history of the disorder, and is not 100% specific for mastocytosis, since it has also been described rarely in juvenile xanthogranuloma [10] and acute lymphoblastic leukaemia of neonates [11]. Lesions may blister in infancy or childhood and may be the presenting feature, but heal without scarring.

Fig. 47.15 Urticaria pigmentosa in a child, showing multiple pigmented lesions on the trunk. (Courtesy of St John's Institute of Dermatology, London, UK.)

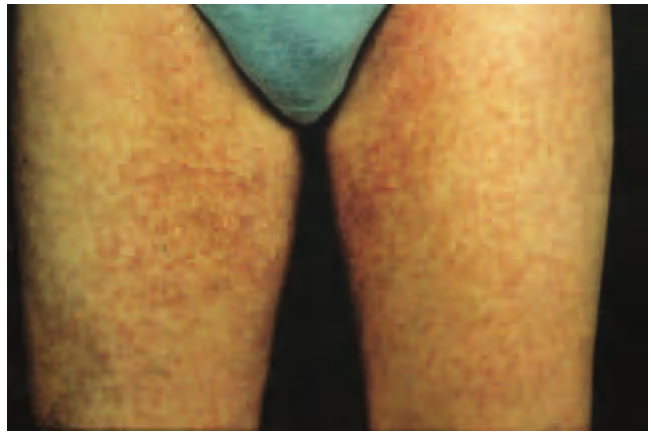

Fig. 47.16 Adult urticaria pigmentosa on the thighs, showing numerous reddish-brown lesions. (Courtesy of St John's Institute of Dermatology, London, UK.)

Flushing occurs in about 50% of patients, alcohol intolerance and pruritus in slightly less [4]. Other symptoms may include heat or cold intolerance, recurrent diarrhoea and headache. Wheezing is often quoted, but is extremely rare. Studies have shown that up to 60% of adult patients have bone marrow involvement [4,12,13], but there is no obvious relationship between finding this on biopsy and symptomatology or prognosis [4]. Clearance or fading

Fig. 47.17 Intense wealing and flare reaction (Darier's sign) induced by gentle rubbing of urticaria pigmentosa lesions on the back of an infant. (Courtesy of Norfolk and Norwich University Hospital, UK.)

Fig. 47.18 Solitary mastocytoma, which urticates and blisters on rubbing. (Courtesy of St John's Institute of Dermatology, London, UK.)

of urticaria pigmentosa was observed in 12 of 106 adult patients with confirmed bone marrow involvement who were followed for 12–20 years, with a parallel overall improvement in the patients' well-being [14].

Mastocytoma

Cutaneous mastocytosis may present with red, pink or yellowish nodules or plaques in infancy or early childhood, measuring up to 3–4 cm in diameter (Fig. 47.18). They are usually solitary. About 15% of young children will present with localized lesions [15]. If multiple, the lesions can overlap in appearance with urticaria pigmentosa. They tend to blister if subject to friction, especially in the nappy area, and occasionally attacks of flushing can be induced by rubbing a solitary mastocytoma [16]. Nearly all mastocytomas involute over the first few years of childhood.

Telangiectasia macularis eruptiva perstans

Telangiectasia may rarely be the predominant clinical feature of cutaneous mastocytosis. Patients are usually adults presenting with red, telangiectatic macules, especially on the trunk, which tend not to urticate on rubbing (Fig. 47.19). Finding excess mast cells on skin biopsy will confirm the clinical suspicion, although they may not be numerous. TMEP tends to be very persistent and unresponsive to treatment.

Diffuse (erythrodermic) cutaneous mastocytosis

This is a very rare form of mastocytosis in which mast cells infiltrate the entire skin diffusely, and it usually presents in the neonatal period. The skin tends to be thickened and doughy in consistency, but may be smooth. Blistering is

Fig. 47.19 Telangiectasia macularis eruptiva perstans after gentle rubbing on the thigh of an adult. (Courtesy of St John's Institute of Dermatology, London, UK.)

common (Fig. 47.20) and pruritus intense. Pigmentation is usually absent. Patients with this type of mastocytosis are at high risk of systemic disease and severe complications including anaphylaxis and diarrhoea [17], but it may resolve spontaneously, as in other types.

Systemic mastocytosis

Not all patients with proven bone marrow involvement will be symptomatic, but in those who are, nausea, vomiting, diarrhoea, palpitations, hypotension, syncope, headache, dyspnoea, wheezing and sometimes fatigue may feature as symptoms. This is partly due to cutaneous mast cell mediator release having distant effects and partly to direct local effects of infiltration in other tissues, such as the gastrointestinal tract. Bone pain, bone cysts, premature osteoporosis, osteopetrosis or spontaneous fractures should prompt further investigation.

Fig. 47.20 Diffuse cutaneous mastocytosis in an infant, showing blistering and crusting on the face. (Courtesy of Dr C.T.C. Kennedy, Department of Dermatology, Bristol Royal Infirmary, Bristol, UK.)

As over half of adult patients investigated for urticaria pigmentosa will have bone marrow involvement and therefore, by definition, indolent systemic mastocytosis, making a distinction between them is more academic than practical. Preliminary evidence suggests that blood tryptase and urinary methylhistamine may be useful markers for bone marrow involvement [18]. Although there is a theoretical risk of progression of systemic indolent mastocytosis to type II disease (associated myeloproliferative or myelodysplastic disorders), the literature indicates that this is unusual and that there are no markers to identify subgroups of patients at greatest risk of this. The occasional presentation of type III disease (aggressive systemic mastocytosis with lymphadenopathy) or type IV disease (mast cell leukaemia) is more likely to be to a haematologist rather than to a dermatologist, with the patient showing changes in the peripheral blood against a background of being unwell.

Histopathology

Skin

There are increased numbers of normal-appearing mast cells in the dermis of all types of indolent mastocytosis. The epidermis is normal apart from an increase in melanin. The mast cells are spindle-shaped and have granules that stain metachromatically with toluidine blue or Giemsa. Human skin mast cells are best demonstrated histochemically with Carnoy's fixative and staining with Alcian blue/safranin or conjugated avidin [1]. Mast cell infiltrates are predominantly found around blood vessels and skin appendages in the papillary dermis (Fig. 47.21). In urticaria pigmentosa, they are increased up to 15-fold above normal [2], but may be less numerous. Careful technique when taking the skin biopsy, to minimize traumatic degranulation, is important. Injecting local anaesthetic around the lesion to be sampled and avoiding epinephrine may yield a higher number of stainable mast cells. A small increase in numbers of mast cells has been found in non-lesional skin of urticaria pigmentosa [3]. Full-thickness infiltration of skin or a band-like involvement of the upper dermis are seen in mastocytomas and diffuse cutaneous mastocytosis. By contrast, mast cells are confined to superficial capillaries and dilated venules in TMEP.

Table 47.8 Protocol for diagnostic work-up and review.

Initial assessment
Skin biopsy
Full blood count (FBC)
If abnormal:
• Blood film + bone marrow biopsy if abnormal
• Any appropriate additional investigation, e.g. gastroscopy
Blood tryptase
If increased for:
• Abdominal ultrasound scan
• Bone densitometry for adults
• Consider bone scan for localized bone pain
Follow-up assessments
If initial assessments normal: none routinely
If probable systemic disease:
• At least yearly review with FBC, blood chemistry and blood tryptase
• Any appropriate additional investigation, e.g. gastroscopy

Bone marrow

Bone marrow involvement is usually seen as focal aggregates of mast cells on biopsy, although infiltration may be diffuse. Mast cell infiltration of the marrow is often accompanied by increased numbers of immature neutrophils, phagocytosing macrophages, eosinophils and lymphocytes and sometimes by fibrosis [4,5].

Investigations

A skin biopsy is desirable to confirm a clinical diagnosis in most patients, although a policy of observation may be appropriate in young children, especially those with a mastocytoma, in whom natural resolution of their condition over childhood is likely. A full blood count should be performed at presentation and at yearly intervals when systemic disease is suspected or proven to detect the onset of significant bone marrow disease. Other investigations should be guided by the clinical presentation. Routine bone marrow examination is not required in the absence of other features, such as an anaemia, persistent leukocytosis, unexplained eosinophilia, bone pain, hepatosplenomegaly or lymphadenopathy. Blood tryptase levels may be a useful surrogate marker for bone marrow involvement [1] and could be done at initial diagnostic evaluation, although a raised result should not influence subsequent management or follow-up. An abdominal ultrasound scan may be helpful initially if there is a suspicion of systemic disease, and perhaps bone densitometry, especially if there is bone pain. A suggested protocol for the initial diagnostic work-up and review is summarized in Table 47.8.

Management

Most patients presenting to dermatology clinics with cutaneous or indolent systemic mastocytosis will have an excellent prognosis, particularly children, so it is important to provide reassurance about the nature and outlook of the condition. Management hinges on avoidance of trigger factors for mast cell degranulation, symptomatic relief and detection of significant systemic disease. No cures are currently available, and there are no predictors for the onset of haematological complications or occurrence of familial disease.

Avoidance measures and management of anaphylactic emergencies

The flushing and itching experienced by many patients with cutaneous mastocytosis are due to release of mast

Table 47.9 Potential mast cell degranulating stimuli.

Physical triggers (especially rubbing)
Alcohol
Non-steroidal anti-inflammatory drugs (including aspirin, diclofenac)
Allergens (confirmed IgE-mediated reactions, e.g. latex allergy)
Insect and snake venoms (allergic and/or toxic effects)
Radiocontrast media (especially if iodinated)
Plasma expanders (especially dextran)
Opiates (including codeine and morphine)
General anaesthetic agents
• Non-depolarizing muscle relaxants (especially benzylisoquinolinium group, e.g. atracurium, gallamine)
• Anticholinergic drugs (e.g. hyoscine)

IgE, immunoglobulin E.

cell mediators. This can be exaggerated by physical stimuli, such as temperature extremes, towelling, massage or alcohol. Potential triggers of systemic mast cell degranulation include known allergens, non-steroidal anti-inflammatory drugs, opiates, Hymenoptera venoms (even in the absence of allergy), iodinated contrast media, dextrans and some muscle relaxants (Table 47.9).

Patients should be advised about the possibility of an anaphylactic emergency. Consideration should be given to carrying an epinephrine pen for self-administration, especially by those with a previous history of anaphylaxis. Oral antihistamines may be helpful for milder attacks not involving respiratory difficulty or hypotension. Venom immunotherapy for patients with anaphylaxis has been reported to reduce the risk of anaphylactoid reactions to Hymenoptera stings, even when there is no evidence of specific IgE [1], but this remains to be confirmed in larger studies. Fatal cardiovascular collapse during general anaesthesia has been reported [2]. Prophylactic administration of corticosteroids (e.g. 1 mg/kg prednisolone or equivalent) and antihistamines 30 min prior to general anaesthesia [3] is not necessarily protective.

Therapies

Antihistamines

Antihistamines are the mainstay of therapy, as for urticaria. Itching and flushing can be controlled by antihistamines in many patients, but can be refractory to treatment. Taking a classical sedating antihistamine at night, with or without a non-sedating antihistamine by day, may be beneficial, although there are no controlled studies of antihistamines in mastocytosis. It seems likely that the newer 'third-generation' antihistamines will be at least as effective as their parent drugs. Doxepin may also be used for its antihistaminic properties. H_2 antihistamines are used for gastrointestinal symptoms, including indigestion and diarrhoea.

Mast cell stabilizing and anti-inflammatory drugs

Abdominal pain, nausea and diarrhoea also respond to sodium cromoglycate which, however, has no value for other systemic symptoms because it is not absorbed from the gut [4]. Aspirin and other non-steroidal anti-inflammatory drugs have been reported to ameliorate prostaglandin-mediated flushing in some patients, but must be introduced with caution if there is any history of intolerance, under cover of antihistamines and with initial observation.

Photochemotherapy and phototherapy

Although oral PUVA may help itch and wealing and improve the appearance of urticaria pigmentosa [5], the benefits are only temporary, so the risks of long-term treatment need to be considered carefully. The mechanism for improvement is not certain, but probably involves a reduction of mast cell numbers in the papillary dermis only and total histamine content in lesional skin [6], with some cosmetic improvement due to tanning. Narrowband UVB therapy may be effective for pruritus when PUVA is not tolerated.

Corticosteroids

Use of potent or very potent topical steroids applied under polythene occlusion, or intralesional injection of individual mastocytomas, can lead to clearance of mast cells and reduction of pigmentation for at least a year [7], but steroid atrophy is an important limitation. Restriction of treatment to limited cosmetically sensitive areas, such as the forearms and lower legs, will minimize the risk of significant adrenocortical suppression.

Others

IFN-α-2a and -2b have been reported anecdotally to ameliorate some features of systemic mastocytosis [8,9], but not the number or appearance of skin lesions. Chemotherapies do not alter the course of the mast cell disease, but may benefit associated haematological disorders.

Prognosis

Most mastocytomas resolve in childhood. Around 50% of children with urticaria pigmentosa clear by adolescence. In a review of 67 paediatric cases, five resolved over 2 years of follow-up and 20 improved but did not clear over a mean period of 6 years [10] (Fig. 47.22). The outlook for paediatric cases that do not remit is the same as for adults with indolent disease. The prognosis for this group is difficult to ascertain due to the obvious limitations of not having information on lifelong follow-up, but it does

Fig. 47.22 Considerable improvement, but not complete resolution, of urticaria pigmentosa by the age of 5 years. (Courtesy of St John's Institute of Dermatology, London, UK.)

appear from the experiences of clinics with large numbers of patients under review that progression to significant haematological disorders is very rare, even with proven bone marrow involvement with mastocytosis [3,11]. Spontaneous resolution of cutaneous mastocytosis was observed in about 10% of adults [12]. The main problems likely to be experienced by patients relate to the risks of anaphylaxis and peptic ulceration. Prognosis of aggressive mastocytosis will relate to the associated haematological disorder, and management will be directed primarily towards this.

Chapter 48

Purpura and Microvascular Occlusion

N.H. Cox & W.W. Piette

Introduction

Purpura, or bleeding into the skin, may occur as an isolated phenomenon or as part of a systemic disorder. It is the hallmark of vasculitis affecting the skin, and may be the dominant feature or a minor part of a systemic vasculitis (see Chapter 49). Purpura may occur as a result of other abnormalities of the blood vessel wall, and in numerous haematological conditions is due to platelet and coagulation disorders. Vasculitis itself may cause other cutaneous lesions, including urticarial lesions, nodules, ulcers, livedo and frank necrosis.

Patients with purpura may require management involving one or more of several disciplines, including haematology, general medicine, nephrology and rheumatology, as well as dermatology; multidisciplinary management is often appropriate as each specialty sees a different range of clinical manifestations and has different areas of expertise.

Classification of purpura is difficult, as no single approach is satisfactory. The same clinical pattern may arise from many different causes, both vasculitic and non-vasculitic, and the aetiology of either purpura or vasculitis may be impossible to determine. Classifications based on morphology or aetiology therefore have limitations. For example, clinically non-specific capillaritis may be idiopathic, drug-induced or a manifestation of cutaneous T-cell lymphoma. Furthermore, intravascular events such as microvascular occlusion may give rise to palpable lesions and inflammation as a secondary component, confusing both the clinical and histopathological picture. Despite these limitations, as a practical matter the initial approach

to a patient with purpura must typically start with a differential diagnosis based on morphology, since few patients present with a known aetiology of their lesions [1]. The importance of trying to differentiate between disorders causing primarily inflammatory or non-inflammatory lesions is clear [2].

This chapter addresses purpura that is not primarily of vasculitic causation; Chapter 49 deals with disorders in which a primary vasculitis is involved.

Definition of purpura

Purpura is discoloration of the skin or mucous membranes due to extravasation of red blood cells. Petechiae are small purpuric lesions usually 1–2 mm (occasionally up to 4 mm) across, often occurring in crops. Ecchymoses or bruises are larger extravasations of blood. The many causes of petechiae and ecchymoses overlap, for example thrombocytopenia usually causes petechiae but more extensive bleeding may occur at lower levels of platelet count. In contrast, coagulation disorders usually cause ecchymoses rather than petechiae.

The sequence of colour changes in a bruise can help to identify it as such, should doubt exist, and can also help to establish its duration. Extravasated blood is broken down to various other pigments derived from haem, usually within 2 or 3 weeks. The characteristic colour changes [1,2] include red, blue and purple in the first 5 days (although these colours can occur at other times, particularly red), green after 5–7 days and yellow after 7–10 days (never less than 18 h). In smaller and more superficial purpuric lesions, orange or brown colours due to residual haemosiderin may predominate. Assessment of traumatic ecchymotic lesions is not a major part of routine dermatological practice, but may be important in suspected child abuse [3].

Unlike purpura, increased intravascular blood in the skin, whether as diffuse erythema or within telangiectatic vessels, can be blanched by pressure, typically using the technique of diascopy (see Chapter 5). However, not all telangiectatic lesions can be emptied in this way. Small angiomas (e.g. in angioma serpiginosum or the multiple minute variant of Campbell de Morgan spots) and angiokeratomas may cause particular confusion [4]. Sometimes, observation over several days is necessary. Capillary microscopy may also be helpful in determining whether blood is intravascular or extravascular.

Classification and investigation of purpura

An aetiological classification of purpura is provided in Table 48.1. However, for clinical purposes, correlations can be made between the clinical features and the mechanism of purpura. Purpura occurs as a result of one or more of the following main mechanisms in cutaneous vessels: simple haemorrhage, inflammatory haemorrhage or occlusion/ischaemia. Characteristics of lesions, including size, number, distribution pattern, and presence or absence of palpability and erythema, can be very useful in focusing on the most likely mechanisms of haemorrhage within these subsets.

In general, simple haemorrhage presents as macules without erythema (Table 48.2), though sufficient haemorrhage into subcutaneous tissue becomes palpable as a haematoma. The size of the macules has diagnostic importance. Inflammatory causes of haemorrhagic lesions usually evolve with increasing erythema in the first 24–36 h, along with increasing purpura. Such lesions are frequently, but not invariably, palpable. A subset of palpable purpura syndromes may uncommonly also produce lesions with retiform or stellate patterning, with accompanying early erythema and palpability (inflammatory retiform purpura). By 48 h, erythema and palpability begin fading in both types of lesions, although the purpura may persist for several days. In contrast, lesions of occlusion/ischaemia usually begin with minimal or no erythema, and may show minimal palpability unless eschar forms, but may develop erythema if sufficient necrosis occurs to induce a wound healing response. Occlusive syndromes tend to manifest retiform or branching patterns of purpura (non-inflammatory retiform purpura), sometimes with accompanying localized livedo reticularis, or as necrotic plaques with minimal erythema.

Non-inflammatory purpura is generally due to haematological causes and detailed discussion is outside the remit of this chapter; specialized haematology texts can be consulted [5–9].

Platelet disorders (see also Table 48.3)
Thrombocytopenia
Abnormal platelet function
Thrombocytosis

Coagulation disorders
Inherited, e.g. haemophilia or acquired factor deficiency or dysfunction (e.g. antibody inhibitor)
Drugs, e.g. anticoagulants
Localized, e.g. heparin injection sites, some insect bites
Metabolic, e.g. vitamin K deficiency, hepatic failure (decreased synthesis of clotting factors)
Thrombophilias, e.g. protein C deficiency, protein S deficiency
Disseminated intravascular coagulopathy and purpura fulminans

Other intravascular causes of purpura/microvascular occlusion
Dysproteinaemias, e.g. hypergammaglobulinaemic purpura (Waldenström), Sjögren's syndrome
Cryoproteinaemias
Emboli: crystal, fat, myxoma, infective

Mechanical vascular causes of purpura
Raised intravascular pressure
Coughing, vomiting, Valsalva manoeuvre, tourniquet
Stasis
Decreased support
Actinic ('senile') purpura
Corticosteroid purpura
Scurvy
Amyloidosis
Inherited disorders of connective tissue (pseudoxanthoma elasticum, Ehlers–Danlos syndrome)
Abnormal vasculature
Purpura around vascular lesions, e.g. targetoid haemosiderotic haemangioma, tufted angioma, aneurysmal fibrous histiocytoma

Purpura with inflammation
Non-thrombocytopenic toxin- and drug-induced purpura
Contact purpura
Purpura associated with infections
Capillaritis (pigmented purpuric dermatoses)
Idiopathic
Drug-induced
Pre-mycotic
Inflammatory purpura/vasculitis (see Chapter 49), e.g. Henoch–Schönlein purpura, acute haemorrhagic oedema
Associated with other inflammatory dermatoses that are not usually purpuric
Solar purpura

External and other causes of purpura or ecchymosis
Physical and artefactual causes
Multifactorial purpura associated with systemic diseases
Easy bruising syndrome and purpura simplex
Paroxysmal finger haematoma (Achenbach's syndrome)
Painful bruising (autoerythrocyte sensitization, Gardner–Diamond) syndrome

Lesions < 4 mm
Thrombocytopenia
Immune thrombocytopenic purpura
Thrombotic thrombocytopenic purpura
Disseminated intravascular coagulation (DIC)
Other causes (see Table 48.3)

Abnormal platelet function
Congenital/hereditary
Acquired: drug, systemic disease
In myeloproliferative disease
Other causes (see Table 48.3)

With normal platelets
Raised intravascular pressure
Trauma
Scurvy (perifollicular pattern)
Hypergammaglobulinaemic purpura (Waldenström)

Intermediate-sized lesions
Hypergammaglobulinaemic purpura (Waldenström)
Infection in patients with thrombocytopenia or immune compromise
Early lesions of vasculitis (sometimes)

Lesions > 1 cm (all causes involve a degree of minor trauma)
Procoagulant defect
Anticoagulation
Liver failure
Vitamin K deficiency
DIC (some)

Poor dermal support
Actinic and corticosteroid purpura
Scurvy
Hereditary: Ehlers–Danlos syndrome
Amyloidosis

Platelet deficiency or functional defect

Other causes
Hypergammaglobulinaemic purpura (Waldenström)
Capillaritis
Easy bruising syndrome; purpura simplex
Physical and artefactual causes
Gardner–Diamond syndrome
Stigmata

Diagnosis and pathophysiology of simple macular haemorrhage [1–6]

Purpura due to simple haemorrhage is suggested by the presence of purpura that is macular (non-palpable) and that has no blanching component in newly developed lesions (Table 48.2). Palpable lesions, or a blanching component, suggest that there is associated inflammation (which may occur as a secondary effect, hence the emphasis that evaluation must concentrate on new lesions). The size of lesions, clinical patterns and body sites affected may all be diagnostically useful.

8 Colman RW, Hirsh J, Marder VJ *et al.*, eds. *Hemostasis and Thrombosis: Basic Principles and Clinical Practice*, 4th edn. Philadelphia: Lippincott, 2001.
9 Ratnoff OD, Forbes CD. *Disorders of Hemostasis*. London: Saunders, 1996.

Size of lesions

Petechiae are often defined as lesions of 2 mm or less in diameter, although non-palpable, non-blanching lesions up to 4 mm usually suggest the same process. There are four main mechanisms of simple haemorrhage: (i) severe thrombocytopenia (platelet count always $< 50 \times 10^9$/L, usually $< 10 \times 10^9$/L); (ii) platelet dysfunction (uncommon); (iii) regional or localized increased intravascular pressure; and (iv) many forms of capillaritis (pigmented purpura). Larger lesions may occasionally result from such syndromes, but petechial lesions will generally predominate.

In contrast, macular lesions of 1 cm or greater in diameter (ecchymoses) usually result from disorders of the cascade coagulation system (especially acquired), platelet dysfunction or poor dermal vascular support. Such lesions are usually provoked by minor trauma. This results in two important clinical clues. The first is that lesions tend to localize to areas prone to frequent minor trauma, such as the extensor forearm and dorsal hand, lateral thigh and anterior lower leg. The second finding is a linear or geometric shape of individual lesions, because such lesions typically result from a frictional injury or extension of blunt trauma. Finally, since photodamage of fair skin is a very common cause of poor dermal support, ecchymotic haemorrhage is very commonly found at areas with chronic exposure to both sun and trauma, for example the extensor forearm and dorsal hand.

Fig. 48.1 Purpura on the face due to the raised intravascular pressure that occurs during vomiting. The lesions are small, non-palpable and all of the same age.

Clinical patterns of purpura

The clinical pattern may help to determine which patients require investigation, and may suggest the most likely major pathophysiological mechanisms. Tiny purpuric spots on the lower legs, for example, are not uncommon in the elderly, in patients taking antiplatelet drugs, or in the context of an inflammatory dermatosis; investigation of such lesions in these settings is seldom needed. Similarly, larger lesions that are macular, purple, stellate or blotchy, and confined to photo-aged skin on the dorsum of hands or forearms are generally diagnosed clinically as a consequence of actinic damage (although the same process on the face may produce smaller or more linear lesions, clinically resembling amyloidosis, and more widely distributed lesions of this morphology occur in Cushing's syndrome). Some degree of purpura is not uncommon in inflammatory skin disease of several types, but investigation is likely to be aimed at the disease process rather than the purpuric component *per se*.

Features that suggest a need for further investigation include:

- larger or variably sized lesions, particularly when not in sun-damaged skin;
- numerous or widespread lesions;
- lesions occurring in crops;
- palpable lesions;
- lesions forming reticulate patterns (livedo, retiform pattern);
- associated features such as pustules, necrosis, nodules, splinter haemorrhages, etc.;
- evidence of bleeding from other sites, e.g. haematuria;
- associated general symptoms, e.g. fever, malaise, arthralgia.

Diagnosis of purpura at various body sites

Gravitational change has a major influence on the distribution of purpuric lesions, as discussed elsewhere in this section. Other body sites of specific importance include the following.

- Eyelids: purpura due to coughing, vomiting, etc. (Fig. 48.1); purpura or ecchymosis in amyloidosis (panda sign); ecchymosis related to neuroblastoma.
- Ears: purpura due to cryoglobulinaemia and other hyperviscosity disorders; purpura due to some drugs, e.g. antineutrophil cytoplasmic antibody (ANCA)-positive propylthiouracil reaction, levamisole.
- Face, ears and acral: acute haemorrhagic oedema; cryoglobulinaemia.
- Acral: purpura due to cryoglobulinaemia and other hyperviscosity disorders; embolic causes of purpura; rickettsial infection.
- Friction sites: clothing contact purpura; some cases of capillaritis; Henoch–Schönlein purpura and other small-vessel vasculitis; ecchymosis of Ehlers–Danlos syndrome.
- Intraoral: thrombocytopenia; amyloidosis; myelomonocytic leukaemia; angina bullosa haemorrhagica.

Laboratory tests

Platelet count and function

This is the most important investigation in patients with non-palpable petechiae. The normal count is $150–400 \times 10^9$/L. It varies greatly from person to person, and from time to time in the same person. It may be affected by numerous exogenous factors such as infections, and by internal factors such as hormonal changes. Purpura due to thrombocytopenia seldom occurs with a platelet count above 50×10^9/L, and significant spontaneous bleeding is unlikely unless the count is less than 20×10^9/L. Thrombocytosis may also be a cause of bleeding. As well as variation in number, variation in function of platelets may need to be assessed by specialized *in vitro* tests. A full blood count should always be undertaken in the investigation of purpura.

Tests of occult bleeding

Simple tests to detect other sites of bleeding, whether in vasculitis or in haematological causes of purpura, include fundoscopy, urinalysis and faecal occult blood tests. Haematuria may occasionally occur in disorders which are felt to be essentially dermatological but non-vasculitic, such as drug-induced pigmented purpuric dermatoses [7].

Histology

Histological examination of non-palpable, non-blanching, small purpuric lesions is usually unhelpful; it is essential, however, to consider whether lesions are palpable or partially blanching. If there are palpable or partially blanching lesions, then vasculitis should be considered and biopsy is likely to be informative. If lesions are larger but not palpable, and platelet parameters are normal, then biopsy of the skin is appropriate, for example to assess disease of the vessel wall or surrounding tissues.

Capillary resistance and fragility [8–10]

If the pressure difference between the tissues and the capillaries is sufficiently increased, leakage of blood cells occurs. This is the basis of a variety of semi-quantitative tests for capillary fragility. However, the integrity of the capillary endothelium itself, and also the ability of platelets to fill any gaps which may arise in it, contribute to this type of bleeding. Abnormal results may therefore occur in conditions where there is thrombocytopenia, abnormal platelet function or intravascular coagulopathy, as well as in conditions where there is a vessel wall defect. Sometimes the capillary leakage is discovered accidentally due to development of a shower of purpura on the arm distal to a blood pressure cuff immediately after the pressure has been released (Rumpel–Leede sign).

The simplest clinical test, which essentially performs the same process, is the Hess test. A standardized increase in capillary pressure is produced by inflating a sphygmomanometer cuff around the upper arm to a constant pressure of 80 mmHg (or less if this approaches the systolic blood pressure) for 5 min. Petechiae develop over the next few minutes and can be counted in a measured area of 5 cm diameter just below the antecubital fossa; up to five may be considered normal. However, our experience is that the greatest density of purpura provoked by a Hess test is usually in the 'snuff-box' area over the space between the thumb and index finger metacarpals on the dorsum of the hand.

'Negative-pressure' tests require some simple apparatus to apply negative pressure to an area of skin usually 1–2 cm across. This technique is suitable for repeated tests in the same subject. The application of such a negative pressure at the rim of a cup may only be acting as a local venous tourniquet. Using these techniques capillary resistance is found to vary greatly, as does the platelet count, from individual to individual and with site and numerous other factors.

Bleeding time [4,11–14]

This is the time taken for bleeding to cease after a standardized tiny incision, usually in the skin of the forearm. This type of bleeding normally ceases because of contraction of the small vessels aided by production of a platelet plug. Techniques can be standardized in various ways, for example with a sphygmomanometer cuff at 40 mmHg the bleeding time is usually 4–10 min. The bleeding time is usually prolonged in thrombocytopenia where the platelet count is below 80×10^9/L and becomes progressively prolonged as the count falls, being 30 min at counts less than 10×10^9/L. It may be prolonged in von Willebrand's disease, other disorders of platelet function, severe anaemia, and in patients taking aspirin or receiving heparin. Although often stated to be normal in disorders of coagulation, it may be prolonged in severe haemophilia. It is a rather insensitive test whose wide range of normal values makes it of limited use, even as a screening test. The bleeding time does not accurately predict internal surgical bleeding [13], although it has been used to investigate the effect of aspirin and non-steroidal anti-inflammatory drugs (NSAIDs), which may be relevant as a cause of bleeding during skin surgery [14]. The PFA-100 is an *in vitro* technique to assess platelet function instead of the bleeding time. Although clinical experience with this technique is recent, this and similar methods are largely replacing the bleeding time in many clinical haematology laboratories.

Coagulation screen

Major coagulation defects can be excluded by a clotting screen including measurement of prothrombin time, kaolin cephalin clotting time, thrombin clotting time and fibrinogen levels. Clinical considerations and the results of the screening tests may suggest further laboratory tests, for example levels of individual clotting factors or antiphospholipid antibodies. Discussion of how these tests are performed is beyond the scope of this book.

Capillary microscopy

Direct microscopic examination of capillaries is disappointing in the elucidation of haemorrhagic and purpuric diseases. Purpura may at times be seen in the nail fold capillaries when not present elsewhere in the skin. Extravasation of blood may occur at the junction of the precapillary arteriole with the capillary, at the tip of the capillary or more usually at the venous end.

Summary

To avoid performing every type of investigation in all cases of purpura, the following broad generalizations may be made.

1 Purpura on the legs of the elderly, especially in association with other skin diseases, is common and seldom requires extensive investigation.

2 Coagulation defects usually present as large ecchymoses and external or internal bleeding but not as petechiae. Capillary fragility tests are normal unless there is severe deficiency of clotting factors.

3 Thrombocytopenia is often associated with petechiae but there may also be external or internal haemorrhages and bruising.

4 External bleeding and large ecchymoses are due to coagulation or platelet defects, or to diseases of connective tissue such as Ehlers–Danlos syndrome.

5 Petechiae are due to platelet defects or capillary changes.

6 Dysproteinaemias may cause lesions of simple haemorrhage, inflammatory haemorrhage or occlusion, depending on the properties of individual abnormal proteins.

7 Thrombophilias may present with livedoid change, retiform purpura or usually non-inflammatory cutaneous necrosis.

8 An initial retiform pattern without blanchable erythema or palpable lesions is generally indicative of microvascular occlusion.

9 Inflammatory lesions of the vessels are seldom the cause of external bleeding or ecchymoses, but are the most common cause of persistent and localized purpura. A blanchable erythematous inflammatory component is often present.

10 Inflammatory purpuric lesions are due to vascular changes rather than simple haemorrhage.

11 Splinter haemorrhages of the nails are due to purpura of the nail bed and are not diagnostic of any one condition (see Chapter 62).

Purpura due to thrombocytopenia or platelet defects

Platelets are an essential component of the haemostatic process. Thrombocytopenia or abnormal platelet function from any cause may therefore produce purpura or a bleeding tendency [1,2].

Platelets exposed to damaged endothelium adhere to one another and to collagen and other subendothelial components. Numerous complex interactions occur, involving von Willebrand factor and its glycoprotein receptor, various integrin adhesion molecules, thrombospondin, fibronectin, laminin, phospholipases and ADP released from damaged cells, as well as collagen and platelets. Platelet activation causes release of serotonin and thromboxane A_2, both of which cause vasoconstriction, and increase platelet adhesiveness and aggregation leading to formation of a platelet plug. This process is aided further by the presence of plasma fibrinogen and by thrombin. Production of prostacyclin, a powerful vasodilator and inhibitor of platelet aggregation, is decreased as a result of endothelial damage. Developing platelet plugs are reinforced by fibrin strands formed as a result of activation of the plasma clotting system by platelet factor 3, when this is exposed by alterations in the surface characteristics of the aggregated platelets.

Purpura due to platelet defects can be divided into three groups:

- thrombocytopenia, i.e. decreased platelet numbers;
- abnormalities of platelet function;
- thrombocytosis, i.e. increased platelet numbers.

Thrombocytopenia

The platelet count at which purpura occurs is extremely variable. Purpura due to platelet deficiency usually occurs with a count below 20×10^9/L and is seldom observed with a count above 50×10^9/L. The main causes of thrombocytopenia are listed in Table 48.3.

Idiopathic (immune) thrombocytopenic purpura [1,3,4]

SYN. AUTOIMMUNE THROMBOCYTOPENIC PURPURA (ATP); WERLHOF'S DISEASE

Idiopathic immune thrombocytopenic purpura (ITP) results from immune destruction of platelets by autoantibodies that often show specificity for the platelet membrane glycoproteins IIb/IIIa and Ib/IX. Viral antigen–antibody reactions may be demonstrated in acute forms of the disease, usually in children following an acute viral illness. Vaccines to prevent viral illness have also been implicated, including recently the combined measles, mumps and rubella (MMR) vaccine. Some cases are drug-induced (see later) or are associated with systemic lupus erythematosus (SLE), agammaglobulinaemia, lymphoproliferative disease or myelodysplasia. Chronic ITP is usually autoimmune and apparently idiopathic.

The disease may occur at any age, but in two-thirds of cases it occurs before the age of 21 years. Either sex is affected in children but in adults there is a strong female predominance of at least 2 : 1. Antibodies may be transmitted from mother to fetus. The onset may be gradual or, especially in children, acute. The platelet count falls below 50×10^9/L and may even be zero. Megakaryocytes are present in normal or increased numbers in the bone marrow. Usually the only symptom is a tendency to bleed from gingivae after brushing teeth, or into the skin to produce crops of petechiae or larger haemorrhages. Bleeding may occur in any organ but joint involvement is unusual. The spleen may be slightly enlarged but gross splenomegaly should suggest an alternative diagnosis. Intracranial haemorrhage occurs in about 0.2% of children and is often fatal, but is very unlikely unless the platelet count is less than 10×10^9/L.

Lupus erythematosus develops in a small proportion of cases [5], although there are recently described differences in immunopathogenesis between the thrombocytopenia of SLE and that of ITP [6]. About 20% of adult patients with immune thrombocytopenia have associated features of the primary antiphospholipid antibody syndrome (APLS), with a prolonged activated partial thromboplastin time (aPTT), lupus anticoagulant and anticardiolipin antibodies. The immune thrombocytopenia associated with APLS is rarely severe [7].

The diagnosis is established by the clinical picture, low platelet count, exclusion of other causes of thrombocytopenia and the mainly negative bone marrow findings. Differential diagnosis includes especially SLE, drug-induced

Table 48.3 Platelet disorders causing purpura.

Thrombocytopenia
Defective platelet production
  Bone marrow abnormality
    Aplasia: toxic, immunological, idiopathic
    Neoplasia: leukaemia, myeloma, carcinomatosis
    Replacement: myelofibrosis, radiation damage, sarcoidosis
    Other impaired production: Wiskott–Aldrich syndrome, vitamin B_{12} or folate deficiency
  Metabolic: uraemia, alcohol, drugs
  Infections
Diminished platelet survival
  Platelet alloantibodies
    Neonatal
    Post-transfusion
    Antilymphocyte globulin
  Platelet autoantibodies
    Idiopathic (immune) thrombocytopenic purpura
    Marrow transplant
    Antiphospholipid antibodies
    Systemic lupus erythematosus
  Mechanical: prosthetic heart valves
Drugs and vaccines
Infections
Excessive platelet consumption
  Disseminated intravascular coagulation
  Haemangioma (Kasabach–Merritt)
  Haemolytic–uraemic syndrome
  Thrombotic thrombocytopenic purpura
Sequestration
  Splenomegaly
  Hypothermia

Abnormal platelet function
Inherited and congenital
  Von Willebrand's disease
  Storage pool disease and Hermansky–Pudlak syndrome (see Chapter 39)
  Bernard–Soulier disease (GpIb/IX deficiency)
  GpIa deficiency
  Glanzmann's thrombasthenia
Drug-induced
Uraemia
Cardiac bypass
Platelet antibodies
  Idiopathic (immune) thrombocytopenic purpura
  Systemic lupus erythematosus
Myeloproliferative disorders
Dysproteinaemias

Thrombocytosis
Essential thrombocythaemia
Other myeloproliferative syndromes
Other causes: blood loss, trauma, burns, post-splenectomy, malignant disease, tuberculosis, sarcoidosis

purpura, disseminated intravascular coagulation (DIC) and renal failure. Spontaneous remission often occurs in acute attacks (most children have spontaneous improvement within a month or two), but is rare in chronic cases of more than 3 months' duration, where a continuous or fluctuating course may occur. Corticosteroid therapy may be indicated; about 50% of adults treated with corticosteroids achieve complete remission. Splenectomy is beneficial in two-thirds of chronic cases and in acute cases in which a spontaneous or steroid-induced remission cannot be achieved. After splenectomy the platelet count tends to remain low but the purpura tends to cease. Immunosuppressive therapy is indicated in cases that fail to respond to splenectomy and steroids or where splenectomy is contraindicated. Other treatments that have been used in patients with refractory ITP include danazol, azathioprine, vincristine, interferon-α, ciclosporin (cyclosporin), Fc receptor blockade using intravenous immunoglobulin or intravenous anti-D antiserum, and various other monoclonal antibodies [3,4,8–11].

ITP may coexist with other haematological abnormalities, for example the combination of ATP and neutrophilia, which presents as mucosal bleeding with infections; the platelet deficiency tends to be chronic. Of greater dermatological importance is Evans' syndrome, which comprises Coombs-positive haemolytic anaemia with ITP; this is also associated with collagen vascular disorders, usually SLE or scleroderma but occasionally dermatomyositis [12,13].

Secondary or symptomatic thrombocytopenia

Drugs and toxins

Drug- or toxin-induced purpura may occur as a result of thrombocytopenia, altered platelet function or vascular damage. Each of these may be caused by many different mechanisms. The latter two are considered later. The main causes of drug- or toxin-induced thrombocytopenia are:

- direct bone marrow toxicity, e.g. benzol, nitrogen mustard;
- immunological bone marrow damage, e.g. chloramphenicol;
- destruction of formed platelets, via either immunological, e.g. apronalide (Sedormid), quinidine, quinine, sulphonamides, or non-immunological mechanisms.

It has been suggested that at least 200 drugs cause thrombocytopenia, the mechanisms often being uncertain. The most common are cytotoxic/chemotherapeutic drugs, quinine, quinidine, gold, heparin, sulphonamides, thiazides and furosemide (frusemide), indometacin (indomethacin) and other NSAIDs, thiouracils and carbimazole, bismuth, arsenicals, rifampicin and isoniazid, acetazolamide, acetylsalicylic acid, imipramine, interferon, phenytoin, carbamazepine and sodium valproate [2,14,15]. Immune-mediated platelet destruction is probably mainly due to binding of drug to platelets such that the platelet acts as a hapten and induces drug-dependent antibodies (type 3 drug-induced immune thrombocytopenia), which exert their effect while the drug is still present. However, the duration of thrombocytopenia after stopping the drug is too long to be explained on the basis of either drug clearance or platelet lifespan in some cases, particularly with quinidine or quinine, suggesting that true autoantibodies may be produced [16]. Heparin-induced thrombocytopenia type II [17–19] is important as it can be confused with post-transfusion purpura in early stages; also, it may be associated with arterial or venous thrombosis (heparin-associated thrombocytopenia and thrombosis syndrome) and can occur in conjunction with heparin-induced skin necrosis. It is due to formation of antibodies against an immunogenic complex involving heparin and platelet factor 4 (PF4), the antibody reaction causing platelet aggregation.

Other toxic causes of thrombocytopenia include alcohol, snake venoms and, rarely, foods and food additives.

Infections

Thrombocytopenia may be associated with a wide variety of infections, often with associated capillary damage as well. Infections that may be associated with thrombocytopenia include septicaemia of many aetiologies, typhoid, typhus, tuberculosis, smallpox, chickenpox, vaccinia, scarlet fever, influenza, measles, rubella, cat-scratch disease, infective hepatitis, subacute bacterial endocarditis, glandular fever, malaria, dengue, human immunodeficiency virus (HIV) and other virus infections.

Bone marrow diseases

Bone marrow diseases, for example leukaemia or aplastic anaemia, are the commonest causes of thrombocytopenia (see Table 48.3). In addition to the abnormal platelet production, there may be platelet antibodies formed in patients with lymphoma or leukaemia. Splenomegaly of many different aetiologies causes sequestration of platelets in the splenic sinuses but rarely produces a platelet count low enough to cause purpura. Purpura and ecchymosis are among the commoner cutaneous features of the haemophagocytic syndrome.

Platelet consumption, thrombotic thrombocytopenic purpura and haemolytic–uraemic syndrome

Thrombocytopenia may be associated with haemangiomas (Kasabach–Merritt syndrome, see Chapter 15). This is caused by ongoing chronic consumption and there is often compensated subacute or chronic DIC. Relevant haemangiomas are usually large and have undergone an

increase in size and become tender when the thrombocytopenia develops.

Thrombotic thrombocytopenic purpura (TTP, Moschowitz's syndrome) [20–25] in adults and haemolytic–uraemic syndrome (HUS) in children are rare forms of thrombotic microangiopathy in which thrombocytopenic purpura and bleeding are associated with fever, haemolytic anaemia and renal and neurological symptoms. HUS has recently been shown to involve a severe prothrombotic coagulation disturbance before onset of clinical features [26,27]. Schistocytes (fragmented erythrocytes) are seen on blood films. Microvascular injury and intraluminal platelet thrombosis occur; this, and platelet plugging in myeloproliferative disorders, are discussed later in this chapter.

Abnormalities of platelet function

Several haemorrhagic syndromes have become recognized in which platelet function is abnormal although the total count may be normal [1,2]. Such changes may be idiopathic or secondary to drugs or many other illnesses. These syndromes include thrombopathia, thrombasthenia, von Willebrand's disease, severe anaemia, chronic renal failure and fibrinogen defects. Hermansky–Pudlak syndrome consists of a bleeding disorder due to storage pool disorder, with oculocutaneous albinism and pigment-containing cells in the bone marrow (see Chapter 39).

Drugs that may cause abnormal platelet function with clinical bleeding include aspirin, diclofenac, some penicillin and lactam antibiotics, alteplase and other antifibrinolytic drugs, ticlopidine and some chemotherapeutic agents. Many other drugs may cause abnormal platelet aggregation *in vitro*, sometimes with abnormal bleeding time, but not necessarily with clinical bleeding [2].

Causes of abnormal platelet function may overlap with causes of thrombocytopenia. For example, both may occur in chronic renal failure (in which the abnormality of function is most important) or in myeloproliferative disorders (in which thrombocytopenia is usually paramount). Patients with IgM myeloma or Waldenström's macroglobulinaemia often have abnormal platelet function, less commonly those with IgA myeloma or benign monoclonal gammopathy, but bleeding in these conditions is usually due to hyperviscosity rather than to the platelet function defect.

Thrombocytosis

Abnormally high platelet counts may occur as a result of essential thrombocythaemia or other myeloproliferative disorders, or secondary to a variety of other disease processes (see Table 48.3). This may lead to a tendency to platelet plugging and thrombosis or, paradoxically, to a bleeding tendency (particularly when the platelet count exceeds 1000×10^9/L with a clonal platelet defect such as an acquired form of storage pool disease). Many cases of thrombocytosis do not achieve this high platelet count and are unlikely to cause purpura unless there are additional reasons related to the causative disorder (such as lymphoma or other malignant disease).

Dermatological manifestations and associations of thrombocythaemia include purpura with or without necrosis, livedo reticularis, acrocyanosis, purple (blue) toe syndrome, Raynaud's phenomenon, erythromelalgia, other vascular symptoms including gangrene, and associated disorders such as pyoderma gangrenosum [28–36]. The latter is relatively uncommon in pure thrombocythaemia [34] (this patient subsequently developed further myeloproliferative features; cited in [35]). In one large study, 22% of patients with essential thrombocythaemia had skin lesions; 41% of these had haematomas, ecchymosis, petechiae or purpura, and 26% had erythromelalgia [36]. Many of these presentations are also seen in other hyperviscosity and dysproteinaemic conditions.

Pigmented purpuric dermatoses

SYN. CAPILLARITIS; PURPURA PROGRESSIVA PIGMENTOSA

Capillaritis is the generic term for a variety of chronic conditions that share certain histological features. The term 'purpura simplex' has also been applied to this group of disorders, on the basis of the common histological aspects. However, the same term has been applied to other mild and unexplained but morphologically different patterns of purpura such as easy bruising, and it is therefore potentially confusing. The term 'pigmented purpuric dermatoses' may be preferred, at least at present, as it conveys the message of a component beyond simple transient purpura.

The sometimes striking morphological patterns of the pigmented purpuric dermatoses have given rise to a wide range of descriptive and eponymous names [1–7]. Typical examples of the various eponymous diseases are sufficiently distinctive to warrant separate description but the clinical features may overlap, their aetiology is generally unknown and no clear distinction has been established between the different patterns other than on clinical morphological grounds. Gravity and increased venous pressure are important localizing factors in many cases. Exercise may be a provoking factor. Most are chronic but two-thirds may improve or clear eventually [5].

Pathologically, they are characterized by narrowing of the lumen and endothelial swelling of superficial small vessels, accompanied by perivascular T-lymphocytic infiltration, extravasation of erythrocytes and haemosiderin deposits in macrophages. The cellular infiltrate contains $CD4^+$ T cells in close contact with $CD1a^+$ Langerhans' cells [8,9], suggesting that a cell-mediated immune reaction is operative. Strong expression of endothelial cell adhesion receptors ICAM-1 and ELAM-1 may determine the pattern of the infiltrate [9]. Immune complex deposition has also been reported.

Capillaritis may on occasion be caused by drugs or food additives [10–12] (drugs caused 14% of cases in one large series [5]), may occur in rheumatoid disease [13], or may be a manifestation (sometimes the only manifestation) of mycosis fungoides [11,14–16]. Drugs reported to cause capillaritis resembling a pigmented purpuric dermatosis include calcium channel antagonists, β-blockers, angiotensin-converting enzyme inhibitors, nitrites, furosemide, antihistamines, antidepressants, chlordiazepoxide, analgesics such as paracetamol, glipizide, vitamin B_1 derivatives, tartrazine, interferon-α (in hepatitis C infection), polyvinyl pyrrolidone and topical 5-fluorouracil [10–12]. The apparently idiopathic variants, while much the commonest cause, are therefore a diagnosis made by exclusion. Stasis dermatitis, purpuric clothing dermatitis and hyperglobulinaemic purpura are also in the differential diagnosis.

Schamberg's disease [17,18]

SYN. PROGRESSIVE PIGMENTED PURPURIC DERMATOSIS

This uncommon eruption is most common in young adult males but may occur at any age including childhood. Familial incidence has been reported [19]. The lesions are most frequent on the lower limbs but may occur anywhere on the body, including the palms [20], and may be few in number or very extensive. They consist of irregular plaques of orange or brown pigmentation due to haemosiderin, with characteristic 'cayenne pepper' spots appearing within and at the edge of old lesions (Fig. 48.2). Slight changes in the epidermis may occur. There are usually no symptoms, although there may be some slight itching. The eruption is characteristically very chronic and may persist for many years. The pattern of the eruption changes, with slow extension and often some clearing of the original lesions. Spontaneous cure may occur eventually. Many patients have an eruption with features both of this disease and of the other pigmented purpuric dermatoses. An annular configuration may occur and there may be small lichenoid papules.

Itching purpura is a disorder that may be similar to

Fig. 48.2 Schamberg's disease.

Schamberg's disease, but the intensity of itch serves to distinguish the two.

Itching purpura [21–23]

SYN. ECZEMATIDE-LIKE PURPURA (OF DOUCAS AND KAPETANAKIS); DISSEMINATED PRURIGINOUS ANGIODERMATITIS

This condition has many similarities to Schamberg's disease but is generally more extensive, develops more rapidly and is characterized by persistent intense itch. It occurs most frequently in adult men and is of unknown aetiology. Purpuric lesions usually commence around the ankles and in a few weeks spread to involve the whole legs, sometimes the lower part of the body, and even elsewhere. They are more pronounced at sites of friction with clothing. The lesions consist of erythematous and purpuric macules that may become confluent. The eruption often has a rather characteristic orange colour. The dermal perivascular changes are those seen generally in the pigmented purpuric dermatoses and there are variable changes in the overlying epidermis, including spongiosis. Spontaneous improvement after a few months is usual, but recurrences may occur and a fluctuating but chronic course is frequent. The itching may respond to topical corticosteroids and oral antihistamines.

An almost identical picture occurs with carbromal sensitivity, and less commonly with other drugs such as meprobamate, carbamazepine and perhaps even some foods. Clothing or rubber dermatitis may produce a similar picture, and may explain many cases of itching purpura.

Pigmented purpuric lichenoid dermatosis of Gougerot and Blum [24]

This eruption occurs especially in men aged between 40 and 60 years. It usually affects the legs, but lesions may occur elsewhere. The characteristic clinical feature of the dermatosis is the presence of lichenoid papules in association with purpuric lesions similar to those of Schamberg's disease, and this may simply be a variation of the same disorder. This clinical pattern has been found in association with porphyria [25] and a similar pattern of eruption may occur in the oral mucosa [26].

Lichen aureus [27,28]

SYN. LICHEN PURPURICUS

This is a more localized, more intensely purpuric but often asymptomatic eruption that may have rather lichenoid morphology. Young adults and children are often affected, on body, limbs or even face. The lesions are often solitary and may be yellowish, golden, rust-coloured or purple. They may resemble a bruise, and hence must be distinguished from non-accidental injury in children, but may persist for a few years. Histologically, lichen aureus is distinguished from other pigmented purpuric dermatoses by a lack of epidermal component and in some cases a Grenz zone.

Purpura annularis telangiectodes [29,30]

SYN. MAJOCCHI'S DISEASE

This eruption occurs especially in adolescents and young adults of either sex but may occur at any age, and may be familial [31]. Exercise may have been a provoking factor in one case [32]. The clinical features are distinctive and described in its name. Lesions occur at any site, often in the absence of venous stasis, and may be few in number or very numerous. They consist of small plaques 1–3 cm across that are usually annular from their onset (Fig. 48.3). Lesions consist of telangiectases and haemosiderin staining of the skin. They may be purple, yellow or brown, and may contain 'cayenne pepper' spots. Individual lesions persist unchanged for many months or years, or there may be slow centrifugal extension with development of slight central atrophy. Sometimes the lesions disappear

Fig. 48.3 Majocchi's purpura annularis telangiectodes.

and are replaced by similar lesions nearby. Treatment is usually ineffective. A variant termed *purpura telangiectatica arciformis (Touraine)* consists of fewer, larger and irregularly arciform lesions [33].

Granulomatous pigmented purpuric dermatosis

An uncommon variant of pigmented purpuric dermatosis has been reported in which there is granulomatous histology [34,35].

Familial pigmented purpuric eruption

There are rare reported instances of the familial occurrence of Schamberg's disease [18] and of purpura annularis telangiectodes [31]. A distinctive pigmented purpuric eruption has been observed in several members of a family in which it was probably determined by an autosomal dominant gene [36]. Discrete reddish-brown spots develop in childhood or adolescence. The individual macules are larger than in Schamberg's disease and are arranged in a mosaic pattern. The lesions gradually cover a larger area and involve new sites, mainly on the limbs and in the larger flexures, but there are no symptoms.

Linear and quadrantic pigmented purpuric dermatoses

Various morphological types of pigmented purpuric eruption may occur in a linear or zosteriform distribution [37–39], or less commonly may diffusely involve a single quadrant of the body [40]. Individual lesions usually resemble lichen aureus or Schamberg's disease.

Treatment of pigmented purpuric dermatoses

These disorders may persist for many years [5,6,28] and are very resistant to any form of therapy; explanation without active intervention, or simply support hosiery, is often the most appropriate approach. Topical steroids may be of some help, especially for itch, but very prolonged use is best avoided. Psoralen and UVA (PUVA) [9,41,42] has proven effective in treating capillaritis of Schamberg, Gougerot–Blum and lichen aureus patterns. Ciclosporin [43] and griseofulvin [44] have also been effective in individual reports.

Non-thrombocytopenic vascular causes of purpura and syndromes of primarily ecchymotic haemorrhage

A number of disorders cause purpura or ecchymosis due to vascular fragility/poor dermal support, intravascular pressure increase, platelet dysfunction (see also earlier) or coagulation cascade defects. Minor trauma is often the precipitant of lesions.

Purpura due to raised intravascular pressure

Raised intravascular pressure may cause purpura in the absence of any other disease. Crops of petechiae after prolonged coughing or vomiting (see Fig. 48.1) occur especially on the relatively loose tissues of the face and neck. They are of no significance.

Gravity and venous stasis are the most important causes of purpura. Many purpuric eruptions are maximal on, or even restricted to, the lower leg. Likewise, many erythematous eruptions on the lower legs, especially in the elderly or those with leg oedema, show some degree of purpura that can usually be ignored. Bizarre patterns of purpura should always suggest the possibility of artefact.

Deaths from asphyxia are said to be associated with facial and conjunctival petechiae but the mechanism is probably due to vascular occlusion causing raised intravascular pressure rather than to hypoxia *per se* [1].

Purpura due to decreased support of blood vessels

Several disorders are associated with abnormal collagen, elastic or other dermal changes leading to poor support of the blood vessels. Conditions such as Ehlers–Danlos syndrome (collagen), pseudoxanthoma elasticum (elastic) and amyloidosis (abnormal protein) are discussed in more detail elsewhere. Facial or periorbital purpura occurs in 15% of patients with primary amyloidosis [2].

Scurvy is discussed in more detail in Chapter 57. Altered collagenous support for the blood vessels is manifest by either petechiae, especially on the legs, or by small or large bruises on the limbs following mild or inapparent trauma. Large deep bruises may lead to woody induration, usually of the legs. Perifollicular purpura is typical but is not diagnostic and is frequently absent. Diagnosis is established by the associated symptoms and signs (twisted 'corkscrew' hairs, gingival bleeding), dietary history, laboratory tests and therapeutic response.

Actinic purpura (*Bateman's purpura*, *'senile' purpura*) and *corticosteroid purpura* [3,4] are the commonest patterns of purpura due to lack of support of the blood vessels. They occur most commonly in skin altered by both age and solar radiation, but may occur in premature ageing syndromes. Corticosteroid purpura has the same pattern whether due to topical, oral, endogenous (Cushing's syndrome) or even inhaled [5] corticosteroids. The precipitating factor is a shearing stress. Patients who develop this type of purpura with ageing, in association with rheumatoid arthritis or with corticosteroids, are more liable to develop osteoporosis of the spine than patients without this sign [6]. The purpura occurs mainly in atrophic skin at exposed parts of the hands and forearms, or on the legs. Lesions appear after minor trauma or apparently spontaneously. They are usually asymptomatic and vary in size from a few millimetres to several centimetres across. They are often arranged linearly, and may show a linear or geometric shape. The appearance of the lesions is characteristic, with irregular areas, usually not palpable, that show little inflammatory reaction and which are usually dark purple rather than having the sequential colour changes of a normal bruise. They may persist for several weeks. Treatment is usually not necessary or possible.

Easy bruising syndrome and purpura simplex

The term 'easy bruising syndrome' has been used in various ways, usually for a mild purpura for which no cause has been detected, especially on the thighs of women ('devil's pinches'). It has been used to include those cases of a mild bleeding tendency in which changes in the morphology of capillaries may be seen by capillary microscopy, and in some of which variable but slight changes in coagulation factors have also been found. There are significant limitations in deciding what constitutes

'abnormal' or excessive bleeding [1]. The term 'purpura simplex' has also been used for any inflammatory purpura without vasculitis including disorders with the morphology of the pigmented purpuric dermatoses [2,3] and this term is therefore also of uncertain value. Autosomal dominant inheritance of purpura simplex has been reported [4] and presumably represents a subtle haemostatic defect; in one family, purpura simplex was co-inherited with ptosis [5].

Physical and artefactual causes of purpura

Bruising due to trauma seldom causes diagnostic problems, as there is usually a clear history, except when it occurs as an artefact or in child abuse. String vests may cause a distinctive reticular pattern of petechiae. Black heel (talon noire) is considered in Chapter 22. Bizarre patterns of purpura may be caused by suction, for example vacuum extractors in the neonate, electrocardiogram leads or around the mouth after sucking out the air from a glass [1]. Cultural remedies such as cupping, coin rubbing (Cao Gio) and spooning (Quat sha) may also produce unusual patterns of purpura that are usually obviously extrinsic in causation [2].

Paroxysmal finger haematoma [3–5]

SYN. ACHENBACH'S SYNDROME

In this syndrome there are recurrent episodes of painful bruising on the palms and palmar aspects of the fingers. It seems likely that it represents venous rupture, as frictional trauma may be reported, such as turning on a tap or twisting the top off a jar. It is probably more common than the number of reported cases would suggest. Its importance is that it may be confused with Raynaud's phenomenon or acute connective tissue diseases and investigated unnecessarily.

Autoerythrocyte sensitization syndrome [6–9]

SYN. PAINFUL BRUISING SYNDROME; GARDNER–DIAMOND SYNDROME

This is a distinctive but rare clinical entity apparently due, in many cases, to allergic sensitivity to red cells in the tissues. Minor extravasations of blood, for example those so common on the thighs of women, are followed by an intense inflammatory reaction. The disease occurs most frequently in young adult and middle-aged females, who are nearly always psychiatrically abnormal. They present with recurrent painful erythematous and purpuric lesions on the thighs and elsewhere. The diagnosis may be confirmed by intradermal injections of red cells or their washed stroma, or of phosphatidylcholine. This reaction occurs even in some subjects in whom a psychological cause is suspected and whose disease responds to psychological intervention [10,11].

Sensitivity to DNA [12,13] or to exogenous antigens attached to red cells [14] may present a similar picture. The condition is usually chronic, seldom disabling or associated with other abnormalities and is unresponsive to treatment. Plasmapheresis has been used successfully in isolated cases [15] and antimalarials are said to be effective in DNA sensitivity [16]. Dermatitis artefacta may produce a similar clinical picture, and is believed by some to account for all such cases [8,11,17].

Stigmata

In this very rare disorder there is exudation of apparently fresh blood through the unbroken skin of the hands, feet and side. The mechanism is obscure but, as with the previous syndrome, many if not all cases may have a traumatic origin [8,18].

Purpura in other dermatoses

Many eruptions on the lower leg, especially in the elderly, tend to become purpuric due to a combination of gravitational changes with vascular damage caused by the dermatosis. Rapid development of lower leg oedema may cause an eczematous eruption in which purpura may be prominent [1].

Even without the gravitational component, many dermatoses may be sufficiently intense to cause purpura. Sometimes this is physically due to scratching, but some disorders such as lichen planus, lichen nitidus and Langerhans' cell histiocytosis are not infrequently purpuric. Purpuric erythema annulare centrifugum, dermatitis herpetiformis, pemphigoid, pityriasis rosea and eczemas (especially of discoid type) may all occur. Purpura may be present in lymphomas and lupus erythematosus, either because of platelet deficiency or, more commonly, because of vascular abnormalities.

Lichen sclerosus often has a haemorrhagic component due to loss of collagenous support for the vessels.

Some insect bite reactions have a purpuric centre due to inoculation of the skin with anticoagulant chemicals in the bite (purpura pulicosa, maculae ceruleae).

Purpura may also occur around localized lesions with a strong vascular component if there are fragile vessels, for example targetoid haemosiderotic haemangioma or aneurysmal fibrous histiocytoma.

A rather characteristic disorder of children under the age of 1 year has been termed the *persistent acrovasculopathy syndrome*. Lesions occur on the ears, cheeks and extremities and are scaly and erosive; they may be purpuric, and there may be local lipoatrophy and distal phalangeal osteopenia.

Most of these conditions are discussed in more detail in other chapters; two disorders are specifically described here.

Solar purpura [2–5]

This condition is distinct from the actinic purpura discussed previously which is a manifestation of cumulative sunlight-induced ageing of the skin. The term 'solar purpura' is used to describe rapid development of purpuric lesions after exposure to sunlight. The precise nature of this disorder is uncertain. Some view it as a variant of polymorphic light eruption. It is distinct from erythropoietic protoporhyria, although purpura clearly occurs in this dermatosis in some patients (Fig. 48.4). Some cases may simply be a variation of purpura in dermatoses that are not usually purpuric, but where profound inflammation has allowed purpura to develop.

Fig. 48.4 Erythropoietic protoporphyria: marked purpura with sharp cut-off after sunlight exposure.

Acroangiodermatitis (of Mali) [6–8]

SYN. DERMITE OCRE OF FAVRE; GRAVITATIONAL PURPURA; PSEUDO-KAPOSI'S SARCOMA

This chronic dermatosis is associated with venous insufficiency or with vascular anomalies such as Klippel–Trenaunay syndrome [9], and there are several reports of it occurring as a stump dermatosis in amputees [10]. It has been reported in a patient with a thrombophilic prothrombin mutation [11]. It may mimic a pigmented purpuric dermatosis (see previously) but is discussed here as the purpura is due to abnormal vasculature rather than to capillaritis. It occurs more often in men than in women.

The lesions occur especially on the lower legs but may extend on to the dorsa of the feet and toes, and up the leg, especially over dilated varicosities. Individual lesions are minute purpuric macules that coalesce to form irregular plaques, which may be several centimetres in diameter. Follicular lesions may occur. The colour of the lesions is not usually the purple colour of fresh purpura but varying shades of yellow (ochre) and brown from haemosiderin and other breakdown products. The epidermis may be normal or show mild eczematous changes. Oedema, sclerosis, ulceration and other signs of venous insufficiency may be associated, but may be entirely absent even in cases of long duration. Differential diagnosis includes ordinary gravitational dermatitis, Schamberg's disease and Kaposi's sarcoma; the latter can be distinguished by the staining pattern with CD34 antigen, which stains perivascular spindle cells in Kaposi's sarcoma but only the endothelial cells in acroangiodermatitis [12]. Treatment is unsatisfactory but support hosiery seems logical.

Dysproteinaemic purpura and Waldenström's hypergammaglobulinaemic purpura

Purpura may be the presenting and sometimes the only symptom of disturbances in plasma proteins. It may occur at exposed skin sites in cryoproteinaemia (see Chapter 23 and below) and may occur due to monoclonal hypergammaglobulinaemia in myeloma. In such instances there may be platelet dysfunction, but clinical bleeding is usually related to the hyperviscosity syndrome rather than to the altered platelet function. Cutaneous features of paraproteinaemia include various patterns of vasculitis and neutrophilic dermatosis (see Chapter 49), cryoglobulinaemia (see below), urticaria and systemic capillary leak syndrome, abnormalities of lipid metabolism (notably diffuse plane xanthomatosis), subcorneal pustular dermatosis, lichen myxoedematosus and scleromyxoedema, amyloidosis, and features due to hyperviscosity (purpura, mucous membrane bleeding, retinopathy and neurological disturbance) [1,2]. Haemorrhagic features are particularly seen in Waldenström's macroglobulinaemia.

Waldenström's hypergammaglobulinaemic purpura is generally taken to imply an idiopathic phenomenon but in fact two of Waldenström's three cases had sicca symptoms, one with sarcoidosis [1]. Hypergammaglobulinaemic purpura is usually a polyclonal disorder most commonly linked with sarcoidosis, lupus erythematosus, Sjögren's syndrome, and other autoimmune conditions [2–8]. The majority of patients have positive antinuclear antibody and anti-SSA (Ro) or anti-SSB (La) antibodies [4–8]. Other features that have been associated include arthropathy (not uncommon), renal tubular acidosis, chest infections, lymphopenia and immune hypersensitivity pneumonitis. Most patients are female [9].

Fig. 48.5 Waldenström's hypergammaglobulinaemic purpura: lower leg lesions, in this patient usually provoked by prolonged standing or heat.

Clinically the pattern of purpura is often non-specific, usually consisting of crops of small erythematous macular or palpable purpuric spots on the lower leg (Fig. 48.5) [1–8], but unusual patterns with reticulate lesions may occur [10]. Prolonged walking, standing or sitting with the legs dependent, or other increase in venous pressure, may be an obvious provocative factor [7,8]. Itch or a burning sensation may occur. It is likely that this disorder is an immune complex vasculitis: immune complexes can be detected, histology may show vasculitic change, and direct immunofluorescence may show immunoglobulin in blood vessel walls [6,10,11]. Hyperviscosity leading to stasis and endothelial damage plays some part. There may be an abnormal ratio of IgG subclasses, with low IgG1/IgG2 ratio [12].

Lesions usually resolve in about a week but may become confluent and permanent. Treatment is often not required, although prednisolone, NSAIDs, hydroxychloroquine and etamsylate (ethamsylate) have been used.

A similar pattern has been reported in association with cystic fibrosis, due to either hypergammaglobulinaemia or cryoglobulinaemia [13,14]. It may appear suddenly, affects the lower legs mainly, and is exacerbated by prolonged standing or by tight garments or footwear. It is associated with severe lung disease and poor prognosis; a high antigenic load due to chronic lung infection may be the cause.

Multifactorial purpura associated with systemic diseases

Non-thrombocytopenic purpura may be caused by a variety of systemic diseases. Many of these have already been discussed, but in some cases there may be mixed mechanisms of purpura or easy bruising. Of these, renal disease is perhaps the most important; petechiae, ecchymoses or mucosal bleeding are common in end-stage renal failure [1]. Platelet dysfunction is probably the major factor [2], but there may also be frank thrombocytopenia. Diabetes, severe anaemia, liver disease, haemochromatosis and carcinomatosis may also cause purpura.

In amyloidosis, with or without myelomatosis, purpura may be due to infiltration of the capillaries and perivascular tissue with amyloid, but platelet changes and liver disease may also contribute.

Purpura occurs in patients with malnutrition. It seems probable that changes in coagulation, platelets and capillaries all play their part. For example, in cystic fibrosis there may be dysproteinaemia, vasculitis and vitamin K deficiency.

Purpura has been associated with ovarian and other endocrine abnormalities [3], for example Cushing's disease, and may vary with the menstrual cycle.

Inflammatory haemorrhage: anaphylactoid purpura and acute haemorrhagic oedema

Vessel damage with inflammation may lead to haemorrhage, typically manifest as palpable purpuric lesions. This is usually caused by one of the types of antigen–antibody reaction discussed in Chapter 10 but may be due to a direct toxic effect. The antigen in the allergic mechanism may be a component of the vessel itself or of surrounding tissues or, more commonly, an exogenous substance bound to the blood vessel or other tissues. Such substances include drugs, bacterial products and food additives; they may reach the blood vessel via the bloodstream or from the skin surface. The antigen–antibody reaction may occur on the surface of the endothelial cells or in adjacent tissues, or the vessels may be damaged by soluble complexes. The localization of many such lesions will be determined by local factors, for example changes due to gravity, cold and trauma. This inflammatory process is therefore a vasculitis, and is discussed in Chapter 49. Two conditions of this type are briefly discussed here, one because it carries the name purpura (Henoch–Schönlein purpura) and the other because it may present with striking haemorrhagic lesions (acute haemorrhagic oedema).

Henoch–Schönlein purpura is a vasculitic process due to immune complex deposition in the walls of arterioles and venules that gives rise to palpable inflammatory lesions; these are often purpuric as well as erythematous and may vary in size from 0.5 to 1 cm or more. However, minor lesions of anaphylactoid purpura may sometimes be confused clinically with other types of purpura.

Acute haemorrhagic oedema is now felt to be a variant of Henoch–Schönlein purpura. It has also been described as cocarde purpura, Seidlmayer's syndrome and Finkelstein's disease. Most cases have been reported from continental Europe [1,2] but English [3] and American [4] cases are also reported. It may be overtly haemorrhagic, but can present as arciform or annular brown lesions that are of acute onset but which have some morphological similarity to pigmented purpuric dermatoses.

Disorders of cutaneous microvascular occlusion

Numerous conditions may cause microvascular occlusion (Table 48.4). This process may involve abnormal coagulation (e.g. DIC, APLS), platelet plugging (e.g. heparin necrosis), emboli or crystal deposition (e.g. cholesterol emboli), abnormal erythrocytes (e.g. sickle cell disease) or abnormal proteins (e.g. cryoproteinaemia). Many of these conditions may cause purpura as one of their manifestations; many cause an initial non-inflammatory purpuric process that can be diagnostically helpful in the differential from vasculitis.

Occlusion due to platelet plugs

Heparin-induced thrombocytopenia and heparin necrosis

Aetiology and pathogenesis. The syndrome of heparin-induced thrombocytopenia (HIT) is an uncommon paradoxical response to heparin, with some female predominance [1]. This syndrome can be defined as any clinical event best explained by PF4/heparin-reactive antibodies (HIT antibodies) in a patient who is receiving, or who has recently received, heparin [1]. While IgA and IgM class antibodies may play a role, IgG antibody is most closely associated with this syndrome [2]. The antibody that causes HIT is not simply an antiheparin antibody. Heparin and certain other polyanions, when bound to PF4, can induce conformational changes in tetrameric PF4, exposing new epitopes on PF4. This may trigger antibody production to these newly exposed regions. When antiheparin/PF4 antibody binds with heparin/PF4 complexes on the surface of platelets, platelet activation and aggregation results. Not all heparin/PF4 antibodies appear to be pathogenic, and some antibodies responsible for HIT do not bind to heparin/PF4 complexes but to chemokines or cytokines such as neutrophil activating peptide-2 (NAP-2) and interleukin-8, somehow activating platelets [1,2].

Unfractionated heparin is three times more likely to be associated with HIT following orthopaedic surgery compared with low-molecular-weight heparin [1]. HIT is more likely to be induced by bovine-derived unfractionated heparin than the porcine-derived variety, consistent with the hypothesis that longer and more flexible heparins bind to PF4 tetramers in ways that induce more conformational change and more exposure of neoepitopes. This may also explain the lower risk of HIT with low-

Occlusion due to vascular coagulopathies§
Sneddon's syndrome
Livedoid vasculopathy/atrophie blanche
Malignant atrophic papulosis
Occlusion due to reticulocyte occlusion¶
Sickle cell disease
Other severe haemolytic anaemias
Occlusion due to unknown or controversial mechanisms
Cutaneous calciphylaxis
Some insect bites, especially Loxosceles (brown recluse spider)
Some snake bite syndromes**

* Most of these disorders present with purpura or necrosis with minimal inflammation, and frequently show retiform (stellate, branching) morphologies.
† TTP/HUS is usually occlusive in visceral vessels, but skin lesions are most often non-palpable petechiae, and not due to occlusion.
‡ Fat emboli typically cause occlusion in viscera, especially lungs; cutaneous lesions are rare and typically petechial, due to minute fat particle occlusion.
§ Sneddon's syndrome typically presents with pathological livedo reticularis; livedoid vasculopathy may have retiform purpura morphologies, but atrophie blanche and malignant atrophic papulosis are often not purpuric, but heal with characteristic atrophic scar with surrounding telangiectasia.
¶ Syndromes involving reticulocyte occlusion often heal with lesions mimicking atrophie blanche, and are seldom purpuric or retiform.
** Most snake bites cause haemorrhage; if fulminant disseminated intravascular coagulation results, some lesions might be occlusive.

molecular-weight heparins. The risk of HIT is highest in post-surgical patients, less so in medical patients requiring heparin, and lowest in obstetric settings [1].

Clinical features. Patients with HIT usually develop absolute or relative thrombocytopenia (90%), often followed by evidence of venous or arterial thromboses or of heparin necrosis in the skin [1]. A proportional drop of over 50% in platelet number from the pretreatment count may be a better indication of early heparin-induced platelet aggregation than an absolute thrombocytopenia of 100–150 $\times 10^9$/L [1]. This may occur immediately after heparin administration if the patient has been previously sensitized and has received heparin within the past 100 days. In two-thirds of patients, the fall in platelet count begins between day 5 and 10 of heparin administration, though significant thrombocytopenia may take 7–14 days to develop [1,3,4]. Uncommonly, patients may develop HIT several days after stopping heparin (delayed-onset HIT); this is attributed to the presence of high-titre antibodies that can recognize PF4 neoepitopes even in the absence of heparin binding [1]. A history of HIT is not predictive of a second episode if the patient last received heparin more than 100 days previously.

Heparin administration commonly induces cutaneous findings of simple haemorrhage with ecchymoses, and occasionally triggers urticaria or infiltrated plaques [5–7]. Uncommonly, the syndrome of heparin necrosis results as a cutaneous microvascular occlusion subset of HIT. Purpuric, tender, sharply demarcated plaques develop; retiform extensions that sometimes develop at the lesional margins are characteristic of heparin necrosis. Erythema may sometimes accompany such lesions, and necrosis is frequent. Lesions are most common at subcutaneous injection sites but can occur elsewhere [8–10] (Fig. 48.6). Interestingly, as few as one-third of patients with skin lesions of heparin necrosis may develop absolute thrombocytopenia, even when HIT antibodies are detected [1]. Haemorrhagic adrenal infarction has been reported in such cases. Histological examination of lesions reveals 'white clots', representing platelet–fibrin thrombi, in the cutaneous microvasculature [4,11].

Treatment. Treatment of HIT and heparin necrosis continues to evolve. The correct diagnosis is important, since many patients on heparin develop thrombocytopenia for reasons other than the development of HIT antibodies; conversely, patients may develop the arterial or venous thromboses, or especially heparin necrosis, without manifesting thrombocytopenia [1]. While replacing heparin with coumadin was previously thought to be effective in treating HIT and heparin necrosis, coumadin substitution is not only ineffective but may in fact induce venous limb gangrene [1]. Although low-molecular-weight heparin is much less likely to cause HIT, it is contraindicated for treatment of patients with HIT due to other types of heparin. Surprisingly, heparin is the appropriate treatment for cardiac surgery patients with a previous history of HIT, but whose antibodies have disappeared (beyond 100 days). The anticoagulants currently used to treat patients with HIT are danaparoid (a heparinoid) and two thrombin inhibitors, lepirudin and argatroban [1]. Even with treatment with one of these agents, there is a 5–20% frequency of new thromboses. Major bleeding in HIT patients has occurred in 3.1% of those treated with argatroban, and in 5.9–14.4% of those treated with lepirudin.

Myeloproliferative disorders

Cutaneous lesions are common in thrombocythaemia and other myeloproliferative disorders (see also Chapter 59). Paradoxically, patients with myeloproliferative thrombocytosis may both bleed and clot abnormally. Skin lesions were documented in 22% of 268 patients with essential thrombocythaemia [1], and included urticaria, livedo reticularis, petechiae, ecchymoses, haematomas, erythromelalgia, Raynaud's phenomenon, recurrent superficial thrombophlebitis, necrotizing vasculitis, leg ulceration and gangrene. Biopsy findings were variable, but some livedo reticularis and acral infarcts were associated with evidence of microvascular occlusion. Additionally, tender erythematous facial plaques and palmar violet macules and papules were reported as manifestations of platelet plugging in a patient with atypical chronic myeloproliferative disease and a history of Budd–Chiari syndrome, another known thrombotic complication of myeloproliferative disease [2]. This patient's cutaneous lesions were unresponsive to coumadin, but cleared within 24 h of aspirin administration following identification of platelet plugs as the cause of previously identified microvascular occlusion.

Essential thrombocytosis and polycythaemia vera, though rare, are the first and second most common causes of elevated platelet counts, with an increased frequency of thrombotic events and of erythromelalgia [3]. These diseases are more common at younger ages and in women. However, reactive or post-splenectomy thrombocytosis at any level is not associated with occlusion, suggesting that thrombosis in the setting of myeloproliferative disease is not a function of thrombocytosis alone. Platelet counts less than 1000×10^9/L are generally not considered sufficient to result in platelet-related vascular occlusion phenomena. The mechanisms for ischaemic or occlusive syndromes in myeloproliferative disease must therefore depend on more than platelet number alone; the following factors may be relevant. Acquired von Willebrand factors in myeloproliferative disease have been associated with both bleeding and thrombotic complications. Anticardiolipin antibodies, factor V Leiden mutations, abnormal endothelial cell function, and decreased levels of protein C and protein S may be synergistic for thrombosis in chronic myeloproliferative diseases [4,5]. In addition to high platelet counts, abnormal platelet function occurs in myeloproliferative or myelodysplastic disease, although whether this can lead to vascular occlusion at platelet counts less than 1000×10^9/L is controversial. Thrombotic events have been reported at platelet counts below 600×10^9/L in patients with essential thrombocytosis, including some events at normal platelet counts [6]. In a study of 56 consecutive patients with essential thrombocytosis, 46 developed complications mostly related to thrombosis [6]. In these 46 patients, severe complications occurred in 22% at platelet counts lower than 600×10^9/L, in 15% at counts lower than 500×10^9/L, and in 4% at counts lower than 400×10^9/L.

Erythromelalgia (erythralgia) can occur as a primary or secondary syndrome. This intensely uncomfortable burning associated with paroxysmal erythema of the distal extremities is frequently triggered by skin contact with a warm surface. While erythromelalgia has been seen in many different settings, the association of purpuric or necrotic areas on hands and feet with the dysaesthetic erythema is exclusively seen with myeloproliferative or myelodysplastic thrombocytosis [7]. Because of the platelet origin of occlusion and vascular symptoms in the myeloproliferative subset of erythromelalgia, aspirin administration is notably effective in clearing lesions and alleviating symptoms, whereas it is much less effective in primary and other secondary forms of erythromelalgia.

Splenomegaly may be seen in all forms of myeloproliferative syndromes. Ruddy cyanosis is characteristic of polycythaemia vera, as is elevation of haemoglobin, haematocrit and red cell mass. All syndromes may show elevations in white count, but this is most characteristic of chronic granulocytic leukaemia, especially in association with elevated eosinophil and basophil counts. Anaemia and altered red cell morphology can occur over time in all patients, and all these diseases have some risk of transition to dyspoiesis and severe anaemia, leukaemia or myelofibrosis.

Many therapies previously used for myeloproliferative thrombocytosis increase the risk of leukaemic transformation and of complications in fertility and pregnancy. Low-dose aspirin has been widely accepted as effective thrombosis prophylaxis, although definitive proof of its

efficacy is lacking. Its dramatic reversal of signs and symptoms in erythromelalgia provides some clinical evidence for its usefulness in thrombocythaemic complications. Anagrelide has become an important therapeutic agent, acting to both inhibit platelet activity and decrease the platelet count [8].

Paroxysmal nocturnal haemoglobinuria

Paroxysmal nocturnal haemoglobinuria (PNH) is an acquired clonal blood disorder associated with deficient haematopoiesis, intravascular haemolysis and venous thrombosis [1,2]. Episodic haemoglobinuria is the characteristic result of nocturnal haemolysis, although it is the presenting feature in only 26% of patients [1,2]. The sleep-associated haemoglobinuria is secondary to an abnormally increased sensitivity of red blood cells to lysis by serum complement [1]. This increased sensitivity to complement lysis is related to abnormal regulation at two different points of the complement cascade, and this abnormal regulation is due in turn to the partial to complete deficiency of two membrane-associated inhibitors of the complement cascade, decay-accelerating factor (DAF) and membrane inhibitor of reactive lysis (MIRL, also known as CD59). DAF inhibits the activity of classic complement pathway C3 convertase and of alternative pathway C3 convertase, while MIRL/CD59 regulates the activity of the complement membrane attack complex on red cells. These two inhibitors are part of a group of roughly 20 red cell membrane proteins that share a common post-translational modification in the glycosylphosphatidylinositol (GPI) anchor. In PNH, a somatic mutation in the phosphatidylinositol glycan class A gene (*PIG-A*) on the X chromosome alters the ability of proteins sharing the GPI anchor to bind to the membrane [1–3].

This complex pathophysiology explains the haemolysis and haemoglobinuria in PNH, but does not yet completely explain other manifestations of this disease such as thrombosis. Thrombosis is a major morbidity; 40% of patients develop venous thrombosis [2]. At least some of the thrombotic tendency may be related to complement-mediated activation of platelets or to platelet–leukocyte complexes, which share the defect in GPI-anchored proteins. Budd–Chiari syndrome (hepatic vein thrombosis) is common, as are thromboses in unusual sites such as cerebral, dermal, hepatic and portal, mesenteric and splanchnic veins [1]. This unusual localization may also favour platelet activation as a pathogenic factor over typical plasma hypercoagulability. Anticoagulants, corticosteroids and thrombolytic therapy may be effective in treating thrombotic episodes; the role of antiplatelet therapy is unclear [4]. Clinical dermatological features of PNH include pyoderma gangrenosum, haemorrhagic bullae and DIC [5].

Thrombotic thrombocytopenic purpura/haemolytic–uraemic syndrome

TTP was first recognized as recently as 1966 as a syndrome of thrombocytopenic purpura, microangiopathic haemolytic anaemia, renal dysfunction or failure, neurological abnormalities and fever, with a fatal outcome in 90% of patients [1]. Once plasma exchange proved at least sometimes effective in treating this disorder, criteria for diagnosis were pared to include only thrombocytopenia and microangiopathic haemolytic anaemia. HUS was originally described in children with acute renal failure, microangiopathic haemolytic anaemia and, usually, thrombocytopenia, but no purpura, neurological findings or fever. Current diagnostic criteria do not distinguish between TTP and HUS. However, childhood HUS is distinguished clinically because most cases are related to enteric infection with *Escherichia coli* O157:H7, HUS developing about 1 week after diarrhoea due to this agent; most children survive without plasma exchange [1]. Epidemic forms of HUS are most common, associated with

prodromal diarrhoea and with verotoxin (shigatoxin S1 or S2)-producing organisms, usually the *E. coli* strain mentioned previously, or enterococcus [2]. *Mycoplasma* can also provoke TTP. Pregnancy can induce TTP/HUS, as well as HELLP syndrome (haemolysis, elevated liver enzymes, low platelet count), as a complication of pre-eclampsia and eclampsia, and these may be difficult to distinguish [2]. TTP/HUS has been reported secondary to drugs (especially mitomycin C, ciclosporin, ticlopidine and quinine), after allogeneic bone marrow transplantation, and associated with autoimmune connective tissue disease (lupus erythematosus, scleroderma), vasculitis (polyarteritis nodosa), APLS [3], Sjögren's syndrome or metastatic carcinoma.

The molecular basis of TTP is a severe deficiency of a protease (ADAMTS13) that cleaves von Willebrand factor, resulting in persistence in plasma of ultra-large von Willebrand multimers secreted by endothelial cells [1,2]. Persistence of such large multimers in the circulation leads to formation of microvascular platelet thrombi. Congenital deficiency of ADAMTS13 leads to lifelong recurrent episodes of TTP; mechanisms for acquired ADAMTS13 are still unclear, but can include acquired autoantibody. Some regard ADAMTS13 deficiency as a diagnostic feature of TTP, whereas ADAMTS13 levels are reported to be normal in most patients with HUS [4,5]. Von Willebrand factor protease is deficient in hereditary, intermittent relapsing, intermittent acute, ticlodipine-induced and clopidogrel-induced TTP, but is normal in HUS and transplantation-related thrombotic micro-angiopathy. However, not all patients with deficient von Willebrand factor protease have active TTP.

Treatment options include plasma exchange with fresh frozen whole plasma or parts of plasma (e.g. cryoprecipitate-reduced plasma, high-molecular-weight fraction); corticosteroids, vincristine and antiplatelet drugs may also have a role. Outcome is usually good in childhood but less so in familial forms. As a practical matter, the response of patients to plasma exchange treatment in TTP or HUS is independent of whether they have deficient or normal levels of ADAMTS13 [6].

Microvascular platelet thrombi are characteristically seen in patients with TTP, especially in the renal and cerebral circulation [2]. Some have reported that HUS patients more often have fibrin-rich thrombi and more limited visceral vessel involvement [7]. Purpuric skin lesions are frequently mentioned in reports and reviews of TTP, but histological characterization of such cutaneous lesions is very sparse. Hyaline microthrombi composed of platelets and fibrin have been reported [8]. It seems likely from evaluation of lesional photographs that many, if not most, of the skin lesions in TTP are related to thrombocytopenia and simple haemorrhage rather than to microvascular platelet plugs as seen in the cerebral and renal vessels.

Occlusion due to cryogelling

Common clinical features

Occlusion syndromes triggered by cold exposure are suggested by an acral distribution of lesions of necrosis or purpura, often with retiform features, and sometimes associated with acral livedo reticularis. An acral distribution must be distinguished from a dependent distribution of lesions. Both patterns may involve hands and feet, but with a dependent pattern there are typically many more lesions on the feet and legs than on the hands. A dependent distribution of lesions suggests immune complex-mediated disease, and usually presents as classical palpable purpura or occasionally as inflammatory retiform purpura, not as bland or non-inflammatory purpura or pauci-erythematous necrosis. An acral distribution of lesions is also characteristic of erythema multiforme. However, erythema multiforme presents with target lesions, atypical target lesions or classical palpable purpura, rather than non-inflammatory retiform purpura or necrosis, and it is not associated with livedo reticularis. In addition, the acral distribution of cryo-occlusion syndromes often includes the ears and nose, sites usually unaffected by erythema multiforme. While ill patients with immune complex vasculitis may develop dependent lesions on the posterior portions of the ears if supine due to their illness, their other lesions are typically in dependent areas as well, and there is usually no history of cold exposure as the precipitating factor. A biopsy of early lesions, before necrosis has had time to trigger a secondary vasculitic histology, should show non-inflammatory occlusion of dermal vessels with cryoprotein or agglutinated red cells.

Careful handling of serum and plasma is necessary to allow identification of cryogelling proteins, since those most likely to cause disease are those that gel at temperatures very close to normal body temperature. Likewise, identification of cryoproteins or cryoagglutinins does not prove a cryo-occlusion syndrome, since these may either gel at temperatures that are not relevant to typical cold exposure or may simply represent incidental findings. The latter is especially true of cryofibrinogens and cold agglutinins.

Cryoglobulins

Cryoglobulins, immunoglobulins that reversibly precipitate or gel in the cold, were first reported in 1933 and were named cryoglobulins in 1947 [1–4]. In 1974, Brouet *et al*. [2] proposed the now standard subset classification of cryoglobulins into types I, II and III. In the 1990s, a large proportion of cases were found to be associated with hepatitis C. While precipitation of cryoglobulins is primarily related to reversible cold-induced denaturation of protein, other factors such as cryoglobulin concentration in the microvascular environment, pH and non-covalent binding factors also influence the likelihood and intensity of precipitation.

Type I (single molecule) cryoglobulins are single monoclonal immunoglobulins, usually IgG or IgM, less commonly IgA, and rarely Bence-Jones protein. Accounting for 10–15% of cryoglobulins, they are often associated with an underlying lymphoproliferative disorder, especially multiple myeloma or Waldenström's macroglobulinaemia [5]. Since type I cryoglobulins are single proteins and are neither immune complexes nor proven to activate complement, then if they are to cause vascular injury or occlusion they can do so only by cryogelling and not by immune complex vasculitis.

Type II and III, termed mixed cryoglobulins, are multiple molecule proteins, typically immune complexes, that gel under laboratory conditions (2–4°C). Unless they gel at temperatures close to body temperature, they are much more likely to cause disease as immune complexes than as cryoproteins, but they can cause disease through either or both mechanisms in any given patient. Rheumatoid factor activity (defined by anti-Fc binding) is detectable in the sera of 87–100% of patients with mixed cryoglobulinaemia [3]. Type II cryoglobulins are composed of monoclonal proteins of IgM, IgG or occasionally IgA class that bind to an antigen present in the blood, most commonly the Fc portion of polyclonal IgG molecules. Those that bind immunoglobulin (usually IgG) by anti-Fc affinity are also, by definition, rheumatoid factors, though only the IgM/anti-IgG rheumatoid factors are recognized by standard rheumatoid factor testing. In up to 95% of type II cryoglobulins with IgM as the anti-rheumatoid factor immunoglobulin, the IgM contains a κ light chain, which would not be expected by chance alone [3,6]. Type III mixed cryoglobulins are also most commonly rheumatoid factors, but the IgM, IgG or IgA anti-Fc antibodies in this group are polyclonal rather than monoclonal. In patients with mixed type II or III cryoglobulins, complement levels are usually reduced, especially the C4 component.

Antibodies to hepatitis C virus (HCV) have been found in more than 50% (42–98%) of patients with type II and III cryoglobulins [2–4]. Conversely, 13–54% of patients with HCV have mixed cryoglobulins detected in the laboratory, and the majority of these are type III cryoglobulins (67–91%). Of HCV-infected individuals with cryoglobulins, only 27% had clinical signs consistent with the syndrome of cryoglobulinaemia [2]. The reasons why only a fraction of HCV-infected and cryoglobulin-positive patients develop symptomatic cryoglobulinaemia are unknown.

In a multicentre Italian cooperative study of 913 patients with cryoglobulinaemia, 8.9% of all patients with symptomatic cryoglobulinaemia had lymphoproliferative disease at diagnosis [2]. Of this subset of patients, 27% had type I, 68% had type II and 5% had type III cryoglobulins. Though type I cryoglobulinaemia is usually associated with lymphoproliferative disease, it is a much less common type than type II and III; the latter two types therefore accounted for the majority of cryoglobulinaemia-associated lymphoproliferative disease in this study from a region with a high endemic rate of HCV and mixed cryoglobulinaemia.

Other syndromes are also associated with cryoglobulins detectable in serum. Patients with connective tissue disease also have higher rates of cryoglobulinaemia: it occurs in up to 25% of patients with SLE, 12.5% of patients with systemic sclerosis, 46% of patients with active rheumatoid arthritis and 17–37% of patients with Sjögren's syndrome [2]. In addition to HCV, other chronic infections such as Lyme disease, subacute bacterial endocarditis (up to 90%), Q fever, hepatitis A and B, hantavirus, cytomegalovirus, human T-cell leukaemia virus I and HIV have been reported [2,7]. Chronic inflammatory disease, such as liver cirrhosis from any cause, is also associated with a higher than expected rate of detectable cryoglobulins. The presence of cryoglobulins in serum does not invariably predict disease; cryoglobulins were present at low titre in as high as 51% of normal individuals in one study [8]. In fact, despite detectable serum cryoglobulins in the patient groups mentioned, most will not develop symptomatic cryoglobulinaemia [2].

There are only two known ways in which cryoglobulins can result in disease. The first is by precipitation within the vascular lumen, typically cold-induced, with hyaline plug formation and minimal early phase inflammation. Typical clinical lesions would be minimally inflammatory cutaneous infarction with or without associated livedo reticularis, or non-inflammatory retiform purpura. Since

there is little evidence that cryogelling of monoclonal antibody induces complement activation, cryogelling is the only known mechanism for vascular lesions for type I cryoglobulins [5]. The second mechanism is that of immune complex vasculitis. Since nearly all type II and III cryoglobulins are immune complexes, they should all be capable of inducing an immune complex vasculitis, though many do not. If they cryoprecipitate near body temperature, they could also cause vascular injury by simple occlusion, although most appear to gel at temperatures well below 37°C.

The median age at diagnosis of cryoglobulinaemia is early to middle sixth decade, with a female to male ratio of 2 : 1 [2]. Recurrent showers of dependent palpable purpura, sometimes with burning or itching, frequently associated with arthritis or arthralgia, is the classic presentation of mixed (type II and III) cryoglobulinaemia (the combination of purpura, asthenia and arthralgia has been termed Meltzer's triad). Patients with symptomatic cryoglobulinaemia of any type most often present with cutaneous lesions, usually purpura (in 55–100%, especially if HCV-associated) [2–4,9]. Ulceration, haemorrhagic crusts or cutaneous infarction are seen in 10–25% of patients, most often with type I cryoglobulins. Cold-induced acrocyanosis of acral areas, and non-inflammatory retiform purpura are also more typical of type I cryoglobulinaemia. Other reported cutaneous findings include acral cyanosis, Raynaud's phenomenon, urticarial lesions, ulceration and livedo reticularis [4,10,11]. Histological demonstration of non-inflammatory hyaline thrombosis is more common in patients with type I cryoglobulinaemia, but some such patients have also been reported to have cutaneous vasculitis [9]. A prospective study of biopsies of only new lesions (duration < 48 h) of purpura in type I cryoglobulin patients has not been published. This leaves unresolved the issue of whether all reports of vasculitis in type I disease are those of vasculitis secondary to occlusive necrosis or ulceration. Non-cutaneous clinical findings most frequently include involvement of the joints (35–92%), peripheral nerves (17–56%), kidneys (21–29%) and liver [2–4].

Confirmation of cryoglobulins in sera requires careful handling of specimens to prevent cryoprecipitation before they can be detected. Collection of 10–20 mL of blood is suggested, and this must be kept warm and allowed to clot at 37°C for 30–60 min before centrifugation. The serum supernatant is left at 4°C for up to 7 days, with types I and II most likely to precipitate by 24 h [2,3,12]. A true cryoglobulin should once again be soluble if the sample is reheated to 37°C. Cryocrit measurements represent the percentage of the precipitate compared with the serum supernatant. Despite the presence of monoclonal protein, polyclonal gammopathy is the most frequent finding on serum protein electrophoresis of serum samples (not cryoprecipitate specimens) in patients with type II cryoglobulinaemia [2]. A more sensitive technique, such as immunofixation, is needed to identify the presence of a clonal protein.

Treatment of cryoglobulinaemia is often problematic, and prospective or controlled trials are rare [3,4]. If symptoms are mild, no treatment may be needed. If symptoms of acral lesions are precipitated by cold, then protection of affected areas may be sufficient. Measures to reduce the concentration of a type I cryoglobulin, such as plasmapheresis, plasma exchange or cytotoxic therapy, are occasionally effective, though unfortunately usually only in the short term. For immune complex-related disease, corticosteroids, cytotoxic agents or plasmapheresis may be effective, but relapse is typical once therapy is stopped. Interferon-α has been used to treat HCV-associated cryoglobulinaemia, with or without ribavarin [3,4,11]. Treatment with these agents has resulted in partial or complete remissions of vasculitic findings, but relapse often follows cessation of therapy. The therapy itself has occasionally been implicated in triggering the onset of vasculitis. In patients with mixed cryoglobulinaemia troubled primarily by recurrent cutaneous vasculitic lesions, colchicine or dapsone therapy may be of some help in reducing the frequency and severity of episodes.

Cryofibrinogenaemia

Cryofibrinogen deposits consist of a complex of fibrinogen, fibrin and fibronectin that forms on cold exposure [13]. Since cryofibrinogens can be cleaved to form fibrin, plasma rather than serum must be tested to detect these cryogelling proteins. Cryoglobulins should be present in both plasma and sera [13,14].

Cryofibrinogenaemia is common as a laboratory abnormality but is a rare cause of symptomatic clinical disease. One study found an incidence of 3% in a random sample of hospital patients, usually as an incidental finding [15]. Therefore, clinicopathological correlation is important. Cryofibrinogenaemia may be idiopathic or can be associated with malignant disorders (especially haematological), thromboembolic disease, IgA nephropathy or various inflammatory, connective tissue or infectious syndromes [16,17].

Acquired dysfibrinogenaemia very rarely may mimic a cryofibrinogen syndrome by acral occlusion, including gangrene. Interestingly, this subset of dysfibrinogenaemia appears to act by greatly increasing red cell aggregation, mimicking occlusion-inducing cold agglutinins. Blood smear preparations show marked rouleaux formation.

The most common cutaneous findings are cold intolerance, purpura, necrosis, livedo reticularis, gangrene and ulceration (Fig. 48.7) [14,16,17]. The purpura or necrosis typically has a non-inflammatory retiform purpura morphology. Biopsy specimens from skin lesions typically show thrombi in small vessels with dermal necrosis [16].

(a)

(b)

Fig. 48.7 Cold-induced lesions due to cryofibrinogenaemia, (a) on the ear and (b) on the foot. Acral location is typical for cryogelling. Foot lesion shows minimal erythema, retiform bullae and haemorrhage with necrosis.

Leukocytoclastic vasculitis has been reported, but is probably due to ischaemic necrosis rather than being a cause [17]. Fibronectin may be a major component of vascular plugs in patients with cryofibrinogenaemia alone, whereas vascular occlusion in patients with both cryofibrinogens and cryoglobulins shows a predominance of cryoglobulin deposition [17]. Treatment of cryofibrinogenaemia should be aimed at the underlying disease, where possible, and at protecting areas from cold exposure [18]. Stanozolol, an androgenic steroid with fibrinolysis-enhancing effects, has also been used for treatment of cryofibrinogenaemia, as have other fibrinolytic agents [19].

Cold agglutinin-related cutaneous occlusion

Cold agglutinins are immunoglobulins that are able to agglutinate red blood cells below normal body temperatures. Since agglutination of red blood cells depends on binding of antibody to more than one cell at a time, pentavalent IgM is almost exclusively responsible for this phenomenon. Just as with cryoglobulins, there are both monoclonal and polyclonal cold agglutinins, usually directed at I, i or Pr antigens of erythrocytes [20,21]. Monoclonal cold agglutinins are idiopathic or secondary to malignant lymphoproliferative diseases. Polyclonal cold agglutinins are usually associated with infection, especially due to *Mycoplasma pneumoniae*, less often HCV, parvovirus B19 or leptospiral infections.

Just as with many cryoglobulins and most cryofibrinogens, cold agglutinins are most likely to be asymptomatic. When responsible for disease, reversible acrocyanosis secondary to cold-induced acral agglutination is most common. Livedo reticularis, Raynaud's phenomenon, cold urticaria and rarely cutaneous necrosis may occur. In addition to acral lesions on environmental cold exposure, cold intravenous infusions can also trigger localized cutaneous necrosis [20]. Cold agglutinins can induce complement activation after cold-induced binding to red blood cells, followed by lysis and haemolytic anaemia, independent of occlusive syndromes from agglutination.

Patients with cold-induced agglutination syndromes must avoid cold exposure. Therapies such as corticosteroids, cytotoxic agents, danazol, rituxan or interferon-α have been occasionally beneficial [21].

Occlusion due to vessel-invasive organisms

Ecthyma gangrenosum

Ecthyma gangrenosum is a cutaneous syndrome characterized by usually painless, minimally erythematous macules or thin papules or plaques that typically progress to bullous lesions, followed by haemorrhage and necrosis, often with retiform extensions from lesional margins [1]. The anogenital area is a frequent site of involvement, but lesions can develop anywhere and at widespread cutaneous sites [2,3]. Patients are almost invariably immunocompromised, and the infectious agent is usually *Pseudomonas aeruginosa*.

In a small series of cases of ecythma gangrenosum, all eight patients had haematological disease and were receiving immunosuppressive medications [4]. All had positive blood cultures, seven of which were *Ps. aeruginosa*. Biopsies of ecthyma gangrenosum reveal minimal vascular neutrophilic infiltration despite necrotizing vessel injury, and special stains show extensive bacillary infiltration of the perivascular region, the adventitia and the media of larger subcutaneous arterioles, with sparing of the lumen and intima [3–5]. Other bacterial-induced vasculitides tend to show bacterial invasion of the vessel lumen and fibrin thrombi.

Prompt recognition of this syndrome is critical, since prognosis correlates partly with delay in instituting effective intravenous antipseudomonal therapy. Other factors correlating with poor prognosis include multiple lesions and neutropenia [4]. Other organisms that may induce ecthyma gangrenosum-like lesions include *Ps. cepacia* and *Ps. maltophilia*, *Serratia marcescens*, *Aeromonas hydrophila*, *Klebsiella pneumoniae*, *E. coli*, *Vibrio vulnificus*, *Morganella morganii*, *Staphylococcus aureus*, *Mucor*, *Aspergillus fumigatus*, *Fusarium*, *Scytalidium dimidiatum*, *Candida albicans* and *Moraxella* [6,7].

Lucio's phenomenon

Lucio's phenomenon (erythema necroticans) is a rare syndrome almost exclusively limited to leprosy patients from Mexico and Central America, but is rarely reported from Cuba, South America, the USA, India, Polynesia, South Africa and South-East Asia [8–10]. It is a type 2 reaction that may be fatal, despite being the presenting feature of leprosy for many patients who develop this reaction. Lesions may be recurrent and sometimes cyclical over periods of 2 months to 10 years, most often on the legs, but occasionally on the arms and trunk [9]. Lesions usually begin as painful purpuric macules or plaques or vesicles, often ulcerate and heal with atrophic scars. Unlike erythema nodosum leprosum, it is restricted to patients with diffuse non-nodular lepromatous leprosy, is not associated with fever, leukocytosis or tenderness, and fails to respond to thalidomide.

At least in some reports, some lesions appear to induce non-inflammatory retiform purpura, eschar or ulceration [8,9]. Ulceration of lesions is common. Histological findings include either leukocytoclastic vasculitis or endothelial proliferation and thrombus formation in dermal or subcutaneous vessels, with a sparse lymphocytic infiltrate [8–10]. How often vasculitic change is secondary to necrosis or ulceration is unclear, but at least in some cases an occlusive mechanism for purpura and necrosis seems likely. Aggregates of bacilli within proliferating cells are evident on acid-fast stain of biopsy material [9,10].

Treatment includes the standard multidrug therapy for lepromatous leprosy (rifampicin, clofazimine and dapsone). Control of infection and attention to fluid and electrolyte balance are important. Prednisone, thalidomide and clofazimine may all be required to control the reaction. Response to treatment is often reported as poor, with severe morbidity and frequent deaths, though numbers of reported cases are small.

Vessel-invasive fungi

As alluded to in the ecythema gangrenosum section, fungi may cause overwhelming infections in immunocompromised patients, often with cutaneous lesions, some of which may become purpuric or necrotic due to vessel-invasive organisms and thrombosis. *Aspergillus* and *Mucor* are two of the most commonly reported fungal groups to cause such vessel-invasive lesions.

Cutaneous lesions of *Aspergillus* may be either primary or secondary from haematogenous dissemination. Primary lesions typically occur at intravenous infusion sites, tubing sites secured by tape, or in skin in chronic contact with a colonized intravenous board [11,12]. Primary cutaneous aspergillosis can occur in immunocompetent patients, as well as in patients with burns or surgical wounds. Cutaneous lesions from systemic involvement have been divided into five categories: (i) a solitary necrotizing plaque; (ii) a subcutaneous abscess or granuloma; (iii) eruptive maculopapules with suppurative, vegetating or necrobiotic features; (iv) erythematous or exanthem-like reactions; and (v) progressive confluent granulomas [12,13]. Organisms in lesions appear as septate hyphae with acute-angle branching, invading blood vessels and surrounding tissues, often with minimal inflammation [13]. *Aspergillus fumigatus* is the most common cause of colonization and of disseminated infection by the *Aspergillus* group of fungi. *Fusarium* infections are increasing in frequency in patients with haematological malignancy; 72–91% of patients with this infection have skin lesions, which may be either metastatic or primary [14]. Metastatic skin lesions are described as either subcutaneous nodules, usually painful, or ecthyma gangrenosum-like.

The class Zygomycetes includes *Mucor*, *Absidia* and *Rhizopus* organisms, which can cause identical clinical manifestations (Fig. 48.8) [11]. Lesions may be either

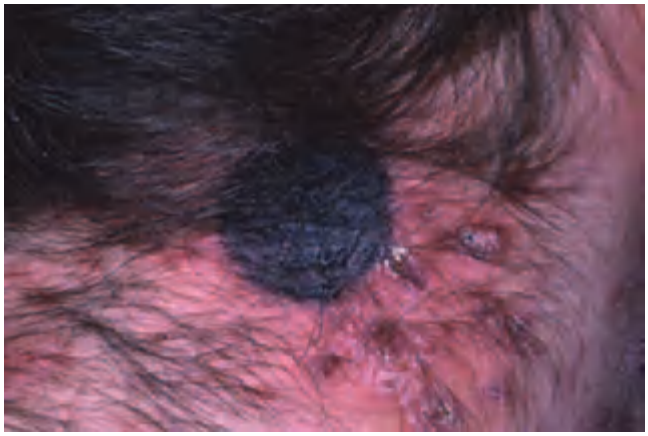

Fig. 48.8 Necrotic cutaneous lesion due to zygomycosis: invasion of vessel walls was apparent histologically.

primary or secondary to disseminated disease, and include superficial vesiculopustules, ulcerating gangrenous lesions, purpuric nodules, cellulitis and necrotic ulcers. These organisms easily invade the epidermis and spread rapidly in the dermis, with vessel invasion by very large and long non-septate hyphae, resulting in thrombosis and infarction [15].

Response to therapy in these types of infection is relatively refractory. With *Fusarium* infections, for example, response rates are 30–48% with current therapies and support measures [14].

Disseminated strongyloidiasis

Strongyloides stercoralis is the nematode responsible for the human parasitic infestation known as strongyloidiasis. Affecting 100 million people worldwide, it is endemic in tropical or subtropical soil that is contaminated by faeces, in some temperate-zone areas such as the rural south-east and Appalachia of the USA, or in closed communities such as immigrant populations, close-quartered military personnel or institutions [16]. Filiform larvae from contaminated soil penetrate the skin, enter the blood vessels, exit through the lungs and migrate to the glottis, where they are swallowed [16–18]. They mature and reproduce in the upper small bowel, with hatching of non-infective (rhabditiform) larvae. Transformation of these into infective larvae can lead to autoinfection through penetration of intestinal mucosa or perianal skin [18]. Skin lesions with simple infection include papules or erythematous serpiginous tracts, which can extend several centimetres per hour and represent cutaneous migration of the larvae (larva currens).

In immunocompromised patients, including those on corticosteroids, hyperinfection and dissemination of organisms can occur [16]. In this setting, the diagnosis is usually made through examination of stool samples, and skin lesions are uncommon. However, with such overwhelming infection, petechiae, purpura and reticulated purpuric skin lesions have been described [16,17,19,20]. These lesions may be widespread but may cluster, particularly in the periumbilical region where they are said to have a thumb-print appearance. Biopsy of purpuric lesions has shown larvae within capillaries and between collagen bundles in the dermis, with extravasated red cells [20].

Mortality in disseminated strongyloidiasis is high, up to 70–90% [16]. Treatment is with oral thiabendazole, and may need to be prolonged in immunocompromised patients [17,18].

Occlusion due to embolus

Cholesterol embolus

Aetiology. The most commonly diagnosed cutaneous embolic syndrome is cholesterol embolus, which occurs

secondary to fragmentation of ulcerated arteriosclerotic plaques, with distal cutaneous and visceral vessel obstruction. Since it occurs secondary to atheromatous plaques, it is no surprise that cholesterol embolus is a syndrome reported primarily in men aged 50 years or older, and is associated with peripheral vascular disease and the known risk factors for atherosclerosis such as diabetes, hypertension and smoking [1,2]. While cholesterol embolus may be spontaneous, known triggers include angiography, angioplasty, vascular surgery, intra-aortic pump placement, cardiopulmonary resuscitation (all inducing traumatic rupture of plaques, usually within hours or days), thrombolytic therapy (acute clot lysis in plaque with release of friable plaque within hours or days) and anticoagulation (slow reduction of clot with release of plaque fragments, usually after at least 2 months of therapy) [2,3]. Blue toe syndrome associated with coumadin use is a syndrome of cholesterol embolus and not of coumadin necrosis.

Clinical features. There are two 'classic' clinical triads of cholesterol embolus. The first comprises leg or foot pain, livedo reticularis and preservation of good peripheral pulses [3]. The second comprises livedo reticularis, renal insufficiency and eosinophilia [4]. Cutaneous findings are frequent in patients recognized as experiencing episodes of cholesterol embolus. Reported in 35% of patients in one series, findings include livedo reticularis (49%), gangrene (35%), cyanosis (28%), ulceration (17%), nodules (10%) and purpura (9%) [1]. Additional clinical findings include fever, myalgia, altered mental status, sudden-onset arterial hypertension, gastrointestinal ulceration and renal insufficiency that may progress to renal failure [3,4].

The incidence of cholesterol embolization syndrome (CES) following vascular procedures has ranged from 0.15% to 30%, with large retrospective studies reporting figures of 0.6–0.9% [5–7]. Autopsy studies have shown cholesterol emboli in 77% of patients who underwent aortic aneurysm resection [6]. A prospective study of 1786 consecutive patients aged over 40 years who underwent left-heart catheterization found an incidence of cholesterol embolus of 1.4%, with nearly half having definite CES and the remainder having possible CES with primarily renal abnormalities [5]. Patients with cutaneous findings (livedo reticularis, blue toe syndrome or digital gangrene) were considered to have definite CES and comprised 48% of the total. In-hospital mortality was 16% and was associated with progressive renal dysfunction.

Investigation. Eosinophilia is a frequent finding in CES, occurring in up to 80% of patients, and may be related to generation of the C5 component of complement [5,8]. Preprocedure elevation in serum levels of C-reactive protein has been associated with an increased risk of post-procedure CES [5]. Additional laboratory findings may include leukocytosis, thrombocytopenia, pyuria, eosinophiluria, blood-positive urine or stool, elevated values of red cell sedimentation rate, creatinine, urea and amylase, and decreased serum levels of complement [1,2,8].

The traditional recommendation for cutaneous biopsy of livedo reticularis has been elliptical excisions centred on normal skin areas within rings of livedo reticularis, deep enough to include ample specimen from the fat layer of skin. However, our experience is that careful examination of the livedo reticularis reveals that many patients will have retiform purpura, and such areas are high-yield biopsy sites for demonstrating the diagnostic cholesterol crystals on histological examination. On histological examination, the arteriole involved in the skin is usually at the dermosubcutaneous junction, with elongated clefts within small-vessel lumina along with thrombi [9]. The clefts result from fixation-related dissolving of cholesterol crystals. In experimentally produced cholesterol embolus, a mixed inflammatory infiltrate may be seen in arterial walls within 24–48 h, followed by multinucleated histiocytes within 3–6 days, and subsequent occasional intimal fibrosis.

Treatment. Treatment of cholesterol emboli involves trying to minimize the risk of further embolization (removal of remaining plaque or perhaps stenting of an atheromatous segment of a major vessel), minimizing damage to end organs, and preventive therapies aimed at slowing progression of atheromatous disease. Statins, iloprost (prostacyclin analogue), pentoxifylline (oxpentifylline) and steroids have been reported as having limited success in therapeutic interventions to minimize organ damage [6,10]. Since anticoagulant use may precipitate cholesterol emboli, avoidance of these agents in patients with known CES seems prudent [3,7]. However, some types of cardiac surgery that may precipitate CES may also require postoperative anticoagulation, e.g. valvular prostheses [3,7].

Oxalate crystal embolus

Oxalate crystals are a rare cause of symptomatic emboli, but can mimic the cutaneous findings of cholesterol embolism. While primary hyperoxaluria is rare, it is the most common cause of oxalate crystal embolus. Two enzyme defects are associated with primary hyperoxaluria: type I hyperoxaluria (glycolic aciduria) is due to deficiency of the hepatic peroxisomal enzyme alanine : glyoxylate aminotransferase; type II hyperoxaluria (L-glyceric aciduria) is due to diminished activity of D-glyceric acid dehydrogenase [11,12]. Absorptive hyperoxaluria is also reported due to idiopathic intestinal hyperabsorption of oxalate. Secondary hyperoxaluria can be due to excessive intake of oxalate or its precursors (ethylene glycol, methoxyflurane anaesthesia, very high dose ascorbic

acid), pyridoxine deficiency, ileal resection, some intestinal diseases or long-term haemodialysis [11,13].

Type I hyperoxaluria is the most common and has three forms. The infantile form has no history of nephrolithiasis but has rapidly progressive renal failure. The juvenile form is the common type I subset. In this group, recurrent calcium oxalate nephrolithiasis precedes renal failure. Patients with the adult form typically present with renal failure and later develop complications of oxalate tissue deposition.

Cutaneous manifestations of primary hyperoxaluria are primarily those of oxalate crystal embolization: livedo reticularis, acrocyanosis, and peripheral gangrene, purpura or ulcerations [12,13]. Secondary hyperoxaluria, especially when due to long-term dialysis, is more likely to lead to extravascular cutaneous deposits of oxalate, producing calcified cutaneous nodules, or firm miliary papules that tend to form on the palmar aspect of the fingers [14].

Cardiac sources of embolization

Atrial myxomas, marantic endocarditis and septic endocarditis can be associated with cutaneous embolic phenomena. While rare, atrial myxomas are the most common benign cardiac tumour, with an estimated incidence of 0.03% [15] and onset usually between the third and sixth decades [16]. The left atrium is the most frequent tumour site. Symptoms may partly mimic those of infectious endocarditis, connective tissue disease, vasculitis or rheumatic fever, with constitutional symptoms such as fever, malaise, arthralgia or weight loss. Obstruction of intracardiac blood flow mimicking valvular disease or embolic phenomena may also occur. Lentigines may be a cutaneous finding in the hereditary NAME or LAMB syndrome, which is associated with cardiac myxomas. Cutaneous findings of myxomatous emboli include livedo reticularis, splinter haemorrhages, Raynaud's phenomenon, an acral papular eruption with claudication, serpiginous or annular purpuric lesions of the fingertips, red violet malar flush, petechiae of hands and feet, or toe necrosis [16–18]. Histology can confirm myxomatous emboli, but finding the emboli may require serial sectioning and multiple biopsies [16,19]. An echocardiogram is useful in evaluating patients with a history or physical examination compatible with emboli. Atrial myxomas require surgical treatment.

Marantic endocarditis results in the attachment of fibrin vegetations to heart valve leaflets, similar to those seen in acute rheumatic endocarditis and Libman–Sacks (APLS) valve disease, and these vegetations can embolize [19]. Infective endocarditis can also produce emboli from vegetations, but these are usually associated with acute bacterial endocarditis. Lesions in subacute bacterial endocarditis may be from either emboli or immune complex-related vasculitis. Idiopathic hypereosinophilic syndrome is associated with intracardiac mural thrombi, which can also produce emboli [20,21]. Documentation of cutaneous emboli is limited, with clinical lesions described as splinter haemorrhages, non-blanching livedoid discoloration, or necrotic, blistering or purpuric lesions [22–24].

Crystal globulin vasculopathy is a rare syndrome, usually associated with IgG or light-chain paraproteins, that can produce intravascular occlusion by spontaneous crystallization [25,26]. This syndrome results in rapidly progressive renal failure, polyarthropathy, peripheral neuropathy and skin lesions. Cutaneous lesions include ulcerations, petechiae and ecchymoses, with intravascular thrombus and crystalline deposits [27].

Other emboli

Petechiae, which may be few or very numerous, are an important sign of fat embolism [28,29]. They occur particularly on the upper part of the body 2–3 days after a major injury and are an important clue to this diagnosis. Minute fat emboli have been found within the vessels at the sites of the petechiae.

Emboli may also occur from tumours at sites other than the cardiac myxomas discussed above.

Systemic coagulopathies with cutaneous predilection

There are several systemic coagulopathies that have a predilection for the cutaneous microvasculature. Cutaneous lesions may occasionally be a minor feature of a multiorgan syndrome, the most prominent findings of multiorgan involvement or sometimes the sole target of occlusion. The importance of recognizing these syndromes is critical in order to begin early, and sometimes syndrome-specific, therapy. There are two natural anticoagulant pathways that exist in humans. The most well known, the antithrombin III–heparin/heparan pathway, is important for primarily venous large-vessel thrombosis. The only cutaneous lesions related to antithrombin III disorders are stasis ulcers secondary to recurrent venous thrombosis with venous insufficiency. In contrast, disorders of the thrombomodulin–protein C/S anticoagulant pathway are important causes of severe cutaneous occlusion syndromes.

An understanding of this pathway is important in diagnosing and treating these syndromes. The end point of the coagulation cascade is conversion of prothrombin to thrombin, which rapidly catalyses the conversion of fibrinogen to fibrin and clot formation. The procoagulant role of thrombin is well known; less well known is its critical role in anticoagulation. When thrombin fails to bind to procoagulant sites on membranes and binds instead to the membrane protein receptor thrombomodulin, this powerful prothrombotic molecule undergoes a remarkable transformation. Bound to thrombomodulin, thrombin becomes ineffective at binding and activating clotting factors, and instead rapidly converts protein C in the plasma to activated protein C. Activated protein C, stabilized by certain phospholipids and by protein S, down-regulates clotting by cleaving circulating activated clotting factors, including factor VIIIa and most importantly factor Va. It thus exerts an anticoagulant effect; deficiency of protein C, or of its co-factor protein S, therefore creates a procoagulant tendency. The factor V Leiden mutation renders the factor V Leiden molecule much less sensitive to cleavage by activated protein C (APC resistance); about 5% of the UK and Caucasian North American population are heterozygous for this mutation (reported incidence is highest in Cyprus, Sweden and Turkey at 10–15%, and lowest incidence in Asia and Africa, and in populations of those ethnicities). This protection from cleavage means that activated factor V Leiden remains longer in the plasma and continues to enhance coagulation. It would be expected then that factor V Leiden mutation should be synergistic with deficiencies in the thrombomodulin–protein C pathway. In fact, in some kindreds of protein C-deficient families, the presence of the factor V Leiden mutation appears to be an important predictor for who will develop large-vessel thrombosis in individuals with similar levels of protein C deficiency.

Another major cluster of systemic coagulopathies with cutaneous microvascular occlusion are those related to lupus anticoagulant activity and APLS. The mechanisms for clotting in this group are less well understood, and will be addressed following discussion of protein C/S-related syndromes.

Protein C/protein S-related disease

Neonatal purpura fulminans: homozygous protein C or protein S deficiency

Protein C and S deficiencies can be inherited autosomally with variable penetrance. Patients who are heterozygous for deficiency may develop repeated venous thrombosis or pulmonary embolism early in adult life, or may be asymptomatic [1,2]. One variable affecting the likelihood of thrombosis in these individuals is known: the previously mentioned co-inheritance of homozygous or heterozygous factor V Leiden mutations [3,4]. The frequency of homozygous protein C deficiency is estimated at 1 in 250 000–500 000 births [1]. Homozygous deficiency of either protein C or protein S is associated with neonatal purpura fulminans as well as with cerebral and ophthalmic vessel thrombosis. Retiform (stellate) purpura and necrosis is the most typical cutaneous finding that results from thrombosis within the cutaneous microvasculature. Skin lesions typically begin within a few hours to 5 days after birth, and are most commonly distributed on the extremities, abdomen, buttocks and scalp; they may localize to sites of pressure or previous trauma [1,5,6]. Laboratory findings are consistent with DIC, with evidence of consumption of clotting factors (prolonged partial

thromboplastin time, PTT), clot lysis (elevated fibrin split products) and often thrombocytopenia. In the absence of appropriate therapy, lesions invariably progress to full-thickness cutaneous necrosis.

Traditional treatment included fresh frozen plasma to try to replace deficient protein C or S, or oral anticoagulants to reduce procoagulant factors. More recently, protein C and activated protein C concentrates have been used for treatment of both acute disease and as prophylaxis against subsequent episodes [7,8].

Coumadin (coumarin, warfarin) necrosis: severe acquired protein C dysfunction

Coumadin necrosis usually presents as the sudden onset of pain within affected areas 3–5 days after beginning coumadin therapy, followed by well-demarcated erythema progressing to haemorrhage, necrosis and often haemorrhagic bullae or eschar [9]. While coumadin necrosis may rarely involve acral areas, acral cutaneous purpura in patients on coumadin is more likely to be due to cholesterol embolus—so-called purple (blue) toe syndrome. The risk of coumadin necrosis is increased if loading doses (10 mg or more) of warfarin are used and if a second form of anticoagulation such as heparin therapy is not used to cover the initial phase of anticoagulant therapy [10,11]. Warfarin (coumadin) necrosis is more likely to occur in areas with abundant fatty subcutis, such as breast, hip, buttocks and thigh [9,10]. The peak incidence is between the sixth and seventh decades, and is four times higher in women.

The therapeutic effect of coumadin is due to inhibition of γ-carboxylation of the vitamin K-dependent coagulant factors II, VII, IX and X. While these factors are still produced and may be antigenically detected within the plasma, without γ-carboxylation they are dysfunctional. Importantly, protein C and protein S are also vitamin K-dependent plasma factors, and their inhibition can lead to a prothrombotic state. Protein C and factor VII, with half-lives of roughly 5 h, are particularly vulnerable to early inhibition, while protein S and the remaining procoagulant factors with much longer half-lives remain active for a considerably longer period [11,12]. There is thus a period, after the early inhibition phase, when the anticoagulant effect of protein C has been inhibited but there is an excess of uninhibited procoagulant clotting factors. Although up to one-third of patients with coumadin-induced skin necrosis may have partial protein C deficiency, the majority of cases appear unrelated to inherited deficiencies of protein C [10]. Since coumadin action mimics that of vitamin K deficiency, it would be expected that depletion of vitamin K should result in coumadin necrosis-like findings, though this has not been documented.

Restoration of protein C activity can be accomplished through protein C concentrates, and presumably also through the use of activated protein C. If these are not available, heparin therapy has been recommended.

Sepsis-related purpura fulminans (bland retiform purpura) with DIC: acquired severe protein C deficiency

The term 'purpura fulminans' is used by physicians for many different situations. It was originally coined in 1887 to describe a syndrome occurring days to a few weeks after some preceding infection, especially varicella zoster or streptococcal infections (now termed 'post-infectious purpura fulminans') [13]. The term 'purpura fulminans' has subsequently been used for widespread cutaneous haemorrhage in patients with sepsis, including infection with *Neisseria meningitidis*, *Staphylococcus aureus*, groups A and B β-haemolytic streptococci, *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Haemophilus aegyptius* [14]. However, haemorrhage in patients with DIC may be due to septic vasculitis, simple bleeding or microvascular thrombosis. The patterns of cutaneous haemorrhage for each of these different mechanisms are distinctive, and can be a guide to pathophysiology and therapy [15]. Cutaneous microvascular occlusion in sepsis with DIC presents clinically as non-inflammatory (bland) haemorrhage, usually with a retiform, stellate or branching configuration, with rapid transition to necrosis and eschar [16,17]. In a small study, early biopsy of retiform purpuric lesions showed microvascular occlusion with fibrin, and perivascular haemorrhage with minimal to no inflammation; these findings correlated with severe protein C deficiency [17]. This was not true of other forms of purpura in sepsis with DIC. The protein C pathway is increasingly recognized as critically important in bacterial sepsis, acting to inhibit both coagulation and inflammation [18]. The use of activated protein C concentrate in sepsis appears to be beneficial, especially in severe cases, though whether all patients with sepsis should receive this is not clear [19–22]. In patients with sepsis, DIC and retiform (occlusion) purpura, it seems reasonable to assume severe protein C deficiency in the acute setting and to treat appropriately. Protein C concentrates and plasma exchange have also been successfully used to replace protein C in purpura fulminans [23].

Post-infectious purpura fulminans: acquired severe protein S dysfunction

As mentioned previously, post-infectious purpura fulminans occurs primarily in children as rapidly progressive purpura a few days to weeks after a febrile illness [14,24,25]. The most common associated infections are varicella zoster and streptococci. This syndrome has been associated with lupus anticoagulant activity and with autoantibodies to protein S [14,25,26]. Replacement of protein S activity is difficult, presumably because this

Table 48.5 International consensus statement preliminary criteria for antiphospholipid antibody syndrome (definitive diagnosis requires at least one clinical and one laboratory criterion) [29].

Clinical criteria
Vascular thrombosis
One or more clinical episodes of arterial, venous or small-vessel thrombosis
Complications of pregnancy
One or more unexplained deaths of morphologically normal fetuses at or after 10 weeks of pregnancy *or*
One or more premature births or morphologically normal neonates at or before 34 weeks of gestation *or*
Three or more unexplained consecutive spontaneous abortions before 10 weeks of gestation
Laboratory criteria
Anticardiolipin antibodies, IgG or IgM, present at moderate or high levels on two or more occasions at least 6 weeks apart
Lupus anticoagulant antibodies on two or more occasions at least 6 weeks apart

condition is not due to simple clearing of protein S but rather to inhibition of protein S function by an antibody. Such antibody-mediated dysfunction is difficult to overcome by replacement of factor, and concentrated sources of protein S are unavailable.

Antiphospholipid antibody/lupus anticoagulant syndrome

From the original description as recurrent venous or arterial thrombosis, repeated fetal loss and thrombocytopenia to more recent consensus statement criteria, APLS continues to be redefined (Table 48.5) [27–29].

A variety of serological markers exist, usually detected as antibody against phospholipids (especially cardiolipin) in combination with antigens from a co-factor molecule (e.g. β_2-glycoprotein, prothrombin, annexin V), or as an inhibitor of an *in vitro* coagulation test, such as aPTT, dilute Russell viper venom time or, occasionally, prothrombin time. Detection of antiphospholipid antibodies is roughly five times more common than detection of lupus anticoagulant [30].

APLS may occur as a primary or secondary disorder. In one large study, primary APLS comprised 53% of cases, lupus-associated APLS 36%, lupus-like APLS 5% and other disease associations with APLS 6%, with catastrophic APLS occurring in 0.8% [31]. Compared with primary syndrome patients, lupus patients with APLS were more likely to have arthritis, livedo reticularis, thrombocytopenia or leukopenia. The mean age was 42 ± 14 years at study entry, onset of symptoms was most often in young to middle-aged patients (2.8% before age 15 years, 12.7% after age 50), and there was a strong female predominance (82%).

Mechanisms of coagulation in APLS are only partially understood. These antibodies were first detected in 1906 in patients with syphilis, and measured as false-positive serological tests for syphilis in 1952 [29]. However, today they are most often detected as lupus anticoagulants or antiphospholipid antibodies. The lupus anticoagulant activity is detected, often incidentally, by prolongation of PTT. While this would seem to predict a tendency towards bleeding, individuals with lupus anticoagulant activity are either normal or paradoxically predisposed to clot formation. Antiphospholipid antibody activity is detected by one of several antibody assays, the most common being screens for IgG or IgM antibody affinity for cardiolipin, a negatively charged phospholipid molecule found in mitochondrial membranes. The most important autoantigen appears to be β_2-glycoprotein I (apolipoprotein H), which binds anionic phospholipids as part of physiological disposal of apoptotic cells [32]. This binding of phospholipid to the glycoprotein induces a conformational change in both molecules, leading to exposure of neoantigens and, in some cases, to autoantibody formation. While anticardiolipin antibodies can be detected in the absence of binding to a co-factor such as β_2-glycoprotein I, such antibodies are almost never physiologically relevant in inducing thrombosis. Studies have shown that in patients with both lupus anticoagulant activity and anticardiolipin activity, there may be little or no cross-reaction between antibodies which bind to each. Both the lupus anticoagulant test and the various antiphospholipid antibody assays can be positive in a great many patients who never develop any thrombosis. Likewise, until the mechanisms responsible for thrombosis in patients with these antibodies are understood, it is highly probable that many patients with thrombosis may test negative with current assays, and yet ultimately be found to have disease mediated by antibodies interfering with physiological pathways responsible for clinical APLS.

Multiple pathways have been implicated by which these antibodies may promote thrombosis: promotion of procoagulant reactions (interfering with protective membrane proteins such as β_2-glycoprotein I or annexin V), interference with anticoagulant pathways (inhibition of protein C/S and antithrombin III pathways), activation of platelets by membrane binding, interference with prostacyclin production and release by endothelium, or interference with fibrinolytic pathways (inhibition of endothelial plasminogen activator or kallikrein activation) [29,33–35].

Clinically, APLS can present with a variety of cutaneous findings (Table 48.6). In one large study the frequency of these findings was livedo reticularis 24%, leg ulcers 5.5%, pseudovasculitis 3.9%, digital gangrene 3.3%, cutaneous necrosis 2.1% and splinter haemorrhages 0.7% [31]. Catastrophic APLS is an uncommon but disastrous variant in which patients typically present with widespread cutaneous necrosis and multiorgan failure, especially renal and pulmonary. Precipitating factors include infections, surgical procedures, drugs and discontinuation of anti-

Table 48.6 Cutaneous findings in antiphospholipid antibody syndrome.

Livedo reticularis, with or without retiform purpura
Sneddon's syndrome
Livedoid vasculopathy/atrophie blanche
Raynaud's phenomenon
Anetoderma-like lesions with thrombosis
Behçet's-like lesions
Nail fold ulcers
Widespread cutaneous necrosis (catastrophic antiphospholipid antibody syndrome)
Leg ulcers, secondary to recurrent thrombosis with stasis, or from conditions in this table
Cholesterol embolus-like proximal livedo reticularis, with or without distal retiform purpura
Acral livedo
Degos (malignant atrophic papulosis)-like lesions
Pseudo-Kaposi's sarcoma
Vasculitis-like lesions
Pyoderma gangrenosum-like ulcers
Splinter haemorrhages
Superficial thrombophlebitis migrans

coagulation. The most common extracutaneous manifestations of non-catastrophic APLS include deep vein thrombosis, pulmonary embolus and central nervous system abnormalities.

Specific therapy in APLS awaits an understanding of the mechanism by which thrombosis occurs in individual patients, and thus the capability to use tailored therapies to specifically oppose that pathway in that one individual. For now, treatment is empirical. Antiplatelet therapy is of uncertain benefit; most therapy depends on acute and often chronic anticoagulation, either with standard or low-molecular-weight heparin initially followed by coumadin [32]. Antimalarial therapy may be of some benefit for atrophie blanche-like or Degos-like syndromes in lupus patients; evidence suggests a protective effect in lupus patients against arterial or venous thromboses [29].

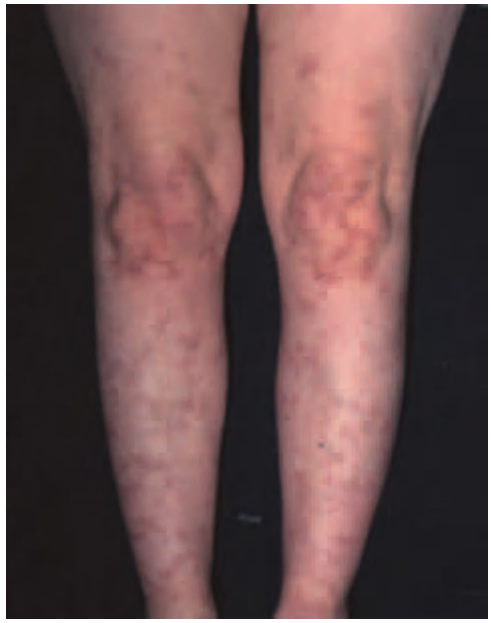

Fig. 48.9 Sneddon's syndrome showing a typical broad racemose livedo patterning.

Occlusion due to vascular coagulopathies

Sneddon's syndrome

Definition. This syndrome comprises generalized livedo racemosa or livedo reticularis with cerebrovascular lesions that cause focal neurological symptoms or signs [1–5].

Livedo racemosa is usually the first manifestation, initially affecting the lower trunk and proximal part of the legs but becoming more generalized. It typically has a broad network pattern (Fig. 48.9). Associated Raynaud's phenomenon or acrocyanosis may occur, and may be the presenting feature.

Incidence. This has been estimated as four cases per million population per year [5]. Sneddon's syndrome is twice as common in women as in men, and typically presents in the fourth or fifth decade of life. It is usually sporadic, although familial Sneddon's syndrome has been reported.

Pathogenesis. Several authors have reported the presence of antinuclear antibodies or of antiphospholipid antibodies/lupus anticoagulant (reviewed in [6]), but others would only accept the diagnosis of Sneddon's syndrome if these antibodies were absent. Differences have been documented between the clinical features of patients with Sneddon's syndrome depending on the presence or absence of antiphospholipid antibodies: those without antiphospholipid antibodies typically have a larger-sized livedo pattern, while those with antiphospholipid antibodies have a higher risk of seizures, mitral regurgitation and thrombocytopenia [7]. It is likely that there is a spectrum of disease from APLS to SLE that includes the preferential arteriolar pattern of Sneddon's syndrome. Antiprothrombin antibodies were demonstrated in 57% of 46 patients in one series [8], and there are reports of platelet activation in a patient with persistently elevated levels of circulating PF4 [9], of increased levels of antithrombin III [10], of factor V Leiden mutation [11] and of activated protein C resistance [12].

Histopathology. Biopsies may show an endarteritis of dermal arterioles. It has been demonstrated that the most informative biopsies are from the clinically normal centre of any network area rather than from the peripheral 'watershed' area of livedo, and that taking multiple biopsies increases the sensitivity [13]. Initial changes are endothelial swelling with a mixed inflammatory infiltrate, progressing to vascular plugging, subendothelial proliferation and eventual vascular occlusion, fibrosis and disappearance of the inflammatory component [14]. It is possible, if not likely, that the histological findings in patients with antiphospholipid antibodies, especially in association with lupus or lupus-like disease, would be more typical of non-inflammatory occlusion.

Clinical features. In addition to the cutaneous livedo, there may be non-specific neurological prodromal symptoms such as headache, migraine, dizziness or vertigo. Later neurological features include focal paresis or hemiparesis, focal sensory or hemisensory symptoms, fits and visual defects, and later cognitive changes. Transient ischaemic attacks are commoner than completed stroke [15]. Peripheral nerves may also be affected. Hypertension may be present and confers a worse prognosis if untreated; hypertension and the neurological aspects are sometimes aggravated by pregnancy or use of oral contraceptives. There may be renal or cardiac involvement, including valve defects such as mitral regurgitation, although internal organ involvement other than neurological is often asymptomatic [5]. Other features such as shortened digits have rarely been reported.

The differential diagnosis is wide, from both the cutaneous and the neurological perspective. In particular, other causes of livedo and microvascular occlusion syndromes discussed in this chapter need to be considered as well as vasculitic causes (e.g. polyarteritis nodosa). However, it should be noted that other patterns of livedo with anticardiolipin antibodies may be associated with evidence of cerebral microthrombosis, for example livedo with summer ulceration or livedo with pyoderma gangrenosum-like lesions [16].

Magnetic resonance imaging (MRI), electroencephalography and arteriography may help to confirm the neurological component; skin biopsy (as above) and exclusion of other causes of livedo are necessary. Patients with

positive antiphospholipid antibodies more commonly have infarcts in the distribution of the main cerebral arteries on MRI, whereas those with negative antibodies have small lacunar infarcts [17] and progressive leukoencephalopathy [15].

Treatment. There is generally no very effective treatment, reflecting the non-inflammatory nature of the disease. Corticosteroids may have some benefit but this is variable and often difficult to assess due to the intermittent nature of the neurological disease; other immunosuppressive agents are often disappointing. Avoidance of smoking and oral contraceptives, and treatment of hypertension and hyperlipidaemia (both of which are commonly present), are important. Thrombolytic agents and vasodilators have been used in the acute situation, and antiplatelet agents appear to be effective in the longer term [7]. In patients with antiphospholipid antibodies or lupus anticoagulants, maintenance of anticoagulation at an international normalized ratio (INR) of 2–3 seems warranted.

Livedoid vasculopathy; atrophie blanche

SYN. LIVEDO RETICULARIS WITH SUMMER ULCERATION; SEGMENTAL HYALINIZING VASCULITIS

This syndrome is most common in young to middle-aged women as either an idiopathic or secondary syndrome [1]. One of the most commonly noted associations is with chronic venous hypertension and varicosities, though the atrophic scarring in this setting is not usually preceded by small painful ulcerations, nor with surrounding livedo reticularis. It would seem appropriate to separate venous stasis-related atrophie blanche from more typical forms of the syndrome.

Pathogenesis. The pathogenesis of livedoid vasculopathy is unknown. Clearly, APLS, with or without a lupus association, can produce this clinical syndrome [2]. Multiple pathophysiological abnormalities have been implicated, including platelet activation, factor V Leiden, altered fibrinolysis, antiphospholipid antibodies and hyperhomocystinaemia; however, definitive evidence is lacking [1–3].

Histology. The most characteristic histological findings in this syndrome are some thickening or hyaline changes in the walls of superficial dermal vessels, and luminal fibrin deposition [1,4]. Red cell extravasation and perivascular lymphocytic infiltrates are expected findings.

Clinical features. Persistent, very painful and often punched-out ulcerations of the legs, especially around the malleoli, in women are typical of atrophie blanche [4]. When accompanied by surrounding livedo reticularis, the term 'livedoid vasculitis' is more likely to be applied. Retiform or stellate purpura or ulcer extension can occur; healing results in a porcelain white scar frequently surrounded by telangiectasia. Besides venous hypertension and antiphospholipid antibody-related syndromes, sickle cell ulcers can show the same porcelain white scar of atrophie blanche.

Treatment. Antiplatelet, anticoagulant and fibrinolytic therapies have been reported to be helpful in this syndrome, as well as anabolic steroids such as danazol and stanozolol [2]. PUVA therapy has been reported as effective in some cases [5]. In patients with lupus and atrophie blanche-like lesions, antimalarial therapy may be effective.

Malignant atrophic papulosis

SYN. DEGOS' DISEASE; KOHLMEIER–DEGOS' DISEASE; LETHAL CUTANEOUS AND GASTROINTESTINAL ARTERIOLAR THROMBOSIS

Definition. Malignant atrophic papulosis is a progressive vasculopathy causing occlusion of small and medium-sized arteries [1–6]. Originally reported separately by Kohlmeier [7] and Degos [8], it was also described as lethal cutaneous and gastrointestinal arteriolar thrombosis [9]. It is characterized by skin and gastrointestinal lesions, but neurological features are also frequent and post-mortem studies show widespread organ involvement. The skin lesions are usually the first feature, and may be the only manifestation over many years [2]; whether this represents a truly 'benign' variant is uncertain.

Incidence. It is rare: a review in 1995 suggested that about 120 cases had been reported [4]. It is mainly reported in whites, has a slight male predominance and is mainly a disease that presents in young adults, although it can affect any age group [3,5]. Familial cases have been reported [10].

Pathogenesis [3,5]. The pathogenesis probably involves abnormal coagulation, although the precise mechanism is uncertain. Platelet and fibrin thrombi are apparent in dermal, mesenteric and nervous system blood vessels, and both abnormal platelet aggregation and inhibition of fibrinolysis have been reported [3,5,11–14]. However, most patients have no clear evidence of a systemic coagulopathy, suggesting that the thrombotic tendency is at the microvascular level. Antiphospholipid antibodies have been documented in a small number of patients, usually in the context of SLE, although they may also occur even in the benign cutaneous variant [15].

There is also some support for a mechanism involving vascular inflammation. An autoimmune mechanism is suggested by the occurrence of lesions resembling malignant atrophic papulosis in some patients with SLE, rheumatoid arthritis, scleroderma or dermatomyositis [16–19]; antiendothelial antibodies have also been demonstrated but are probably not the cause of the disease [5]. Circulating immune complexes, or deposition of immune complexes or complement, are not usually demonstrated [2,20]. Although there can be a prominent lymphocytic infiltrate in later lesions, especially around venules, true arteritis and leukocytoclasis are not found [3,5,21].

Abnormal mucin deposits, which may be thrombogenic, occur even in early lesions although they tend to be more apparent in later lesions [3,5,21]. It is possible that they may be induced by activated T cells.

A viral aetiology was proposed on the basis of electron microscopic demonstration of interwoven tuboreticular structures resembling viral inclusions within endothelial cells [22], but these are seen in other disorders, including SLE, and can be induced by interferon [5]. Cases have been reported with HIV infection but a causal association is unproven.

Histopathology [2–6]. The histological picture in Degos' disease depends upon the duration of the lesion biopsied. Early lesions show a superficial and deep perivascular, perineural and peri-appendageal chronic inflammatory cell infiltrate [21]. Deep dermal vessels show endovascular inflammation, proliferation and thickening with thrombosis [23]. Mucin deposition is seen at all stages [2–4,21,24], and fibrin deposition may be demonstrated; fibrinoid necrosis of vessel walls may occur [23]. Immunofluorescence is occasionally positive for IgG or C3. Later lesions show a classical 'wedge-shaped' pattern of sclerotic change in the dermis, which is usually only sparsely cellular. Between these stages there is a phase with neutrophilic and eosinophilic infiltrate around adnexae and a dense perivascular lymphocytic infiltrate [21]. The epidermis, initially showing a mild vacuolar reaction, becomes atrophic with slight scaling, resembling that seen in lichen sclerosus and corresponding with the typical 'porcelain white' colour seen clinically. There may be some associated pigmentary incontinence.

Panniculitis resembling that seen in lupus profundus has recently been reported [25].

Similar changes occur in the intestinal wall, particularly the submucosa. The muscularis mucosae is intact. Blood vessels are thickened and disorganized, with fibrinoid degeneration; platelet–fibrin thrombi are more prominent than in skin biopsy material.

Microaneurysms of the bulbar conjunctival vessels have been described. Renal changes include thickening of the afferent glomerular arterioles and of the capillary basement membrane.

Clinical features [1–8]. Cutaneous lesions usually precede systemic manifestations by months to years. They develop as crops over a period of time and are usually asymptomatic, although they may be preceded by slight burning. Skin lesions affect any site, mainly the trunk and proximal limbs; the face, palms and soles are generally spared. Although they may evolve gradually, and the number of lesions may vary considerably, about 30–40 active lesions are usually present [4]. Oral mucosal lesions are rare but penile lesions may occur [26]; the bulbar conjunctiva

is often affected by lesions, which appear as sharply demarcated avascular areas [4]. Peristomal lesions have been reported.

Early skin lesions are pink or red, dome-shaped papules, usually 2–5 mm in size but sometimes up to about 15 mm. Papules soon become necrotic and umbilicated with central 'porcelain-white' pallor and scaling, and the pink oedematous border becomes telangiectatic. Most heal rather slowly to leave a small white scar, often surrounded by telangiectases as in atrophie blanche. Urticaria-like, ulceropustular and gumma-like nodules have been reported. New crops of lesions may continue for several years.

Similar lesions occur in many organs. Gastrointestinal lesions are the most important, as perforation of the gut is a cause of death. Neurological symptoms are also relatively common. The features in different systems include the following [4].

- Gastrointestinal: dyspepsia, abdominal pain or distension, bleeding, perforation, peritonitis, fistulae (enteroenteral or enterocutaneous), obstruction, pancreatitis.
- Neurological: cerebral infarction (causing headache, aphasia, dementia, focal epilepsy, hemiparesis, pseudobulbar palsy), cord infarction (paraplegia/quadriplegia, transverse myelopathy), peripheral nerve (cauda equina syndrome, mononeuritis multiplex), various sites (sensory disturbance).
- Ocular: ptosis, diplopia, nystagmus, ophthalmoplegia, optic neuritis, papilloedema, visual field loss, pupillary reaction defects, conjunctival avascular lesions, posterior subcapsular cataract.
- Cardiovascular: renal artery occlusion, pericardial effusion, constrictive pericarditis, ventricular wall defects.
- Pulmonary: pleuritis.

Differential diagnosis. There is sometimes a resemblance to atrophie blanche or to guttate lichen sclerosus, although the evolution of lesions is different. Identical lesions have been described in cases of various connective tissue diseases [16–19] and in a patient with Crohn's disease [27]. The characteristic features can scarcely be confused. A disorder termed 'cutaneous–intestinal syndrome with oropharyngeal ulceration' [28] included a combination of macular, blistering and crusting lesions of the skin, with oropharyngeal ulceration and death from perforation of one of many intestinal ulcers. This differed both clinically and histologically from Degos' disease. Patients in whom systemic disease precedes skin lesions may cause particular diagnostic problems.

Prognosis [4]. Although possibly overestimated by reporting bias, and acknowledging that there does appear to be a benign cutaneous ('skin-limited') variant, mortality of 50–60% within 2–5 years is anticipated. Prognosis in males appears to be worse than in females.

Treatment. There is no consistently effective treatment [2–4]. Steroids do not help, although some benefit in neurological symptoms has been suggested. Aspirin, antiplatelet agents, fibrinolytic agents and pentoxifylline, alone or in combination, may lead to remission and are perhaps most effective in the cutaneous disease [2–6,11,15,29–31]; phenylbutazone has been reported to be effective. Heparin may produce short-term benefit. There is one report of a good response to transdermal nicotine patches [32]. Warfarin, dextrans, chloroquine, immunosuppressive agents and plasma exchange have all been tried. Surgery to treat intestinal perforation may resolve the acute situation but is difficult as there are usually multiple lesions, and there is no long-term benefit from this approach.

Occlusion due to reticulocytes

Patients with sickle cell anaemia may develop leg ulcers, which in tropical climates typically progress rapidly due to secondary bacterial infection [1]. However, in temperate climates the lesions are often perimalleolar, quite painful, and may heal with a porcelain-white scar often mimicking atrophie blanche. While this ulceration might be attributed solely to sickling of erythrocytes with microvascular occlusion, similar ulcers have been reported in other instances of severe chronic haemolytic anaemia, such as thalassaemia or antibody-mediated haemolysis, where sickling is not possible [2]. Multiple studies of possible occlusive mechanisms in sickle cell disease have shown that both young and old red cells in sickle patients also have abnormally sticky membranes. In addition, abnormal leukocyte adhesion may initiate occlusion episodes, followed by adhesion of erythrocytes to these leukocytes, with a drop in tissue perfusion, followed by hypoxia and sickling with propagation of occlusion [3]. A number of platelet, procoagulant, anticoagulant and fibrinolytic abnormalities have been noted in sickle cell disease [3–5]. Patients with sickle cell disease who are treated with hydroxycarbamide (hydroxyurea) appear to have a higher rate of ulcer development than other patients treated with hydroxycarbamide [6]. While the mechanism is unclear, macroerythrocytes may play a role in initiation of ulcers in this and also in syndromes of severe haemolytic anaemia with high reticulocyte count, very early reticulocytes, but with no sickling [2]. Whatever studies eventually prove, it seems that erythrocytes may play an active role in some occlusive syndromes.

Occlusion due to unknown or controversial mechanisms

Cutaneous calciphylaxis

Cutaneous calciphylaxis (also termed 'calcific uraemic arteriolopathy') is a rare, but increasingly frequent, complication of renal failure and dialysis [1]. It may very rarely occur in other situations, such as alcoholic liver disease, and occasionally after chemotherapy, in patients with normal renal function. Obese middle-aged women appear to be most at risk.

Early lesions tend to present as painful plaques, often with a retiform or stellate pattern, and may show central necrosis. It may resemble hyperoxaluria. Woody induration with extending ulcer and eschar formation typically follows. Thrombosed vessels are seen occasionally; an expected finding is calcification in the medial layer of the wall of small subcutaneous vessels, with necrosis of overlying tissue [1,2]. Both vascular and extravascular calcification occur. The calcification of small-vessel walls extends more widely than the thrombotic change or the extravascular calcification. Most patients have secondary or tertiary hyperparathyroidism, although the occurrence of calciphylaxis in primary hyperparathyroidism is very rare.

The mechanism of this syndrome is unclear, as is the role of parathyroid hormone and calcium and phosphorus. An elevated calcium–phosphorus product is usual but is not always present.

Parathyroidectomy has been cited as effective, but there is clearly bias in patient selection for this procedure towards those who are most healthy. Reduction of the calcium–phosphorus product when elevated is recommended (using low calcium dialysis), as is good wound care and attention to possible accompanying infection. The prognosis is generally considered poor, with mortal-

ity of 50–80%, though occasional reports of a more benign course exist [1,3].

Specific clinical presentations

This section briefly discusses clinical presentations that are common to a number of occlusive, embolic or vasculitis disorders, in order to allow an approach to the differential diagnosis.

Livedo [1,2]

Livedo describes a reticulate pattern of slow blood flow, with resultant desaturation of blood and bluish discoloration of the skin, which should be completely blanchable. Livedo has been divided into two patterns.

Livedo reticularis tends to develop as a tight net-like pattern of discoloration, often symmetrically distributed, and is more likely to be associated with general disturbances of blood flow such as cold-induced cutaneous vasoconstriction or vascular flow disturbances such as seen in polycythaemia or some cryogelling syndromes. Cutis marmorata in infancy is a perfect example of this pattern. Cutis marmorata telangiectatica congenita is a condition that causes a similar livid reticulate pattern because of telangiectasia.

Livedo racemosa typically has breaks in the tight net-like pattern, resulting in larger irregular rings than livedo reticularis. It is seldom symmetrical. Livedo racemosa may be more indicative of focal impairment of blood flow, such as with vasculitis, and seems most often the pattern of livedo described in European cases of Sneddon's syndrome. The distinction between livedo reticularis and racemosa may be important, but frequently the term 'livedo reticularis' is used to describe both patterns, so careful documentation of the clinical usefulness of this distinction is limited. Finally, lesions of a variety of vascular occlusion syndromes have sometimes been described as lesions of livedo (as discussed above). Although livedo reticularis or racemosa may accompany or surround lesions of retiform purpura, the presence of purpura provides a more specific finding to aid in diagnosis. Whether such conditions frequently present with livedo alone is clouded in the literature.

Conditions that may present as livedo are listed in Table 48.7.

Table 48.7 Acquired livedo reticularis, non-physiological.

Vascular disease associated
Vasculitis, especially microscopic polyangiitis, cutaneous periarteritis nodosa, rheumatic vasculitides, mixed cryoglobulinaemia, temporal arteritis, Sneddon's syndrome, livedoid vasculitis, arteriosclerosis
Rheumatic diseases
Lupus erythematosus, dermatomyositis, scleroderma, Sjögren's syndrome
Increased blood viscosity, decreased blood flow
Polycythaemia rubra vera, thrombocytosis, cryoglobulinaemia, cryofibrinogenaemia cold agglutinaemia
Embolic and hypercoaguable disorders
Cholesterol emboli, oxalate emboli, decompression sickness with nitrogen bubble embolization, ventilator gas embolization, antiphospholipid antibody syndrome
Infection
Some reports of livedo with infection may be secondary to emboli (e.g. endocarditis), angiitis (rickettsial) or purpura fulminans-related occlusion (meningococcal). Syphilis, tuberculosis and viral diseases are also important
Endocrine
Hyperparathyroidism, pseudohyperparathyroidism, hypothyroidism, Cushing's disease, carcinoid syndrome, phaeochromocytoma
Nutritional
Pellagra
Iatrogenic
Bismuth (intra-arterial), catecholamines, amantadine, quinidine (with drug-induced lupus syndrome), arsphenamine

Cutaneous necrosis

Necrosis of the skin occurs in numerous diverse conditions and may present a diagnostic and therapeutic dilemma. Many of the conditions leading to skin necrosis are discussed elsewhere in this chapter or in Chapter 49; vasculitis and vascular occlusion disorders comprise a significant proportion of such cases, but other disorders are briefly considered here [1–9]. Table 48.8 lists some of the more important causes of cutaneous necrosis. It is not intended to be comprehensive, and the disorders listed are those that either commonly cause cutaneous necrosis or in which cutaneous necrosis is a significant risk. The table therefore lists the most important diagnoses to consider. Not uncommonly, more than one cause may be present, for example in patients with HIV treated for HCV infection with interferon, or use of anticoagulants or chemotherapy in patients subsequently found to have protein C deficiency. In some instances cutaneous necrosis may have predictive value, for example it has been

Table 48.8 Some causes of cutaneous necrosis.

Coagulation defects [1]
Purpura fulminans, disseminated intravascular coagulopathy
Protein C or S deficiency, antithrombin III deficiency

Vasculitis
Most vasculitides may cause skin necrosis, e.g. polyarteritis nodosa, Behçet's disease, Wegener's granulomatosis, Churg–Strauss disease, Henoch–Schönlein purpura (see Chapter 49)

Connective tissue disease (see Chapter 56)
Antiphospholipid syndrome/lupus anticoagulant, dermatomyositis [2], relapsing polychondritis, systemic lupus erythematosus, systemic sclerosis

Immunological
Shwartzmann reaction [3]

Hyperviscosity
Cryoglobinaemia, cryofibrinogenaemia, cold agglutinins, paraproteinaemia, POEMS syndrome

Embolic
Cholesterol emboli, cardiac myxoma, bacterial endocarditis, emboli from arterial aneurysms

Metabolic (see Chapter 57)
Diabetes, hyperhomocystinaemia, oxalosis, calciphylaxis [4], subcutaneous calcification

Arterial occlusion
Arteritis (e.g. temporal arteritis, Buerger's disease), Degos' disease, thrombosis, aneurysm, anastomosis, compartment syndrome

Infections (see Chapters 25–31)
Bacterial, e.g. necrotizing fasciitis, cellulitis, streptococci, clostridia, meningococcus, pseudomonas (ecthyma gangrenosum), leprosy (Lucio's reaction)
Viral, e.g. Rocky Mountain spotted fever, HIV, cytomegalovirus, hepatitis B or C, herpes zoster
Fungal, e.g. deep/disseminated fungal infection (especially *Aspergillus*, *Mucor*, *Rhizopus*)

Venoms
Snake bites, spider bites, stings (e.g. scorpion, stingray)

Drugs and toxins (see Chapter 73)
Systemic
- Anticoagulants, e.g. warfarin (coumadin), heparin
- Vasoactive drugs, e.g. vasopressin, norepinephrine, dopamine [5–8], metaraminol, β-blockers
- Chemotherapeutic drugs, e.g. methotrexate, bleomycin, cyclophosphamide, vincristine
- Cytokines and growth factors, e.g. tumour necrosis factor, interferons, interleukin-3, G-CSF, GM-CSF
- Antimicrobials, e.g. penicillins, sulphonamides, aciclovir, levamisole
- Antithyroid, e.g. thiouracils, carbimazole
- Toxins, e.g. carbon monoxide poisoning
- Miscellaneous, e.g. penicillamine, iodides, bromides, phenytoin

Topical
- Glutaraldehyde, cetrimide, calcium chloride, mustard gas, hydrofluoric acid

Injection sites
- Calcium salts, interferon, aminoglycosides, collagen, silicone, hydrocarbons, vaccines (DTP, BCG), iron dextran, chemotherapy extravasation, Depo-Provera, several illicit drugs, intra-arterial injections

Malignant disease
Leukaemia, lymphoma, mycosis fungoides, lymphomatoid granulomatosis, hypereosinophilic syndrome, myelodysplastic syndrome, Langerhans' cell histiocytosis
Phaeochromocytoma (localized or acral necrosis)
Paraneoplastic thrombosis, paraneoplastic acral vasculopathy

Physical damage
Burns, radiation, trauma, factitious ulcer, sclerotherapy, liposuction

Inflammatory dermatoses
Sarcoidosis, pityriasis lichenoides acuta, pyoderma gangrenosum and neutrophilic dermatoses, panniculitides

Miscellaneous
Intrauterine epidermal necrosis [9]

BCG, bacillus Calmette–Guèrin; DTP, diphtheria–tetanus–pertussis; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte–macrophage colony-stimulating factor; HIV, human immunodeficiency virus; POEMS, polyneuropathy, organomegaly, endocrinopathy, M protein, skin changes.

suggested to be linked with the presence of underlying malignancy in patients with dermatomyositis [2].

Neonatal purpura [1]

The differential diagnosis of purpura or bleeding in neonates includes most of the causes of purpura. However, it is discussed as a separate entity due to the diagnostic dilemmas that may arise. The main causes are listed below.

- Deficiency of clotting factors and coagulation disorders (including purpura fulminans and vitamin K deficiency).
- Thrombocytopenia: congenital, maternal antibodies (ITP, SLE, others).
- Extramedullary erythropoiesis ('blueberry muffin' baby).
- Infections, e.g. TORCH syndrome, which comprises *t*oxoplasmosis, *o*ther infections (syphilis and viral), *r*ubella, *c*ytomegalovirus and *h*erpes simplex, may cause blueberry muffin baby; others infectious causes include HIV, parvovirus B19 and sepsis.
- Congenital/inherited conditions, e.g. Wiskott–Aldrich syndrome.
- Maternal antibody mediated: autoimmune (ITP, SLE, drug) or alloimmune (isoimmune) due to fetomaternal incompatibility.
- Associated with haemangiomas.
- Traumatic: caput succedaneum and facial petechiae (prolonged vertex delivery).
- Others, e.g. vascular purpura, non-accidental injury (both rare in this age group).

The three most important groups for dermatologists are purpura fulminans, blueberry muffin baby and infections [1]. Purpura fulminans in the neonate is an important manifestation of protein S or protein C deficiency (discussed above). Skin lesions in blueberry muffin baby are distinguished from purpura as they are palpably firm and elevated, but non-palpable purpura may coexist. The TORCH group of infections may cause this condition, but haemolysis (such as rhesus incompatibility), hereditary spherocytosis and twin transfusion syndrome may also be associated with extramedullary erythropoiesis.

Haemorrhagic disease of the newborn is due to accentuation of the normal fall of prothrombin within the first week of life but is now uncommon due to routine vitamin K prophylaxis. An early form within the first 24 h of life may occur if there is maternal intake of drugs that interfere with vitamin K (such as oral anticoagulants), and a late form (1–12 months) occurs in children with impaired gastrointestinal absorption and may cause deep nodular ecchymoses. Haemophilia and other coagulation factor deficiencies only rarely cause bleeding at this age.

The causes of purpura fulminans [2] have been classified as follows.

- Acute infectious: meningococcus, streptococcus, *Haemophilus* and other infections.
- Post-infectious: varicella, streptococcus and others.
- Congenital protein C or S deficiency; factor V Leiden mutation.
- Acquired protein C or S deficiency: coumarins, hepatic cholestasis, nephrotic syndrome, renal dialysis, marrow transplantation.
- Antiphospholipid antibody (termed 'catastrophic antiphospholipid syndrome'; may have associated SLE).
- Vasculitis: polyarteritis nodosa, Henoch–Schönlein purpura, others.
- Heparin-induced skin necrosis (most cases are related to local skin injection).
- Toxins and poisons: snake and spider bites (usually maximal purpura at the inoculation site).

However, the use of the term purpura fulminans as a broad term for widespread cutaneous purpura of any type is probably more confusing than helpful. It may be more helpful to restrict the term purpura fulminans to disorders in which cutaneous microvascular occlusion is the known cause of widespread cutaneous purpura.

Miscellaneous causes of purpura

Non-thrombocytopenic toxin- and drug-induced purpura [1–6]

Many agents may lead to purpura by causing thrombocytopenia (discussed above). There are also many substances capable of causing capillary damage with or without any change in platelets, either by direct toxicity or

through an allergic reaction. The purpura varies in degree from a few petechiae to massive extravasation of blood. Sometimes there is obvious evidence of inflammatory lesions, as well as purpura, implying a frankly vasculitic process [7]. Exposure may be industrial, accidental or therapeutic. Some drugs may cause thrombocytopenia and either vascular purpura and/or frank vasculitis; the thrombocytopenia in such cases may be caused by a direct effect on platelets or by endothelial damage leading to platelet aggregation.

Substances capable of causing capillary damage include acetylsalicylic acid, allopurinol, *p*-aminosalicylic acid, arsenic, atropine, bismuth, barbiturates, carbimazole, carbromal, chloramphenicol, chlordiazepoxide, chlorothiazide, chlorpromazine, diethylstilbestrol, furosemide, gold, hair dye, indometacin, iodides, isoniazid, menthol, meprobamate, methyldopa, piperazine, quinidine, quinine, reserpine, snake venoms, sodium salicylate, sulphonamides, tartrazine and other food additives, thiouracil, tolbutamide and glyceryl trinitrate.

Carbromal is one of the few drugs that caused a rather distinctive pattern of purpura. The widespread areas of capillary leakage combined with erythema produced a picture which resembled itching purpura and Schamberg's disease. Drug-induced pigmented purpuric dermatoses are considered elsewhere.

Trimethoprim–sulfamethoxazole has been reported to cause an acral purpuric eruption, proven by rechallenge, that resembled the purpuric 'gloves and socks' syndrome more commonly caused by parvovirus B19 [8].

A diagnosis of toxin- and drug-induced purpura usually depends on circumstantial evidence. Unfortunately, laboratory tests are mainly unhelpful, although some drugs that cause purpuric reactions will produce a purpuric reaction when patch tested. Rechallenge may be dangerous; generally the diagnosis is made by careful history-taking.

Drug-induced vasculitis or livedo are also discussed in Chapter 73; drugs that cause skin necrosis are considered in Table 48.8.

Contact purpura [1]

Purpura may occur as an irritant reaction to mechanical friction from abrasive agents such as woollen clothing or fibreglass. Some topical medications may rarely cause purpura that appears to be of irritant or toxic causation, such as clioquinol (at flexural sites), benzoyl peroxide or EMLA local anaesthetic [2,3]. Textile and rubber chemicals [4–6] are particular causes of contact purpura that may have little or no eczematous component, although itch or lichenoid morphology may be prominent in some instances. Such reactions may be widespread, the distribution corresponding only approximately with the distribution of contact, and may therefore be confused with idiopathic pigmented purpuras.

Purpura around the acrosyringium may occur at patch-test sites to cobalt, and purpuric patch tests to apronalide and quinidine have been reported in subjects with a purpuric rash after systemic administration of these agents.

The main groups of chemicals that have been reported to cause contact purpura are listed below.

- Dyes and textile agents: azo dyes, paraphenylenediamine, optical whiteners.
- Rubber antioxidants: IPPD, isopropylaminodiphenylamine.
- Resins: urea formaldehyde compounds, epoxy resin.
- Plants: *Rhus*, *Agave*.
- Others: topical medicaments, balsam of Peru, mercury.

Purpura associated with infection

Purpuric skin lesions associated with infection [1] may be due to numerous mechanisms, more than one of which may be operative, including:

- thrombocytopenia (discussed above);
- localized or disseminated intravascular coagulation (discussed above);
- direct vascular damage (invasion or occlusion by organisms);

- vascular effects of toxins;
- immunological vascular damage (vasculitis, immune complex deposition);
- emboli.

Purpura is a characteristic feature of certain bacterial infections, for example meningococcal or other septicaemias and bacterial endocarditis, and of many viral and rickettsial infections, for example typhus, Rocky Mountain spotted fever and the viral haemorrhagic fevers (see Chapters 25 and 27) [2,3]. Acral purpuric lesions are typical of Rocky Mountain spotted fever; the histological features include a lymphohistiocytic capillaritis and venulitis with variable leukocytoclastic vasculitis, fibrin thrombi, capillary wall necrosis and immunofluorescent evidence of organisms within endothelial cells, suggesting that it is therefore a type of septic vasculitis. In typhus, however, acral sites are generally spared.

Skin lesions are the presenting feature in 70–90% of patients with meningococcaemia and are purpuric in 50%, often stellate in shape and tender. There may be a leukocytoclastic vasculitis with thrombi and meningococci within endothelial cells or leukocytes, typically resulting in a clinical lesion of classical palpable purpura, ranging in size from 2 to 8 mm in diameter. Lesions may progress to purpura fulminans due to microvascular occlusion, with lesions typically enlarging and often developing stellate or retiform features with minimal to no erythema (discussed above). In some cases of meningococcal septicaemia, organisms can be seen on blood smears taken from scraped skin lesions [4].

Various congenital infections may cause neonatal purpura (discussed above). Purpura may appear in the prodromal period of many infections, for example measles, in which case it is often a sign of a severe infection. When it occurs at the height of the infection it is of less serious importance. A large number of infections may cause purpuric lesions in children [5].

The petechial gloves and socks syndrome, or papular–purpuric gloves and socks syndrome, is a distinctive syndrome that has been attributed to parvovirus B19 infection [6,7] or to other viruses such as measles, hepatitis B, coxsackievirus B6 and cytomegalovirus [5,8] (see also Chapter 25). Purpura may also occur in the laterothoracic eruption, which may have an infectious aetiology.

Other infections may be associated with characteristic distributions of purpura, for example *Strongyloides* causes 'thumb-print' periumbilical purpuric lesions [9].

Vasculitis and Neutrophilic Vascular Reactions

K.L. Barham, J.L. Jorizzo, B. Grattan & N.H. Cox

Vasculitis

Introduction

Vasculitis is a term applied to inflammation and necrosis of blood vessels, whether they be arteries, veins or both. Vasculitis may be local or systemic, and may be primary or secondary to another disease process. Small vessels (such as capillaries, arterioles and venules), medium-sized vessels (such as visceral vasculature, including renal, coronary or hepatic arteries) and large vessels (the aorta and its great vessels) may be affected. Many vasculitides have a cutaneous component. A dermatologist can provide invaluable assistance in the clinicopathological diagnosis of vasculitis and by guiding patient evaluation and treatment.

Because of the wide range of organ systems affected by vasculitis of blood vessels of various sizes, the clinical presentation of the many vasculitides is varied. However, classic cutaneous manifestations such as palpable purpura in dependent areas, typically the ankles and lower legs, characterizes smaller vessel involvement, whereas necrosing livedo reticularis or multiple sites of peripheral gangrene characterize larger vessel vasculitis. It is also important to note that vasculitides may be present without any cutaneous signs or symptoms.

Infiltration of inflammatory cells with subsequent destruction of blood vessel walls is classically demonstrated in nearly all vasculitides. However, specific histopathological features are dependent on the type and size of the affected blood vessel.

Many vasculitides are triggered by various antigenic agents, such as infection or medication, or are related to underlying disease such as connective tissue, vascular or inflammatory bowel disease, myelodysplastic or other malignancies. However, a single trigger may be associated with several distinct vasculitides, implying that different and more specific mechanisms of inflammation apply in different disorders. Pathogenetic factors in vasculitis are discussed below.

Classification

The classification of vasculitides has been a confusing and debate-provoking topic over the last half century. The first attempt at a classification was by Zeek in 1952 [1]. In this classification of necrotizing vasculitis, she incorporated a clinicopathological evaluation based on the size of the blood vessel involved in the inflammatory process. Zeek differentiated five types of necrotizing angiitis: periarteritis nodosa, hypersensitivity arteritis, rheumatic arteritis, allergic granulomatous angiitis and temporal arteritis [2].

Other factors that may be considered in the classification of vasculitis were discussed by Winkelmann [3]. He incorporated clinical classification, systemic versus cutaneous involvement, muscular vessel versus small vessel

Table 49.1 1990 American College of Rheumatology criteria for hypersensitivity vasculitis (traditional format) [5].*

1 Age at disease onset > 16 years
2 Medication at disease onset
3 Palpable purpura
4 Maculopapular rash
5 Biopsy including arteriole and venule with histological changes showing granulocytes in a perivascular or extravascular location

* At least three of the five criteria must be present. The presence of three criteria was associated with a specificity of 83.9% and a sensitivity of 71.0% [5].

• Allergic granulomatosis of Churg and Strauss
• Lymphomatoid granulomatosis (Chapter 54)
Giant cell arteritis
• Temporal arteritis
• Takayasu's arteritis
Larger vessel vasculitis with collagen vascular disease
Nodular vasculitis

disease, and histopathological features in his schema. He also discussed 'laboratory vasculitis', which reviewed the laboratory findings of patients with vasculitis as part of a classification scheme, as well as aetiological factors of various vasculitides [3].

In 1976, James Gilliam [4] proposed a classification of necrotizing vasculitis as part of Medical Grand Rounds at the University of Texas Southwestern Medical Center.

The American College of Rheumatology published classification criteria for vasculitis in 1990 [5]. However, several problems exist with this classification scheme, which is illustrated in Table 49.1. Particular problems with the criteria include an attempt to codify histological findings of small vessel ('hypersensitivity') vasculitis using 14 biopsy criteria. Furthermore, the use of such terms as 'maculopapular rash', 'medication at onset' and 'eosinophils on biopsy', as well as the separate classification of Henoch–Schönlein purpura, seem inappropriate to most dermatologists.

In 1994, the Chapel Hill Consensus Conference [6] proposed a new naming system for primary systemic vasculitides, which is depicted in Table 49.2. This system classifies the vasculitides into small, medium and large vessel types.

A further attempt to classify vasculitides based on an updated version of Gilliam's 1976 scheme is presented in Table 49.3.

Despite numerous attempts over 50 years, the development of a clinically relevant and easy-to-use classification system for vasculitis that incorporates clinical features, vessel size, histopathological and laboratory features, and aetiologies, is a goal that has not yet been fully achieved.

Pathogenesis of vasculitis

The pathogenesis of vasculitis is a complex subject, not least because there are likely to be many different pathogeneses reflecting the many different causes and pathological entities. This brief overview describes some of the major mechanisms and systems involved, with emphasis on those that have clinical importance (such as the diagnostic potential of antineutrophil cytoplasm antibodies;

ANCA). More detailed recent reviews can be consulted [1–7].

Factors that play a part in the pathogenesis of vasculitis include antigen–antibody related mechanisms (including autoantibodies and immune complex diseases), inflammatory cells and their lysosomal content, complement, cytokines, chemokines, adhesion molecules, vascular and cellular growth factors, genetic influences and the fibrinolytic system, as well as direct vessel wall damage (e.g. by some infectious organisms). Local blood flow influences the development of the vasculitis lesion, as evidenced by lesions occurring at areas of constriction by tight clothing, and local release of histamine also has a role.

Antigens, immune complexes and complement

Antigenic triggers of immunological responses targeted at components of blood vessel walls elicit most vasculitides. The importance of circulating immune complexes has long been recognized in studies of serum sickness [8], and the deposition of immune complexes in blood vessel walls is the best characterized mechanism for the vascular injury associated with vasculitis [9]. It is this mechanism that may be particularly important in cutaneous small vessel vasculitis; potential antigens of relevance include bacteria, viruses, drugs and other chemicals. Most evidence for an immune complex-mediated pathogenesis is circumstantial (e.g. the demonstration of immunoglobulins in skin lesions) and is better documented for cutaneous small vessel vasculitis than for systemic vasculitides. It is generally accepted that immune complexes have a role in Henoch–Schönlein purpura (HSP), serum sickness, hepatitis B and C virus-induced vasculitis and in cryoglobulinaemic vasculitis.

A theory about the pathogenesis of cutaneous small vessel vasculitis is described below and depicted in Table 49.4 [6,7]. The circulating immune complexes mediating vasculitis interact with the complement system to generate C3a and C5a anaphylatoxins which degranulate mast cells. They stimulate the production of chemotactic factors and subsequent chemotaxis, the release of vasoactive amines (such as histamine) and the release of pro-inflammatory cytokines which induce the subsequent expression of adhesion molecules (such as P- and E-selectin in endothelial cells). Immune complexes with a sedimentation coefficient greater than 19S are deposited in vessel walls, a process that is strongly influenced by platelet-derived vasoactive amines. After vasoactive amine-induced endothelial cell retraction, the immune complex deposition leads to increased expression of selectins by endothelial cells. Neutrophils that are attracted to the site of immune complex deposition release lysosomal enzymes in a teleological attempt to engulf the deposited immune complexes, and are activated *in situ* through binding of the fragment crystallizable (Fc) portion of the antibody. This causes degranulation and destruction of the neutrophils (visible histologically as leukocytoclasis) with release of collagenase and elastase, and generation of reactive oxygen species, ultimately resulting in inflammation and 'bystander' fibrinoid necrosis of vessel walls. It is of practical importance to appreciate that neutrophils degrade immune complexes within 24–48 h after they are deposited [10], usually within 24 h; hence, direct immunofluorescence of vasculitis lesions older than 3–12 h will generally yield negative results [6,11]. Immune complexes may also activate endothelial cells to produce tissue plasminogen activator (t-PA) and thus alter local fibrinolysis and vascular permeability [6]. There are therefore many complex and dynamic changes that occur.

Table 49.4 Theory of pathogenesis of cutaneous small vessel vasculitis. (Modified from [7].)

Immune complexes interact with the complement system to generate C3a and C5a anaphylatoxins, which stimulate: • Production of chemotactic factors which initiate chemotaxis of neutrophils • Release of vasoactive amines (such as histamine), which cause endothelial cell retraction • Release of proinflammatory cytokines (e.g. IL-1, TNF-α), which induce the expression of adhesion molecules (P- and E-selectin) in endothelial cells
Immune complexes deposit in vascular walls after histamine-induced endothelial retraction which increases selectin expression in endothelial cells
Attracted neutrophils produce lysosomal enzymes in an attempt to engulf deposited immune complexes: • Neutrophils are activated through Fc binding and degranulate, and also produce reactive oxygen species • Ultimate inflammation and 'bystander' fibrinoid necrosis of blood vessel wall

Paraneoplastic vasculitis is thought to be caused by tumour antigens stimulating cell-mediated immunity or forming tumour antigen immune complexes, although direct vessel wall damage or occlusion can occur as a result of emboli. Haematological malignancies are the most common to be associated with vasculitis [12].

Antiphospholipid antibodies are important as a cause of microvascular thrombosis (Chapter 48). However, they also bind to endothelial cells and have numerous effects; they are pro-inflammatory, induce monocyte activation, stimulate cytokine and vascular adhesion factor expression, and result in a thrombophilic state [13]. In autoimmune conditions, binding requires plasma β_2-glycoprotein-I (β_2-GP-I), which itself binds to endothelial cells and complexes with phospholipids.

Superantigens have also been implicated in development of vasculitis, notably in Kawasaki syndrome, but this concept has been disputed [4].

Complement activation leads to the adherence of C3b to immune complexes, such that they remain soluble and are cleared by macrophages. Immune complexes that have

bound C3b also bind to erythrocytes via the complement receptor type 1 (CR1), leading to clearance from the reticuloendothelial system. Complement deposition is documented in skin lesions (e.g. in HSP) and genetic deficiency of complement is associated with immune complex diseases. However, IgA immune complexes in patients with HSP do not appear to activate the classical complement pathway, although activation of the alternative pathway by IgA1 (the main IgA subclass in HSP) may allow complexes to be made soluble.

Antiendothelial cell antibodies and other factors in vessel wall injury

Antiendothelial cell antibodies (AECA) are of uncertain importance in the pathogenesis of vasculitis [1,2,14]. They can be identified at high titre in most patients with Takayasu's arteritis or with active thromboangiitis obliterans, and are variably demonstrated in patients with Wegener's granulomatosis (WG), microscopic polyangiitis, Kawasaki disease, Behçet's syndrome and systemic lupus erythematosus (SLE) associated vasculitis. They are also found in several other connective tissue diseases and in haemolytic uraemic syndrome/thrombotic thrombocytopenic purpura, IgA nephropathy, ulcerative colitis and diabetes mellitus. Some studies correlate their titre with disease activity in medium or large vessel arteritis, but whether this reflects a pathogenic role or vascular damage is unclear. The fact that they bind preferentially to endothelium of mesenteric vessels supports the possibility of a pathogenic role in visceral arteritis [15]. AECA can cause endothelial damage by complement-mediated or complement-independent antibody-dependent cellular cytotoxicity.

AECA may also activate endothelial cells leading to up-regulation of adhesion molecules such as intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1) and E-selectin [3,16]; this may be mediated by nuclear factor (NF)-κB [17]. Increased neutrophil cytotoxicity results. E-selectin is a promoter of endothelial cell activation and of leukocyte–endothelial cell interaction, being expressed on cytokine-activated endothelial cells, and might therefore have an active role in the pathogenesis of vasculitis; however, E-selectin levels in a variety of systemic vasculitides do not correlate with disease activity [18]. Von Willebrand factor, factor VIII and soluble thrombomodulin levels may all be increased in vasculitis, probably as a secondary effect resulting from vascular damage; the latter has been shown to be related to disease activity in WG [18]. However, soluble thrombomodulin is also increased in disseminated intravascular coagulopathy, thrombotic thrombocytopenic purpura, sepsis, malaria, diabetic microangiopathy and various other disorders in which there is damage to vessels. High levels of soluble VCAM-1 are found in Kawasaki disease but were even higher in febrile controls [3], and this finding is therefore presumably also a non-specific result of vascular injury.

Nitric oxide production is also increased in some vasculitides; neutrophil-derived nitric oxide is known to be damaging to endothelial cells [19].

Antineutrophil cytoplasm antibodies

By comparison with other pathogenetic factors, many of which are either not routinely measurable or are of uncertain relevance to pathogenesis, antineutrophil cytoplasm antibodies (ANCA) have diagnostic value as well as an important role in the pathogenesis of vasculitis [1–7,14,20–22].

ANCA are classified, according to their indirect immunofluorescence (IIF) pattern on ethanol-fixed neutrophils, into C-ANCA (granular cytoplasmic staining with accentuation between the nuclear lobes), P-ANCA (perinuclear and/or nuclear staining) and atypical ANCA (various patterns, including diffuse cytoplasmic and 'very perinuclear'; atypical ANCA are also termed X-ANCA or snowdrift-ANCA) [3,20]. These patterns correlate with varying degrees of specificity to specific neutrophil granule contents (Table 49.5). ANCA are usually of IgG type but may be IgM or IgA. In addition to systemic vasculitides, ANCA may be positive in various infections (malaria, human immunodeficiency virus infection; HIV), connective tissue disorders (SLE, rheumatoid arthritis) and gastrointestinal disease (inflammatory bowel disease, chronic autoimmune liver and biliary tract disease).

In most disorders other than vasculitides, the pattern is P-ANCA or atypical ANCA, and in most of these disorders there is no consistent ANCA specificity or correlation with disease activity. However, there are some exceptions, such as the association of cathepsin G-ANCA with malaria [23]. The presence of P-ANCA in SLE, although originally felt not to have any particular link with disease pattern [24], has been associated with serositis, livedo reticularis, venous thrombosis, anticardiolipin and anti-SSA/Ro positivity, and periodontal disease [25,26]; in particular, lactoferrin-ANCA is strongly linked with livedo reticularis [25]. Bactericidal/permeability increasing protein (BPI) ANCA and proteinase 3 (PR3) ANCA have also been linked with serositis in patients with SLE. Anti-dsDNA and anti-SSA/Ro antibodies may resemble P-ANCA, depending on fixation methods [27]. Human lysosome-associated membrane protein-2 (h-lamp-2) ANCA has been linked with pyoderma gangrenosum.

Generally, the P-ANCA pattern is relatively non-specific, having various (often undetermined) antigen specificities and often no link with disease activity. By contrast, the C-ANCA pattern almost always corresponds with antibodies against PR3, a 29-kDa neutral serine pro-

Table 49.5 Antigenic specificity and clinical correlates of antineutrophil cytoplasm antibodies.

Antigen	Usual ANCA pattern on IIF	Most commonly associated diseases
PR3	C-ANCA	WG, MPA, CSS, necrotizing and crescentic GN
MPO	P-ANCA	Idiopathic progressive GN, MPA, CSS, WG, SLE, ANCA-positive drug-induced systemic vasculitis, thromboangiitis obliterans
Cathepsin G	P-ANCA	IBD, especially ulcerative colitis, PSC, malaria
BPI (= CAP 57)	C-ANCA	Systemic vasculitis, SLE, IBD, PSC, cystic fibrosis, chronic airway infections
Azurocidin (= CAP 37)	P-ANCA or C-ANCA	Systemic vasculitis, drug-induced systemic vasculitis
Lactoferrin	P-ANCA or atypical ANCA	Rheumatoid arthritis, SLE especially with serositis or livedo reticularis, systemic vasculitis, ulcerative colitis, PSC, hydralazine-related vasculitis, thromboangiitis obliterans
Elastase	P-ANCA	WG, propylthiouracil-related systemic vasculitis, HIV infection
β-glucuronidase	P-ANCA	IBD
Lysozyme	P-ANCA	SLE, IBD, HIV infection
h-lamp-2	P-ANCA	Necrotizing and crescentic GN, pyoderma gangrenosum
Others (actin, catalase, α-enolase)	P-ANCA or atypical	Uncertain. Anti-actin may be present in autoimmune hepatitis

BPI, bactericidal/permeability increasing protein; C-ANCA, cytoplasmic antineutrophil cytoplasm antibody; CSS, Churg–Strauss syndrome; GN, glomerulonephritis; HIV, human immunodeficiency virus; h-lamp-2, human lysosome-associated membrane protein-2; IBD, inflammatory bowel disease; MPA, microscopic polyangiitis; MPO, myeloperoxidase; P-ANCA, perinuclear antineutrophil cytoplasm antibody; PBC, primary biliary cirrhosis; PR3, proteinase-3; PSC, primary sclerosing cholangitis; SLE, systemic lupus erythematosus; WG, Wegener's granulomatosis.

tease, and clinically with WG or other systemic vasculitis. In the context of systemic vasculitis, the important P-ANCA group are those with antibodies against myeloperoxidase (MPO). It is therefore important to confirm MPO or PR3 antibodies, usually by enzyme-linked immunosorbent assay (ELISA), in the context of a positive ANCA test identified by IIF screening, and to refer to the more specific result where possible (e.g. as PR3-ANCA) [20]. A positive C-ANCA has a sensitivity of 66% (91% if only considering active disease) and specificity of 98% for WG [28], but may be positive in about one-third of patients with microscopic polyangiitis or with necrotizing crescentic glomerulonephritis, and in about 20% with Churg–Strauss syndrome (CSS). Patients with WG who are negative for C-ANCA/anti-PR3 usually have positive P-ANCA/anti-MPO. In addition, anti-MPO are found in about 65% with progressive idiopathic glomerulonephritis, in about 50% with microscopic polyangiitis or CSS, and may be found in SLE or in ANCA-associated drug reactions (notably to propylthiouracil or hydralazine). If ANCA are present in drug-induced systemic vasculitis the pattern is usually P-ANCA or atypical ANCA.

Numerous studies suggest a pathogenetic role for at least anti-PR3 and anti-MPO antibodies in systemic vasculitides. In particular, the IgG3 subclass of PR3 is implicated, a rise in titres in WG being predictive of relapse [3]; this subclass is a particularly strong activator of neutrophils. The role of ANCA in the pathogenesis of vasculitis is multifactorial. ANCA cause activation of neutrophils primed by tumour necrosis factor-α (TNF-α), leading to production of reactive oxygen species, nitric oxide and cytokines such as interleukin-1 (IL-1) and IL-8 (a neutrophil chemoattractant). Neutrophils activated by ANCA up-regulate adhesion molecules, adhere to platelet monolayers or to TNF-activated endothelial cells *in vitro* rather than their usual behaviour of 'rolling', and develop pseudopodia [5]. ANCA also up-regulate expression of adhesion molecules and IL-6 production by endothelial cells, cause neutrophil degranulation with release of proteolytic enzymes, and stimulate monocytes to produce reactive oxygen species and to produce IL-8; monocyte activation may also be important in non-ANCA-associated vasculitides such as Behçet's disease [4].

Elastase is one of the main tissue-damaging enzymes released by neutrophil degranulation. It is potentially important that elastase stimulates release of tissue factor from cultured endothelial cells (human umbilical vein endothelial cells; HUVEC), as this may be relevant in development of microthrombi *in vivo* (PR3, but not MPO, also stimulates production of tissue factor from HUVEC) [29]. It is also of interest that autoantibodies to elastase enhance rather than decrease elastase activity, thus leading to tissue damage [30]; this might be a pathogenetic role for elastase-ANCA. It appears that the major role of ANCA in vasculitis is probably caused by their effects on the neutrophil, thus leading to endothelial cell damage.

Other cytokines and chemokines, and the cellular response [1,3,4]

Numerous cytokines have been implicated in vasculitis; some have already been discussed. Many are released as part of an acute phase response or because of up-regulation of production by peripheral blood neutrophils or monocytes, such as IL-1, IL-2, IL-6, IL-8, interferon (IFN) and TNF-α. These may therefore be non-specifically elevated in vasculitis, but may play a part in ongoing damage. TNF-α is important for priming endothelial cells

to express E- and P-selectin, ICAM-1 and 2, and VCAM-1 (see above), and also primes neutrophils to produce reactive oxygen species and to degranulate after exposure to ANCA. IL-8 is a potent neutrophil chemoattractant that is expressed by endothelial cells after stimulation by ANCA. IL-6 has been studied especially in giant cell arteritis and Takayasu's arteritis, in which it appears to reflect disease activity. Increased levels of soluble TNF receptor have been demonstrated in ANCA-positive vasculitides.

Other chemokines that have enhanced tissue expression in vasculitis include monocyte chemotactic protein-1 (MCP-1), macrophage inflammatory protein-1α and -1β and RANTES (regulated upon activation, normal T-cell expressed and secreted) [22]. Expression of MAC-1 by neutrophils is up-regulated by ANCA.

Based on a mouse model in which genetic deficiency of IL-1 receptor antagonist (IL-1Ra) is associated with arterial inflammation, it has been suggested that IL-1Ra has a significant role in vasculitis and that a recombinant IL-1Ra might be a useful treatment [31].

T cells, monocytes and macrophages play a part in vasculitis injury, in addition to the role of neutrophils discussed above. Both $CD4^+$ and $CD8^+$ T cells accumulate at the site of injury. In WG there is a Th1 cytokine profile, with increased IFN-γ, TNF and IL-12 but not IL-4, IL-5 or IL-10 [22], and CD28 expression; however, some studies have suggested a Th2 response in nasal mucosa, which may be of importance as nasal staphylococcal infection is associated with relapses in WG. Monocytes from patients with systemic necrotizing vasculitis produce more superoxide and MPO than monocytes from controls, and they can also be induced to express PR3 and to release IL-8 when exposed to ANCA [5]. However, monocyte activation also occurs in Behçet's disease, which is not ANCA-related. Defective macrophage apoptosis may lead to persistence and ongoing damage at the vasculitic site, as occurs with neutrophils [4].

Genetic factors

Familial clustering has been documented in some vasculitides such as WG, although this is uncommon [4,32]. Various explanations have been proposed, including the occurrence of TNF gene polymorphisms, genetic heterogeneity of ANCA antigens or their expression, and neutrophil Fcγ receptor polymorphisms. For example, expression of PR3 on resting neutrophils shows marked individual variation, the proportion of neutrophils expressing PR3 varying from approximately 10% to 80%, but being quite stable in any individual [4,33]; high expression has been associated with a higher risk of WG. Severe renal disease in WG has been linked with expression of the neutrophil receptor FcγRIIIb-NA1, although this is disputed [22,32]. The genetic region for elastase, azurocidin and PR3 is highly polymorphous, but no apparent associations with clinical disease have been identified [4].

α_1-Antitrypsin (α_1AT) is a natural inhibitor of PR3 and elastase (as is caeruloplasmin for MPO). Deficiency of α_1AT may be genetic or may be acquired by the formation of α_1AT–PR3 complexes by anti-PR3 ANCA. An association between the α_1AT-deficient PiZZ phenotype and ANCA-positive vasculitis has been described, and PiZ heterozygosity has been linked with poor prognosis in ANCA-positive systemic vasculitis [1,34]. However, a large study of PiZZ-deficient sera showed an association with antibodies against elastase but not against PR3, MPO or lactoferrin, and α_1AT deficiency is not in itself sufficient to induce ANCA-associated vasculitis [22,35]. An α_1 protease inhibitor has been used with dramatic response in the treatment of chronic vasculitis in a patient with α_1AT deficiency [36].

Evaluation of the patient with suspected vasculitis

The evaluation of a patient with suspected vasculitis involves histopathological confirmation of the clinical diagnosis, an assessment of the extent of the disease and an attempt to establish an underlying aetiology. Clinical patterns that may suggest a vasculitis, other than the overtly vasculitic lesions discussed in this chapter, include cutaneous livedo, cutaneous necrosis, non-specific purpura and purple (blue) toe syndrome; these patterns can also occur in non-vasculitic microvascular occlusion disorders, and their significance and likely causes are discussed in Chapter 48.

Histopathological confirmation of suspected small vessel vasculitides is best performed by taking a punch biopsy of the lesions at the appropriate stage, recognizing that lesions represent various chronological stages of the disease process. Deeper elliptical incisional biopsies should be performed for suspected larger vessel vasculitides.

In attempting to assess the extent of the disease, it is important to consider where circulating immune complexes may deposit. Specifically, the following systems should be evaluated for immune complex-mediated pathology:

- *General*. Myalgia, arthralgia, fever
- *Renal*. Proteinuria, haematuria
- *Nervous system*. Central or peripheral, diffuse or localized findings
- *Musculoskeletal*. Non-erosive polyarthritis
- *Gastrointestinal*. Abdominal pain, gastrointestinal bleeding
- *Pulmonary*. Pleural effusion, pleuritis
- *Cardiac*. Pericardial effusion

It is helpful to work with a colleague in internal medicine or paediatrics when evaluating the patient.

Finally, an attempt should be made to determine the aetiology of the vasculitis. It may be helpful to screen for medications, infections or diseases associated with immune complexes (connective tissue vascular diseases, malignancy, inflammatory bowel disease, etc.). It is important to remember, however, that cutaneous small vessel vasculitis is idiopathic in up to 50% of cases.

The information in the following sections discusses the definition, history, aetiology, pathogenesis, histopathology, clinical features, diagnosis and treatment of various vasculitides affecting small, medium and large blood vessels.

Cutaneous small vessel vasculitis

SYN. CUTANEOUS LEUKOCYTOCLASTIC VASCULITIS; HYPERSENSITIVITY ANGIITIS/VASCULITIS VARIANTS CONFINED TO SKIN; CUTANEOUS NECROTIZING VENULITIS (NECROTIZING VARIANT INVOLVING PREDOMINANTLY VENULES)

Definition. Affecting mainly cutaneous post-capillary venules, cutaneous small vessel vasculitis (CSVV) is the most common type of vasculitis in dermatology. Features of CSVV include palpable purpura, urticaria or ulcers on the legs involving only small vessels. It affects both children and adults, and is seen primarily in women. Extracutaneous manifestations of CSVV are uncommon.

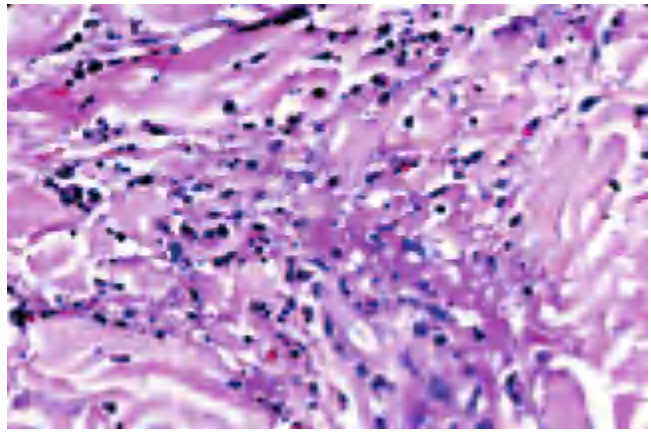

Fig. 49.2 Leukocytoclastic vasculitis. Higher magnification demonstrates nuclear dust, fibrinoid deposits, vascular alteration and collagen degeneration. (Courtesy of Dr Omar Sangueza, Wake Forest University School of Medicine, Winston-Salem, NC, USA.)

History and nomenclature. In the 1950s, Zeek described small vessel vasculitis related to drug exposure as a separate entity from large vessel vasculitis, and termed the small vessel vasculitis 'hypersensitivity angiitis'. Because of ambiguity, the term hypersensitivity angiitis was redefined by the Chapel Hill Consensus Conference in 1994 to describe patients with a small vessel vasculitis with primarily cutaneous involvement [1].

Aetiology and pathogenesis. A history of drug exposure or recent infection is frequently present in cases of CSVV. Circulating immune complexes can be identified in a large percentage of patients with CSVV.

Histopathology. Leukocytoclastic vasculitis with segmental inflammation in an angiocentric pattern, swelling of the endothelium, fibrinoid necrosis of vessel walls, extravasation of erythrocytes, and an infiltrate of neutrophils with karyorrhexis of nuclei (i.e. leukocytoclasia) are major features of CSVV (Figs 49.1 & 49.2). In superficial dermal papillary vessels, IgM or C3 perivascular deposits are often demonstrated in fresh lesions.

Clinical features. The skin lesions of CSVV typically arise as a simultaneous 'crop', resulting from the exposure to an inciting stimulus. They usually resolve within several weeks or a few months, although approximately 10% of patients will have recurrent disease at intervals up to years. The major cutaneous manifestation of CSVV is palpable purpura, ranging in size from 1 mm to several centimetres (Fig. 49.3). Sometimes macular in the early stages, such purpura may progress to a wide array of lesions including papules, nodules, vesicles, plaques, bullae or pustules, with secondary findings of ulceration, necrosis and post-inflammatory hyperpigmentation. Other cutaneous findings include livedo reticularis, oedema and urticaria. Lesions typically occur in areas prone to stasis, commonly including the ankles and lower legs [2–5], and typically sparing intertriginous regions. Although normally asymptomatic, pruritus, pain or burning may be experienced, as well as systemic symptoms including fever, arthralgia, myalgia and anorexia. The presence of symptoms affecting other organ systems should raise the suspicion of other vasculitides such as HSP, mixed cryoglobulinaemia, or CSVV associated with polyarteritis nodosa (PAN) or with WG. Renal involvement in patients with CSVV in one study led to reclassification as HSP, microscopic polyangiitis (MPA) or WG in 29 of 90 patients [6].

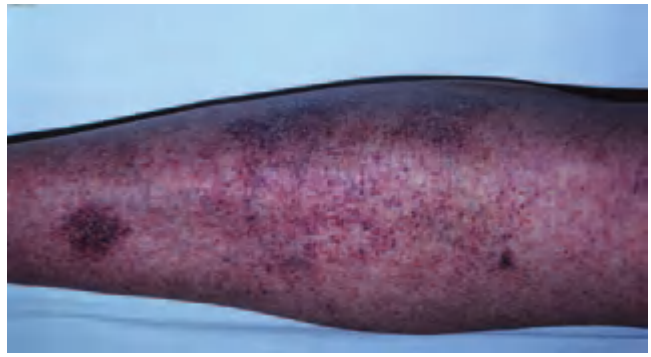

Fig. 49.3 Cutaneous small vessel vasculitis. Note the purpura on the anterior aspect of the leg.

Diagnosis. A thorough history and physical examination is essential for correct diagnosis of CSVV, with screening for infections, connective tissue disease, medication usage and cancer. Vasculitides with systemic manifestations must be ruled out, as CSVV is diagnosed by exclusion. Table 49.6 describes the evaluation of a patient with a suspected CSVV.

Table 49.6 Evaluation of a patient with suspected cutaneous small vessel vasculitis.

Confirm the clinical diagnosis histopathologically
Punch biopsy of lesion at the appropriate stage
Incisional biopsy for suspected larger vessel vasculitis

Assess the extent of the disease
General
- Myalgia
- Arthralgia
- Fever

Renal involvement
- Proteinuria
- Haematuria

Nervous system
- Central or peripheral
- Diffuse or local findings

Musculoskeletal involvement
- Non-erosive polyarthritis

Gastrointestinal system
- Abdominal pain
- Gastrointestinal bleeding

Pulmonary involvement
- Pleural effusion
- Pleuritis

Pericardial involvement
- Pericardial effusion

Attempt to establish the aetiology
Drugs
Infections
Diseases associated with immune complexes
- Connective tissue vascular diseases
- Malignancy
- Inflammatory bowel disease
- Chronic active hepatitis

Idiopathic (50%)

Treatment. Treatment of CSVV is typically unnecessary, as the disease is usually self-limiting. However, if any triggering agents are identified, such as a drug or infection, they should be removed or treated. Efforts to minimize stasis, such as use of compression hosiery and elevation of dependent areas, as well as the use of non-steroidal anti-inflammatory drugs (NSAIDs) and antihistamines, typically produce a decrease in symptoms [7]. Furthermore, oral corticosteroids at a dosage of 30–80 mg once daily, tapered over 2–3 weeks, often give effective symptom control, although no controlled trials have been carried out to evaluate the treatment of CSVV with oral corticosteroids. Corticosteroid use may be of particular benefit in cases with painful progressive cutaneous lesions. No data support the use of topical corticosteroids or antibiotics in CSVV, although such therapies are commonly used. Colchicine given at a dose of 0.6 mg twice daily has been shown to be of benefit by anecdotal evidence and open-label studies [8–10]. Similarly, the use of dapsone is based only on anecdotal or small case series, yet some believe that the use of dapsone along with colchicine may be advantageous in the treatment of CSVV [11–14]. In patients with disease refractory to the above therapies, cytotoxic agents may be considered. Such agents include azathioprine (typically at a dosage of 2 mg/kg/day; see also Chapter 72), methotrexate at a low dose of less than 25 mg/week, ciclosporin and cyclophosphamide [15–19]. Table 49.7 describes a therapeutic ladder for patients with CSVV.

Table 49.7 Therapeutic ladder for patients with cutaneous small vessel vasculitis.

Skin lesions alone
Supportive therapy (3)
Antihistamines (3)
Non-steroidal anti-inflammatory drugs (2)
Pentoxiphylline (3)
Colchicine (2)
Dapsone (2)

Ulcerative skin lesions alone
Thalidomide (3)
Low-dose weekly methotrexate (3)
Prednisone (2)

Systemic disease
Prednisone (2)
Azathioprine (2)
Cyclophosphamide (2)
Mycophenolate mofetil (3)
Ciclosporin (3)
Interferon-α (if hepatitis C-associated) (1)
Intravenous gammaglobulin (3)
Extracorporeal immunomodulation (3)

1, double-blind studies; 2, case series; 3, case reports.

Drug-induced vasculitis

Definition. Vasculitis of various morphological types caused by drug ingestion. This is briefly discussed as a discrete topic as it is always important to consider medications and other ingested drugs as a possible cause of vasculitis. The clinical pattern is often that of a small vessel cutaneous vasculitis but other patterns occur. Drug-induced vasculitis is also considered in Chapter 73 with emphasis on causative agents.

Causes. Many drugs may cause vasculitis, and are listed in several reference sources [1–4]. A list of drugs that cause vasculitis is provided in (Chapter 73). Drugs that may cause skin necrosis and drug-induced purpura are discussed in Chapter 48. It is important to be aware that illicit drugs, drug excipients, vaccines and food additives can all cause vasculitis, as these may otherwise be overlooked as possible triggers. Cocaine in particular is recognized as a cause of systemic vasculitis.

Mechanisms. Most drug-induced vasculitis is of hypersensitivity type and presumed to be immune complex-mediated; it probably accounts for 10–20% of small vessel cutaneous vasculitis [4]. The evidence for this assumption is often indirect, although sulphonamide crystals have been observed in blood vessel walls [5]. This pattern occurs resulting from various antibiotics, diuretics, NSAIDs, anticonvulsants, antipsychotics, cardiac drugs such as diltiazem, and others [3,4]. Relatively recent drugs that can cause this pattern include zidovudine, various haemopoietic growth factors and etanercept.

The link between drugs and systemic vasculitis is often less clear. In some instances, such as leukotriene antagonists administered for asthma 'causing' CSS (Chapter 59), there is an argument that the asthma may simply have been an early feature of CSS and that the drug is not relevant. However, ANCA-positive (particularly MPO-positive) vasculitis has been convincingly linked with drugs such as hydralazine and thiouracils, and less commonly with penicillamine, allopurinol, minocycline and sulfasalazine [6–8]. Glomerulonephritis may occur related to propylthiouracil-induced ANCA-positive vasculitis. Hydralazine may also cause small vessel leukocytoclastic vasculitis.

Drug-induced lupus erythematosus is discussed in Chapter 56; drug-induced neutrophilic dermatoses are discussed later in this chapter.

Pathology. A small vessel vasculitis with a lymphocytic infiltrate and little leukocytoclasia, or the presence of some degree of tissue eosinophilia, are suggestive of the possibility of drug-induced vasculitis but are neither sensitive nor specific features. Serum complement levels are generally normal. ANCA may be positive (see above).

Clinical features. Drug-induced leukocytoclastic vasculitis presents with palpable purpura, petechiae, necrosis and urticarial lesions, indistinguishable from other causes of this pattern of vasculitis.

A serum sickness pattern of eruption, originally related to use of hyperimmune sera, is more commonly seen in relation to penicillins or sulphonamides, and less commonly with drugs such as thiouracil, phenytoin (hydantoin), phenylbutazone or streptokinase. The initial rash may be acral, with urticaria or purpura, followed by more generalized annular urticarial lesions. There may be fever, arthralgia, haematuria or proteinuria, lymphadenopathy and decreased complement levels.

Medium and large vessel vasculitides mimic the patterns described elsewhere in this chapter, although there may be atypical features such as eosinophilia or the fact that all lesions appear to be of similar duration. Some drug-induced cases resembling CSS have relatively minor respiratory symptoms compared with the idiopathic condition.

Treatment. Stopping any suspect drug is important and may be all that is required for cutaneous vasculitis. In cases with systemic disease, corticosteroids and even other immunosuppressive agents may be necessary. Supportive treatment such as compression hosiery may be required as in other forms of small vessel vasculitis. Renal function and urinalysis should be monitored.

In most instances, the causative drug should not be used again. It is also important to be aware of possible cross-reactions (notably between diuretics) when substituting a different drug.

Henoch–Schönlein purpura

SYN. IGA IMMUNE COMPLEX VASCULITIS; ANAPHYLACTOID PURPURA; PURPURA RHEUMATOIDE

Definition. Originally described as a tetrad of palpable purpura, arthritis, gastrointestinal involvement and renal glomerular involvement [1,2], HSP is defined by the Chapel Hill Consensus Conference as a vasculitis affecting small vessels, involving deposition of IgA immune complexes, that characteristically involves the skin, gastrointestinal system and glomeruli with or without arthralgia or arthritis [3]. Unfortunately, many literature reports assume that all cutaneous small vessel vasculitis in children is HSP, rather than insisting on confirmed presence of IgA immune complexes, which causes great confusion. Although it can occur in adults, HSP is much more common in childhood; 75% of cases occur in children under 10 years old [4]. Furthermore, HSP occurs in various racial and ethnic groups [5,6].

History and nomenclature. Heberden first described HSP in 1801, in a young boy with abdominal pain, emesis, bloody stools, arthritis and a purpuric eruption. The eponymous term Henoch–Schönlein purpura was later applied after Johann Schönlein and Eduard Henoch described features of the vasculitis in the mid-19th century.

Aetiology and pathogenesis. Although some infections, such as those caused by group A β-haemolytic streptococci, were once thought to have a prominent role in the cause of HSP, no single pathogen has been linked as the major antigenic trigger [7]. However, IgA is thought to play a pivotal part in the pathogenesis of HSP, as increased levels of IgA in the serum, increased circulating immune complexes containing IgA, and increased deposition of IgA in blood vessel walls and in the renal mesangium are associated with HSP. In patients with HSP, IgA1 rather than IgA2 is the main IgA subclass deposited in the skin lesions [8]. Aberrant glycosylation of the hinge region of IgA1 may be an important factor in allowing the IgA to activate the alternative pathway of complement [9].

Histopathology. Biopsy specimens of the purpuric lesions demonstrate leukocytoclastic vasculitis. Direct immunofluorescence microscopy of lesional and perilesional skin reveals deposition of IgA, C3 and fibrin in dermal blood vessel walls.

Clinical features. Most commonly, HSP manifests at the outset with the classic findings of purpura, arthralgia and abdominal pain [7,9]. The cutaneous findings are typically erythematous urticarial papules, which may evolve within 24 h into palpable purpura with haemorrhage. Furthermore, urticaria, vesicles, bullae and necrotic ulcers may develop. Typically involving the extensor aspects of the limbs (especially elbows and knees) and buttocks in a symmetrical fashion, HSP may also affect the trunk and face. Usually fading within 5–7 days, crops of lesions can recur for a few weeks to several months. Although HSP is chronic in 5–10% of patients, the cutaneous involvement usually lasts between 6 and 16 weeks and then subsides. Rarely, gastrointestinal involvement and arthritis can occur in the absence of skin disease. Renal involvement with HSP is common, occurring in approximately 30–90% of patients. Most patients with renal involvement have mild disease, demonstrating only minimal proteinuria and haematuria. Only 1% of these patients progress to end-stage renal disease, although one-third to half of patients have renal abnormalities on long-term follow-up. Furthermore, gastrointestinal involvement is common, with gastrointestinal bleeding being demonstrated in 50–75% of patients with HSP. Arthritis is seen in about 75% of patients with HSP, most frequently affecting the knees and ankles.

Diagnosis. HSP is a clinical diagnosis, with confirmation by direct immunofluorescence and routine histology. Perivascular IgA deposits are characteristic of HSP and can help to distinguish it from other vasculitides including cutaneous small vessel vasculitis, WG, CSS and microscopic polyangiitis. IgA immune complexes are not specific to HSP, but can be seen in a variety of patients including those with SLE, endocarditis, dermatitis herpetiformis, alcoholism, IgA nephropathy, inflammatory bowel disease, ankylosing spondylitis, Sjögren's syndrome, rheumatoid arthritis, some cancers and in some drug hypersensitivity reactions [10–13]. No laboratory tests are specific for HSP, and although IgA ANCAs have been described in several adults with HSP, they are more typically negative [7].

Treatment. HSP is frequently self-limiting, the majority of patients fully recovering within several weeks or months, so treatment is mainly supportive. Although no data demonstrate the effectiveness of systemic corticosteroids in treating purpura, shortening the duration of HSP or decreasing the frequency of recurrences, they have been

shown in retrospective studies to be effective in the treatment of abdominal pain and arthritis. Dapsone (100 mg once daily) seems to shorten the duration of HSP as well as having a beneficial effect on the cutaneous lesions [7]. One trial proposed that factor XIII replacement may be useful in the treatment of abdominal pain and gastrointestinal bleeding associated with HSP, and another small trial demonstrated a decrease in the duration and severity of abdominal pain, as well as a decreased bleeding risk, with the use of ranitidine [14,15]. The presence of renal disease is the major factor determining the long-term morbidity and mortality associated with HSP [16]. Although no controlled trials have been conducted, data from several studies, as well as a case series, suggest a benefit from high-dose corticosteroids, either alone [17] or with cyclophosphamide and dipyridamole [18–20] in patients with progressive renal involvement associated with HSP. Furthermore, some case reports show that gastrointestinal involvement and cutaneous disease may be lessened, and rapidly progressive nephritis may be halted, by the use of intravenous immunoglobulin [21,22]. Patients with severe nephritis typically receive high-dose methylprednisolone at a dosage of 30 mg/kg once daily for 3 days followed by oral corticosteroids and an immunosuppressive drug such as azathioprine or cyclophosphamide [7]. NSAIDs have minimal, if any, benefit in the treatment of HSP, and should not be used in patients with renal involvement. The therapeutic ladder presented for cutaneous small vessel vasculitis is relevant for these patients as well.

Urticarial vasculitis

SYN. CHRONIC URTICARIAL LESIONS AS A MANIFESTATION OF VENULITIS; UNUSUAL SYSTEMIC LUPUS ERYTHEMATOSUS-LIKE SYNDROME; HYPOCOMPLEMENTAEMIC VASCULITIS; HYPOCOMPLEMENTAEMIC–URTICARIA–VASCULITIS SYNDROME (HUVS)

Definition. Of patients with urticarial lesions, roughly 5–10% have urticarial vasculitis (UV) [1,2]. This is a chronic disease, which presents as urticarial lesions that most often occur on the trunk or proximal limbs, frequently with associated angioedema [3]. Lesions differ from those of simple urticaria in that individual lesions persist for greater than 24 h, often demonstrate purpura and post-inflammatory pigmentation, and cause symptoms of burning. Two types of UV have been described: UV associated with hypocomplementaemia, and UV without associated hypocomplementaemia (normocomplementaemic UV). Hypocomplementaemic UV is defined by the presence of anti-C1q precipitin and/or a decrease in the level of C1 [2,4]. Although all patients with hypocomplementaemic UV have these antibodies, this process must be distinguished from SLE, which can show similar laboratory findings [5,6]. Urticarial vasculitis may be described as a continuum starting with patients who have only skin lesions, progressing to patients with skin lesions and hypocomplementaemia, and finally to those who meet the criteria for SLE. UV without hypocomplementaemia has a slight female predominance, whereas hypocomplementaemic UV is seen almost exclusively in female patients.

History and nomenclature. Agnello *et al*. [7] first discussed UV, which was later described as a syndrome consisting of hypocomplementaemia, cutaneous vasculitis and arthritis by McDuffie *et al*. [8].

Aetiology and pathogenesis. UV is strongly associated with some connective tissue diseases, having a prevalence of 32% in patients with Sjögren's syndrome and 20% in patients with SLE [1]. Other associations include physical urticarias, hepatitis B or C, IgM or IgA gammopathies, serum sickness, colon cancer and drug ingestion. Some cases of UV have been reported in association with exercise or with exposure to ultraviolet light and cold. UV is thought to represent a type III hypersensitivity reaction, as circulating immune complexes may be demonstrated in up to 75% of patients [9]. Complement and immunoreactant deposition in vessel walls, with complement cascade activation in patients with UV [10], further supports this theory. Additionally, removal of immune complexes via plasmapheresis has been shown to briefly alleviate some symptoms of UV [11]. In hypocomplementaemic UV, autoantibodies are directed against the collagen-like region of C1q, resulting in a reduction of C1q in the serum with subsequent activation of the complement pathway [12].

Histopathology. Lesions of UV demonstrate leukocytoclastic vasculitis. Hypocomplementaemic UV shows a large number of interstitial neutrophils, rather than eosinophils, and may therefore be distinguished from normocomplementaemic UV [13,14].

Clinical features. Cutaneous lesions of both the hypocomplementaemic and normocomplementaemic forms of UV are erythematous indurated weals that may contain purpuric foci. Angio-oedema and macular erythema may also occur; livedo reticularis, nodules and bullae may be evident, and may also contain purpuric foci. Patients with the hypocomplementaemic form may have constitutional symptoms such as fever, malaise and myalgia, as well as other symptoms and signs including lymphadenopathy, hepatosplenomegaly, abdominal pain with or without nausea and/or diarrhoea, laryngeal oedema, dyspnoea, chronic obstructive pulmonary disease (COPD), glomerulonephritis, conjunctivitis, uveitis and episcleritis. Although hypocomplementaemic UV has features similar to SLE, signs such as ocular inflammation, angio-oedema and COPD distinguish the two processes.

Diagnosis. If urticarial lesions last for longer than 24 h (which can be determined by drawing around their margin), then by definition they are not ordinary urticaria and a skin biopsy should be performed. Pain rather than itch, or the presence of purpura, also suggest UV. History, physical examination and laboratory studies including C3, C4 and antinuclear antibody (ANA) should help to establish the extent of disease and to exclude underlying disease (e.g. hepatitis C), and to evaluate for SLE. Some patients may demonstrate an elevated erythrocyte sedimentation rate (ESR), hypocomplementaemia, a low-titre positive ANA and haematuria. A biopsy must be performed to confirm the diagnosis and to exclude other disorders such as atypical erythema multiforme.

Treatment. Although no single treatment is effective for all cases of UV, the majority of patients respond to systemic corticosteroids. However, other agents should be considered as steroid-sparing therapies [15–17]. Drugs that have been shown to be effective for the treatment of UV include dapsone (100–200 mg once daily), colchicine (0.6 mg twice to three times daily) and hydroxychloroquine (200 mg once to twice daily) [18–22]. Dapsone plus pentoxifylline (400 mg three times daily) has been used in one patient [23], and mycophenolate mofetil (2 g once daily) has been successfully tried as a maintenance therapy in two other patients [24]. Some patients require oral antihistamines for control of angio-oedema and urticaria-like lesions, in addition to the aforementioned therapies directed at the vasculitis.

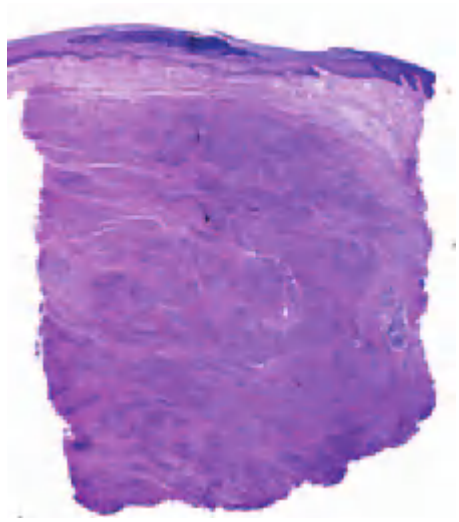

Fig. 49.4 Erythema elevatum diutinum. Low-power photomicrograph shows diffuse infiltrates throughout the entire dermis and areas of fibrosis. (Courtesy of Dr Omar Sangueza, Wake Forest University School of Medicine, Winston-Salem, NC, USA.)

Erythema elevatum diutinum

Definition. Erythema elevatum diutinum (EED) is a rare chronic cutaneous eruption that is most commonly seen in adults. It is characterized by fibrosing plaques with histological evidence of leukocytoclastic vasculitis.

History and nomenclature. The first patient with EED was described by Hutchinson and Bury in the 1880s. The condition was later named in 1894 by Radcliffe-Crocker and Williams.

Aetiology and pathogenesis. Although EED is thought to be related to immune complex deposition with subsequent inflammation, the exact aetiology is unknown. It has been associated with autoimmune diseases such as rheumatoid arthritis, coeliac disease, inflammatory bowel disease and type 1 diabetes mellitus. Associations with infections, including streptococcus, hepatitis and syphilis, have also been suggested [1–10]. Lesions characteristic of EED have been induced by injection of streptococcal antigen into the dermis [11–14]. EED has also been associated with HIV infection, as lesions of EED have responded to antiretroviral and dapsone treatment in HIV-positive patients [15–21]. In addition, EED has been associated with hypergammaglobulinaemia and IgA monoclonal gammopathies, as well as with myelodysplasia, pyoderma gangrenosum and relapsing polychondritis. The association with haematological disorders, such as multiple myeloma, is strong; however, EED may precede the haematological disease by several years [22].

Histopathology. Acute lesions of EED demonstrate leukocytoclastic vasculitis. Eosinophils may also be present in the upper and mid-dermis. Depending on the degree of oedema and infiltration into the dermis, unaffected collagen may be present just under the epidermis. Chronic lesions demonstrate fibrosis, capillary proliferation and infiltration of macrophages, plasma cells and lymphocytes. Cholesterol deposits in the intracellular and extracellular tissue may be present in older lesions. Figures 49.4 and 49.5 show the histopathology of EED.

Clinical features. Lesions of EED most commonly appear chronically in a symmetrical fashion over the dorsa of the hands, the knees, buttocks and Achilles tendons. They are red-violaceous, red-brown or yellowish papules, plaques or nodules. Occasionally, the face and ears are also affected by EED. Initially, the lesions are soft, but eventually they fibrose, and later leave atrophic scars. Although they are often asymptomatic, the lesions of EED may be painful. EED may last from 5 to 35 years, with crops of new lesions developing every few weeks to months.

Diagnosis. Although EED may be difficult to distinguish from cutaneous small vessel vasculitis histologically, the clinical presentation differs from that of other chronic small vessel vasculitis syndromes, allowing an accurate diagnosis. EED differs from Sweet's syndrome in the character of the lesions and their distribution, as well as in the histopathological features.

Treatment. Several medications have been used in the treatment of EED. Dapsone has a remarkable affect on EED [14], although discontinuation of dapsone is often

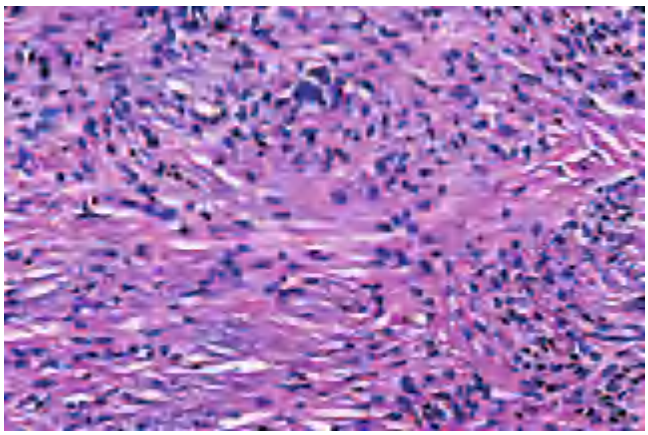

Fig. 49.5 Erythema elevatum diutinum. At higher magnification there is evidence of marked fibrosis and inflammatory infiltrates composed of lymphocytes, histiocytes, neutrophils and nuclear dust. (Courtesy of Dr Omar Sangueza, Wake Forest University School of Medicine, Winston-Salem, NC, USA.)

followed by swift return of the lesions. Niacinamide has also been used with good effect in EED [23]. High-potency topical or intralesional corticosteroids may minimize the size of lesions in patients with limited disease. Other therapies used for cutaneous small vessel vasculitis may also be effective in treating EED.

Eosinophilic vasculitis

SYN. RECURRENT CUTANEOUS EOSINOPHILIC NECROTIZING VASCULITIS [1,2]

Definition. A relatively recently described and rare vasculitis consisting of a predominantly centripetal purpuric papular rash, angio-oedema, peripheral blood eosinophilia and an eosinophilic necrotizing vasculitis of small vessels.

History. This condition was recently distinguished from other eosinophilic vasculitides that affect medium to large vessels (CSS; see later in this chapter) and from eosinophilic disorders in which pruritic papules and/or angio-oedema may occur, such as hypereosinophilic syndrome, episodic angio-oedema with eosinophilia, dermatitis herpetiformis, Wells' syndrome, polymorphic eruption of pregnancy or drug eruptions. Association with connective tissue diseases and with rheumatoid arthritis has been reported [3,4].

Aetiology and pathogenesis. The cause is unknown. As in other strongly eosinophilic disorders, eosinophil cytokines such as IL-5, and toxic eosinophil granule proteins such as the major basic protein, have been demonstrated in serum and tissues, respectively, and presumably play a part in the tissue damage. Neutrophil elastase is prominent around vessels, and mast cell degranulation occurs. Eosinophilic vasculitis has also been reported in a patient with the hypereosinophilic syndrome; in this patient, CD40 (a glycoprotein of the TNF receptor family) was considered to be important in pathogenesis [5].

Histopathology. Shows fibrinoid deposition and necrosis of small dermal vessels with an infiltrate of eosinophils and absent or minimal leukocytoclasis. Small epidermal

vesicles containing eosinophils may be present. Immunoglobulin deposition is not a feature. This eosinophilic small vessel vasculitis is distinct from other vasculitides such as CSS, in which medium to large vessels are affected, and from most drug-induced vasculitis in which eosinophils are generally scanty.

Clinical features. Recurrent pruritic papules and urticarial lesions occur at any site, especially the head and neck, with angio-oedema of the face and extremities. Either sex and any age group may be affected. The course is long and recurrent but fever, arthralgia and visceral involvement are absent. Raynaud's phenomenon and digital gangrene were reported in a patient with cutaneous eosinophilic vasculitis associated with the hypereosinophilic syndrome [5], but they can also occur in the hypereosinophilic syndrome in the absence of cutaneous eosinophilic vasculitis [6].

Treatment. Oral corticosteroids, intermittently or as prolonged maintenance therapy depending on response, appear to be effective.

Granuloma faciale

Definition. Granuloma faciale (GF) is an uncommon condition typified by asymptomatic cutaneous nodules occurring primarily on the face, with occasional extrafacial involvement. Granuloma faciale is limited to the skin, without any systemic manifestations. It is most common in males [1], typically in white people, although cases have been observed in populations of African or oriental ancestry [1,2].

History and nomenclature. Wigley [3] first described GF in 1945 as a type of eosinophilic granuloma, although it was distinguished from other eosinophilic granulomas by Lever and Leeper in 1950 [4]. Pinkus recommended the present name in 1952 [5].

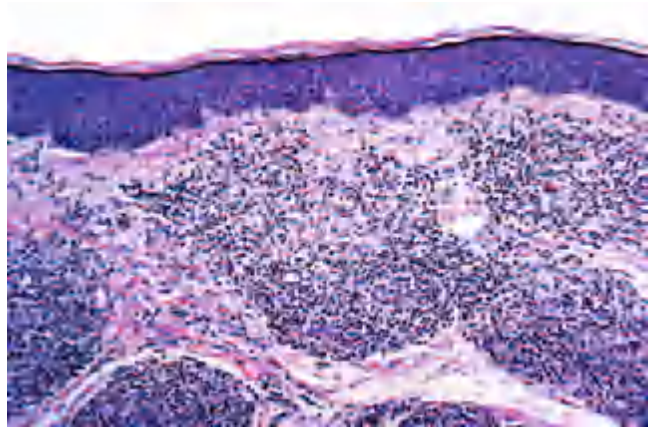

Fig. 49.6 Granuloma faciale. Low-power view shows perivascular nodular infiltrates within the dermis. (Courtesy of Dr Omar Sangueza, Wake Forest University School of Medicine, Winston-Salem, NC, USA.)

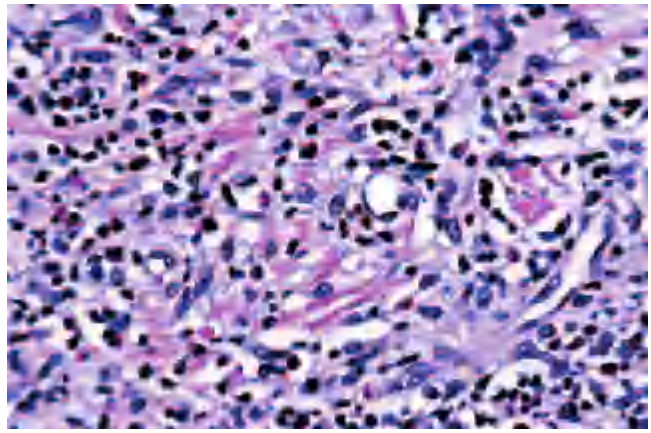

Fig. 49.7 Granuloma faciale. At higher magnification the infiltrate shows lymphocytes, eosinophils and a few neutrophils. (Courtesy of Dr Omar Sangueza, Wake Forest University School of Medicine, Winston-Salem, NC, USA.)

Aetiology and pathogenesis. Although the aetiology is somewhat unclear, GF is considered to be a histological variant of leukocytoclastic vasculitis with a prominent eosinophilic infiltrate, and confined to the skin [6]. Deposition of IgG in and around dermal vasculature has been demonstrated, lending some support to the idea that GF is immune complex-mediated [7].

Histopathology. GF is characterized by a mixed inflammatory infiltrate with a predominance of neutrophils and eosinophils, mainly in the upper half of the dermis but with occasional spread into the lower dermis and subcutaneous tissue (Figs 49.6 & 49.7). A band of normal collagen referred to as a 'Grenz' zone typically separates the inflammatory infiltrate from the epidermis and pilosebaceous appendages. Nuclear dust (fragmented neutrophil nuclei) may be observed near capillaries. Vasculitis, with

Fig. 49.8 Granuloma faciale. A reddish-brown plaque on the nose. (Courtesy of Dr G. Dawn, Cumberland Infirmary, Carlisle, UK.)

fibrinoid deposits near and within vessel walls, as well as haemorrhage, may be noted.

Clinical features. Lesions of GF are soft brown-red nodules or plaques that most commonly occur on the face (Fig. 49.8), although extrafacial involvement does rarely occur. The nodules or plaques are smooth, with prominent follicular orifices and telangiectatic surface changes or scaling. Lesions of GF never ulcerate. They are almost always asymptomatic, although some patients may describe itching, burning or pain associated with the lesions [8].

Diagnosis. A definitive diagnosis of GF requires clinically consistent lesions and a confirmatory biopsy. Although most laboratory studies are normal, mild peripheral blood eosinophilia may be present [9].

Treatment. A wide variety of treatment methods, both surgical and medical, have been used to treat GF. Examples include dermabrasion [10], laser treatments using both argon [11] and carbon dioxide (CO_2) lasers [10], electrosurgery [10], cryosurgery [12] and psoralen with ultraviolet A (PUVA) [13], as well as medical treatments with dapsone [14], clofazimine [15], antimalarial medications [16] and intralesional or systemic corticosteroids [9,16]. A therapeutic ladder for GF is depicted in Table 49.8.

Acute haemorrhagic oedema of childhood

SYN. HAEMORRHAGIC OEDEMA OF CHILDHOOD; ACUTE HAEMORRHAGIC OEDEMA OF INFANCY; FINKELSTEIN'S DISEASE; SEIDLMAYER'S SYNDROME; PURPURA EN COCARDE AVEC OEDEME; POST-INFECTIOUS COCKADE PURPURA

Definition. Acute haemorrhagic oedema of childhood (AHEC) is a rare disorder, which has almost exclusively cutaneous manifestations. It most commonly occurs in children under 2 years old. Patients with AHEC often have recently had an upper respiratory infection and/or have been treated with antibiotics. Clinical features include petechiae and ecchymoses of the head and distal extremities.

History and nomenclature. Snow first described AHEC in 1913.

Aetiology and pathogenesis. Infections, drugs or vaccines may trigger AHEC, which may be a variant of childhood cutaneous small vessel vasculitis [1,2].

Histopathology. Leukocytoclastic vasculitis is evident in lesions of AHEC.

Clinical features. Non-tender facial oedema may be the presenting sign of AHEC lesions, which are often asymmetrical. There is sudden development of tender oedematous petechiae and ecchymoses on the head and distal extremities, as well as large annular, coin-shaped or targetoid lesions that may later develop into bullae or necrotizing lesions. Lesions of AHEC start distally and spread proximally, sometimes involving the scrotum in males. Clinically, patients with AHEC are typically medically stable, although they may be febrile. Although AHEC may rarely involve joints, the gastrointestinal tract or the kidneys with vasculitic manifestations, the typical course of AHEC is a disorder that lasts 1–3 weeks with no persistent adverse effects following resolution [1,2].

Diagnosis. AHEC may be diagnosed only after meningococcaemia, erythema multiforme, UV, cutaneous small vessel vasculitis and Kawasaki disease have been ruled out.

Treatment. Wound care is the only treatment necessary for patients with AHEC.

Nodular vasculitis

SYN. ERYTHEMA INDURATUM OF BAZIN AND OF WHITFIELD

Definition. Nodular vasculitis (NV) is a chronic relapsing lobular panniculitis with septal vasculitis. It is characterized by a vasculitis of subcutaneous arteries and veins, with subsequent ischaemia of subcutaneous tissue which results in clinical suppuration. The cause may be a hypersensitivity reaction to an antigenic trigger such as a bacterial infection. It occurs primarily in middle-aged women, and is manifest as tender nodules or plaques on the legs that may later progress to ulceration.

History and nomenclature. Erythema induratum of Bazin was initially described by Bazin in 1861 as indurated plaques on the legs of women of middle age [1]. In 1900, French dermatologists described an association between erythema induratum and tuberculosis [2], although British physicians reported similar patients without evidence of tuberculosis at approximately the same time, a pattern which was later designated 'Whitfield's erythema induratum' [3–5]. In the middle of the 20th century, American physicians suggested the term nodular vasculitis for Whitfield's erythema induratum, which was thought to be distinct from erythema induratum of Bazin [6]. Recently, there has been a move to consider erythema induratum of Bazin and nodular vasculitis as the same entity, regardless of aetiology [7–9].

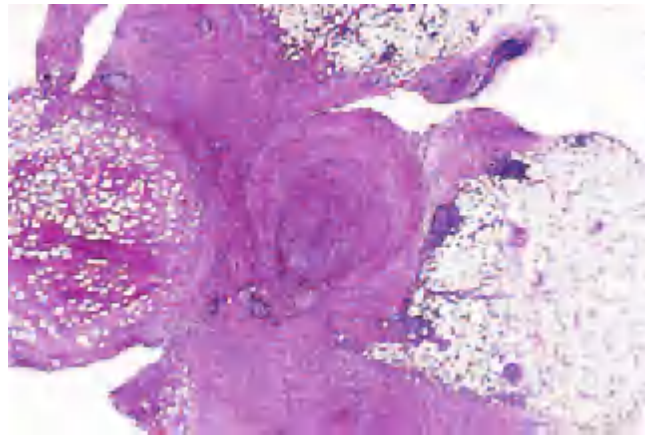

Fig. 49.9 Nodular vasculitis. Lobular panniculitis with prominent inflammation. Note the alteration of a vascular structure in the middle of the photograph. (Courtesy of Dr Omar Sangueza, Wake Forest University School of Medicine, Winston-Salem, NC, USA.)

Aetiology and pathogenesis. Several antigenic triggers have been implicated as the source for the hypersensitivity reactions with resultant subcutaneous vasculitis and lobular panniculitis in NV. These include bacterial infections, such as streptococcal or mycobacterial infections, and drugs. The pathogenesis may be similar to that of cutaneous small vessel vasculitis, but with septal vessels in the panniculus as the target.

Histopathology. Controversy exists as to whether arteries, veins or both are affected in NV. Regardless of the type of vessel involved, the early changes are of leukocytoclastic vasculitis of vessels in the subcutaneous tissue leading to ischaemic changes, followed by inflammation and injury to lipocytes [10]. The resulting occlusion leads to ischaemia and necrosis of fat lobules that may eventually involve the overlying dermis. Early in the disease process, the necrotic subcutaneous fat demonstrates fat cysts bordered by a finely granular eosinophilic substance with pyknotic nuclei. Later, foamy histiocytes encircle the necrotic areas (Figs 49.9 & 49.10).

Clinical features. NV is manifest as tender, dusky, often suppurative, nodules or plaques on the posterolateral aspect of the legs. It is typically seen in healthy, middle-aged, sometimes obese, women who may have venous stasis. Patients often have 'thick' calves with erythro-

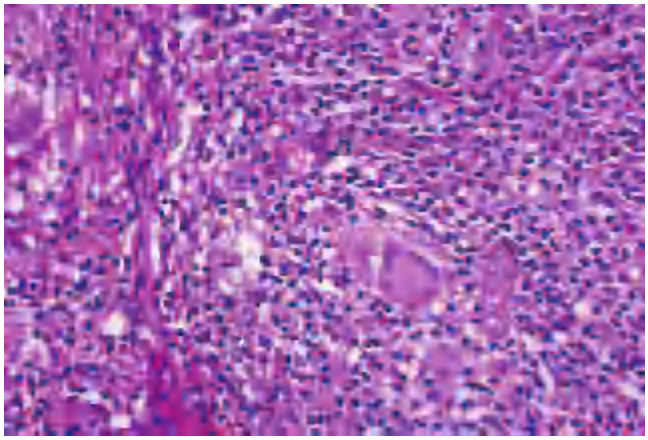

Fig. 49.10 Nodular vasculitis: the inflammatory infiltrate within the vessel wall is composed of lymphocytes and histiocytes, some of them multinucleated. (Courtesy of Dr Omar Sangueza, Wake Forest University School of Medicine, Winston-Salem, NC, USA.)

cyanosis and perifollicular erythema. Lesions may be unilateral, are often inflamed and may progress to ulceration. The lesions of NV heal slowly, sometimes leaving an atrophic scar. The course of NV is chronic, with relapses typically occurring over several years. Nodular vasculitis may sometimes be seen in men, with unilateral nodules or plaques involving the anterior aspect of the thighs and legs, and other locations.

Lesions that have previously been termed 'erythrocyanosis with nodules' may have been examples of NV, or alternatively a pattern of perniosis (Chapter 23). Equestrian panniculitis is a type of perniosis.

Diagnosis. NV is a clinicopathological diagnosis, which requires deep incisional biopsy of active lesions. In cases where a tuberculous aetiology is suspected, a tuberculin skin test and chest X-ray should be performed. Evaluation is otherwise similar to that for patients with cutaneous small vessel vasculitis.

Treatment. In patients in whom tuberculosis is demonstrated, at least a 9-month course of triple-agent antituberculosis therapy should be given (Chapter 28) [11,12]. In non-tubercular cases, supportive measures, such as compression hosiery, bed rest and NSAIDs are recommended. Systemic corticosteroids may also be considered, as well as potassium iodide, which has been reported as an effective treatment of NV [13,14]. Other treatments outlined for patients with small vessel vasculitis might also be appropriate for patients with NV. The treatment of NV is shown in Table 49.9.

Table 49.9 Treatment of nodular vasculitis.

Tuberculosis present
Triple-agent antituberculosis therapy for a minimum of 9 months
Tuberculosis not present
Palliative treatments
• Compression hosiery
• Bed rest
• Non-steroidal anti-inflammatory drugs
Systemic corticosteroids

Polyarteritis nodosa

SYN. PERIARTERITIS NODOSA

Definition. A disease typically affecting medium-sized arteries, PAN is a segmental vasculitis. Affected patients may have several signs and symptoms involving multiple organ systems. Ischaemia, infarcts and haemorrhage result from the vasculitis and lead to end-organ damage in patients with PAN. The incidence of PAN is 4.6–9 per million per year [1], with men more commonly affected than women. PAN has been described in all racial groups [2–4].

History and nomenclature. Kussmaul and Maier [5] originally described 'periarteritis nodosa' in 1866. The disease was termed 'polyarteritis nodosa' in 1903 after Ferrari recognized its multivessel involvement as well as its transmural inflammation.

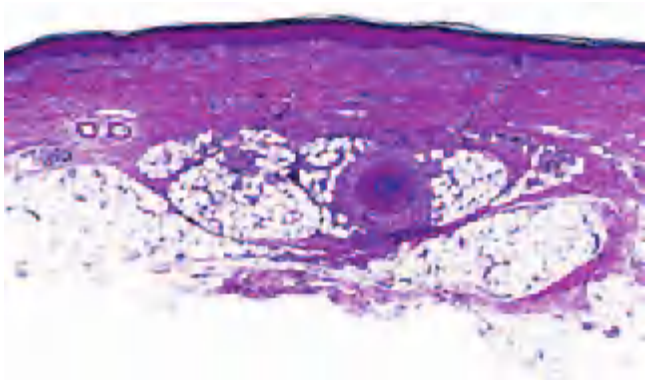

Fig. 49.11 Polyarteritis nodosa. Note the characteristic targetoid alteration of a vascular structure within the subcutaneous tissue. (Courtesy of Dr Omar Sangueza, Wake Forest University School of Medicine, Winston-Salem, NC, USA.)

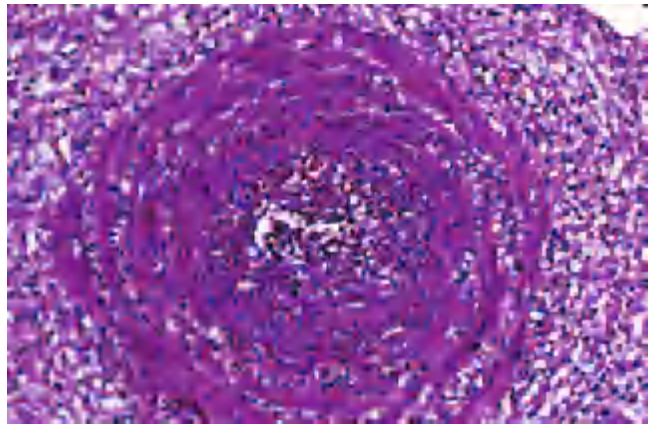

Fig. 49.12 Polyarteritis nodosa. Higher magnification demonstrates the partial destruction of the vascular wall and the inflammatory infiltrate composed of lymphocytes and neutrophils. (Courtesy of Dr Omar Sangueza, Wake Forest University School of Medicine, Winston-Salem, NC, USA.)

Aetiology and pathogenesis. Patients with PAN commonly have underlying infections caused by organisms such as streptococci, hepatitis B or C viruses. Approximately 5–7% of patients with PAN have associated hepatitis B virus infection, although incidences as high as 10–54% have been reported [1,6]. Other associations with PAN include SLE, inflammatory bowel disease, hairy cell leukaemia, familial Mediterranean fever and Cogan's syndrome. Although it has yet to be proven, one theory about the pathogenesis of PAN is that it may be related to the increased shear stress that occurs at arterial branch points, causing up-regulation of endothelial inflammatory factors [7–10]. There may also be a greater number of macrophages in the tunica intima at these stress points [11,12], adding to the susceptibility of endothelial cells at arterial branch points to inflammatory activity.

Histopathology. Biopsy material shows an inflammatory necrotizing obliterative arteritis affecting small and medium-sized arteries, with focal panniculitis. Aneurysms can form as blood vessel walls become weak and potentially necrotic secondary to nodose swellings caused by focal vasculitis. The most severely affected arterial branch points of vessels may rupture, leading to luminal thrombosis and obliteration, thus resulting in widespread distal tissue ischaemia and ultimately necrosis (Figs 49.11 & 49.12).

Clinical features. The distribution of vasculitic lesions of PAN is variable, accounting for the great variety of reported signs and symptoms. Constitutional symptoms are common, including fever, weight loss, arthralgia and malaise; more specific signs and symptoms occur relating to affected organ systems, such as congestive heart failure, hypertension, abdominal pain, orchitis and mononeuritis multiplex. Typically, there is no pulmonary involvement in PAN. Although not specific to PAN, arteriography may demonstrate multiple dilatations along medium-sized arteries in the renal, hepatic and visceral vasculature. Up to 60% of patients with PAN have cutaneous manifestations [13], usually a subcutaneous nodule or group of nodules along the course of a blood vessel. Typically seen around the knee, anterior lower leg and dorsum of the foot, these 5–10-mm nodules may be tender, pulsatile or secondarily ulcerated, with either normal or erythematous overlying skin. Other cutaneous findings include livedo reticularis with or without ulceration, digital gangrene and 'punched-out' ulcers. Cutaneous lesions in patients with PAN are depicted in Figs 49.13 and 49.14.

Fig. 49.13 Polyarteritis nodosa. Note the location of the lesion on the patient's foot.

Diagnosis. Although patients may have laboratory abnormalities such as leukocytosis with neutrophilia, thrombocytosis, normocytic anaemia, hypergammaglobulinaemia and cryoglobulinaemia, as well as haematuria,

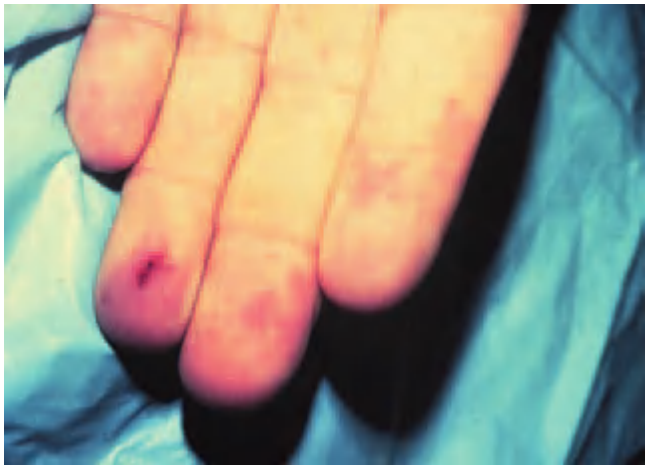

Fig. 49.14 Polyarteritis nodosa. Multiple lesions on the fingers.

proteinuria and the presence of casts in the urine, the diagnosis of PAN is best made from muscle or sural nerve biopsy. The sensitivities of the muscle and sural nerve biopsy specimens are 60% and 70%, respectively, in cases of symptomatic muscle involvement and nerve involvement demonstrated electrophysiologically [14,15]. Renal biopsy specimens (when urinalysis is abnormal) and angiography and/or aortography demonstrating pathognomonic aneurysmal dilatation of vessel walls may also be used to help establish a diagnosis of PAN. Although very sensitive, skin biopsy is not specific, and is not sufficient to establish the diagnosis of PAN. The P-ANCA is positive in 20% of cases of PAN, and is more commonly seen in MPA or CSS. A positive C-ANCA is typically associated with WG, CSS or MPA but not with PAN.

Treatment. Treatment with systemic corticosteroids remains the mainstay of therapy for systemic PAN. The use of corticosteroids has improved the 5-year survival in patients with PAN from 10–13% to 48–57% [1,4,16,17]. A regimen of 1–2 mg/kg/day of prednisone or prednisolone is typically used for patients with PAN with visceral involvement, and is eventually tapered to a maintenance regimen. The response to treatment may be evaluated by sequential measurement of the ESR. Although combination therapy of corticosteroids and cyclophosphamide may improve survival in patients with severe PAN [18], no controlled trials have demonstrated the level of absolute benefit necessary for cyclophosphamide to become the routine adjunct to corticosteroid therapy [19]. Plasma exchange combined with IFN-α_2 and/or vidarabine is an effective treatment for patients with PAN associated with hepatitis B infection. Some success has been reported with the use of these antiviral treatments without concomitant immunosuppression [20–22]. Corticosteroids should only be used initially on a short-term basis in patients with hepatitis B-associated PAN because of the possibility of viral replication [6,23].

Microscopic polyangiitis

SYN. MICROSCOPIC POLYARTERITIS NODOSA; MICROSCOPIC POLYARTERITIS

Definition. MPA is a systemic vasculitis affecting blood vessels ranging in size from capillaries to medium-sized arteries. In some instances, there is only venous involvement with MPA. MPA is strongly associated with lung involvement (primarily alveolar haemorrhage) and crescentic glomerulonephritis [1]. The incidence of MPA is 6–8 per million per year [2].

History and nomenclature. Patients demonstrating signs of PAN without cutaneous nodules were first described by Wohlwill in 1923, and then by Arkin in 1930. In 1948, articles were published that distinguished MPA from PAN. In 1994, MPA was termed microscopic polyangiitis instead of microscopic polyarteritis by a consensus conference because of the lack of arterial involvement in some patients and the involvement of vessels other than arteries [1].

Aetiology and pathogenesis. The exact pathogenesis of MPA is poorly understood, although it is considered a pauci-immune vasculitis because of the relative absence of immunoglobulins or complement in affected vessel walls [3–7]. P-ANCA may have a role in the aetiology by activating neutrophils and monocytes via interactions with enzymes on the surface of or directly around endothelial cells [8], initially causing direct injury to the vessel endothelium. This is demonstrated in early findings of pauci-immune small vessel vasculitides in which there is fibrin accumulation in the subendothelium [7,9] as well as lysis of leukocytes within the vascular space [9] associated with endothelial injury. Products from neutrophils and monocytes (such as serine proteinases and metalloproteinases) may be inactivated at distant sites [10], accounting for the large degree of local tissue injury in lesions of MPA. Direct interactions between these cells and the endothelium may also explain the predilection of the disease for small rather than larger sized vessels. In some patients, there is a relationship between MPA and infection with either hepatitis B or C viruses [11,12].

Histopathology. Histological specimens from MPA lesions demonstrate segmental vascular necrosis. Neutrophils and monocytes permeate vessel walls, causing leukocytoclasia, accumulation of fibrin and haemorrhage. Biopsy specimens from lesions of palpable purpura demonstrate leukocytoclastic vasculitis.

Clinical features. Many patients with MPA initially experience constitutional symptoms, including fever, weight loss, myalgia and arthralgia. These may be present for several years before the onset of the pulmonary and renal disease that often occurs in patients with MPA. Between 79% and 90% of patients with MPA have necrotizing glomerulonephritis, and 25–50% have lung involvement, sometimes leading to pulmonary–renal syndrome [13], and leading to pulmonary haemorrhage in up to 29% of patients [14–16]. Symmetrical peripheral neuropathies or mononeuritis multiplex may occur in patients with MPA, but less commonly than in individuals with PAN. Although nearly half of patients have palpable purpura upon presentation [17], the presence of nodules should raise the suspicion of PAN, WG or CSS.

Diagnosis. MPA must be clinically distinguished from other vasculitides such as WG, CSS, CSVV or PAN. In patients with MPA, positive P-ANCA and rheumatoid factor tests are common, unlike in patients with PAN. About 50% have a positive MPO P-ANCA, and 30% a positive PR3 C-ANCA. Some authors claim that the presence of small vessel vasculitis in the skin can distinguish MPA from PAN, stating that cutaneous small vessel vasculitis lesions do not typically occur in patients with PAN, although this is controversial. When palpable purpuric lesions are present in the absence of constitutional symptoms, patients are more likely to have CSVV than MPA, although with constitutional symptoms the differential diagnosis can also include WG and CSS. Small vessel vasculitis and systemic symptoms in the absence of granulomatous inflammation or asthma suggests MPA instead of CSS or WG [1].

Treatment. Initially, patients with MPA should be treated with high-dose corticosteroids if renal and/or pulmonary disease is present. Cytotoxic agents (e.g. cyclophosphamide) are sometimes used as corticosteroid-sparing agents when treating patients with severe disease, although strong evidence-based support, such as that supporting their use in patients with WG, is lacking. The course of MPA is characterized by relapses, in contrast with that of PAN [18].

Cutaneous polyarteritis nodosa

SYN. BENIGN CUTANEOUS PERIARTERITIS NODOSA; LIVEDO WITH NODULES

Definition. Cutaneous polyarteritis nodosa (C-PAN) is a variant of PAN that is limited primarily to the skin. Controversy exists over whether or not C-PAN simply represents an early or more limited form of PAN [1,2]. The course of C-PAN is typically benign and relapsing, despite the presence of moderate constitutional symptoms and mild nerve and muscle involvement in some patients [3,4].

History and nomenclature. C-PAN was first described by Lindberg in 1931 [5] as a more benign variant of systemic PAN that did not have visceral involvement.

Aetiology and pathogenesis. Infections such as *Streptococcus* (particularly in children), parvovirus B19, HIV and hepatitis B virus, as well as inflammatory bowel disease (IBD), have been associated with C-PAN [6], although the exact aetiology is unknown. Immunological mechanisms are thought by some authors to be involved only in the pathogenesis of systemic PAN, and not in the development of C-PAN [7].

Histopathology. Early in the course of C-PAN, there is a predominantly neutrophilic inflammatory infiltrate in the walls of medium-sized arteries and arterioles of septae in the upper portions of the subcutaneous fat. The involved vessels classically demonstrate a target-like appearance resulting from an eosinophilic ring of fibrinoid necrosis. Later in the disease process the infiltrate becomes less neutrophilic, consisting predominantly of lymphocytes and histiocytes. Complement and IgM deposits in vessel walls of lesions of C-PAN from some patients may be demonstrated by direct immunofluorescence [8]. Unlike those of systemic PAN, lesions of C-PAN do not typically involve arterial bifurcations.

Fig. 49.15 Cutaneous polyarteritis nodosa. Erythematous lesions on the leg.

Clinical features. Although some patients with C-PAN may report constitutional symptoms as well as chronic mild involvement of both muscles and nerves [3,4], cutaneous manifestations are the most striking feature of the disease. Dermal or subcutaneous nodules are most commonly located on the lower legs near the ankles (Fig. 49.15) and may extend proximally to the thighs, buttocks, arms or hands. Patients may report tenderness associated with the nodules, which may ulcerate, or more commonly demonstrate livedo reticularis, which may be necrotizing. Gangrene of the digits can ultimately occur, most commonly in children with C-PAN [9,10].

Diagnosis. Patients with necrotizing lesions of livedo reticularis must be evaluated for vasculitis or vasculopathy (e.g. antiphospholipid antibody syndrome, cholesterol emboli or other factors that can produce non-vasculitic vessel occlusion; see Chapter 48). If nodules are present, they should be biopsied by incisional biopsy, as a panarteritis of muscular arteries would confirm a diagnosis of C-PAN. The distinction from systemic PAN requires patient evaluation by history, physical examination, screening laboratory tests and ongoing follow-up.

Treatment. Although no double-blind prospective trials have been performed, several reports suggest that NSAIDs and salicylates can be an effective treatment for symptoms of C-PAN [11]. High-dose corticosteroids, with the dose subsequently tapered off, may occasionally be necessary for some patients [12,13]. Although no controlled trials have been performed, penicillin is often

used for treatment and prophylaxis in children with C-PAN because of the strong association with streptococcal infection. Other treatments documented in anecdotal reports include dipyridamole, sulfapyridine, pentoxifylline and dapsone in patients with C-PAN. A low-dose weekly methotrexate regimen (7.5–20 mg/week) has been successful in some patients with skin lesions unresponsive to corticosteroids intralesionally and orally [14]. Anecdotally, a low-dose weekly methotrexate regimen and gradient support hosiery are adequate therapy for the majority of patients with C-PAN.

Wegener's granulomatosis

Definition. WG is classically described as a triad consisting of systemic small vessel vasculitis, necrotizing granulomatous inflammation of both the upper and lower respiratory tracts, and glomerulonephritis. If not treated, WG can lead to end-organ damage and/or death. Affecting males and females equally, the incidence of WG is 5–10 per million per year, with the majority of cases occurring in white people [1–3]. The average age at onset is 40 years [4].

History and nomenclature. The first patient with WG was described in 1931 by Klinger, but the disease was later defined in 1936 by Wegener who described three patients.

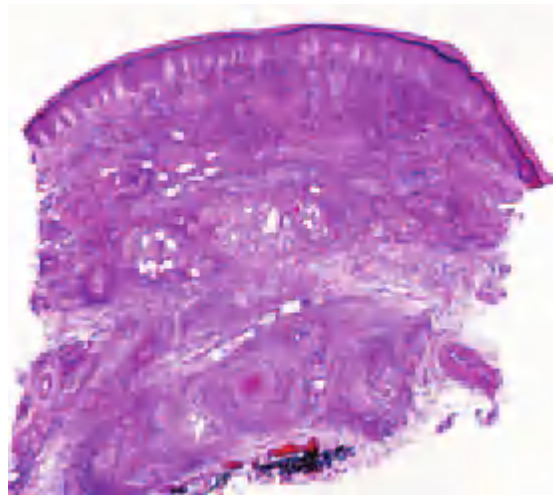

Fig. 49.16 Wegener's granulomatosis. There is extensive leukocytoclastic vasculitis involving the entire dermis. (Courtesy of Dr Omar Sangueza, Wake Forest University School of Medicine, Winston-Salem, NC, USA.)

Aetiology and pathogenesis. Although the pathogenesis of WG is not well understood, it is believed that it may involve an amplified immune response to an antigenic stimulus, such as an infection. One theory regarding the pathogenesis of WG is that neutrophils are activated via cytokines or apoptosis and degranulate, expressing cytosolic proteins on their surfaces and releasing harmful oxygen radicals as well as chemoattractants [5–8]. This enables ANCA to bind cytoplasmic antigens such as PR3, at which C-ANCA are directed, and MPO, at which P-ANCA are directed. Activated neutrophils then attract additional neutrophils and damage vascular endothelium by attaching to blood vessel walls [9–11]. Another theory about the role of ANCA in the pathogenesis of WG is that activated neutrophils located at damaged blood vessels release antigens, causing a secondary ANCA response [12].

Histopathology. Biopsy specimens of skin lesions usually show a perivascular lymphocytic infiltrate, but this is non-specific and may not be directly related to the pathogenesis of WG [13]. Leukocytoclastic vasculitis and/or granulomatous inflammation may be present in up to 50% of skin biopsy specimens (Figs 49.16 & 49.17), although granulomatous inflammation around vessels or palisading necrotizing granulomas are uncommonly demonstrated.

Clinical features. Features of the classic triad of WG are not always all present early in the course of the disease, which can make the diagnosis difficult. Furthermore, presentation without involvement of the classical sites can occur. However, in up to 80% of patients, symptoms involving the upper or lower respiratory tract are present

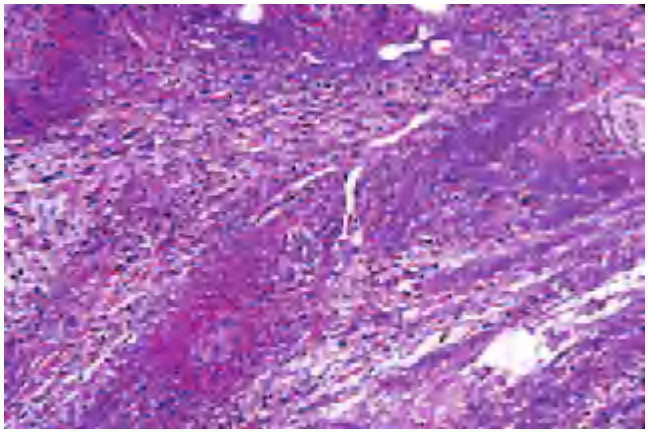

Fig. 49.17 Wegener's granulomatosis. Note the extensive area of collagen degeneration, destruction of vessels and mixed inflammatory infiltrate. (Courtesy of Dr Omar Sangueza, Wake Forest University School of Medicine, Winston-Salem, NC, USA.)

Fig. 49.18 Wegener's granulomatosis: ulcerated lesions.

[14], and at presentation approximately 73% of patients will have nasal, sinus, tracheal or ear involvement. Less than half of all patients with WG present with pulmonary infiltrates or nodules. Renal disease is initially present in only 18% of patients, although approximately 77% will eventually develop glomerulonephritis [15]. Although 40% of patients with WG will eventually manifest skin findings, cutaneous manifestations and oral ulcers are only found in 13% and 6% of patients at initial presentation, respectively [15]. The most common cutaneous manifestation of WG is palpable purpura, although others include tender subcutaneous nodules, papules, vesicles and petechiae, as well as pyoderma gangrenosum-like lesions. It is thought that patients previously diagnosed as having 'malignant pyoderma' may actually have had lesions secondary to WG. Papulonecrotic lesions, most commonly on the limbs but also occurring on the face and scalp, are ulcerated papules that may be mistaken for rheumatoid nodules. However, these non-specific lesions (also found in CSS, rheumatoid arthritis, SLE, IBD and some infectious states) differ from rheumatoid nodules in that they ulcerate and also that they are mobile within the dermis [16–18]. Oral ulcers are the second most common mucocutaneous sign of WG, and it has been suggested that 'strawberry' gingival hyperplasia is pathognomonic [19]. The upper respiratory tract is most commonly affected by WG, with otitis, epistaxis, rhinorrhoea and sinusitis as common presenting signs and symptoms. A saddle-nose deformity may result from necrotizing granulomas of the nasal mucosa. Lower respiratory signs and symptoms include cough, dyspnoea, chest pain and haemoptysis. An example of ulcerative lesions in a patient with WG is shown in Fig. 49.18.

Diagnosis. WG must be differentiated from CSS. Important differences between these two larger vessel vasculitides are the lack of upper respiratory involvement and of severe glomerulonephritis in CSS, and the presence of asthma and eosinophilia in CSS but not in WG. Laboratory findings in WG include elevated ESR and C-reactive protein, anaemia, leukocytosis and positive rheumatoid factor [2,3]. Although a small percentage of patients have a positive P-ANCA or no ANCA reactivity, up to 80% of patients have a positive C-ANCA (with anti-PR3 specificity) [20]. Those few patients with no ANCA reactivity may well have localized WG and a better prognosis when compared with those who are ANCA-positive [21,22]. Nodular densities from necrotizing granulomatous inflammation of lung tissue and pulmonary haemorrhage may be present on chest radiography; almost any change on chest radiography may represent WG, with the exception of hilar adenopathy [23].

Treatment. WG is most successfully treated using a combination of corticosteroids and cytotoxic agents, such as cyclophosphamide. This combination of therapy results in a significant resolution of symptoms in more than 90% of patients, with remission in 75%, and 87% surviving between 6 months and 24 years [15]. However, the median survival for untreated WG remains only 5 months, and this prognosis is not appreciably altered by treatment with corticosteroids given as a monotherapy. Long-term treatment with trimethoprim-sulfamethoxazole (co-trimoxazole) has been documented to reduce the incidence of relapses, although side effects are relatively common [24]. The benefit of this treatment may be because of a decrease in respiratory infections (it is known that nasal staphylococcal carriage increases the risk of relapse), although such infection was not a consistent factor in patients with relapses in this study.

Churg–Strauss syndrome

SYN. ALLERGIC GRANULOMATOSIS; VASCULITIS OF CHURG AND STRAUSS

Definition. CSS is a rare vasculitis affecting multiple organ systems. The majority of patients demonstrate cutaneous findings while in the active phase of the disease. The disease is characterized by asthma, peripheral blood eosinophilia and necrotizing vasculitis with extravascular granulomas.

History and nomenclature. In 1939, the first patients with an allergic disease not classified as periarteritis nodosa were described by Rackermann and Greene. Churg and Strauss later described the syndrome and its histopathological characteristics in 1951.

Aetiology and pathogenesis. The aetiology of CSS is unknown, although vaccination, desensitization and rapid discontinuance of corticosteroids have been associated with the onset of symptoms [1]. Leukotriene antagonists have been associated with development of CSS (Chapter 59). The pathogenesis of CSS is not completely understood. Immune complex deposition was once thought to be the mechanism of vasculitis in CSS, although eosinophils, mediated by a Th2 response, are now thought to be the effector cells in the disease [2]. Serum levels of eosinophil cationic protein, which is a marker of eosinophil activation, often correspond with disease activity [3] and may be used to predict relapse [4]. Recent evidence based on detection of both eosinophil (major basic protein and neurotoxin) and neutrophil (elastase) enzymes, and of eosinophil-activating cytokines, suggested that both cell types are involved in the pathogenesis of CSS [5].

Histopathology. CSS is characterized by three key features: eosinophilic infiltration of tissue, formation of extravascular granulomas of the visceral and cutaneous tissue, and necrotizing vasculitis involving both arteries and veins. A biopsy specimen of a cutaneous lesion from a patient with CSS may demonstrate any or all of these features [6]. The granulomas of CSS contain necrotic polymorphonuclear leukocytes, eosinophils, severe fibrinoid and fibrillar collagen degeneration, and a proliferation of granulomatous tissue.

Clinical features. Three phases of CSS have been described. The first phase, which may continue for years, consists of allergic rhinitis, nasal polyps, asthma and peripheral blood eosinophilia. The asthma component of this phase typically begins in adulthood, in contrast with allergic asthma. The second phase of CSS is vasculitis; this phase is characterized by disease affecting almost all organ systems, including cardiac, pulmonary, nervous, gastrointestinal, renal, genitourinary and musculoskeletal systems. In this vasculitic phase, 70% of patients have skin lesions. The third stage of CSS is characterized by allergic rhinitis, asthma, hypertension resulting from damage to the kidneys that occurred in the second phase and peripheral neuropathies. There is typically complete resolution of damage to other organ systems. Nearly half of patients in all phases of the disease have cutaneous manifestations [1,6], with approximately 5% demonstrating cutaneous vasculitis [6]. Palpable purpura and infiltrated nodules (typically located on the scalp or limbs) [7] are the most common skin manifestations, but livedo reticularis,

migratory erythema, new-onset Raynaud's phenomenon, aseptic pustules or vesicles, and infiltrated papules may also be present.

Diagnosis. The manifestations of CSS may be easily confused with lesions of WG, although CSS is associated more strongly with both asthma and involvement of the gastrointestinal tract, spleen and heart, in contrast with the upper airway disease and strong association with renal disease in WG. The triad of asthma, eosinophilia and extravascular granulomas may also be used to distinguish CSS from other disease processes.

Treatment. Corticosteroids alone have been shown to be an effective treatment of CSS, with clinical remission achieved in over 90% of patients. However, the addition of cytotoxic agents may be useful in patients with recalcitrant disease, although no double-blind prospective trials have been performed to establish their use.

Giant cell arteritis

SYN. TEMPORAL ARTERITIS; CRANIAL ARTERITIS

Definition. Considered a disease of persons over 50 years of age, giant cell arteritis is a granulomatous panarteritis associated with considerable morbidity, including blindness. It can affect any medium or large artery and typically demonstrates signs or symptoms including an elevated ESR, pain and morning stiffness often involving the neck, shoulders and pelvis [1]. It is three to four times more common in females than males, and the incidence is higher in persons of northern European descent than those from more southern regions. However, giant cell arteritis can occur in various races and ethnic groups [2].

History and nomenclature. Giant cell arteritis was described clinically by Hutchinson in 1890, who discussed an older man who displayed swelling of the temporal arteries. In 1931, giant cell arteritis was described both clinically and pathologically by Horton, Magath and Brown (cited in [2]).

Aetiology and pathogenesis. The aetiology of giant cell arteritis is unclear. The pathogenesis is thought to involve IFN-γ-producing T lymphocytes that are in the adventitia of inflamed arteries [3]. Multinucleated giant cells and macrophages located at the junction of the tunica media and tunica intima may be stimulated by IFN-γ [4,5] to produce platelet-derived growth factor (PDGF) and vascular endothelial growth factor (VEGF) [6], thus stimulating the production of myofibroblasts, which may proliferate and deposit extracellular matrix in the subendothelium of the artery, as well as angiogenesis (for support of the new hyperplastic intima). PDGF has been shown to play an important part in occluded arterial lumina [7]. Macrophages may also produce reactive oxygen species and matrix metalloproteinase-2 (MMP-2) [8], and may contribute to the dissolution of the elastic lamina with subsequent intimal hyperplasia [9] by creating a path for the myofibroblasts to migrate to the subendothelium, leading to intimal hyperplasia and subsequent occlusion of the arterial lumen.

Histopathology. Although it can extend anywhere from the tunica intima to the tunica adventitia, giant cell arteritis is a chronic granulomatous inflammatory disease that typically affects the tunica media of medium or large arteries. The non-specific infiltrate includes histiocytes, lymphocytes, monocytes, giant cells and sometimes eosinophils.

Clinical features. Cutaneous involvement is uncommon in giant cell arteritis; the most common skin finding is painful nodules over involved superficial arteries. The classic sign of giant cell arteritis is a tender, swollen, nodular, pulseless, indurated temporal artery, although it is uncommon to find all of these pathognomonic features in a single patient. Scalp ulcers occur rarely. Tongue involvement may be manifest as a swollen, cool, atrophied, cyanotic or tender tongue. Other extracutaneous symptoms include, most commonly, headache, jaw claudication, sore throat, vestibular symptoms, earache and the feared involvement of the retinal arteries causing unilateral blindness in up to 17% of patients, followed up to 7 days later by blindness in the second eye. Intracranial involvement, including transient ischaemic attacks (TIAs), infarcts or psychiatric conditions, is unusual but may also occur. Medium or large arteries other than those of the head and neck are affected by this granulomatous vasculitis in only 10–15% of cases. Many patients with giant cell arteritis also have features indicative of polymyalgia rheumatica, which includes at least 4 weeks of

aching and stiffness of the muscles of the neck, shoulders and pelvic girdle, an elevated ESR and rapid response to corticosteroids.

Diagnosis. A pathological diagnosis from a biopsy specimen of the temporal artery is the gold standard for the diagnosis of giant cell arteritis. However, in 90–100% of patients with giant cell arteritis, the ESR is greater than 40 mm/h, although the degree of elevation of the ESR does not parallel the severity of the disease.

Treatment. The first-line treatment for giant cell arteritis is systemic corticosteroids, as the disease is usually very corticosteroid responsive [10]. The dose of corticosteroids can be tapered after remission, although a regimen of 2.5–20 mg/day for at least 2 years is often required for maintenance. In one blinded controlled trial, methotrexate was useful as a corticosteroid-sparing treatment in patients with giant cell arteritis [11].

Takayasu's arteritis

SYN. TAKAYASU'S DISEASE; TAKAYASU'S SYNDROME; AORTIC ARCH SYNDROME; PULSELESS DISEASE; OCCLUSIVE THROMBOARTERIOPATHY; AORTITIS SYNDROME

Definition. Most commonly seen in patients from Japan, Korea, China, South East Asia, India, Africa, Mexico or South America, Takayasu's arteritis is a rare chronic recurrent inflammatory vasculitis involving the aorta and the great vessels. Takayasu's arteritis is uncommon in males, the majority of cases occurring in women between the ages of 15 and 30 years. It can also be seen in children, in whom it has a more aggressive course than in adults.

History and nomenclature. Although Takayasu's arteritis was named after a Japanese ophthalmologist, the first descriptions of the disease were published in 1830 by Rokushu Yamamoto. Autopsy confirmation of the vasculitis was described in 1920 by Ohta [1].

Aetiology and pathogenesis. Infective, autoimmune and genetic factors have been implicated [2]. An association with connective tissue diseases such as rheumatoid arthritis supports the autoimmune theory, although no autoantigens have been identified as triggers for a potential autoimmune response. Tuberculosis infection has been associated with Takayasu's arteritis in some populations, suggesting a possible role for this infection in its pathogenesis [2–4]. Viral infections may also play a part in triggering the disease [5]. As suggested by Seko *et al*. [6], natural killer cells, $CD4^+$ and $CD8^+$ T lymphocytes may also have a role in the vasculitis, as aortic tissue in patients with Takayasu's arteritis expresses a heat shock protein to which $CD4^+$ T lymphocytes strongly react. A genetic component is suggested by human leukocyte antigen (HLA) associations; susceptibility seems to be linked to the *MICA* gene. However, the exact pathogenesis of Takayasu's arteritis is unknown.

Histopathology. During the prepulseless phase of Takayasu's arteritis, there is intermittent involvement of the blood vessel wall with granulomatous inflammation. Lymphocytes and plasma cells typically make up the infiltrate, which may also contain eosinophils and histiocytes. Medial smooth muscle-derived giant cells, as well as Langhans' foreign body-type giant cells, have been observed in the inflammatory infiltrate. Later, in the pulseless phase, there is little or no infiltrate but there is transmural sclerosis. The duration and severity of the disease correlates with the degree of intimal proliferation and adventitial fibrosis. Finally, there may be secondary thrombus formation [2,7]. The cutaneous lesions consist of a necrotizing vasculitis with polymorphonuclear leukocytes, fibrinoid necrosis within the vessel walls, a granulomatous vasculitis with polymorphonuclear leukocytes, eosinophils, giant cells and fibrinoid necrosis that may also be associated with lobular panniculitis with fat necrosis and septal panniculitis [8].

Clinical features [2]. Two phases of Takayasu's arteritis have been described. Early, in the prepulseless disease phase, patients may have constitutional symptoms such

as weight loss, fever, malaise, myalgia and arthralgia. Later, in the pulseless disease phase, they may present with bruits, blood pressure inequality between the arms or with actual loss of pulses. Some other signs and symptoms from ischaemia caused by the vessel inflammation include hypertension, TIAs, headaches, angina and seizures. Retinopathy is a notable feature, termed Takayasu's retinopathy [2]. Cutaneous manifestations are present in 15–20% of patients with Takayasu's arteritis. In the early phase, erythema nodosum-like nodules or lesions of erythema induratum are present, whereas in the late pulseless phase there are pyoderma gangrenosum-like lesions, or lesions related to necrotizing or granulomatous vasculitis [8].

Diagnosis. Clinical signs and symptoms are often the initial identifying factors for Takayasu's arteritis. However, vascular studies are necessary for diagnosis; angiography remains the gold standard. Other radiological studies, such as computed tomography (CT) or magnetic resonance imaging (MRI) and colour Doppler ultrasound, may be used in the future as non-invasive techniques for both diagnosis of Takayasu's arteritis and for monitoring of the response to therapy [2,9].

Treatment. Although corticosteroid treatment alone may control the inflammation associated with Takayasu's arteritis, cytotoxic agents such as cyclophosphamide are used to reduce the risk of relapse. Takayasu's arteritis should be treated during the acute phase; corticosteroids may be necessary for 6 months to 2 years to induce remission, which may be maintained with a prednisone dose of 7–10 mg once daily. Even during the acute phase, vascular occlusions may be relieved surgically by patch angioplasty or bypass grafting [2,7,10].

Pityriasis lichenoides [1,2]

SYN. MUCHA–HABERMANN DISEASE

Definition and nomenclature. This disorder or group of disorders is difficult to classify. Clinically, pityriasis lichenoides is generally divided into two main forms [1–5]. *Pityriasis lichenoides chronica* (PLC) is the more common. It is largely a disease of young adults, with a male predominance of approximately 2 : 1. The more acute form, *pityriasis lichenoides et varioliformis acuta* (PLEVA, Mucha–Habermann disease), is less common, usually occurs in childhood and has an equal sex incidence. However, some patients may have simultaneous lesions of both types, or may have transitional lesions [1,2,4]. There is also a more recently described subset of PLEVA with a more aggressive course, known as *febrile ulcerative Mucha–Habermann disease* (FUMHD) [2,5]. All types are rare in infancy and old age, but PLEVA has been present at birth [6].

Nosologically, pityriasis lichenoides has been considered to be a variant of parapsoriasis (previous terms include parapsoriasis en gouttes and guttate parapsoriasis) and to overlap with lymphomatoid papulosis, and there are several reported cases with associated development of lymphoma. On the other hand, an overlap with vasculitis has been suggested—extravasation of erythrocytes is typical at a histological level, the acute form causes necrosis and may have vasculitic changes histologically, and the lymphomatous end of the spectrum is associated with an angiocentric destructive pattern of disease. In the absence of a clear aetiological or pathological classification, pityriasis lichenoides has been retained in this chapter, but the lymphomatous and lymphoma-associated end of the spectrum is discussed in more detail in Chapter 54. Recent evidence of clonality in most cases of PLEVA and some cases of PLC may mean that classification as a T-cell lymphoproliferative disease is more accurate [7–9]. However, to date, there is no evidence to support clonal development of PLC from PLEVA and most cases follow a prolonged but benign and apparently 'reactive' course.

Aetiology and pathogenesis. Pityriasis lichenoides has been reported mainly from Europe and America, but there is no specific geographical variation in incidence, and the cause is unknown.

The acute necrotic lesions of PLEVA bear some resemblance to allergic vasculitis [10,11], but recent reviews have found no evidence of a primary vascular injury [12]. One hypothesis is that the vascular injury is a hypersensitivity reaction to an infective organism, for which there are various lines of support. Cases have been reported in association with seroconversion against toxoplasmosis [13,14], cytomegalovirus [15], parvovirus [16], adenovirus and Epstein–Barr virus (EBV) [17] (although EBV could not be demonstrated immunohistochemically in one

series [18]). Bacteria such as *Streptococcus* have been implicated as a cause [19], and therapeutic response to tonsillectomy [20] and to antibiotics such as erythromycin [2,3] or tetracycline [21] can occur. Immune disturbance such as that caused by HIV infection or associated with common variable immunodeficiency have been reported with pityriasis lichenoides [22,23]. The occurrence of $CD8^+$ T-cell clonality, with IgM and C3 deposition in the vessels, suggests a form of chronic antigen stimulation with resulting immune complex deposition [1]. Paraneoplastic and drug-induced pityriasis lichenoides have also been reported; the association with lymphoma is discussed in Chapter 54.

Histopathology [1,2,7,24,25]. The histology varies with the stage, intensity and extent of the reaction; changes are more severe in PLEVA than in PLC. In the early lesions, an infiltrate of predominantly small lymphocytes surrounds and involves the walls of dilated dermal capillaries, which show endothelial proliferation. In PLEVA, the infiltrate may be deep, dense and wedge-shaped rather than predominantly perivascular. The epidermis is oedematous, with an interface dermatitis comprised mainly of $CD8^+$ lymphocytes; some necrotic keratinocytes are generally present, especially in PLEVA. Intraepidermal and perivascular extravasation of erythrocytes is typical. Later, over the centre of the lesion, a parakeratotic scale forms, containing lymphocytic pseudo-Munro abscesses. If the reaction is still more intense, as occurs in FUMHD, frank necrosis occurs and the lesion may not be histologically distinguishable from other forms of acute necrosis of the skin. In FUMHD there may be marked fibrinoid necrosis of deep vessels with luminal thrombi, partial necrosis of follicles and complete necrosis of eccrine glands [2].

Immunofluorescence studies commonly demonstrate IgM, C3 and fibrin in vessel walls of fresh lesions. Macrophages are increased in number and Langerhans' cells decreased. HLA-DR is expressed by the lymphocytic infiltrate and the overlying epidermis.

There is a histological resemblance to many other conditions, including common conditions such as psoriasis and resolving eczema. The most important is the distinction from parapsoriasis and particularly (as they may also be clinically similar) differentiation between PLEVA and lymphomatoid papulosis. The most useful distinction from lymphomatoid papulosis is that the latter has a predominant population of large $CD30^+$ cells, most of which are also $CD4^+$, whereas $CD30^+$ cells in pityriasis lichenoides are usually few and $CD8^+$ [26].

Clinical features [1–4]. The eruption is usually the first manifestation of the disease, and generally the only manifestation in PLC, but constitutional symptoms such as fever, headache, malaise and arthralgia may precede or accompany the onset of PLEVA.

PLEVA. The eruption develops in crops, and consequently appears polymorphic. The initial lesion is an oedematous pink papule that undergoes central vesiculation and haemorrhagic necrosis, which may be intense. In the vesicular forms [4], the vesicles may be small or so large that the eruption appears frankly bullous. The rate of progression of the individual lesions varies greatly, as do the frequency and extent of the crops of new lesions. New lesions may cause irritation or a burning sensation as they appear, but are often asymptomatic. The trunk, thighs and upper arms, especially the flexor aspects, are chiefly affected, but the eruption may be generalized. Lesions of the palms and soles are less common, and the face and scalp are often spared; erythematous or necrotic lesions of mucous membranes may be present. Lesions heal with scarring, which may be varioliform. PLEVA in pregnancy carries a potential risk of premature labour if there are mucosal lesions in the region of the cervical os [27].

FUMHD. In the acute ulceronecrotic form there is high fever and large necrotic lesions, with a fulminating course that may even be fatal [2,5,28,29]. About 50% of cases occur in children, and new crops of lesions may develop over many months. General malaise, weakness, myalgia, neuropsychiatric symptoms and lymphadenopathy occur, with non-specific serological markers of inflammation such as raised ESR and C-reactive protein; there may be serological evidence of associated viral infection [15].

PLC. The characteristic lesion of the chronic form is a small firm lichenoid papule 3–10 mm in diameter, and reddish brown in colour. An adherent mica-like scale can be detached by gentle scraping to reveal a shining brown surface—a distinctive diagnostic feature. Over the course of 3 or 4 weeks the papule flattens and the scale separates spontaneously to leave a pigmented macule which gradually fades. Post-inflammatory hypopigmentation may occur, and is occasionally persistent, but scarring is unusual in PLC. The body site distribution is the same as for PLEVA but an isolated acral form may occur [30,31]; segmental forms have been reported but at least some of these represent early lymphoma (Chapter 54).

The course of pityriasis lichenoides varies. If the onset is acute, new crops may cease to develop after a few weeks, and many cases are clear within 6 months. However, acute recurrences may occur over a period of years, or chronic lesions may supervene. In some cases, all lesions are of the chronic scaly type from the onset, and new crops of similar lesions may develop from time to time for years. Uncommonly, acute attacks occur after chronic lesions have been present for months or years. In general, the immediate prognosis is said to be better when the onset is acute and the lesions in successive crops are also of the acute type.

Differential diagnosis. The acute vesicular form must be distinguished from varicella; acute necrotic lesions may suggest necrotic skin infections, vasculitis or pyoderma gangrenosum. Lymphomatoid papulosis is a particularly difficult differential diagnosis in patients with necrotic lesions in view of its histological similarity, discussed above, although lesions of this disorder are usually less vesicular and more necrotic than those of PLEVA.

Pityriasis lichenoides chronica must be differentiated from guttate psoriasis or lichen planus. The acral form of PLC in particular may mimic psoriasis, and secondary syphilis may be mimicked, especially if the palms and soles are involved or if there are mucosal lesions. The single detachable mica-like scale on the red-brown papule is a characteristic sign of PLC. Gianotti–Crosti syndrome is less likely to be confused with pityriasis lichenoides, but insect bites and drug eruptions come into the differential diagnosis of any of the forms of the disease.

Treatment [1–4]. Treatment options include antibiotics such as tetracyclines [21] or erythromycin (preferred in young children because of dental pigmentation side effects of tetracycline) [2,3], and phototherapy of different types, including natural sunlight, UVB [32] and PUVA [33]. Topical corticosteroids may improve symptoms and healing of lesions but are not felt to alter the course of the disease [1]. In more aggressive disease of PLEVA or FUMHD pattern, and less commonly in PLC, additional therapeutic options include oral corticosteroids, methotrexate, dapsone, ciclosporin and intravenous immunoglobulin.

Other vasculitides and mimics of vasculitis

Occlusion disorders

It is important in the differential diagnosis of vasculitis to be aware of disorders that may present with livedo or infarcted lesions, such as *cryoglobulinaemic vasculitis*, *cholesterol embolization*, *Sneddon's disease* and *malignant atrophic papulosis* (*Degos' disease*). The major pathology in these is either initially occlusive, or is probably mediated by antiphospholipid antibodies (in Sneddon's syndrome), so they are all discussed in the section on microvascular occlusion in Chapter 48. Other disorders associated with antiphospholipid antibodies are also discussed. In

calciphylaxis (Chapter 48), the earliest event is vessel wall calcification [1], therefore this also is discussed in the section on microvascular occlusion rather than as a primarily vasculitic disorder. *Hyperoxaluria* may cause acrocyanosis, gangrene and livedo reticularis. *Hyperhomocysteinaemia*, typically in homozygotes for methyl tetrahydrofolate reductase mutation C677T, also predisposes to endothelial damage and vasculopathy.

Thromboangiitis obliterans (*Buerger's disease*) [2] is a disorder of small or medium-sized arteries (less commonly veins) in which there is an inflammatory non-suppurative panarteritis or panphlebitis with thrombosis. Antiendothelial cell antibodies may be significantly elevated in active disease and have a role in monitoring the disease [3]. This disorder is discussed in more detail in Chapter 50.

Other arterial thrombotic disorders that may mimic vasculitis include hypothenar hammer syndrome (Chapter 22), thrombosis resulting from polyvinyl chloride haemodialysis tubing [4], vessel wall invasion by tumour or organisms and sickle cell anaemia. Amyloid infiltration of the vessel wall may cause occlusion. Drugs such as ergot, amphetamines or epinephrine (adrenaline) typically cause vasospasm but there may be histological evidence of vasculitis.

Other systemic diseases

Vasculitis is a feature of many *connective tissue diseases* (Chapter 56) and of disorders such as *sarcoidosis* (Chapter 58) in which there may be either a large vessel granulomatous vasculitis or an immune complex-associated small vessel cutaneous vasculitis [5].

Churg-Strauss granulomas, a histological feature known under several other names, are seen in some autoimmune disorders with circulating immune complexes in which small vessel leukocytoclastic vasculitis may also occur. These have been grouped together as 'palisaded neutrophilic and granulomatous dermatitis of immune complex diseases' [6]. A particular clinical entity that exhibits these occurs predominantly in women with rheumatoid arthritis or other autoimmune disease, and has been termed (amongst others) *interstitial granulomatous dermatitis with plaques*, *palisaded neutrophilic granulomatous dermatitis* and *interstitial granulomatous dermatitis with cutaneous cords and arthritis* [7–9]. Clinical features are: erythematous plaques, papular or nodular lesions, and firm linear subcutaneous cords or bands. It has been suggested that the lesions start as leukocytoclastic vasculitis but progress to form palisaded granulomas and dermal fibrosis [6].

Vasculitis can occur in *familial Mediterranean fever (FMF)*, *hyperimmunoglobulinaemia D* and the *periodic fevers* (Chapter 59). It is important to consider FMF as a cause of vasculitis in children with apparent HSP in areas where FMF is prevalent, as HSP is much more common in families with FMF compared with the general population [10]; diagnostic delay is common. Tests for faecal occult blood are often positive during acute attacks of FMF. Other vasculitic features in FMF include purpura, subcutaneous nodules and associated PAN (which occurs in about 1% of patients); in particular, perirenal haematoma is usually associated with PAN secondary to FMF [10]. Both circulating IgD immune complexes and IgD deposits on direct immunofluorescence of the skin have been identified in hyperimmunoglobulinaemia D [11].

Paraneoplastic vasculitis is particularly associated with haematological malignancies; mechanisms include vasculitis related to paraproteins, cryoglobulins or to the presence of antinuclear antibodies.

Vasculitis may also be a feature of *Wiskott–Aldrich syndrome* (Chapter 12), usually leukocytoclastic small vessel vasculitis but aortitis and mesenteric or renal arteritis may occur.

Neutrophilic vascular reactions

Introduction

Neutrophilic vascular reactions are vessel-based dermatoses typified by neutrophilic infiltrates and changes in blood vessels within the dermis. The vessel damage responsible for these dermatoses is thought to be a result of immune complex deposition as well as to neutrophil-induced injury.

The following sections define and discuss the history, aetiology, pathogenesis, histopathology, clinical features,

Table 49.10 Dermatoses associated with neutrophilic vascular reactions.

Vasculitis
• Small vessel variants (cutaneous small vessel vasculitis and variants) (Table 49.3)
• Large vessel variants
Sweet's syndrome
Pustular vasculitis
• Behçet's disease
• Bowel-associated dermatosis–arthritis syndrome
Erythema nodosum
Other
• Familial Mediterranean fever
• Selected disseminated infections
Pyoderma gangrenosum

diagnosis and treatment of Sweet's syndrome, pyoderma gangrenosum, erythema nodosum, Behçet's disease and bowel-associated dermatosis–arthritis syndrome, with brief mention of rheumatoid neutrophilic dermatitis and neutrophilic eccrine hidradenitis.

Classification

Neutrophilic vascular reactions can be classified as vasculitis syndromes (see above), pustular vasculitides, Sweet's syndrome, erythema nodosum, pyoderma gangrenosum and miscellaneous forms (Table 49.10).

Sweet's syndrome

SYN. ACUTE FEBRILE NEUTROPHILIC DERMATOSIS

Definition. Sweet's syndrome is characterized by fever, peripheral neutrophil leukocytosis, acute onset of painful, erythematous papules, plaques or nodules and histological findings of a dense neutrophilic infiltrate without evidence of primary vasculitis [1]. Sweet's syndrome can be subdivided into three groups depending on the clinical setting: (i) classical or idiopathic; (ii) malignancy-associated; and (iii) drug-induced [2].

History and nomenclature. Sweet first described eight women with a 'distinctive and fairly severe illness' in 1964 [1].

Aetiology and pathogenesis. Sweet's syndrome is associated with underlying disease in approximately 50% of cases [3]. Classical or idiopathic Sweet's syndrome typically affects middle-aged women and has been associated with infection (streptococcal upper respiratory infections and yersinial gastrointestinal infections), IBD (ulcerative colitis and Crohn's disease) and pregnancy [3–6]. It is estimated that 20–25% of cases of Sweet's syndrome have an associated malignancy [7,8]; men and women are equally affected [9,10]. Most are haematological malignancies, especially acute myelogenous leukaemia. However, solid tumours, most commonly of genitourinary organs, breast and gastrointestinal tract, are present in about 15% [7,8]. The skin lesions of Sweet's syndrome may be the initial manifestation of malignancy or may precede the diagnosis by months to years, making close follow-up essential. In addition, recurrent episodes of Sweet's syndrome may be an indication of cancer recurrence [2,10]. Drug-induced Sweet's syndrome most commonly occurs in patients receiving granulocyte colony-stimulating factor (G-CSF) therapy [11–13]. Additional drugs implicated include all-*trans*-retinoic acid [14,15], minocycline [16,17], trimethoprim-sulfamethoxazole [18], carbamazepine [5], hydralazine [19] and oral contraceptives [20]. Other conditions reported in association with Sweet's syndrome include Behçet's disease [21], erythema nodosum [22], sarcoidosis [23–25], rheumatoid arthritis [4,26] and thyroid disease [27]; however, these reports may represent coincidental occurrences rather than true disease associations.

As with the other neutrophilic dermatoses, the pathogenesis of Sweet's syndrome is unknown, but it is thought to be related to altered immunological reactivity. A hypersensitivity reaction to bacterial, viral, drug or tumour antigens has been suggested as a possible aetiology [28,29]. This hypothesis is supported by the frequent association of Sweet's syndrome with infection, drugs or malignancy, along with the clinical improvement of symptoms and lesions with corticosteroid treatment [2]. Circulating autoantibodies [30], immune complexes [31] and cytokines [4,7] have also been proposed to play a part in the pathogenesis of Sweet's syndrome. ANCA have been found in a few cases of Sweet's syndrome but not in others [4,5,30]. Immunohistochemical studies to detect immune complex deposition in blood vessels have yielded inconsistent results. Some investigations have demonstrated evidence of immunoglobulins and complement within vessel walls [32–34] but this is not consistent [4,9]. Additional studies have found perivascular IgG, IgM, C3 and fibrin, thought to represent non-specific leakage from damaged vessels [35]. Cytokine dysregulation is currently a favoured theory in the pathogenesis of Sweet's syndrome. Potentially involved cytokines include IL-1, IL-3, IL-6, IL-8, G-CSF, granulocyte–macrophage colony-stimulating factor (GM-CSF) and IFN-γ [4,36–38]. As an example, drug-induced Sweet's syndrome is most commonly associated with G-CSF therapy [11–13]. Recently, an imbalance of cytokine secretion from helper T cells (Th) has been implicated. Th1 cytokines (IL-2 and IFN-γ) rather than Th2 cytokines (IL-4) are the proposed mediators, which in turn may stimulate the cytokine cascade leading to activation of neutrophils and release of toxic metabolites [39,40].

Histopathology. The diagnostic histopathological features of Sweet's syndrome include a dense, predominately

neutrophilic, infiltrate located in the superficial dermis, and prominent papillary dermal oedema which may occasionally lead to subepidermal vesiculation. The infiltrate may also contain lymphocytes, eosinophils and histiocytes [2]; an initial lymphocytic infiltrate has been reported. The infiltrate often occurs in a diffuse pattern, but may be perivascular or have an upper dermal band-like distribution [9]. Neutrophil karyorrhexis (fragmented neutrophil nuclei) is a common finding [3]. The epidermis is often normal but spongiosis may be present, and rarely neutrophils may extend into the epidermis to form subcorneal pustules [41]. Historically, the presence of vasculitis excluded the diagnosis of Sweet's syndrome; however, recent studies have reported histopathological features consistent with leukocytoclastic vasculitis. These findings include fibrinoid necrosis along with the presence of inflammatory cells within vessel walls. Additional evidence of vessel wall damage includes extravasated erythrocytes and intraluminal thrombi. However, multiple immunofluorescence studies have failed to demonstrate immune complex-mediated injury, further supporting the theory of secondary vessel damage rather than a primary vasculitis. It has been proposed that toxic metabolites released by activated neutrophils may have a role in the secondary vessel wall injury [4,9,42,43].

Clinical features. The clinical presentation of Sweet's syndrome is usually distinctive. The patient typically appears ill, with a persistent high fever, neutrophilia and an elevated ESR. The cutaneous manifestations consist of erythematous to violaceous tender papules or nodules that often coalesce to form irregular plaques (Figs 49.19 & 49.20) [44]. The lesions typically involve the arms, face and neck, but may occur anywhere [10,18]. The patient may present with a single lesion or multiple lesions. The distribution may be localized, particularly on the face [45,46], or widespread, as may occur in malignancy-associated cases [12]. Later lesions may appear pseudovesicular because of the prominent dermal oedema [29,47] and may be studded with tiny pustules resulting from neutrophil migration into the epidermis. The plaques may develop central yellowish discoloration, producing a targetoid appearance [4]. Healing usually occurs without scarring [2]. Oral lesions are uncommon but have been reported in patients with haematological disorders [7]. A variety of systemic manifestations can occur. Fever is the most common but may be absent, especially in malignancy-associated Sweet's syndrome [10]. Arthralgia, myalgia and arthritis are also frequent. The most common ocular manifestations include conjunctivitis and episcleritis. Neurological, pulmonary, renal and hepatic involvement have also been reported and are usually responsive to systemic corticosteroid therapy [3,4,48].

Diagnosis. The proposed diagnostic criteria for Sweet's syndrome state that patients must meet both of the two major criteria and two of the four minor criteria for the diagnosis [40].

Major criteria:

1 Acute onset of typical skin lesions

2 Histopathological findings consistent with Sweet's syndrome

Minor criteria:

1 Fever > 38°C or general malaise

2 Association with malignancy, inflammatory disorder or pregnancy *or* antecedent respiratory or gastrointestinal infection

3 Excellent response to systemic corticosteroids or potassium iodide (KI)

Table 49.11 Treatment of Sweet's syndrome.

Corticosteroids
Systemic for 4–6 weeks
Adjuvant therapy for localized lesions
• Topical
• Intralesional
Corticosteroid-sparing agents
Potassium iodide
Colchicine
Indometacin
Clofazimine
Dapsone
Ciclosporin
Etretinate
Interferon-α

4 Abnormal laboratory values at presentation (three of four required: ESR > 20 mm; leukocytes > 8000; neutrophils > 70%; positive C-reactive protein)

For drug-induced Sweet's syndrome, both major criteria but only one minor criterion (fever > 38°C) are required, together with two proposed additional criteria: (i) a temporal relationship between drug administration and clinical presentation; and (ii) a temporal relationship between drug withdrawal and disease resolution [18].

Treatment. Systemic corticosteroids are a standard and effective therapy for Sweet's syndrome. A 4–6-week course of prednisone is generally sufficient to resolve cutaneous and systemic symptoms and signs, but occasionally prolonged low-dosage treatment may be required to prevent recurrences. In addition, topical and intralesional corticosteroids may be used alone or as adjuvant therapy for localized lesions [8,49,50]. Many corticosteroid-sparing agents have been reported to be effective in the treatment of Sweet's syndrome. Oral therapy with potassium iodide and colchicine has led to rapid regression of lesions and symptoms. These agents may be reasonable first-line therapy in patients with milder disease [51–55]. Indometacin and clofazimine have been used with success but appear to be less effective than corticosteroids, potassium iodide and colchicine [12,56–58]. Dapsone and ciclosporin have also been reported to be effective therapeutic agents, but require laboratory monitoring because of their potentially serious adverse effects [39,59–62]. Small studies have reported clinical improvement in Sweet's syndrome using etretinate or IFN-α [50,63,64]. Therapies for Sweet's syndrome are depicted in Table 49.11.

Neutrophilic dermatosis (pustular vasculitis) of the dorsal hands

This is a disorder of uncertain nosology. An early case series described lesions that morphologically and histologically resembled Sweet's syndrome, but had additional histological features of vessel wall necrosis and deposition of fibrin around vessels, thereby constituting a vasculitis [1]. The presence of vasculitic change in this pattern of disease has varied in subsequent reports [2,3] and there remains controversy about whether this should be viewed as simply Sweet's syndrome, a specific subset of Sweet's syndrome or a vasculitic process in the spectrum of EED [4–6]. The fact that vasculitis has been documented as a feature in more classical Sweet's syndrome [7] supports the view that these clinical patterns are part of the same disease [4], as does the fact that some patients have lesions at other sites.

A link with myeloproliferative disease has been suggested [5], and it is possible that an earlier report of Sweet's disease confined to the dorsum of the hand in a patient with myeloproliferative disease may represent the same entity [8]. However, the number of cases reported is rather small for any conclusion about specific disease associations.

Treatment is as for Sweet's syndrome.

Pustules on the palms and soles have also been reported as a presentation of Sweet's syndrome [9].

Pyoderma gangrenosum

Definition. Pyoderma gangrenosum (PG) is a rare non-infectious neutrophilic dermatosis commonly associated with underlying systemic disease. Diagnosis is based on typical clinical features and exclusion of other cutaneous ulcerating diseases [1]. Several clinical variants of PG have

been described including ulcerative, pustular, bullous and vegetative forms [2].

History and nomenclature. In 1916, Brocq first described PG [3]. It was later described in 1930 by Brunsting *et al*. [4]. The prevalence of PG in IBD was discussed by Greenstein *et al*. in 1976 [5].

Aetiology and pathogenesis. Although the pathogenesis of PG is not fully understood, an immune-mediated process is thought to have an important role. Approximately 50% of patients with PG have an associated systemic disease [6]. Common associations include IBD, arthritis, haematological malignancies and monoclonal gammopathies [7]. PG occurs in immunosuppressed patients secondary to accompanying disease, infection or therapy [8]. Both humoral and cell-mediated abnormalities have been associated with PG. Humoral defects reported include autoantibodies against skin and bowel, a dermonecrotic factor present in the serum that produces necrosis when injected into the subject's own skin, and a serum factor present in patients with PG that produces PG-like lesions when injected into guinea pigs [9,10]. Cell-mediated defects found include cutaneous anergy to *Candida*, streptokinase and purified protein derivative, as well as altered production of macrophage inhibition factor by lymphocytes [11]. Additional reports have described decreased neutrophil chemotaxis and impaired monocyte phagocytosis in association with PG [12]. These leukocyte abnormalities may contribute to the pathergic phenomenon that occurs in up to 50% of PG patients, whereby new lesions can be induced at sites of minor skin trauma including venipuncture, vaccination and surgical procedures [13–15]. Other studies have suggested the mechanism underlying PG is consistent with the Arthus and Schwartzmann reactions in which circulating immune complexes are deposited in vessels leading to activation of the classical and alternative complement pathways [9,16,17]. Direct immunofluorescence staining studies to detect immunoglobulins, complement and fibrin deposits in post-capillary venules have yielded inconsistent results [6,18].

Histopathology. Although the histopathological findings of PG are often variable and non-specific, they can be useful in excluding other possible aetiologies. Several variables must be considered when evaluating the histopathology, including the type of lesion, the site of the lesion from which the biopsy is obtained, the stage of evolution of the lesion, and therapy [2]. Typical findings include central necrosis and ulceration of the epidermis and dermis surrounded by an intense acute inflammatory cell infiltrate, with a more peripheral mixed to chronic inflammatory cell infiltrate [19]. Each clinical variant has additional more specific histopathological findings. In the ulcerative variant of PG, there is massive dermal–epidermal neutrophilic infiltrate with abscess formation; in pustular PG, a perifollicular neutrophilic infiltrate with subcorneal pustule formation; the bullous variant shows a neutrophilic infiltrate with intraepidermal vesicle formation; and in vegetative PG, there is a granulomatous reaction with peripheral palisading histiocytes and giant cells [20]. The presence of vascular involvement in PG is an area of debate. Many investigators have reported findings consistent with a neutrophilic vascular reaction or leukocytoclastic vasculitis, granulomatous vasculitis and lymphocytic vasculitis [21–23], although this is not supported by all studies [24].

Clinical features. PG can have a variety of clinical presentations. The classic presentation begins with small tender papules or pustules that evolve into painful ulcers with characteristic violaceous undermined edges [25]. There may be granulation tissue, necrosis or purulent exudate at the ulcer base. Lesions may be solitary or multiple. Healing usually occurs with an atrophic cribriform scar [26]. Associated symptoms include fever, malaise, myalgia and arthralgia [1]. Extracutaneous involvement has been reported, with sterile neutrophilic infiltrates and PG manifestations occurring in bone and lungs (Chapter 59) [27–30].

Clinical features of the four types of PG [2] are as follows.

The *ulcerative* variant is the classic type of PG, in which there is ulceration with an undermined border and surrounding erythema that may develop from an inflammatory pustule or nodule, or may be secondary to the pathergic phenomenon [2]. It typically begins on the legs or trunk but can occur at any site [31]. Frequent disease associations include IBD, arthritis and monoclonal gammopathy [2].

Pustular PG is a variant that often occurs during acute exacerbations of IBD. Discrete painful pustules, with a surrounding halo of erythema, develop on normal skin. These pustules commonly arise on the extensor aspects of the limbs and may evolve into the typical ulcerations of PG. The lesions often resolve with control of IBD [2].

Bullous or 'atypical' PG typically presents with rapidly arising superficial haemorrhagic bullae, often located on the arms [24]. It shares clinical and histopathological findings with Sweet's syndrome, but typically ulcerates and heals with scarring [26]. Bullous PG is often associated with myeloproliferative disorders [2].

Vegetative PG or superficial granulomatous pyoderma presents as a non-painful superficial ulcer with a non-purulent base and generally lacks the violaceous undermined border [2,32]. It is often a solitary, slowly progressing lesion that resolves with less aggressive treatment [33] and is not usually associated with any systemic disease [34].

Diagnosis. PG is often a diagnosis of exclusion as laboratory and histopathological findings are variable and nonspecific. Patient evaluation should include a detailed history, physical examination and skin biopsies for histopathology and culture, as well as appropriate laboratory tests to help rule out other possible aetiologies. Infectious ulcers may mimic PG. Histological stains and cultures of skin biopsies for bacteria, mycobacteria, fungi and occasionally viruses can aid in excluding these aetiologies. Syphilis serology and anticardiolipin antibody may be indicated because syphilitic gummatous ulcers and antiphospholipid syndrome can simulate ulcerative or vegetative PG [35]. Sweet's syndrome can often be distinguished by its rather sudden onset of non-ulcerating lesions that generally heal without scarring. Syndromes with vasculitis such as WG, Behçet's disease and SLE can also be confused with PG; however, leukocytoclastic vasculitis is not a feature of PG [2].

Treatment. Many effective treatment strategies have been reported. Choice of treatment generally depends on disease severity as well as on the presence of associated disease. For early or mild lesions, topical therapy may be sufficient [7]. This includes wet compresses, hydrophilic occlusive dressings, antimicrobial agents and topical corticosteroids. Topical tacrolimus has recently shown promising results for the treatment of early PG lesions [36], and intralesional corticosteroids are another therapeutic option of reported benefit [37]. For more severe disease or for PG resistant to topical therapy, oral corticosteroids have been the mainstay of therapy. Pulsed intravenous corticosteroid therapy has been reported to be effective in some cases refractory to oral corticosteroids; it is recommended in PG refractory to other forms of treatment [38]. Sulphones and other antimicrobials such as dapsone, clofazimine and minocycline have been found to be useful in treating PG. Their mode of action is likely related to their anti-inflammatory effects or their alteration of neutrophil function [39]. Immunosuppressant agents have been found to be useful as adjunctive or alternative therapy in corticosteroid-unresponsive PG or as corticosteroid-sparing agents. Because of the risk of severe adverse effects such as bone marrow suppression, these agents should be limited to severe or refractory PG. Azathioprine was among the first of these agents to be used [40] but ciclosporin may be the immunosuppressant of choice [41]. It is often effective at a dosage of less than 5 mg/kg/day, with a response time of 1–3 weeks [39]. Methotrexate may be useful in patients with underlying arthritis or IBD [24], and new biological TNF-α inhibitors such as infliximab and etanercept are now being used. Cyclophosphamide, melphalan and chlorambucil appear to be effective in the limited number of patients reported [35,42–44]. Several other effective treatments that have been reported in small studies include oral tacrolimus, plasmapheresis, intravenous immunoglobulin and thalidomide [45–50]. Aggressive surgical débridement is contraindicated because of possible exacerbation of PG by the pathergic response. However, split-skin grafts and cultured keratinocyte autografting have been demonstrated to be effective if performed while the pathergic response is minimized using prolonged courses of immunosuppressants [51–53]. Gradient support hosiery is also beneficial for leg lesions. Therapy decisions depend on an assessment of the degree of active inflammation as opposed to simple wound healing requirements in refractory ulcers. Treatment of PG is usually discontinued after complete healing of lesions. Recurrences may occur but are unpredictable and therefore do not justify prolonged maintenance therapy [2]. A therapeutic ladder for PG is depicted in Table 49.12.

Table 49.12 Therapeutic ladder for pyoderma gangrenosum.

Topical or intralesional corticosteroids (2)
Topical cromolyn sodium (3)
Topical tacrolimus (2)
Minocycline (3)
Clofazimine (3)
Colchicine (3)
Dapsone (2)
Sulfasalazine (2)
Thalidomide (3)
Methotrexate—weekly pulse (3)
Prednisone (2)
Ciclosporin* (2)
Azathioprine (3)
Cyclophosphamide (3)
Mycophenolate mofetil (3)
Intravenous gammaglobulin (3)
Etanercept (3)
Infliximab (3)
Granulocyte–monocyte colony-stimulating factor

* Pyoderma gangrenosum secondary to chronic underlying diseases (e.g. inflammatory bowel disease or rheumatoid arthritis) is best treated (in the opinion of the authors) with ongoing therapy of the underlying disease (e.g. methotrexate plus prednisone, or etanercept or infliximab) rather than with ciclosporin which can usually only be given for a number of months because of renal toxicity.

Pyoderma gangrenosum associated with novel antineutrophil cytoplasmic antibodies to azurocidin

An unusual case of PG, polyarthritis and lung cysts associated with a novel ANCA to azurocidin was reported by Grattan *et al*. [54]. The patient initially presented with multiple skin lesions on the lower legs consistent with bullous and ulcerative PG. Subsequent analysis of this patient's sera revealed that azurocidin was the novel antigen for ANCA. The patient later developed a lesion on the

ankle resembling blastomycosis-like pyoderma that was associated with autoantibodies to BPI.

Azurocidin and BPI are antimicrobial components of neutrophil azurophilic granules. Azurocidin has been isolated from BPI and is distinct from other granule proteins such as PR3, MPO and cathepsin G. Antibodies to azurocidin and BPI may interfere with their antibacterial activity, thereby reducing innate immunity. Autoantibodies to azurocidin have also been associated with systemic and cutaneous vasculitis as well as with hydralazine-induced vasculitis [55].

Malignant pyoderma

Malignant pyoderma (MP) was first described by Perry *et al*. in 1968 [56] as a rapidly progressive ulcerative disease localized to the head, neck and upper trunk. Controversy exists as to whether MP represents a head and neck variant of PG or a cutaneous manifestation of WG. PG and WG may have similar clinical and histopathological findings, and both have been the reported cause of MP in some cases [57–61]. Interestingly, two of the original three reported cases of MP are now believed to represent WG. The presence of C-ANCA, which is highly specific for WG, may be useful in distinguishing PG from WG. However, some patients with WG may have negative C-ANCA test results, and thus close follow-up is warranted for possible pulmonary or renal lesions that may develop in WG [60–62]. Because of the uncertainty regarding the nosology of MP, it has been suggested that this term should not be used as a final diagnosis [60].

Erythema nodosum

SYN. ERYTHEMA NODOSUM MIGRANS; SUBACUTE NODULAR MIGRATORY PANNICULITIS; CHRONIC ERYTHEMA NODOSUM

Definition. Erythema nodosum (EN) is characterized by painful erythematous, and sometimes ecchymotic, nodules on the anterior surface of the legs. The condition may be idiopathic or secondary to various internal diseases or treatments. The incidence of EN is 1–5 in 100 000 population per year, with women between the ages of 15 and 40 years being most commonly affected [1–5].

History and nomenclature. EN was initially described by Willan in 1798 [6]. The disorder was further discussed by Wilson in 1842, who believed it to be a type of erythema multiforme. In 1860, Hebra further described the clinical manifestations of the condition, and suggested 'dermatitis contusiformis' as a name for the disorder [7]. A more chronic variant was described as 'erythema nodosum migrans', 'chronic erythema nodosum' or 'subacute nodular migratory panniculitis' [8–10].

Table 49.13 Causes of erythema nodosum.

Infections
Group A β-haemolytic *Streptococcus*
Tuberculosis (uncommon) [3,5,8]
Coccidioidomycosis [9]
Histoplasmosis [10]
Blastomycosis [11]
Chlamydia [12–16]
Yersinia [17]
Bacterial gastroenteritis
• *Salmonella* [18–23]
• *Shigella* [24,25]
• *Campylobacter* [19–21]
Leprosy [22,23]
Dermatophytes [24,25]
Medications
Sulphonamides
Bromides
Oral contraceptive pill (uncommon)
Others
Sarcoidosis
Inflammatory bowel disease
Rheumatological and autoimmune disease
Malignancy
Pregnancy
Idiopathic

Aetiology and pathogenesis. EN is thought to be a hypersensitivity reaction that may be triggered by antigens usually associated with infections, typically group A β-haemolytic *Streptococcus*. Other infectious aetiologies are listed in Table 49.13 [3,5,11–28]. Sarcoidosis, rheumatological and autoimmune diseases, IBDs, medications, pregnancy and malignancies also have been cited as potential aetiological agents. In many patients with EN, the cause is unknown. Triggers of the chronic EN variant are generally unknown, although pregnancy and oral contraceptives have been implicated [29]. The exact pathogenesis of EN is not understood, although it is thought that it may be the result of deposition of immune complexes in the venules of the septae of subcutaneous fat.

Histopathology. Early lesions of EN demonstrate septal oedema and a lymphohistiocytic infiltrate, with an admixture of neutrophils and eosinophils [30]. The inflammation is typically concentrated at the periphery of

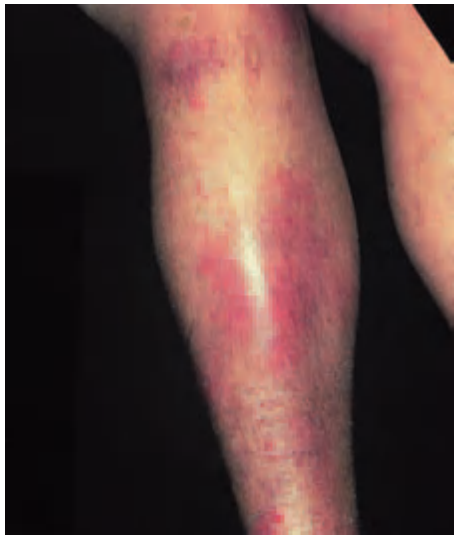

Fig. 49.21 Erythema nodosum. Note the location of the plaques on the anterior aspect of the lower leg.

the septae and spreads into surrounding fat lobules between adipocytes. Miescher's radial nodules, which are clusters of macrophages around small vessels or a slit-like space, are also seen in these lesions [31,32]. Finally, there may be oedema and lymphocytic infiltration of the walls of veins, although the amount of vascular involvement is variable [33,34]. Older lesions of EN demonstrate widened septae with peripheral fibrosis, and inflammation extending into peripheral regions of fat lobules. There are fewer vascular changes and a shift from a primarily neutrophilic infiltrate to one of primarily lipid-rich macrophages with a 'foam-cell' appearance. Macrophages without phagocytosed lipid surround multinucleated giant cells, forming granulomas. Histologically, chronic EN is similar to the later findings in acute EN. However, vascular proliferation is accompanied by endothelial thickening and extravasation of red blood cells [35], along with more marked formation of granulomas and lipogranulomas.

Clinical features. EN is typically manifest by the sudden onset of painful erythematous warm nodules and plaques on the shins, knees and ankles. These lesions are often more easily palpated than visualized, and are typically bilateral and symmetrical, ranging between 1 and 5 cm in diameter. The nodules may coalesce to form plaques (Fig. 49.21). After several days, the erythematous nodules often flatten and become ecchymotic in colour, finally taking on a yellow-green appearance (similar to an old ecchymosis), referred to as erythema contusiformis. This transformation is characteristic of EN, making retrospective diagnosis possible. Lesions of EN never ulcerate, atrophy or scar. Lesions erupt and are usually present for 3–6 weeks. In addition to cutaneous manifestations of EN, constitutional signs and symptoms may also be present. Fever, fatigue, malaise, gastrointestinal upset, headache and arthralgia may accompany the characteristic lesions of EN, as may ocular manifestations such as conjunctivitis.

In the chronic EN variant, lesions may be solitary or few, usually on the lateral part of the lower leg. They are initially nodular but become broader and flatter, vaguely circular or arciform in shape, and often last several months.

Table 49.14 Therapeutic ladder for erythema nodosum.

Non-steroidal anti-inflammatory drugs (3)
Potassium iodide (2)
Colchicine (3)
Hydroxychloroquine (3)
Dapsone (3)
Thalidomide (3)
Prednisone (3)

1, double-blind studies; 2, case series; 3, case reports.

Diagnosis. The diagnosis of EN is clinical, although histopathological evaluation may sometimes be necessary to support the diagnosis. In atypical cases of suspected EN (such as the absence of lesions on the legs, persistence or ulceration of the lesions), a deep elliptical biopsy of an active lesion should be performed. In some cases it may be necessary to search for an underlying cause of EN. A chest X-ray, tuberculin skin test and antistreptolysin (ASO) titre [5] may be obtained in such instances to exclude causes such as sarcoidosis, tuberculosis or streptococcal infection.

Treatment. EN typically resolves without treatment, therefore symptomatic support may be all that is necessary for the majority of patients. NSAIDs may also be used [36], as may potassium iodide at a dosage of 360–900 mg/day [37–40]. Systemic corticosteroids are infrequently required for the treatment of EN and may worsen underlying disease such as tubeculosis. A therapeutic ladder for EN is depicted in Table 49.14.

Behçet's disease

Definition. Behçet's disease is a multisystem disease that is defined by the presence of oral aphthosis with at least two of the following: genital aphthae, synovitis, posterior uveitis, cutaneous pustular vasculitis or meningoencephalitis, in the absence of IBD or autoimmune diseases [1–3]. Children sometimes develop Behçet's disease, but it typically affects young adults [4]. It is uncommon in northern Europe and the USA, but is common in Middle Eastern and Japanese (i.e. 'silk route') populations [5].

History and nomenclature. Behçet's disease was named after the Turkish dermatologist who first described the multisystem disease.

Aetiology and pathogenesis. Although the exact cause of Behçet's disease is unknown, a genetic component of the disease is suggested by its association with HLA-B51 [2,6]. The possibility that infections may stimulate an abnormal immune response in persons susceptible to Behçet's disease is under consideration, although the idea that it may be the direct result of an infection is doubted.

Histopathology. Biopsy specimens of early aphthae or of lesions of pustular vasculitis demonstrate leukocytoclastic vasculitis or a neutrophilic vascular reaction [1,7–10], although late lesions are lymphocytic. Some case series even allow inclusion of follicular-based lesions, which the present authors discourage.

Clinical features. The clinical course of Behçet's disease is highly variable, although patients typically have oral aphthae with any combination of genital aphthae, cutaneous pustular vasculitis, ocular lesions or arthritis (Figs 49.22 & 49.23) [7,11,12]. Only pustular vasculitis and erythema nodosum-like nodules should be used to satisfy diagnostic criteria when considering Behçet's disease, although a wide range of cutaneous findings (especially Sweet's-like and pyoderma gangrenosum-like lesions) may be present in patients with the disease [2,8]. Posterior uveitis is the only ocular criterion for the diagnosis of Behçet's disease, yet there is an array of ophthalmological manifestations. The posterior uveitis observed in Behçet's disease is a consequence of retinal vasculitis and may result in blindness. Hence, loss of vision is a feared complication of Behçet's disease. Mimicking rheumatoid arthritis, the musculoskeletal involvement of Behçet's disease is an asymmetrical migratory non-erosive oligoarthritis [2,3,13]. Many neurological manifestations may be present in patients with Behçet's disease, although only meningoencephalitis is considered to be a diagnostic criterion [14]. Vascular involvement in Behçet's disease may affect arteries and veins, leading to aneurysms or occlusions that are

Fig. 49.22 Behçet's disease. This patient demonstrates oral aphthosis.

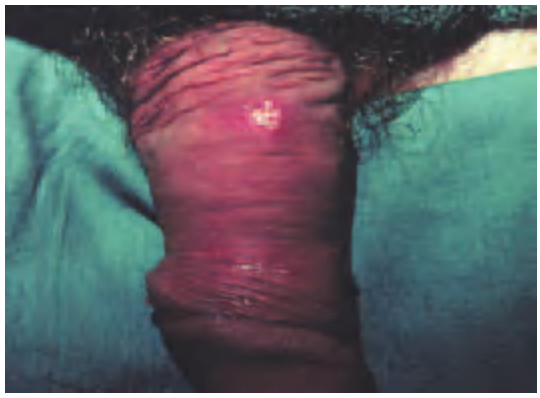

Fig. 49.23 Behçet's disease. An aphtha is present on the penis.

sometimes fatal [15,16]. Vascular complications should always be borne in mind in patients with known Behçet's disease, particularly pulmonary artery aneurysm as a cause of haemoptysis (the presence of haemoptysis and deep-vein thrombosis may erroneously suggest pulmonary emboli). However, these vascular complications are not a direct consequence of vasculitis and they typically do not respond to medical therapies.

Diagnosis. The diagnosis of Behçet's disease should be suspected in any patient with recurrent and extensive oral aphthosis. However, in these persons, other causes of aphthosis such as IBD, as well as lesions that mimic aphthae such as herpes simplex infection, must be excluded before a diagnosis of Behçet's disease can be made. The diagnosis should also be considered in young patients with deep-vein thrombosis, especially in the absence of other risk factors or thrombophilia. In addition, ophthalmology, neurology and rheumatology consultations may be beneficial when evaluating a patient with suspected Behçet's disease. A positive pathergy provocation test may further support the diagnosis [17]. The International Study Group criteria for the diagnosis of Behçet's disease [18] are depicted in Table 49.15.

Treatment. Aphthae may be treated palliatively with topical or intralesional corticosteroids, topical tacrolimus and/or with viscous lidocaine (lignocaine) applied topically to individual lesions. Colchicine (0.6 mg two to three times daily) may also be used to treat mucocutaneous manifestations, although this treatment option is limited by gastrointestinal intolerance and requires monitoring for neutropenia [1,19,20]. Dapsone in combination with colchicine has anecdotally been effective in treating Behçet's disease [21]. Behçet's disease that has manifestations other than mucocutaneous involvement may be treated with systemic corticosteroids, although such treatment may not control severe ocular, neurological or non-vasculitic vascular disease [2,3,7,11,13]. Immunosuppressive agents such as azathioprine, methotrexate or ciclosporin may be used in the treatment of patients with severe Behçet's disease [2,22]. Treatments for Behçet's disease are summarized in Table 49.16.

Recurrent oral ulceration	Minor aphthous, major aphthous, or herpetiform ulceration observed by physician or patient that recurred at least 3 times in one 12-month period
Plus two of the following criteria:	
Recurrent genital ulceration	Aphthous ulceration or scarring observed by physician or patient
Eye lesions	Anterior uveitis, posterior uveitis, or cells in vitreous on slit-lamp examination; *or* retinal vasculitis observed by ophthalmologist
Skin lesions	Erythema nodosum observed by physician or patient, pseudofolliculitis or papulopustular lesions; *or* acneiform nodules observed by physician in post-adolescent patients not receiving corticosteroid treatment
Positive pathergy test	Read by physician at 24–48 h

Table 49.16 Treatments for Behçet's disease.

Palliative treatment of aphthae
Topical corticosteroids
Intralesional corticosteroids
Topical tacrolimus
Topical viscous lidocaine (lignocaine)
Mucocutaneous manifestations
Colchicine (0.6 mg two to three times daily)
Dapsone
Dapsone and colchicine
Systemic involvement
Systemic corticosteroids
Immunosuppressants for most severe disease
• Azathioprine
• Methotrexate
• Ciclosporin

Bowel-associated dermatosis–arthritis syndrome (see also Chapter 59)

Definition. Bowel-associated dermatosis–arthritis syndrome (BADAS) is defined by the presence of pustular vasculitic lesions associated with blind loops of bowel, either from Billroth II or ileojejunal bypass surgery, or caused by IBD.

Fig. 49.24 Bowel-associated dermatosis–arthritis syndrome, showing a papule on an erythematous base.

History and nomenclature. BADAS was first described in 1971 as pustular vasculitis cutaneous lesions and serum sickness-like reactions in patients who had undergone jejunoileal bypass surgery for morbid obesity [1–4]. The term has now been extended to include the same syndrome in patients with IBD or in patients who have had creation of a blind loop following surgery for peptic ulcer disease [5].

Aetiology and pathogenesis. Blood vessel damage secondary to bowel flora antigen-associated circulating immune complexes is thought to be the pathogenesis of the cutaneous lesions. In these patients, peptidoglycans from gastrointestinal flora may be the antigenic trigger for immune complex-mediated vessel damage [4].

Histopathology. The changes noted in dermal blood vessels from early lesions of pustular vasculitis in patients with BADAS are similar to those in biopsies from patients with Sweet's syndrome [4–7] and Behçet's disease.

Clinical features. The cutaneous manifestations of BADAS begin as small macular lesions that progress into papules and later pustules on a purpuric base, most often on the arms and other areas of the upper body (Fig. 49.24). These pustules measure 0.5–1.5 cm in diameter and typically occur in crops, with each crop lasting up to 2 weeks, and recurring at intervals of several months [4,5,7–9]. Like Behçet's disease, pathergy seems to have a role in the distribution of the lesions. The cutaneous eruptions may be preceded by constitutional signs and symptoms such as fever, flu-like symptoms or myalgia, or by gastrointestinal upset. Arthralgia or non-erosive polyarthritis affecting hands, wrists and other peripheral joints have been described in patients affected by BADAS [1,3].

Table 49.17 Treatment of bowel-associated dermatosis–arthritis syndrome.

Secondary to previous bowel surgery
Surgical correction of bowel anatomy (may not eliminate symptoms if following blind loop)
Symptoms not secondary to or correctable by surgery
Systemic tetracycline
Systemic metronidazole
Systemic erythromycin
Treatments used to treat patients with cutaneous small vessel vasculitis (Table 49.7)
• Colchicine
• Dapsone
• Thalidomide

Diagnosis. It is important to distinguish between BADAS and Behçet's disease, as both may include oral aphthosis and lesions of pustular vasculitis. In order to distinguish between these two disease processes, an evaluation of the bowel, which may include barium studies as well as endoscopy, should follow a thorough patient history and physical examination. Clinicopathological evaluation of skin lesions is required but does not exclude lesions of Behçet's disease or early lesions of either PG or Sweet's syndrome.

Treatment. For patients with BADAS following bowel bypass surgery, surgical correction of bowel anatomy often eliminates the signs and symptoms. In other cases, such as patients with blind loops, surgical correction may be difficult and resolution of symptoms is therefore less likely. Manifestations of BADAS may be effectively controlled by the use of systemic tetracycline, metronidazole or erythromycin [4,5]. Systemic corticosteroids are typically unnecessary for the treatment of BADAS. Other treatments outlined for patients with cutaneous small vessel vasculitis, especially oral colchicine, dapsone or thalidomide have been used (Table 49.7). Treatments for BADAS are outlined in Table 49.17.

Other neutrophilic dermatoses

Rheumatoid neutrophilic dermatosis [1,2]

Rheumatoid neutrophilic dermatosis was described by Ackerman in 1978 [3], and a number of cases have been described subsequently. It is thought likely to be immune complex-mediated, and tends to occur in patients with active rheumatoid disease and elevated rheumatoid factor. Lesions occur at any site, mainly the limbs and face, and may consist of papules, nodules or plaques, sometimes with an annular morphology. Urticated, vesicular and crusted lesions may all occur.

Histologically, there is a dense neutrophilic infiltrate that may extend into the epidermis or deeply into the subcutaneous fat; papillary microabscesses may be present [1,4]. Vasculitis is not seen but leukocytoclasis may occur. The picture is similar to that of Sweet's syndrome, but the latter usually has more prominent dermal oedema and less admixture with other cell types (some eosinophils, plasma cells and lymphocytes may be present in rheumatoid neutrophilic dermatosis).

Lesions may resolve spontaneously or as a result of treatment of the rheumatoid disease with immunosuppressive agents. Some plaques may be chronic over a period of months [5]. Topical or oral corticosteroids, dapsone and hydroxychloroquine have all been used with benefit.

A disorder termed 'neutrophilic lobular panniculitis associated with rheumatoid arthritis' is of uncertain aetiology, and has been classified as a lobular panniculitis with vasculitis. However, the few cases reported had perivascular neutrophilic infiltrate and leukocytoclasis without fibrinoid change or definite vasculitis, although one had associated leukocytoclastic vasculitis in the upper dermis [6].

Neutrophilic eccrine hidradenitis

Neutrophilic eccrine hidradenitis [1,7] is characterized by a neutrophilic infiltrate that is centred on and extends into the eccrine coils. Typically, the eccrine apparatus shows vacuolar degeneration or necrosis. Approximately 90% of cases have been in patients with malignancy, usually leukaemias, and there is a strong link with induction chemotherapy; most cases occur in the setting of neutropenia. Cytotoxicity of drugs on the eccrine coil is the most likely explanation for this dermatosis. Implicated drugs are discussed in Chapter 73.

Clinically, lesions may resemble those of Sweet's syndrome. They may affect predominantly the head

(especially the periorbital regions), neck and upper trunk, or may be limited to the limbs. Lesions may be plaques, papules or nodules, and may be grouped. They may resemble erythema multiforme, and sometimes occur as a pathergic phenomenon. Pustules and occasionally purpura may be present.

A paediatric variant of neutrophilic hidradenitis, variously termed 'idiopathic plantar hidradenitis' or 'recurrent palmoplantar hidradenitis' is discussed in Chapter 45. These disorders are not discussed further here as they are primarily neutrophilic eccrine rather than neutrophilic vascular reactions.

Subcorneal pustular dermatosis and neutrophilic bullous disorders

Subcorneal pustular dermatosis is a rare neutrophilic dermatosis that is associated with monoclonal gammopathy, multiple myeloma, lymphomas, PG, connective tissue disease and IBD [8]. Intraepidermal (neutrophilic) IgA pustulosis has some similarities, and has also been linked with monoclonal gammopathy (in 20% of cases) and with lymphomas. These disorders are bullous (Chapter 41) and are not discussed further here as they do not include a neutrophilic vascular reaction.

Chapter 50

Diseases of the Veins and Arteries: Leg Ulcers

P.S. Mortimer & K.G. Burnand

Vasculogenesis, angiogenesis and arteriogenesis

Vasculogenesis is the first step in the development of the blood vessels and is the process whereby endothelial cells are generated from their mesenchymal precursors to form the primary vascular plexus of the embryo [1]. **Angiogenesis** is the process whereby existing vessels sprout, expand and remodel. Vasculogenesis precedes angiogenesis but the two processes continue in parallel during early development. The skin, being of ectodermal origin, is vascularized mainly by angiogenesis. A complex orchestration of molecular regulators is required for blood vessels to grow. First, extracellular matrix is degraded by local tissue proteases. This permits migration of budding endothelial cells under the influence of angiogeneic stimuli, particularly the family of vascular endothelial growth factors (vascular endothelial growth factors A, B, C and E plus placenta growth factor) and their receptors VEGFR-1 and VEGFR-2 [2]. Stabilization and maintenance of the newly formed vessels occurs mainly through the angiopoietins and the tie-receptors.

Differentiation into arteries, veins and capillaries is the responsibility of angiogenesis. **Arteriogenesis** produces rapid circumferential growth in the pre-existing collateral vessels, which are less perfused with blood under normal flow conditions [3]. It seems likely that endothelial stem cells from the bone marrow also contribute to the expansion of collateral vessels. While hypoxia is the main driving force for angiogenesis, inflammation mainly induces arteriogenesis.

Arterial and peripheral ischaemic disorders

Arterial disease

Current concepts on aetiology of arterial disease, atherosclerosis and peripheral ischaemia. The mechanisms that initiate arterial disease are still poorly understood, but subtle endothelial injury is the likely final common pathway [1]. Evidence suggests that cardiovascular risk factors induce endothelial injury and endothelial dysfunction. Endothelial progenitor cells derived from circulating mononuclear cells may protect against cardiovascular disease [2] and perhaps against atherosclerosis. Atherosclerosis is a patchy accumulation of lipid, mostly in the form of cholesterol within the intima of the vessel wall. Such plaques eventually ulcerate through the endothelial lining, presenting a highly thrombogenic surface [3]. Platelets adhere to the ulcerated plaque and aggregates (platelet thrombi) may embolize distally or may initiate local thrombosis. Inadequate collaterals, or rapid occlusion by thrombosis or embolism, will lead to tissue infarction (e.g. peripheral gangrene). Atherosclerosis is responsible for more than

90% of all arterial disease in the Western world. It affects 5% of men over the age of 50 years, of which 10% may develop critical limb ischaemia; this increases to 20% if diabetic patients are included [4].

Atherosclerosis of the lower limb vessels. Many patients present initially with claudication (cramping pain on walking, which is usually experienced in the posterior calf muscles and which is relieved by rest). The presence of persistent pain in the foot at night indicates the onset of critical ischaemia, which will lead to gangrene or ulceration if left untreated.

In the past, arteriosclerosis (hardening of the arteries) has been classified as a disease, but most authorities would now regard this as a physiological response to ageing. Thickening of the arterial wall, with an increase in collagen and calcium deposition, causes loss of elasticity and increased tortuosity of the vessels in the elderly [3]. Similar changes are seen in the vessels of younger patients with hypertension.

Clinical features [3–6]

All aspects of the patient's history and lifestyle are relevant, with particular attention being paid to risk factors such as cigarette smoking, hypertension, diabetes, diet, hyperlipidaemia, lack of exercise, obesity, occupation, medication (including oral contraceptive pill in females and use of β-blockers [7]) and family history of cardiovascular disease.

Patients usually present with intermittent claudication, but ischaemic ulceration or infarction of the skin is the likely presenting feature to a dermatologist (Fig. 50.1). As the disease progresses, rest pain occurs. This is experienced predominantly in the foot or calf, usually at night. Altered skin colour (pallor or deep erythema) indicates ischaemia, and may be accompanied by other skin trophic changes such as dryness, scaling, loss of hair and thickened nails (Fig. 50.2).

Fig. 50.1 An ischaemic hallux with pregangrene; the rest of the foot has an ischaemic erythema.

Fig. 50.2 An ischaemic foot showing patchy areas of gangrene and rubor. The skin is flaky and the nails are brittle.

A full general examination is essential. Particular attention should be paid to signs of anaemia, polycythaemia, xanthelasma and other xanthomatous deposits. Genetic disorders such as pseudoxanthoma elasticum and Marfan's syndrome should be considered. Cardiac examination should focus on dysrhythmias, particularly atrial fibrillation, murmurs and signs of heart failure. Abdominal examination should exclude the presence of any pulsatile mass, suggestive of an abdominal aortic aneurysm. The fundi should be examined for evidence of diabetic and hypertensive retinopathy. The blood pressure should be taken in both arms; a marked difference suggesting a stenosis or occlusion of the subclavian artery (although ischaemic disorders of the upper limbs are unusual).

The skin of the legs may have an erythematous or dusky mottled hue. If the ischaemia is marked, limb elevation causes pallor of the foot while dependency results in delayed but exaggerated hyperaemia, best observed on the dorsum of the foot (Buerger's sign) (Fig. 50.3) [8]. Inspection between the toes may reveal ulceration at sites of pressure (Fig. 50.4); small cracks may appear over the sole of the foot or heel (Fig. 50.5). Platelet emboli lodging in the plantar and digital vessels cause areas of discoloration, which are often present over many toes or on the sole. They often look like eccymoses initially and may be confused with vasculitis (Fig. 50.6). The aortic, femoral, popliteal, dorsalis pedis and posterior tibial pulses must be carefully palpated. Abnormally situated pulsations may indicate a collateral circulation or a congenital arteriovenous fistula. Auscultation over the course of the arteries may reveal the presence of a bruit indicative of turbulent flow. This is commonly caused by an up-stream stenosis or by an arteriovenous fistula (which usually causes a 'machinery' murmur, present throughout systole and diastole). Significant arterial disease demanding

Fig. 50.6 Multiple platelet emboli into the skin of the foot.

Fig. 50.7 Measurement of the ankle Doppler pressure using a sphygmomanometer cuff. The pressure at which the Doppler signal disappears in the leg is compared with the brachial pressure to give an index of blood supply.

further investigation is uncommon when the foot pulses are easily palpable.

Investigations. Confirmation of arterial disease can be obtained by measuring the ankle–brachial Doppler pressure index if a reduction or absence of pulsation is suspected or if a bruit is heard [9]. To perform this test, a sphygmomanometer cuff is placed around the limb above the ankle and inflated, after the Doppler ultrasound probe has been used to locate the dorsalis pedis or posterior tibial vessel (Fig. 50.7). The red cells flowing past the tip of the ultrasound probe deflect the beam, creating an audible noise. As the cuff is inflated above systolic pressure, flow in the artery ceases and the noise disappears. This pressure can be obtained for all vessels at the ankle and compared with the brachial artery pressure. This ankle–brachial systolic gradient is normally unity. A fall in the pressure of the ankle vessels results in a reduction of the pressure index. A ratio between 0.5 and 0.9 corresponds with claudication; less than 0.5 suggests arterial

ischaemia, and is associated with rest pain and gangrene. Falsely high indices may be obtained in some limbs if the vessels are very calcified and fail to compress at systolic pressure. This is especially true of diabetic limbs.

A more accurate means of assessment is to measure the Doppler pressures after exercise. This exaggerates the fall in the arterial pressure, allowing detection of minor reductions in blood flow; the degree of the post-exercise pressure fall is indicative of the severity of the ischaemia. Attenuation of the sound heard through the Doppler stethoscope when the limb is raised is another easily elicited sign of severe ischaemia. Other tests used to assess ischaemia include measurement of the transcutaneous Po_2 using a heated (Clark's) electrode applied to the skin of the lower limbs and compared with a reference site on the chest wall [10,11] (which may include a failure to increase with inhalation of oxygen), and isotope-washout studies (which estimate clearance of inert isotope from a tissue injection [12]).

Investigations in patients suspected of having peripheral arterial disease or critical leg ischaemia [4] should include: a full blood count to exclude anaemia or polycythaemia; electrolytes, urea and creatinine to monitor renal function; and an electrocardiogram (often repeated after exercise) to detect rhythm abnormalities or cardiac ischaemia. A chest radiograph allows the measurement of cardiac size and excludes a coincidental bronchogenic carcinoma, which is common in smokers. Diabetes should be excluded, and plasma cholesterol and fasting triglycerides should be measured.

When surgery is contemplated, a detailed assessment of the anatomy of the arterial tree is also required. Duplex Doppler scanning is often the initial investigation, especially as a screening test [13,14]. A duplex Doppler scan provides both a B-mode image of the artery and a measurement of blood velocity; these can be combined to provide a map of the stenoses and occlusions within the arterial tree from the aorta to the crural (calf) vessels. The greater the velocity, the tighter the stenosis. Most surgeons also obtain an arteriogram before angioplasty or bypass surgery is performed. Arteriography is performed by injection of non-ionic contrast media into the vascular tree, usually through a retrograde catheter inserted into the common femoral artery at the groin over a guide wire (Seldinger-type retrograde aortography), or from an intravenous or intra-arterial injection using digital subtraction equipment to enhance picture quality [15]. Each of these methods has its proponents, but retrograde aortography performed as an outpatient, or a combination of intravenous digital subtraction arteriography of the aorta, iliac and femoral vessels combined with femoral arteriography of the distal vessels, provide equivalent information.

The further management of arterial disease is discussed under the heading of the individual diseases, and usually requires referral to an appropriately experienced surgeon.

Differential diagnosis. Thromboangiitis obliterans (Buerger's disease, p. 50.7) may be very difficult to distinguish from atherosclerosis. The preservation of the proximal femoral and popliteal pulses and the early age at first presentation usually indicate the possibility of this condition. Associated venous thromboses and characteristic histological changes on vessel biopsy make the diagnosis more secure.

In patients with acute ischaemia it is important to exclude the possibility of embolism, which may be suggested by a recent myocardial infarction or the presence of atrial fibrillation. Transoesophageal echocardiography can demonstrate small amounts of intracardiac thrombus and structural abnormalities, especially of the valves, with great accuracy [1].

Rarer causes of ischaemia include external arterial compression (popliteal entrapment or a cervical rib), dissecting or thrombosed aneurysms, ergot poisoning, intra-arterial injections of noxious substances, traumatic disruption of the arterial wall, coagulation disorders, particularly polycythaemia and thrombocytosis, and various forms of vasculitis. Diabetes must always be considered as a potentiating condition, even in patients with atherosclerotic disease.

Claudication pain may be mimicked by arthritic conditions of the hip, such as osteoarthritis or rheumatoid arthritis. Pain in the leg may also result from referred pain

arising in the lumbosacral spine, and spinal claudication is sometimes very difficult to differentiate from arterial claudication. Occasionally, venous claudication may be misdiagnosed. Ischaemic rest pain may have to be differentiated from other painful conditions of the feet and toes, such as gout, interdigital neuromas, glomangiomas, ingrowing toenails, flat feet, calcanial bursitis and plantar fasciitis. Other causes of gangrene may need to be excluded (e.g. clostridial infection, diabetes, other causes of vascular obstruction, vasculitis and coagulation disorders).

Prognosis. In addition to the surgical mortality discussed above, patients with atherosclerotic disease of the lower limb vessels usually have other arteries affected. The extent of the atheroma in the coronary and carotid arteries determines the life expectancy of the patient, although antiplatelet agents [2], lipid-lowering agents and bypass surgery may improve the prognosis as well as the symptoms of ischaemia. Silent myocardial infarction is present in about one-third of patients who have intermittent claudication.

Treatment. Treatment options differ for claudication, rest pain or gangrene and acute limb ischaemia.

Claudication. The indications for intervention in a patient with claudication are always relative and must be weighed against the risks of the procedure and the fact that the condition normally has a very benign course [3]. Only 5% of all patients with claudication progress each year to develop rest pain or gangrene; a far greater proportion die every year from other causes, such as myocardial infarction. Patients with intermittent claudication are therefore usually managed conservatively at first, as collateral vessels may develop with an associated improvement in the symptoms.

Patients should be advised to stop smoking, and encouraged to walk through the pain as this tends to stimulate development of collateral circulation, to recruit capillaries and to increase the claudication distance. There are a number of studies demonstrating that supervised exercise programmes are as effective as therapeutic intervention in alleviating claudication, although the benefits may not persist [4]. Antihypertensive treatment should not be instituted in the early stage of claudication in patients whose systolic pressure in the limb in the standing position is lower than 80 mmHg. An alternative medication such as an angiotensin-converting enzyme inhibitor should be considered if the patient is already taking a β-blocker, as withdrawal of the latter may improve the walking distance. Some drugs improve cardiac stroke volume and hence enhance peripheral perfusion. Many vasodilators have been tried but there are few reports that they are of benefit [5]. Similarly, anticoagulants, antiplatelet agents, haemorrheological drugs and prostaglandin analogues are mostly of little efficacy [6].

Further investigation is indicated if the claudication distance remains unacceptable when the patient has stopped smoking after a reasonable period of conservative treatment. Stenotic lesions confirmed by arteriography can be treated by balloon dilatation (angioplasty), using specially designed coaxial balloon catheters that are constructed to withstand high external pressures [7]. This technique is usually performed by radiologists under image-intensifier control, using a percutaneous femoral puncture to insert the balloon catheter in a prograde or antigrade direction. A specially slippery guide wire is used to cross the lesion and the balloon is then railroaded into the stenotic area and inflated [8]. As the balloon distends, the plaque is compressed outward and longitudinal fissures are produced. This technique works best on stenoses in large proximal vessels, and least well on long occlusions of the distal arterial tree. The results remain disappointing, with a 30% restenosis rate at 1 year. Most clinicians would, however, still try angioplasty as the first line of management for a single iliac stenosis causing moderate or severe claudication [9]. Potential complications include arterial rupture, aneurysm formation, thrombosis and dissection.

The technique of subintimal angioplasty has increased the scope of angioplasty to treat longer, more peripheral stenoses, although its long-term efficacy still remains to be assessed. Long-term follow-up data are not yet available but recurrent stenosis in and around the stents still seems to be a problem. Chemically treated slow-release stents may overcome 'restenosis' in the future. Angioplasty and stenting has become the standard method of treating stenoses and short occlusions of the iliac vessels. A number of endoarterial devices have been developed but have still not found widespread application. Most are based on a cutting or resecting principle and have similarities to transurethral resectoscopes.

Surgical endarterectomy or bypass remains the treatment of choice for extensive occlusions of the iliac or femoropopliteal segments. Aortofemoral bypass has an excellent 5-year patency (90–95%), but the operative mortality varies between 1 and 5% [8]. Femoropopliteal vein bypass grafting has a lower 5-year patency (60–70%) but a lower operative mortality (usually less than 1%) [10]. Distal bypass surgery (the lower anastomoses being below the popliteal artery into one of the three crural vessels) has no part to play in the treatment of claudication, although this procedure is of considerable value in patients with rest pain and early gangrene (see below) [11]. Operative or chemical lumbar sympathectomy does not help to relieve claudication [12].

Rest pain or gangrene. Once rest pain or early gangrene have developed the situation changes, for if this state is

left untreated amputation will be necessary to relieve pain and preserve life. Patients with rest pain or gangrene must be rapidly admitted and investigated, because successful revascularization can avert limb loss [4]. The position of the foot suffering from necrosis should be as low as possible without inducing oedema. Any anaemia or polycythaemia should be corrected, and if diabetes is found this should be brought under control by diet and hypoglycaemic agents. Dehydration and infection must be treated. The increasing use of more distal surgery with bypasses to the dorsalis pedis, posterior tibial, peroneal and even plantar vessels has saved many limbs that in the past would have certainly been amputated [11,13]. Angioplasty, stenting and surgery to the proximal vessels are, of course, still of value if these arteries are the main sites of disease. In patients without evidence of frank ischaemia, chemical sympathectomy may alleviate rest pain [14]. Prostacyclin, prostaglandin E and prostacyclin analogues, such as iloprost, are being tried in patients in whom a bypass cannot be constructed. There is now some evidence that these compounds can preserve a small proportion of threatened limbs [15]. Therapeutic angiogenesis with vascular endothelial growth factors has been tried experimentally but there is as yet no evidence of its efficacy.

The immediate amputation rate can be lowered from the 80% of a few years ago to 40% or less by a policy of aggressive reconstruction, but this improvement is probably at the cost of a few higher amputations and some increased loss of life when graft failure is associated with a further episode of ischaemia and consequent amputation [16].

Acute limb ischaemia. Patients presenting with acute limb ischaemia should be rapidly assessed and, unless there is unequivocal evidence of an embolus (suggested, for example, by normal vessels in the other limb, atrial fibrillation or recent myocardial infarction), the patient should have urgent catheter angiography to confirm the diagnosis and to assess the cause of the occlusion. This should be followed by infusion of a tissue plasminogen activator into the thrombus or embolus via the catheter unless the state of the limb demands urgent revascularization or amputation [17]. Repeat angiography, to confirm continuing or successful thrombolysis, is required at frequent intervals, and residual stenoses responsible for the thrombosis may require angioplasty, stenting or surgery. Patients whose vessels are opened up by thrombolysis must remain on anticoagulants.

Balloon-catheter embolectomy should be reserved for embolic occlusions. When platelet emboli are suspected, aspirin or dipyridamole may be prescribed before a definitive surgical or radiological intervention to remove the source of the emboli.

Amputation remains the final option in all types of ischaemic disease of the lower limbs where revascularization is impossible or ineffective. The value on subsequent mobility of preserving the knee joint is well recognized. The mortality of amputation stays stubbornly high (15–20%).

Painful vascular disorders of the extremities

Small vessel calcification (calciphylaxis) [1,2]

Arterial calcification is a common and usually symptomless complication of chronic renal failure. More rarely, especially when associated with hyperparathyroidism, there is complete vascular occlusion and infarction of the skin (Fig. 50.8). There is usually extensive livedo reticularis and patchy subcutaneous thickening attributable to fat necrosis, which often underlies the infarcted skin, involving principally the inner aspects of the thighs [3]. The radiological appearances are characteristic with considerable small vessel calcification in addition to the involvement of large vessels. The pathogenesis is unexplained, but the term calciphylaxis is often used because of the similarity to changes occurring in rats in experiments that induced hypercalcaemia and metastatic calcification. Uraemia and hyperphosphataemia are often

Fig. 50.8 Ulceration associated with calcification of arteries in secondary hyperparathyroidism.

more obvious than hypercalcaemia in the human. Women are most often affected. The exact role of hyperparathyroidism and, indeed, even its necessity for the diagnosis, is debated. Mehta *et al*. [4] identified a functional, although not quantitative, protein C deficiency in five patients: a hypercoagulable state has been inferred and the histology of the skin often reveals fibrin in the small vessels (Chapter 48). The prognosis is poor and treatment unsatisfactory. The management of uraemia, serum calcium and phosphorus is essential. Parathyroidectomy is only appropriate where there is definite evidence of hyperparathyroidism. The relevance of controlling a hypercoagulable state is unproven.

Thromboangiitis obliterans [1,2]

SYN. BUERGER'S DISEASE [1]

This appears to be a distinct condition separate from other forms of vascular occlusion [2,3], with differences in the pathological appearance of the vessel wall, and in the affected population compared with other arterial diseases [2].

Definition. This condition was first recognized as an obliterative disorder of peripheral arteries of young males by Leo Buerger in New York in 1908 [1]. The affected young men were all heavy smokers and the disorder involved the small vessels of the upper limb much more commonly than in atherosclerosis. It is common in the Middle and Far East, and in the Indian subcontinent, but there is no evidence that Jews are particularly affected (Leo Buerger worked at Mount Sinai Hospital in New York where the clientele were almost exclusively Jewish). The accompanying veins and nerves are involved in the inflammatory process and there are often other signs of non-specific inflammation, such as erythema nodosum.

Aetiology [2]. The aetiology of the condition is unknown, although tobacco addiction is invariably a major contributing factor, and a failure to overcome this addiction is associated with progressive occlusion of the vessels. Autoantibodies have been found in the circulation within the blood [4] and there may be changes in the behaviour of complement and the release of endogenous vasodilators and anticoagulants. In particular, antiendothelial cell antibodies are present in high titre in active disease, may be used to monitor disease activity, and may have a pathogenic role [2] (Chapter 49).

Pathology [2,5]. The full thickness of the vessel wall is invaded by lymphocytes, eosinophils, plasma cells and monocytes, especially disrupting the internal elastic lamina, and there is occlusion as a result of highly cellular thrombosis. Accompanying nerves and veins may become involved in the inflammatory process. All changes are segmental or focal. At a later stage in the disease, fibrosis occurs, which spreads to involve surrounding structures.

Clinical features. The condition usually appears in men between the ages of 25 and 40 years; however, women may also be affected. Pain is the main presenting symptom and may be of several types: intermittent claudication; rest pain, more severe at night; pain associated with ischaemic neuropathy, ulceration or thrombophlebitis. Sensitivity to cold is a frequent complaint. Claudication of the foot is especially characteristic [2].

Ulceration or gangrene may develop early in the disease, particularly following trauma, and often starts around the sides of the nails or tips of the digits (Fig. 50.9). Trophic changes, thrombophlebitis and oedema are also often present. Red or cyanotic acral colour changes are often unilateral, asymmetrical or may affect isolated digits.

Recurrent venous thrombosis is a frequent problem and may take the form of superficial red streaks and cords of 0.5–3 cm [2] or deep-vein thrombosis presenting with pain and swelling. Erythema nodosum may also develop (Chapter 49).

Ischaemic areas are found on the tips of the fingers and toes and may initially present as chronic painful paronychia. The proximal pulses are usually present (the femoral, popliteal and brachial), while the distal pulses

Fig. 50.9 Ischaemic toes in Buerger's disease.

Fig. 50.10 An arteriogram in a patient with Buerger's disease. No major vessels are seen, just multiple collateral arteries.

(dorsalis pedis, posterior tibial and radial) are lost at an early stage.

Investigations. The erythrocyte sedimentation rate (ESR) is often elevated, antiendothelial cell autoantibodies may be detected, and arteriography is often diagnostic (Fig. 50.10). The proximal vessels are usually entirely normal while the distal arteries are diffusely affected with multiple stenoses and occlusions. Many collaterals are often present and are typically described as 'corkscrew' collaterals. Arterial biopsy may show the histological changes described above.

Differential diagnosis. This includes atypical 'young onset' atherosclerosis, diabetic vasculopathy and rheumatoid arteritis. Collagen-vascular diseases, such as scleroderma and systemic lupus erythematosus, must also be considered in the differential diagnosis. Multiple emboli derived from a proximal source may pose real diagnostic difficulty, and ergotism must not be forgotten. In mild cases, acrocyanosis, livedo reticularis and erythromelalgia may be considered. Gout and osteoarthritis of the hip and knee may cause leg pain, and interdigital neuromas and metatarsalgia cause foot pain. Spinal cord compression and sciatica can also be responsible for pain in the lower limb.

Treatment and prognosis. The dermatologist may be faced with the problem of a patient referred for ulceration or erythema of the foot and toes. Once the diagnosis is established, the matter is best dealt with by the vascular surgeon, whose advice should be sought. Collateral anastomosis can be expected to occur during phases of inactivity of the disease. Warmth, bed rest and strict abstinence from smoking are the main facets of conservative treatment. There is little evidence that anticoagulants or corticosteroid therapy influence the outcome. Surgical or chemical sympathectomy is usually helpful; vasodilators (except alcohol and reflex warmth) are not [6]. In a double-blind study of a chemically stable prostacyclin analogue, 85% of patients treated showed ulcer healing or relief of pain compared with 17% of an aspirin-treated group [7].

Arterial reconstructive surgery has little part to play in the management of this condition because of the distal nature of the disease. After sympathectomy every effort should be made to avoid major amputations by the use of antibiotics and, when necessary, toe excisions. Below-knee amputation may eventually be required, particularly if gangrene extends to the foot. It should not be unreasonably delayed. The prognosis is poor in those patients who continue to smoke; hands as well as feet may be lost.

Erythromelalgia [1]

Definition [2]. A condition of painful red extremities in which a sensation of burning is associated with a vasodilatation of the affected skin. The synonyms erythermalgia [3] and erythralgia are confusing and will not be used further. Essentially there are three types:
1 *Type 1*: Associated with thrombocythaemia and relieved by aspirin;
2 *Type 2*: Primary or idiopathic and usually congenital, provoked by exercise or exposure to warmth;
3 *Type 3*: Secondary to inflammatory or degenerative peripheral vascular disease.

Pathogenesis. Type 1 is the result of thrombocythaemia and is seen in polycythaemia and myelofibrosis. It may be unilateral or even affect one finger or toe [4–7]. It is not often relieved by cooling, and often progresses to ischaemic necrosis. There is fibromuscular intimal proliferation and occlusive thrombosis of digital arterioles and arteries [8].

Little is known of the primary pathology of type 2 [9]. It is confined to the lower legs and does not progress to ischaemia. It is often familial and the gene has recently been located to chromosome 2 [10]. Attenuation of vasomotor nerves, beginning in childhood, was observed in one case and caused diminished capacity to vasoconstrict, equivalent to a sympathectomy [11]. Other authors [12,13] have implicated a temperature-triggered release of chemical pain mediators and vasoactive substances, especially serotonin. Microvascular arteriovenous shunting has been proposed as the cause [14], symptoms being caused by tissue hypoxia induced by a maldistribution of skin blood flow. Dysfunction of autonomic nervous function has been demonstrated [15] as well as disturbances in the regulation of microvascular perfusion [16]. Post-ganglionic sympathetic dysfunction and denervation hypersensitivity may have a pathogenic role whereas local neurogenic and endothelial function appear to be unaffected [17].

Pain occurs in direct relationship to the temperature of the limb, occurring about a 'critical point', which normally lies between 32 and 36°C and which is constant for each individual [18,19]. Pain is not a direct result of vasodilatation itself and can be induced or maintained by warming the limb with its blood supply occluded by a cuff. Pain is worse with the limb dependent, irrespective of its temperature, and may be induced by obstructing venous return. Because such manoeuvres do not cause pain or distress in normal subjects, it must be assumed that those who suffer from erythromelalgia have an undue sensitivity to warmth in the skin of the extremities.

In considering secondary erythromelalgia [18,20], it must be understood that peripheral vascular disease is often characterized by high resting flows and vasodilatation of the microvascular bed. There is usually a failure to respond to a further increase in metabolic demand, such as reflex hyperaemia, or to the needs of tissue repair following injury and ischaemic necrosis.

Clinical features. Types 1 and 3 are rare in childhood, and most commonly affect those over middle age. The idiopathic type is more likely to be seen in younger subjects and is more often bilateral [19]. A dominant inheritance was noted in 19 out of 51 affected members of a family of five generations [21]. Females are more often affected [22]. In types 1 and 3, the hands and feet are usually involved but sometimes only a part of one extremity is affected. The principal feature of erythromelalgia of all types is that attacks are precipitated by exercise or heat, such as a warm bed, and are relieved by rapid cooling, such as immersion in iced water. The patient complains of intense burning associated with erythema and increased warmth of the extremity. Attacks last from a few minutes to several hours. A warm climate and fever may also increase the distress.

Ulceration and trophic changes, indicating a relative insufficiency of blood supply needed for tissue repair, may occur in all three types but are more likely to be a presenting sign in secondary erythromelalgia associated with arterial disease, or may result from cold immersion injury when relieving symptoms.

Differential diagnosis. The fully developed characteristics of the syndrome and the description given by the patient seldom leave doubt about the correct diagnosis. Complex regional pain syndrome (reflex sympathetic dystrophy) following trauma can produce a similar clinical pattern. The effect of dependency, and the bizarre measures usually taken by the patient to obtain relief, are also indicative of the diagnosis.

The relationship to temperature can be confirmed by reflex or direct heating to above the 'critical level'. Some young patients may complain of pain and colour change of the lower legs on prolonged standing. This presentation has been termed angiodyskinesia (p. 50.11).

Associations. Once the diagnosis is confirmed, the patient must be investigated for possible organic causes of the syndrome. These include hypertension, diabetes, rheumatoid arthritis, lupus erythematosus [23], thromboangiitis obliterans, gout and vasculitis [24]. The most important association of secondary erythromelalgia, however, is with myeloproliferative disorders, for example polycythaemia vera or thrombocythaemia, of which it may be a presenting and premonitory symptom, often by several years. Of 51 cases in one series [19], 30 were idiopathic and 10 of the remaining 21 had some form of myeloproliferative disease. Further cases of thrombocythaemia have been reported [7]. Vasoactive drugs, such as nicardipine, have been incriminated [25,26] as has mercury poisoning [27].

Prognosis. Although held to be poor—even fatal—in the past, this gloomy forecast was probably affected by the inclusion of cases of atherosclerosis and polycythaemia rubra vera. Nevertheless, there is a significant decrease in survival compared to the general population and most cases get worse over time [22].

Treatment. No treatment is consistently effective with a dearth of adequate studies. Management rests with avoiding exacerbating factors, and controlling secondary and underlying factors [28]. Thrombocythaemia, or causes of inflammatory vascular disease, must be treated where possible. Small doses of aspirin give considerable relief in some cases—presumably by preventing platelet aggregation and clopidogrel may be a more effective antiplatelet agent [5,29]. Patients with vasodilatation and warmth in their affected painful extremities prefer immersion in cold water. Elevation also provides some relief by decreasing oedema. Some have claimed relief of erythromelalgia with benoxybenzamine hydrochloride or propranolol [30]. Amitriptyline is often a useful first-line therapy. Pain has been totally controlled using epidural blocks for 3 weeks to obtain healing of ulceration. The response of one family to pizotifen has been reported as spectacular [31]. In a child with erythromelalgia and growth hormone deficiency, recombinant growth hormone therapy immediately relieved pain and healed cutaneous ulcers [32].

Complex regional pain syndrome

SYN. COMPLEX REGIONAL PAIN SYNDROME TYPES I AND II; REFLEX SYMPATHETIC DYSTROPHY; CAUSALGIA; SUDECK'S ATROPHY

Complex regional pain syndrome (CRPS) is the name now given to a syndrome of chronic pain and hyperalgesia, associated with sensory, motor, autonomic and dystrophic disturbances, usually in a limb. Patients typically describe pain, swelling and difficulty with use of the affected limb. The pain has a burning or deep aching quality and is aggravated by movement, consequently there is a tendency not to use the limb. Similarly, hyperalgesia causes guarding of the limb to protect it. The skin takes on a deep red to blue colour, suggesting vasodilatation, and is initially warmer than the unaffected contralateral limb but becomes cooler in the later stages. Oedema may result from disuse and dependency, and atrophy develops (Sudeck's atrophy). Increased blood flow is an important diagnostic feature of early CRPS [1]. It is usually demonstrated objectively using a three-phase bone scan [2]; the delayed phase of this scan is very sensitive, and a segmental diffuse increase in uptake of radionuclide is very specific, but additional vascular scans may be helpful in some patients. Increased periarticular uptake is also typically seen.

The classic syndrome usually develops after a trivial injury or surgical operation (CRPS type II, causalgia) but the same syndrome can occur for no obvious reason and where peripheral nerves remain undamaged (CRPS type I, reflex sympathetic dystrophy) [3]. The mechanism for both types has been better clarified; there appears to be inhibition of cutaneous sympathetic vasocontrictor neurones, but in chronic CRPS the secondary effect of adrenergic supersensitivity overcompensates in response to this loss of sympathetic vasomotor control [4].

Treatments include physical therapy (first-line) with the addition of anticonvulsants, antidepressants and then opioid analgesia according to severity. Severe cases may require regional anaesthetic blockade [5]. In selected patients with severe and chronic pain, electrical stimulation of the spinal cord can reduce pain and improve quality of life [6].

Angiodyskinesia

Paraesthesiae, painful burning sensations and redness or pallor of the legs after prolonged walking or dancing have been described in young people [1,2] and it has been suggested that these were a consequence of abnormal functioning of arteriovenous communications. The term 'angiodyskinesia' has been applied to this condition [3].

Under this title, Ryan and Wilkinson described a blotchy erythema of the legs in a 14-year-old boy [4]. His condition developed at the same time as osteochondritis dissecans. The erythematous areas were 2–3°C warmer than the adjoining skin, and disappeared when the patient was recumbent, reappearing and becoming uncomfortable when he was standing. These features suggest failure of the normal vasoconstriction that occurs when a limb is lowered. The condition was more marked in warmer conditions and after a bath.

Restless legs syndrome

This syndrome characterizes a discomfort that forces those affected to fidget and to move their legs when at rest. Restless legs syndrome (RLS) is a disorder of motor activity with a circadian pattern, which occurs frequently in neurological disorders such as Parkinson's disease [1] but also in fibromyalgia and rheumatoid arthritis [2]. Dopaminergic agents and dopamine agonists are considered to be the treatment of choice [3]. Repeated blood donation and resulting iron deficiency can also be associated with RLS [4].

Arteriovenous shunts and aneurysms

It is convenient to consider separately the following:
1 Arteriovenous shunts;
2 Arteriovenous aneurysms ('fistulae'):
(a) congenital;
(b) acquired.

Arteriovenous shunts

These form an alternative peripheral system of blood flow and are an integral part of a reserve or compensating mechanism at times of capillary stress and injury. They are called into play when the microcirculation is damaged and the superficial vessels congested, diverting blood away from the papillary capillary plexus [1]. Their presence can be demonstrated by finding a high oxygen saturation in venous blood and a reduced circulation time [2]. They are active in venous hypertension and varicosity [3] and in leg ulcers [4], in atherosclerosis [5] and perhaps with the hormonal changes of pregnancy [6]. They are also active in psoriasis, with neoplasia [7] and in skin flaps. They may be responsible for the postural changes seen in angiodyskinesia, and are a feature of arborizing telangiectasia.

Persistent arteriovenous shunts cause local venous hypertension, which may lead to ischaemia [1]. The

changes this produces in the vessels make the interpretation of biopsies difficult.

Arteriovenous fistulae

Arteriovenous fistulae [8] consist of direct connections between larger arteries and veins and are always pathological. Their various congenital and acquired forms have been given a large number of descriptive titles (cirsoid aneurysm, aneurysmal varix, pulsating angioma, etc.) but are best described here simply as congenital and acquired. Localized and pulsating, they may present as red nodules with overlying telangiectasia, like a giant spider naevus. While most common on acral sites, they also occur in the head and neck and on the trunk.

Congenital

These are discussed fully elsewhere (Chapter 15). They result from failure of embryological differentiation into artery and vein [8]. The many clinical varieties that affect the skin and visceral organs have been grouped together under the term congenital dysplastic angiopathy [6]. When such congenital fistulae involve the limb vessels they often give rise to distinctive physical signs which are described below.

Acquired

These are almost always traumatic; they are often large, and may therefore cause significant cardiovascular effects. Early diagnosis is important. Treatment is entirely within the province of the vascular surgeon, who should be consulted if there is suspicion of the existence of such a fistula. Treatment is by inserting a covered stent to close off the opening from 'within', or by open surgical closure.

Signs and effects of arteriovenous fistulae [9,10]

Traumatic fistulae following penetrating wounds, or occasionally operations, can occur anywhere in the body. They should be suspected whenever venous varicosity is unilateral or when signs of venous insufficiency develop unexpectedly after an injury. Increased warmth of a limb and the finding of a machinery-like constant murmur or palpable thrill establish the diagnosis. Arteriography confirms the site and indicates the size of the communication. Congenital fistulae commonly affect the limbs and are often multiple. They should be suspected when unilateral varices present early in life without a genetic background. The limb is warmer and may be larger than the contralateral limb. Slowing of the pulse produced by inflation of a proximal tourniquet at the root of the limb (Branham's sign) is indicative of a large arterial shunt.

The effects of arteriovenous aneurysms depend on their size and the volume of blood flow through the fistula, rather than its site. When small, no cardiovascular changes may be evident, although there will inevitably be some permanent diversion of blood from the capillary bed. Larger fistulae cause dilatation in the superficial veins distal to the site, with a varying degree of impairment of the arterial circulation. The cardiac output increases, often considerably; the heart is dilated and the diastolic blood pressure is reduced, increasing the pulse pressure.

In skilled hands, embolization under angiographic control is the most effective therapy. An alternative is to mobilize the vessel and ligate all the branches (skeletonization). It is now possible to insert a covered stent to block off a localized fistula and this is the treatment of choice in a traumatic fistula in an inaccessible location. Amputation may occasionally be necessary if congestive cardiac failure is a problem.

Venous disorders

Anatomy, physiology and pathophysiology [1,2]

Anatomy

Although the general architecture of the veins is similar to that of the arteries, their walls are thinner, the middle (muscular) coat being particularly weak. Most veins are endowed with semilunar valves; these are usually in pairs, but sometimes only one, or sometimes three, are present. These valves are lined by endothelium and are found especially in the smaller veins and at the junction of these with larger branches. They prevent the reflux of blood and are particularly important in the leg, where their integrity, and that of the calf-muscle pump (the venous heart), must effectively counter the gravitational hydrostatic pressure. There are three systems: the deep veins; the superficial veins; and the communicating veins,

numerous and inconstant, connecting the other two systems. During muscular activity, blood is directed from the superficial to the deep system, from the foot to the thigh and up into the abdomen, such that venous blood returns towards the heart. Bicuspid valves are found in all three systems. The smallest veins containing valves lie at the dermal subcutaneous junctions [3] and are extremely variable. A complete avalvular state has been reported but, more often, valves are absent in just one of the three systems. Valves may become damaged, thickened or degenerate with age [4]. Thrombosis also causes vulvular destruction and a recanalized post-thrombotic vein is valveless, anatomically distorted and functionally inefficient [4]. There are approximately 80 potential communicating veins in the thigh and leg; the most important of these are considered to be the medial perforating veins (communicating veins) of the lower leg, the incompetence of which has been emphasized as a predominant factor in venous ulceration [4]. Many communicating veins link with a vein in the muscle before joining the deep veins, and are probably of little significance even when incompetent.

Physiology

In health, venous return occurs as described above, the valves within the communicating veins preventing blood passing from the deep veins into the superficial veins of the legs. Factors affecting the normal venous return include the venous tone, the amount of muscular activity and the intrathoracic pressure. In the absence of muscular movement, an increase in the leg volume occurs without pitting oedema, and the tissue pressure rises considerably.

Little is known about the factors governing venous tone, but a loss of tone may be important in hypotensive or endotoxic shock, vasovagal syncope and in response to cooling [1,2]. Venous tone is reduced in pregnancy and it also changes during the menstrual cycle.

The efficient return of blood to the heart depends upon a functioning deep-vein system. In the erect posture, at rest, the pressure at the ankle is governed entirely by the individual's height (i.e. distance to the heart). Patients with venous disease were on average 1.4 cm taller in one study [3]. Venous pressure at the ankle is normally 70–100 mmHg (100–140 cmH_2O), dropping to 0–30 mmHg (0–40 cmH_2O) on exercise or recumbency, and remaining at about 55 mmHg (75 cmH_2O) while sitting [4]. The Western child spends 8–10 waking hours in a sitting posture, causing constantly high venous pressure [5]. There is also evidence that children in the developed world are no longer undertaking adequate physical activity [6].

Even apparently insignificant muscular movements of the lower leg cause a dramatic fall in venous pressure. This slowly returns to its original level after exercise ceases. A walking rate of only 40 paces/min is sufficient to empty the deep veins with a normal heel to toe gait. The venous network in the sole of the foot is emptied by compression from muscular contraction while standing and walking. This is known as the foot pump.

Physiology of small veins predisposing them to disease

The physiology of small veins is of particular importance. When venules and veins were first fully investigated [7–9] by electron microscopy [10], dye studies [11] and the identification of sites of increased permeability with radiolabelled carbon [12], it was appreciated that there was a gradient of permeability from arterioles to venules, with protein exchange occurring in the latter [12]. Endothelial contractility [12], leukocyte adherence and endothelial proliferation [13] all occur maximally at the venous end of the microvascular system. Manipulation of venous outflow compared with arterial inflow has a disproportionately greater effect on transcapillary exchange [7]. The blood enters the capillary bed under a reasonably constant head of pressure, and local shifts in capillary pressure are introduced by changes in the resistance presented by the effluent venules [8]. These venules are the most reactive of the microcirculatory components: they also have a larger surface area of endothelium than the capillaries [14].

Antigen–antibody complexes can be observed to injure the venules in experimental models such as the rabbit's ear chamber [11]. The Arthus and Schwartzmann phenomena occur in venules [15].

In this section, most of the pathology discussed relates to the legs, where venous hypertension and impaired flow readily occur and where cold further increases blood viscosity [13,16].

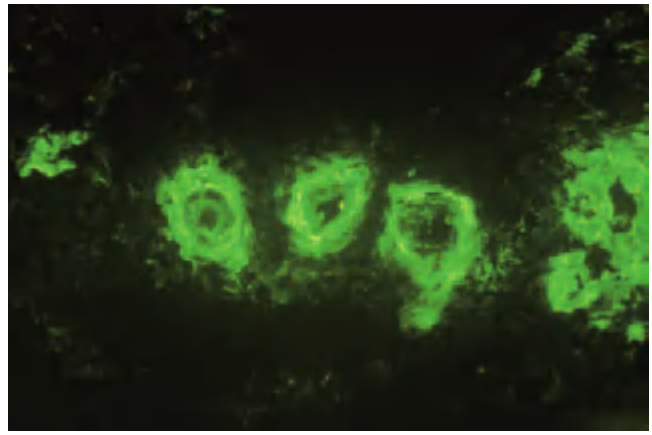

Fig. 50.11 Pericapillary fibrin cuffs. Immunofluorescence with antifibrinogen–fibrin antibodies on lipodermatosclerotic skin.

Pathophysiology

In patients in whom venous valves have become incompetent, blood is able to reflux back into the superficial veins, abolishing the normal pressure drop that occurs on exercise and causing a persistently elevated venous pressure during walking and other forms of erect exercise. This occurs when there is incompetence of the long or short saphenous veins, or of the communicating veins; incompetence of communicating veins may be especially important where the medial calf 'perforating' veins become incompetent such that the high pressure generated within the calf muscle pump (200 mmHg) is directly transmitted to the overlying dermal venous plexus beneath the skin. Incompetence of the perforating veins may occur as an extension of the varicose process but may also develop as a result of damage within the deep veins. Defective function of the deep veins is almost always the result of previous thrombosis, which can cause valvular damage or obliterate large segments of venous lumen. Subsequent perivenous fibrosis may prevent the veins from dilating and act as a 'functional' obstruction. For blood to return from the lower leg and bypass these obstructed segments, the valves in the perforating veins must cease to function, allowing blood to pass into the superficial channels which then become secondarily incompetent. The consequent raised venous pressure gives rise to abnormal microvascular responses, discussed below, with associated clinical features that are discussed later.

Microvascular response to raised venous pressure [1–3]

Persistently elevated venous pressure affects capillary function. The transmural and intraluminal pressures increase, particularly at the venous end of the capillary bed, encouraging more fluid and electrolytes to enter the tissues. This results in oedema. In addition, the individual capillary beds elongate and distend, allowing a larger surface area for transluminal migration [4–8], although there is also a reduction in the number of capillary loops supplying the epidermis [6]. As the capillaries distend, larger molecules and the cellular moieties of blood escape into the interstitial fluid. Normally, these cells and macromolecules are broken down and cleared by macrophages and the lymphatics, but if sufficiently large quantities enter the interstitial fluid, the normal homoeostatic mechanisms are swamped. This results in accumulation of solid particles in the interstitial space around the capillaries, particularly in the dermis where 'halos' have been found around the capillaries using cutaneous microscopy [1].

Fibrinogen is one of the largest molecules normally retained within the vascular compartment and when this escapes, becoming supersaturated within the tissues, it is capable of becoming cross-linked and forming insoluble fibrin. Pericapillary 'fibrin cuffs' have been found in the dermis of almost all patients with the pre-ulcerative changes of lipodermatosclerosis (pigmentation, induration and inflammation) [8]. They have also been found in limbs with chronic venous insufficiency (those with defective calf-pump function and post-thrombotic limbs) before the skin changes of lipodermatosclerosis are present [9]. An impaired hyperaemic response after 3 min of arterial occlusion in patients with venous ulcers was proposed to be caused by a mechanical barrier of fibrin or oedema around the small vessels [10]. Additionally, the number of capillaries with perivascular fibrin 'cuffing' (Fig. 50.11) was shown to correlate with the amount of oxygen crossing the dermis; the greater the number of capillaries with fibrin cuffs, the lower the transcutaneous Po_2 measured by a modified Clark electrode heated to 45°C [9]. However, *in vivo* diffusion studies in patients with lipodermatosclerosis [11] did not show a defect in xenon diffusion (xenon having similar diffusion char-

acteristics to oxygen), and modelling of oxygen diffusion suggests that fibrin cuffs would not act as a barrier [12]. It is therefore unlikely that the fibrin cuff theory could explain sufficient dermal hypoxia to cause ulceration. Theoretical models of fibrin cuffs [12] do not, however, take into account the thickened vessel walls and other constraints such as collagen, laminin and fibronectin found within the cuff.

Any fibrin that is formed should be broken down to soluble fragments (fibrin degradation products) by the action of plasminogen activators that convert plasminogen to the active enzyme plasmin. Investigation of the fibrinolytic capacity of patients with lipodermatosclerosis has shown diminished production of plasminogen activators and an increased level of inhibitors in both the blood and tissues, resulting in tissue inability to lyse fibrin clots artificially formed within the calf tissues. It is not known if the reduction in fibrinolytic ability is a primary tendency present from birth, or if it is an acquired abnormality as a result of exhaustion of fibrinolytic capability following extensive deep-vein thrombosis.

Homans [13] suggested that stagnation of venous blood as a result of defective venous return caused hypoxic tissue damage. Although there was initially some support for this hypothesis, the measurement of venous oxygen tensions failed to confirm hypoxia, and instead revealed that the oxygen tension of the venous blood from ulcerated limbs was high rather than low [14].

There is considerable controversy over what some believe to be the myth of 'venous stasis ulceration' [15,16]. 'Gravitational ulceration' is another unsatisfactory term that does not wholly explain the pathophysiology of ulcers. Nevertheless, the capillary venous bed in limbs with venous disease during sitting or standing may be composed of areas of impaired blood flow, at the same time as short circuits or preferential vascular pathways open up [6].

The finding of increased oxygen tension in the veins led to the hypothesis that arteriovenous shunts may have opened up in response to the raised venous pressure [14]. The presence of increased numbers of arteriovenous shunts has not been a consistent finding [17], and functional studies using isotopically labelled macroaggregates gave no indication of a physiologically important shunt [18,19]. High resting flows as a consequence of both persistent arteriolar dilatation and loss of vasoconstrictor response to changes in posture are suggested by laser Doppler studies [20].

Positron emission tomography (PET scanning) confirmed that patients with lipodermatosclerosis or venous ulceration had an increased calf blood flow in the ulcer-bearing region and a decreased oxygen uptake by these tissues [18]. Such findings obviously fit with the diffusion (fibrin) block hypothesis and do not exclude the presence of arteriovenous fistulae. It is also possible that high resting flows cannot increase further to meet the demands of wound healing following injury, a concept that is currently popular in diabetology and is based on vessel-wall stiffness caused by fibrin and collagen [21].

Dependency of normal limbs causes white cells to disappear from the venous effluent draining the dependent limb [22]. This observation was extended by Thomas *et al*. [23], who showed that dependency caused even more white cells to disappear in limbs with venous hypertension and chronic venous insufficiency.

Coleridge-Smith *et al*. [24] found that dependency appeared to reduce the number of capillary tufts seen on cutaneous microscopy and assumed that the 'disappearing' white cells were lodging in the capillary bed and occluding flow through the cutaneous capillaries [25]. These two sets of observations led to the development of the theory that white-cell plugging impairs perfusion and this could be exacerbated by vessel narrowing or stiffening caused by the fibrin cuff. It is sometimes forgotten that the capillary bed is a network in which preferential or low-resistance pathways can virtually act as shunts while less preferred channels are slow-flowing or static. While whole-skin blood flow is enhanced, the nutritional bed can experience ischaemia.

Histological studies have failed to show white cells blocking capillaries but have shown a greater number of leukocytes within the tissues [26]. This suggests that white cells migrate in the same way as fibrin. Another histological study [27] shows that the 'fibrin cuff' contains many more proteins than just fibrin; for example collagen and often proteins like laminin are important constituents. The expression of specific adhesion molecules on both leukocytes and endothelial cells is influenced by a number of cytokines, some of which may even be trapped in the 'fibrin cuff' surrounding the venules. Such adhesion molecules are discussed in Chapter 10. The relationship between the release of the endogenous vasodilator endothelial-derived nitric oxide and the control of the adhesion molecule P-selectin is but one of many discussed in a review of this topic [28]. There does appear to be an increase in adhesion molecules and activated neutrophils both locally and in the circulation [29,30] in venous hypertension, but the cause of this remains to be elucidated. Vascular cell adhesion molecule 1 (VCAM-1) seems to be the most significant factor in this process [26].

Falanga and Eaglstein [5] have suggested that the pericapillary cuffs block epidermal growth factor migration and this leads to inadequate tissue repair, which eventually causes ulceration. Other theories on venous ulcer causation include reperfusion injury from ischaemia and reperfusion caused by the venous hypertension associated with changes in posture [29]. More recently it has again been suggested that the whole mechanism is a purely mechanical problem [31]. No current theory fits all

the circumstances that are known to be associated with venous ulceration.

Venous thrombosis

Deep-vein thrombosis (DVT)

Incidence. Prevalence studies have relied on a clinical history in population surveys and hospital records of clinically diagnosed thrombosis. Autopsy studies are also available. Studies of selected populations by phlebography or by clinical symptoms and signs do not correlate well with subsequent clinical behaviour [1]. It seems likely that improved post-operative management and the use of anticoagulants has reduced the incidence of DVT. On the other hand, the ageing population and sedentary lifestyle may increase the prevalence of both venous and arterial thrombosis.

Pathogenesis. This involves coagulation, platelet aggregation and injury to venous endothelium. The maintenance of the fluidity and circulation of the blood and its ability to thrombose are essential for the maintenance of life and are governed by extremely complex homoeostatic mechanisms. The mechanisms of thrombosis, a protective device to prevent loss of blood and to seal off a damaged blood vessel, and of fibrinolysis, which counteracts or stabilizes the effects of thrombosis, depend upon systems of consecutive enzyme activity with activators and inhibitors finely balanced at every stage.

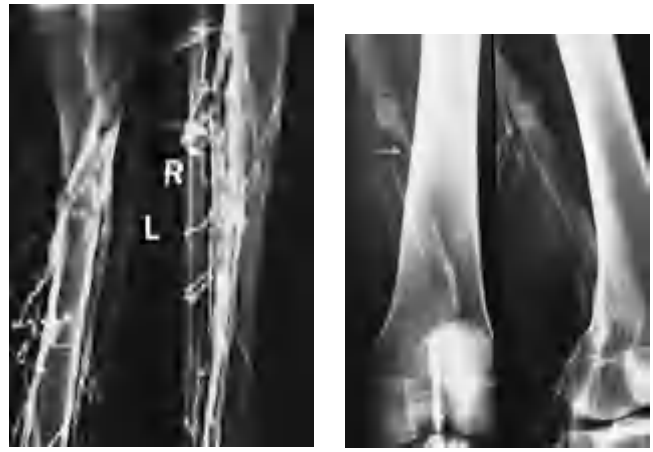
Thrombosis is discussed in Chapter 48. Alterations in the blood coagulability, platelet population and agglutinating power, with changes in blood flow and endothelial damage, are the precursors of intravenous thrombosis. Of these, the loss of normal function of the vascular endothelium is probably of primary importance [1]. Anticardiolipin antibody is also now recognized as an important cause of thrombosis [2,3]. A number of other hereditary and acquired conditions that predispose to thrombosis (the thrombophilias) have now been recognized. These include protein C and S deficiency, antithrombin deficiency and activated protein C resistance (which is usually associated with a factor V genetic abnormality [4]). Screening for these 'thrombophilias', and for anticardiolipin antibody, should be performed in patients having sporadic or recurrent thrombosis [5]. Surgical operations and pregnancy remain important triggers, and prolonged immobility as in aeroplane flights, or hormonal influences, such as the contraceptive pill, are also well-documented risk factors.

Any agent that causes inflammation or damage of the vein wall is a potential cause of thrombophlebitis. In some

Fig. 50.12 An iliofemoral venous thrombosis causing swelling and erythema of the whole left limb.

cases, this agent is obvious: sclerosing agents, intravenous infusions, chemotherapy lines, ionizing radiation or neighbouring inflammatory processes. Injuries, especially tibial fractures, are a common cause of thrombosis [6]. Venous thrombosis may be an important and presenting sign of thromboangiitis obliterans (p. 50.7). Thrombophlebitis also occurs in malignant disease, in conditions such as Behçet's syndrome, and in infective fevers such as typhoid.

Clinical features. The onset of a thrombosis is often 'silent' and may remain so. It commonly occurs at or about day 7–10 after a surgical operation, parturition or the onset of an acute infection, concomitant with a rise in the platelet count and an increase in young 'sticky' platelets. Between one-third and two-thirds of patients complain of some swelling and pain in the leg, usually in the calf [1]. An iliac thrombosis should be suspected (Fig. 50.12) if the whole leg is swollen and dusky. Direct pressure on the calf muscles or over the course of the deep veins usually elicits direct tenderness; but the foot dorsiflexion test (Homan's sign) [5] should be abandoned as it is inaccurate. There may be a cyanotic hue to the leg and superficial venous dilatation. The temperature of the leg may be raised, and oedema of one ankle is an important physical sign. However, chest pain or cardiac arrest from pulmonary embolism are often the first indications of a DVT. Pulmonary hypertension may follow repeated small emboli, and is associated with the development of progressive dyspnoea.



(a) (b)

Fig. 50.13 (a) Thrombus in all the calf veins with localized thrombus in the popliteal veins. (b) Massive fresh thrombus extending up the common femoral and profunda femoris veins occluding the external iliac vein.

Pain and tenderness in the calf and popliteal fossa may occur resulting from other conditions such as a ruptured Baker's cyst or a torn plantaris tendon [7], and it is important to make a definitive diagnosis of thrombosis before anticoagulating the patient unnecessarily for 3–6 months.

Diagnosis. Compression ultrasonography has become the preferred first-line investigation; venography and/or phlebography is only performed where clinical doubt remains. However, bipedal ascending phlebography using non-ionic contrast media remains the most accurate method of confirming the diagnosis and of determining the best method of treatment (Fig. 50.13) [1,8]. Duplex Doppler scanning can detect thrombus in the iliac, femoral (Fig. 50.14) and popliteal veins with considerable accuracy (98–99% compared with phlebography) but is far less successful at detecting thrombi in the calf veins (approximately 70% concordance) [8]. Measurement of circulating D-dimer concentration (a by-product of fibrin production) is a useful adjunct to ultrasonography as it has a high negative predictive valve (i.e. low values strongly exclude thrombosis) [9].

Complications. Pulmonary embolism, post-thrombotic syndrome and recurrent thrombosis are the main complications of DVT. Post-thrombotic syndrome develops as the result of high venous pressure from valvular damage and venous obstruction.

Prevention. Dermatologists should be aware of risk factors for DVT, particularly in elderly bedridden in-patients with widespread skin disease and infection (Table 50.1). Prolonged sitting is as harmful as lying. Active exercise and early mobilization is desirable when possible. The

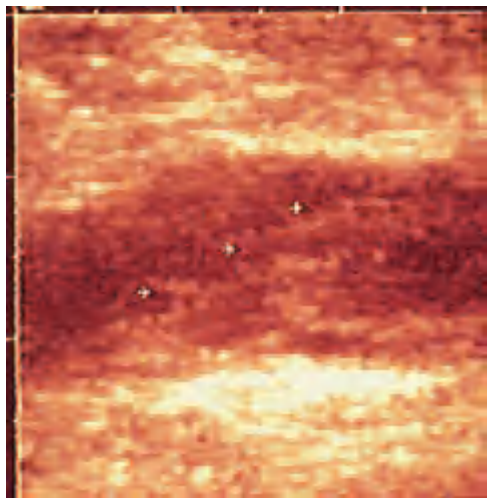


Fig. 50.14 A duplex scan showing non-compressible thrombus seen as a filling defect within the vein lumen. The proximal surface is outlined with markers.

Table 50.1 Risk factors for deep-vein thrombosis.

Obesity
Varicose veins
Paralysis or immobility
Surgical procedure lasting more than 30 min
Personal or family history of thromboembolism
Active cancer
Hormonal influences (pregnancy, oral contraceptive pill, hormone replacement therapy, tamoxifen)
Serious illness
Hypercoaguable states (protein C and S deficiency, activated protein C resistance, antiphospholipid syndrome, antithrombin III deficiency)

incidence of thrombosis is reduced from approximately 30% to 10% by graduated compression stockings [10]. Below-knee stockings appear to be as effective as thigh-length hosiery. Pneumatic compression therapy has been proved effective but is probably only realistic in post-operative circumstances.

Antiplatelet drugs such as aspirin provide some protection. Low-molecular-weight heparin given by daily subcutaneous injection provides effective prophylaxis with little increase in the risk of serious bleeding [11].

Treatment. The diagnosis should be confirmed as soon as possible by compression ultrasonography if a DVT is suspected. Initial treatment with a low-molecular-weight heparin given subcutaneously once a day should be based on a clinical suspected diagnosis plus an assessment of the patient's risk and a raised result on D-dimer testing. On confirmation of the diagnosis, once daily tinzaparin should be continued for up to 72 h. Warfarin treatment should be started after 24–48 h, unless contraindicated. When the activated partial thromboplastin time (APPT) is above 2, heparin may be discontinued. Warfarin should be maintained for 3–6 months, depending on the site and extent of the thrombosis. Warfarin is usually given in a dosage of 10 mg, 10 mg and 5 mg on the first 3 days. Elevation of the leg is recommended, particularly if oedema is present.

Superficial thrombophlebitis

In the absence of an obvious vein injury, thrombosis in the superficial veins usually develops because of slow flow within a varicose vein, and may occur in isolation. Nevertheless, coexistence of a silent DVT should be considered [1]. Thrombophlebitis occurring in apparently normal superficial veins should alert the clinician to the possibility of an underlying malignancy or thrombophilia.

Superficial thrombophlebitis of a varicose vein. This is the most common presentation of superficial thrombophlebitis. Pain, heat and tenderness overlying a palpable subcutaneous nodule or cord makes the diagnosis straightforward. Cellulitis may extend for some distance into surrounding tissue making distinction from infection sometimes difficult. There is no lymphadenitis or peripheral limb oedema unless accompanied by a DVT. Local oedema may be profound. Duplex ultrasound should be performed if the diagnosis is in doubt or if a DVT is suspected.

Superficial thrombophlebitis in non-varicose veins. Superficial thrombophlebitis may occur after an intravenous injection or insertion of an intravenous cannula with or without infection (septic thrombophlebitis). Damage to the

venous endothelium from needle trauma or an irritating substance (e.g. a chemotherapeutic agent) may induce both phlebitis and local thrombosis; extravasation of injected material into the perivenular tissues may have the same effect. When recurrent or widespread, consideration should be given to the possibility of a systemic cause such as cancer, a hypercoaguable state (protein C or protein S deficiency, antiphospholipid syndrome) or other diseases such as Behçet's syndrome or Buerger's disease.

Treatment. Superficial thrombophlebitis, unless accompanied by a DVT, is harmless but may be exquisitely painful. Spontaneous resolution usually occurs and only symptomatic treatment required. Oral non-steroidal anti-inflammatory agents may be helpful. Anticoagulation is not necessary, unless there is extension to the saphenofemoral or saphenopopliteal junction or an associated DVT. In some instances, post-inflammatory hyperpigmentation remains for some time along the course of the inflamed segment of vein. Elastic hosiery support is very valuable once the acute tenderness has eased, and exercise is essential.

Post-thrombotic syndrome [1]

SYN. POST-PHLEBITIC SYNDROME

Post-thrombotic syndrome (PTS) causes venous hypertension as a consequence of thrombotic damage to valves. It complicates 50–75% of deep-vein thromboses [2–6]. The more proximal the DVT, then the greater the risk of PTS. Elastic hosiery worn after a DVT will halve this risk.

Recanalization of the vein after thrombosis is variable. The walls of the vein are damaged and the lumen irregular. The valves are incompetent or missing. Even though not directly affected, the valves upstream may become incompetent with time as the proximal pressure progresses. Occasionally the vein does not recanalize and may fibrose or calcify. Any increase in venous outflow resistance further enhances venous hypertension.

Consequences of post-thrombotic damage include further DVT, superficial thrombophlebitis, oedema, skin changes from venous hypertension and eventually ulceration. Lipodermatosclerosis with prominent perforating veins are characteristic. Subcutaneous calcification can occur and calcium may be extruded through the skin, leading to ulceration.

The main differential diagnosis is primary varicose veins with deep-vein incompetence, or primary superficial venous incompetence which eventually leads to a decompensated deep-vein system as well. Consideration should also be given to other venous disorders (e.g. Klippel–Trenaunay syndrome, Parkes Weber syndrome, venous aneurysms, Ehlers–Danlos syndrome, arteriovenous fistulae and chronic deep-vein obstruction).

Chronic deep-vein obstruction [1]

The most common cause of deep-vein obstruction is DVT. Non-thrombotic causes include malignant disease or other pelvic masses compressing the iliac veins. Increased intra-abdominal pressure from obesity can result in venous hypertension and venous ulcers. In one report gastric bypass treated all but three of 37 venous ulcers [2]. Retroperitoneal fibrosis can obstruct the iliac veins and the inferior vena cava. The iliac compression syndrome (Cockett's or May–Thurner syndrome) is present when the left common iliac vein is compressed by the right common iliac artery crossing its path (Fig. 50.15) [3]. Flow alterations do not usually cause problems unless thrombosis supervenes. Large tumours (e.g. soft-tissue sarcomas) or aneurysms in the thigh may compress the deep femoral vein. In the popliteal fossa an aneurysm or a Baker's cyst can compress the popliteal vein. Primary tumours of the vein wall (leiomyosarcoma) are rare but are found more often in the lower limb. Ligation of deep veins may be unavoidable when removing malignancy or when repairing damage from accidental trauma.

Mondor's disease

Mondor's disease is diagnosed when palpable tender cords develop around the breast and chest wall [1].

Fig. 50.15 Iliac vein compression syndrome. There is a filling defect where the left common iliac vein is compressed by the right common iliac artery. Collateral veins confirm the presence of venous obstruction.

Occasionally they can 'bowstring' across the axilla and even extend down the upper limb as far as the hand. Doubt exists if this disorder is truly a phlebitis and it may be the result of a lymphangiothrombosis or even perineural inflammation. Thrombo-occlusive lymphangitis can also occur in the lower leg [2] or in the penis [3].

Thrombophlebitis migrans [1–4]

Recurrent migratory thrombophlebitis is an uncommon form of thrombophlebitis that affects large and small veins throughout the body. The condition may last months or years. The superficial veins of the lower extremities, abdominal wall, flank, arms or elsewhere undergo segmental thrombosis, causing crops of tender, linear or oval subcutaneous lumps or streaks. This is the pattern in Behçet's disease [5,6].

Much of the literature regarding migratory thrombophlebitis is concerned with the link with underlying malignancy, termed Trousseau's syndrome. This association was carefully reviewed by Sack *et al*. [7] and by Samlaska *et al*. [8], who suggested that migratory thrombophlebitis is chronic disseminated intravascular coagulation disorder.

The identification of many new factors contributing to coagulation has shed light on these syndromes. They include deficiencies of factor XII, antithrombin III, protein C, protein S, as well as abnormal plasminogen activators, lupus anticoagulant and anticardiolipin antibody syndrome, and activated protein C resistance. Clues to a primary hypercoaguable state include a family history, recurrent thrombosis, unusual anatomical site, early age of onset and resistance to conventional anticoagulation. Secondary hypercoaguable states are a consequence of malignancy, infection, pregnancy, the contraceptive pill, nephritis or liver disease [3,4,8]. A follow-up study of 4399 patients who had venography for suspected DVT recorded that 150 of 1383 with proven DVT and 182 of 2412 without thrombosis developed cancer; although the overall difference was not significant, there were significantly more cancers in the DVT group (66 cancers) than in the non-DVT group (37 cancers) in the first 6 months after the venography [9]. A more severe type of thrombophlebitis is associated with malignant disease. In 1500 cases of thrombophlebitis, 31 of 77 occurring with malignancy were of a migratory type [2]. The lung and pancreas were the most common sites of malignant tumours, although the breast, colon and stomach were also responsible. The cause of the thrombosis is unknown: a blood-borne neoplastic cell embolus seems unlikely; a coagulation factor associated with carcinomatous tissue has been postulated [4] but has not yet been isolated. A fibrinolytic defect has been found in some patients; often this is the result of an increase in inhibitors and may be associated with high levels of plasma triglycerides.

Treatment. Malignancy must be carefully excluded in patients with migratory thrombophlebitis. It may be difficult to locate, especially pancreatic carcinomas. Computed tomography (CT) scanning, ultrasound and magnetic resonance imaging (MRI) and even PET scans of the abdomen may be necessary to detect cancers in the pancreas and other organs. Treatment is otherwise conservative. Lowering triglycerides may be advisable; exercise is good prophylaxis. Stockings or bandage support for the legs are helpful. Stripping of the saphenous system has been advocated [1]. Earlier observations on the good effects of oral fibrinolytic agents [10,11] in Behçet's disease have not been substantiated by some later case reports [12].

Varicose veins and venous reflux

Varicose veins [1]

SYN. VENOUS VARICOSITY

The term should be reserved for visible tortuous elongation and dilatation of the larger superficial venous trunks and their tributaries. Leg varicosities seldom develop before adolescence in women [2]. Nevertheless, other types of venous dilatation are often incorrectly included within the category of varicose veins. Capillary telangiectasias (diameter 0.1–0.4 mm) are predominantly red and intradermal. The colour of telangiectasias depends upon the calibre of the dilated venule; large dilatations are dark blue and often palpable (although still less than 1 mm in diameter) [3–5]. Reticular varicose veins are subcutaneous (2–4 mm in diameter) and arise from a blue leash of small veins.

Aetiology. It has long been recognized that varicose veins of the leg are inherited [6,7]. They are about three times more common in women than in men; the influence of pregnancy, and possibly of other hormonal factors, is probably important. They often present for the first time in pregnancy, 8–20% of women being affected. An increased blood volume and cardiac output, a rise in vena caval pressure and a direct effect of hormones on the smooth muscle of the vein wall may particularly affect those with a genetic predisposition. Persistence may be the result of simple superficial valvular incompetence, or the result of an unsuspected antepartum, postpartum or postoperative thrombosis.

Two main theories have been put forward to explain the nature of the inherited defect responsible for varicose veins: an inherent weakness of the vein wall or a congenital absence of the valves [8]. Each theory is justified by some experimental evidence. Most of the evidence is now in favour of an inherited structural defect of the vein walls, which have been shown to contain altered amounts of mucopolysaccharide and collagen when compared with control normal vessels [9–12]. Congenital valvular aplasia is extremely rare.

The most common cause of secondary varicose veins is PTS. Varicose veins can also complicate Parkes Weber syndrome (congenital arteriovenous fistulae) and Klippel–Trenaunay syndrome, but these are also rare conditions.

Incidence and prevalence [1,13]. A number of surveys have shown that the prevalence of varicose veins is high in the developed world. A community study in London in 1992 concluded that the prevalence of varicose veins in men and women aged 35–70 was 17% and 31%, respectively [14]. A study in Edinburgh found the prevalence to be 40% in men and 32% in women [15]. Varicose veins may, however, be underestimated in the developing world.

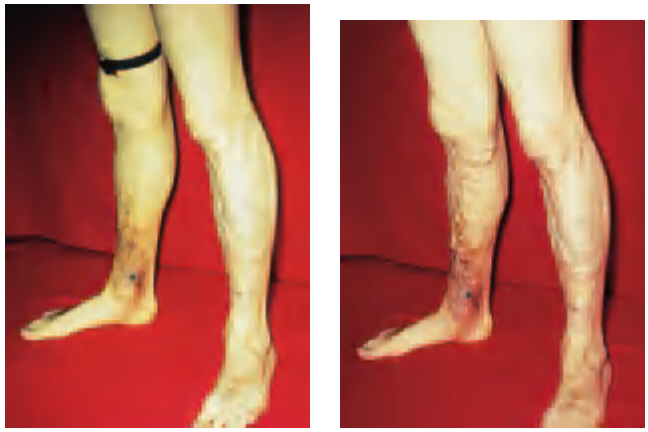
Clinical features. Varicose veins may be a purely cosmetic problem but many patients also complain of aching pain, which tends to be worse on prolonged standing at the end of the day. Patients with varicose veins may also complain of itching and ankle swelling, and many ultimately develop lipodermatosclerosis with ulceration, although some authorities believe that this only occurs if there is associated incompetence of the calf perforator veins [16].

Legs must be carefully examined with the patient standing erect, with the leg exposed from the foot to the groin. The distribution of the varices may indicate long saphenous incompetence (Fig. 50.16) (over the anteromedial aspect of the lower limb) or short saphenous incompetence (over the posterior aspect of the calf), but this may occasionally give a totally false impression as varices on the back of the calf may connect to the long saphenous vein. Short saphenous incompetence is invariably present if a large venous channel can be palpated crossing the popliteal fossa (which should be examined when the patient is standing erect with the knees slightly bent to relax the popliteal fascia). Tourniquet tests are used to confirm the clinical suspicion of the sites of venous incompetence (Fig. 50.17).

Complications of varicose veins, such as haemorrhage and thrombophlebitis, result from the varicose veins themselves; oedema, haemosiderin pigmentation, varicose eczema, atrophie blanche, lipodermatosclerosis and venous ulceration result from venous hypertension.

Investigations. Reflux at the saphenofemoral junction, saphenopopliteal junction and within the deep venous system can be confirmed with the hand-held Doppler. Colour duplex Doppler ultrasound scanning is increasingly being used to investigate all patients with varicose veins, and is the investigation of choice for detecting deep-vein reflux. Duplex scanning is also essential to investigate patients with skin changes attributed to

Fig. 50.16 Tortuous dilated long saphenous vein tributaries.



(a) (b)

Fig. 50.17 The Brodie–Trendelenburg tourniquet test. (a) An above-knee tourniquet controls the varicose veins indicating long saphenous incompetence. (b) When the tourniquet is released, the varicosities fill from above downwards.

venous hypertension. Ascending phlebography, while delineating the veins more clearly, is better at detecting post-thrombotic changes and incompetent communicating veins (Fig. 50.18) [17]. Other methods such as light reflective rheography and foot volumetry are primarily used in research.

Management. The recognition of skin changes associated with varicose veins is important because of the likely

Fig. 50.18 Incompetent communicating veins shown by ascending phlebography (arrowed).

risk of progression to venous ulceration. Causes of secondary varicose veins should be sought, including DVT and intra-abdominal pathology. Approximately one-third of patients presenting with varicose veins have symptoms unrelated to their varicose veins, and only require explanation and reassurance. Patients whose main symptom is discomfort may benefit from compression hosiery [18].

Venous surgery is potentially curative for refluxing superficial veins when the deep veins are competent. Conversely, surgery should be avoided in patients in whom the superficial veins may be acting as collaterals, which are the major route for venous return, in a severely post-thrombotic limb.

Surgery for saphenofemoral incompetence consists of high saphenous ligation (saphenofemoral ligation) with stripping of the long saphenous vein, to the level of the knee, combined with multiple avulsions of the tributaries [19]. Short saphenous incompetence and varicosities are treated by saphenopopliteal ligation, short saphenous stripping and avulsion of prominent tributaries. Subfascial endoscopic perforator surgery ligation (SEPS) is performed by inserting an endoscope through the deep fascia via a small incision in the upper calf [20]. This operation has never been tested in a prospective randomized trial and is ineffective in patients with post-thrombotic limbs.

Surgical reconstruction of the post-thrombotic limb remains a controversial topic, with anecdotal reports of good results for valve transplantation, valve reconstruction, vein transposition and bypass grafts. There is no evidence from any randomized studies that this type of surgery prevents recurrent or future ulceration. The long-term use of good graduated below-knee compression stockings is, however, of proven value [18]. Injection sclerotherapy is now used to treat minor branch vein varicosities but not truncal varices because the recurrence rate was very high in the presence of major saphenous incompetence. Patients with reticular veins and capillary telangiectasia can be treated by microinjection sclerotherapy, laser or application of high intensity light.

Venoactive drugs (e.g. coumarin, rutin) have been shown to relieve 'aching' pain and oedema, but their value is still disputed [21].

Clinical features of chronic venous disease

It is not varicose veins *per se* but the mechanical failure of venous return, and the sustained periods of raised venous pressure, that lead to the characteristic skin changes of chronic venous disease [1–3]. Trophic skin changes are more likely to be seen in the post-thrombotic syndrome (post-phlebitic leg) but can arise from a superficial venous reflux that occurs in primary varicose veins. Thrombosis may be silent in up to half of those patients in whom it occurs [4]. Conversely, even after a definite major thrombosis, the development of post-phlebitic sequelae is both variable and unpredictable.

Varicose veins

The widening, elongation and tortuosity of the venular end of the upper dermal capillary (capillary telangiectasia) (Fig. 50.19), the venules in the subpapillary plexus (blue

Fig. 50.19 Surface telangiectases.

Fig. 50.20 'Sunburst veins'.

'venous' telangiectasia, 'venectasia') and truncal varicose veins are usually associated with venous hypertension. Telangiectasias are fed by blood refluxing from a venule or varicose vein. The term corona phlebectatica paraplantaris is used to describe the dilated venules behind and below the medial malleolus, a finding invariably associated with venous hypertension.

Reticular varicose veins of small calibre (2–3 mm) (Fig. 50.20), frequently seen around the popliteal fossa, are less likely to be associated with venous reflux.

Haemosiderin pigmentation and erythrocyte extravasation

Raised capillary pressure and vessel wall changes resulting from raised venous pressure permit red cell extravasation into the dermis. At first this takes the form of petechiae or purpura and occurs in the distal part of the lower limb (the foot or gaiter region) where pressures are highest. As red cells degenerate so haemosiderin remains and a brown pigmentation develops. Sometimes this may be an isolated finding. Only by examining the patient standing will an underlying varicose vein be identified as the cause.

Gravitational purpura (dermite ocre, Favre pigmented and purpuric angiodermatitis) is very common on the anteromedial part of the lower leg. Distinction from forms of capillaritis and from post-inflammatory hyperpigmentation (e.g. in lichen planus) may be difficult. Biopsy may risk a leg ulcer if venous hypertension is severe.

Acroangiodermatitis of Mali (pseudo-Kaposi's sarcoma)

A pigmented purpuric eruption occurring around the malleolae and in the skin of the dorsal forefoot (particularly the base of the second toe) suggests acroangiodermatitis. Brown to plum-red papules coalescing into plaques resemble Kaposi's sarcoma clinically. The term acroangiodermatitis was introduced by Mali *et al*. in 1965 [1]. In 1967, Stewart [2] and Bluefarb and Adams [3] independently described similar lesions on the legs of patients with arteriovenous malformations; in these cases the findings are usually unilateral and a palpable thrill may be noted. The condition can lead to ulceration of the toes and forefoot, in which case an arteriovenous (AV) shunt is the more likely underlying cause.

Histologically, there is marked capillary proliferation, plump endothelium and red cell extravasation.

Rashkovsky *et al*. [4] described five possible causes:

1 Chronic venous hypertension
2 Arteriovenous malformations
3 Iatrogenic AV shunts in haemodialysis patients
4 Paralysed limbs
5 Amputation stumps

Oedema

Increased capillary filtration is a direct result of raised capillary pressure, and in turn of raised venous pressure. Pericapillary oedema occurs at an early stage in venous disease [1]. Pitting oedema does not occur until the interstitial fluid volume has doubled. Any oedema is the result of an imbalance between capillary filtration and lymph drainage. Therefore oedema should be avoided if the lymph drainage is compensating properly for increased filtration. The term 'venous' oedema fails to consider the contribution of local lymph drainage (Chapter 51).

Venous disease may not be the only cause of oedema. Raised venous pressure from right-sided heart failure or inferior vena caval or iliac vein obstruction should be considered, as should hypoalbuminaemia. It is important to examine the internal jugular vein, and to ask the patient to stand up to look for collateral veins over the abdomen.

The oedema resides mainly in the subcutis but there is a significant increase in the papillary dermis [2]. Oedema affects the nutrition of the epidermis and reduces com-

pliance of the skin, making it more susceptible to injury. Oedema also seems to increase the likelihood of eczema, particularly of asteototic pattern, presumably through its effect on the epidermis and particularly on the stratum corneum. This is typically a chronic effect but can occur acutely, usually a result of oedema of cardiac causation [3].

Eczema ('varicose' eczema, 'stasis' dermatitis)

The mechanism for 'varicose' eczema is unknown. Any eczema affecting the leg or foot should prompt a search for underlying venous disease. The presentation may vary from an acute exudative diffuse or discoid eczema to a more chronic lichenified form. Mention has already been made of an asteototic type (eczéma craquelé), particularly if oedema is present. The presence of any inflammation of the lower leg, particularly eczema, may contribute to oedema through increased vascular permeability and so set up a vicious cycle of more oedema and worse dermatitis. Autosensitization (secondary generalization of eczema) occurs frequently with 'varicose' eczema and may be the presenting feature, so it is important to examine the lower legs, if necessary removing any bandage or elastic stocking in such cases.

Lower leg eczematous dermatitis may also occur with venous disease because of the contact irritant effect of any skin exudation. Contact dermatitis from medicaments may also occur and may be through irritant or allergic mechanisms. Patch tests should be carried out in all patients with persistent 'varicose' eczema.

Any break in the skin integrity, not least oozing eczema, increases the risk of infection. Impetiginization of varicose eczema is common. The use of topical steroids in an ointment base increase the risk of staphylococcal folliculitis, particularly with occlusion and maceration from wet dressings and bandages.

Cellulitis and the red leg [1]

The risk of cellulitis is increased in the presence of oedema or lymphatic insufficiency. Typical lower leg cellulitis is characterized by redness, pain, swelling and systemic upset (fever, flu-like symptoms, vomiting, rigors). Blistering and necrosis may occur if the oedema is marked.

The differential diagnosis includes DVT, superficial thrombophlebitis, acute venous obstruction, acute dermatitis and acute lipodermatosclerosis. Suspected bilateral cellulitis is a diagnostic pitfall but is rare. Much more likely is lipodermatosclerosis or eczematous dermatitis, both of which are often bilateral.

Necrotizing fasciitis needs to be distinguished from necrotizing cellulitis. Blistering and necrosis occur in both. Marked local tenderness and increasing 'crescendo' pain, early neutrophilia and hypotension from associated shock are common in fasciitis.

Lipodermatosclerosis

Lipodermatosclerosis was a term coined by Browse and Burnand [1] to describe the progressive induration, inflammation and pigmentation, associated with excessive fibrosis of the skin and subcutaneous tissues, that is induced by chronic venous hypertension (Fig. 50.21). It appears in two forms—acute and chronic. The acute variety is painful (often burning in quality) and disabling, and is characterized by plum-red skin which is oedematous and very tender. A firm mass can be palpated in the subcutis, with a distinct edge, usually in the lower third or 'gaiter' region of the lower leg. This involvement of the subcutis has led to other descriptive terms such as sclerosing panniculitis and fat necrosis. Thrombophlebitis within the superficial truncal veins almost certainly coexists. Often misdiagnosed as 'chronic' cellulitis, acute lipodermatosclerosis does not cause fever, leukocytosis or lymphadenitis. It is frequently bilateral. Antibiotics have no effect but elevation and a reduction in venous pressure often alleviate the symptoms.

Chronic lipodermatosclerosis may result from progression of acute lipodermatosclerosis or develop spontaneously and insidiously. The skin is thickened and tight with fixed to hard, indurated fibrosing subcutaneous tissues. Progressive subcutaneous fibrosis gives the leg an

Fig. 50.21 Lipodermatosclerosis and ankle flare.

Fig. 50.22 'Champagne bottle' legs.

Fig. 50.23 Atrophie blanche: white scars with a central ischaemic ulcer and telangiectasia at the edge of the white areas.

inverted 'champagne bottle' shape (Fig. 50.22). The skin is not usually red by this stage but pigmented brown. Pitting oedema is invariably found in the calf above the affected area.

Lipodermatosclerosis has also been described in association with lymphoedema [2], suggesting that oedema or 'chronic congestion' within a leg from venous or lymph hypertension is the main cause. In the absence of any venous or lymphatic abnormality, the diagnosis of lipodermatosclerosis cannot be sustained, and other conditions such as panniculitis must be considered. Biopsy may then be indicated.

Atrophie blanche [1–4]

SYN. MILIAN'S WHITE ATROPHY

Definition. A smooth ivory-white plaque of sclerosis stippled with pinpoint telangiectasia (grossly enlarged tortuous capillaries seen end on) and often surrounded by haemosiderin pigmentation. The condition occurs chiefly but not exclusively on the lower leg or foot, particularly in women (Fig. 50.23). Rarely, lesions occur on the dorsum of the hand or elsewhere on the limbs. Blister formation and crusting may precede ulceration. In the absence of ulceration the condition is often symptomless. Ulceration occurs in about one-third of cases and takes two forms: a small, exquisitely painful ulcer may form within a patch of atrophie blanche, or a larger crusted superficial ulcer may develop. Both forms are notoriously slow to heal.

Aetiology. The most common cause is chronic venous insufficiency. Twenty-one of 81 patients attending a surgical clinic with venous insufficiency were observed to have this condition [5]. Capillary hypertension is probably the major aetiological factor. In patients with atrophie blanche, 35 of 41 cases were found to have varicose veins [1]. Each telangiectatic vessel is greatly elongated and coiled, resembling a renal glomerulus when viewed with an ophthalmoscope. The telangiectasias may thrombose, which presumably undermines local skin viability leading to scarred (white atrophy) areas and ulceration.

Atrophie blanche can be associated with naevus flammeus, thalassaemia minor [6], cryoglobulinaemia, systemic lupus erythematosus and scleroderma [7]. It may also coexist with livedoid vasculitis (livedo vasculitis), but neither condition represents a true 'inflammatory' vasculitis [8].

Histopathology [1]. The epidermis is atrophic with scleroderma-like changes in the dermis, with little or no

evidence of inflammation. There is new vessel formation in the subpapillary layer with capillary tufting and increased vessel diameter. Thrombosis of small vessels and proliferative endothelial changes may be present. A striking fibrinoid change has been noted.

Differential diagnosis. Around the ankle, the only condition likely to be confused is the scar of a healed venous or arterial ulcer. However, lesions elsewhere on the body may be confused with discoid lupus erythematosus, lichen sclerosus or malignant atrophic papulosis [4].

Treatment. The patient should be instructed to protect the area from all knocks, abrasions, known allergens or ill-fitting shoes. Only in this way will ulceration be avoided. Rest and compressive therapy are seldom successful, although warmth and reflex vasodilatation may offer benefit, provided they are combined with elevation [7]. Intralesional injections of lidocaine (lignocaine) and triamcinolone may relieve pain dramatically, and thus allow conventional pressure therapy to be applied. Nicotinic acid has been advocated [8]. Low-molecular-weight dextran is sometimes useful in providing immediate relief of pain. A satisfactory response to phenformin and ethinylestradiol, or now more commonly stanozolol 5 mg twice daily, has been reported [9]. Others have favoured 5000 i.u. heparin subcutaneously twice weekly, or use of drugs that inhibit platelet aggregation [10].

Livedoid vasculopathy [1]

SYN. LIVEDO VASCULITIS; SEGMENTAL HYALINIZING VASCULITIS

The mechanism may be identical to atrophie blanche as it usually occurs in the same location (foot and gaiter regions) and is associated with chronic venous disease. The distorted leaky vessels are fibrinolytically exhausted and easily thrombose. Ischaemic necrosis of the overlying epidermis is a consequence. It would appear to be a thrombotic disorder of small dermal blood vessels rather than a true vasculitis, as suggested by its association with factor V mutation [2] and antiphospholipid syndrome (Chapter 48) [3]. Suggestions for treatment are anecdotal but include intravenous immunoglobulins [4].

Congenital venous abnormalities

Klippel–Trenaunay syndrome (KTS; MIM 149000)

The combination of varicose veins, port-wine stain and increased bone length form the major features of this syndrome. First described in 1900 [1], the condition almost certainly represents a post-zygotic genetic fault (somatic mutation) in mesodermal development. Presentation is usually soon after birth. The naevus is usually first to appear; 95% of KTS patients exhibit a cutaneous haemangioma (port-wine stain) usually involving only the affected limb but sometimes beyond [2]. Limb hypertrophy develops later in childhood; venous abnormalities may not be evident until adolescence. Lymphatic abnormalities frequently coexist, and affected children may present with a swollen limb. Veins are large and extensive with an abnormal distribution. A characteristic feature is a large ectatic 'primitive' vein in the lateral thigh. Varicosities may extend into the pelvis as well as down the leg. Superficial thrombophlebitis is not uncommon in children. The bones may overgrow, resulting in increased leg length. Soft-tissue hypertrophy often occurs but may be difficult to distinguish from swelling caused by oedema or engorged veins.

Skin changes other than the vascular naevus occur because of venous or lymphatic hypertension. Other abnormalities described with the syndrome include lymphangiectasia (cutaneous vesicles that leak lymph) and consumptive coagulopathy (Kasabach–Merritt syndrome) [3].

The diagnosis is largely clinical, supported by venous duplex Doppler scanning or by ascending phlebography to demonstrate the abnormal venous anatomy. The differential diagnosis includes multiple arteriovenous fistulae (Parkes Weber syndrome), phlebectasia, gigantism and PTS.

Treatment includes epiphyseal stapling for excessive longitudinal bone growth, and compression hosiery to control venous hypertension. Superficial veins should not be removed unless the deep veins are competent. As the vascular naevus improves with time, treatment is not necessary.

Parkes Weber syndrome [4]

This syndrome is caused by multiple arteriovenous fistulae, but can manifest with varicose veins and limb overgrowth as in KTS. Whereas in KTS leg length disparity rarely increases after the age of 10 years, overgrowth gets progressively worse in Parkes Weber syndrome. An obvious pulsatile swelling may be present with discoloration of the overlying skin and large veins radiating from it. Duplex ultrasound will demonstrate high blood flow and abnormal enlargement of the arteries; cardiac enlargement and failure may occur.

Diffuse phlebectasia

SYN. BOCKENHEIMER'S SYNDROME

Phlebectasia is the term used to describe enlarged and irregular superficial and deep veins. Histology of the phlebectasia shows a decrease in elastin in the wall of the ectatic veins. Thrombus and calcification are often present [5]. **Phlebangiomatosis** involves cavernous angiomas, which manifest with cutaneous angiomas that extend into deeper layers including bone. Both conditions resemble KTS and Parkes Weber syndrome but without bone overgrowth.

Leg ulceration

Ulceration of the lower limb affects 1% of the adult population and 3.6% of people older than 65 years [1]. The main causes are venous hypertension, arterial disease and diabetes, but many factors may contribute (Table 50.2). Venous disease is the single most common cause, but gravitational and venous influences may be contributory to inducing other pathologies in the lower leg (e.g. vasculitis).

Table 50.2 Causes of lower limb ulceration.

Venous hypertension	Varicose veins, deep-vein thrombosis, venous obstruction, congenital vascular malformations, Klippel–Trenaunay syndrome
Arterial disease	Atherosclerosis, diabetes, hypertension, embolism, arteriovenous fistula, calciphylaxis
Skin cancer	Basal and squamous cell carcinoma, melanoma, Kaposi's sarcoma, malignant fibrous histiocytoma
Vasculitis	Connective tissue disease (systemic lupus erythematosus, rheumatoid disease, systemic sclerosis)
	Livedoid vasculopathy
Haematological disorders	Coagulation states/protein S or C deficiency, sickle cell disease, thalassaemia, spherocytosis, lymphoproliferative disorders (myeloma, cryoglobulinaemia), myeloproliferative disorders (polycythaemia), cholesterol and platelet emboli
Peripheral neuropathy	Leprosy, diabetes
Infections	Diabetes, osteomyelitis, Buruli ulcer, fungal infections, syphilis, mycobacteria, Leishmaniasis, leprosy, acute 'desert' sore, necrotizing fasciitis and cellulitis
Trauma	Physical, chemical or thermal
	Self-harm
	Intravenous drug use
Drugs/therapy	Radiation
	Hydroxyurea
	Iododerma
Skin conditions	Pyoderma gangrenosum
	Necrobiosis lipoidica
	Scleroderma
	Graft-versus-host disease
	Blistering disorders (e.g. pemphigoid), insect, snake and scorpion bites
Genetic	Prolidase deficiency
	Klinefelter's syndrome
Cold injury	Perniosis
	Immersion injury

Venous ulceration of the leg [2]

Definition. Ulceration of the lower leg is the result of persistently elevated venous pressure and its secondary effects on the microvascular system. Nearly half of all venous ulcers are associated with deep-vein valvular incompetence or post-thrombotic damage while the remainder result from incompetence of the superficial or communicating veins. Venous ulceration of the leg is an age-related disease with a maximal prevalence in middle-aged or elderly women. It has a chronic or relapsing course and is often exacerbated or originated by external injury.

Epidemiology [3–5]. Community surveys suggest an overall incidence of about 0.2% [4]. It is clearly an age-related disease, mainly affecting older women; 2% of all those over the age of 80 years suffer from the problem. The aetiological groups are difficult to define, and patients with leg ulcers present at different clinics. Sixty per cent of patients receive no specialist opinion.

Venous ulceration is a common disease of all civilized communities. It appears to be associated with a sedentary and physiologically unnatural mode of life and is comparatively rare in African people [6,7], although the incidence may be underrated [8].

A study of 4422 healthy working adults in Basle found 'chronic venous insufficiency' in 19% of men and in 25% of women [9]. Ulceration was present in 1.1 and 1.4%, respectively. Figures from other areas are similar. It has been emphasized that up to one-third of ulcers in elderly people have coexisting arterial insufficiency as one factor contributing to their failure to heal. A family history of leg ulcers is found in over half of those affected [10]; this applies about equally to those who have suffered a known thrombosis and to those who have not. The significance of this is not known, although inheritance of coagulation defects may be one factor.

Over the last 10 years, the incidence of DVT has decreased significantly, whereas arterial insufficiency is becoming more common. The incidence of venous ulcers is influenced by the recurrence rate, and this is influenced by the effectiveness of both treatment and regular supervision in the healed state. Once treated, up to 72% of patients can suffer recurrence.

Venous disease accounts for 1–2% of the health care budgets of European countries [11].

Pathogenesis. Venous ulcers are the end result of superficial venous insufficiency or PTS described above. The consequent alterations in the microvasculature and interstitium make the skin more liable to break down, or to fail to repair, following minor degrees of trauma. The fundamental fault is a sustained capillary hypertension resulting from persistently raised venous pressure. A failure to reduce venous pressure satisfactorily when the lower limb is dependent is a combination of haemodynamic failures, mainly consequent upon a failure of venous valves (allowing reflux) and poor calf muscle pump function. The skin changes resulting from venous hypertension often, but not always, culminate in ulceration. The lack of skin viability must reflect local hypoxia but the exact mechanism is not understood. The pathogenesis of microvascular damage is discussed on p. 50.14.

A history of deep leg-vein thrombosis is obtained from a significant proportion of patients. In Anning's carefully documented series [10], a story of prior thrombosis was obtained in 75% of the patients. Leg injuries, particularly fractures, are frequently followed by thrombosis [12]. Other relatively common causes include hip replacements, pelvic and lower abdominal operations, medical illnesses and prolonged recumbency from any cause. In one study, 12 of 46 patients admitted to hospital with leg ulcers demonstrated resistance to activated protein C [13], a finding that has been observed in 20–40% of patients known to have had a previous DVT. Patients with chronic venous ulcers have a 41% prevalence rate of thrombophilia which is 30 times higher than the general population. Interestingly, thrombophilia does not necessarily appear to be related to past DVT [14].

Recent studies have shown that up to 60% of patients with venous ulcers have isolated superficial vein incompetence with normal deep veins [15]. The concept of a primary defect in collagen or elastic tissue [9] has been revised by the recognition of ulceration consequent on prolidase deficiency (p. 50.39). Congenital absence of venous valves as a cause of leg ulcers is probably rare [16].

Clinical features. The ulcer may be preceded by patchy erythema or discoloration of an intense bluish red colour, in which ischaemia of the skin finally leads to necrosis, often following a minor episode of trauma. This intense bluish colour can be seen by capillary microscopy to be caused by capillary congestion [17].

The ulcer is characteristically situated on the medial lower aspect of the leg, the 'gaiter' region, which is drained on the medial side by three large pairs of perforating veins (Fig. 50.24). Venous ulcers do not usually develop initially below the level of the malleoli or in the foot unless complicated by livedoid vasculitis or arterial disease.

Two events may lead to a break in the continuity of surface epithelium. The first is capillary thrombosis, when the complete outline of the capillary can be seen to be filled with broken-up thrombus, which does not disperse on pressure. The second is a small bleed from the peak of the capillary; this separates the epidermis from its blood supply. These changes in the capillaries supplying the epidermis are frequently induced by small knocks, scratching or epidermal pathology such as dermatitis. The

Fig. 50.24 A venous ulcer on the medial side of the leg surrounded by pigmented sclerotic skin (lipodermatosclerosis).

skin around an ulcer is frequently irritated by exudate, and inflamed varicose or medicament dermatitis may contribute. Other signs of venous hypertension are usually present, for example lipodermatosclerosis, varicose veins (corona phlebectasia), varicose eczema or oedema; sometimes a nearby perforator vein may be evident by a palpable depression in the subcutaneous fat. Venous ulcers can develop as a result of ulceration of atrophie blanche.

Ulcers often show pseudoepitheliomatous hyperplasia at their edge, which may be mistaken for a squamous cell carcinoma. The ulcer bed is oedematous, with abundant newly formed capillaries lying in a granulation tissue covered by serous exudate or slough. Such ulcers most frequently occur within a few years of a thrombosis. Neglect and attempts at self-treatment may cause delay in seeking proper advice. By then, one or more infected ulcers are present, sometimes completely encircling the leg.

Healing ulcers have a shallow sloping edge with healthy granulation in their base and little slough. Epithelial islands may become scattered over the surface of a well-vascularized bed, and quickly enlarge (Fig. 50.25). The pink lip of the epithelium at the edge of an ulcer is uniform and supplied by relatively uncongested capillaries. The overall appearance is like a normal nail fold and cuticle. By contrast, a non-healing ulcer resembles severe paronychia, being boggy, undermined and congested.

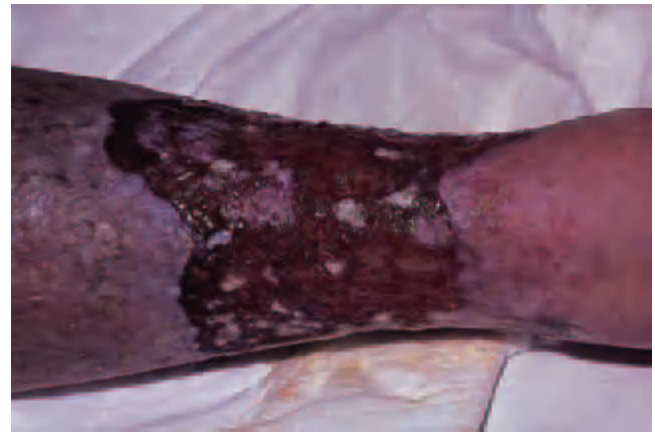

Fig. 50.25 A healing venous ulcer. There are multiple islands of reforming epithelium spreading over healthy granulation tissue.

The coexistence of arterial disease can contribute to the progression of a venous ulcer so symptoms and signs of peripheral ischaemia should be sought in all patients with leg ulceration. Rest pain can occur in the absence of arterial disease. Patients develop typical ischaemic pain on elevation of the ulcerated leg, which is oedematous. To relieve pain, the patient keeps the leg in a dependent position, especially at night; this exacerbates the underlying pathogenesis. After excluding arterial disease, a period of enforced elevation, necessitating strong analgesia, results in disappearance of the oedema with subsequent relief of pain. Occasionally, venous ulceration occurs at other sites in the limb, but other aetiologies should be suspected in such instances, especially if ulcers are present over the foot or just below the knee. Hyperkeratosis and papillomatosis around an ulcerated area or along the border of the foot, particularly below the malleoli, is a result of impaired local lymphatic drainage.

Associations and complications of venous leg ulcers

The main conditions associated with venous ulceration are anaemia and malnutrition (especially in elderly people living alone), and these must be assessed and corrected as far as possible.

General disease [1–3]. Coincidental obesity and hypertension are common. The relationship of these to the presence of the ulcer is uncertain, but they are undoubtedly perpetuating causes. Increased intra-abdominal pressure increases cardiac filling pressures, femoral venous pressures, renal vein pressure, systemic blood pressure and vascular resistance [4]. Cardiovascular disease is common and heart failure can be a major contributor to venous ulceration through its effect on: (i) further raising venous pressure; (ii) creating peripheral oedema; and (iii) encouraging long periods of sitting. Joint disease, peripheral arterial disease and neurological disease can obviously impair the already precarious nutrition of the skin and the action of the muscle pump. Severe rheumatoid disease or long-standing poliomyelitis also reduce the effectiveness of the muscle pump and encourage recurrence. They also discourage healing.

Anaemia and hypoproteinaemia. Sickle cell anaemia [5], iron-deficiency anaemia and thalassaemia can cause ulceration, and the presence of marked anaemia may prevent other ulcers from healing by reducing peripheral oxygenation. Repeated infection or chronic inflammation arising from the ulcer may itself cause a normochronic normocytic anaemia. A poor diet, combined with continuous seepage of protein and blood from an untreated ulcer, relatively commonly leads to anaemia and hypoalbuminaemia.

Diabetes. Diabetes is common, and will compound any venous ulcer through arterial disease, infection and neuropathy.

Personal attitudes and habits: sociology [6]. It is common, in patients with long-standing ulcers, to find a number of complications that stem from the personality, domestic and social situation of the patient. Walking has long been abandoned and substituted by more damaging motionless sitting. The ankle becomes fixed in equinus and the foot inverted. The leg becomes transformed into a useless and deformed peg and the calf muscles atrophy. An attitude of apathetic acceptance, often associated with depression, is frequent. The patient retires to the fireside chair, beslippered, ill-nourished, useless to the family but, nevertheless, the object of much attention and sympathy. Many such patients never go to bed but sit motionless in the chair all night. In a few cases, it is clear that any real attempt to cure the ulcer will be resisted unless this can be accompanied by a vigorous social and psychological rehabilitation. Lonely patients may find that an ulcer is their only means of obtaining a visitor, be it district nurse or doctor.

Zinc depletion. This has received considerable attention [7–14], following the observation that zinc deficiency in rats impairs wound healing. Low plasma zinc levels have been found in patients with venous ulceration, and accelerated healing of such ulcers after oral zinc sulphate therapy has been reported. However, it is the tissue levels of zinc that are of most importance to ulcer healing, and these have never been shown to be low in patients with leg ulcers. Analysis of six randomized trials indicates that oral zinc does not aid healing of leg ulcers, except possibly in patients with low serum zinc [15].

Infection [1]. The role of antisepsis in the healing of leg ulcers is much debated [2–4]. Pathogenic organisms are commonly found in leg ulcers of all types [3]. The bacterial flora is often profuse and usually mixed, but *Staphylococcus aureus* predominates. There is still insufficient evidence to determine to what extent such a flora influences the rate of healing, but quantitative bacteriology has indicated that fewer than 100 000 organisms per square centimetre of surface area or per gram of tissue does not delay repair [5]. However, certain pathogens are traditionally taken seriously; for example, the group A β-haemolytic *Streptococcus* or a heavy growth of *Pseudomonas*. Unimpeded resolution of uncomplicated leg ulcers under occlusive compressive bandaging is frequently accompanied by considerable pus formation, but healing is not necessarily impaired. Sometimes lakes of pus develop in an atrophic skin that readily breaks down. Referred to as erosive pustular dermatosis of the leg, the pus is sterile and the condition responds to intermittent use of potent topical steroids [6].

Fusiform bacilli and spirochaetes are found in the phagedenic anaerobic or 'tropical' ulcer of hot humid regions [7]. Fungi vary in extent and importance. Some authors have found *Candida albicans* only rarely [8], but it can be a common commensal organism, perhaps because of the widespread use of specific antibiotics. Ointment-impregnated bandages without preservatives were blamed for candidal overgrowth in one study [9]. Moist wound healing using contemporary occlusive dressings seems not to encourage infection [10].

Penicillin- and tetracycline-resistant staphylococci, and *Pseudomonas aeruginosa*, are very common in hospital-treated patients, and cross-contamination is the rule in leg ulcer clinics [11]. *Proteus vulgaris* and other Gram-negative organisms are probably of little importance. The importance of non-clostridial anaerobic organisms such as *Bacteroides* spp. has probably been underestimated. As with other types of infection, large controlled trials are required to measure healing after the ulcer surface has been sterilized. This information is not currently available to provide advice on the value of infection control. Venous ulcers are less likely to develop infection than arterial or diabetic ulcers [12].

Contact dermatitis. The skin around an ulcer frequently becomes red and sore, caused predominantly by the irritant effect of exudate (Fig. 50.26). Small pustules and superficial ulcers may develop, especially in the presence of β-haemolytic streptococci. Eczema may be responsible for further compromising skin viability, and so increasing the size of an ulcer. In most cases, the eczema is the result of local treatment (Table 50.3) and sensitivity can be demonstrated by patch testing. Patients with venous ulcers appear to become sensitized easily (Fig. 50.27) [13], often to several medicaments including lanolin and rubber [14–16]. The components of paste bandages may be responsible [17]. True medicament sensitivity is a frequent complication of therapy (Fig. 50.28).

Fig. 50.27 A sensitivity reaction to strapping showing blistering.

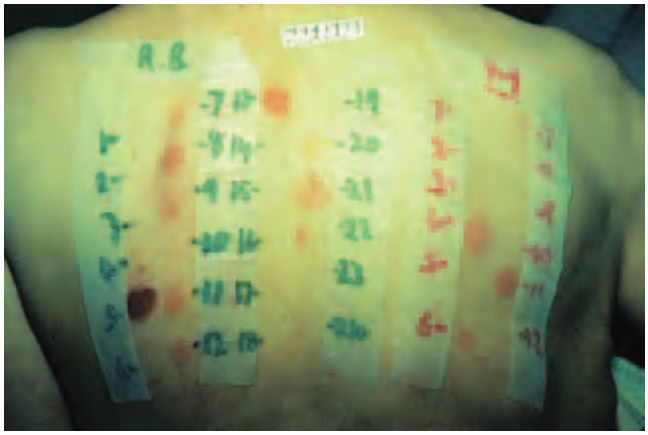

Fig. 50.28 Patch testing: 72-h reading showing multiple sensitivities, typical of patients with a long history of ulcer therapy.

It is unfortunately not widely appreciated that the effect of potent topical corticosteroids on leg ulcers may inhibit healing for several weeks by producing an indolent 'arterial-type' ulcer with a deep adherent slough, 'steroid ulcer' (p. 50.37).

Haemorrhage [18,19]. Spontaneous haemorrhage occasionally occurs, especially from large ulcers [19]. This may be severe and can cause death if the patient faints and is held in the vertical position. First-aid measures include immediately lying the patient on the floor and elevating the limb while applying firm direct pressure to the bleeding point in the base of the ulcer. Occasionally, a suture will be required, but a tight bandage and elevation usually prevents further bleeding.

Fig. 50.29 Heaped-up squamous epithelioma.

Lymphoedema (Chapter 51). The superficial lymphatics are absent in and around ulcers and their distortion or obliteration contributes to hyperkeratosis, papillomatosis, dermal fibrosis and oedema. An inadequacy of the lymphatic drainage predisposes to attacks of cellulitis [20], and with each episode of infection damage is compounded and chronic lymphoedema delays ulcer healing.

Malignant change [21]. Primary malignancies of the leg presenting as ulcers are increasingly common in an ageing population or those with sun exposure or transplantation-associated immunosuppression. Malignant change in an established ulcer is much rarer but carries a worse prognosis. Squamous epitheliomas may be difficult to distinguish from pseudoepitheliomatous hyperplasia, but if missed because of a failed diagnosis will often metastasize [22]. Biopsy should be considered if the diagnosis is in doubt [23]; multiple biopsies have been recommended as features may vary throughout the ulcer-associated tumour [24]. The edge becomes progressively heaped up (Fig. 50.29), vegetating and cauliflower-like and does not flatten with compressive therapy. Basal cell carcinomas may remain quite flat and undetected (Fig. 50.30).

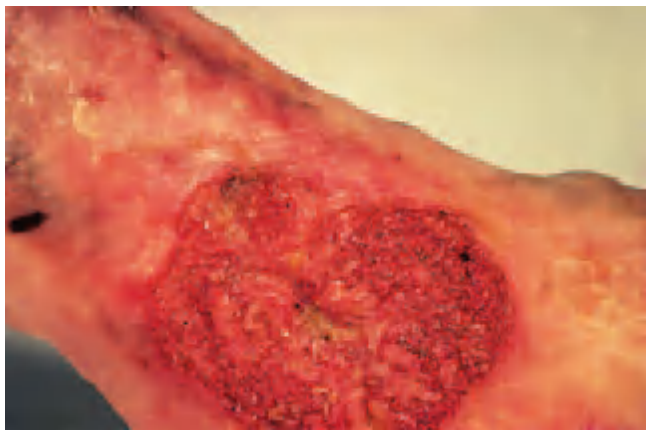

Fig. 50.30 A flat basal cell carcinoma complicating lipodermatosclerosis.

Suspicion may be aroused when the ulcer fails to respond to compression therapy. A distinction should be made between the rarity of malignant change in a chronic ulcer associated with disorders of the venous system, and the common primary malignancy occurring in the skin of legs that have had prolonged exposure to sunlight.

Subcutaneous calcification (post-phlebitis subcutaneous calcinosis) [25]. This is often widespread. It occurs in up to 10% of patients with chronic venous insufficiency [25]. It may cause non-healing of an ulcer or be found incidentally. The calcification, which is sometimes osteoid, occurs around areas of fat necrosis and fibrosis [26]. Radiography reveals a coarse network of calcification, the edges of individual plaques impinging on the dermis. Other causes of calcification include phleboliths, atherosclerotic calcification, cysticercosis and a ligamentous form of dystrophic calcification (in which the serum calcium and phosphorus levels are normal). Calcium deposits act as a foreign body nidus for organisms and delay healing.

Bone changes. Periostitis is commonly seen beneath a chronic ulcer. Osteoporosis is often present in the later stages as the result of disuse atrophy. Osteoarthritis is a common concomitant condition in the affected or unaffected leg, especially the knee. Fibrous ankylosis occurs in the ankle of neglected cases. Old tibial fractures are common in patients with post-thrombotic ulceration.

Diagnosis of venous ulceration

This is essentially clinical, based on ulceration in the gaiter area and the presence of signs of venous hypertension (p. 50.23). Arterial disease must be excluded and the ulcer should respond to compression therapy. A past history of venous thrombosis, treatment for varicose veins or a family history of venous disease is supportive evidence.

An ankle–brachial pressure index should be performed if foot pulses are not easily palpable, although the diagnosis of arterial disease does not exclude the possibility of an ulcer predominantly caused by venous disease (mixed origin). Arterial duplex Doppler scanning or arteriography should be undertaken if doubts remain regarding the presence of arterial ischaemia. Colour duplex Doppler ultrasound should be performed, not just for confirmation of venous reflux but also to see if superficial venous incompetence is responsible, in which case venous

surgery may be an option if the deep veins are competent [1].

A skin biopsy may not heal in the presence of venous hypertension but is indicated if alternative causes such as skin malignancy [2] or vasculitis are possibilities. The preference is to wait for ulceration to heal before fully assessing the venous system, although some may wish to carry out photoplethysmography and duplex scanning at an early stage. Signs of a peripheral neuropathy should be excluded and the range of hip, knee and particularly ankle movement should be tested.

Other causes of leg ulceration

The main causes of leg ulceration are listed in Table 50.2.

Arterial ulceration

Death of the skin automatically follows occlusion of its arterial blood supply unless this occurs slowly enough to allow a collateral circulation to be established. Arterial or arteriolar occlusion, if present, also complicates the treatment and prognosis of ulcers that are primarily venous in origin. A study of 600 leg ulcer patients in the Lothian and Forth Valley, Scotland, revealed evidence of arterial disease in slightly less than one-quarter [1].

Atheroma of the abdominal and limb vessels is the single most common cause of ischaemic ulceration likely to be seen by the dermatologist involved in the care of patients with leg ulcers. Many other pathological states may, however, cause arterial occlusion, and not all can be defined with accuracy on clinical grounds. A useful empirical approach to the diagnosis of clinically ischaemic ulcers is to consider the causes in three main groups:

1 Extramural 'strangulation'
2 Mural thickening or accretion
3 Intramural restriction of blood flow

There is often considerable overlap, and the exact pathology cannot always be well defined.

Extramural. Scar tissue and radiodermatitis cause a fibrotic strangulation of the arterioles and may give rise to small but persistent ulcers. Ulceration occurs in a number of diseases associated with dermal sclerosis, including scleroderma and progeria (Werner's syndrome; Chapter 12). Such ulceration is often located over the medial malleolus, and is associated with atrophie blanche. Compression by tumours may also obstruct arterial flow; tumours may also require an increased blood supply that cannot be provided by existing vessels.

Mural. Ulceration depends on the speed with which changes take place in the vessel wall. In vasculitis this is often sudden, but in hypertension it is slower and is preceded by pain, erythema and tenderness. In atherosclerosis the accretion of intimal plaques may proceed with a reduced flow until thrombosis, embolism or infection precipitate complete closure.

Intramural. Microvascular occlusion caused by changes in blood viscosity and clotting mechanisms is discussed in Chapter 48.

Clinical features [2]. The general symptoms and signs shown by the patient with advancing ischaemic disease of the limbs have already been described (p. 50.2).

Arterial ulcers frequently arise in the pretibial area or on the toes, whereas venous ulcers favour the gaiter region. Severe pain is usual, but is not a reliable discriminator from venous ulceration, which can also be very painful. Pain is as marked in small ischaemic ulcers as in large ulcers. The edges of the ulcers are sharply defined and the ulcer itself is often punched out.

There is often no pigmentation or lipodermatosclerosis in the surrounding skin, unlike the changes around venous ulcers, but the two can coexist. Usually, exudation from arterial ulcers is minimal. The base is often pale and covered with a slough (Fig. 50.31), which may have bare tendons in its base. When smaller arteries and arterioles are occluded, the ulceration may have an irregular outline with strands of infarction extending along a vascular pattern in the skin. The condition is often indolent, healing only when the blood supply is improved and the ulcer base is excised and grafted.

Vasculitis

Most acute forms of vasculitis, and some subacute and chronic forms, are likely to cause ulceration. Vasculitic lesions are usually but not always multiple. Palpable purpura is characteristic but vasculitis may be polymorphous, even pustular. Raynaud's disease, scleroderma and lupus erythematosus typically affect the fingertips rather than the leg, but lupus should be considered in any abnormal form of leg or foot ulceration.

Fig. 50.31 An ischaemic ulcer with slough and exposed tendons.

Rheumatoid disease [1]. Leg ulceration in rheumatoid arthritis is common and the causes can be multifactorial. Poor joint movement impairs the calf muscle pump and immobility increases the risk of DVT. True 'rheumatoid ulcers' occur as a manifestation of rheumatoid arteritis. Ulcers are often situated in the gaiter region and have a sloughy base with poor granulation. The absence of surrounding lipodermatosclerosis or of other signs of venous disease, the presence of a positive rheumatoid factor (particularly if at high titre) and demonstration of normal Doppler pressures and venous duplex studies suggest that the ulcer is truly 'rheumatoid'. Biopsy may be helpful but is not always confirmatory and the site may not heal. Ulceration of rheumatoid nodules is uncommon except at pressure sites in bedridden patients. Thin skin because of long-term corticosteroid treatment, and the use of methotrexate, also increase the risk of ulceration. Healing can be very impaired, particularly in the presence of muscle atrophy, immobility and oedema.

Other autoimmune disease. Leg ulceration in patients with lupus erythematosus is well recognized [2]. In Felty's syndrome and Still's disease, multiple painful ulcers occur on the legs and feet and are difficult to heal. Ulcers also occur in polyostotic fibrous dysplasia (Jaffe–Lichtenstein disease), in which a diffuse mesenchymal abnormality is present. Ulceration occurs over large areas of subcutaneous or muscular calcinosis, especially around the knee.

Fig. 50.32 Sickle cell ulcer.

Livedo reticularis. Livedo reticularis, a fixed but broken pattern of mottling, may result from vasculitis but also occurs with intravascular thrombosis caused by cryoproteinaemias [3], antiphospholipid and Sneddon's syndrome (Chapter 48).

Livedoid vasculopathy (livedo vasculitis) is a more specific form of occlusive vasculopathy limited to the gaiter skin and often extending onto the dorsum of the foot. Ulcers are small, painful and heal with ivory white scars (atrophie blanche).

Livedo with summer ulceration is a variant of the same condition (see p. 50.27).

Haematological disorders

Indolent non-healing ulcers on the leg are a feature of sickle cell anaemia (Fig. 50.32), hereditary spherocytosis and other haemolytic anaemias. In thalassaemia [1], the skin is shiny and pigmented [2]. Myelo- and lymphoproliferative disorders may contribute to leg ulceration if cell size compromises capillary perfusion or if thrombosis develops. Leg ulceration is common in sickle cell disease, occurring in 43% of patients in one series; venous disease is a major contributing factor [3]. Other haemolytic anaemias also predispose to leg ulceration [4].

Traumatic, decubitus and neuropathic ulceration

This is common on the shins and ankles and may accompany or follow fractures. Arteriovenous aneurysm formation or arterial insufficiency should be suspected if the ulcer persists. Pressure sores occur easily and with little warning on the heels and ankles of elderly people, especially in those who are comatose or paralysed. Ill-fitting calipers or pressure bandages may cause ulceration in those with 'polio legs' or in limbs with a diminished blood supply. Accidental burns usually occur in a domestic setting, but may also occur from hot-water bottles used to warm an unconscious or anaesthetized patient. Chemical burns are unusual unless factitious, but extravascular leakage from intravenous injections, especially in those having sclerotherapy for varicose veins, may cause local sloughing. In all cases where ulceration is protracted in the absence of venous, arterial or trophic disease, artefacts must be considered; interference with ulcers already present may also occur, even through bandages. Drug addicts develop ulcers at sites of injection into superficial veins, and also at extravascular sites when extravasation occurs.

Neuropathic ulcers are most common in diabetic subjects (Fig. 50.33). About 70% of diabetic foot ulcers are caused by neuropathy with adequate vasculature. Infection frequently coexists and osteomyelitis must always be considered [1].

Fig. 50.33 Neuropathic–ischaemic ulcers over the base of the foot (diabetic).

Fig. 50.34 'Steroid ulcer' with totally suppressed granulation tissue.

'Steroid ulcers'

Intralesional steroid injections, especially if made in areas with an already impoverished blood supply, may cause an indolent ulcer with a characteristic greyish slough (Fig. 50.34) [1]. This condition is most commonly seen when strong topical corticosteroids are applied to venous or other ulcers of the lower leg and ankle.

Infection

Infection may lead to ulceration, which is often slow to heal because of associated oedema, cellulitis, thrombophlebitis, diabetes or underlying vascular disease. Primary uncomplicated pyococcal ulceration is rare; ecthyma is an example. Meleney's ulcer (bacterial synergistic gangrene) extends rapidly and has a burrowing, bluish, undermined and painful edge (Fig. 50.35).

Fig. 50.35 Meleney's spreading gangrene.

Tuberculous ulcers occur in erythema induratum (Bazin's disease) and are chronic, often on the back of the calves. They usually have undermined edges and considerable surrounding inflammation (Chapter 28). Occasionally, an unusually extensive tuberculous ulceration occurs and often remains misdiagnosed. Other mycobacterial infections may be more common than suspected (Chapter 28). Ulcers in leprosy are usually on the foot, especially the dorsum, and on the proximal phalanx of the great toe, but can occur occasionally on the leg. The 'classical' appearances of the ulceronodular form of tertiary syphilis are well known, but this is extremely rare today. Multiple tissue-paper scars on the legs occur typically in yaws (Chapter 29). The so-called 'desert' or 'veldt' sore is shallow and crusted: the role of *Corynebacterium diphtheriae* is uncertain. The 'tropical' ulcer is a variety of phagedenic ulcer with a mixed symbiotic infection and rapid spread. Other phagedenic ulcers are seen rarely, only occurring in the seriously ill or undernourished. Leishmaniasis, relatively uncommon on the legs, should be remembered as a possible cause of an indolent granulomatous ulcer. Among other uncommon infective causes of ulceration are glanders, tularaemia, brucellosis and cat scratch fever.

Pyoderma gangrenosum (Chapter 49)

This causes rapidly spreading and often bizarre and extensive ulceration, which may mimic an artefact, particularly when it precedes obvious ulcerative colitis. Two-thirds of cases are associated with inflammatory bowel disease, rheumatoid arthritis or haematological malignancies [1].

Necrobiosis lipoidica and granulomatous diseases

Necrobiosis lipoidica may ulcerate following trauma, is extremely indolent, and should be regarded as ischaemic. Similarly, any granulomatous lesion may ulcerate if its blood supply is inadequate or if the vessels are involved in the granulomatous process, as may occur in sarcoidosis.

Hypertensive ulcer

SYN. MARTORELL'S ULCER

This ulcer was first described by Martorell [1] and there have been several other reports subsequently [2].

Pathogenesis. Hypertension may arise spontaneously in elderly people in association with a gradual reduction in the density of the capillary bed. The density of the capillary bed in the middle and deep dermis of the shin, particularly on its lateral aspect, is much reduced even in healthy persons [3], and this may predispose them to ischaemic necrosis when the somewhat sparse arterioles are subjected to severe hypertension. Hypertensive ulceration is more common in women and tends to be bilateral. It produces superficial ulceration because the affected vascular bed is near the surface; the peripheral pulses are always present, distinguishing the condition from atherosclerosis. The ulcer characteristically has a reddish or yellowish edge with livedo patterning at its periphery. It is often initiated by trauma, and the ischaemia may be a consequence of a failure to meet the demands for repair.

Fig. 50.36 A Martorell ulcer. High blood pressure causes vessel wall hypertrophy or vasospasm. Pain and ulceration with a livid reticulate edge but no lipodermatosclerosis is diagnostic. It is usually more proximal than a venous ulcer.

Histology. There is increased thickening of the arteriolar walls with luminal narrowing by subendothelial hyalin degeneration. Smooth-muscle hyperplasia is most marked in the media and is most easily recognized by an increase in the number of smooth-muscle nuclei. It is later replaced by collagen fibres. Whether it truly represents a specific disease has been questioned [4].

Clinical features. The ulcer is initially preceded by a small macular cyanotic lesion present on the anterior external aspect of the leg at a point between the middle and lower thirds of the limb. It is usually extremely painful, and this may be alleviated by holding the leg in the dependent position. The livid edge is a characteristic feature (Fig. 50.36).

Treatment. The blood pressure should be controlled, and the leg should be placed in a position to prevent oedema but not so high as to promote further ischaemia. A firm non-elastic support bandage, without compression, is the most helpful dressing. At this site on the leg, the blood supply is difficult to re-establish, and several weeks may

pass before the ischaemic necrotic tissue separates and granulation tissue begins to form. Smoking should be stopped and β-blockers avoided. Excision of the ulcerated area with grafting has been advised.

Prolidase deficiency

Prolidase deficiency is transmitted as an autosomal recessive condition. It is a rare cause of recurrent ulceration of the skin, especially in young people, often beginning in childhood [1–5]. Fragility of the skin, resulting in breakdown at the site of injury, is often preceded by purpura or bruising (Fig. 50.37). Fine scarring and telangiectasia may be a feature. The facies are characteristic, consisting of hypertelorism with a saddle nose. Other associations, not present in all cases, are dental caries, splenomegaly, hyperextensibility of ligaments, osteoporosis, respiratory infections, corneal opacities, amblyopia and optic atrophy. The skin may have a doughy consistency as in other collagen disease. The diagnosis is ascertained by iminopeptiduria greater than 5 mmol/24 h. The predominant peptide is glycylproline. A characteristic feature of the disorder is absolute resistance to all forms of treatment including rejection of skin grafts. It is thus a highly disabling affliction. Because co-factors of prolidase are ascorbic acid and manganese, these have been recommended therapy, as has diphenylhydantoin [6]. Japanese investigators recommend an ointment containing 5% glycine and 5% proline [7], and this was confirmed to be effective by Jemec and Moe [6]. Apheresis exchange was successful in two patients [8].

Hydroxyurea therapy

Painful leg ulcers associated with hydroxyurea have been reported several times. The ulcers healed after the drug was withdrawn [1].

Ulcers of the foot [1]

In industrialized societies, shoe wearing protects the tissues from the effects of the gravitational thrust when the leg veins are incompetent. It is unusual therefore to see ulcers of purely venous origin below the line of the edge of shoes, although atrophie blanche or livedoid vasculopathy are not uncommon on the dorsum of the foot or on the relatively unsupported region at the base of the first and second toes. Nevertheless, in one study of all ulcers of the leg, 30% were of the foot; men developed them earlier than women [2].

Vasoconstriction operates more powerfully in the feet than in the legs, and it is here that the earliest effects of arterial insufficiency or of peripheral neuropathy are

found. A reduction in the capillary blood supply is present even in healthy subjects and may predispose to delayed healing at an affected site [3]. The foot is subject to almost constant pressure at several points. When a diminished vascular supply or prolonged recumbency intensifies the pressure on the heel or edge of the toes, ulceration quickly develops (gravitational or decubitus ulcers). This is the most frequent cause of ulceration seen in dermatological practice, especially in elderly people, and may be avoided by good nursing care, padding and polo rings to prevent excessive pressure developing. Atherosclerotic ulcers may occur in the distribution of a single artery or extend widely when a larger, more proximal vessel is affected. Foot ulceration between the toes has recently been described in patients who have received tight compression bandaging to treat their venous ulcers [4].

In impoverished populations who do not wear fitted shoes, the foot is also prone to infection and infestation.

Diabetic foot ulcers [5]

Apart from conventional arterial disease there are two major causes of foot ulcers in diabetes: neuropathy and infection. Lack of sensation makes the patient unaware of any ulceration or progressive damage from footwear or bandage, so underlying osteomyelitis or deep soft-tissue infection may pass unnoticed.

Trophic ulcers

The term is an unsatisfactory one. Some occur as the result of pressure (decubitus) and friction on areas that have become anaesthetic as a result of a neurological disease (Fig. 50.33), but others are associated with underlying vascular abnormalities (gravitational). Most commonly there is a reduced arterial supply, as in diabetes, but sometimes there is an increased resting blood flow to the skin. This is a consequence of arteriovenous shunting. It also occurs in patients with features of 'acropathie ulcéromutilante', originally described in male alcoholics in France [6,7], in which dilated stiff-walled microvasculature is unable to respond to injury by the further vasodilatation necessary for repair. It may obviously complicate other neuropathies. Such shunts have been demonstrated by non-pictorial tracer techniques and arteriography [6]. Some therapeutic success has been claimed by tying off the feeding artery or by 'skeletonizing' all its branches [7]. This may allow the ulcer to heal and thus may arrest progression of the destructive bony changes.

Neuropathic ulceration of the foot benefits from protection from shearing forces [8] by the use of a plaster cast or 'Scotchcast boot'. If this fails to achieve healing, the pressure must be taken off the foot and the base of the ulcer excised before being grafted. Split skin, rotation flaps or pedicle flaps may be used to cure the defect. It may be simpler to excise the toe and most of the first metatarsal to achieve rapid healing if the ulcer is situated over the ball of the foot. Patient education is of prime importance to avoid recurrent inadvertent self-trauma.

Management of venous ulcers [1–4]

Many venous ulcers are cared for in the community by appropriately trained nurses and general practitioners. The diagnosis of venous ulceration is essentially clinical. The ankle–brachial pressure index (ABPI) should be measured unless peripheral pulses can be easily felt. Sensory testing is always important in diabetic patients and in any patient with foot ulceration. While in an ideal world every healed venous ulcer should have a colour Doppler duplex ultrasound performed to exclude a surgically correctable superficial venous incompetence, resources and logistics do not always permit this [5]. The presence of venous reflux on duplex scanning does not necessarily confirm a venous cause; basal cell carcinomas, for example, can develop in a limb with varicose veins.

General management

First-line therapy for venous ulcers is compression bandaging. The concept is to reduce venous pressure, particularly during walking, by improving calf muscle pump function and by opposing gravitational venous reflux. Exercise and movement are to be encouraged, while long periods spent sitting and standing are discouraged. When resting, the legs should be elevated, ideally with the ulcer just above the level of the heart to ensure the maximum reduction in venous pressure. Thus, lying is always preferable to sitting with the leg elevated. Patients should always be instructed to sleep in a bed; this might sound obvious but it is remarkable how many patients with venous ulcers fall asleep and remain in chairs with

dependent legs both day and night, so exacerbating venous ulcers (despite bandaging).

Obesity is often a problem that becomes worse with immobility, boredom and social isolation. Weight control is therefore essential, but malnourishment with anaemia and poor protein intake can coexist with obesity.

The contribution of other medical conditions, particularly heart and chest problems, needs to be considered. Heart failure exacerbates venous hypertension, while the need to sit upright in bed or in a chair to alleviate dyspnoea will further compound the situation.

Compression therapy [6]. Graduated multilayer high compression bandage regimens capable of sustaining compression for a week at a time should be the first line of treatment for uncomplicated venous ulcers with an ABPI ≥ 0.8. Randomized controlled trials (RCTs) have shown that compression provided by Unna's boot [7], two-layer [8], four-layer [9] or short-stretch bandages [10] improved healing rates compared to treatments using no compression.

Three RCTs compared elastic high compression (Tensopress® or Setopress®) with low compression (Elastocrepe®) [11]. More patients were healed at 12–15 weeks with high compression.

Multilayer high compression systems have been compared with single-layer systems. Four-layer bandaging was superior to a single-layer adhesive bandage [12,13]. However, no differences were found in healing rates when four-layer compression bandaging was compared with short-stretch bandaging and with Unna's boot, although the studies were small [14,15]. A recent study has shown that a rigid three-layer paste regimen produced healing rates as good as four-layer compression [16]. When leg ulcer clinics have promoted high compression treatment, healing rates have generally improved when compared with usual care given by community nurses [9,17]. Enthusiasm by professionals and a defined strategy, however, may explain the improvement.

In the UK, elastic (long-stretch) bandages are mainly used, whereas in Europe short-stretch bandages are preferred. Elastic bandages sustain compression for longer, whereas short-stretch bandages produce high 'venous' pumping pressures during exercise but lower resting pressures [18]. Multilayer bandaging (e.g. the Charing Cross four-layer bandage) has gained popularity owing to the high healing rate success reported in one study [19]. Unfortunately, all large ulcers were excluded and grafted in this study, and other surgeons have had difficulty in producing equivalent results. Nevertheless, multilayers provide good conforming properties for distribution of pressures as well as good sustainability of pressures.

Adequate training is essential for good results [20]. Incorrectly applied bandages can be harmful.

Dermatological assessment. The condition of the ulcer and of the surrounding skin influences treatment outcome. If eczema is present, exudation and scratching will jeopardize the integrity of the surrounding skin. Consideration must be given to the underlying cause of the eczema which may be: (i) varicose; (ii) contact allergy, or; (iii) contact irritant (e.g. caused by maceration from soaked dressings). A topical steroid is indicated to treat eczema, whereas emollients alone are sufficient for non-inflamed skin. Fragile oedematous skin needs careful application of compression bandages (but not necessarily less compression).

Cleansing and débridement. Management of the leg ulcer itself is important but should only be addressed once the patient's general health and venous hypertension have been considered. Cleansing of the ulcer should be kept simple [21,22]. Irrigation of the ulcer with warmed tap water or sterile saline is usually sufficient [23].

Any dressing technique should be clean and aimed at preventing cross-infection. Strict antisepsis is unnecessary. It is customary to remove sloughy or necrotic tissue from the ulcer bed by débridement, as this improves wound healing [24]. Maggots are used in some clinics for débridement but have never been compared with surgical débridement [25].

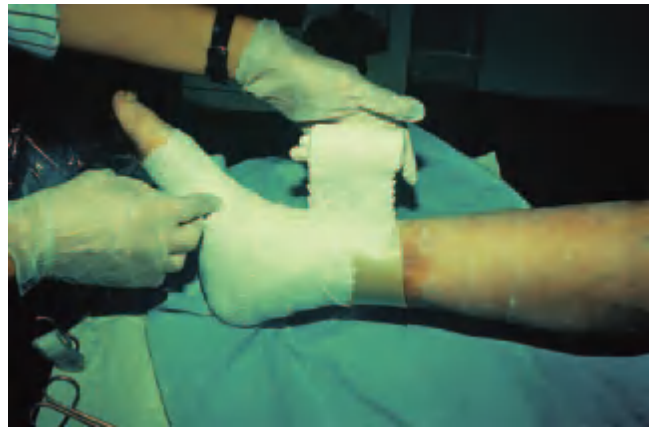
Dressings and topical therapies [26]**.** Dressings should be simple, low adherent, inexpensive and safe. There is no evidence that any particular dressing or dressing type is more effective in healing venous leg ulcers. 'It's not what you do with the ulcer that is important, it is what you do with the leg' is a good axiom, reflecting the fact that the most important aspect of treatment is reversing the venous hypertension, not the choice of wound dressing. Nevertheless, an absorptive dressing may be valuable in a highly exuding wound; more frequent dressings are an alternative option.

Ideally, a dressing should be left undisturbed for as long as possible so the ulcer can get on with the job of healing. Changes of dressing only disrupt new fragile epithelium. Conversely, a wet soaked dressing and bandage tends to produce maceration of surrounding skin and encourage infection. 'Strike-through' of exudate to the outside of a bandage is usually an indication for a dressing change. Patients can develop allergies after using a product for some time. Patch testing should be considered if dermatitis develops or is difficult to control.

Tissue-engineered skin equivalent (e.g. Apligraf®) has been shown to aid healing over and above that achieved by compression [27] and was found to be particularly effective in therapy-resistant ulcers. Granulocyte–macrophage colony-stimulating factor appears to promote healing of venous ulcers, but further research is required [28].

Fig. 50.38 A hydrocolloid dressing applied to an ulcer provides comfort and stimulus to healing. The centre of the dressing dissolves and contributes to odour and exudate on removal.

(a)



(b)

Fig. 50.39 Applying a paste bandage to an ulcer, avoiding a tourniquet effect by frequent: (a) cutting; (b) folding.

First-line primary dressings [29] include a knitted viscose primary dressing (e.g. N-A Dressing®) with a superimposed absorbent pad (secondary dressing). Tulle dressings impregnated with paraffin (e.g. Jelonet®) can increase maceration; medicated tulle dressings are not generally recommended unless infection is likely [30]. Foam dressings are helpful in exuding wounds. Hydrocolloid dressings can be helpful in dry sloughy wounds to reduce pain but are not recommended if there is much exudate (Fig. 50.38). Alginate dressings are highly absorbent and are suitable for exuding wounds. Zinc paste bandages (e.g. Steripaste®) can be applied directly to the wound base and to the intact skin from the base of toes to knee, with a covering compression bandage in one or two layers (Fig. 50.39).

Microbiology. Chronic leg ulcers are usually colonized by microorganisms but whether this affects healing is debatable [31,32]. Routine wound swabs for bacteriology are unnecessary unless there is evidence of clinical infection such as: (a) surrounding inflammation, redness or cellulitis; (b) increased pain; (c) purulent exudate; (d) a rapid deterioration of the ulcer; or (e) fever. The discovery of group A haemolytic *Streptococcus* should prompt use of a course of penicillin, but otherwise antibiotics should not be used too readily.

Pain relief. Most patients with venous ulcers suffer moderate to severe pain [33]. Pain can result in reduced mobility, particularly of the range of joint movement, leading to a poor calf muscle pump. Pain may also indicate other pathology such as arterial insufficiency, malignancy or infection. Analgesia is recommended if compression fails to resolve pain from a venous ulcer. Opioids may be necessary in some cases. Some deep pain is mediated by the autonomic nervous system and may be helped by amitriptyline or a guanethidine block [34]. Quinine is a useful therapy for night cramp [35].

Measurement [8]. It is unwise to recommend any agent for the healing of ulcers that has not been subjected to a properly controlled trial. The only measurement that matters is the time taken for total healing of a large number of ulcers, which would, if possible, be stratified by initial ulcer size. The size influences the time taken for total healing to occur [36]. Large ulcers generally take significantly longer to heal than small ones. The healing rate is a poor measure; however, it is of value in monitoring the progress of individual ulcers (Fig. 50.40).

Systemic therapy. Systemic antibiotics have not been shown to improve the healing rates of venous ulcers and should be reserved for ulcers with clear evidence of infection [37].

The effectiveness of pentoxifylline in healing venous leg ulcers may be because of its fibrinolytic action and a reduction in leukocyte adhesion. Although randomized

Fig. 50.40 Tracing around the margins of an ulcer to ensure that healing is occurring.

trials have reported both positive and negative results, a systematic review was positive [38]. A dose of 800 mg three times daily may be better than 400 mg three times daily as conventionally used.

An increased rate of venous ulcer healing with the use of oral enteric-coated aspirin (300 mg) daily was reported in one randomized trial [39]. Mixtures of flavanoid drugs (e.g. oxerutins) are licensed for use in venous disease. Daflon 500 accelerated healing of small ulcers in a randomized trial [40].

Stanozolol, an androgenic steroid with fibrinolytic properties, is helpful in lipodermatosclerosis [41] but no studies have demonstrated improved ulcer healing.

Fig. 50.41 A large ulcer (a) before and (b) after skin grafting.

Surgical treatment [1]

The exact role of surgical treatment is a matter of considerable dispute. Recurrence rates of 30–50% after different surgical manoeuvres have been reported within 5 years [2–4]. Ligation and stripping of the saphenous veins and compressive sclerotherapy are the procedures most frequently undertaken. Complete extirpation of the communicating veins 'feeding' the ulcer is a logical approach but other communicating veins are easily missed [3].

It would appear that surgical eradication of superficial incompetent veins is effective in preventing recurrence but it is of little or no value in preventing recurrent ulceration in patients with damage to the deep venous system [5]. The newer procedures of deep-vein bypass, valvuloplasty and brachial valve transplant have still not been subjected to rigorous assessment by independent centres concerned with treating large numbers of patients with post-thrombotic limbs and venous ulcers. The value of these techniques in preventing ulcer recurrence in post-thrombotic limbs is therefore unknown. Elastic stockings must be worn for life and renewed at 6-monthly intervals if recurrence is to be prevented, and even these are not totally effective [6].

Shave therapy, a method of excision of ulcer and surrounding lipodermatosclerosis followed by meshed split-skin graft, healed 88% of ulcers in 18 patients [7].

Skin grafting. Skin grafting on the lower legs is a means of considerably reducing the time taken for the ulcers to heal. It is usually performed on in-patients but can be carried out as an outpatient ambulatory procedure [8]. Pinch grafting provides small quantities of dermis as well as epidermis but leaves unsightly donor sites; large ulcers usually require split-skin grafts, which must be placed on surgically débrided beds. The application of mesh grafts has proved very effective when combined with ulcer excision (Fig. 50.41) [9]. Recurrence rates depend on patient selection. Those with many underlying medical or social problems are likely to have ulcer recurrence within a few weeks or months of grafting. Many studies of skin grown *in vitro* have indicated that keratinocytes will stimulate healing with the repopulation of host tissues even though the grafts may not themselves survive. Mechanisms underlying growth stimulation by cytokines have led to a growth-factor industry [10]. However, no cytokine can be relied upon to promote healing unless most of the above-mentioned management factors are first attended to. If the underlying causes of ulceration are well managed, healing rates are excellent and added cytokines are not necessary [11].

Recurrent ulcers

Once their ulcer is healed, patients should be transferred from a bandage regimen to compression hosiery [1,2]. There are three categories of compression hosiery [3]:

1 *Class I*: Ankle pressure 14–17 mmHg
2 *Class II*: Ankle pressure 18–24 mmHg
3 *Class III*: Ankle pressure 25–35 mmHg

Class II or III should be chosen, depending on the severity of the venous hypertension. It is of the utmost importance that stockings are carefully fitted and that patients are instructed about how to put them on and take them off. An applicator may need to be purchased. Hosiery should not be worn overnight. At least two pairs should be provided, to allow for daily changing and washing. Washing is necessary to retain the elastic property of Lycra-containing hosiery. Two stockings per leg should last 6 months before compression is lost and replacements are required.

Many recurrences are the result of poor follow-up and inadequate or worn-out elastic stockings. Indeed, the 50% overall recurrence rate over 5–7 years has been shown to be higher in those prescribed stockings and is an indication of poor supervision [4]. Some recurrences are the result of superimposed arterial disease causing tissue ischaemia and skin necrosis. Many ulcers are precipitated by minor trauma, in which case a foam or felt pad should be worn over or under the stocking over vulnerable areas. Despite this, a considerable proportion of well-treated formerly ulcerated limbs develop recurrences from time to time, often for no obvious reason. These recurrences are more likely in post-thrombotic limbs. Obsessional attention to detail in stocking use, avoidance of minor trauma and early vigorous treatment of any breakdown should reduce the period of re-ulceration to a minimum. Surgical ligation of the saphenous veins and of incompetent communicating veins appears no better than stanozolol and stockings in preventing ulcer breakdown.

Telangiectases

Telangiectases (Latin: Tel, end + Greek: Angos, vessel + ectasis from Greek: ektasis, expansion) are chronically dilated capillaries or small venules. They appear on the skin and mucous membranes as small, dull red, linear, stellate or punctate markings. Telangiectases (telangiectasias) represent dilatations (expansion, stretching) of pre-existing vessels without any apparently new vessel growth (angiogenesis) occurring. As such, telangiectases can be bracketed with spider angioma (spider naevi) and capillary aneurysm-venous lake, whereas vascular malformations represent anomalies of embryological development (disturbances in vasculogenesis or angiogenesis). Hamartomas include proliferation of other tissue elements, e.g. melanocytic, eccrine and are not solely vascular [1].

Development of telangiectasia [2]

The common telangiectases can be explained by abnormalities in the organization and ultrastructure of the small vessels rather than by neovascularization (angiogenesis) or random anastomoses. The *macular telangiectases* seen in scleroderma, generalized essential telangiectasia and naevus flammeus are produced by dilatation of postcapillary venules of the upper horizontal (subpapillary) plexus (Fig. 50.42). *Cherry angiomas* are produced by spherical and tubular dilatations of capillary loops in dermal papillae with tortuous cross-connections between individual loops. *Angiokeratomas* of Fabry and Fordyce have the ultrastructure of collecting venules that contain valves and appear to represent the ectopic development or placement of small valve-containing collecting veins. The cutaneous lesions of hereditary haemorrhagic telangiectasia (HHT) represent microvascular arteriovenous anastomoses.

The development of telangiectases is nevertheless a complex dynamic process where different mechanisms may be at play. In HHT, for example, where arteriovenous anastomoses cause focal dilatations of postcapillary venules, mutations in Endoglin (ENG) HHT-1 or activin receptor-like kinase I (ALK-1 or ACVRL1) HHT-21, are responsible. Mutations in ALK-1 interfere with an integral membrane protein on vascular endothelial cells responsible for binding transforming growth factor-β (TGF-β). TGF-β signalling mediates vascular remodelling through effects on extracellular matrix production [3]. Disruption of this latter maturation phase of angiogenesis seems to be important in the development of HHT [4].

Secondary telangiectasia and dilatation of pre-existing vessels

Telangiectases commonly represent the effect of wear and tear on the skin, and are particularly frequent on ageing, light-exposed skin, or following trauma or X-irradiation. In fact, they are found in most processes which cause atrophy of the skin whatever the aetiology, for example poikiloderma. Smoking and UV radiation are known to have a detrimental effect on human skin characterized by elastosis and telangiectasia. The association between increasing age, sun exposure and amount of telangiectasia is strong among men but less apparent among women; similarly smoking is associated with elastosis in both sexes but only with telangiectasia in men [1].

Prolonged vasodilatation may be followed by permanent telangiectases, for example, in rosacea. Varicose veins are frequently the cause of telangiectases on the legs, where they may produce a type of arborescent telangiectasia. Telangiectasia associated with chronic venous disease are assumed to be due to rise in venous pressure so stretching the vulnerable venous end of the capillary or draining venule [2]. The significance of telangiectasia of the lower limbs must not be underestimated. Considered a 'cosmetic' problem, their presence is often indicative of early or established abnormalities of the main leg veins. Telangiectases may be present individually, in sheets or as an arborizing appearance. The colour of the telangiectasia depends on the calibre of the dilated venule. Large dilatations (< 1 mm) are dark blue and often palpable. The smallest (0.1 mm), most superficial, telangiectases are red and barely empty when the leg is raised. The term *corona phlebectatica paraplantans* is used to describe perimalleolar and paraplantar venous telangiectasia which is always associated with venous hypertension.

Telangiectases around the lower border of the ribs are virtually physiological in older age groups.

Telangiectases may be an important diagnostic sign in certain systemic disorders, especially lupus erythematosus, dermatomyositis and scleroderma, or in association with Raynaud's phenomenon. Capillary microscopy of nail-fold telangiectases in such patients may help in the differential diagnosis (Figs 50.43–50.45). Usually, the distribution and associated abnormalities leave little doubt about the diagnosis, but on occasion telangiectases may be the presenting or only sign, or may be the end result of an otherwise burnt-out process. Thus, patients with scleroderma, especially of the so-called Thibierge–Weissenbach or CREST type, may present with telangiectases that closely mimic HHT, and even cause severe bleeding; patients with dermatomyositis may have telangiectases on the eyelids, hands or elsewhere; and localized areas of telangiectases on the face may be a manifestation of discoid lupus erythematosus. Telangiectases of the face and also of the mucous membranes are a common feature of Raynaud's phenomenon without other evidence of scleroderma. Telangiectases may be a manifestation of neonatal lupus erythematosus, with or without any other eruption [3].

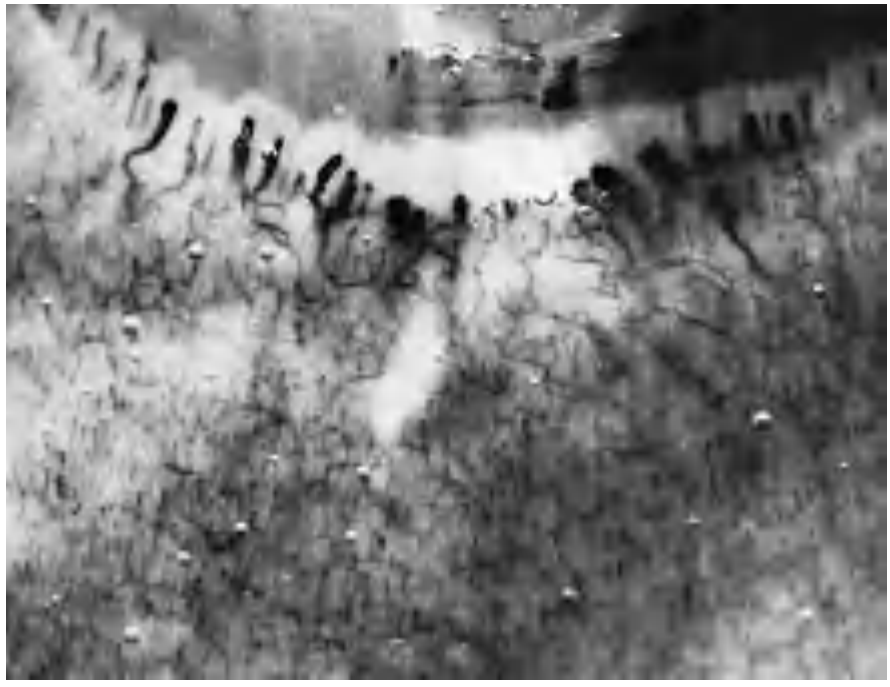

Fig. 50.44 Nail-fold capillaries in scleroderma. (Courtesy of Dr H.R. Maricq, Lyons, NJ, USA.)

Unusual mat-like telangiectases, especially on the upper back, have been reported in men working in an aluminium plant [4]. Telangiectases on the chest wall [5] and other sites [6] have been reported in patients with AIDS.

Telangiectasia are also described secondary to other conditions including cutaneous mastocytosis (telangiectasia macularis eruptiva perstans) and angiotropic (intravascular) lymphoma [7].

Spider telangiectases

SYN. ARTERIAL SPIDER; SPIDER NAEVUS; NAEVUS ARANEUS; SPIDER ANGIOMA

Aetiology and pathology. Spider telangiectases occur in up to 15% of completely normal persons, and more frequently in children [1,2]. They occur in large numbers during pregnancy—one or more spiders are found in two-thirds of all pregnant women [1]. They may appear in the first few months, but tend to increase in number until term: they usually disappear within 6 weeks of delivery but may persist or recur in the same sites in subsequent pregnancies. They are also characteristically found in liver disease, of which they may be a presenting sign [3]. A relationship to oestrogens has been suggested on this clinical evidence. Palmar erythema may be associated with spiders, with or without liver disease or pregnancy.

The main vessel of the spider is an arteriole. The blood flows from this to the periphery, and then passes into a capillary network [4]. The lesion is not therefore a true arteriovenous anastomosis, although glomus cells may be associated with the lesions.

Clinical features. Spiders vary in size and shape, and may be up to 1.5 cm across. The central body may be raised, and is usually pulsatile on diascopy. The radiating vessels are just visible to the naked eye (Fig. 50.46). They occur on the upper half of the body, especially the face, neck and hands. They are frequently solitary, but may be multiple, even in health. Liver disease is seldom found, but should be suspected at any age when lesions are numerous. They

Fig. 50.46 Spider telangiectasis.

may develop at sites of trauma and may be unilateral [5]. Similar lesions occur on the mucous membranes of the lips and nose. Here, the typical morphology is less apparent and differentiation from HHT may be difficult.

Natural history. The majority of lesions which occur in pregnancy disappear spontaneously, but some may persist. Lesions appearing in otherwise healthy children tend to persist indefinitely, but a small proportion regress spontaneously.

Diagnosis. The typical morphology, with a central pulsating vessel, does not occur in other conditions. In HHT, the telangiectases are macular, punctate or linear; when they are stellate they do not pulsate.

Cherry angiomas (Campbell de Morgan spots)

These are particularly common on the trunk of middle-aged or elderly people. They disappear in extreme old age. Increased numbers have been recorded in diabetics [1], but this may not be significant. Ultrastructural examination has shown that they have reduplicated basement membranes and fenestrations of the endothelium [2].

When fully developed they are readily recognized. Tiny lesions, which may be very numerous, can resemble either petechiae or other types of telangiectases. They cannot

always be made to blanch with pressure, and may need to be observed repeatedly to distinguish them from petechiae.

Angiokeratomas

Angiokeratomas are probably not vascular neoplasms but acquired telangiectases of pre-existing blood vessels of the papillary dermis, although some types of venular malformation cannot be excluded. They possess the ultrastructure of collecting venules with valves [3].

Telangiectasia with calcium channel blocking drugs

There have been increasing numbers of reports associating telangiectasia with calcium channel blockers [1–3], particularly in sun-exposed sites. In a study of renal transplant recipients the grade of photodamage was strongly associated with the use of calcium channel blockers [4].

Venous lakes [1]

A form of senile angioma occurring on the face, lips and ears of elderly patients. Histologically, they consist of greatly dilated, thin-walled venules without the proliferation of vascular tissue of the true angioma. There is degeneration of the supporting connective tissue [2].

Palmar varices. Small varicosities of the palms and fingers, particularly on the palmar phalangeal creases, are common in elderly people [3].

Treatment of telangiectasia [1,2]

The central vessel of a spider naevus can be destroyed with electrolysis or pin-point hyfrecation without anaesthetic. A significant proportion of such lesions recur. Larger isolated angiomas can quite readily be sealed off by diathermy or cautery. Treatment of extensive small lesions is unsatisfactory. Various types of laser have been recommended [3]. Cryotherapy is somewhat disappointing. Injection with sclerosants for venous telangiectasia [1–4] is helpful. Cosmetic camouflage certainly has its uses.

Primary telangiectasia

Angioma serpiginosum [1–4]

Angioma serpiginosum is a rare naevoid disorder affecting the small vessels of the upper dermis. Histology shows that the affected papillae are distended by a large, single, ectatic capillary lined by flattened endothelial cells of normal appearance. Inflammatory changes are not usually present.

The disease occurs predominantly in females (90%), and usually starts in childhood. Most cases are sporadic, but a family history suggesting dominant inheritance has been reported [5]. The common sites are the lower limbs and buttocks, but it may be more widespread. It is often unilateral initially. Characteristically, there are red or purple puncta up to 1 mm in diameter (Fig. 50.47). These are grouped in areas a few centimetres across, or sometimes form large sheets. Irregular lesions may arise, and commonly there is livedoid patterning of the puncta. Frequently, there is a background of more diffuse erythema. The lesions may not blanch completely on pressure, but nevertheless true purpura does not occur, and angioma serpiginosum should not be classified among the purpuric dermatoses. The dilated capillaries are easy to see under the capillary microscope. The background erythema is due to dilatation of the subpapillary venous plexus. The condition starts as one or more small lesions, and characteristically extends over a period of months or years. After this period further extension usually ceases, but may recommence in adult life. Individual puncta often disappear spontaneously, and complete regression of the eruption

(a)

(b)

Fig. 50.47 Angioma serpiginosum.

may occur, or traces may persist indefinitely. There are no symptoms, and no other changes in the skin, although slight atrophy has been reported. A single case associated with retinal and spinal nerve-root angiomas has been reported [6]. Histologically dilated and tortuous capillaries are observed in the papillary dermis but without any inflammation or red cell extravasation. Epiluminescence microscopy can be helpful in diagnosis by demonstrating 'red lagoons' [7].

Differential diagnosis includes angiokeratoma corporis diffusum (Chapter 57), angiokeratoma circumscriptum naeviforme (Chapter 15) and forms of capillaritis. Treatment, if necessary, with pulsed dye laser improves the disorder [8].

Hereditary haemorrhagic telangiectasia [1]

SYN. OSLER–RENDU–WEBER DISEASE

Hereditary haemorrhagic telangiectasia (HHT) is an autosomal dominant disorder characterized by epistaxis, cutaneous telangiectasia and visceral arteriovenous malformations (AVMs). HHT is more prevalent than previously estimated [1]. Clinical diagnosis is made on the basis of: (i) epistaxis—spontaneous, recurrent nose bleeds; (ii) telangiectases—multiple, at characteristic sites (lips, oral cavity, fingers, nose); (iii) visceral lesions—such as gastrointestinal telangiectasia (with or without bleeding), pulmonary AVMs, hepatic AVMs, cerebral AVMs, spinal AVMs; and (iv) family history—a first-degree relative with HHT. Three criteria indicate a definite diagnosis of the disorder; two a possible or suspected case [2].

Aetiology and pathogenesis. Mutations in at least two genes are associated with HHT. Endoglin (ENG) on chromosome 9 is the gene responsible for HHT-1, while activin receptor-like kinase 1 (ACVRL-1 or ALK) on chromosome 12 is responsible for HHT-2. HHT-1 families have a higher prevalence of pulmonary AVMs than HHT-2 families who generally have a milder phenotype and later onset [3]. ENG and ALK both encode a homodimeric integral membrane glycoprotein which is the surface receptor for TGF-β. Both genes have been reported to be essential for angiogenesis. Mice lacking the ENG or ALK genes develop age-dependent vascular lesions of the skin, extremities, oral cavity and internal organs in a phenotype very similar to the human condition [4].

Clinical features (Fig. 50.48). Recurrent epistaxis is usually the presenting symptom. It may begin in childhood or even in infancy, but far more commonly begins at puberty or in early adult life. Telangiectasia of the skin is not often seen before puberty, and usually appears in the third or fourth decade, but it may be extensive in early childhood. The individual lesions are punctate or linear. On the rare occasions when they are spider naevus-like,

Table 50.4 Some causes of telangiectasia.

Secondary telangiectasia
Prolonged vasodilatation (rosacea, varicose veins)
Prolonged exposure to sunlight, tar, etc.
Post-traumatic
Radiodermatitis
Xeroderma pigmentosum
Atrophy, e.g. poikiloderma, topical corticosteroids
Raynaud's disease
Lupus erythematosus
Dermatomyositis
Systemic sclerosis
Morphoea
Mastocytosis (telangiectasia macularis eruptiva perstans)
Acquired immune deficiency syndrome
Primary telangiectasia
Vascular naevi
Angiomas and angiokeratomas
Angioma serpiginosum
Hereditary haemorrhagic telangiectasia
Ataxia–telangiectasia
Generalized essential telangiectasia
Unilateral naevoid telangiectasia syndrome
Hereditary benign telangiectasia
Spider telangiectases
Bloom's syndrome
Morquio's syndrome
Angiotropic lymphoma
Mycosis fungoides
Naevus anaemicus with telangiectatic vessels
Cutis marmorata telangiectatica
Solitary plaque-like telangiectatic glomangioma

they do not pulsate. Nodular lesions may be present but are sparse in comparison with the smaller lesions which may be very numerous. Lesions may occur anywhere, but especially on the upper half of the body—face, lips, ears, conjunctiva, trunk, forearms, hands and fingers. They are often conspicuous in the nail beds. The soles and toes may also be affected. The skin lesions seldom bleed.

The mucous membranes are almost invariably involved. Lesions occur on the nasal septum, in the mouth, nasopharynx, and throughout the gastrointestinal tract [5,6], where they may be demonstrated by endoscopy or arteriography but not by barium studies. They may also be found in many other organs, including the retina. The lesions on the tongue have a characteristic and perhaps diagnostic appearance on capillary microscopy. Within a fungiform papilla there is a single, much-dilated vessel, which may cause the papilla to be expanded [7]. Haemorrhages may occur from any site, and their severity and frequency determine the clinical manifestations and course. Pulmonary arteriovenous fistulae are present in some cases, and occur particularly in some families [8,9]. They reveal their presence by dyspnoea, cyanosis and clubbing of the fingers in adolescence, and can be demonstrated radiologically. Paradoxical embolization to the systemic circulation may occur. This disease is the commonest cause of pulmonary arteriovenous anastomoses. Hepatic arteriovenous anastomoses have been reported, and liver enlargement and cirrhosis also occur [8]. Aneurysms of other vessels, the aortic arch and splenic artery [5], have occurred. Lesions of the eye [10] and CNS are uncommon.

Diagnosis. The history and morphology of the individual lesions are usually sufficient to establish the diagnosis. The lesions do not have the characteristic morphology of the arterial spider. Other causes of telangiectasia (Table 50.4) have to be excluded. Capillary microscopy may be helpful. Phlebectasia of the lips may be familial [11].

Treatment. In mild cases, no treatment is needed. Individual lesions may be destroyed with the cautery, diathermy or laser. In some severe cases, where nasal bleeding is causing severe anaemia, more extensive surgery may be required, replacing the nasal mucous membrane with a split-skin graft, an operation not without hazard. Usually, however, treatment is limited to the control of secondary anaemia. Iron replacement is necessary in all but mild cases. In some cases of severe recurrent epistaxes, oestrogens seem to be helpful, perhaps by inducing keratinization of the mucous membrane rather

than by any direct effect on the blood vessels themselves [12]. The smaller dosage of oestrogens in contraceptive pills may aggravate the condition [13,14]. Antifibrinolytic therapy with ε-aminocaproic acid may be helpful [15]. The disease does not usually shorten life. The mortality rate is less than 10%.

Pulmonary and other systemic arteriovenous malformations may be amenable to resection, ligation or embolization.

Ataxia–telangiectasia

SYN. LOUIS–BAR SYNDROME

Ataxia–telangiectasia syndrome [1] is a rare recessive disease with pleiotropic involvement of the nervous and lymphoid systems, caused by homozygous mutations in the ataxia telangiectasia mutated (*ATM*) gene. Defective excision repair of DNA damaged by UV light, gamma or X-rays is therefore responsible.

The syndrome manifests with telangiectases, progressive cerebellar ataxia, combined immunodeficiency and a marked susceptibility to cancer. A diminished level of, or absent, IgA is especially characteristic but there may be a reduction in other immunoglobulins. Defects of T and B cell function may also be present.

Affected children, who are usually small, are apparently normal until the second year of life when they are noticed to be clumsy, and the ataxia becomes progressive, so that by the age of 12 years they are unable to walk without assistance. Other signs of cerebellar disease occur, such as nystagmus and slurred speech, and mental deterioration may be observed. Neurological symptoms may not commence before the age of 6 years. Telangiectases may be present as early as the second year, but usually develop between the ages of 3 and 5 years. They first appear on the bulbar conjunctiva, and subsequently involve the ears (Fig. 50.49), eyelids, butterfly area of the cheeks and limbs. Not all sites are affected in every case. Bleeding is very uncommon. There may be some associated atrophy, the skin may be dry, and the hair prematurely grey. Disturbances of pigmentation and eczematous lesions may also occur [2], as may granulomas [3]. Recurrent sinus and pulmonary infections are frequent, and may dominate the clinical picture; they are not infrequently fatal. Ovarian agenesis is not uncommon. Treatment has until recently been directed only at control of secondary infection, but the use of gammaglobulin has given rise to some more hopeful reports.

Fig. 50.49 Ataxia–telangiectasia. (Courtesy of Dr P.W.M. Copeman.)

These patients should have as few X-ray investigations as possible.

The laboratory diagnosis currently relies on measurement of serum alphafetoprotein (AFP) and cellular sensitivity to ionizing radiation. Improved diagnostic testing by immunoblotting of nuclear lysates from lymphoid cell lines for ATM has recently been described [4].

Generalized essential telangiectasia

Generalized essential telangiectasia [1–3] is a condition which is not as rare as the paucity of reported cases suggests. Many cases may be misdiagnosed as atypical HHT. The heading 'essential telangiectasia' probably includes more than one disease.

The condition occurs more frequently in females, and commonly commences in late childhood or early adult life. Extensive sheets of telangiectases, unassociated with other changes in the skin, occur on the limbs or body (Fig. 50.50). The telangiectases are usually linear, but small angiomas may be present. Recurrent haemorrhages from the skin and mucous membranes or into the eye may produce incapacity, but in the majority of cases, the disease is of cosmetic importance only.

Differential diagnosis is from other causes of telangiectasia. HHT is distinguished clinically by the distribution of the lesions, their presence in large and sometimes asymmetrical sheets, and by the usual lack of haemorrhages in generalized essential telangiectasia. Laser treatment may be helpful but lesions tend to relapse [4].

Unilateral naevoid telangiectasia syndrome [1,2]

Unilateral naevoid telangiectasia can be congenital or acquired. There have been reports to suggest an increase in skin oestrogen and progesterone receptors. When acquired, it arises almost exclusively during periods of relatively increased oestrogen levels such as pregnancy or puberty or in association with alcoholic cirrhosis or hepatitis C infection [1]. Polymorphic light eruption has been described confined to an area of acquired naevoid telangiectasia [2].

Hereditary benign telangiectasia

This disorder probably has a dominant inheritance [1] and is characterized by the presence of sometimes extensive telangiectases resembling generalized essential telangiectasia, starting in childhood and without other systemic lesions [2,3]. Less commonly, they may be present at birth [4]. They tend to occur more in light-exposed skin. Histology and electron microscopy have been used to distinguish this condition from HHT [5]. Distinction from HHT is dependent on the lack of bleeding, although lesions do appear related to arteriovenous anastomoses as in HHT [6].

Naevus anaemicus with telangiectatic vessels [1]

Following dermabrasion of the epidermis overlying a naevus anaemicus, enlarged telangiectatic vessels were observed within the previously pale area. The area was transplanted with thin epidermal grafts but 1 year later the naevus looked the same as before grafting. The explanation proposed for a naevus anaemicus and port-wine stain coexisting was vascular twin spotting, but the primary abnormality could be telangiectasia with surrounding skin blanched through a 'steal' effect of blood flow.

Chapter 51

Disorders of Lymphatic Vessels

P.S. Mortimer

Introduction

The lymphatic system comprises the lymph, lymphatic vessels, lymph nodes and other organs containing lymphoid tissue, especially the spleen and bone marrow. Although not a true circulation like the blood vascular system, the lymphatic vessels do provide an important 'limb' to the microcirculation, particularly in the skin, and, with the blood vessels, cater for the constant recirculation of protein and cells. This is done in partnership with the macrophage system. Through its own specialist cell, the lymphocyte, a close relationship exists between peripheral lymphatics, the blood circulation and the spleen and liver. Therefore, while lymph drainage serves a predominantly 'plumbing' role, the lymphatic system does possess important immunological responsibilities. The lymphatic vessels are essential for the continual drainage from the tissues of the body of both plasma proteins and lymph-borne cells. If this drainage ceases death will ensue [1].

While technology has advanced our knowledge of human biology at the cellular and molecular level, our understanding of whole-body physiology lags behind. There is no better example than the importance of lymphatics to disease processes, where the theoretical basis for a causal relationship may be strong but the evidence is often limited, usually because of a lack of reliable and sensitive investigatory methods.

Lymphangiogenesis

The embryonic origin of the lymphatic system has long been uncertain, but its close development with the venous system is not in doubt. Sabin proposed that early in fetal development, isolated primitive lymph sacs originate by endothelial cell budding from embryonic veins [1,2] and that the skin lymphatics develop by endothelial sprouting from these primary lymph sacs (centrifugal

development). Alternatively, it has been suggested that initial lymph sacs develop from precursor cells, 'lymphangioblasts', in the mesenchyme (centripetal development) [3].

VEGFR-3

In 1995, the first specific growth factor receptor of lymphatic vessels was identified and termed FLT-4 [4]. It is now termed vascular endothelial growth factor receptor-3 (VEGFR-3). The family of vascular endothelial growth factor receptors and their ligands are central to the development of blood and lymph vessels [5]. In embryos, VEGFR-3 is initially expressed in all vasculature, but during development its expression in blood vessels (veins not arteries) becomes restricted to the developing lymphatic vessels. In embryos, therefore, VEGFR-3 is important for cardiovascular development, but in adults it is responsible for the regulation of the lymphatic vessels [6].

Signalling via VEGFR-3 has been shown to be critical for growth, migration and survival of isolated lymphatic endothelial cells in culture [7]. VEGFR-3-positive lymphatic vessels have been observed to sprout from preexisting lymphatics and to grow into the granulation tissue in healing skin wounds [8].

VEGF C/D

Blood vessel development depends upon the vascular endothelial growth factor (VEGF) family of proteins. This family consists of VEGF-A, VEGF-B, VEGF-C, VEGF-D, VEGF-E and placenta growth factor (PLGF). A paracrine expression pattern is seen between VEGF-C and VEGFR-3 at sites where the first lymphatic sprouts occur [9]. VEGF-C and VEGF-D are the main ligands for VEGFR-3 and therefore for lymphangiogenesis. Overexpression of VEGF-C in skin keratinocytes leads to dermal lymphatic hyperplasia [10]. VEGF-D is also lymphangiogenic when overexpressed in skin keratinocytes.

Prox-1

Prox-1 is a homeobox-containing transcription factor involved in the growth and elongation of the lymphatic vessel sprouts during development [11].

Angiopoietins and Tie-2

A second family of receptor tyrosine kinases known as Tie-1 and Tie-2 are important for vessel (including lymphatic) stabilization and maintenance during development. The ligands for Tie-2 are angiopoietin-1 and angiopoietin-2 (Ang-2). Ang-2 knock-out mice develop lymphatic abnormalities including chylous ascites and a disorganized and leaky lymphatic vasculature [6].

Anatomy

In the skin, lymphatic vessels form two horizontally running networks, a narrow-meshed superficial network lying subepidermally and a deeper wide-meshed network. The networks are connected to each other through obliquely running vessels (Fig. 51.1). Although fewer in number than blood vessels, lymphatics are potentially larger at capillary level. Lymphatics are essentially of two types:

1 Smaller, non-contractile, initial lymphatics (these used to be called terminal lymphatics), which commence or 'initiate' the drainage process within the tissues.

2 Larger, contractile, lymphatic collectors or trunks, into which the initial lymphatics drain [1].

Afferent collectors drain to lymph nodes and efferent collectors drain from lymph nodes. Lymphatic capillaries originate as blind-ending endothelial lined tubes in the subpapillary region and are rarely seen within dermal papillae except in certain disease states—for example, psoriasis [2,3]. From the superficial lymphatic plexus in the upper dermis, lymph drains through a series of enlarging precollectors into the contractile collecting trunks close to the dermosubcutaneous junction [1]. The lobules of adipose tissue have lymphatics only in their periphery, and clearance of lymph from the centre of the lobule is slow [4].

Initial lymphatics in the skin are arranged in loosely constructed polygonal meshes (Fig. 51.2) high in the dermis [1,5]. Territories of skin are drained by these meshes into the vertically draining precollectors. A series of

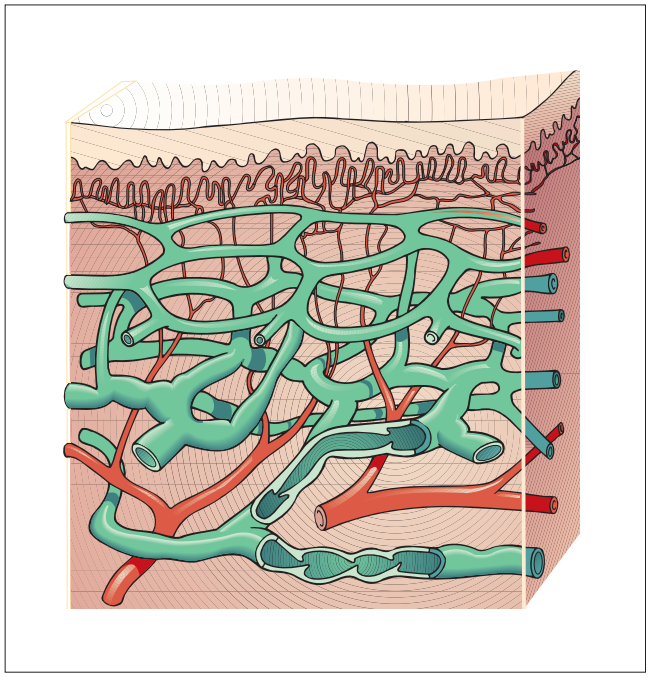

Fig. 51.1 Diagram of superficial and deep initial lymphatic vessels in the skin. Lymph vessels are coloured green, blood vessels are coloured red. (From Kubik and Manestar [1], with permission.)

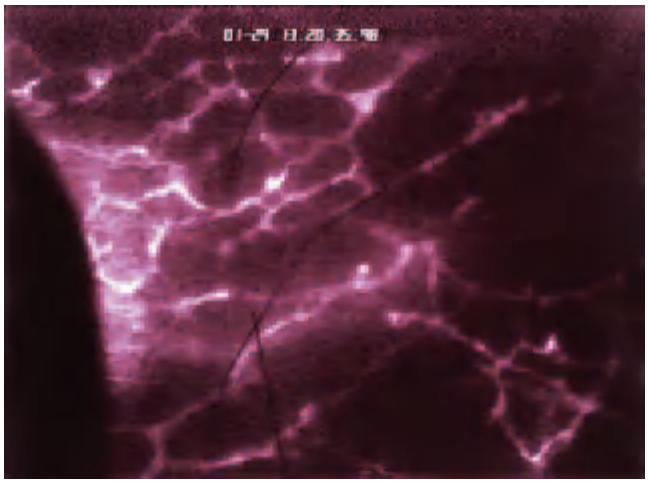

Fig. 51.2 Superficial network of dermal lymphatic vessels as viewed *in vivo* using fluorescence microlymphography.

valves ensure that flow is unidirectional. Such is the capacity of initial lymphatics for dilatation that the valves can become incompetent. Obstruction to deeper lymphatic routes leads to re-routing of lymph and results in 'dermal backflow', as witnessed both on conventional X-ray lymphography and lymphoscintigraphy. In this way, the initial lymphatic network of the skin provides collateralization by which lymph can escape to other (more) normally draining areas [6].

Structure

The lymphatic capillary is lined by a fine endothelium which is more attenuated than that of blood capillaries (Fig. 51.3). Potentially larger than blood capillaries, lymphatics are frequently not visualized in histological sections, because they are collapsed. A distended lymphatic exhibits characteristically thin attenuated walls with nuclei bulging into the lumen. On electron microscopy, the gaps between overlapping endothelial cells are much larger than in the blood capillary. These 'open junctions' act as flap valves and clearly serve as the entry point for macromolecules [1]. Lymphatics have little in the way of a basement membrane or pericytes [2]. The lymphatic endothelium contains very few pinocytotic vesicles and lacks Weibel–Palade bodies and fenestrae [3]. Attached to the outside of the endothelium is a network of reticulin and elastic fibres which act as anchoring filaments [4]. The elastic fibres form a partial envelope around the dermal lymphatics [5]. In addition to the flap valves in the lymphatic wall are bileaflet intralymphatic valves [6].

Contractile lymphatics are endowed with smooth muscle, are innervated and respond to vasoactive mediators

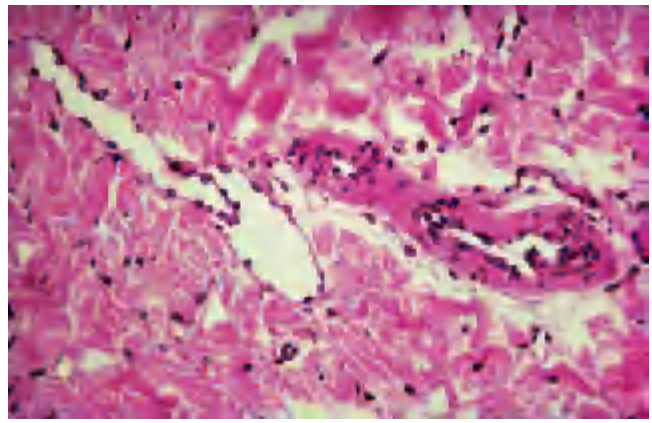

Fig. 51.3 Mid-dermal vessels showing the typical appearance of a mid-dermal blood capillary with plump endothelium compared with adjacent lymphatic vessels with attenuated endothelium and a valve. Such valves are not present in blood vessels high in the dermis.

including nitric oxide [7]. The contractile lymphatics contain a regularly spaced chain of intralymphatic valves that prevent retrograde flow even at high pressures.

Identification of skin lymphatics—specific lymphatic markers

The recent discovery of specific markers for lymphatic endothelium has contributed greatly to the identification of skin lymphatics in tissue sections. Previously, the only certain way of distinguishing a lymphatic from a blood vessel was by electron microscopy. Flap valves or wide open junctions between overlapping endothelial cells are pathognomonic of skin lymphatic vessels [1]. If large skin biopsies are fixed in an expanded condition by stretching the specimen in different directions, lymphatic vessels become visible for both light and transmission electron microscopy [2]. In normal skin, demonstration of the elastic fibre envelope can help distinguish upper dermal lymphatics from nearby capillaries [3], but elastin readily disappears with photo-ageing and inflammation.

A number of markers are available for labelling endothelial cells, but the majority stain both blood and lymph vessels (e.g. factor VIII-related antigen, CD31 (PECAM-1), ulex europaeus agglutinin 1 and EN4). Because initial lymphatics lack a continuous basement membrane, immunocytochemistry for the extracellular matrix components type IV collagen and laminin has been used to distinguish them from blood capillaries [4]. Pal-E monoclonal antibody is consistently negative in lymphatic vessels but positive in venules and small veins, the vessels most likely to be mistaken for lymphatics [5].

Of the newer molecular markers, VEGFR-3 was the first to be documented to be expressed in lymphatic endothelium, but it can also be found in a subset of blood vessels and in angiogenic vessels in certain pathological conditions. The most robust marker for skin lymphatics is LYVE-1 [6]. This is a receptor for extracellular matrix/lymphatic fluid glycosaminoglycans in lymphatic endothelial cells (Fig. 51.4). Podoplanin is a glomerular podocyte membrane mucoprotein which serves as a specific marker for the isolation of lymphatic endothelial cells

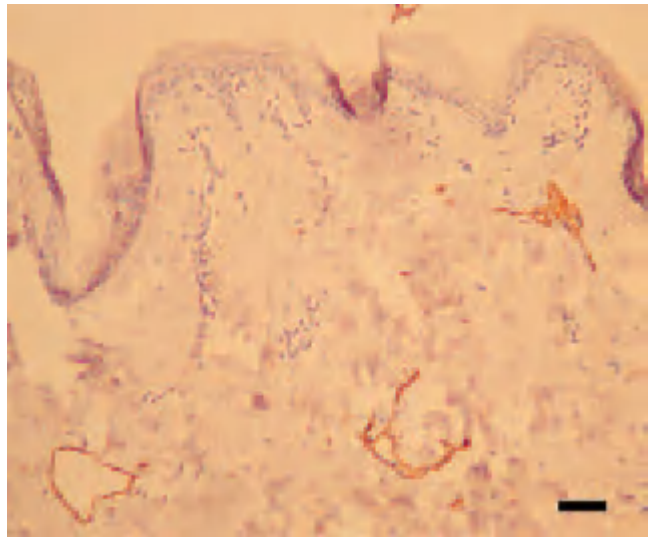

Fig. 51.4 LYVE-1 antibody marker for lymphatic endothelium. (Courtesy of Dr D.G. Jackson.)

[7]. It is present in small lymphatics, but not in the larger contractile lymphatics.

Other markers reported to be positive in lymphatics, but not in blood vessels, include Prox-1 [8] and a β-chemokine receptor, D6 [9], the latter only being positive on a subset of lymphatic vessels and therefore suggesting functional heterogeneity. These markers are summarized in Table 51.1 [10]. It is unlikely that any one marker will be totally specific, particularly in disease states, and the use of several markers is recommended.

Table 51.1 Markers for lymphatic vessels.

Molecule	Protein class	Biological effect
VEGFR-3	Receptor tyrosine kinase on endothelial cell	Lymphangiogenesis survival of LEC
LYVE-1	Receptor for extracellular matrix glycosaminoglycan	Transport of HA from tissues to lymph nodes
Prox-1	Transcription factor	Developmental lymphangiogenesis
Podoplanin	Integral membrane protein	Unknown
Desmoplakin	Component of intercellular adhering junction in LECs	Adhesion of LECs

HA, hyaluronan; LEC, lymphatic endothelial cell; LYVE-1, lymphatic vessel endothelial HA receptor; VEGFR-3, vascular endothelial growth factor receptor-3.

Purpose of lymphatics

Lymphatics are primarily concerned with draining, from the tissue spaces, materials which cannot directly return to the bloodstream. Colloids, and particularly protein, fall into this category as do many cells—extravasated erythrocytes, macrophages, lymphocytes and, of course, malignant cells. Lymphatics carry material that has penetrated the dermis, including microorganisms, injected vaccines, solvents of skin cosmetics, inorganic material such as silica and stains from tattoos [1]. Under normal circumstances, water is acting predominantly as a vehicle for the colloids, cells and particulate matter which can only be drained via the lymph route. Nevertheless, lymphatics also serve as an 'overflow pipe' in order to drain excess interstitial fluid. It is important to understand this role of the lymphatic acting as a 'safety valve' or buffer against fluid overload, because it incriminates the lymphatic to some degree in every form of oedema.

Bacterial and other microorganisms are channelled through lymphatics as a protective mechanism to prevent noxious agents from directly entering the bloodstream. Presumably this failure to 'police' infection is the reason why cellulitis/erysipelas can be such a recurrent problem with lymphoedema. Similarly, immobilization slows lymph flow—for example, causing venom to remain contained within the lymphatics following a snake bite [2].

Lymph transport

After filtration from the microvasculature, interstitial fluid enters a series of passive initial lymphatics and is then propelled within the collecting trunks through a series of intervalvular pumping segments (lymph hearts) to the lymph nodes before eventually returning to the venous system at the thoracic duct. Transport of fluid and other materials (prelymph) across the interstitial space towards initial lymphatics is a passive process dependent upon changes in local pressures (convective flow) [1,2]. Deformation or movement of the dermis by surface pressure and underlying muscle contractions and by dermal components, such as arterioles, causes expansion or compression of the initial lymphatics. The process of expansion is likely to result from pulling of the anchoring filaments on the abluminal surface of the lymphatic [3]. These probably act to prevent lymphatic collapse when interstitial pressure is high, as in oedema [4]. Negative fluid pressure inside the initial lymphatics serves to open the interendothelial junctions (flap valves) and to permit inflow of interstitial fluid. After filling and equilibration of pressure the flap valves close. Pressure on the skin surface, e.g. massage, or from below, e.g. muscle contractions, compresses the filled lymphatic. Lymph then moves downstream, i.e. towards bigger lymphatics; the valves within the lymphatic vessels ensure that flow is in one direction. Recoil of the lymphatic occurs when the compression wave (squeezing) of the lymphatic ceases and the cycle repeats itself. Cardiac arrest leads to cessation of lymph flow, but lymph flow can be maintained with active skin motion even after the arrest of the heart.

Immune functions

The lymphatic vessels form part of the immune system. Lymphocytes and mononuclear phagocytes constantly patrol the skin, leaving via the afferent lymphatic vessels for the lymph nodes. Langerhans' cells of the epidermis, and dermal dendritic cells, screen the skin for invading antigens. They migrate from skin to regional nodes where a primary immune response is initiated [1]. Dendritic cells enter dermal lymphatics by transmigration through

intercellular spaces of adjacent endothelial cells, frequently carrying material such as melanosomes and apoptotic bodies [2]. Receptors on lymphatic endothelial cells facilitate migration of proteins and cells to and within lymphatics. LYVE-1 [3] is related to the CD44 receptor for hyaluronan and is involved in its uptake from the dermis and transport in the lymph. When dendritic cells are activated by a variety of inflammatory stimuli, e.g. bacterial lipopolysaccharide or cytokines such as tumour necrosis factor-α or secondary lymphoid tissue chemokine (SLC/CCL21), the cell surface expression of CC chemokine receptor 7 (CCR-7) on lymphatics is increased [4]. CCL21 is a chemokine that is produced constitutively by lymphatic endothelial cells in the skin [5]. Disruption of the CCR7 gene which prevents expression of CCL21 prevents migration of dendritic cells from tissue to regional nodes.

Bacteria, viruses, fungi and toxins which penetrate the skin are absorbed by lymphatics and not by blood capillaries [6,7]. Virulent haemolytic streptococci, tubercle bacilli and many types of soluble or particulate antigens injected intradermally readily reach the regional lymph node [8].

Without intact lymphatics a primary immune response cannot develop. In the case of allogeneic skin grafts, removal of the lymph drainage channels causes cessation of the cellular reactions in the lymph nodes until lymphatic pathways are re-established [9]. Rejection is delayed in grafted skin sites where all draining lymphatics are severed [10]. Lymphatic vessels draining skin appear to play an important role in immunosurveillance. Studies in lymphoedema following curative breast cancer treatment demonstrated an impaired response to dinitrochlorobenzene testing in the swollen limb but not in the contralateral control limb [11]. Similar results were reported in lymphoedema associated with Kaposi's sarcoma [12].

Oedema

Oedema is an excess of interstitial fluid. Interstitial fluid volume must increase by over 100% before oedema is clinically detectable. Dermal oedema manifests as 'peau d'orange' due to expansion of the interfollicular dermis, whereas subcutaneous oedema gives rise to pitting.

Any oedema, whatever the cause, is due to capillary filtration overwhelming the lymph drainage for a sufficient period of time [1]. Interstitial fluid is reabsorbed almost entirely by the lymphatics. Contrary to popular belief, venous reabsorption of interstitial fluid cannot be maintained for any length of time except in certain vascular beds, e.g. that of the kidney [1]. The causes of oedema formation are listed in Table 51.2. Most oedemas arise from increased capillary filtration overwhelming lymph drainage. To some extent, therefore, any oedema incriminates the lymphatic through its failure to keep up with demand. Lymphoedema, however, is oedema arising principally from a failure in lymph drainage.

Lymphoedema

Definition: swelling due to the excess accumulation of lymph in the tissues caused by inadequate lymph drainage. Lymphoedema differs clinically from other forms of chronic oedema by its altered skin texture and the brawny quality of the subcutaneous tissues, which limit pitting. There may be no distinguishing features, particularly in the early stages of swelling. A more precise definition would be 'a swelling of soft tissues which is the result of accumulation of protein-rich interstitial fluid caused by a low output failure of lymph' [1].

Epidemiology

Lymphoedema *per se* is perceived as uncommon, yet lymphatic insufficiency is a major contributing cause in chronic ankle oedema, which is considered common (particularly in the elderly) [2]. Because lymphoedema can be a difficult diagnosis, particularly if mild or in the early stages, it is frequently underdiagnosed. A recent epidemiological survey, which determined the problem

Table 51.2 Causes of oedema.

Increased capillary filtration
Increased capillary pressure
- Increased venous pressure, e.g. right heart failure, DVT, obstructing malignancy, overtransfusion
- Increased blood flow, e.g. inflammation, arteriovenous fistula

Reduced plasma proteins
- Increased loss, e.g. nephrotic syndrome, protein-losing enteropathy
- Reduced synthesis, e.g. cirrhosis, advanced cancer
- Malabsorption, malnutrition

Increased capillary permeability
- Inflammation, e.g. varicose eczema, psoriasis, urticaria and angioedema

Reduced lymph drainage
Primary lymphatic insufficiency
- Familial
  Milroy's disease (onset at or soon after birth)
  Lymphoedema, distichiasis (postpubertal)
  Meige's disease (postpubertal)
- Sporadic

Secondary lymphatic insufficiency
- Surgery, e.g. lymph-node dissection
- Radiotherapy for cancer
- Recurrent cancer
- Infection, e.g. filariasis, cellulitis
- Accidental trauma

Dysfunctional lymphatics
- Dependency syndrome
- Loss of mobility
- High output failure in venous disease

DVT, deep vein thrombosis.

of chronic oedema in the community, ascertained 823 patients in a catchment area of 619 000 in south-west London. This estimated the overall prevalence of chronic oedema as 1.33/1000 population; the prevalence increased with age and was 5.4/1000 in subjects aged over 65 years. In only a quarter did the oedema arise from cancer treatment. Twenty-nine per cent had experienced at least one attack of cellulitis over the previous year. Ten per cent of subjects had lost, or had had to change, employment as a result of their chronic oedema. Chronic oedema that was likely to be lymphatic in origin is common in the community and often goes unrecognized [3].

Primary types of lymphoedema tend to affect females more frequently (70–80% of patients are female). In less than 10% of cases is swelling present at birth; most cases present at or soon after puberty. It is estimated that 80% will present before the age of 35 years (lymphoedema praecox) and 10% after the age of 35 years (lymphoedema tarda) [4]. Data on prevalence of lymphoedema are few, and a figure for overall prevalence of primary lymphoedema is not available. However, a recent study of 1000 young adults showed that 8% of women demonstrated signs of lymphoedema in the lower limb [5], and the cumulative prevalence of swelling following breast cancer treatment in women is 28% [6]. Similar prevalence studies for the lower limb following cancer treatment are lacking, but lymphoedema was noted in 11 of 58 patients undergoing radical vulvectomy with bilateral inguinal lymphadenectomy for vulval carcinoma [7].

Pathophysiology

Lymphatics may fail for a number of reasons. First, there may be an intrinsic abnormality of the lymph-conducting pathways. Such cases are referred to as *primary lymphoedemas*: in practice, this simply means that no identifiable extrinsic cause can be found. *Secondary lymphoedemas* are those due to some factor originating from outside the lymph system, such as surgical removal of lymph nodes, radiotherapy or a severe infection. Physiologically, there are only a limited number of ways lymphatics may fail. They may be reduced in number, obliterated, obstructed or simply fail to function. A lack of sensitive methods for investigation makes it difficult to distinguish between these mechanisms (Table 51.3).

A reduction in lymphatics may be due to total *aplasia*, such as the absence of skin lymphatics in Milroy's disease, or, more commonly, to partial *hypoplasia*. In the commonest form of primary lymphoedema, that presenting at or soon after puberty with distal leg swelling, lymphangiograms usually demonstrate a reduction in the size and number of peripheral leg lymphatic collectors. It is often assumed that the lymphatics have been abnormal since birth but it is always possible that the lymph vessels have undergone an accelerated atrophy or ageing process. The congenitally determined abnormality may not therefore be an underdevelopment of lymphatics from birth, but

Table 51.3 Possible causes of lymph drainage failure.

Mechanism	Causes
Reduced lymph-conducting pathways	Aplasia, hypoplasia of whole vessel
	Acquired obliteration of lymphatic lumen (e.g. lymphangiothrombosis, lymphangitis)
Poorly functioning lymphatics	Pump (contractility) failure
Obstructed lymphatics	'Scarring' from lymphadenectomy, radiotherapy or infection
Grossly incompetent lymphatics with reflux	Megalymphatics, lymph vessel hyperplasia

rather a failure of growth/regeneration following damage or injury. This would explain the latent period before swelling manifests, particularly in those forms presenting later in life (lymphoedema tarda). In truth, we do not know and these possibilities are speculative.

An *obliterative process*, where there is permanent obliteration of the lymphatic lumen and consequently of the vessel itself, probably develops through lymphangiothrombosis or lymphangitis in the same way as for veins. Lymph, like blood, will clot, but not so readily. Unfortunately, there is no clinical investigation for lymph thrombosis.

Pathology. Decreased transport of lymph from the skin leads to an increase in protein-rich interstitial fluid. In circumstances other than where dermal lymphatics are congenitally absent (for example, Milroy's disease) or are destroyed (for example, post-erysipelas), interstitial pressure consequently rises and lymphatics dilate. Temporal changes observed in experimental lymphoedema indicate that the collagen fibres initially become swollen and separated [8]. Mononuclear cells are seen around the lymphatic and blood vessels [9]. Lymphatic walls thicken and fibrose. The muscular elements of the collecting trunks atrophy and new collagen is deposited underneath the intima. Macrophages, fibroblasts and lymphocytes accumulate perivascularly. Overgrowth of the interstitial connective tissue gradually transforms the soft stage of lymphoedema into the hard late-stage form [10]. The simple excess of protein seems to be the cause of the fibrosis [11,12]. The number of blood vessels greatly increases.

In human skin, the epidermis overlying an area of lymphoedema becomes acanthotic, with reduplication of the epidermo-dermal basement membrane. In the dermis, there is an increase in collagen, but the elastic fibres, including anchoring filaments, disappear. Ultrastructurally, the basal lamina of the dermal lymphatics thickens, but remains discontinuous, connective tissue microfilaments are increased, myofibroblasts appear and the connective tissue ground substance becomes hyalinized [13]. Inflammatory cells are conspicuous in the dermis. In the infiltrate, mast cells, macrophages, plasma cells and lymphocytes can be observed. Extravasated erythrocytes are often seen and large amounts of fibrin become deposited. Well-characterized morphological changes develop in the blood vessels (lymphostatic vasculopathy). In the upper dermis, numerous newly formed vessels can be seen. Angiogenesis results in a highly vascularized dermis.

Aetiology and classification

Lymphoedema may be primary (Table 51.4), secondary (Table 51.5), dysfunctional, or cancer-related.

Primary lymphoedema

Lymphoedema arising from an intrinsic abnormality of the lymph-conducting pathways is referred to as primary lymphoedema [1]. A simple classification by age of onset without reference to aetiology or other clinical features is into the following subdivisions: congenital (present at or very soon after birth), praecox (presenting before age 35 years) and tarda (presenting after age 35 years). The development of lymphangiography in the 1950s resulted in a radiological classification: aplasia (no formed lymph pathways found), hypoplasia (lymphatics smaller or fewer than normal) and hyperplasia (lymphatics larger and more numerous). Aplasia, hypoplasia and hyperplasia refer to abnormalities in the main (leg) conducting lymph vessels as opacified on lymphangiography, and not to initial lymphatics, which are not imaged with this method. Further investigation revealed types of lymphoedema where few, if any, lymph conducting vessels could be identified in the foot, but vessels were found to be normal further up the limb [2].

The last 5 years have seen an increasing understanding of the genetic abnormalities causing lymphoedema.

Inherited forms of lymphoedema where the gene is known

1 *Milroy's disease* (primary congenital lymphoedema, hereditary lymphoedema type 1; MIM 153100). In 1892, Milroy published a large pedigree with lymphoedema beginning at or soon after birth [3]. Although the same

Table 51.4 Causes of primary lymphoedema.

Congenital onset		Postpubertal onset	
Familial	Sporadic	Familial	Sporadic
• Milroy's disease: below knee and bilateral	• Turner's syndrome, Noonan's syndrome: can be transient; other phenotype abnormalities • Neurofibromatosis, Proteus syndrome • Pure or mixed vascular lymphatic malformations, lymphangiomatosis, Klippel–Trenaunay syndrome, Maffucci's syndrome: usually unilateral • Amniotic bands: associated with autoamputation	• Distichiasis–lymphoedema, Meige's disease: below knee and bilateral	• Distal hypoplasia, lymph reflux: bilateral foot and lower leg swelling • Ilio-inguinal node sclerosis: whole limb and unilateral • Yellow nail syndrome: bilateral, widespread oedema

condition was described earlier by Nonne [4], it was Milroy who gave the most complete description, and the eponym 'Milroy's disease' is universally accepted. Milroy's disease is often considered synonymous with primary lymphoedema, but the term should be restricted to cases of familial lymphoedema where the onset is at birth. Linkage studies in families with Milroy's disease showed mapping to chromosome 5q35.3 [5,6] and were subsequently localized to the VEGFR-3 locus. Therefore, a failure of lymphangiogenesis due to inactivation of VEGFR-3 appears to be responsible for the autosomal dominant inheritance of Milroy's disease [7]. Genotype–phenotype correlation demonstrates swelling which is confined to below the knee, and which is often brawny in the extreme with little pitting. Hydrocoele can be an additional feature but, much as Milroy described, there appear to be no other manifestations.

2 *Lymphoedema–distichiasis syndrome* (LDS; MIM 153400). Distichiasis is a congenital anomaly in which accessory eyelashes occur along the posterior border of the lid margins in the position of the Meibomian glands. It causes symptoms of corneal irritation, conjunctivitis and photophobia and occurs from birth. Lymphoedema, however, does not develop before puberty and may be delayed in onset until the fifth decade. Other features of this syndrome include ptosis, congenital heart defects and varicose veins [8]. The lymphatic abnormality appears to be lymph reflux with an increased number of lower limb lymph vessels [9].

LDS shows an autosomal-dominant pattern of inheritance with variable expression and has been mapped to 16q24.3 [10]. Subsequently, mutations in FOXC2 (MFH-1), a forkhead family transcription factor, have been found to be responsible for this condition [11].

3 *Incontentia pigmenti* (MIM 308300). Incontentia pigmenti (IP) is not usually associated with lymphoedema in surviving females. The second liveborn male to be reported recently led to the identification of a NEMO (MF-kappa β essential modulator) stop codon mutation in the affected child and in his mother, who had classical IP [12]. He had features of hypohidrotic ectodermal dysplasia with immune deficiency, recurrent infections and lower limb lymphoedema which developed at a few weeks of age. A lymphoscintigram showed severe lymphatic obstruction. MRI suggested a lymphangiomatous malformation. Cutaneous capillary angiomas and possible mixed vascular/lymphatic malformations coexisted in the gut [13].

Other genetic forms of lymphoedema

1 *Meige's disease* (Kinmonth's lymphoedema praecox, hereditary lymphoedema type II; MIM #153200). In 1898, Meige described the pedigree of a family with a distinct history of lymphoedema appearing at puberty [14]. The eponym Meige's disease has therefore come to be associated with this, the commonest variety of primary lymphoedema, which predominantly affects adolescent females. Swelling is usually mild, rarely extends above the knee and is generally bilateral. Lymphography demonstrates a reduced number of distal lymphatics (hypoplasia) with proximal collectors remaining patent. The term Meige's disease should be reserved for familial lymphoedema developing at or soon after puberty in which there are no associated abnormalities, e.g. distichiasis.

2 *Turner's syndrome*. This well-known abnormality is due to the absence of one X chromosome. Early spontaneous abortion occurs in over 95% of fetuses. Severely affected fetuses who survive to the second trimester can be detected on ultrasonography, which may reveal cystic hygroma, chylothorax, ascites and hydrops fetalis. The diagnosis may be suggested in the newborn by redundant neck skin and peripheral oedema. Surviving children have webbed necks and may exhibit peripheral oedema which often diminishes with age. Conversely oedema may present later in life. Chromosomal testing should always be

undertaken in neonates or young children with primary lymphoedema.

3 *Noonan's syndrome* (MIM #163950). Noonan's syndrome is a multiple congenital anomaly syndrome for which a gene has recently been discovered [15]. Lymphoedema is usually present at birth but the age of onset may vary from prenatal period to adulthood. Phenotypic characteristics include short stature, ptosis, low-set ears and posterior hairline, neck webbing and congenital cardiac anomalies (typically pulmonary stenosis).

4 *Hennekam lymphangiectasia–lymphoedema syndrome* (MIM *235510). A syndrome of intestinal lymphangiectasia with severe lymphoedema of the limbs, genitalia and face, with mental retardation [16]. The intestinal lymphangiectasia causes hypoproteinaemia, hypogammaglobulinaemia and lymphopenia. Facial anomalies are characteristic and look somewhat oriental, with flat face, flat nasal bridge, epicanthic folds, hypertelorism, tooth abnormalities and small ears. Onset of lymphoedema is between birth and 12 years, with probable autosomal-recessive inheritance.

5 *Cholestasis–lymphoedema syndrome (Aagenaes syndrome)* (MIM *214900). Jaundice becomes evident soon after birth and recurs throughout life. Oedema of the leg, due to hypoplasia of the lymph vessels, begins at school age and progresses [17].

6 *Proteus syndrome* (MIM 176920). This very rare syndrome causes many varied (protean) manifestations. Characteristic features are asymmetrical overgrowth of almost any part of the body, macrodactyly, and rugose or cerebriform overgrowth of the palmar and plantar soft tissue. Verrucous epidermal naevi, angiomas and lymphangiomatous swelling also occur. Germ-line mutations in P10 have been proposed [18].

7 *Microcephaly lymphoedema–chorioretinal dysplasia* (MIM *152950). An autosomal-dominant syndrome [19] in which microcephaly and lymphoedema are linked to chorioretinopathy.

8 *Pes cavus and lymphoedema* Lymphangiography revealed hypoplasia of leg lymphatics [20].

9 *Yellow nail syndrome* (MIM #153300) (YNS). The evidence that YNS is inherited is unsubstantiated, only one report describing YNS with familial primary hypoplasia of leg lymphatics [21].

Congenital non-hereditary forms of lymphoedema

A number of sporadic forms of lymphoedema occur, usually presenting at birth or during childhood. The defect in such cases is likely to be due to a somatic rather than a germ-line mutation. The most common type is Klippel–Trenaunay syndrome (MIM 149000), in which lymphoedema may be the presenting abnormality. Subsequently, more characteristic features such as limb overgrowth, cutaneous angiomas and venous disease may develop. Another poorly understood form of congenital lymphoedema is that associated with amniotic bands. These bands, which allegedly wrap around digits or limbs, cause circumferential fibrosis and scarring. This can lead to amputation of digits or lymphoedema distal to the band [22].

Maffucci's syndrome (dyschondroplasia with haemangioma, MIM #166000) usually manifests with venous cavernous malformations in infancy, but cavernous lymphangiomas are also often seen, and may be the sole manifestation, giving rise to limb swelling. Hard nodules arise from the bones, especially of the fingers and toes; these are pathologically enchondromas and are radiologically translucent. The malignant potential of the syndrome is high [23].

Clinical patterns of primary lymphoedema

1 Distal hypoplasia. The most common presentation, contributing about 80% of all cases of primary lymphoedema, is that of mild oedema of both feet and ankles. Patients are usually female with onset at puberty. The swelling is often asymmetrical and deteriorates slowly. Extension above the knee is uncommon and mild (Fig. 51.5). The cause is a paucity of distal lymph vessels.

Fig. 51.5 The commonest form of primary lymphoedema: distal hypoplasia of peripheral lymphatic vessels presenting with asymmetrical but usually bilateral swelling of feet and lower legs.

2 Proximal obstruction. This variety is unilateral in 85% of cases. It usually involves the whole limb and develops rapidly. There is no family history. It is of paramount importance to exclude pelvic causes of venous or lymphatic obstruction—for example, tumour or thrombosis. The cause in primary lymphoedema is fibrosis within ilioinguinal lymph nodes or obliteration of proximal lymph vessels [1].

3 Bilateral whole-limb swelling. Reflux of lymph due to gravitational forces and gross incompetence of valves leads to huge dilatation of lymphatic collectors (megalymphatics) in a manner similar to venous reflux and varicose veins. Chylous reflux may coexist.

Progressive distal failure of lymphatic collectors, the so-called 'die-back' phenomenon, occurs with time as a result of proximal obstruction or reflux [2].

Secondary lymphoedema

Secondary lymphoedema refers to those forms of lymphoedema resulting from acquired obstruction or obliteration of lymph-conducting pathways due to some identifiable pathological process arising extrinsic to the lymphatic system. These processes include infection, inflammation, trauma (including surgery and radiation) and malignant disease. No form of lymphoedema is mutually exclusive, and frequently a number of factors

combine to produce swelling. For example, lymphoedema may become clinically obvious only when the lymphatic load is increased because of increased blood flow.

Lymphoedema associated with infection. Infection may cause progressive damage to lymph drainage routes by intraluminal obliteration of lymphatic vessels through processes such as lymphangitis and lymphangiothrombosis.

In recurrent cellulitis or erysipelas, the damage to lymphatics may ultimately lead to formation of lymphoedema, which itself predisposes to further episodes of infection, so exacerbating the lymphoedema [3].

Lymphatic filariasis is concentrated in the tropics and subtropics and is the most common cause of lymphoedema worldwide, with an estimated 90 million people affected [4]. Infection is transmitted by mosquitoes, which introduce microfilariae into the skin. These larvae migrate to the lymphatics, where they mature into adult worms. Progressive and permanent damage to the infested lymphatics causes lymphoedema. It has been established in animal studies that, within days of infection, vigorous movement by adult worms directly impacts on the endothelial lining of the lymphatic trunks and indirectly distorts the local lymph-node architecture. Dilated lymphatics with thickened walls and valves, thrombus formation and perilymphangitis result [5].

Lymphogranuloma inguinale and tuberculous node infection can cause lower limb lymphoedema [6]. Lymphoedema of the ear lobe has been described following head lice infestation [7].

Lymphoedema associated with inflammation. Circumstances exist in which chronic inflammation without evidence of infection is associated with the development of lymphoedema. It is assumed that the inflammation progressively damages lymph drainage routes.

Facial lymphoedema may result from rosacea or even acne vulgaris. Skin or subcutaneous initial lymphatics fail rather than main regional collecting trunks. The forehead, cheeks or periocular regions are usually affected and swelling is often asymmetrical.

Upper limb swelling may occur following chronic hand dermatitis, with or without documented episodes of lymphangitis [8]. Like other forms of lymphoedema, once established it tends to be permanent irrespective of remission of the skin disease.

Podoconiosis (non-filarial elephantiasis) is a form of lymphoedema caused by particles of silica dust, present in certain soils, which penetrate the skin of the foot during barefoot walking. The microparticles are taken up by the lymphatics, causing damage. Soils rich in these substances determine the geographical distribution of the condition [9].

Studies with quantitative lymphoscintigraphy and fluorescence microlymphography have confirmed functional and structural changes to lymph drainage in pretibial myxoedema. It is likely that mucin deposition in the dermis impairs initial lymphatic function, resulting in the clinical appearance which resembles lymphoedema [10].

A small number of patients with rheumatoid arthritis develop lymphoedema, predominantly of the upper limbs. A study in rheumatoid arthritis found impaired lymph drainage only in patients with lymphoedema [11]. This suggested that inflammatory arthritis alone does not directly impair lymphatic drainage. Similar findings have been described in psoriatic arthritis [12].

Granulomatous diseases such as Crohn's disease, sarcoidosis and orofacial granulomatosis cause inflammatory changes in local skin and subcutaneous lymphatics, leading to lymphoedematous swelling.

Panniculitis that is extensive enough to cause severe fibrosis may produce lymphoedema. This has been described following idiopathic retroperitoneal fibrosis [13].

Lymphoedema secondary to trauma. Trauma to lymphatics, either from elective surgery or by accident, usually needs to be extensive to induce lymphoedema. Indeed, the experimental production of lymphoedema is extremely difficult to achieve owing to the excellent regenerative powers of lymphatics [14]. It is probably the failure of lymphatics to regenerate and re-anastomose satisfactorily through scarred or irradiated tissue which is responsible for lymphoedema following cancer treatment. Surgical excision of axillary or ilioinguinal lymph nodes will not uncommonly produce limb lymphoedema. The puzzles are why such intervention in animal models rarely produces chronic swelling and why there can be such a delay—up to 20 years—before lymphoedema manifests [15]. Radiotherapy to lymph nodes can be as much a risk factor towards lymphoedema as surgery [16]. The incidence of lymphoedema following varicose vein surgery is estimated to be 0.5% [17].

Accidental trauma, such as a degloving injury to a limb, will produce lymphoedema distal to the injury if widespread circumferential scarring occurs.

Self-inflicted injury, such as the repeated application of a tourniquet, will eventually cause permanent lymphatic damage and chronic swelling (Secrétan's syndrome) [18]. The abrupt termination of the swelling often coincides with a depression due to subcutaneous atrophy caused by a tight constricting band. Skin pigmentation may also coexist at the site.

Intravenous drug abuse may cause lymphoedema due to a combination of infection and associated venous damage.

Lymphoedema and venous disease. Oedema is a common complication of venous insufficiency. It is assumed that venous oedema is the sole consequence of increased

Fig. 51.6 Lymphoedema associated with chronic venous disease.

capillary filtration from venous hypertension. As lymph drainage is the main buffer against oedema, it is in fact the failure of local lymphatics to compensate for the increased lymph load from filtration that leads to oedema. Thrombosis of the major veins and deep vein incompetence does not generally affect the main collecting lymphatics but the small initial and precollecting lymphatics of the skin and subcutaneous tissues of the lower leg are damaged by prolonged venous hypertension. Lymphoedema develops with chronic lipodermatosclerosis, with or without venous ulceration. Lymphoscintigraphy has shown impaired limb lymph drainage [19] while fluorescence microlymphography has revealed damaged skin lymphatics [20]. Lymphoedema associated with venous disease can give rise to the most gross swelling and skin changes owing to the combined effect of impaired lymph drainage in the face of increased lymph load (capillary filtration) (Fig. 51.6).

Malignancy-related lymphoedema. Lymph flow is maintained remarkably well through malignant nodes, therefore cancer does not usually present with swelling. The few exceptions to this general rule are lymphophilic tumours, such as malignant eccrine poroma or Kaposi's sarcoma, as well as advanced cancers where other factors such as venous obstruction and hypoproteinaemia will contribute to oedema formation. Recurrent cancer, however, should always be considered as a cause of limb swelling, particularly if associated with pain. Full staging investigations should always be undertaken in such circumstances. Therefore, in general, malignancy-related lymphoedema usually results from cancer therapy, i.e. surgery, radiotherapy or a combination of the two, or from recurrent tumour directly infiltrating collateral drainage routes.

Kaposi's sarcoma may present with lymphoedema, sometimes years before tumour is evident. The association with lymphoedema [21] supports the view that Kaposi's sarcoma arises from lymphatic endothelium [22].

Lymphoedema arising from dysfunctional lymphatics. Lymph drainage, unlike blood flow, requires intermittent changes in local tissue pressure generated by movement and exercise in order to produce initial lymphatic transport. Consequently, immobility tends to encourage swelling, particularly if gravitational forces (dependency syndrome) encourage ongoing fluid filtration. A common scenario is 'armchair legs', a term coined by Sneddon and Church [23], where patients sit in a chair day and night with their legs dependent. No premorbid abnormalities of lymphatics exist, but the immobility results in minimal lymph drainage and a functional lymphoedema due to a lack of movement or exercise to stimulate normal lymph drainage. Dependency of the limb compounds the problem by increasing capillary filtration. Armchair legs is otherwise known as elephantiasis verrucosis nostras because of the severe lymphoedema skin changes that ensue. The syndrome is not confined to the legs, but can affect any chronically dependent and immobile part, as demonstrated in the pendulous abdomen [24]. With time, pathological changes within the failing lymphatics occur and an irreversible lymphoedema develops.

Clinical features and diagnosis

Lymphoedema most commonly affects the extremities. This predilection for the limbs is due, at least in part, to the limited collateral drainage available at the root of a limb. Careful examination often reveals extension of the swelling to the associated quadrant of the trunk because the lymph drainage routes are shared with the limb.

The major clinical changes of lymphoedema take place in the skin and subcutaneous tissues; such changes are of value in diagnosis. Lymphoedema differs from all other oedemas (in which increased capillary filtration is the major factor) in that cells, proteins, lipids and debris accumulate in addition to water. This results in a 'solid' as well as a 'fluid' component to the swelling, so giving rise to the brawny nature of the oedema which does not readily pit [25]. The lack of pitting is an unreliable sign in lymphoedema, however, because easy displacement of tissue fluid on pressure can often be demonstrated particularly in the early stages.

Fig. 51.7 The Kaposi–Stemmer sign: a failure to pinch or pick up a fold of skin at the base of the second toe indicates lymphoedema.

A reticulate pattern on a background of lymphoedema has been associated with thermal injury on the lower legs [26].

Lymphoedema does not usually respond to elevation or diuretics, except in the early stages or when it is compounded by increased capillary filtration. Chronic oedema that does not reduce significantly after overnight elevation is likely to be lymphatic in origin. The symptoms accompanying uncomplicated lymphoedema are few. Swelling frequently develops rapidly, for example, overnight. In the distal hypoplastic type one ankle may swell. Pain may feature initially, prompting diagnoses including deep vein thrombosis or soft-tissue injury. Oedema is often intermittent before becoming permanent, and is often painless although discomfort, aching and tightness are commonly reported symptoms. Eventually both legs swell. In proximal obstructive lymphoedema, swelling usually develops in the thigh and progresses distally.

Disfigurement from lymphoedema can lead to significant psychological morbidity in terms of depression and adjustment to psycho-social issues in areas such as the workplace, home and personal relationships [27]. Pain, in particular chronic aching, occurs commonly with lymphoedema and may require regular analgesia [28]. Although swelling occurs most in the subcutaneous layer, the skin exhibits most changes. It becomes thicker, as demonstrated by the Kaposi–Stemmer sign (a failure to pick or pinch a fold of skin at the base of the second toe) (Fig. 51.7) [29]. Skin creases become enhanced and hyperkeratosis develops. Dilatation of upper dermal lymphatics with consequent organization and fibrosis gives rise to papillomatosis. As dermal lymph stasis progresses these skin changes become more marked and are referred to as elephantiasis. Occasionally the tissue fibrosis and thickening may become so marked in the later stages of lymphoedema that pitting is absent.

Complications

Complications of lymphoedema are mainly due to swelling and infection.

Swelling. Limb swelling leads to discomfort, limb heaviness, reduced mobility and, on occasions, impaired function. The size and weight of affected limbs can result in secondary musculoskeletal complications such as back pain and joint problems. Thickening of the skin causes pseudoscleroderma and consequently impairs small-joint mobility. The difficulty in finding clothes or shoes to fit creates social problems. Poor footwear will further compound the swelling by discouraging a normal gait or enough exercise.

Leakage of lymph through the skin (lymphorrhoea) may occur from engorged dermal lymphatics (lymphangiectasia).

Infection. Episodes of secondary infection are a characteristic feature of lymphoedema. It is probable that patients with lymphoedema from any cause are liable to these attacks and this presumably reflects a failure of immune surveillance. Recurrent cellulitis or erysipelas is a particular problem. Constitutional symptoms such as fever, rigors, headache or vomiting can be profound and sudden in onset. Within 24 h, redness and pain appear within the lymphoedematous area. Recurrent episodes may be frequent and further impair lymph drainage so exacerbating the lymphoedema. Thus, a vicious cycle is established. Haemolytic streptococci of group A, B or G have been demonstrated [30] although the bacterial aetiology has been brought into question [31]. Indeed, it is not unusual for patients to comment that attacks of cellulitis can be induced by strenuous exercise or long car journeys. This suggests a mechanism not dissimilar to herpes simplex where the microorganism is always present but becomes reactivated.

Fungal infections, particularly tinea pedis, are difficult to avoid because of web-space skin maceration from swollen toes. Local immune deficiency may also be a contributing factor as illustrated by a case of cryptococcosis complicating congenital lymphoedema [32].

Malignancy. A rare but important complication of chronic lymphoedema is the development of cutaneous malignancy. Although the most well-known association is lymphangiosarcoma [33], other tumours have been recorded and include basal cell carcinoma [34], squamous cell carcinoma, lymphoma [35–38], melanoma [39,40], malignant fibrous histiocytoma [41] and Kaposi's sarcoma [42]. The Stewart–Treves syndrome describes lymphangiosarcoma developing from well-established postmastectomy oedema. However, lymphangiosarcoma is now described as occurring with lymphoedema of any cause. The

favoured theory for these associations is altered immune surveillance in the lymphoedematous region [43].

Miscellaneous conditions. A range of other cutaneous conditions have been reported as occurring preferentially at sites of lymphoedematous involvement. These include xanthomatous deposits [44], atypical pemphigoid [45], toxic epidermal necrolysis [46], atypical neutrophilic dermatosis [47] and severe necrotizing fasciitis [48].

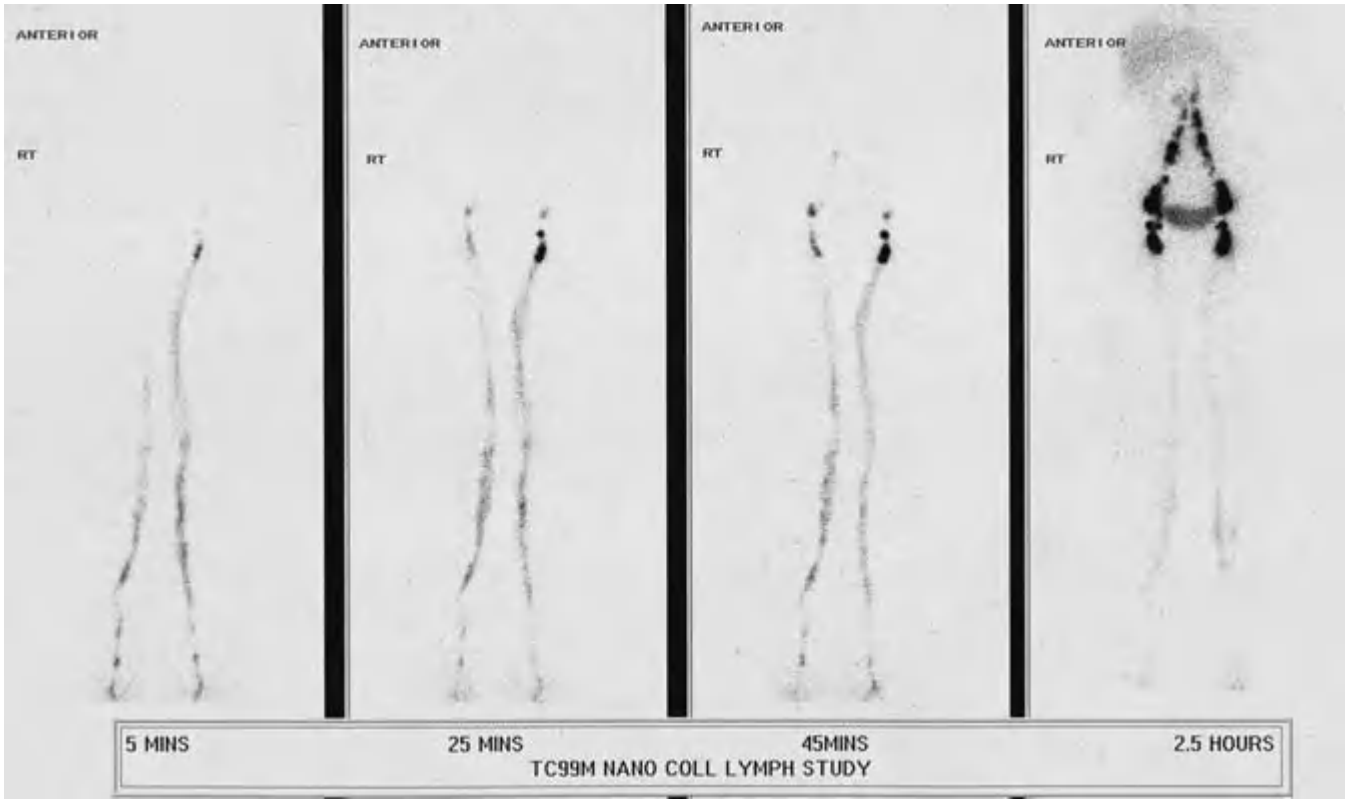
Investigations

Swollen limb

There are limited methods available which permit reliable investigation of lymphatics. Lymphoscintigraphy (isotope lymphography) involves the interstitial (dermis or subcutis) injection of a radiolabelled protein or colloid. Radioactivity, measured using a wide field-of-view γ-camera, is determined over the injection site depot and at regions of interest over vessels or nodes. Measurement of transit times and time activity curves permit quantitative analysis of lymph drainage [1]. Measurement of tracer uptake within axillary or inguinofemoral lymph nodes at a specified time following a standardized exercise routine will discriminate lymphoedema from oedema of non-lymphatic origin [2] (Fig. 51.8).

(a)



(b)

Fig. 51.8 (a) Normal lymphoscintigraphy. Images show patent lymph routes draining tracer from feet to ilio-inguinal nodes. (Courtesy of Professor A.M. Peters.) (b) Obstruction of lymph drainage at the groin leads to re-routing of tracer through skin collaterals (dermal backflow).

Computed tomography (CT) of lymphoedematous limbs has demonstrated a characteristic 'honeycomb' pattern in the subcutaneous compartment which other oedemas do not show [3]. CT not only provides information through cross-sectional area of volume change to a limb, but will also identify the compartment in which that change takes place. Whereas in post-thrombotic syndrome the muscle compartment deep to the fascia is enlarged, in lymphoedema it is unchanged or may even show some reduction in size. Thickening of the skin is also a characteristic feature of lymphoedema, although not specific. Magnetic resonance imaging (MRI) is poten-

tially better than CT for distinguishing types of oedema [4].

X-ray contrast lymphography remains the gold standard for demonstrating lymphatic collecting trunks and nodes [5]. The technique is invasive and difficult to perform in the presence of oedema. It involves first of all the interstitial subcutaneous injection of a vital dye—for example, patent blue—to visualize the lymphatic for cannulation. The oily contrast medium Lipiodol is then administered directly into the peripheral lymphatic identified, usually on the dorsum of the foot. The failure to opacify subcutaneous collectors with the vital dye and its persistence in the tissues for days afterwards are sufficient evidence for a diagnosis of lymphoedema. If there is lymphatic obstruction, the dye will often flow retrogradely into the dermal network—so-called 'dermal backflow'. Lymphography has been used less often to confirm lymphoedema since the advent of lymphoscintigraphy.

Initial lymphatics in the skin

In vivo visualization of lymphatic vessels (lymphangiography) was first achieved using vital dyes—for example, patent blue—to delineate intradermal and subcutaneous lymphatics. Some classic studies were undertaken in this way [6]. Fluorescence microlymphangiography enables the superficial lymphatic network of the skin to be seen under the vital microscope by means of fluorescing molecules (FITC-Dextran, Sigma) which, when injected subepidermally, are taken up by the initial lymphatics. Information regarding the morphology of initial lymphatics and the extent of tracer propagation within the dermal lymphatic network can be recorded on video for analysis [7].

Indirect lymphography involves the intracutaneous injection of a water-soluble contrast medium. Using an infusion pump, the contrast medium is administered over 10 min to create a depot of approximately 3 mL. Intradermal and subcutaneous lymphatics can be opacified by X-ray using the mammography film method, sometimes as far as the first lymph node [8,9]. The advantages over conventional lymphography are the convenience of the interstitial injection without recourse to direct access into the lymphatics, and the ease of application to multiple sites.

Differential diagnosis of the swollen limb (Table 51.6)

Swelling of a limb may be caused by oedema, in which case pitting should be evident to some degree, or it may be caused by an increase in volume of other tissue elements, e.g. bone, muscle or fat. MRI scanning is useful in circumstances where the nature of the swelling is uncertain. One must remember also that a patient may perceive one leg to be swollen when in fact the other leg has become smaller, e.g. through atrophy of muscle or fat.

Obvious lymphoedema with characteristic skin changes is not usually a difficult diagnosis but such cases are relatively uncommon. Milder cases frequently go unrecognized. Chronic non-inflammatory, and in particular asymmetrical, limb oedema should always suggest lymphoedema. In such cases lymphoscintigraphy is the investigation of choice.

Systemic causes of oedema including cardiac disease, renal disease or hypoproteinaemia should always be considered, particularly if bilateral leg swelling is present. Calcium channel blocking agents cause peripheral oedema in 50% of cases.

A condition frequently misdiagnosed as lymphoedema is lipoedema (lipidosis, lipodystrophy) in which a 'fatty' non-pitting swelling is confined to the legs, thighs and hips [1]. Lipoedema is peculiar to females and is usually dismissed as a variant of normality in women with chunky legs and a 'bottom-heavy' weight distribution. Features of importance in recognition include onset at or after puberty, bilateral and symmetrical involvement of the legs, sparing of the feet resulting in an 'inverse shouldering' effect at the malleoli (Fig. 51.9), tenderness, easy bruising, absence of pitting and lack of benefit from elevation. Dieting tends to result in weight loss from body sites other than those affected by lipoedema. Lymph drainage within main leg lymphatics is relatively normal [2] until the later stages when foot oedema develops—the so-called lipoedema–lymphoedema syndrome.

Limb hypertrophy may also simulate lymphoedema. Occasionally, lymphoedema coexists with complete hemihypertrophy, Klippel–Trenaunay syndrome, Parkes–Weber syndrome (multiple arteriovenous anastomoses) or Proteus syndrome. Elephantiasis neurofibromatosa is a diffuse neurofibromatosis of nerve trunks with overgrowth of the subcutaneous tissue and of the skin, producing considerable enlargement of that region.

YNS is associated with peripheral oedema, but the clinical features rarely resemble classical lymphoedema. Lymphangiogram abnormalities have been described [3], although a lymphoscintigraphic study demonstrated that a primary lymphatic abnormality is unlikely [4].

Management of lymphoedema

Lymphoedema represents end-stage failure of lymph drainage and is essentially irreversible and incurable; treatment is difficult because of the presence of the 'solid' component in the swelling. In addition, most of the underlying causes are irreversible. As a non-fatal condition, and considering the shortcomings and difficulties of treatment, most patients are told to learn to live with it. This is neither necessary nor acceptable. While incurable, much can be done to improve quality of life. Indeed, improvements in the strategy for lymphoedema care and the development of dedicated lymphoedema clinics have provided fresh impetus for treatment.

Fig. 51.10 Reduction of swelling in lymphoedema following 3 weeks' intensive therapy with multilayer bandaging and an exercise programme. (The same patient as in Fig. 51.5.)

The management of lymphoedema varies greatly around the world. In developed countries, the emphasis is more on physical forms of therapy involving compression, whereas in poorer, hotter countries where hosiery and appropriate bandages are too costly, surgery may be the mainstay of treatment. There is therefore a need to consider treatment based on the underlying cause(s), the problems created for the patient and the circumstances of that patient.

Two particular problems need to be overcome with lymphoedema: the swelling and the predisposition to infections, particularly recurrent cellulitis.

Physical (decongestive lymphatic) therapy

Physical methods of treating lymphoedema have been practised in Europe for many years [1]. Therapy essentially aims to control lymph formation (capillary filtration), including treatment of inflammatory causes or of venous hypertension, and to improve lymph drainage through existing lymphatics and collateral routes by applying normal physiological procedures that stimulate lymph flow. Physical treatment can, in the majority of cases, improve quality of life considerably (Fig. 51.10). Central to management is getting patients to understand their condition and know what they can do for themselves [2]. Only then can a high level of motivation and compliance with treatment be generated.

It is important to explain to patients that, unlike the blood, which is propelled by the heart, lymph drainage relies on local changes in tissue pressure generated by exercise and movement. Physical treatment exploits these principles, enhancing lymph flow as much as possible within the limits of a compromised drainage. It should be appreciated that lymph flow still exists in lymphoedema, otherwise swelling would be a relentlessly progressive process.

1 *Exercise* is crucial to lymph drainage [3,4]. Dynamic muscle contractions (isotonic exercises) encourage both passive (movement of lymph along tissue planes or through non-contractile lymphatics) and active (increased contractility and therefore propulsion of lymph within contractile lymphatics) phases of lymph drainage. Overexertion and excessive static (isometric, e.g. gripping) exercise increase blood flow, which therefore tends to increase oedema.

2 *External compression (hosiery or bandage)* complements the exercise programme. Such compression is not intended to 'squeeze' oedema, but to limit capillary filtration by opposing capillary pressure and to act as a counterforce to striated muscle contractions which act as the most powerful stimulus to lymph drainage. Without exercise, the emphasis for which should be movement not vigour, external compression is much less effective. Breathing and posture are also important particularly for clearance of lymph flow from the thorax and abdomen; without the dispersal of truncal lymph, more peripheral oedema will persist. Elevation *per se* does nothing to improve lymph drainage, but lowering venous pressure (and therefore filtration) can help to reduce swelling. Rest and elevation alone, however, are not the correct treatment for lymphoedema! Hosiery (below-knee or full-length stockings, half or full tights, sleeves) usually requires high compression and double hoses may occasionally be required. Most garments last no more than 6 months. Two garments (or pairs) should be provided, one to wear and one for the wash. Washing is necessary to maintain the compression properties of the garment.

3 *Massage* is a contentious treatment, despite being accepted as a necessary component of lymphoedema therapy in continental Europe [1]. The problem is that there are different forms of massage, used mostly for increasing blood flow and therefore of vigorous nature. Tissue movement, if gentle, is a stimulus to lymph flow without increasing blood flow [5]. Indeed, in the absence of lymphatic contractility, massaging of filled lymphatics by muscle exercise or surface massage may be the major stimulus to lymph flow, just as it is with blood flow during cardiac arrest [4]. The skin lymphatic network is the likely route for collateral drainage to areas which have normal lymph drainage [6]. The practice that encourages such

flow, referred to as manual lymphatic drainage therapy (MLD), is directed at normally draining lymph node regions; this 'siphons' or 'milks' lymph away from congested lymphoedematous areas, so complementing attempts to improve drainage 'upstream' by exercise and external compression [7].

Multilayer bandaging can be used for limb reduction, but also has the advantage of restoring limb shape so that containment hosiery is more effective at controlling swelling [8]. Bandaging may be the only method suitable for huge limbs and for controlling lymphorrhoea. Layers of strong non-elastic (short-stretch) bandages are applied to generate a high pressure during muscular contractions but low pressure at rest. The use of foam or soft padding helps to distribute pressure more evenly and to protect the skin. The digits are also bandaged to control swelling of fingers and toes. The strategic positioning of rubber pads 'irons out' pockets of swelling and deep skin folds. Multilayer bandaging is a skill which takes time to learn and should not be undertaken by any professional without appropriate training.

Pneumatic compression therapy (intermittent/sequential pneumatic compression) is employed widely [9]. An inflatable boot, legging or sleeve is connected to a motor-driven pump and lymph is displaced towards the root of the limb. If hosiery is not fitted immediately following compression therapy, the swelling readily recurs. Pneumatic compression softens the tissues and reduces limb volume during treatment, but it is doubtful that any long-term benefit is gained over hosiery and exercise alone.

Microwave heat therapy has been popular in China [10]. Possibly it activates macrophage clearance of macromolecules and reduces fibrosis by stimulating collagenase or by altering the viscosity and stiffness of the tissues.

Evidence of efficacy

While decongestive lymphatic therapy has become accepted first-line therapy, evidence for best treatment is weak. Using limb volume change as the main outcome measure, bandaging plus hosiery was significantly more effective at 6 months than hosiery alone [8]; hosiery was more effective than no hosiery [11]; MLD and hosiery were no more effective than hosiery alone [12]; and pneumatic compression therapy was no better than no treatment [13].

Care of the skin and prevention of infection. Elephantiasis skin changes are not only unsightly, but lead to problems including infection, odour, lymphorrhoea, restricted movement (pseudoscleroderma) and possibly poor wound healing. Such problems can be particularly troublesome where scarring and fibrosis have become excessive—for example, after trauma or surgery. Tinea pedis is almost invariable because of the closely apposed swollen toes, circumstances not improved by elastic hosiery. Modern antifungal creams unfortunately macerate skin further and therefore it is preferable to apply half-strength Whitfield's ointment prophylactically each night. For deep cracks and crevices which bacteria may readily colonize, regular toilet is necessary followed by an antiseptic drying agent, for example eosin, Brilliant Green or Castellani's paint applied with a cotton bud. Areas which constantly seep lymph should respond to sustained compression, but at sites where this is not possible, simple cautery or carbon dioxide laser therapy will often discourage leakage, even if only for a period of time. Hyperkeratosis can often be improved through the regular application of 5% salicylic acid ointment, but the best treatment to reverse elephantiasis skin changes is long-term compression.

Prevention of infection, particularly lymphangitis/cellulitis, is crucial to the control of lymphoedema. Care of the skin, good hygiene, control of tinea pedis and good antisepsis following abrasions and minor wounds are important. Administration of antibiotics at the time of an attack of cellulitis must be prompt, otherwise they do not significantly influence the course of the illness. Therefore, patients need to carry a supply of antibiotics—for example, co-amoxiclav or amoxicillin—with them at all times. For attacks recurring more than once a year, prophylactic antibiotics are the only effective treatment [14]. Phenoxymethyl penicillin 500 mg daily is as effective as any broad-spectrum antibiotic. Long-term prophylaxis is often necessary. Control of the oedema and diabetic type skin care may help reduce antibiotic requirements.

The only trials investigating prophylaxis against infection were undertaken in filarial lymphoedema and compared the efficacy of diethylcarbamazine (DEC), ivermectin and skin care in preventing lymphangitis/adenitis [15]. The authors concluded that a foot care programme alone can drastically reduce the number of attacks of acute adenolymphangitis. In a second study [16], the same group compared oral penicillin, diethylcarbamazine and antibiotic cream. Both the penicillin group and the DEC group had significantly reduced frequency of attacks of lymphangitis compared with patients treated with placebo. The authors concluded that antifilarial drugs do not have a role in reducing acute inflammatory attacks (lymphangitis, cellulitis), but that penicillin does contribute significantly to a reduction in attacks when combined with foot care.

Drug therapy

Drug therapy is generally disappointing. Diuretics remain the most commonly used treatment because most doctors consider oedema to be an indication for such drugs. Diuretics alone have little benefit in lymphoedema

because their main mode of action is to limit capillary filtration by reducing circulating blood volume. Improvement with diuretics suggests that the predominant cause of the oedema is not lymphatic.

The benzopyrone group of drugs have been advocated as treatment for lymphoedema, but their clinical effect seems to be small. In the UK, the only available or prescription medication in this class (although only actually licensed for venous disease) is oxerutins (Paroven). Three randomized and placebo-controlled trials have been published, all demonstrating a marginal significant effect on limb volume but of little clinical benefit [17]. Other benzopyrone drugs investigated include Daflon and coumarin (5,6-benzo-α-pyrone) and, while most trials claim significant volume reduction, the poor reporting means a meta-analysis is not possible. One robust trial concluded that there was no difference in effect between coumarin and placebo, and reported serious liver toxicity from coumarin [18].

Surgery

Surgery has a specific role in the management of lymphoedema. It is of value in a few patients in whom, even after conservative treatment, the size and weight of a limb inhibit its use or interfere with mobility. Surgery involves either removing excessive tissue or bypassing local lymphatic defects. Lifelong non-surgical measures—for example, hosiery—must be continued postoperatively.

Reduction (excisional) operations remove a longitudinal ellipse of skin and the underlying abnormal subcutaneous tissue down to the deep fascia. Undercutting of the skin allows removal of additional tissue. This procedure is preferred to circumferential excision and skin grafting or to the addition of in-rolling of one of the skin flaps (which can be followed by troublesome dermal sinuses). Two or three ellipses may be required for each circumference; the operations are separated by 3–6 months. Procedures involving surgery both above and below the knee or the elbow are usually undertaken one region at a time, because blood loss can be extensive.

Bypass operations involve either bridging an area of defective lymphatics with tissue containing lymphatics or with a vessel graft. If the lymphoedema results from excision of, or damage to, a local group of lymph nodes (e.g. in the axilla or groin) the area can be bridged with omentum or with an isolated and opened-out segment of gut. Lymph node-to-venous and direct lymph vessel-to-venous shunts have been undertaken but long-term patency is doubtful [19]. Lymph vessel transplantation, where autologous lymphatics are removed from an unaffected part of the body and anastomosed end-to-end with other unaffected collectors proximal and distal to the obstruction, has been shown to improve lymph transport [20].

Provision of care

The best results are obtained with an interdisciplinary approach to care, ideally delivered from a dedicated lymphoedema clinic. Improvement will be gained by implementing all measures known to improve lymph drainage and to control capillary filtration. The philosophy of care is to transfer the responsibility for treatment to the patient. Enabling patients to understand their condition and know what they should, and should not, do for themselves is central to care; only then can a high level of motivation and compliance with treatment be generated. Many patients with lymphoedema are overweight, because of morbid obesity as well as fluid retention. Excessive weight gain is likely to impair lymph drainage in the same way as it impairs venous drainage, and obesity reduces mobility (and therefore exercise). Control of weight in combination with physical treatment may be sufficient to resolve oedema completely in some patients.

Midline lymphoedema

Lymphoedema localized to central regions such as the head and neck, trunk or external genitalia is uncommon, presumably because bilateral drainage routes operate and cross-flow from one region to another prevents swelling. Midline lymphoedema therefore usually develops when the lymphatics of the skin or subcutaneous tissue rather than the regional lymphatics fail. A course of MLD therapy may be helpful for any form of midline lymphoedema, but remains unproven in clinical trials.

1 *Facial swelling* can coexist with obvious primary lymphoedema of one or more limbs, suggesting that there is widespread congenitally determined lymphatic insufficiency. More commonly, the problem occurs later in life secondary to a variety of inflammatory or traumatic mechanisms. Rosacea, and less commonly acne [1,2], are the commonest causes of facial lymphoedema. Swelling affects the central forehead, periocular skin and cheeks where it may be surprisingly asymmetrical. In rosacea, erythema is always present, but inflammatory pustules and papules may be conspicuous by their absence. Treatment should start with attempting to control the rosacea but the erythema and swelling are notoriously resistant. General measures which can be helpful include raising the head of the bed to help prevent overnight reaccumulation of oedema, and perhaps even wearing a custom-made pressure garment. Avoidance of overheating is important.

2 *Chronic oedema of the eyelids* is common and may be quite simply due to acquired lax skin from photo-ageing and other processes which have undermined tissue compliance. Medical conditions to be considered with periocular oedema are dermatomyositis, thyroid or renal disease, and even YNS. Recurrent inflammatory processes, for example contact allergy or angio-oedema, may slowly compromise lymphatic function. Equally, one severe attack of facial erysipelas or cellulitis may damage lymphatics sufficiently to cause lymphoedema. Once underlying conditions have been excluded or treated, plastic surgery to the eyelids may be the treatment of choice.

3 *Oedema of the upper or lower lip* (or both) may start with intermittent bouts of swelling resembling angio-oedema, but with time the condition may become persistent. Extension of oedema within the mouth is common and is the reason for the rugose changes on buccal mucosal and tongue (scrotal tongue). Biopsy may or may not reveal the presence of granulomas. If present, a diagnosis of orofacial granulomatosis (granulomatous cheilitis, Melkersson–Rosenthal syndrome) is made, but it remains unclear if the granulomas are cause or effect despite the occasional documentation of Crohn's disease or sarcoid elsewhere [3]. Treatment remains difficult. Once simple emollient, antiseptic measures and prophylactic antibiotics have been tried, a therapeutic trial of oral or intralesional steroids is worth considering [4].

4 *Genital lymphoedema* is more common in the male and may develop from lymphatic obstruction due to advanced pelvic/abdominal cancer or its treatment. In an otherwise healthy patient with oedema confined to the scrotum or mons pubis, the cause is usually a primary abnormality of local lymphatics. Recurrent cellulitis is frequently associated and may antedate the swelling. Genital swelling may be precipitated by compression therapy to one or both lymphoedematous legs by forcing fluid into the adjoining trunk. Treatment rests with prevention of infection and if necessary prophylactic antibiotics. Good support is essential if the scrotum is very enlarged and pendulous. Plastic surgery may be the only way to reduce scrotal size. Penile oedema may respond to night-time application of tubular finger-sized bandages in layers.

Congenital lymphatic malformations

Like the venous system, the lymphatic system is subject to many minor aberrations. Surgeons are only too well aware of the individual differences in position and number of regional lymph nodes, and of the territories drained, a significant problem in cancer management. Because of the similar ontology of veins and lymphatics, it is hardly surprising that malformations of each can coexist. It is also not unusual to find blood within a pure lymphatic malformation such as lymphangioma circumscriptum.

Generally speaking, lymphatics may be absent (aplasia), reduced (hypoplasia) or increased (hyperplasia). Congenital hyperplasia of lymph vessels may occur in isolation without other anomalies being present—for

example, circumscribed hyperplasia of lymph vessels of extremities may be found fortuitously by lymphography or at post-mortem.

Lymphangioma/lymphangiectasia (lymphangiectasis)

Simple sustained dilatation of otherwise normal lymphatic vessels is referred to as lymphangiectasia, but when lymphatics are distended due to structural abnormalities of a tumour-like nature the term lymphangioma is best used. Lymphangiectasia can be seen as translucent flat areas in the skin, which may ooze lymph spontaneously or after trauma. They may also be a consequence of defective collagen or elastin as documented in a report of penicillamine dermopathy [1]. Congenital lymphangiomas, like angiomas, are best classified as hamartomatous malformations. The most important feature of all congenital lymphangiomas is that they are not part of the normal lymph conducting system. Lymphangiomas may appear localized to the skin (lymphangioma circumscriptum) but there is frequently communication with a more extensive malformation arising from the main lymphatic vessels of the region, particularly at the root of a limb. The vesicles on the skin surface are very small and the surface can be so warty that the diagnosis may be missed. Lymphangiomas consist of dilated lymph channels of various sizes lined by normal lymphatic endothelium. The majority of lymphatic malformations arise in infancy but some may not manifest clinically until later in life. Familial cases do not seem to occur.

Lymphangioma circumscriptum

Lymphangioma circumscriptum is a term best reserved for a lymphatic malformation which is localized to an area of skin, subcutaneous tissue and sometimes muscle [2]. Clinically the condition manifests with fluid-filled vesicles which bulge on the skin surface (Fig. 51.11). The vesicles may be well defined and discrete, or may be grouped into structures resembling frogspawn. The lymphangiomas may be translucent when the overlying epidermis is very thin, or they may vary in colour from red to blue-black when they contain blood, a frequent finding. Alternatively, the surface of the lymphangiomas may appear extremely warty and the lesions may be mistaken for viral warts. There may or may not be swelling of the underlying tissues, depending on the presence and size of enlarged anastomosing lymphatic channels beneath the skin. The term 'circumscriptum' may in many cases be misleading, because there may be an extensive deeper component to the malformation which is not clinically apparent [3]. Indeed, simple surgical excision of the visible lymphangioma will frequently result in further development of surface vesicles, indicating a more widespread

Fig. 51.11 Lymphangioma circumscriptum: fluid-filled vesicles resembling frogspawn. At times the vesicles can contain blood, weep clear fluid (lymphorrhoea) or become warty.

subcutaneous malformation. It has been postulated that the original malformation arises from deep contractile lymphatics which are malformed and not in continuity with the normal lymph-conducting pathways [4]. Tissue drainage into these abnormal lymphatics results in their gradual dilatation into lymphatic cisterns, contraction of which results in retrograde flow into the skin initial lymphatics. Only by identifying the limits of the subcutaneous cisterns prior to wide excision will there be any chance of cure.

Lymphangioma circumscriptum may present at any age but is usually noted at birth or appears during childhood. The commonest sites are the axillary folds, shoulders, flanks, proximal parts of the limbs and perineum. Frequently the vesicles are filled with fresh or altered blood but how the blood gets there is a mystery. The presence of limb swelling suggests an extensive underlying lymphatic abnormality. Lymph weeping (lymphorrhoea) from one or more surface vesicles is common and is likely to increase the risk of infection. Squamous cell carcinoma is described arising within lymphangioma circumscriptum [5]. The treatment of choice for lymphangioma circumscriptum is radical surgery. If this is not possible or is inappropriate, then intralesional administration of a sclerosant—for example, doxycycline [6] or picibanil (OK-432) [7]—can be helpful. Simple electrocautery and vaporization with carbon dioxide laser can be of palliative benefit, and superficial X-rays have been successfully used [8].

Diffuse lymphangioma (deep cavernous lymphangioma)

There is no clear distinction between lymphangioma circumscriptum and diffuse lymphangioma. The difference depends solely on the extent of the malformation. MRI can provide excellent evaluation of the extent of lymphangioma [9]. Diffuse lymphangioma usually gives rise to

ill-defined swelling, sometimes involving large areas of a limb. The swelling may be due either to lymphoedema (tissue oedema) or to gross dilatation of abnormal lymphatic channels (lymphangioma) or both [10]. Surface pressure with a digit will result in an indentation but a cavernous lymphangioma will rapidly refill, unlike the situation in pitting oedema where it takes many seconds for the interstitial fluid to redistribute when the pressure is released (like a sponge). Surface lymphangiomas are the result of dermal backflow. In diffuse lymphangiomas, the vesicles are more widely distributed, indicating the more extensive nature of the underlying malformation. Diffuse lymphangioma may not necessarily have any surface vesicles.

Diffuse lymphangiomas, although present from birth, may go unnoticed for many years and only manifest when disturbed by accidental injury, surgery or infection. Bleeding into a lymphangioma may be a cause of sudden pain. Swelling may or may not be apparent and the diagnosis can understandably be missed.

Cystic hygroma (cystic lymphangioma)

Lymphangiomas with few but large cyst-like cavities containing clear lymph are called cystic hygromas (hygroma = moist or watery tumour). Most occur in the neck, but they frequently extend into the upper mediastinum. Cystic hygromas are to all intents and purposes no different from cavernous lymphangiomas, but in structure hygromas have larger cystic spaces. The term tends to be reserved for those congenital lymph malformations which appear at birth or in infancy. In the neck, they presumably arise from an embryonic jugular lymph sac, whereas lymphangiomas derive from more peripheral lymph vessels [11]. Exceptionally, a cystic hygroma occurs in the groin, presumably from an embryonic iliac lymph sac. Fetal cystic hygroma can give rise to severe abnormalities, leading to fetal death [12].

Acquired lymphatic abnormalities

Lymphangitis

In theory, the lymphatic system has evolved in humans as a host defence mechanism. Noxious agents and predators such as bacteria, if not dealt with at the point of entry to the host, access the lymphatic system. Lymphatic vessels, together with adjoining lymph nodes, effectively act as the second line of defence, hopefully preventing further onward spread and so limiting systemic involvement. In some circumstances, the inflammatory response may be profound, perhaps due to a heavy infection load, and either an overt lymphangitis or lymphadenitis, or both, arise. Lymphangitis represents inflammation of the lymphatic collectors and is clinically seen as tender red streaks up the limb corresponding to the inflamed vessels. In the lower limb, oedema is so often an accompanying feature that red streaks, such as are seen with lymphangitis of the arm, are rarely seen. A more diffuse erythema is seen extending up the medial side of the leg and thigh. Distinction from an ascending cellulitis becomes difficult.

Infection is usually limited by the lymph nodes, and in the lower limb lymphadenitis may give rise to painful swelling in the groin. Occasionally, infection bypasses a group of lymph nodes and affects those at a higher level. Constitutional upset can be severe and is greater the more proximally the infection has extended.

Lymphangitis may occur without any demonstrable inflammation or may be recurrent, e.g. following relapsing herpes simplex infection. Permanent obliteration of lymphatic collectors may follow severe or recurrent lymphangitis. In such cases, if reserve lymphatic capacity is limited, permanent swelling (lymphoedema) can result.

Recurrent acute inflammatory episodes

SYN. RECURRENT CELLULITIS, ERYSIPELAS OR LYMPHANGITIS

Where lymphatic insufficiency exists and the local lymphoid tissue/lymphatic system fails in its host defence duty, recurrent infection can occur. Clinically, this manifests as recurrent cellulitis/erysipelas. Indeed, any patient who presents with recurrent attacks of cellulitis in one leg almost certainly has a compromised lymph drainage in that leg, whether overt lymphoedema is present or not. In most cases, however, subtle signs of lymphoedema are evident particularly in the skin over the toes and forefoot. Because there is no localization of infection by the

lymphatics, the first sign of illness will be constitutional upset with fever, rigors or vomiting. Only later may redness and tenderness appear in the leg and the diagnosis become clear.

Lymphangitis, as witnessed by red streaks up the leg, is generally not seen, presumably because the infection, uncontrolled by the lymphatic system, has spread through tissue planes (cellulitis) with rapid dissemination into the circulation. However, inflammation following the line of lymphatic channels can sometimes be apparent at the proximal border of a cellulitic area in patients with lymphoedema [1].

Treatment for recurrent cellulitis should first of all address predisposing factors such as tinea pedis, foot dermatitis, leg ulcers, etc. If no portal of entry or cause can be identified, then long-term prophylactic antibiotics may be necessary if the debilitating attacks are to be controlled.

Carcinoma erysipeloides

SYN. CARCINOMA TELANGIECTATICA

Carcinoma erysipeloides manifests clinically with a fixed erythematous patch or plaque resembling cellulitis/erysipelas, but without fever [2]. The inflamed area may show a distinct raised periphery and oedema secondary to lymphatic obstruction. Histology reveals plugging of superficial and deep dermal lymphatics by adenocarcinoma, usually carcinoma of the breast, but the condition has been described with melanoma, lung, ovarian, colonic and pancreatic tumours. The redness appears to be a consequence of the dermal lymphatic plugging with tumour, presumably through the release of cytokines. The term carcinoma telangiectatica refers to the presence of purpuric plaques, papules and vesicles where only the more superficial lymphatics are involved. 'Inflammatory breast carcinoma' has been suggested as an alternative term to 'carcinoma erysipeloides', but oncologists already classify inflammatory breast carcinoma as a subtype of cancer within the breast.

Lymphangiothrombosis

Lymph is capable of clotting, but the circumstances in which this happens and what pathological effect lymph thrombosis has are totally unknown. Extrapolating from venous thrombosis would suggest that lymph thrombosis is likely to impair the function of lymphatic valves and the contractility of lymph-collecting vessels.

Mondor's disease is alleged to be a superficial thrombophlebitis of the breast and chest wall [3] (see Chapter 50). A similar process, whereby cords or threads like violin strings extend down the inner arm, is frequently seen following axillary lymphadenectomy. The manner in which the cords 'bowstring' across the axilla with the arm abducted, their diameter and the fact that the cords can snap between finger and thumb suggests that lymph thrombosis may be a more likely explanation than phlebothrombosis/thrombophlebitis. An equivalent condition may well exist in the lower limb but be mistaken for thrombophlebitis.

'Seroma'

SYN. LYMPHOCOELE; LYMPHOCYST

Following lymphadenectomy, it is not unusual for a localized swelling containing clear fluid to develop. Often referred to as a 'seroma', the fluid is not serum, but lymph which has drained from the cut ends of the lymphatic collectors, so filling the space originally occupied by the nodes. The wall of lymphocoeles is 'false', in that no endothelial lining exists and instead a dense network of fibrin with lymphocytes is present [4]. Aspirated fluid is indistinguishable from lymph. Repeat aspiration is often necessary until a collateral lymph drainage forms. A 'seroma', particularly if infected, may herald the onset of lymphoedema if alternative drainage routes are not established.

Acquired lymphangiomas

SYN. LYMPHANGIECTASIA

Acquired or secondary lymphangiomas arise following damage to previously normal deep lymphatic vessels [5]. The mechanism by which they form is identical to congenitally determined lymphangiomas, i.e. obstruction to drainage leads to back-pressure and dermal backflow, with subsequent dilatation of upper dermal lymphatics. Acquired lymphangiomas are not true neoplasms or hamartomas, but represent simple dilatation (lymphangiectasia) of surface lymphatics. Lower-limb lesions usually arise in association with lymphoedema following either ilioinguinal block dissection or pelvic surgery and radiotherapy for gynaecological cancer. Acquired lymphangiomas have been described in association with scarring processes including recurrent infections, radiotherapy, scrofuloderma, scleroderma, keloid, tumour, tuberculosis and repeated trauma [6].

The clinical appearance of acquired lymphangiomas may vary greatly, ranging from clear fluid-filled blisters to smooth flesh-coloured nodules. Histologically, the latter show oedematous polypoid nodules within which are dilated lymphatics. Lesions may be solitary but scattered throughout a lymphoedematous limb, or they may be grouped, as seen in lymphangioma circumscriptum.

Lymphangiomas of the vulva are described following cancer treatment, tuberculous inguinal lymphadenitis and genital involvement with Crohn's disease. Clinically, the most common pattern is that of circumscribed groups of tense, thin-walled vesicles. However, a hyperkeratotic appearance may make distinction from viral warts difficult

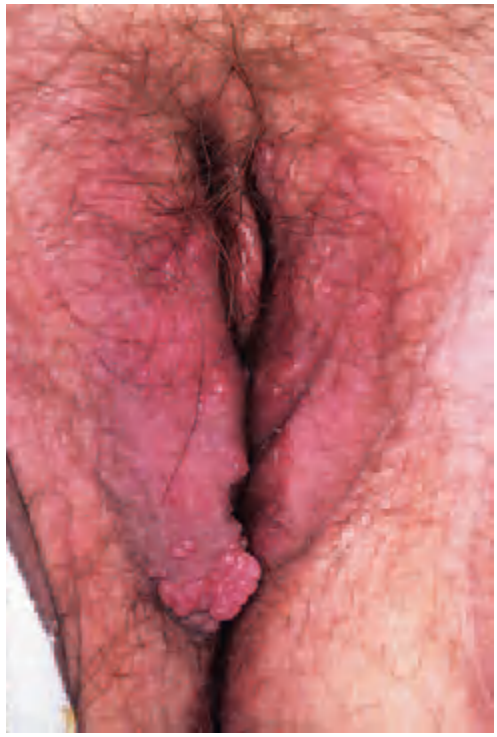

Fig. 51.12 Acquired lymphangiomas (lymphangiectasias) following cervical cancer treatment. The lymphangiomas were mistaken for genital warts.

[7] (Fig. 51.12). Recognition and appropriate treatment of vulval lymphangiomas is important primarily because the lesions may act as portals of entry for infection. In addition, persistent leakage of lymphatic fluid may be mistaken for urinary incontinence.

Treatment of acquired lymphangiomas is essentially the reduction of underlying lymphoedema and control of infection. This may be relatively straightforward on the leg, but is not so easy on the genitalia, where compression is not possible. Simple excision may prove successful at this site, particularly as tightening of the labial skin will discourage recurrence.

Acquired lymphangiomas may be widespread and problematic in palliative circumstances where advanced cancer produces profound oedema of lower limbs, genitalia and lower trunk. In these circumstances, widespread lymphangiomas weep copious lymph. Opposing intralymphatic pressure with equivalent surface compression is the only way of controlling the lymphorrhoea unless the lymphatic obstruction can be relieved.

Lymphatic tumours

Acquired progressive lymphangioma

SYN. BENIGN LYMPHANGIOENDOTHELIOMA

This benign tumour differs from simple acquired lymphangioma by its clinical behaviour and histopathology [1,2]. Acquired progressive lymphangioma presents as reddish or bruise-like plaques which are usually located on the abdominal wall, thigh or calf. Typically the condition affects young adolescents but may also arise in adults. It is usually localized, flat and grows slowly. Considered to originate from lymphatic endothelium, the histopathological appearance can mimic a low-grade sarcoma or Kaposi's sarcoma. Anastomosing dilated channels, with a tendency to dissect the collagen bundles, are lined by swollen endothelial cells but without cellular atypia. It usually runs a long and benign course.

Lymphangiomatosis

A deep cavernous or diffuse lymphangioma that slowly progresses due to an intrinsic proliferative process, as opposed to extension due solely to raised hydraulic pressure, is termed lymphangiomatosis. Typically, it presents in children and in a significant proportion of cases is confined to one limb with or without bone involvement [3].

Involvement of visceral organs, as opposed to soft tissues and bone, is associated with a poor prognosis [4]. Cases in soft tissue present as diffuse, fluctuant swellings which may have surface lymphangiomas. Histologically, it can be impossible to distinguish from simple lymphangioma, but it shows dissection of collagen reminiscent of angiosarcoma and the lymphatic channels are far more extensive. Haemosiderin may be present in the interstitium. The diagnosis is based on the slow progression and infiltration of surrounding structures including bone.

Maffucci's syndrome consists of diffuse haemolymphangiomatosis accompanied by severe widespread deformities of bone and cartilage, notably enchondromas of digits [5]. The lymphangiomas do not appear on lymphography to communicate with the main lymphatic pathways and often possess both blood vascular and lymphatic elements. Bony deformity may be gross and slowly uniting pathological fractures are common. The disease has high malignant potential including lymphangiosarcoma.

Lymphangiomyomatosis

SYN. LYMPHANGIOPERICYTOMA

This condition, exclusive to females, presents with central lymphatic problems, namely progressive dyspnoea associated with chylous effusions and a chest X-ray which reveals honeycombing of the lungs [6]. Masses of spindle cells proliferate in and around the walls of lymph vessels in a hamartomatous manner, particularly in retroperitoneal tissues and mediastinum. Lymphoedema of one or both legs can coexist.

Lymphangiosarcoma

This is a rare but well-recognized complication of any chronic lymphoedema, irrespective of cause. Red–brown or purple discoloration, like a bruise, appears in the skin of the lymphoedematous limb. Nodules or raised plaques may appear later. As the tumours proliferate, the oedema may increase and older lesions may ulcerate. The tumour metastasizes early and has a poor prognosis.

The tumour is best described in the upper limb following breast cancer treatment (Stewart–Treves syndrome) [7], but it is well reported in the lower limb in association with lymphoedema, usually of many years duration [8]. Radical amputation, if performed early enough, may offer hope of cure.

Kaposi's sarcoma

There is increasing evidence that Kaposi's sarcoma (KS) may arise from lymphatic rather than vascular endothelium, although its origins may lie with a primitive cell capable of either differentiation [9]. Histologically the earliest stages of the disease show jagged proliferations of capillaries extending out from the normal capillaries in the mid-dermis. As the lesion develops a network of spindle cells and large vascular spaces will be seen with characteristic thin-walled 'back-to-back' capillaries.

The classical form of the disease, as described by Kaposi, presents with dark-blue or purple lesions, usually on the feet. Initially, lesions may be flat; when they become tumid, diascopy may produce partial blanching to reveal a brown tinge from extravasated blood. Individual tumours enlarge to a diameter of 10–30 mm and stop growing, whereupon adjacent areas fuse to form a plaque or tumour. New lesions appear proximally alongside a superficial vessel. Unlike the situation in patients with lymphangiosarcoma, lymphoedema is rarely evident at the time the first lesions appear, but otherwise the morphology is similar. KS, however, is characteristically multifocal and, in time, symmetrical, affecting both lower limbs. In prolonged venous hypertension of the lower legs, nodules with a close resemblance to KS may develop (termed acroangiodermatitis or pseudo-Kaposi's sarcoma; see Chapter 48); they differ, however, in lack of progression, and spindle cell proliferation is not seen histopathologically in acroangiodermatitis.

Brawny oedema resembling lymphoedema develops with advanced KS. In the African and Mediterranean types of KS, oedema is often the first sign with lymph nodes as the main tissue involved.

KS associated with immunodeficiency, whether HIV-induced or not, produces subtle lesions which are often widely scattered and quite dissimilar from the classical type.

Where a small area is involved, excision or radiotherapy can be used. Superficial radiotherapy is rapid and effective, and is the treatment of choice for the majority of patients with nodular disease of the extremities.

Chylous reflux

Chyle is a 'milky lymph' which flows from the lacteals of the gut through the cisterna chyli and even through the thoracic duct. Incompetence of valves within megalymphatics, i.e. large varicose main lymphatic trunks, results in gross reflux of chyle to the skin below the waist [1]. The most common sites to be affected are the perineum and thigh. Lymphoedema may be present, but the characteristic symptom is oozing of milky fluid through the skin, usually from visibly dilated chylous vesicles (chylous lymphangioma). Rupture of such vesicles may result in a spurt of chyle under pressure, or chronic leakage may give rise to warty plaques of a cream-yellow colour.

Chapter 52

Histiocytoses

A.C. Chu

The histiocytoses are a heterogeneous group of diseases that are characterized by the accumulation of reactive or neoplastic histiocytes in various tissues. Many of the signs and symptoms of the histiocytoses may be the result of the functional activity of these cells, and abnormal or altered regulation of histiocyte activity may be important in the pathogenesis of these diseases (Fig. 52.1).

Ontogeny of the histiocyte

SYN. TISSUE MACROPHAGE

Histiocytes are derived from circulating monocytes and thus share a common bone marrow progenitor cell, the *neutrophil/macrophage colony-forming unit* (NM-CFU) (Fig. 52.2). Promonocytes are actively dividing cells and their replication is controlled by a series of stimulatory glycoprotein hormones, colony-stimulating factor (CSF) and inhibitory prostaglandins. CSF has a molecular mass of 20–50 kDa. Its main source is cells of the monocyte/macrophage lineage [1] but activated T cells [2], keratinocytes [3] and neoplastic monocytes and macrophages [4] are also capable of secreting CSF. Cell division is limited by a negative feedback mechanism involving the E prostaglandins, which are released by macrophages after stimulation by CSF.

Other factors have been shown to influence the maturation of monocyte precursors, including 1,25-dihydroxyvitamin D_3 [5], retinoic acid [6], interferon-γ (IFN-γ) [7] and phorbol esters [8]. The promonocyte matures into a monocyte, which is released into the circulation where it represents a replacement pool for tissue macrophages or histiocytes. The half-life of a circulating monocyte is about 71 h [9], after which the cells migrate into various tissues where they differentiate into histiocytes without further division. Most histiocytes do not actively divide, although in some tissues, such as the lung, they are capable of replication [10]. The trophic factors that induce migration of precursor cells into certain tissues and induce their maturation into phenotypically recognizable cells are unknown.

The *Langerhans' cell* is a histiocytic cell that represents a resident immigrant population in the epidermis. As with all histiocytic cells, Langerhans' cells are of bone marrow origin [11] and it is assumed that the $CD34^+$ NM-CFU is the most likely precursor cell. The intermediate stages of Langerhans' cell development are unknown, but a possible intermediate cell in the bone marrow has been identified, which, in common with the Langerhans' cell, expresses the CD1 complex [12]. In the blood of healthy individuals, $CD1a^+$ cells are found in very low numbers, but in cord blood [13] and blood from burns patients [14] high levels of $CD1a^+$ cells are observed. It is speculated that these represent immature Langerhans' cells.

The factors that control the migration and development of Langerhans' cells in the skin are still poorly understood

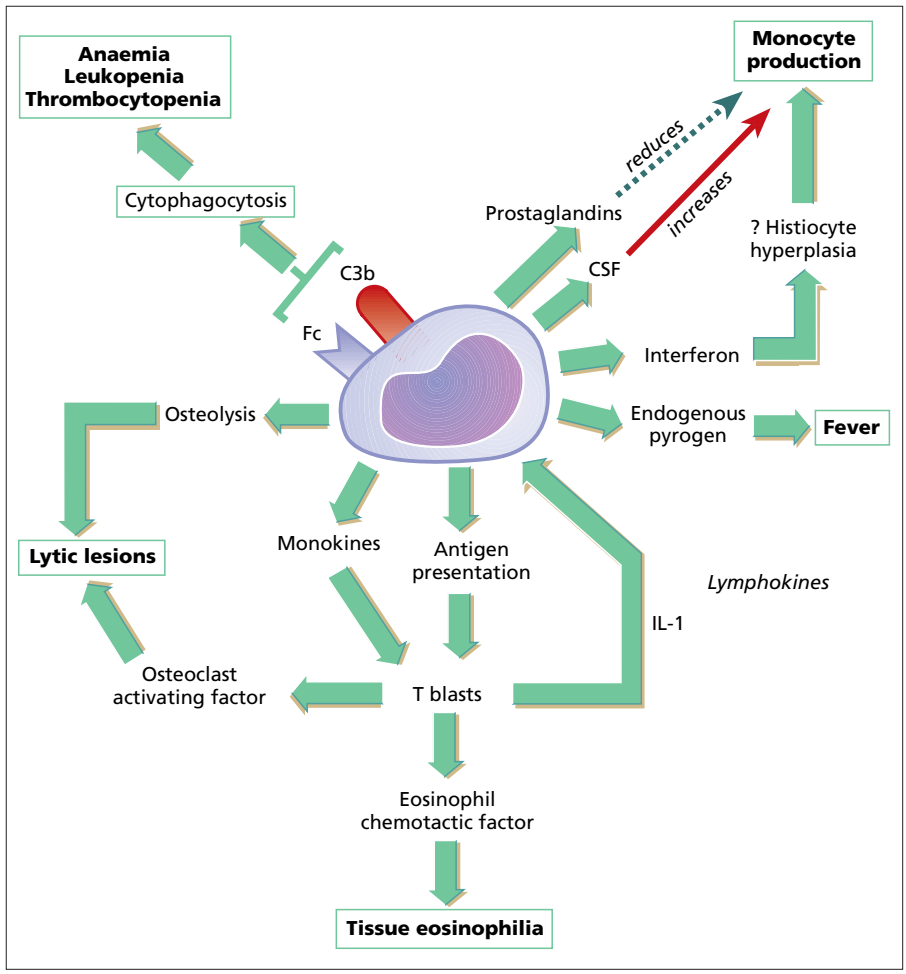

Fig. 52.1 Alteration in histiocyte function causing symptoms of the histiocytoses. CSF, colony-stimulating factor; C3b, complement 3b; Fc, heavy chain fragment of immunoglobulin; IL-1, interleukin-1; T blasts, thymus-derived lymphoblasts.

but granulocyte/macrophage CSF (GM-CSF), interleukin-3 (IL-3) and tumour necrosis factor-α (TNF-α) all induce $CD34^+$ cells to develop the phenotypic features of Langerhans' cells. Caux *et al.* [15] generated $CD1a^+$ cells from $CD34^+$ bone marrow cells using GM-CSF and TNF-α. The cells demonstrated potent antigen-presenting function. However, further research has shown that the whole field of Langerhans' cells ontogeny is more complex. Studies have now shown that GM-CSF will induce CD1a, CD1b and CD1c on blood monocytes [16]. It thus appears that although *in vivo* CD1a is a very specific marker for Langerhans' cells, this antigen can be induced on a variety of cells by cytokines such as GM-CSF. The interpretation of *in vitro* studies must therefore be cautious. A possible immediate precursor of the Langerhans' cell in the epidermis is the *indeterminate cell* [17], which bears the Langerhans' cell surface phenotype but lacks the characteristic Birbeck granule (see Chapter 3 and section on phenotype of Langerhans' cell below).

The fate of Langerhans' cells after their development in the skin is speculative. Some authors maintain that Langerhans' cells migrate from the skin in the efferent lymphatics as *veiled cells* and eventually develop into *interdigitating reticulum cells* in the paracortical zone of the regional lymph nodes. If Langerhans' cells are cultured, they lose their characteristic phenotype and adopt an interdigitating reticulum cell phenotype [18]; this phenomenon has been proposed as evidence for the extra-epidermal differentiation of Langerhans' cells. However, the *in vitro* culture conditions are very unphysiological, and it is more probable that the Langerhans' cell, veil cell and interdigitating cell are related but differentiate separately from an early common progenitor cell series.

The dermal dendrocyte, first described by Headington in 1986 [19], is an interstitial cell of the dermis that is highly dendritic. These cells are distributed throughout the papillary and reticular dermis. They are positive for adenosine triphosphatase (ATPase), α-napthylbutyrate esterase, β-glucuronidase and acid phosphatase, indicating that they are cells of the monocyte/macrophage lineage. They are also phagocytic *in vivo*, showing melanin and haemosiderin phagocytosis. Dermal dendrocytes are of bone marrow origin and are thought to have a possible role in phagocytosis, antigen presentation or in homeostasis of macromolecules of the dermis [20]. Elegant computer-assisted three-dimensional reconstruction of

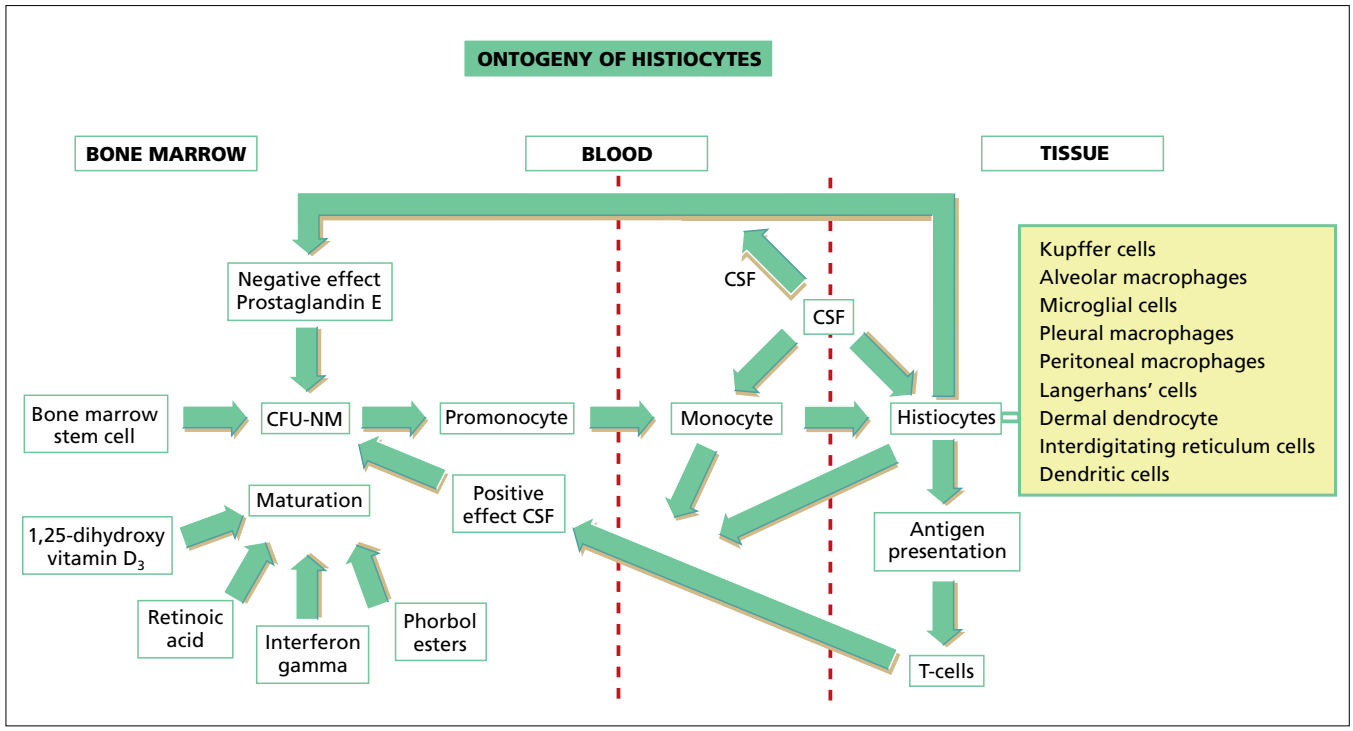

Fig. 52.2 Ontogeny of histiocytes showing factors that can influence the division and maturation of the cells. CFU-NM, neutrophil/macrophage colony-forming unit; CSF, colony-stimulating factor.

dermal dendrocytes in adult human skin has shown that in those associated with superficial blood vessels, the dendrites are thin membrane-bound flaps that enshroud the vessel wall. In subepidermal dermal dendrocytes, the flap-like dendrites are parallel to the dermal–epidermal junction. Between 20 and 40% of perivascular dermal dendrocytes and some subepidermal dermal dendrocytes are closely associated with mast cells, their membrane flaps enshrouding 50–90% of the surface of the mast cell [21].

Phenotype of Langerhans' cells

For many years after the original description of Langerhans' cells [22], this epidermal clear cell was considered to be an effete melanocyte. Major interest in this cell was generated by the finding that Langerhans' cells expressed a number of surface molecules, which suggested immunological importance. These molecules include major histocompatibility complex (MHC) class II molecules (which are constitutively expressed by Langerhans' cells), FcIgG receptors and C3b receptor. Langerhans' cells also express the chemokine receptors CCR5 and CCR6. A full list of the phenotypic markers of Langerhans' cells is given in Table 52.1.

A major advance was the finding that epidermal Langerhans' cells expressed the CD1 complex [23], previously considered to be restricted to cortical thymocytes. CD1 is a group of non-polymorphic membrane glycoproteins that non-covalently bind to β_2-microglobulin. Five genes have been identified and cloned [24]. Four

molecules have been described: CD1a, CD1b, CD1c and CD1d [25]. CD1a and CD1c have been shown to be expressed by Langerhans' cells and may play a role in presenting antigen to γ/δ T cells [26]. Langerhans' cells have since been shown to express other molecules, identified by CD4 and CD25 antibodies, which were initially thought to be specific for lymphocytes.

The unique phenotypic feature of Langerhans' cells is the trilaminate cytoplasmic organelle, the *Birbeck granule* [27]. This organelle is only observed in Langerhans' cells, Langerhans' cell histiocytosis (LCH) cells (which are abnormal Langerhans' cells) and some hairy cell leukaemia cells. The granules are rod-shaped structures with a central lamella. They are of uniform width (33 nm) and of variable length (200–360 nm). The granules often have terminal vesicular dilations, giving rise to the characteristic 'tennis racket' appearance. The Birbeck granule was initially thought to originate from the Golgi apparatus, but studies now suggest that it arises from the cytoplasmic membrane by receptor-specific endocytosis [28]. The exact function of the Birbeck granule remains unknown and the factors that induce its appearance in Langerhans' cells remain speculative.

The phenotype of the Langerhans' cell changes with activation or with culture *in vitro*. Activation involves up-regulation of human leukocyte antigen (HLA)-DR and expression of CD4 and the co-stimulatory molecules CD80 and CD86 [29]. At the same time, Birbeck granules become sparser and CD1a is down-regulated (see Table 52.1).

Phenotype of the dermal dendrocyte

In addition to showing the enzyme histochemical features of the monocyte/macrophage lineage, a characteristic feature of dermal dendrocytes is expression of factor XIIIa. The cells are always negative for CD1a, which differentiates them from Langerhans' cells, and express HLA-DR, HLA-DQ, CD36, CD68, CD34, CD11a and CD11b but not CD15, CD54 and CD2. Thus they show the immunophenotype of monocyte/macrophages and antigen-presenting cells, with no features of granulocytes or T cells [30]. Following IFN-γ stimulation, expression of HLA-DR increases and dermal dendrocytes express CD54. In atopic dermatitis and psoriasis, cells positive for factor XIIIa, HLA-DR and CD54 are observed in the upper dermis and foci of factor XIIIa-positive cells are seen in the epidermis [30].

In recent studies, dermal dendrocytes have been shown to express S100A6 [31] and type XVI collagen [32]. $CD14^+$ peripheral blood monocytes stimulated with GM-CSF and IL-4 express factor XIIIa [33] and collagen XVI [32]. It is postulated that type XVI collagen forms an intermolecular cross-link through its non-collagenous domain, contributing to the integrity of factor XIIIa.

Dermal dendrocytes also express the von Willebrand factor receptor GPIbα. Expression of this factor *in vitro* is up-regulated by mast cell degranulation [34]. Expression of GPIbα on dermal dendrocytes suggests that these cells may have a role in skin remodelling and repair.

The fate of dermal dendrocytes is unknown. The factors that influence maturation of these cells include mast cell products, although *in vitro* studies using TNF-α have failed to demonstrate up-regulation of GPIbα on factor XIIIa-positive cells [35]. When skin is maintained in organ culture, dermal dendrocytes lose their dendritic morphology and become more rounded. This change is accentuated by mast cell degranulation, regardless of stimulus. These non-dendritic cells express variable amounts of factor XIIIa, CD34 and CD68.

Function of the histiocyte

Histiocytes can be broadly divided into two functionally separate cell populations: the 'professional' phagocyte and the antigen-presenting cell.

Phagocytes include the majority of resident tissue macrophages and immature macrophages. Immature macrophages are cells that have migrated, as monocytes, from the blood but remain responsive to chemotactic stimuli and are attracted to sites of inflammation where they become inflammatory macrophages. Phagocytes take up foreign or altered material and digest it using a number of lysosomal enzymes. Phagocytes recognize material to be taken up by a variety of different surface receptors. Important in this are the carbohydrate and lectin receptors, which are involved in the phagocytosis of bacteria and possibly tumour cells. The cells also express the specific complement component receptors CR1 and CR3, which bind to C3b and C3bi respectively, and FcIgG receptors, which bind to the Fc fragment of IgG. These receptors are important in the phagocytosis of material that has bound IgG and complement, which act as opsonins and augment phagocytosis.

Phagocytosis is important in the removal of particulate matter and destruction of bacteria and parasites. The phagocytosed particles are internalized and destroyed in phagolysosomes. Partially degraded antigen may subsequently become associated with MHC class II antigens and be re-expressed on the surface of the macrophage, where it can be presented to T-helper cells.

Phagocytes also possess some antigen-presenting capacity, although this is limited—cells express class II MHC molecules and can process and re-express antigen on their surface in association with these specific molecules, but only elicit responses in specific responder T-cell populations. In general, phagocytes present antigen to sensitized T cells but not to naive or 'memory' T cells.

Antigen-presenting cells are histiocytic cells, or in some instances other cell types, that have specialized functional

activity in presenting antigen to T cells. These cells are represented in humans by the blood dendritic cell, epidermal Langerhans' cell, interdigitating reticulum cell of the lymph node paracortex and veil cell of the efferent lymph. These cells have no phagocytic activity and, unlike professional phagocytes, are unable to adhere to surfaces. They are able to internalize antigen by endocytosis, process it by lysosomal digestion and re-express the antigen on their surface in association with MHC class II molecules. In addition these cells are potent antigen-presenting cells and are able to present antigen not only to sensitized T cells but also to memory and naive T cells, and are also able to present self antigen to allogeneic T cells to elicit an allogeneic or mixed-cell reaction [36].

Langerhans' cells are central to the sensitization and elicitation phases of contact allergic dermatitis, are responsible for cutaneous immune surveillance and are the target for skin graft rejection [37]. Intraepidermal Langerhans' cells are immature but, following stimulation, they migrate from epidermis to lymphatics and thus to the regional lymph nodes, and during this process undergo maturation. The signals that initiate and regulate the directed movement of Langerhans' cells from the skin to regional lymph nodes include chemokines and cytokines. In cutaneous sensitization, TNF-α, GM-CSF, IL-1β and IL-18 are required, while IL-4 and IL-10 antagonize this process [38,39]. Maturation of Langerhans' cells is accompanied by specific phenotypic changes, with up-regulation of HLA-DR, down-regulation of CD1a, and expression of CD4 and CD25. There is a switch in chemokine receptor expression from CCR5 and CCR6 to CCR7 and CXCR4, which enables Langerhans' cells to exit the epidermis and follow a gradient of chemokines (CCL19, CCL21 and CXCL12) to the paracortical zone of the lymph nodes [40]. Langerhans' cells also express other activation markers, including CD83 and CD40 and the T-cell co-stimulatory molecules CD80 and CD86 [41].

Classification of the histiocytoses

Understanding of the histiocytoses has been severely hampered by the lack of a universally accepted classification of these diseases and the widespread use of eponyms to describe them. For these reasons, the Histiocyte Society published their classification of the histiocytoses for use as a standard in both diagnosis and management [1]. This classification has been generally accepted and is now widely used. In this chapter I have modified the original classification in the light of new insights into reactive histiocytoses of dermal dendrocyte phenotype. The histiocytoses are separated into four classes according to our current understanding of the biology of these diseases.

Class I: Langerhans' cell histiocytosis

Class I histiocytoses are a diverse group of clinical diseases that are all reactive histiocytoses in which the predominant histiocyte is of Langerhans' cell phenotype. Patients with LCH can be further subdivided on the basis of the clinical organ involvement present. Bone disease and lung disease in adults appear to be significantly different in their biology from other single-system involvement and it is valid to separate them. The significance of organ involvement is discussed further in the section on LCH.

Class IIa: histiocytoses involving cells of the dermal dendrocyte lineage

Class IIa histiocytoses are reactive diseases in which cells with the phenotype of the dermal dendrocyte (positive for CD68 and factor XIIIa) accumulate in the skin and other tissues causing tissue damage. The typical histological change is a xanthogranulomatous reaction, although the histological changes reflect the cell type present. Juvenile xanthogranuloma is typical of this group of diseases, and some of the conditions described may not be specific disease entities but clinical variants of a single disease. These diseases are reactive with no clinical evidence of malignancy.

Class IIb: histiocytoses involving cells other than Langerhans' cells and dermal dendrocytes

Class IIb histiocytoses are reactive diseases in which histiocytes other than those bearing the Langerhans' cell or dermal dendrocyte phenotype accumulate in various tissues and may cause tissue damage. Within this heterogeneous group of diseases are included a number of rare and often poorly understood disorders. The major features of all these histiocytoses are that they are reactive, with no clinical or laboratory evidence of malignancy, and that Langerhans' cells and related cells are not involved.

Class III: malignant histiocytic disorders

Class III histiocytoses include all the malignant histiocytic diseases. These include monocytic leukaemias, malignant histiocytosis, which may be of the mononuclear phagocyte, dendritic cell or Langerhans' cell type, and the true histiocytic lymphoma, which once again may be of the mononuclear phagocyte, dendritic or Langerhans' cell type.

Class I histiocytosis: Langerhans' cell histiocytosis

SYN. HISTIOCYTOSIS X; EOSINOPHILIC GRANULOMA; LETTERER–SIWE DISEASE; HAND–SCHÜLLER–CHRISTIAN SYNDROME; HASHIMOTO–PRITZKER SYNDROME; SELF-HEALING HISTIOCYTOSIS; PURE CUTANEOUS HISTIOCYTOSIS; LANGERHANS' CELL GRANULOMATOSIS; TYPE II HISTIOCYTOSIS; NON-LIPID RETICULOENDOTHELIOSIS

Definition. LCH is a reactive condition in which a clonal population of cells with the phenotype of the Langerhans' cell accumulate in various tissues and cause damage. Tissue damage appears to be due, in part, to cytokine production.

Aetiology. The aetiology of LCH is unknown but over the last century several possibilities have been considered, including tuberculosis [1] and a lipid abnormality [2,3]. The discovery of Birbeck granules in the cytoplasm of lesional cells using electron microscopy [4] led to the suggestion that these cytoplasmic bodies could be viral inclusion bodies and that LCH could be a virally mediated disease [5]. However, a large retrospective study on the fulminant form of LCH showed a random geographical distribution and little month-to-month variation in the

incidence of the disease, which argued against it being due to a conventional virus [6]. A study of 56 LCH samples using *in situ* hybridization and polymerase chain reaction (PCR) analysis failed to show any consistent evidence of adenovirus, cytomegalovirus, herpesvirus, parvovirus, human T-cell virus or human immunodeficiency virus infection [7].

The possibility of an immunological aetiology for LCH has been suggested by the occurrence of a number of immunological abnormalities in this disease. The fact that the lesional cell bears the phenotype of the Langerhans' cell, which is a key cell in the immune system, also suggests that the immune system is in some way involved in its pathogenesis. However, none of the immunological abnormalities have been a consistent feature, and most authors now consider them to be epiphenomena.

Serum immunoglobulins may be increased or decreased. The most common finding is that of reduced IgG and IgA levels, with normal IgM and IgE levels. In some reported cases, IgM and IgE levels were elevated [8].

In some patients, particularly those with aggressive disease, cutaneous anergy has been found on cutaneous testing, and *in vitro* studies have shown reduced T-cell responses to mitogens, recall antigens and alloantigens [9]. A reasonably consistent feature in three reported series of LCH [10–12] is a reduction of the $CD8^+$ T-cell subpopulation in the blood, with an associated normal or reduced total T-cell number. In one report [12], this reduction in the number of $CD8^+$ cells was associated with reduced suppressor T-cell activity *in vitro*.

Considering that Langerhans' cells are members of the monocyte/macrophage series of cells, very few abnormalities of this group of cells have been reported. Reduced monocyte-mediated, antibody-dependent cytotoxicity occurred in six patients with LCH, all of whom were in clinical remission [13]. This certainly warrants further study. LCH cells are unable to provide accessory cell function in a mitogen-driven T-cell response, and were inhibitory to T-cell proliferative responses [14]. Only one study has investigated the functional activity of LCH cells in depth [15]. In this report, LCH cells were shown to be functionally deficient in presenting alloantigen to T cells. It is possible that the defect in functional activity may be linked with the apparent arrest of these cells in an early stage of activation, leaving the cells immature so that they do not have the functional capacity of a normal Langerhans' cell.

Historically, LCH has been considered a malignant disease, and care of children with the disease has been in the hands of paediatric oncologists. The main reason for this is the clinical course and high mortality associated with the more fulminant forms of LCH. Flow cytometric studies have in general failed to identify aneuploidy in LCH [16,17]. In one report of an adult case with clinical and histologically confirmed LCH involving the skin, flow cytometry revealed an aneuploid peak [18]. Many features of this case were unusual and it is possible that the patient had the rare form of malignant histiocytosis of Langerhans' cell type.

Recent studies have demonstrated that lesional $CD1a^+$ cells in LCH are clonal. Clonality studies in LCH have been difficult to perform because of the lack of cell-specific markers. Unlike the T-cell receptor in T cells and immunoglobulins in B cells, histiocytic cells have no markers that can be employed in such studies. The study of genes carried on the X chromosome have now allowed such studies in female patients with this disease. Of the gene loci examined, the human androgen receptor (*HUMARA*) is the most informative as there is a high degree of heterogeneity for this locus in the population. The underlying theory behind the assay is that the two alleles for *HUMARA* are acquired from maternal and paternal genes, each of which is a different size because of the presence of tandem repeats. Only one allele is activated, the other being inactivated by methylation, and the use of methylation-sensitive restriction enzymes in PCR allows the inactivated allele to be expanded and identified. In a normal population of cells, activation of the alleles is random so that 50% are derived from maternal and 50% from paternal genes, giving two bands on gel electrophoresis. In a clonal population of cells, all cells are derived from a single cell and therefore all these cells will have an inactivated allele, which is either maternal or paternal, giving a single band on gel electrophoresis. In a study of four female patients with LCH, purified lesional $CD1a^+$ cells were shown to be clonal using this assay system [19]. Studies by Willman *et al.* [20] have confirmed these studies and shown that lesional cells are clonal regardless of the extent or severity of the disease. In isolated pulmonary LCH in adults, a recent study using X chromosome inactivation at the *HUMARA* locus has shown that 29% were clonal and 71% non-clonal. Discrete lung nodules from the same patient showed different allele inactivation [21]. Pulmonary LCH in adults is often an isolated disease that may remain restricted to the lungs and thus behaves in a different way biologically than other forms of LCH. It is possible that primary lung disease is a separate entity and only when it progresses to involve other organs does it become a clonal disease.

What clonality in LCH means is difficult to interpret. It certainly identifies the LCH cell as the primary cell in this disease but this does not mean that LCH is a malignancy. Many reactive diseases, for example lymphomatoid papulosis, have been shown to be clonal. Although of major interest, such studies have thus not altered our management of patients with this disease, nor have they identified the disease as malignant.

Pathology. The histological picture of LCH depends on the age of the lesion biopsied and the organ involved. The

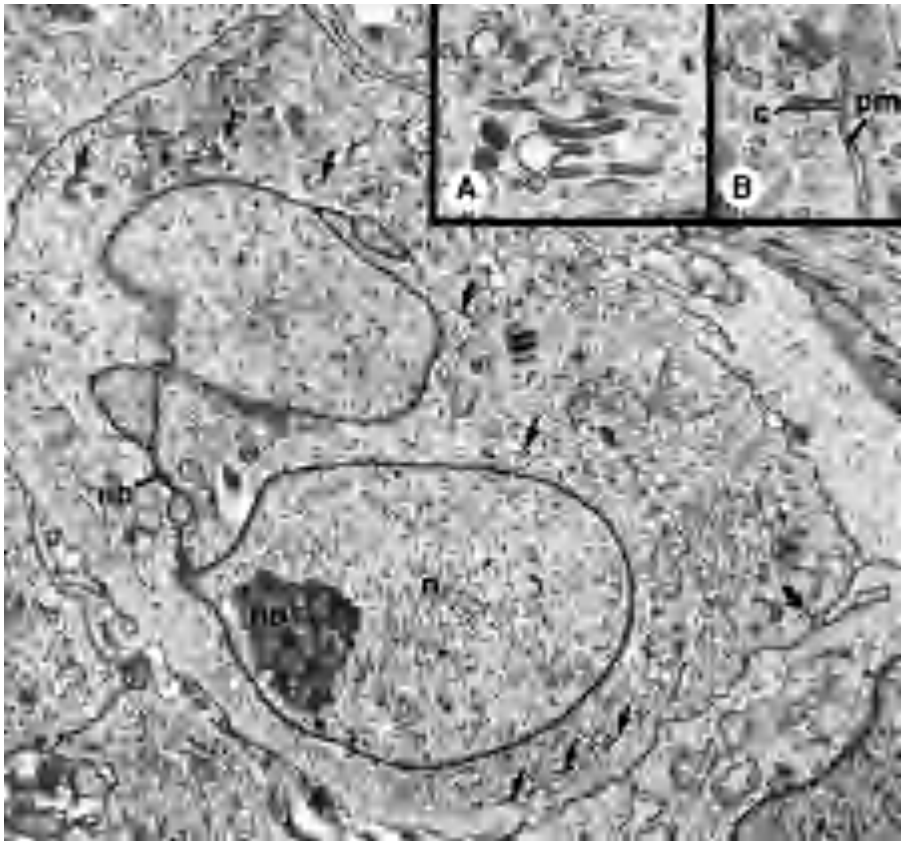

Fig. 52.3 Electron micrograph of a Langerhans' cell histiocytosis (LCH) cell in the epidermis of a patient with multisystem LCH. The cell shows a lobulated nucleus (n) with a prominent nucleolus (no) and attenuated nuclear bridge (nb). Numerous Birbeck granules (straight arrows) are evident in the cytoplasm. One granule (curved arrow) is seen projecting from the plasma membrane (× 13 000). (A) Birbeck granule in the cytoplasm. Some show characteristic vesiculation of the end, forming typical tennis-racket bodies. (B) Birbeck granules appear to be budding from the plasma membrane (pm) (× 39 000). (Courtesy of Professor R.A.J. Eady, St John's Dermatology Centre, London, UK.)

pathology of LCH was reviewed by the Histiocyte Society in 1987 [22], who recommended three levels of diagnostic confidence. A presumptive diagnosis is made when the histological appearance of the biopsy is consistent with the diagnosis of LCH. Diagnostic confidence increases if marker studies are performed and lesional cells are found to be positive for S100 protein, peanut agglutinin or α-D-mannosidase. If lesional cells are found to express the CD1 complex or to exhibit Birbeck granules on electron microscopy (Fig. 52.3), this constitutes a definitive diagnosis.

The characteristic histological appearance of LCH in the skin is of an upper dermal and junctional accumulation of large histiocytic cells with homogeneous pink cytoplasm. These cells have lobulated, bean-shaped or boat-shaped nuclei (Fig. 52.4). There is a variable lymphocytic infiltrate, deep to the aggregates of LCH cells. In some patients with LCH, large numbers of γ/δ T cells have been identified in the lymphocytic infiltrate [23]. Eosinophils are present in variable numbers, being rare in the more fulminant forms of LCH but present in high numbers in the less aggressive spectrum of LCH. Within the epidermis, LCH cells are often observed either singly or forming Pautrier-like microabscesses (Fig. 52.5).

With time, the histological picture changes, with fewer LCH cells present and the emergence of a more xanthomatous pattern, which is eventually followed by fibrosis. Several studies have shown no correlation between

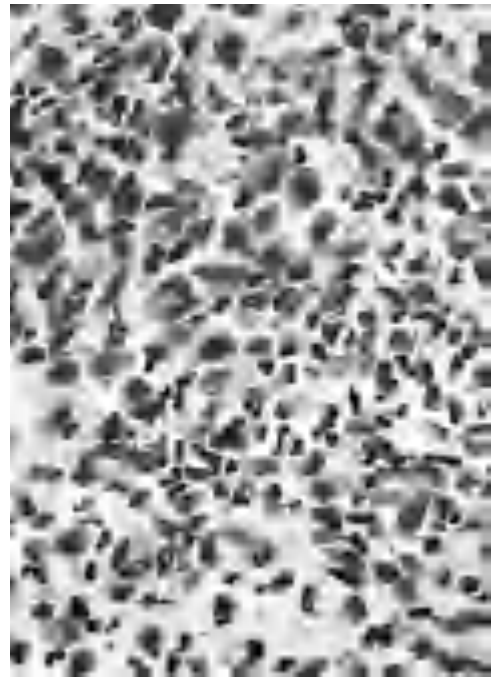

Fig. 52.4 Langerhans' cell histiocytosis cells in the dermis intermingled with polymorphs and eosinophils (H&E × 250). (Courtesy of Professor E. Wilson Jones, St John's Dermatology Centre, London, UK.)

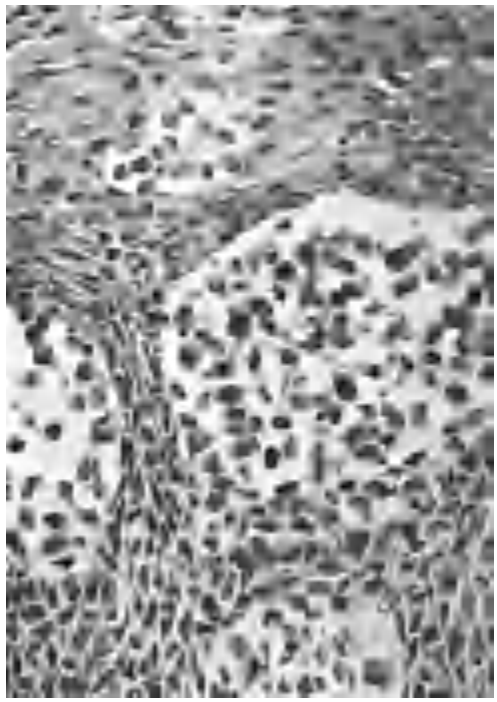

Fig. 52.5 Langerhans' cell histiocytosis (LCH). Details of a papillary tip containing LCH cells, with a small intraepidermal abscess overlying it (H&E × 250). (Courtesy of Professor E. Wilson Jones, St John's Dermatology Centre, London, UK.)

histology and extent of disease, morbidity or mortality [24–27].

In one clinical variant of LCH, described by Hashimoto and Pritzker [28], in which the disease is restricted to the skin and regresses spontaneously over a period of several months, the pathology in the skin is sufficiently different to warrant separate description. In this variant, the infiltrate is deep within the dermis, with sparing of papillary dermis and epidermis. Lesional cells are large histiocytic cells with copious glassy eosinophilic cytoplasm. Multinucleate giant cells are often observed. Up to 25% of these histiocytes contain Birbeck granules.

Immunocytochemistry. Immunohistochemical studies have demonstrated that LCH cells show many of the characteristics of the epidermal Langerhans' cell, particularly in its activated state (see Table 52.1) [29–31]. The labelling pattern with certain markers (C3b and C3bi receptors, CDW14, Ki-M1 and Ki-M6) has been shown to be variable. This does not correlate with the clinical course of the disease but probably reflects different phenotypic 'ages' of the Langerhans' cell [30].

Three markers have now been shown to be expressed by LCH cells but not by normal epidermal Langerhans' cells. These are peanut agglutinin, an epitope shared with IFN-γ [32,33] and placental alkaline phosphatase [34]. Placental alkaline phosphatase is negative in normal

Table 52.2 Diagnostic markers for Langerhans' cell histiocytosis (LCH) cell.

Marker	Tissue needed
S100	Paraffin-embedded
Peanut agglutinin	Paraffin-embedded
Placental alkaline phosphatase	Paraffin-embedded
α-D-Mannosidase	Fresh
CD1a	Fresh-frozen (paraffin-embedded with 010 monoclonal antibody)
Birbeck granules	Electron microscopy prepared

Langerhans' cells and is not observed in reactive dermatoses where Langerhans' cells are present in the dermal infiltrate. However, *in vitro* studies have shown that placental alkaline phosphatase expression is an early and transient activation marker of Langerhans' cells [35]. These observations are of particular interest, as they show that LCH cells are not merely reactive Langerhans' cells but are Langerhans' cells arrested at a particular stage of their ontogeny.

Immunohistochemistry is important in confirming the diagnosis of LCH. For retrospective studies where only formalin-fixed and paraffin-embedded tissue is available (Table 52.2), three markers are of value: S100 protein, peanut agglutinin and placental alkaline phosphatase. S100 protein staining is a consistent feature of LCH cells but is also present in normal Langerhans' cells and a variety of other skin cells and structures, including nerve tissue, melanocytes and naevus cells. In a study by Rowden *et al.* [36], the histiocytic cells and giant cells in juvenile xanthogranuloma, necrobiotic xanthogranuloma, papular xanthoma, eruptive histiocytoma and reticulohistiocytosis were all negative for S100 protein, but all LCH specimens were positive.

Peanut agglutinin shows characteristic labelling of LCH cells, with paranuclear and cell-surface deposition of reaction products. Peanut agglutinin labels other cell types in the same way, including interdigitating reticulum cells [37], but normal Langerhans' cells and other histiocytic cells show diffuse cytoplasmic labelling with this marker [32].

Placental alkaline phosphatase is normally found in placental tissue and in the female reproductive tract. It is also expressed in malignancies of the ovary and testis. In normal skin, placental alkaline phosphatase is negative and cells expressing this enzyme are absent in reactive disorders. It is perhaps the most informative marker that can be used in archival LCH material, where only the LCH cells express this enzyme [34].

A recently described marker for dendritic cells is now being used by some histopathologists to differentiate LCH from other histiocytoses. Fascin is a 55-kDa actin bundling protein that is highly selective for dendritic

cells of lymphoid tissue and blood. It is involved in the formation of dendritic processes in maturing epidermal Langerhans' cells. In a study of 34 samples of LCH from skin, bone, lymph node, thyroid, orbit and extradural cranial tissue, all samples stained positive for fascin, CD1a and S100. Normal epidermal Langerhans' cells were consistently negative for fascin [38].

To establish a definitive diagnosis by the criteria of the Histiocyte Society, the involved tissue must be examined for anti-CD1a staining or for the presence of Birbeck granules (which requires fixation and processing for electron microscopy). Until recently, staining with anti-CD1a antibodies required fresh frozen tissue. A new monoclonal antibody, 010, has now been described that works in paraffin-embedded tissue [39].

Incidence. The incidence of LCH is unknown because of the heterogeneity of clinical expression of the disease. In many patients, the disease is undiagnosed, with mild skin involvement being attributed to seborrhoeic dermatitis and isolated bone disease remaining undetected. Also, the diverse clinical presentation of the disease means that patients may be under the care of orthopaedic surgeons, ear, nose and throat surgeons, paediatricians, paediatric oncologists or dermatologists. In the UK, 15–20 cases are reported to the UK Children's Cancer Study Group Register each year. These represent only the more severe paediatric cases, and the real incidence in the general population is more likely to be at least four to six per million, with 50–70 new cases presenting annually.

Clinical features. LCH can affect many different organs and may cause fever, malaise and, in children, failure to thrive.

Of 58 patients with LCH seen at the Hospital for Sick Children, London, over a 7-year period, 14 had single-system disease (13 bone and one skin) and 44 had multisystem disease, of whom 50% had vital organ dysfunction [40]. At the Children's Hospital in Philadelphia, 64 patients were seen over a 14-year period of whom 33 had single-organ involvement in bone (27 patients) or skin (six patients), 22 had multifocal single-organ disease affecting bone (17 patients) or soft non-osseous tissue (five patients), and nine patients had disseminated disease with dysfunction of liver or lungs [41].

In a large series of 124 patients [42], bone, lymph node and skin lesions were the most frequently seen, but 50% of patients showed liver disease and 23% lung disease with frequent haematological changes.

Skin. The most characteristic presentation is with scalp involvement. The scalp is erythematous with greasy scales, looking very like seborrhoeic dermatitis (Fig. 52.6). On the trunk, the lesions are discrete, yellow-brown, scaly papules, often showing areas of purpura (Figs 52.7 & 52.8). Lesions may become nodular and crusted or eroded. Ulceration of the flexures, groin or perianal or vulval region is a common presentation in adult patients (Fig. 52.9).

Fig. 52.6 Langerhans' cell histiocytosis of the scalp and ear of a child showing the characteristic seborrhoeic dermatitis-like eruption.

In the Hashimoto–Pritzker variant of LCH, the eruption starts in the neonatal period with nodular lesions that resemble healing chickenpox. The eruption may involve any skin surface, including palms and soles, and is self-limiting over a few weeks. In a recent report of four cases of Hashimoto–Pritzker LCH, follow-up showed recurrence of disease in two children, with cutaneous relapse in one at 3 months of age and bony relapse requiring systemic therapy at 6 months in the other child. Follow-up of such children is therefore necessary [43].

In patients with peripheral lymph node involvement, chronic draining sinuses may develop over involved sites (Fig. 52.10).

Juvenile xanthogranuloma has been associated with LCH. In a report of three children with multisystem LCH, juvenile xanthogranulomas appeared 3–6 years after the initial presentation with LCH [44]. It is possible that the juvenile xanthogranulomas developed as a reaction to the inflammatory reaction in LCH.

Nails. Nail involvement in LCH is rare. Changes include paronychia, nail fold destruction, onycholysis and subungual expansion with nail plate loss (Fig. 52.11) [45].

Fig. 52.7 Langerhans' cell histiocytosis in a child. Scaly maculopapular eruption on the back with mild purpura.

Fig. 52.8 Langerhans' cell histiocytosis in an infant showing typical eruption on the abdomen and groins mimicking seborrhoeic dermatitis and napkin eruption.

Ears. Disease of the ears is common [46], with involvement of external and middle ear and mastoid. This may present with persistent aural discharge due to skin involvement or polypoid involvement of the external auditory canal. If the middle ear or mastoid is involved, deafness is common.

Oral. The commonest presentation in the mouth is with periodontal involvement, affecting particularly the lower molar areas [47]. There may be destruction of the alveolar ridge with infiltration of the gums with LCH cells resulting in the teeth floating free from their sockets (Fig. 52.12). Premature eruption of the teeth may be a presenting sign [48]. Mandible involvement is frequently observed in adults, with a palpable tender mass over the affected area. This is usually associated with oral involvement.

Fig. 52.9 Langerhans' cell histiocytosis in an adult showing a characteristic erosive lesion in the groin.

Bone marrow. Involvement may be occult or there may be pancytopenia. When bone marrow involvement is severe, splenomegaly is generally present.

Lungs. Primary pulmonary LCH is rare and is usually seen in young or middle-aged adults. In adult patients, smoking is invariably associated with lung involvement, and in any adult smoker with LCH the lung should be examined for possible involvement. Computed tomography is usually more informative in such patients as it identifies lung disease at an earlier stage than chest X-ray. Diagnosis is established by lung biopsy or bronchial lavage, as LCH of the lungs may be impossible to differentiate from other chronic interstitial lung diseases on clinical and radiographic findings.

Pulmonary signs and symptoms are non-specific and are rarely observed until there is frank dysfunction, with dyspnoea, tachypnoea and subcostal recession. Pain and sudden dyspnoea may indicate a pneumothorax due to rupture of a peripheral bulla. Pneumothoraces are common [49], but up to 23% may be asymptomatic.

Fig. 52.10 Langerhans' cell histiocytosis in an adult with multisystem involvement. Scarring is present at sites of previous fistulae from underlying involved lymph nodes. Active skin lesions are scattered over the chest. These are scaly, erythematous, maculopapular lesions. Marked striae are the result of high-dose steroids used in therapy.

Fig. 52.11 Langerhans' cell histiocytosis: involvement of nails in an adult patient showing nail fold destruction. (Courtesy of Dr D.A.R. de Berker, Bristol Royal Infirmary, Bristol, UK.)

Gastrointestinal tract. Liver involvement is very common as part of multisystem LCH, producing hepatomegaly or ascites. Cholestatic jaundice may be a late feature due to fibrotic obstruction of the biliary tree. Diarrhoea may be the result of infiltration of the lamina propria by LCH cells or may be caused by abnormal bile acid metabolism or

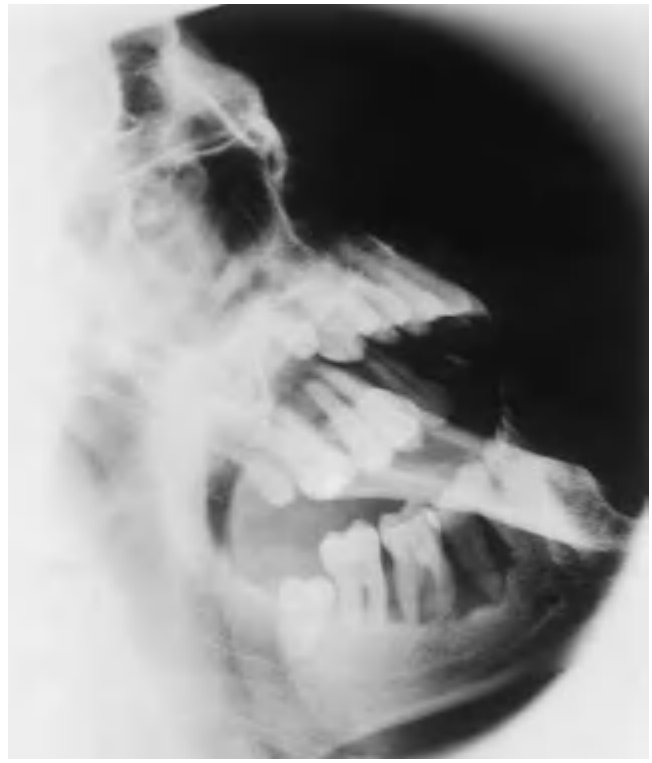

Fig. 52.12 Radiograph of the jaw of an adult with oral involvement in Langerhans' cell histiocytosis. The alveolar bone shows marked reabsorption and the teeth have become detached and appear to be floating.

infection within the gastrointestinal tract. In children, even mild involvement of the gastrointestinal tract, which produces no overt symptoms of diarrhoea, may still cause failure to thrive due to mild malabsorption.

Central nervous system. Diabetes insipidus may be the presenting feature of LCH. Other focal lesions may occur, commonly affecting the cerebellum, temporal lobe and occipital lobe. Intracerebral disease is more frequently seen with bone involvement of the skull. A cerebellar syndrome with ataxia, dysarthria and choreoathetoid movements may be a late sequela of LCH. This is caused by progressive cerebellar atrophy. Biopsies of the cerebellum have so far failed to show infiltration with LCH cells but only gliosis.

Bone. Solitary bone involvement with LCH is common but occasionally goes undiagnosed. The commonest sites are the bones of the calvarium, but femur, scapula, rib, mandible and vertebra are often affected [50]. Lesions may be asymptomatic or may present with swelling over the affected bone, pain or pathological fracture. Radiography is better than radionucleotide studies in detecting bone involvement in LCH [51]. Lesions appear as osteolytic areas that are sharply demarcated and may have a

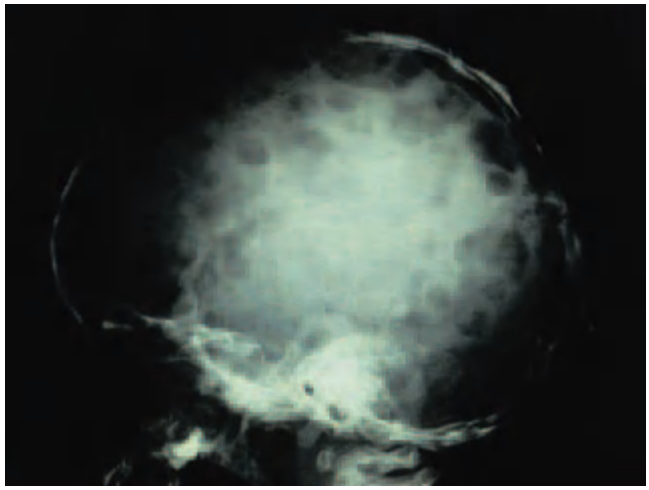

Fig. 52.13 Multiple osteolytic lesions in the skull of an infant with Langerhans' cell histiocytosis.

scalloped border (Fig. 52.13) [52]. When vertebrae are affected, the structural bone is lost and the vertebra may collapse. Spinal cord compression resulting from vertebral collapse has been reported with LCH [24]. Healing of bone lesions is usually seen as peripheral sclerosis of the lytic lesion. Radiographic changes may still be evident for long periods after the disease has been adequately treated or has undergone spontaneous remission.

Endocrine system. Diabetes insipidus is the commonest endocrine problem, the incidence in children with multisystem disease ranging from 22 to 50% [53–55]. Diabetes insipidus may result from pituitary involvement or hypothalamic involvement. Magnetic resonance imaging may show thickening of the pituitary stalk with recent-onset disease.

Short stature in children with LCH has been associated with growth hormone deficiency, which may be secondary to hypothalamic involvement [56]. Some of these children respond to treatment with growth hormone [54,56]. Hypogonadism with delayed puberty and thyroid involvement have also been reported [57,58].

Prognosis. Three important, independent, prognostic indices in LCH are the age of the patient, the extent of the disease and the presence of vital organ failure.

Children under the age of 2 years with multisystem disease have a much poorer prognosis than older children. In a study by Komp *et al.* [58], the mortality in children under the age of 2 years with disseminated LCH was 37% compared with 16% in the group aged over 2 years.

Lahey [59] found a positive relationship between increased mortality rate and widespread organ involvement, but Greenberger *et al.* [60] found that organ failure was a better prognostic indicator than organ involvement. Both Lahey and Greenberger *et al.* [59,60] looked at prognosis in relation to mortality, but since LCH is a reactive rather than a malignant disease, prognosis should consider morbidity as well as mortality. The long-term sequelae of LCH can be related to both disease and treatment. Morbidity caused by the disease itself may be minor (e.g. skin lesions) or there may be major consequences if organs such as the liver, lungs and brain are damaged. Treatment with cytotoxic reagents may result in sterility and may cause leukaemias and other secondary malignancies.

Diagnosis. Pathological diagnosis is most important as many diseases can clinically mimic LCH, and S100 staining or even CD1a staining is insufficient to establish a diagnosis of LCH if the histological picture is not consistent. The differential diagnosis in cutaneous LCH includes seborrhoeic dermatitis, juvenile xanthogranuloma, xanthoma disseminatum and benign cephalic histiocytosis. In disseminated LCH there may be diagnostic problems with familial haemophagocytic lymphohistiocytosis, sinus histiocytosis with massive lymphadenopathy (SHML) and virus-associated haemophagocytic syndrome. Histological examination of tissue biopsy with specific marker studies is usually sufficient to differentiate LCH from these other conditions.

Treatment. Treatment depends on the extent and severity of disease. Patients with single-system bone or skin disease have a good prognosis and often require no or only limited treatment. In one study, McLelland *et al.* [40] showed that in 14 patients with single-system disease, eight required no treatment. In isolated bone disease, curettage to establish the diagnosis may be curative. In weight-bearing bones that are symptomatic, intralesional steroid injections are effective [9]. If vital structures are compromised, such as the optic nerve or spinal cord, low-dose radiotherapy (700–1000 cGy) can be given.

In single-system skin disease, topical treatment with 20% nitrogen mustard is effective [61]. Psoralen and UVA (PUVA) therapy may be useful for those patients who do not tolerate topical nitrogen mustard or fail to respond adequately. Recent reports have shown a good response of isolated skin disease to thalidomide [62].

In multisystem LCH where there is evidence of organ dysfunction, systemic chemotherapy is indicated. Treatment in children should initially be with prednisolone 2 mg/kg for a short course of about 2 months, with dose being adjusted to disease response [40]. Adults tend not to respond to systemic steroids and often suffer severe side effects from their use. In unresponsive disease, disease in adults or more aggressive disease, a number of chemotherapeutic agents have been tried, mainly the vinca alkaloids, especially vinblastine, but also methotrexate and 6-mercaptopurine in combination with prednisolone. Response rates of about 50–70% can be achieved using

these agents. Evidence suggests that the epipodophyllotoxin etoposide as a single drug is better than other drugs tested [63], and ciclosporin and IFN-α have also been beneficial [64]. 2-Chlorodeoxyadenosine, a purine analogue with antiproliferative effects on histiocytes and lymphocytes, has been used in recurrent or high-risk LCH. Treatment is with 5–7 mg/m^2 daily for 5 days every 21–28 days. In a recent study of six children with LCH, five patients remained in clinical remission with a follow-up of 15 months [65].

Class IIa histiocytosis: histiocytoses involving cells of the dermal dendrocyte lineage

Class IIa histiocytoses are non-malignant diseases in which mononuclear phagocytic cells with the dermal dendrocyte phenotype accumulate in various tissues where they may or may not cause symptoms.

In many of these diseases the histological features are of a xanthogranulomatous reaction in the skin. This pattern is seen in juvenile xanthogranuloma, benign cephalic histiocytosis, generalized eruptive histiocytosis, xanthoma disseminatum and necrobiotic xanthogranuloma. In reticulohistiocytosis, the histological features are dominated by the presence of eosinophilic histiocytes with finely granular cytoplasm giving a ground-glass appearance. In some, such as progressive nodular histiocytosis, the cells have a more spindle-shaped appearance in a storiform pattern, particularly as the lesions progress.

Recent histopathological studies have suggested that benign cephalic histiocytosis represents a clinical variant of a xanthogranulomatous reaction rather than being a distinct entity in its own right. In one study [1], biopsies from benign cephalic histiocytosis, generalized eruptive histiocytosis, papular xanthoma and juvenile xanthogranuloma were examined in an observer blinded fashion. In all specimens examined, three distinct patterns of histiocyte proliferation were observed—papillary dermal, lichenoid and diffuse. Benign cephalic histiocytosis, generalized eruptive histiocytosis and early non-xanthomatous juvenile xanthogranuloma could not be specifically differentiated on histopathological grounds. This study certainly suggests that benign cephalic histiocytosis may be a localized form of generalized eruptive histiocytosis or an aborted phase of juvenile xanthogranuloma. In a further study, sequential biopsies were taken from a patient with solitary giant xanthogranuloma and from a patient with benign cephalic histiocytosis. In both cases, early stages of the disease showed infiltration with histiocytes positive for Ki-M1p, HAM56 and factor XIIIa. This was followed by a polymorphic infiltrate of mononuclear and multinuclear histiocytes, which were CD68 positive. This study suggests that both entities are variants of a xanthogranulomatous reaction [2]. In one case report, a 2-year-old girl with clinical, histopathological and ultrastructural benign cephalic histiocytosis developed a varicella-zoster infection with evolution of her skin disease both clinically and histologically to juvenile xanthogranuloma [3]. In a further report of a child with generalized eruptive histiocytosis, where the diagnosis was made on clinical, histological and ultrastructural grounds, the disease progressed with the growth of yellowish confluent papules and the development of diabetes insipidus. At this stage the diagnosis was changed to xanthoma disseminatum [4].

Dermatofibroma

This benign, nodular, dermal lesion is discussed in Chapter 53.

Juvenile xanthogranuloma

SYN. NAEVOXANTHOENDOTHELIOMA; XANTHOMA MULTIPLEX; JUVENILE XANTHOMA; MULTIPLE ERUPTIVE XANTHOMA IN INFANCY; CONGENITAL XANTHOMA TUBEROSUM; XANTHOMA NAEVIFORME; JUVENILE GIANT CELL GRANULOMA

Definition. Juvenile xanthogranulomas are benign tumours of histiocytic cells that occur predominantly in infancy and early childhood and spontaneously regress.

Aetiology. The aetiology of juvenile xanthogranuloma is unknown. The tumours represent accumulations of

differentiated histiocytes. These cells express the phenotype of the dermal dendrocyte, although a recent study has suggested that the cell of origin could be the plasmacytoid monocyte [1]. The appearance of giant cells and foamy lipid-laden histiocytes occurs late, and they are almost certainly secondary events, possibly in response to cytokine production by the lesional histiocyte. Serum lipid levels are normal. Conflicting reports have suggested that juvenile xanthogranuloma can be associated with cytomegalovirus infection. A recent study by Vasconcelos *et al.* [2] has demonstrated early and late cytomegalovirus antigens in some histiocytes in a case of oral juvenile xanthogranuloma.

Pathology. An established lesion shows a mixed cellular dermal infiltrate with histiocytes, lymphocytes, eosinophils and occasional neutrophils and plasma cells. This extends from the epidermis into the subcutaneous fat but epidermal involvement is rare. A typical feature is the presence of giant cells with a wreath-like arrangement of nuclei (Touton giant cells).

In very early lesions, only spindle-shaped fibrohistiocytic cells are seen. In older lesions, foamy lipid-laden histiocytes appear, and resolution is marked by gradual replacement by fibrous tissue. A spindle cell variant of juvenile xanthogranuloma has been described [3].

Immunocytochemical examination in most cases shows that lesional cells are positive for lysozyme, α_1-antichymotrypsin, CD68, fascin, factor XIIIa and may express HLA-DR and CD4, but are negative for S100 protein [4]. However, Tahan *et al.* [5] found a small population of S100 dendritic cells in juvenile xanthogranuloma, which they felt were important in pathogenesis, and Kraus *et al.* [1] have shown reactivity to polyclonal S100 in six of eight specimens they examined. Cells are always CD1a negative.

At the ultrastructural level, the lesional histiocytes do not exhibit Birbeck granules but do show complex interdigitation of the cytoplasmic membrane [6].

Incidence. Half of the cases of juvenile xanthogranuloma have been reported in infants less than 6 months of age. Lesions may occur in children over 3 years of age and cases have been reported in adults [7]. There is no sex association and no familial tendency. Juvenile xanthogranuloma is 10 times more frequent in white than in black people.

Clinical features. The characteristic clinical features of juvenile xanthogranuloma are its onset in infancy, sudden appearance of lesions and spontaneous regression. Most patients develop single lesions, but in others several lesions may develop and occasionally hundreds of lesions may be present. In one case report, a generalized lichenoid variant of xanthogranuloma was described. The eruption consisted of small, flat, shiny papules, which resolved spontaneously [8]. The lesions most commonly occur on the upper part of the body, particularly affecting the face, neck, scalp and upper trunk (Fig. 52.14). Lesions may occur in the oral mucosa with or without skin involvement [9]. They generally start as reddish-yellow papules, which may enlarge up to 1 cm in diameter and evolve into yellow–brown plaques and macules. The lesions are firm and rubbery and can develop surface telangiectasia. Larger lesions, up to 2–3 cm in size, have been reported [10] and ulceration and satellite lesions have been described [11]. Resolution occurs spontaneously over a period of months or years, leaving small atrophic scars. There are no subjective symptoms.

Fig. 52.14 Juvenile xanthogranuloma in an infant with typical lesions on the back.

Visceral involvement may occur in lung, liver, spleen, testes [12], pericardium, gastrointestinal tract, kidney [13], deeper soft tissues [14] and central nervous system. Eye involvement occurs in up to 10% of cases [15] and may lead to secondary glaucoma or may be mistaken for a malignant tumour, such as melanoma or neuroblastoma. The iris is most commonly affected, producing haemorrhage into the anterior chamber, which may result in secondary glaucoma. Infiltration of the orbit, iris, ciliary body and episclera may occur, with unilateral glaucoma, recurrent hyphaema, uveitis, heterochromia, iritis or severe and sudden proptosis [16]. Eye lesions may precede the appearance of skin lesions. Central nervous system involvement is rare but several reports have recently been

published. Lesions may present as isolated or multiple tumours of the brain involving the cortex and cerebellum [17,18], and extensive involvement of cranial nerves has been reported [19]. Central nervous system involvement may occur with or without cutaneous involvement.

Juvenile xanthogranuloma has been associated with neurofibromatosis [20], Niemann–Pick disease [21], myelogenous leukaemia [22], lymphocytic leukaemia [23], urticaria pigmentosa [24] and LCH [25].

Prognosis. Juvenile xanthogranuloma is a self-healing tumour and lesions resolve in 1–5 years.

Diagnosis. Juvenile xanthogranuloma can be differentiated from xanthomas by the distribution of the lesions and the absence of lipid abnormalities. Papular urticaria can be distinguished by the symptomatic nature of the lesions and histology. The major difficulty in clinical diagnosis is with the nodular forms of LCH. Histology and immunocytochemistry will easily differentiate the two disorders.

Treatment. No treatment is necessary for the cutaneous lesions as they are self-healing. Where treatment is indicated in ocular and central nervous system lesions, surgery or radiotherapy gives good results [26]. In patients with symptomatic visceral involvement, chemotherapy with vinca alkaloids has been used successfully [27].

Multicentric reticulohistiocytosis

SYN. RETICULOHISTIOCYTIC GRANULOMA; LIPOID DERMATOARTHRITIS; GIANT CELL HISTIOCYTOMA; RETICULOHISTIOCYTOMA CUTIS; MULTICENTRIC GIANT CELL RETICULOHISTIOCYTOSIS

Definition. This is a rare histiocytic proliferative disease in which joints, skin and mucous membranes are affected [1]. The arthropathy usually precedes nodular skin involvement and mucosal infiltration. Other organs may be involved and 20% of patients have an associated internal malignancy. This must be differentiated from solitary or multiple reticulohistiocytomas that are restricted to skin with neither associated arthropathy nor internal malignancy.

Aetiology. Pathogenesis is unknown. The cells involved are phagocytic histiocytes, and the disease is considered to be a reactive histiocytosis. No infective agent has been implicated but there is evidence of exposure to tuberculosis in some patients. In one study, 33% of patients had evidence of exposure to tuberculosis and 5% of patients had active tuberculosis on clinical examination [2]. There is no recorded genetic link. Those cases with internal malignancy have no clinical or pathological differences from those without associated malignancy.

Pathology. The characteristic pathological picture in the skin and mucous membranes is of infiltration by

mononucleated and multinucleated giant cells with voluminous ground-glass cytoplasm. In early lesions, the predominant infiltrating cells are histiocytes, lymphocytes and eosinophils, with few giant cells, but the giant cell infiltrate quickly follows. The giant cells are large (100 μm) with 1–20 nuclei. The cells are periodic acid–Schiff (PAS) positive and contain variable amounts of lipid and free or esterified cholesterol. In older lesions, fibrosis usually signals regression of the lesions, with a reduction in the inflammatory cell infiltrate.

Recent electron microscopic studies have shown type IV collagen inclusions in multicentric reticulohistiocytosis. These inclusions were both intracytoplasmic and extracytoplasmic. Such inclusions are usually found in lymphohistiocytic neoplasms, suggesting that multicentric reticulohistiocytosis is a proliferative rather than an inflammatory disorder [3].

Immunocytochemical studies show a histiocytic phenotype of the cells, which are positive for acid phosphatase, ATPase, lysozyme, α_1-antitrypsin [4] and factor XIIIa. The cells are also positive for vimentin, CD68 and CD45, but negative for CD1, S100 and CD34 [5]. Cells contain TNF-α, IL-1β and IL-12 [6]. Electron microscopic studies have shown that the cells contain dense bodies, coated vesicles, fat droplets in limiting membranes and myeloid bodies [7].

Clinical features. The disease typically affects women, with a male to female ratio of 1 : 3 [8]. It is a disease of middle age, and rarely affects children [9] and adolescents. Some 60% of patients present with polyarthritis, which typically affects the hands. The interphalangeal joints are affected with symmetrical, erythematous, deforming polyarthritis, which ultimately results in shortening of the fingers and mutilation (Fig. 52.15). Other joints may be involved, including the knees, shoulders, wrists, hips, ankles, feet, elbows, spine and temporomandibular joints. Radiography of the affected joints shows destruction of the articular surfaces, with bone resorption and eventually secondary osteoarthritis [10].

Fig. 52.15 Multicentric reticulohistiocytosis showing the characteristic skin changes, with multiple firm papular lesions on the sides of the fingers and obvious destructive arthropathy. (Courtesy of Professor N. Saxe, Groote Schuur Hospital, Cape Town, South Africa.)

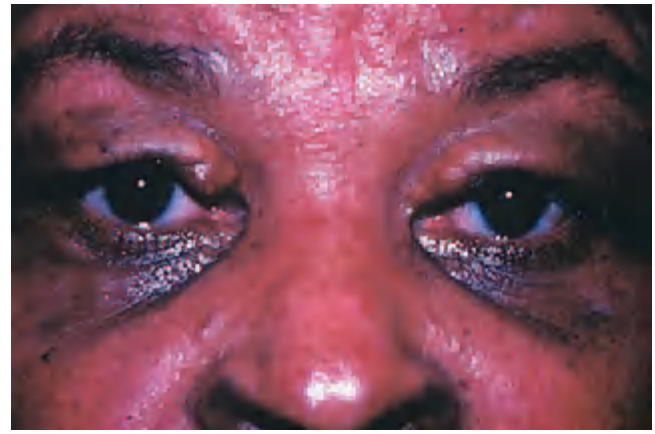

Fig. 52.16 Multicentric reticulohistiocytoma with characteristic lesions around the eyes. (Courtesy of Professor N. Saxe, Groote Schuur Hospital, Cape Town, South Africa.)

The classical skin lesions are firm brown or yellow papules and plaques, which predominantly affect extensor surfaces, particularly on the hands and forearms. The face (Fig. 52.16), scalp, hands and ears are often affected but involvement of the lower trunk and legs is rare. Coral bead-like lesions may occur around the nail folds, which may result in nail dystrophy. Skin lesions are of variable size and rarely ulcerate. Large nodular lesions in proximity to affected joints and cystic swellings of tendon sheaths may occur. About 25% of patients complain of pruritus associated with skin lesions. Diffuse cutaneous reticulohistiocytosis without arthropathy [9] and isolated reticulohistiocytomas [11] have been described. The cutaneous lesions have the same histology as lesions in multicentric reticulohistiocytosis but are not associated with joint problems or neoplasms.

More than 50% of patients have mucosal involvement affecting the mouth, gingiva, pharynx, larynx and sclera. Characteristically, the lips and tongue are involved [12], and 30% of patients have abnormalities of serum lipids. Laboratory findings are normal with a negative rheumatoid factor. Even in the most active stages of the disease, the erythrocyte sedimentation rate is only marginally elevated.

Constitutional symptoms of pyrexia and weight loss may occur. Involvement of bone marrow, skeletal muscle, lymph nodes, heart, pericardium, lungs, pleura, bones, liver, duodenal mesentery and kidney have been reported. Deaths have occurred with cardiac involvement [13]. Multicentric reticulohistiocytosis has been reported in association with Sjögren's syndrome [14] and thyroid involvement [15].

Around 20% of patients have been found to have an associated internal malignancy. The commonest tumours are gastric, ovarian, breast and uterine carcinomas, myeloma [16], melanoma [17] and lymphomas. Rare case reports have described Ki-1 lymphoma occurring in association with multicentric reticulohistiocytosis [18]. Myelodysplastic syndrome has been reported in one patient with multicentric reticulohistiocytosis, although this patient had been treated with cytotoxic drugs for many years and the myelodysplasia may have been drug related [19]. The diagnosis of multicentric reticulohistiocytosis precedes that of the neoplasm in most cases, and the disease may relapse with recurrence of the neoplasm [20].

Prognosis. The prognosis is good if there is no systemic malignancy, the disease becoming quiescent in 7–8 years. Fatal cardiac involvement may occur with widespread systemic involvement [13]. It does, however, leave considerable morbidity, with a crippling arthropathy and scarred skin.

Diagnosis. Biopsy of skin nodules helps to differentiate multicentric reticulohistiocytosis from eruptive xanthomas and juvenile xanthogranulomas. The disease can usually be clinically differentiated from other disorders involving cutaneous nodules and arthritis (e.g. rheumatoid arthritis, sarcoidosis, gout and xanthomatosis).

Treatment. No treatment is of consistent value in this disease. Systemic steroids may be successful for brief periods but their long-term value is uncertain. Combination of systemic steroids with azathiopine has been used with success [21]. Non-steroidal anti-inflammatory agents have no effect on the arthropathy. Immunosuppressive drugs give variable results. Cyclophosphamide is reported to give high success rates [22], and ciclosporin has been reported to give good results [23].

Benign cephalic histiocytosis

SYN. PAPULAR HISTIOCYTOSIS OF THE HEAD

This is a rare self-limiting histiocytosis that typically starts at the end of the first year of life [1]. Erythematous papules, nodules and macules develop on the cheeks and spread to the forehead, earlobes and neck. The lesions, which are asymptomatic, gradually become reddish-brown and may spread onto the trunk, upper limbs and rarely the buttocks. Mucous membrane involvement has not been described.

No sex predisposition has been reported. The disease is self-limiting, and in 13 cases the mean age at resolution was 9 years [2]. In one case report, a 5-year-old girl developed diabetes insipidus 1 year after presenting with typical benign cephalic histiocytosis. Imaging demonstrated infiltration of the pituitary stalk [3]. Histologically, the epidermis is thinned over a well-circumscribed histiocytic infiltrate in the superficial and mid-dermis. In older lesions, a few giant cells may be present. The cells are S100 negative [4]. Electron microscopy shows that 5–30% of the infiltrating cells have cytoplasm rich in comma-shaped bodies and coated vesicles [2]. Dense bodies may be present and worm-like bodies have been described [5]. Since the condition is self-limiting, no therapy is indicated.

Erdheim–Chester disease

SYN. UBER LIPOIDGRANULOMATOSE

This is a rare lipoid granulomatosis characterized by infiltration of viscera, bones, retroperitoneum and skin. It was first described by William Chester while working in the laboratory of Jakob Erdheim in 1930 [1] and the eponym was first used by Jaffe in 1972 [2].

Veyssier-Belot *et al.* [3] reviewed the literature on Erdheim–Chester disease in a comprehensive study of 59 patients. The age range was 7–84 years with a mean of 53 ± 14 years, and there was a male to female ratio of 33 : 26. The most common presentation is with chronic mild bone pain, particularly of the lower limbs. Radiography shows symmetrical sclerosis, typically affecting the long bones, with involvement of the diaphyseal and metaphyseal regions; 86% of reported cases have involvement of the long bones [4], with the distal femur, proximal tibia and fibula being most commonly affected [5]. Up to 30% of patients show lytic lesions of flat bones, which can cause problems in differentiating this disease from LCH.

Half of patients have extraosseous involvement involving the retroperitoneal space, lungs, heart, kidneys, liver, pituitary, central nervous system, orbit and skin. Approximately 30% of patients have exophthalmos, diabetes insipidus or retroperitoneal involvement. Retroperitoneal disease is often asymptomatic and may develop over many years. It may present with dysuria, abdominal pain, obstructive renal damage or renal artery stenosis [6]. Skin involvement is seen in about 20% of patients, usually presenting with xanthoma-like lesions, usually on the eyelids but occasionally on the trunk and submammary area. Two patients have been reported with cutaneous masses. Lung disease is seen in 35% of patients, with accumulation of histiocytes and fibrosis in a perilymphatic and subpleural pattern. It is generally asymptomatic and found on chest X-ray with diffuse interstitial fibrosis or infiltration. Advanced pulmonary involvement is associated with extensive fibrosis, which may result in cardiopulmonary failure. Prognosis tends to be poor despite treatment [7]. Pericardial involvement is uncommon and myocardial involvement has not been described, but three reported cases died of heart failure. Central nervous system involvement is seen in 15% of patients, presenting with ataxia, paraparesis, hemiparesis or change in mental state. Imaging has shown thickening of the dura, with infiltration extending into the cerebellum. More rarely, intracerebral masses have been described. A case of slowly progressive cerebellar syndrome, similar to that seen in LCH, has been reported in a 50-year-old patient with Erdheim–Chester disease associated with unilateral exophthalmos, secondary hypogonadism and skin lesions [8].

Histological examination shows a xanthogranulomatous infiltration by lipid-laden histiocytes within a mesh and surrounded by fibrosis. Touton giant cells and eosinophils may be prominent. Cells are positive for CD68 and factor XIIIa [6] but negative for CD1a and S100 [9]. In one study of a 35-year-old woman with Erdheim–Chester disease, clonality studies based on the *HUMARA* assay in paraffin-embedded tissue showed only random distribution of allele activation and thus no evidence of clonality [10].

A variety of treatments have been used in Erdheim–Chester disease, including IFN-α [11], corticosteroids, radiotherapy, vinblastine, vincristine, cyclophosphamide [3] and 2-chlorodeoxyadenosine [12], with variable responses. There is no clear consensus as to the best therapeutic regimen. Overall mortality is 57%, with death resulting from pulmonary, cardiac or renal failure [3].

Fat-storing hamartoma of dermal dendrocytes

A single case report has described this entity [1]. The patient was a 30-year-old man who had a very large, circumscribed, red-brown plaque in the lumbosacral area. The plaque was composed of firm papules and nodules and was asymptomatic. The lesion had been present since birth and had slowly grown since that time.

Histology showed a slightly acanthotic epidermis and a Grenz zone, below which was a dense infiltrate of foamy histiocytes, which extended deep into the dermis. Occasional Touton giant cells were present. Lesional cells stained for factor XIIIa and vimentin and 40% of the cells labelled with Mac-387, a monoclonal antibody directed against monocyte-derived macrophages. S100 and CD1a staining were negative. Electron microscopy showed large histiocytic cells with convoluted nuclei filled with lipid droplets.

Generalized eruptive histiocytoma

This is a rare cutaneous histiocytosis that mainly affects adults [1], although children with the disease have been reported [2,3]. Clinically, the disease presents as multiple symmetrical papules that occur on the face, trunk and proximal extremities. The papules are skin coloured, brownish or blue-red and tend to come up in crops, although they are not grouped. The number of lesions is variable but may reach hundreds. Mucosal lesions are rare. The lesions are asymptomatic and resolve spontaneously to leave a macular area of hyperpigmentation.

Histology shows a proliferation of monomorphic histiocytic cells in the upper and mid dermis. No giant cells or foam cells are present. Scattered lymphocytes may be present. Ultrastructural studies have shown that the histiocytic cells lack Birbeck granules but do have cytoplasmic laminated bodies [4]. These bodies are often clustered in the cytoplasm of the cells and each measure about 1.5 μm. They are not restricted to generalized histiocytoma but have been reported in congenital self-healing histiocytosis [5].

In one case report of a 4-year-old boy with generalized eruptive histiocytoma, diagnosed using clinical, histological and ultrastructural studies, the patient subsequently developed a new eruption of yellowish confluent papules with associated diabetes insipidus. Histology of the lesions and ultrastructure confirmed the diagnosis of xanthoma disseminatum. The authors suggest that generalized eruptive histiocytoma and xanthoma disseminatum are variants of a continuous spectrum of histiocytoses [3].

Papular xanthoma

This is a rare histiocytic disorder that was first described in adults [1] and subsequently reported in children [2]. Whether it represents a separate clinicopathological entity or a variant of other xanthogranulomatous conditions is open to debate. Clinically it can resemble juvenile xanthogranuloma but has not been associated with systemic involvement or café-au-lait spots, and may resemble xanthoma disseminatum but papules do not coalesce and there is no predilection for flexures.

Clinically, papular xanthoma is characterized by 2–15 mm yellow or reddish-yellow papules affecting both skin and mucous membranes. The back and head are most commonly affected. There are marked clinical differences between papular xanthoma occurring in adults and children. Mucous membranes are affected in adults but this has not been reported in children. In adults progessive disease has been reported [3] but in children spontaneous resolution is the norm, with involution starting after weeks or months and being complete in 1–5 years, often leaving anetoderma-like scarring [4].

Histologically, there is an upper- and mid-dermal infiltrate of foamy histiocytes and giant cells. Few inflammatory cells are present. Histiocytic cells are positive for CD68 and factor XIIIa and negative for S100 and CD1a [2]. One case report in a 13-month-old boy demonstrated that the cells were CD68 positive but factor XIIIa negative. In such a rare condition, further studies are needed to confirm the dermal dendrocyte origin of lesional cells [5]. Electron microscopy shows similar changes to those seen in mature juvenile xanthogranuloma, with myeloid bodies filling the cytoplasm of the histiocytes with associated lysosomal inclusions, laminate bodies and lipid droplets.

No treatment is needed in children while none is effective in adults.

Progressive nodular histiocytosis

SYN. PROGRESSIVE NODULAR HISTIOCYTOMA; SPINDLE CELL XANTHOGRANULOMA

This is a rare histiocytosis first described by Taunton *et al.* [1] in 1978. The eruption consists of two different types of lesions, superficial papules and deep nodules, both of which may number into hundreds [2,3]. Papules are 2–10 mm and yellow-orange (Fig. 52.17). Nodules are 1–5 cm and may be skin coloured or reddish-orange. Distribution is random with no predilection for the flexures. Lesions may occur in the oral cavity, larynx and conjunctival mucosa.

Over the years new lesions may develop and although patients remain in good general health, the eruption may be very disfiguring causing a marked reduction in quality of life.

Histologically, this is a dermal disease with neither epidermal involvement nor epidermotropism. Early lesions show an accumulation of xanthomatized and scalloped histiocytes with some infiltrating lymphocytes. In older lesions the histiocytes are spindle shaped and arranged in a storiform pattern. Occasional giant cells may be present. Cells are positive for CD68 and factor XIIIa and negative for S100 and CD1a [4].

Progressive nodular histiocytosis is not generally associated with systemic involvement or other disorders. In one case report, a 57-year-old man had suffered from progesssive nodular histiocytosis for 26 years and during that time had developed chronic myeloid leukaemia, hepatosplenomegaly, hypothyroidism, hyperuricaemia and hypocholesterolaemia, although the relationship between progressive nodular histiocytosis and the systemic disorders remains unclear [5].

Progressive nodular histiocytosis is a benign disease and no treatment has yet been shown to be effective in reducing the size of skin lesions or in inducing remission.

Xanthoma disseminatum

SYN. DISSEMINATED XANTHOSIDEROHISTIOCYTOSIS; MONTGOMERY'S DISEASE

This is a rare non-familial disease, characterized by proliferation of histiocytic cells in which lipid deposition is a secondary event. The disease predominantly affects male children and young adults, with involvement of the skin, mucous membranes of eyes and upper respiratory tract, the meninges and rarely other organs including liver, spleen and bone marrow [1–4].

The clinical lesions of xanthoma disseminatum are erythematous, yellow-brown papules and nodules, which are symmetrically distributed on the trunk, face and proximal extremities (Fig. 52.18). The lesions become confluent, especially in flexures, to form xanthomatous plaques, which may become verrucous (Fig. 52.19). In 30% of patients, the mucous membranes are affected, with particular involvement of the lips, pharynx, larynx, conjunctivae and bronchus. Respiratory tract involvement has been fatal in one reported case of a 61-year-old woman with involvement of large and medium-sized bronchi who died of acute respiratory failure [5]. Meningeal involvement is common, with infiltration at the base of the brain leading to diabetes insipidus in up to 40% of cases. Other manifestations of meningeal involvement are seizures and growth retardation. Intracranial involvement presenting as a discrete mass simulating glioma has been reported [6]. Progressive bone disease has been reported in xanthoma disseminatum [7,8], but this is a rare complication of the disease. One case report demonstrated hepatic involvement on computed tomographic

Fig. 52.18 Xanthoma disseminatum. (Courtesy of Dr R. Cerio, St John's Dermatology Centre, London, UK.)

Fig. 52.19 Xanthoma disseminatum with verrucous lesions over the back of a 10-year-old boy.

examination [9]. Lytic bone lesions have been reported in a patient with xanthoma disseminatum, although the clinical features of the patient were atypical for this diagnosis [10].

A clinical variant of this disease was described by Halprin and Lorincz [11] under the name xanthosiderohistiocytosis. In this variant, there is diffuse infiltration of the skin, subcutaneous tissue and muscle, giving rise to sclerodermatous changes in the skin and muscle wasting. The foamy histiocytes that are involved contain significant amounts of iron, which gives the skin a greenish-brown colour.

Histologically, xanthoma disseminatum is a dermal disease, characterized by early infiltration of the dermis with spindle-shaped mononuclear cells, foamy histiocytes, giant cells, lymphocytes, polymorphs and eosinophils. Lesional cells in xanthoma disseminatum have irregular scalloped borders with extensive cytoplasm and ovoid vesicular nuclei. Cells label strongly with factor XIIIa and KP1 [12]. Iron and lipid can be detected in the histiocytes. In older lesions, more foamy histiocytes are evident and Touton giant cells may be observed. At the ultrastructural level, histiocytic cells contain myeloid bodies and membrane-bound fat droplets.

Xanthoma disseminatum is a self-limiting disease but may persist for years. Lesions are only mildly radiosensitive. Skin lesions of xanthoma disseminatum are disfiguring and patients often request treatment. The carbon dioxide laser has been used with good results [13]. Conjunctival involvement can be treated with surgery.

Class IIb histiocytosis: histiocytoses involving cells other than Langerhans' cells and dermal dendrocytes

Diffuse plane xanthomatosis

SYN. ATYPICAL XANTHOMA DISSEMINATUM; DIFFUSE NORMOLIPAEMIC PLANE XANTHOMATOSIS

This is a rare non-lipaemic disease in which xanthomatous lesions develop in the skin in association with paraproteinaemia. Patients present with large, flat, plaque-like, xanthomatous skin lesions involving the eyelids, neck, upper trunk, buttocks and flexures [1,2]. Serum lipids are usually normal. About 50% of patients have a myeloproliferative disorder with multiple myeloma, granulocytic or lymphocytic leukaemia [3]. The majority of patients have a circulating paraprotein and have some abnormalities of serum complement [4,5].

The histological features include both xanthomatous and inflammatory elements. Accumulations of foamy macrophages infiltrate the dermis, with a distinct perivascular accentuation, and are associated to a variable degree with a mixed inflammatory cell reaction.

The condition arises as a result of perivascular deposition of lipoprotein–immunoglobulin complexes. Antilipoprotein antibodies are formed in association with paraproteinaemia [5]. Although serum lipid levels are usually normal, they may be raised, possibly due to reduced clearance of lipoprotein–antibody complexes. Treatment of this condition is that of the underlying myeloproliferative disease or paraprotein. Theoretically, plasma exchange should be of value but its use has not yet been reported.

Familial haemophagocytic lymphohistiocytosis

SYN. FAMILIAL HAEMOPHAGOCYTIC RETICULOSIS; GENERALIZED LYMPHOHISTIOCYTIC INFILTRATION; FAMILIAL ERYTHROPHAGOCYTIC LYMPHOHISTIOCYTOSIS; FAMILIAL HISTIOCYTIC RETICULOSIS; FAMILIAL LYMPHOHISTIOCYTOSIS; FARQUHAR'S DISEASE

This is a rare reactive histiocytosis in which there is widespread infiltration of multiple organs by lymphocytes and mature histiocytes showing prominent cytophagocytosis. It is rapidly fatal in most patients. The incidence is 1.2 per million children [1], with a slight preponderance in boys. Three-quarters of cases are familial, and it is generally considered to be an autosomal recessive disease [2].

The gene responsible is unknown, but in one patient a constitutional inversion 9 (p23;q31) was observed in cells from bone marrow, lymphocytes and fibroblasts [3]. Studies have now identified mutations of the perforin gene on chromosome 9 in 10% of cases [4].

Fever is usually the first sign, with symptoms of an upper respiratory or gastrointestinal tract infection in 30%. Pallor, anorexia, vomiting and irritability are often noted. Hepatosplenomegaly is usually present at presentation and is progressive. Moderate lymphadenopathy is common. Around 50% of patients develop a transient, non-specific, maculopapular rash, which is often seen at times of high fever, but no persistent skin infiltration is seen. About 20% of patients have neurological symptoms, due to meningeal involvement, usually with convulsions but also with other signs of meningeal irritation.

Laboratory tests show anaemia, thrombocytopenia and raised liver enzymes and hyperbilirubin. Hyperlipidaemia (with elevation of triglycerides and very low-density lipoproteins) and hypofibrinogenaemia are common.

Immunological testing shows abnormalities of both the humoral and cellular limbs of the immune system. Natural antibody titres are low, antibody titres after previous immunization are low and there is an impaired response to primary immunization. All T-cell responses to mitogens, antigens and alloantigens are reduced. There is also a T-cell-suppressor factor, probably related to triglycerides, in the plasma of the patients [5]. Cytotoxic T-cell and natural killer cell activity is markedly reduced or absent in affected patients. Recent studies have shown mutations in a lytic granule constituent, perforin, in a number of individuals with familial haemophagocytic lymphohistiocytosis. A study of 34 families and linkage studies of a subset of consanguineous families indicates that perforin mutations account for 20–40% of cases of familial haemophagocytic lymphohistiocytosis and that the familial haemophagocytic lymphohistiocytosis I locus on chromosome 9 accounts for approximately 10% of cases [4]. The mutation in the perforin gene occurs at position 374, resulting in a premature stop codon. Other mutations include nonsense and missense mutations and deletions of amino acids [6].

A number of studies have now demonstrated hypercytokinaemia in this disease, with elevated circulating IFN-γ, TNF-α and IL-6 during active disease [7]. Serum levels of IL-6 have been shown to be of no prognostic importance [8]. Soluble CD8 has also been shown to be elevated, suggesting a role for cytotoxic T cells in the pathogenesis of this disease.

Histologically, the involved tissue shows a diffuse infiltrate with lymphocytes and mature histiocytes. The histiocytes exhibit active phagocytosis, especially of erythrocytes but also of leukocytes and occasionally platelets. The histiocytes stain positively for acid phosphatase, non-specific esterase, lysozyme and α_1-antichymotrypsin. A striking histological finding is lymphocyte depletion of lymph nodes, spleen and thymus.

Prognosis is poor, with median survival of 2–3 months [9] from diagnosis and 96% dying within 12 months. Central nervous system disease and persistently low natural killer cell activity are associated with poorer prognosis [10]. Long-term survivors have been reported after chemotherapy, but maintenance therapy is always required.

Initial treatment regimens used splenectomy, exchange transfusion [11] and chemotherapy [12], including vinblastine and intrathecal methotrexate. Recently, Henter *et al.* [13] reported a more successful regimen using etoposide and teniposide with prednisolone and intrathecal methotrexate until remission is achieved, followed by maintenance therapy with teniposide or etoposide.

Bone marrow transplantation and haemopoietic stem cell transplantation are now regarded as being the most effective treatments for this disease. Results are much better when HLA-identical siblings are used as donors. Studies have now shown that even partial engraftment is compatible with long-term remission [10,14].

Familial sea-blue histiocytosis

This is a rare inherited abnormality of lipid metabolism [1] in which characteristic histiocytic cells are found in the bone marrow and other tissues. The histiocytes are identified by the May–Gruenwald stain, which colours the cytoplasmic granules a deep azure blue, hence the name 'sea-blue histiocytosis'.

Familial sea-blue histiocytosis in an autosomal recessive trait [2]. It usually presents in young adulthood with hepatosplenomegaly and thrombocytopenia, although the age at presentation ranges from 1 to 83 years. The skin, lungs, gastrointestinal tract, eye and nervous system may be involved. In the skin, patchy and irregular brownish-grey pigmentation of the face, upper chest and shoulders has been reported. In one case [3], skin involvement, with eyelid swelling and facial nodules, was confirmed histologically. In the eye, white stippled deposits may be observed at the margins of the fovea or macula, with discoloration of the macular region. Neurological symptoms occur early, with ataxia, epilepsy and dementia.

Sea-blue histiocytosis is not malignant, but it may disseminate and lead to death from liver or lung involvement. The biological abnormality is poorly understood, but the condition probably represents a storage disease in which glycolipid, phospholipid or both accumulate in histiocytic cells in various organs. Sea-blue histiocytes have also been described in chronic myelogenous leukaemia [4,5], adult Niemann–Pick disease [6], following the prolonged use of intravenous fat emulsions in children [7] and in partial sphingomyelinase deficiency [8].

Hereditary progressive mucinous histiocytosis

This is a rare autosomal dominant genodermatosis, which was first described in 1988. Skin lesions appear in the first decade of life and gradually increase throughout life. Lesions consist of skin-coloured to red-brown papules that characteristically affect the nose, hands, forearms and thighs. Two sets of case reports have described mothers and daughters who have both presented with the disease [1,2]. Histologically, the epidermis is normal but within the dermis there are small collections of epithelioid histiocytes with telangiectatic vessels in the upper dermis in early lesions. As tumours develop, the infiltrate changes to nodular mid-dermal aggregates of tightly packed, spindle-shaped cells. In both early and established lesions, there is moderate to extensive mucin production by the epithelioid histiocytes and spindle-shaped cells. On electron microscopy, the spindle-shaped cells are shown to be dendritic histiocytes with abundant lysosomal storage organelles, myelin bodies and zebra bodies.

Immunohistochemically, these cells stain with CD68 and MS1 [3]. The condition is progressive, with gradual increase in numbers of tumours throughout life. These patients show no evidence of spontaneous resolution. No systemic involvement has been described and no treatment seems to have any impact on the disease [4].

Malakoplakia

Malakoplakia is an immunodeficiency disease in which macrophages fail to phagocytose and digest bacteria adequately. The term 'malakoplakia', which means soft plaque, was adopted as a descriptive term [1].

Malakoplakia can affect many organs but most commonly affects the urinary and gastrointestinal tracts [2]. Cutaneous lesions are rare, non-specific and variable. Draining abscesses, sinuses, ulcers, fluctuant masses, isolated tender nodules and grouped papules have been reported. Mucous membranes may be affected, including the tongue [3] and cervix [4]. The disease generally runs a benign self-limiting course, but fatal cases have been reported [5].

Histologically, sheets of large histiocytic cells with abundant cytoplasm are present in the skin, affecting any level from epidermis to subcutaneous fat. The cells have fine eosinophilic granules in their cytoplasm and are referred to as Hansemann cells. They also contain one or more round basophilic inclusion bodies (Michaelis–Gutmann bodies). Michaelis–Gutmann bodies are 5–15 μm and stain positively with PAS, von Kossa stain (for calcium) and Perls ferrocyanide reaction (for ferric iron). They are considered pathognomonic for this disease and are thought to represent abnormal degradation of bacteria, with calcium and iron deposited on the remaining glycolipid.

The commonest bacterium found in this disease is *Escherichia coli* [6–8], although *Staphylococcus aureus* has also been cultured [9]. Recently, mycobacteria have been identified in two cases of cutaneous malakoplakia using polyclonal anti-*Mycobacteria bovis* antibodies [10]. In some patients, the disease is related to drug-induced immunosuppression [11]. In one patient [6], intracellular cyclic guanosine monophosphate (cGMP) levels were found to be low, and *in vivo* and *in vitro* treatment of the cells with bethanechol chloride, a cholinergic agonist, increased cGMP and restored their bactericidal activity.

Necrobiotic xanthogranuloma

The syndrome of necrobiosis with xanthomatous granulomas and an associated paraprotein has been recognized since 1966 [1–3], but it was not until 1980 that it was recognized as a distinct dermatosis [4].

The characteristic clinical lesions are periorbital nodular and ulcerative lesions, which have the reddish-yellow colour of xanthomas (Fig. 52.20). On the trunk and limbs,

Fig. 52.20 Early lesions of necrobiotic xanthogranuloma with characteristic distribution in the periorbital area. (Courtesy of Dr A. Layton, Leeds General Infirmary, Leeds, UK.)

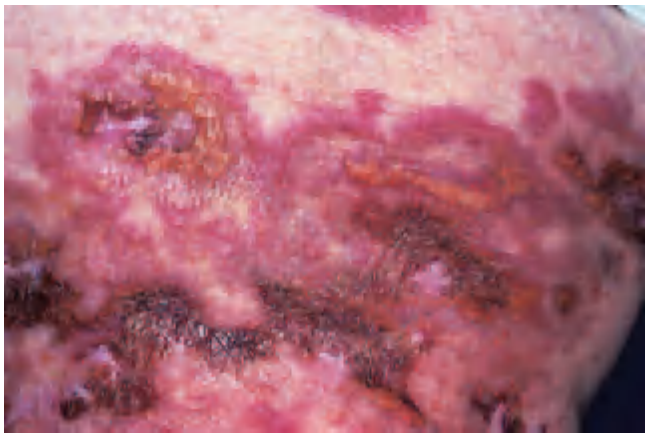

Fig. 52.21 Established lesions of necrobiotic xanthogranuloma on the abdomen showing xanthomatous plaques and atrophy. (Courtesy of Dr P. Holt, University Hospital, Cardiff, UK.)

subcutaneous nodules and xanthomatous plaques are present with atrophy and ulceration (Fig. 52.21). The eyes are often affected with conjunctivitis, keratitis, uveitis, iritis and proptosis. Blindness has been reported in two affected patients [4]. Systemic symptoms have been reported, including nausea, vomiting, fatigue, epistaxis, back pain and Raynaud's phenomenon. Atypical forms of necrobiotic xanthogranuloma have been reported, including solitary tumours of the skin [5].

The majority of cases have an associated paraprotein, usually an IgG κ or λ monoclonal protein. In a series of 22 patients, 16 had IgG monoclonal protein, three had multiple myeloma, three had cryoglobulinaemia and one had normal serum protein electrophoresis [6].

Decreased levels of C1 inhibitor have been reported in some patients with necrobiotic xanthogranuloma, occasionally associated with angio-oedema. Immune complex formation resulting from autoantibodies against the paraproteins have been implicated in the depletion of C1 inactivator [7].

Histologically, confluent granulomatous masses are present as either sheets or nodules, replacing much of the dermis and extending into the subcutaneous tissue [8]. Hyaline areas of necrobiosis separate individual nodules. Numerous giant cells are present, with Touton cells and bizarre angulated giant cells. Cholesterol clefts, lymphoid nodules (some of which develop germinal centres) and perivascular aggregates of plasma cells are frequent features. Less common, but characteristic when present, are palisading cholesterol cleft granulomas and xanthogranulomatous panniculitis. Granulomatous invasion of blood vessels with thrombosis has been described.

The pathogenesis of necrobiotic xanthogranuloma is unknown. Bullock *et al.* [9] suggested that the abnormal paraprotein becomes complexed with lipid and deposited in the skin, where it produces a foreign-body granulomatous reaction.

Treatment is generally directed to the associated paraproteinaemia. Alkylating agents such as melphalan, with or without prednisolone, have resulted in temporary clearing of the skin [10]. In one patient where cytotoxic drugs had failed, plasmapheresis reduced the level of the circulating monoclonal IgG and resulted in clearing of the skin [11]. Successful treatment with chlorambucil 2 mg/day for 7 months has been reported in a 51-year-old man with necrobiotic xanthogranuloma and associated paraproteinaemia [12]. Radiotherapy was successful in one case involving the eye [13].

Sinus histiocytosis with massive lymphadenopathy

SYN. ROSAI–DORFMAN DISEASE

SHML is a rare histiocytic proliferative disorder that is defined by its histopathological features [1,2]. A registry of this disease now contains information on 423 patients [3].

SHML is currently considered to be a reactive rather than a malignant histiocytosis. An infectious cause has been suggested by the occurrence of fever and pharyngitis, which often precede the onset of SHML. However, the search for a possible infectious agent has been inconclusive. Some patients show evidence of Epstein–Barr virus infection while others have demonstrable infection with *Klebsiella rhinoscleroma* and *Brucella*, but these are not consistent findings. A recent study failed to show evidence of human herpesvirus 6 and 8 in skin lesions [4].

The onset of SHML is usually in young adults, with a range from birth to 74 years. The sex incidence is equal. Clinical presentation is usually with painless lymph node enlargement, which may reach massive proportions. About 90% of patients present with cervical adenopathy, the rest presenting with axillary, inguinal or mediastinal node enlargement. Fever, weight loss, malaise and night sweats have been reported, usually at presentation.

Extranodal involvement is common, with 43% of patients having at least one extranodal site of involvement. Skin is the most common extranodal site and may be involved without nodal disease. Pure cutaneous SHML may remain localized to the skin with no systemic involvement even with long-term follow-up [5]. Skin lesions are normally yellow, but may be violaceous or purple. Macular erythema, papules, nodules or infiltrated plaques have been reported. Scaling is often present and telangiectasia may be observed. Skin lesions may occur at any site [6]. Of patients with skin SHML, 50% have evidence of one or more additional extranodal sites, particularly involving the nasal cavity, with polyps and paranasal sinuses.

Other organs involved in SHML include bone, salivary gland, central nervous system, genitourinary system, lower respiratory tract, liver, gastrointestinal tract, heart and thyroid gland. Isolated central nervous system involvement in SHML is well recognized. In a report of 11 cases, seven were male and four female, with an age range of 22–64 years. Presentation was with headaches, seizures, numbness or paraplegia. Eight cases involved the cranial area and three the spinal cord. Most lesions were dura based and only one case involved the brain parenchyma [7]. Treatment of these patients was surgical, with one patient dying of surgical complications and nine showing no evidence of disease progression after a mean of 15 months follow-up.

Laboratory investigations usually show a mild normochromic normocytic anaemia or hypochromic microcytic anaemia with elevation of erythrocyte sedimentation rate. Serum proteins are often abnormal, with a low serum albumin and polyclonal gammopathy. Serum lipids are normal.

Histology of involved nodes reveals the pathognomonic features of SHML. The sinuses are expanded by large pale histiocytes. The histiocytes have abundant pale-pink cytoplasm and indistinct margins or may have glassy eosinophilic cytoplasm and well-defined cytoplasmic membrane. Nuclei are round or oval, usually with a single small nucleolus. Occasionally, multinucleate cells or cells showing nuclear atypia are present but mitoses are rare. Lymphophagocytosis or emperipolesis (phagocytosis of leukocytes, particularly lymphocytes) is always present, and less frequently intracytoplasmic plasma cells, neutrophils and red blood cells may be seen. Between the expanded sinuses, lymphocytes and plasma cells are present and reactive germinal centres are occasionally seen. Rarely, neutrophils are observed scattered throughout the involved node. Electron microscopy shows numerous lipid vacuoles and moderate numbers of lysosomes in the cytoplasm of the histiocytes. The surface of the cells is often thrown into complex convoluted villous processes.

In extranodal SHML, the histological picture is strikingly similar to that seen with nodal disease, with what appears to be abnormal lymph node architecture, dilated sinuses and reactive germinal centres in the extranodal site. Extranodal SHML usually shows more fibrosis and lymphophagocytosis.

On immunophenotypic analysis, SHML cells show pan-macrophage markers (EBM11, HAM56 and Leu M3, FcIgG and C3 receptors), monocyte markers (OKM5 and Leu M1), activation antigens (Ki-1, transferrin receptor and CD25) and lysosomal enzymes (lysozyme and α_1-antichymotrypsin) [8]. Surprisingly, however, these cells also display factor XIIIa, a marker of dermal dendrocytes [9], and the S100 antigen that is usually present on dendritic cells; and of two frozen samples tested, both were positive for NA1/34, one for OKT6 but neither for Leu 6. These three monoclonal antibodies react with different epitopes on CD1a, which is characteristic for Langerhans' cells. The exact cell lineage is therefore still uncertain.

The prognosis in SHML is reasonably good. In 238 patients followed for more than a year [6], 49 were well and clear of the disease, 126 had persistent disease, three had progressive disease and 21 patients died, although four deaths were unrelated to SHML. Poor prognostic features in this disease are immunological abnormalities and multiple extranodal sites of disease.

Many treatments have been tried, including the vinca alkaloids, etoposide, ciclosporin and X-rays but no ideal treatment has been identified and the response is poor [10]. A recent review of the literature showed that 32 of 40 patients received no treatment and underwent spontaneous regression. Radiotherapy gave complete remission in

three of nine patients. Surgical debulking was successful in eight of nine patients, resulting in complete remission. Chemotherapy was generally unsuccessful [11].

Virus-associated haemophagocytic syndrome

SYN. VIRUS-INDUCED HISTIOCYTOSIS WITH ERYTHROPHAGOCYTOSIS; VIRUS-INDUCED HISTIOCYTIC MEDULLARY RETICULOSIS

Virus-associated haemophagocytic syndrome is a rare reactive histiocytosis in patients with an active viral infection. Patients can be divided into two groups: group 1 have no evidence of underlying disease; group 2 are receiving immunosuppressive therapy for underlying disease [1–3]. The disease results from a cytokine storm derived from an inappropriate immune reaction caused by proliferating or activated T cells or natural killer cells associated with macrophage activation or inadequate apoptosis of immunoresponsive cells.

Any age group can be affected and, although children and neonates are often affected, many adult cases have been reported. The syndrome presents suddenly with fever, constitutional symptoms, hepatosplenomegaly, lymphadenopathy, pancytopenia, coagulopathies with thrombocytopenia and hypofibrinogenaemia, raised liver enzymes and bilirubin, pulmonary involvement and skin rashes. Non-specific, generalized, macular eruptions occur fairly frequently.

The viruses implicated include adenovirus, herpesvirus [4], human herpesvirus 6 [5], Epstein–Barr virus and measles virus [6]. In the bone marrow, lymph nodes and other involved tissue, there is infiltration by histiocytes showing erythrophagocytosis. These cells are banal-looking histiocytes with no cytological evidence of malignancy.

The differential diagnosis includes familial haemophagocytic lymphohistiocytosis, malignant histiocytosis and LCH. In the past, many patients with virus-associated haemophagocytic syndrome have been misdiagnosed as malignant histiocytosis and given inappropriate treatment with cytotoxic drugs. It is important to differentiate between these two entities, as the administration of cytotoxic drugs in a viral disease such as virus-associated haemophagocytic syndrome can precipitate a fulminant fatal infection.

The prognosis is variable. In a series of 19 patients [7], 30% died in the acute stages of the disease. The other patients recovered completely in 1–8 weeks with no recurrence in a follow-up period of 32 months. Prognosis is related to prompt introduction of immunosuppressive therapy to control the cytokine storm; ciclosporin or systemic steroids are used in low-risk groups and etoposide-containing regimens in high-risk groups [8].

Class III histiocytosis: malignant histiocytoses

Class III histiocytoses are malignancies of the monocyte/macrophage series of cells. These diseases are separated into monocytic leukaemia, malignant histiocytosis and true histiocytic lymphoma on clinical criteria, but there is an enormous overlap and it may not always be possible to differentiate them.

In monocytic leukaemia, the malignancy primarily affects the bone marrow and blood but extramedullary

involvement is common. In malignant histiocytosis, the histiocytes retain their ability to migrate through the body, which results in widespread involvement of the reticuloendothelial system. In true histiocytic lymphoma, the cells are derived from fixed tissue histiocytes and the tumours are localized, although they may disseminate.

In a recent study by the International Lymphoma Study Group [1], tumours of histiocytes were phenotypically assessed using a panel of markers. Four groups were identified:

1 Histiocytic sacrcoma: CD68 and lysozyme positive, CD1a and CD21/35 negative, with 33% showing S100 reactivity. This tumour was predominantly extranodal and associated with a high mortality.

2 Langerhans' cell sarcoma: CD68, lysozyme, CD1a and S100 positive but CD21/35 negative. This tumour was predominantly extranodal, with a 50% mortality rate.

3 Follicular dendritic cell sarcoma: CD21/35 positive. This tumour was localized to lymph nodes and associated with a low mortality.

4 Interdigitating dendritic cell sarcoma: S100 positive, 50% CD68 positive, CD1a and CD21/35 negative.

Most of these tumours were localized to lymph nodes and associated with a low mortality.

This is a useful phenotypic aid for recognizing tumours of histiocytic origin. In the Histiocyte Society classification, malignant histiocytosis and true histiocytic lymphoma can be subdivided into tumours of these four phenotypes.

Monocytic leukaemia

Definition. Monocytic leukaemia may be acute or chronic. The acute myelogenous leukaemias have been classified in the Franco-American–British classification according to the characteristics of the cells involved. Acute myelomonocytic leukaemia is classified as M5. The chronic myelomonocytic/monocytic leukaemias usually transform into acute forms of the leukaemia in a matter of months.

The monocytic leukaemias typically exhibit increased extramedullary disease and organomegaly, and are associated with reduced remission rates and a poorer prognosis.

Aetiology. The aetiology of monocytic leukaemias is unknown. A characteristic karyotype has been reported in M5 leukaemias, translocation t(9;11)(p22;q23).

Pathology. Leukaemic cells in monocytic leukaemia show varying degrees of monocyte differentiation. In acute forms of the disease, the cells stain positively for peroxidase, Sudan black B and non-specific esterase. The cells also contain granules that stain for α-naphthylbutyrate esterase [1]. The cells demonstrate CD13 and CD33, with 30% of cells exhibiting HLA-DR. Monocyte-associated membrane antigen (CD14) expression is variable [2].

Ultrastructurally, the cells have irregular nuclei with nuclear blebs, numerous pinocytic vesicles and perinuclear fibrillar bodies [3].

Skin infiltration favours the lower dermis and subcutaneous fat, with prominent involvement of adnexal structures, nerves and vessels of the superficial and deep plexus. Cellular atypia may be prominent and mitotic figures are common. Differentiation from other forms of leukaemia depends on examination of the blood and bone marrow and special stains in skin sections. The best marker for monocytic leukaemia is non-specific esterase.

Clinical features. Skin lesions in monocytic leukaemia may be specific, for example leukaemia cutis, or non-specific, related to anaemia, thrombocytopenia, infection or drugs. Leukaemia cutis occurs in about 20% of patients with acute monocytic leukaemia [2,4]. Specific skin lesions are light-red, brown or violaceous macules and nodules [1]. These are firm and generally asymptomatic. Skin lesions may undergo rapid cycles of development and spontaneous regression. Skin involvement is not related to the circulating white cell count. Gum involvement occurs in 25–50% of patients.

The prognosis in acute monocytic leukaemia is not related to skin involvement, and leukaemia cutis may spontaneously regress. The prognosis depends on the age of the patient, presence of renal failure and serum β_2-microglobulin levels. Aggressive chemotherapy is associated with complete remission in 60% of patients.

Diagnosis. Diagnosis is made on clinicopathological features of the disease. Differentiation from other forms of leukaemia cutis demands examination of the blood or bone marrow and the use of special stains. M4 and M5 leukaemias are associated with elevated serum lysozyme levels [1].

Treatment. Treatment of leukaemia cutis is that of the underlying leukaemia. Leukaemia cutis in monocytic leukaemia has a tendency to spontaneous regression, but large lesions or ulcerating lesions may be treated with local radiotherapy. Acute monocytic leukaemia is resistant to the chemotherapeutic regimens used in acute myeloid leukaemias but the epipodophyllotoxin drugs are achieving good results [5].

Malignant histiocytosis

SYN. MALIGNANT RETICULOHISTIOCYTOSIS; MALIGNANT RETICULOSIS; HISTIOCYTIC MEDULLARY RETICULOSIS; SINUSOIDAL HAEMATOLYMPHOID MALIGNANCY; MALIGNANT ASTROCYTOSIS; ALEUKAEMIC RETICULOSIS; HISTIOCYTIC RETICULOSIS

Definition. Malignant histiocytosis is a widespread neoplastic proliferation of histiocytic cells that typically involves liver, spleen, lymph nodes and bone marrow. The cells usually arise from sinusoidal histiocytes, although very rare cases of malignant histiocytosis of Langerhans' cell phenotype have been reported.

Aetiology. Malignant histiocytosis is a neoplastic proliferation of cells of the mononuclear phagocyte system. There is no evidence of a viral aetiology in this disease and no reported familial incidence. There have been reports of a characteristic chromosomal translocation t(5;6)(q35;p21) in malignant histiocytosis [1,2]. The major problem with these reports is that the large cell anaplastic lymphoma (Ki-1-positive lymphoma) is often grouped with malignant histiocytosis, but these are T-cell lymphomas. However, the 5q35 break-point does appear to be specific for malignant histiocytosis [3].

Incidence. Malignant histiocytosis is a rare disease with a male to female ratio of 3.5 : 1. It has been reported in all age groups, with a median age of 35 years [4]. Childhood disease is uncommon with few reported series [5]. The disease tends to occur earlier in women (second to third decades) than in men (third to fourth decades) [6]. Reports have suggested an increased incidence of this disease in parts of tropical Africa, with reports from Malawi [7] and Uganda [8].

Pathology. The histological picture in skin and lymph nodes is similar and the diagnosis can be established in either site. Characteristically, there is an infiltrate of histiocytic cells showing varying degrees of atypia that are typically non-cohesive. Cells are large (up to 50 μm in diameter) with abundant cytoplasm and distinct cytoplasmic membranes.

The histiocytic cells are heterogeneous. Some show more marked histiocytic differentiation, with pale cytoplasm, prominent vacuolation or even foamy cytoplasm, and exhibit phagocytosis of erythrocytes, leukocytes and cellular debris. Other cells are more 'primitive', with deeply eosinophilic or amorphous cytoplasm. Nuclei are usually lobulated, with finely granular or reticulated chromatin and prominent or bizarre nucleoli. Nuclear membranes tend to be thickened. Mitoses are common.

Cytochemical and immunohistochemical studies have shown that the cells in malignant histiocytosis are negative for chloracetate esterase, Sudan black B, alkaline phosphatase and β-glucuronidase [9]. Presence of non-specific esterase, acid phosphatase and lysozyme is variable, with the better differentiated cells showing these enzymes [10]. The more differentiated phagocytosing cells usually stain for factor XIIIa and the antimonocyte monoclonal antibody MOI [11]. In some cases, EMA, HLA-DR, CD25, CD30, CD68 and CD71 have been detected. In rare cases CD1a or CD21/35 may be found. In lymph nodes, the architecture is disarranged but not effaced by the malignant cells.

In the skin, there is extensive perivascular and periappendageal infiltration of the dermis, with extension into subcutaneous fat. In advanced lesions, fat necrosis may occur. The epidermis and papillary dermis are characteristically spared but in the more tumid lesions epidermal ulceration may be present.

Clinical features. Malignant histiocytosis is usually of acute onset, with fever, sweats, wasting, generalized painful lymphoadenopathy and hepatosplenomegaly. As the disease progresses, jaundice, purpura, anaemia and leukopenia occur. In 50% of patients, extranodal extension of the disease is seen, most commonly affecting the skin, bone and gastrointestinal tract.

In the skin, single or multiple lesions may be present [12,13], ranging from skin coloured to violaceous. Large lesions may ulcerate. A widespread papulonodular eruption similar to that in acute monocytic leukaemia may also be seen.

In bone, the lesions are focal, destructive, lytic and may become widespread with associated hypercalcaemia. Gastrointestinal involvement is usually observed late in the disease. Small and large bowel may be involved, with infiltration of the lamina propria and local intraluminal masses. This presents with obstruction or haemorrhage or both. A rare presentation with multiple lesions is with malabsorption.

In the past, this disease has been associated with a poor prognosis. However, with aggressive management (radiotherapy or radiotherapy and chemotherapy) complete remission has been reported in up to 50% of cases, with a mean duration of complete remission of over 12 months [4]. Microscopic evidence of vascular invasion carries a poor prognosis.

Diagnosis. The major differential diagnosis is with large cell anaplastic lymphomas, in which the clinical and

histological features may be similar. Other diseases that may be confused with malignant histiocytosis are familial haemophagocytic lymphohistiocytosis, virus-associated haemophagocytic syndrome, Hodgkin's disease and SHML. Diagnosis can usually be established on clinicopathological features of the disease, although special stains may be needed to exclude large cell anaplastic lymphoma.

Treatment. Malignant histiocytosis is sensitive to both radiotherapy and chemotherapy but treatment must be started early, as many patients die before therapy can be started [5]. Chemotherapy is usually with a combination regimen, which includes Adriamycin and radiotherapy. In one series, complete remission was achieved in seven of nine patients treated [4]. In a study of 27 children with malignant histiocytosis, complete remission was achieved in 22 children using a regimen of vincristine, cyclophosphamide, doxorubicin and prednisolone, with a 5-year survival of 81% [14]. In patients who relapse after conventional chemotherapy, autologous bone marrow transplantation has successfully achieved long-term remission [15]. Large skin tumours or ulcerated tumours can be treated with local radiotherapy. A review of the treatment of malignant histiocytosis has recently been published [16]. Conventional chemotherapy and radiotherapy are still the mainstay of treatment.

True histiocytic lymphoma

SYN. RETICULUM CELL SARCOMA; HISTIOSARCOMA; MONOCYTIC SARCOMA

Definition. A malignant histiocytic neoplasm that may disseminate.

Aetiology. The aetiology is unknown. The disease represents malignant proliferation of non-Langerhans' cell histiocytes or more rarely of Langerhans' cells. Differentiation from malignant histiocytosis may be difficult.

Pathology. True histiocytic lymphoma exhibits many of the features described in malignant histiocytosis, infiltrating cells being predominantly dermal and non-cohesive. Nemes and Thomazy [1] suggest that the cells in true histiocytic lymphoma are more differentiated than those in malignant histiocytosis and that the cell population is more homogeneous, showing phagocytosis and labelling for factor XIIIa. These cells stain with macrophage markers CD11c and CD68 and are negative for T- and B-cell markers [2].

Clinical features. This is a localized tumour of malignant histiocytes that may be nodal or extranodal. In 40% of patients, presentation is with the painless enlargement of one or more groups of superficial lymph nodes. Constitutional symptoms of malaise, anorexia, sweating and fever may be present.

Extranodal presentation may be with bone, gastrointestinal tract or skin lesions. Bone and gastrointestinal tract lesions are as described in malignant histiocytosis. Skin lesions are localized bluish-red tumours that can attain a large size. An isolated skin tumour of true histiocytic lymphoma in a 79-year-old patient has been described that reached 20 cm in diameter at presentation [3]. In one case report from Japan, an isolated dark-red skin tumour developed on the leg of a 49-year-old woman. Histology showed a monomorphous infiltrate of large cells, with erosion of the overlying epidermis. These cells were CD1a positive and on electron microscopy contained multiple Birbeck granules. This Langerhans' cell, true histiocytic lymphoma disseminated to regional lymph nodes, liver, lungs, kidneys, bone marrow and skin and the patient died 3 years after diagnosis [4]. Hepato-

splenomegaly occurs in only a minority of patients with true histiocytic lymphoma, and peripheral blood involvement is rare. In one case report, a 44-year-old man with true histiocytic lymphoma was treated with autologous bone marrow transplantation and subsequently developed histiocytic leukaemia classified as M5c monocytic leukaemia [5].

Prognosis. True histiocytic lymphoma is treatable, and the prognosis is probably better than in malignant histiocytosis.

Treatment. True histiocytic lymphoma is both radiosensitive and chemosensitive. Complete remission has been achieved in localized skin disease using electron-beam therapy [3]. Reports of therapeutic responses are difficult to evaluate because of doubt over the diagnosis in older series.

Chapter 53

Soft-Tissue Tumours and Tumour-like Conditions

E. Calonje & R.M. MacKie

Introduction

For many clinical dermatologists, soft-tissue tumours arising in the dermis, subcutis or deeper soft tissues are a confusing group of lesions. This is probably partly explained by the fact there is a very long list of soft-tissue tumours, and a large majority can arise in the skin or affect it secondarily. Most of these tumours have no characteristic clinical appearance, and present as non-specific, dermal, or deep-seated nodules. However, it is necessary for all clinical dermatologists to have an understanding of the range of tumours that may arise in the dermis, and also

of the likely biological behaviour of individual lesions. Although cutaneous malignant soft-tissue tumours are rare, many benign lesions may be histologically confused with a malignancy. Furthermore, there is a group of soft-tissue tumours that have low-grade malignant potential with frequent local recurrences but little or no potential for metastatic spread (e.g. dermatofibrosarcoma protuberans). These tumours may cause important morbidity, and their recognition is therefore essential for the planning of treatment and follow-up. Recognizing a wide range of soft-tissue tumours is also important as a number of these lesions—particularly when multiple—may be markers of genetic syndromes (for example, multiple neurofibromas and plexiform neurofibroma in neurofibromatosis type I).

A broad division can be made between tumours according to the morphological lines of differentiation. The latter include fibroblastic, myofibroblastic, neural, vascular, muscular and adipocytic types. In a number of tumours, the line of differentiation is not clear, as a normal cell of origin cannot be identified (e.g. epithelioid sarcoma). In a still larger group of tumours, their origin is descriptively ascribed to fibrohistiocytic cells, but with mounting evidence that many of these lesions have fibroblast and/or myofibroblastic differentiation and almost none display true histiocytic differentiation. The list of tumours discussed in this chapter is not all-inclusive. For a full account of the very wide range of these tumours, the reader is referred to the standard major work in this field [1]. True histiocytic tumours are discussed in Chapter 52, and keloids and hypertrophic scars in Chapter 46. Metastatic malignant tumours are covered in Chapter 59.

The most useful biological triage is into totally benign lesions; lesions that may recur locally and never or almost never metastasize; and those that are truly malignant and may metastasize. The great majority of dermal or superficial soft-tissue tumours come into the first two categories, whilst truly malignant soft-tissue tumours arise much more frequently below the deep fascia. In the case of these rare malignant tumours, there is a relationship between bulk and prognosis, smaller lesions carrying a better prognosis. More superficially situated lesions tend to carry a better prognosis than those deeply situated. Mitoses (particularly abnormal mitotic figures) and necrosis both tend to be associated with malignant rather than benign lesions.

The usual clinical presentation of many of the tumours described in this chapter is of a non-specific lump or nodule. An incisional biopsy should be arranged, and it must be adequately deep so that the nature of the lesion at its deepest margin can be determined. Once the pathologist has established the nature of the tumour, appropriate definitive surgery can be planned. Prior consultation with the pathologist is strongly recommended, as samples may be needed for cytogenetics, electron microscopy or immunohistochemistry. All of these may be of supportive value in arriving at an accurate diagnosis.

Fibrous and myofibroblastic tumours

Fibrous papule of the face [1]

SYN. FIBROUS PAPULE OF THE NOSE

Definition and incidence. A small facial papule with a distinctive fibrovascular component on histological examination. The condition is relatively common, and several large series have been reported [2–4].

Clinical features [2–4]. The lesions usually occur singly on the nose. Occasionally, they may occur on the forehead, cheeks, chin or neck, and there may be several lesions. The lesion usually presents in middle life, and both sexes are equally affected. Similar papules may present on the fingers or oral mucosa, where they have been described as reactive nodular hyperplasia or giant cell fibroma [5,6].

The papule develops slowly as a dome-shaped, skin-coloured or slightly red or pigmented lesion, which is usually sessile. Most are asymptomatic, but about one-third bleed on minor trauma.

Pathology [2–4]. The epidermis appears normal, although there may be an increased number of clear cells overlying the lesion. In the dermis there are broad bands of connective tissue orientated vertically to the surface. These are interspersed with multinucleate, somewhat bizarre cells, often with a few cells resembling melanocytic naevus cells. There are prominent dilated capillaries, but relatively few elastic fibres.

It has been suggested that the condition may be a variant of a melanocytic naevus [2,4], but others disagree [3]. S100 protein, which is an immunohistochemical marker of neuroepithelial elements, is present neither in the stellate cells in the papillary dermis nor in the mesenchymal 'naevus' cells [7].

Treatment. The lesion is benign, but it may easily be excised or surgically pared for cosmetic reasons.

Storiform collagenoma [1,2]

SYN. SCLEROTIC FIBROMA

Definition. Storiform collagenoma is a fibrous hypocellular cutaneous lesion which, when multiple, may be associated with Cowden's disease (multiple hamartoma and neoplasia syndrome; see Chapter 59) [3].

Clinical features. It usually presents as a small solitary asymptomatic papule in adults of either sex, with wide anatomical distribution.

Pathology. It typically consists of a fairly well-circumscribed dermal nodule with prominent hypocellular hyalinized collagen bundles in a storiform pattern. Bland spindle-shaped cells are rare. A similar histological pattern may be seen in the late stages of lesions as diverse as fibrous histiocytoma (FH) and myofibroma.

Treatment. Simple excision is curative.

Pleomorphic fibroma

Definition [1]. Pleomorphic fibroma is a relatively rare lesion with features very similar to those of a fibroepithelial polyp (skin tag), but characterized histologically by bizarre mono- or multinucleated stromal cells.

Clinical features. Lesions present in adults as a polyp, with no sex predilection and a wide anatomical distribution.

Pathology. Normal or mildly acanthotic epidermis surrounds a collagenous and vascular stroma containing scattered bizarre mono- or multinucleated cells with hyperchromatic and pleomorphic nuclei. Mitotic figures are rare.

Treatment. Simple excision is curative, and there is no tendency for local recurrence.

Fig. 53.1 Clinical appearance of an acquired digital fibrokeratoma.

Acquired digital fibrokeratoma [1]

Definition. A benign lesion, possibly a reaction to trauma, which occurs on the fingers and toes [2] (Fig. 53.1), although the palms and the soles have occasionally been involved.

Clinical features. The lesion usually occurs in adults as a solitary dome-shaped lesion, with a collarette of slightly raised skin at its base. Occasionally, it may be elongated or pedunculated. The surface may appear to be slightly warty.

There is a wide clinical differential diagnosis, which includes dermatofibroma, viral wart, supernumerary digit and cutaneous horn. Histologically, the lesion is extremely similar to the Koenen tumour [3], the periungual fibrous papule that arises from the nail fold in tuberous sclerosis.

Pathology. The histology shows thick collagen bundles, thin elastic fibres and increased vascularity. Occasionally, there is an obvious increase in fibroblasts, and rarely the collagen bundles may be separated by oedema [4]. The epidermis is relatively normal, but acanthosis and hyperkeratosis may occur.

Treatment. Acquired digital fibrokeratoma is cured by simple excision.

Nodular fasciitis [1–4]

SYN. SUBCUTANEOUS PSEUDOSARCOMATOUS FIBROMATOSIS

Definition. A rapidly enlarging subcutaneous nodule, which is due to a benign proliferation of myofibroblasts and fibroblasts and has a superficial resemblance to a sarcoma.

Incidence and aetiology. A number of quite large series have been published in the last 10 years, suggesting that the condition is not uncommon. It is most frequent in young adults, but has been reported in patients from 5 months to 75 years. There is no predilection for either sex. It is not associated with other diseases. There is no evidence that trauma initiates the lesions.

Clinical features [4–7]. The majority of tumours appear as tender, rapidly growing masses beneath the skin. The average size is 1–3 cm in diameter. The commonest situation is the upper extremities, particularly the forearm, but the lesion can occur anywhere, including the orbit and the mouth. Lesions on the head and neck often present in children. In nearly half the patients, the tumour has been noticed for only 2 weeks or less when they come for advice. Prolonged follow-up has shown that the condition is benign.

Pathology [1–4]. These lesions may look extremely worrying in view of the high mitotic rate and rapid growth (see below). The tumour is only focally circumscribed and it is composed of bundles of fairly uniform fibroblasts and myofibroblasts with pink cytoplasm, vesicular nuclei and a single small nucleolus. Myxoid change and mucin deposition is often prominent, resulting in a typical tissue culture-like appearance (Fig. 53.2). In the background, there are numerous small, delicate blood vessels, extravasated red blood cells and scattered mononuclear inflammatory cells. Multinucleated giant cells may be seen, and they resemble osteoclasts. Mitoses are usually numerous, but there are no abnormal forms. Hyalinized collagen bundles are often present and may display a keloidal appearance. At the periphery, compact bundles of fibroblasts and capillaries probe the fascial planes and may infiltrate fat or skeletal muscle. It is not surprising that this histological picture is relatively often confused with that of a malignant tumour. Variants of nodular fasciitis include those with metaplastic bone (ossifying fasciitis); a variant that involves the periosteum (periosteal fasciitis); a variant that involves the scalp and tends to occur in children (cranial fasciitis); and a variant within the lumen of a blood vessel (intravascular fasciitis) [5]. A rare variant of intradermal nodular fasciitis has also been described [5]. Tumour cells are variably positive for smooth muscle actin.

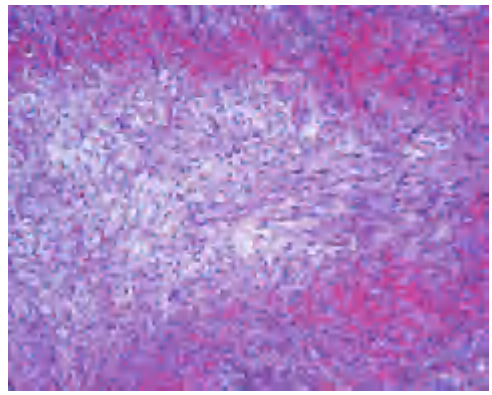

Fig. 53.2 Typical tissue culture-like appearance of nodular fasciitis with prominent myxoid background.

Treatment. Resolution usually follows incomplete surgical removal. Simple excision is therefore an adequate treatment. Local recurrence is exceptional.

Fibro-osseous pseudotumour [1,2]

SYN. FLORID REACTIVE PERIOSTITIS

Definition. This is a reactive myofibroblastic proliferation with bone formation, which occurs exclusively on the digits.

Clinical features. It presents predominantly in young adults, with predilection for females. The fingers are more commonly affected than the toes. The lesion grows rapidly and it is not attached to bone.

Pathology. The tumour is ill-defined and is very similar to nodular fasciitis, except for the fact that there is formation of osteoid and mature bone.

Treatment. Local recurrence is rare, and excision is the treatment of choice.

Ischaemic fasciitis [1–3]

SYN. ATYPICAL DECUBITUS FIBROPLASIA

Definition. Ischaemic fasciitis is a reactive fibroblastic/myofibroblastic proliferation that simulates malignancy and occurs as a result of alterations in local circulation and sustained pressure.

Clinical features. Most patients are elderly and immobilized, and there is a slight predilection for females. The lesion presents as an asymptomatic subcutaneous mass, predominantly over bony prominences, that may extend to deeper soft tissues and to the overlying dermis.

Pathology. The lesion is poorly circumscribed and contains areas of fibrosis, vascular proliferation, necrosis and focal myxoid change. Thrombosed blood vessels with recanalization and areas of fibrinoid necrosis, focal haemorrhage and mononuclear inflammatory cells are additional features. In the background, there are variable numbers of spindle-shaped myofibroblasts/fibroblasts with vesicular or hyperchromatic nuclei and a prominent nucleolus. Mitotic figures may be seen, but are not prominent.

Treatment. Excision of the lesion is an adequate treatment.

Fibrous hamartoma of infancy [1–4]

Definition. This is a benign fibroblastic/myofibroblastic deep dermal and subcutaneous tumour presenting in children and characterized by three distinctive pathological components, as described below.

Incidence and aetiology. This is a rare tumour, often considered to be a hamartoma, but probably neoplastic in nature.

Clinical features. Most cases present in children under 2 years as an asymptomatic solitary lesion only a few centimetres in diameter. A quarter of the cases present at birth. Males are more affected than females. The tumour grows rapidly and has a predilection for the axillae, arm and shoulder girdle [1–3]. A familial association has not been reported.

Pathology. The tumour is composed of three components:
1 Bundles of interlacing, elongated, bland, wavy spindle-shaped cells in a variable collagenous background.
2 Nests of more immature round cells with focal myxoid change.
3 Mature adipose tissue.

A focal resemblance to a neurofibroma may be seen when the first component predominates, but tumour cells are actin-positive and S100-negative [5].

Treatment. Simple excision is the treatment of choice; recurrences are exceptional.

Calcifying fibrous tumour/pseudotumour [1,2]

Definition. This is a rare benign hypocellular tumour characterized by dense collagen bundles, areas of calcification and a patchy mononuclear cell infiltrate.

Clinical features. Most lesions occur in children, and less commonly in young adults, as a fairly large subcutaneous or deeper asymptomatic mass with a wide anatomical distribution.

Pathology. The tumour typically consists of haphazardly arranged collagen bundles with scattered bland fibroblasts, focal small calcifications and focal aggregates of lymphocytes and plasma cells.

Treatment. Local recurrence is rare, and the treatment of choice is simple excision.

2 Fetsch JF, Montgomery EA, Meis JM. Calcifying fibrous pseudotumour. *Am J Surg Pathol* 1993; **17**: 502–8.

Calcifying aponeurotic fibroma [1,2]

Definition. This is a rare fibroblastic tumour characterized by a nodular proliferation of bland spindle-shaped cells surrounding nodules at different stages of calcification. Cartilage and, less commonly, bone formation may be seen.

Clinical features [1]. Most cases present in children, with a predilection for the hands and, less commonly, the feet. Occurrence at other sites is very rare [2]. Tumours are small, slowly growing and usually asymptomatic.

Pathology. The growth pattern is multinodular. Tumour cells are elongated, with scanty pink cytoplasm, vesicular nuclei and very rare mitotic figures. Tumour nodules frequently contain areas of calcification, which are surrounded by tumour cells in a pattern reminiscent of palisading.

Treatment. Local recurrence is observed in up to 50% of the cases, but malignant transformation is exceptional [3] and conservative treatment is therefore indicated.

Dermatomyofibroma

SYN. DERMAL PLAQUE-LIKE FIBROMATOSIS

Definition [1–4]. A benign dermal and superficial subcutaneous myofibroblastic proliferation microscopically mimicking a fibromatosis. The tumour, however, has no potential for local recurrence and lacks an infiltrative growth pattern.

Clinical features. It presents as a solitary, asymptomatic, skin-coloured or hypopigmented plaque measuring less than 4 cm in diameter. Most lesions occur on the trunk, and there is a predilection for young adults, particularly females. Children are only exceptionally affected.

Pathology. Low-power examination reveals a plaque-like proliferation of fascicles of myofibroblast-like cells with an almost parallel orientation to the epidermis. Tumour cells are bland, and mitotic figures are very rare. The tumour does not destroy adnexal structures, but may extend focally into the subcutaneous tissue.

Treatment. Simple excision is curative.

4 Colome MI, Sanchez RL. Dermatomyofibroma: report of two cases. *J Cutan Pathol* 1994; **21**: 371–6.

Elastofibroma [1–3]

Definition. Elastofibroma is a reactive, probably degenerative, process of the elastic fibres of deep soft tissues that occurs almost exclusively around the shoulder.

Clinical features. It presents as an asymptomatic, slowly growing mass on the posterior upper trunk of middle-aged individuals. Lesions in other locations including internal organs are exceptional.

Pathology. The mass is poorly circumscribed, and the appearances are characteristic. Abundant hypocellular hyalinized collagen containing numerous large, thick eosinophilic elastic fibres is the most distinctive feature. Sometimes the fibres are beaded and fragmented. Staining for elastic tissue nicely highlights the changes.

Treatment. Simple excision is all that is necessary, as the tumours do not have a tendency to recur.

Infantile myofibromatosis and adult myofibroma [1–6]

SYN. CONGENITAL GENERALIZED FIBROMATOSIS; INFANTILE HAEMANGIOPERICYTOMA

Definition. This tumour is composed of cells showing differentiation towards perivascular contractile cells, and has been described in the past as infantile haemangiopericytoma [7]. Infantile myofibromatosis and adult myofibroma are part of the spectrum of lesions recently described as myopericytomas [8].

Clinical features [1–3]. Most cases of infantile myofibromatosis present before the age of 2 years, with slight male predominance. Congenital tumours occur in up to a third of the cases. Multiple lesions are present in 25% of

patients. The preferred sites are the head and neck, followed by the trunk. Familial cases are rare. Involvement of other organs, including the gastrointestinal tract, lungs and bone, is seen in some cases. Multicentric involvement may be associated with mortality. Multiple lesions in the skin and soft tissues behave in a benign fashion and may regress spontaneously. Solitary myofibroma tends to occur in adults, with the same anatomical distribution as that of cutaneous and soft-tissue lesions presenting in infantile myofibromatosis [4,5]; multiple superficial tumours are rarely seen in adults.

Pathology [1,2,5,6]. Tumours have a distinctive biphasic growth pattern:
1 Areas composed of bundles of mature, spindle-shaped myofibroblasts with pink cytoplasm and vesicular nuclei.
2 Areas composed of immature round cells, with scanty cytoplasm arranged around small blood vessels, often displaying a haemangiopericytoma-like pattern ('staghorn-like').

Protrusion of tumour cells into vascular lumina is frequent, often mimicking vascular invasion. Old lesions often undergo hyalinization of the more mature areas. Mitotic figures and necrosis are relatively common. Tumour cells, particularly in the mature areas, are focally positive for actin.

Treatment. Lesions tend to regress spontaneously, but it is important to remember that patients with visceral tumours may die from the disease. Solitary lesions are treated by simple excision and do not tend to recur locally.

Inclusion body (digital) fibromatosis [1–3]

SYN. INFANTILE DIGITAL FIBROMATOSIS

Definition. Inclusion body fibromatosis is a fibro/myofibroblastic proliferation that almost only occurs on the fingers and toes. It is characterized by bright round intracytoplasmic eosinophilic inclusions.

Clinical features. Most lesions present either at birth or during the first year of life as small multiple nodules with predilection for the third, fourth and fifth digits. Involvement of the first digits (thumb and hallux) does not occur. New lesions often develop over a long period of time. Only rare cases have been described at other sites or in adults [4,5]. Spontaneous regression is sometimes seen. Aggressive behaviour has not been described.

Pathology. Monomorphic bundles of bland, myofibroblast-like cells are seen in the dermis and often the subcutis. Tumour cells have vesicular nuclei, an inconspicuous nucleolus and pink cytoplasm. Some mitotic figures may be seen. A distinctive feature is the presence of variable numbers of small round eosinophilic intracytoplasmic inclusions in tumour cells. These are periodic acid–Schiff (PAS)–negative, but stain red with Masson's trichrome. They also stain for actin.

Treatment. Simple excision may be required for lesions that interfere with function, but simple observation of histologically confirmed lesions may be all that is necessary.

Fibroma of tendon sheath [1,2]

Definition. This is a distinctive, well-circumscribed fibroblastic tumour, presenting almost exclusively on the distal extremities.

Clinical features [1,2]. It is a small, slowly growing asymptomatic tumour, presenting in young to middle-aged adults and with a marked predilection for the distal upper limb, particularly the hand and fingers. Lesions on the foot are much less common.

Pathology [1,2]. The neoplasm is multilobular and well-circumscribed and consists of cellular or poorly cellular areas on a background of variably hyalinized stroma. Stromal clefting is usually prominent. Tumour cells are

spindle-shaped, with scanty cytoplasm and vesicular nuclei. Cytological atypia tends to be absent, and the mitotic count is low.

Treatment. About 25% of cases recur locally, but the growth is not destructive.

Collagenous fibroma [1,2]

SYN. DESMOPLASTIC FIBROBLASTOMA

Definition. Collagenous fibroma represents a distinctive, subcutaneous fibroblastic tumour consisting of a prominent collagenous stroma.

Clinical features. It is relatively common and presents in adults as an asymptomatic nodule less than 4 cm in diameter, at any body site.

Pathology. This is a well-circumscribed tumour composed of bland elongated or stellate cells, with a background collagenous stroma and focal myxoid change. Mitotic figures are very rare.

Treatment. Simple excision is the treatment of choice, as there is no tendency for local recurrence.

Nuchal fibroma [1,2]

Definition. Nuchal fibroma is a dermal or subcutaneous tumour consisting of hypocellular dense collagen.

Clinical features. Tumours are rare and occur in adult males. Patients often have diabetes. The great majority of cases present on the nape of the neck. Coexistence with scleroedema is possible, probably reflecting the association with diabetes, and this lesion is now recognized to occur in Gardner's syndrome (Chapter 59).

Pathology. Dense aggregates of collagen with very few cells and entrapment of adipose tissue.

Treatment. Simple excision is the treatment of choice but local recurrence is possible.

Palmar and plantar fibromatosis (superficial fibromatoses) [1,2]

SYN. PLANTAR FIBROMATOSIS: LEDDERHOSE'S DISEASE; SYN. PALMAR FIBROMATOSIS: DUPUYTREN'S DISEASE, DUPUYTREN'S CONTRACTURE

Definition. Palmar and plantar fibromatoses are superficial neoplastic proliferations of fibroblasts and myofibroblasts that have a tendency for local recurrence, but do not metastasize.

Incidence and aetiology. Palmar fibromatosis is more common than plantar fibromatosis. Both lesions are more common in men, but the sex difference is more marked in palmar lesions. Both conditions affect middle-aged to elderly patients and are exceptional in younger individuals. Affected patients are mainly of Northern European origin; non-whites are rarely affected. Coexistence between the two variants of fibromatoses and desmoid tumours, penile fibromatosis (Peyronie's disease) and knuckle pads may be seen. Genetic predisposition as well as trauma are thought to play an important role in the pathogenesis of these conditions. Associations with diabetes, alcoholic liver disease and epilepsy have also been described.

Clinical features. Palmar fibromatosis presents as indurated nodules or as an ill-defined area of thickening, bilateral in about 50% of cases, that may result in contracture. Plantar fibromatosis usually consists of a single nodule. Functional limitation is common.

Pathology. Early lesions are fairly cellular and consist of bundles of bland fibroblasts with some collagen deposition. The latter increases considerably in older lesions.

Treatment. Complete excision is desirable, as there is otherwise a risk of local recurrence.

Penile fibromatosis [1–3]

SYN. PEYRONIE'S DISEASE

Definition. Although usually regarded as a variant of

superficial fibromatosis, it is more likely that this disease represents a reactive fibrotic disorder of unknown aetiology.

Clinical features. It presents as a solitary nodule or multiple nodules close to the corpus cavernosum on the dorsal surface of the shaft. Most patients are middle-aged, and in most the lesion is small. Pain and curvature of the penis on erection are frequent complaints.

Pathology. In early lesions, there is a patchy chronic mononuclear inflammatory cell infiltrate and focal vasculitic changes. These changes lead to dense bands of hyalinized collagen in late stages.

Dermatofibrosarcoma protuberans [1–3]

Definition. Dermatofibrosarcoma protuberans (DFSP) is a locally invasive tumour arising in the dermis and likely to show fibroblastic differentiation.

Incidence and aetiology [1–3]. DFSP is uncommon, with equal frequency in males and females. Most patients present in the third and fourth decades of life. Some cases develop at the site of previous trauma.

Clinical features. The tumour is more often situated on the trunk (up to half of the cases), particularly in the flexural regions, than on the extremities or the head [1,2]. Involvement of the limbs is usually proximal. It may begin in early adult life with one or more small, firm, painless, flesh-coloured or red dermal nodules (Fig. 53.3). There are rare examples of DFSP occurring in infancy [4–6], and congenital cases have been described [6].

The tumour starts as a plaque, which may occasionally be atrophic [5,7]. Progression is usually slow, and may occur over many years. Eventually, nodules develop, coalesce and extend, becoming redder or bluish as they enlarge to form irregular, protuberant swellings. At this stage, the base of the lesion is a hard, indurated plaque of irregular outline. In the later stages, a proportion of lesions become painful and there may be rapid growth, ulceration and discharge.

Local recurrence of ordinary DFSP is reported to vary from 15% to up to 60% [3,8,9], and that of the fibrosarcomatous variant is as high as 75% [10–13]. Metastases to lymph nodes and internal organs tend to be extremely rare in pure DFSP [10,14,15] but occur in up to 20% of cases with fibrosarcomatous transformation [11–13].

Pathology [1–3,8]. The tumour is usually a solitary multinodular mass. The dermis and subcutaneous tissue are replaced by bundles of uniform spindle-shaped cells with little cytoplasm and elongated hyperchromatic, but not pleomorphic, nuclei. Usually there is little mitotic activity. Deeper involvement may be seen in some cases. Laterally, the tumour cells infiltrate widely between collagen bundles of the deeper dermis and blend into the normal dermis, forming quite definite bands, which interweave or radiate like spokes of a wheel; this is described as a 'storiform' pattern (Fig. 53.4). The interstitial tissue contains collagen fibres, except in the most cellular parts of the tumour. The subcutaneous tissue is extensively infiltrated and replaced in a typical lace-like pattern. Myxoid change may be focal or, rarely, prominent; in the latter setting, the histological diagnosis is difficult. Some tumours are colonized by scattered, deeply pigmented melanocytes, a variant known as pigmented

Fig. 53.3 Recurrent abdominal dermatofibrosarcoma protuberans.

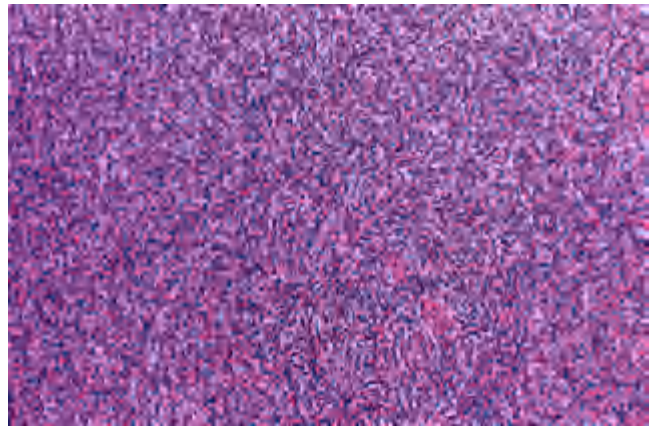

Fig. 53.4 Pathological appearance of dermatofibrosarcoma protuberans, showing the storiform or 'cartwheel' distribution of the fairly uniform spindle-shaped tumour cells.

DFSP (Bednar tumour) [16,17]. A further variant consists of myoid nodules and is thought to represent myofibroblastic differentiation [18]. Rare cases show focal granular cell change.

Fibrosarcomatous DFSP [11–13] is an important variant of this tumour, which is recognized by the focal presence of areas with long sweeping fascicles of tumour cells intersecting at acute angles in a typical 'herring-bone' pattern, almost identical to that seen in fibrosarcoma. In these areas, mitoses are increased and there is more nuclear hyperchromatism. Identification of this pattern and its quantity is very important, as it seems to be related to metastatic potential. Fibrosarcomatous areas are more common in recurrent tumours.

DFSP may show areas of giant cell fibroblastoma (see below) and either tumour may recur, displaying features of the other tumour [19].

The majority of the lesions are positive on staining with the antibody CD34, although this is not specific for DFSP [8]. Fibrosarcomatous areas often show decreased staining with CD34 [13].

Cytogenetic studies are helpful, as ring chromosomes indicative of a 17:22 translocation are invariably found [19]. The same cytogenetic abnormality is found in giant cell fibroblastoma, confirming that both tumours are part of the same spectrum.

Diagnosis. In the early stages, it may be impossible to distinguish this tumour from a histiocytoma or a keloid. Some lesions may also be confused with morphoea profunda. The slow progression, deep red or bluish-red colour, and the characteristic irregular contour and extended plaque-like base, are strongly suggestive of DFSP.

Treatment. The tumour should be excised completely, with a generous margin of healthy tissue. Local recurrence invariably follows inadequate removal; the clearance necessary to cure the tumour is often underestimated [20]. A margin of between 2 and 4 cm has been recommended [9,21]. Mohs surgery has been reported as effective in reducing the rate of local recurrence [22,23]. If this type of treatment is used it should be performed using formalin-fixed paraffin-embedded sections rather than frozen sections, and evaluation should be by an experienced pathologist.

Giant cell fibroblastoma [1–3]

Definition. This is a locally recurrent fibroblastic tumour, closely related to DFSP. It is characterized by spindle-shaped, oval or stellate, mono- or multinucleated cells in a fibromyxoid stroma with irregular pseudovascular spaces lined by tumour cells.

Clinical features [1–3]. The large majority of cases present as a subcutaneous ill-defined mass in the first few years of life. It is rare in adults. The trunk is much more commonly involved than the proximal limbs. Tumours measure a few centimetres in diameter, have a predilection for males and tend to be asymptomatic.

Pathology. Solid fibromyxoid areas with variable collagen deposition contain stellate and spindle-shaped mono- and multinucleated tumour cells with hyperchromatic nuclei. Dilated, irregularly branching pseudovascular spaces are commonly seen scattered throughout the lesion. These spaces are lined by tumour cells, which often appear multinucleated. Mitotic figures are exceptional. Focal areas identical to DFSP may be seen and can occupy a substantial part of the tumour. Excised lesions can recur as a pure giant cell fibroblastoma, as a tumour with focal DFSP, or as pure DFSP [4–6]. Tumour cells are focally positive for CD34 and only very focally positive for actin. Ring chromosomes with sequences of chromosomes 17 and 22 identical to those found in DFSP have been described in this tumour, confirming their close histogenetic relationship [7].

Treatment. Recurrence may be seen in about half of the cases, but metastasis has not been reported.

Fibrohistiocytic tumours

Giant cell tumour of tendon sheath [1,2]

SYN. BENIGN SYNOVIOMA

Definition. This is a benign tumour that in its localized variant occurs mainly on the hands, and consists of a nodular proliferation of histiocyte-like cells with scattered multinucleated giant cells and variable numbers of mononuclear inflammatory cells. The diffuse variant of this tumour that involves joints is not discussed further in this chapter.

Clinical features. Tumours present mainly on the hands with predilection for the fingers. They are typically between 1 and 3 cm in diameter and asymptomatic, although they may interfere with function. There is a predilection for young females.

Pathology. It is a multinodular lesion composed of sheets of histiocyte-like cells with bland vesicular nuclei, intermixed with multinucleated giant cells, foamy cells, siderophages and scattered mononuclear inflammatory cells. Hyalinization, haemosiderin deposition and cholesterol clefts are often seen.

Treatment. Excision is the treatment of choice; the rate of local recurrence is around 30%.

Fibrous histiocytoma [1–4]

SYN. DERMATOFIBROMA, HISTIOCYTOMA CUTIS; SUBEPIDERMAL NODULAR FIBROSIS; SCLEROSING ANGIOMA

Definition. Fibrous histiocytoma (FH) is a benign dermal and often superficial subcutaneous proliferation of oval cells resembling histiocytes, and spindle-shaped cells resembling fibroblasts and myofibroblasts. Their line of differentiation remains uncertain, but these lesions are descriptively classified as fibrohistiocytic tumours because of the microscopic appearance of the tumour cells. The aetiology of FH is unknown, but recent cytogenetic studies demonstrating clonality favour these lesions being neoplastic [5,6]. The neoplastic nature of FH is also suggested by their clinical persistence and by the frequency of local recurrence of some variants (cellular, aneurysmal and atypical; see below). The previous theory that they are a dermal response to injury, such as insect bite, has been challenged [7].

Clinical features. FH is commonest on the limbs and appears as a firm papule, which is frequently yellow-brown in colour and slightly scaly (Fig. 53.5). If the overlying epidermis is squeezed, the 'dimple sign' will be seen, indicating tethering of the overlying epidermis to the underlying lesion. Giant lesions (>5 cm in diameter) are occasionally seen [8]. A number of clinicopathological variants of FH have been described, which should be recognized by clinicians and pathologists in order to avoid a misdiagnosis of malignancy. These variants include: cellular FH [9,10], aneurysmal FH [11,12], atypical FH (pseudosarcomatous FH, dermatofibroma with monster cells) [13,14] and epithelioid FH [15,16]. A further variant, described as 'atrophic', does not usually pose a problem in differential diagnosis.

Cellular FH represents less than 5% of all FHs [9]. Like

Fig. 53.5 Clinical appearance of a fibrous histiocytoma or dermatofibroma.

ordinary FH, it has a predilection for the limbs of young adults, but it tends to occur more commonly in males. However, the distribution of age and site is wide; cellular FH is not infrequent in children, and on sites such as the head, neck, fingers and toes. The size of these lesions is also larger than that of ordinary FH. Most cellular FHs are less than 2 cm in diameter, but lesions measuring more than 5 cm may occur. Recognition of this variant is important, because it has a local recurrence rate of 25%, and metastases have been reported anecdotally [10].

Aneurysmal FH has the same age and sex distribution as ordinary FH [11,12]. Tumours are usually rapidly growing and may attain a very large size. They clinically mimic a vascular tumour. The rate of local recurrence is 19% [12].

Atypical FH presents mainly in young adults, with a predilection for the lower limbs [13,14]. It is commoner in males than in females. The clinical presentation is that of a papule, nodule or plaque, usually less than 1.5 cm in diameter. The rate of local recurrence is around 14%, and exceptional metastases have been reported [14].

Epithelioid FH [15,16] presents on the limbs of young patients, with a predilection for females [15,16]. The typical clinical appearance is that of a polypoid, often vascular, lesion resembling a non-ulcerated pyogenic granuloma.

Pathology. The overlying epidermis frequently shows a degree of epidermal hyperplasia [17] (Fig. 53.6). Occasionally, the epidermal proliferation is associated with immature follicular structures, which are often confused with a basal cell carcinoma. In the dermis, there is a localized proliferation of histiocyte-like cells and fibroblast-like cells, associated with variable numbers of mononuclear inflammatory cells. Foamy macrophages, siderophages and multinucleated giant cells are also variably present. A focal storiform pattern is often seen. The tumour blends with the surrounding dermis. Collagen bundles at the periphery of the lesion are surrounded by scattered tumour cells and appear somewhat hyalinized. As variable expression of factor XIIIa antigen is often seen, it has been suggested that this tumour shows differentiation towards dermal dendrocytes [18]. Focal myofibroblastic differentiation is often suggested, particularly in the cellular variant. Older lesions show focal proliferation of small blood vessels in association with haemosiderin deposition and fibrosis, hence the older name of 'sclerosing haemangioma'.

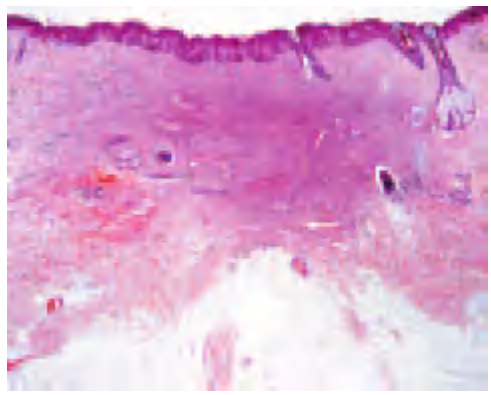

Fig. 53.6 Histological appearance of dermatofibroma, showing epidermal hyperplasia overlying the dermal sclerotic component.

Cellular FH [9] also shows epidermal hyperplasia, but the lesions are more cellular, less polymorphic and consist of bundles of spindle-shaped cells with pink cytoplasm and a focal storiform pattern (Fig. 53.7). The mitotic rate varies, and necrosis may be found in up to 12% of cases. Extension into the subcutaneous tissue is more prominent than that seen in ordinary FH. However, the pattern of infiltration is mainly along the septae, and only focally into the subcutaneous lobule in a lace-like pattern. The cellularity and growth pattern often make distinction from DFSP difficult, particularly in small biopsies. DFSP is, however, more monomorphic, tends to infiltrate the subcutaneous tissue diffusely and is generally uniformly positive for CD34 [18]. Cellular FH may be focally positive for CD34, but this is predominantly seen at the periphery of the tumour. Staining for FXIIIa is positive in FH and negative in DFSP. Furthermore, cellular FH is often focally positive for smooth muscle actin, whereas this marker is negative in DFSP.

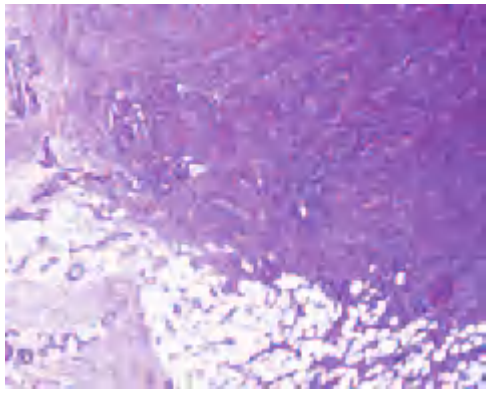

Fig. 53.7 Cellular fibrous histiocytoma. Note the increased cellularity, fascicular appearance and focal extension into the subcutis.

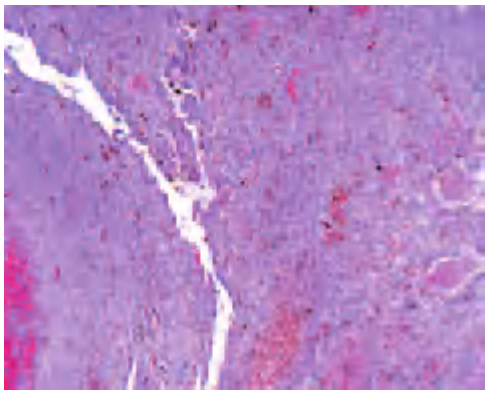

Fig. 53.8 Aneurysmal fibrous histiocytoma. Prominent haemorrhage and cavernous-like spaces obscure the typical background of a fibrous histiocytoma.

Aneurysmal FH [11,12] shows extensive haemorrhage, with prominent cavernous-like pseudovascular spaces (Fig. 53.8) which are not lined by endothelial cells. The mitotic rate varies, but may be prominent. The background is that of an ordinary FH.

Atypical FH [13,14] shows variable numbers of mono- or multinucleated, pleomorphic, spindle-shaped or histiocyte-like cells on a background of an ordinary FH. These cells may be very prominent, making the histological diagnosis difficult. Mitotic figures, including atypical forms, may be seen. These lesions used to be classified as 'atypical fibroxanthoma occurring in non-sun-exposed skin of young patients'.

Epithelioid FH [15,16] contains a predominant population of cells with abundant pink cytoplasm and vesicular nuclei, and there is often myxoid change and a prominent vascular component. Distinction from a Spitz naevus may be difficult, but in epithelioid FH there is no junctional component, tumour cells are not nested and they are negative for S100.

Many histological variants of FH have been described; recognizing these variants is important to avoid misdiagnosis. They include lesions with palisading, granular cell change [19], lipid [20] and prominent clear cell change [21].

Treatment. Most FHs are no more than a cosmetic nuisance, and no treatment is necessary. However, cellular, aneurysmal and atypical variants should be completely removed, because of the risk of local recurrence and the occurrence of occasional distant metastases.

Angiomatoid fibrous histiocytoma [1–3]

SYN. ANGIOMATOID MALIGNANT FIBROUS HISTIOCYTOMA

Definition. Angiomatoid FH was initially described as a variant of malignant FH [1]. It has recently been

reclassified as a neoplasm with low-grade malignant behaviour, unrelated to malignant FH. Although it is considered to be 'fibrohistiocytic' due to the cytological resemblance of tumour cells to histiocytes, focal positivity of these cells to desmin raises the possibility of muscular differentiation.

Clinical features. It presents in children and young adults, with no sex predilection, as an asymptomatic blue or skin-coloured subcutaneous or deeper mass. Most cases occur on the limbs and patients may present with systemic symptoms including fever, anaemia and weight loss. Generalized lymphadenopathy may also be seen.

Pathology [1–3]. Low-power examination reveals haemorrhagic, pseudovascular, cavernous-like, cystic spaces filled with red blood cells. Mononuclear inflammatory cells are prominent and germinal centres are present in some cases. Tumour cells are arranged in sheets and consist of short spindle-shaped and round cells with pink cytoplasm and vesicular nuclei. Cytological atypia is sometimes present, and the mitotic count tends to be low. Tumour cells are focally positive in some cases to desmin [3], muscle-specific actin and CD68, but not for smooth muscle actin.

Prognosis and management. Most cases are cured after adequate excision, but local recurrence is observed in about 15% of patients and, exceptionally, metastasis to neighbouring soft tissues or regional lymph nodes may occur. Complete excision and follow-up are therefore indicated. Local recurrence is more likely with deep tumours, those with an infiltrative growth pattern and those that are incompletely removed [2].

Plexiform fibrous histiocytoma [1–3]

SYN. PLEXIFORM FIBROHISTIOCYTIC TUMOUR

Definition. Plexiform FH is a distinctive, predominantly subcutaneous tumour with two distinctive components:
1 A fibro/myofibroblastic fascicular component.
2 A nodular histiocytic-like component, which also includes giant cells.

Despite its new name, it does not represent a plexiform variant of an ordinary FH (dermatofibroma).

Clinical features [1,3]. It mainly occurs in children and young adults, most commonly in females, and has a predilection for the upper limbs. The tumour is solitary, measures no more than a few centimetres in diameter and is asymptomatic.

Pathology [1–3]. Low-power examination reveals a predominantly subcutaneous tumour, with focal involvement of the dermis and a distinctive plexiform growth pattern. Purely dermal lesions are occasionally seen. Two components are usually identified and consist of fascicles of bland spindle-shaped fibro/myofibroblast-like cells and nodules of histiocyte-like cells with scattered giant cells, focal haemorrhage and haemosiderin deposition. In some tumours, one of the components may predominate. The spindle-shaped cells stain focally for smooth muscle actin, and the cells in the nodules are focally positive for CD68.

Prognosis and treatment. Local recurrences are observed in up to 30% of cases. Metastases to regional lymph nodes or to the lungs have been reported [1,3,4]. Complete surgical excision and follow-up are therefore indicated. The histological features do not predict aggressive behaviour.

Atypical fibroxanthoma [1–3]

Definition. Atypical fibroxanthoma (AFX), by definition, arises in sun-damaged skin of elderly people. Recently, ultraviolet radiation-induced *p53* mutations have been observed in these lesions, confirming the association with sun-damaged skin [4]. Tumours described in younger patients in non-sun-damaged skin represent examples of atypical FH.

Clinical features. The lesions occur most frequently on the ears, bald scalp and cheeks of elderly males (Fig. 53.9). Females are much less frequently affected. The lesions are often ulcerated and have a red, fleshy appearance; they rarely exceed 30 mm in diameter, and are usually of less than 6 months' duration. Many cases of AFX have been misdiagnosed clinically as granuloma telangiectaticum and—treated by curettage and cauterization—have been cured. Local recurrence has occasionally been seen, and

Fig. 53.9 Typical clinical appearance of an atypical fibroxanthoma with a polypoid architecture.

spread to lymph nodes is reported. However, since the advent of immunohistochemistry, reports of metastatic tumours have been very rare. This suggests that many lesions reported in the past as metastatic AFX, which were diagnosed by examination of haematoxylin and eosin stained slides alone, probably represented other tumours, such as spindle cell melanomas or sarcomatoid squamous cell carcinoma.

Pathology. The tumours are exophytic, fairly well-circumscribed and surrounded by an epidermal collarette. The remarkable and paradoxical feature of AFX is its histological resemblance to a highly malignant soft-tissue sarcoma (Fig. 53.10) [5–8]. It arises in the dermis and may extend into the fat, but the edge is pushing rather than infiltrative. It is composed of large spindle-shaped and histiocyte-like pleomorphic cells, many of which appear multinucleated. The cells are arranged in a haphazard fashion and mitotic figures, including atypical forms, are frequent. The histiocytic cells may contain lipid or haemosiderin [9,10]. There is current controversy as to whether the very atypical giant cells are aneuploid [11] or diploid [12]. A small series of a less pleomorphic spindle cell variant, which may cause considerable problems in differential diagnosis, has recently been described [13]. The diagnosis of AFX is a diagnosis of exclusion. An immunohistochemical panel to rule out melanoma (S100), sarcomatoid squamous cell carcinoma (pan-keratin) and

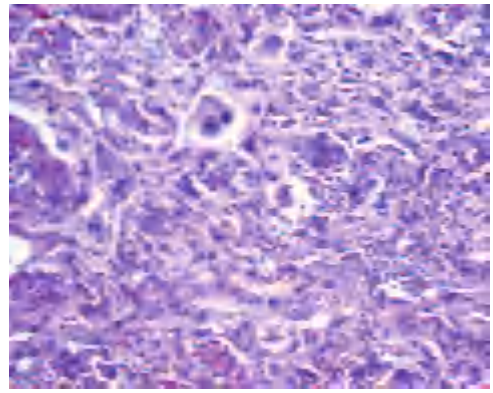

Fig. 53.10 Prominent cellular pleomorphism in a case of atypical fibroxanthoma.

even leiomyosarcoma (desmin) should be performed in all cases.

Treatment. The benign behaviour of the tumour enables it to be treated by limited local removal. Radiotherapy is not recommended.

Malignant fibrous histiocytoma [1–4]

Definition. 'Malignant FH' is an umbrella term encompassing a heterogeneous group of neoplasms that initially included five different clinicopathologic subtypes: pleomorphic, myxoid, giant cell, inflammatory and

angiomatoid. There is little relation between the different subtypes; the angiomatoid variant has recently been reclassified in the group of fibrohistiocytic tumours and the name changed to 'angiomatoid FH'. The concept of pleomorphic malignant FH has been challenged as not representing a distinct group of neoplasms but a heterogeneous category, including pleomorphic poorly differentiated sarcomas. If cases classified as such are extensively studied with ancillary studies including immunohistochemistry and electron microscopy, a large percentage may be reclassified as pleomorphic variants of other soft-tissue tumours, including liposarcoma, rhabdomyosarcoma and leiomyosarcoma [5]. The myxoid variant of malignant FH is now known as 'myxofibrosarcoma', and it is likely to show fibroblastic differentiation; this tumour often involves the skin because of its frequent origin in the subcutis, and it will therefore be discussed in more detail below. Angiomatoid FH has been described under fibrohistiocytic tumours. The inflammatory and giant cell variants of malignant FH hardly ever involve the skin and will not be discussed further.

Myxofibrosarcoma [1–4]

SYN. MYXOID MALIGNANT FIBROUS HISTIOCYTOMA

Definition. Myxofibrosarcoma is a neoplasm of the subcutis and deeper soft tissues with variable cellularity, myxoid change and cells with pleomorphic nuclei. The cellular end of the spectrum is identical to a pleomorphic malignant FH, and the diagnosis is made based on the presence of myxoid areas with less cellularity and a lobular pattern. The myxoid change should be seen in 10% or more of the tumour before a lesion is classified as myxofibrosarcoma.

Clinical features. This tumour mainly presents in middle-aged to old adults, with a slight predilection for females and for involvement of the extremities or trunk [4]. Typically, an asymptomatic mass, measuring several centimetres in diameter, is found in the subcutis or deeper soft tissues. This is one of the sarcomas that more often involves the dermis as a result of extension from the subcutis or deeper soft tissues, rather than having a dermal origin.

Pathology [4]. These tumours have a lobular growth pattern. They are classified according to the degree of cellularity and pleomorphism into low, medium and high grade. Low-grade tumours are paucicellular and consist of round or elongated bland and pleomorphic cells in a prominent myxoid stroma. The atypical cells have irregular hyperchromatic nuclei, and mitotic figures are relatively frequent. In the background, a fairly prominent number of thin-walled vascular channels with a typical curvilinear pattern are seen. Vacuolated Alcian blue-positive cells, focally mimicking lipoblasts, are relatively frequent. In some tumours, hypocellular areas blend with more cellular areas containing cells with increased pleomorphism; such tumours are classified as intermediate-grade. Tumours with high cellularity (high-grade) are indistinguishable from the so-called pleomorphic malignant FH and may have necrosis. Grading of lesions is important, because the rate of local recurrence and metastasis varies (see below). Tumour cells are positive for vimentin and only rarely display very focal positivity for actin.

Prognosis and treatment [4]. Excision with clear margins is essential. High-grade lesions have a higher tendency for local recurrence and for metastatic spread to regional lymph nodes. The overall 5-year survival is around 60%.

Intravascular papillary endothelial hyperplasia [1–4]

SYN. MASSON'S PSEUDOANGIOSARCOMA; MASSON'S VEGETANT INTRAVASCULAR HAEMANGIOENDOTHELIOMA

Definition. Intravascular papillary endothelial hyperplasia is regarded as a form of organizing thrombus in which endothelial cells line hyalinized papillae.

Incidence and aetiology. This is a relatively common lesion, which usually presents as a primary phenomenon within a thrombosed blood vessel, usually a vein [2–4]. The secondary variant is commonly seen as an incidental finding within other vascular tumours, or in lesions such as haemorrhoids. Exceptionally, the same phenomenon is seen within a haematoma [4]. The primary form presents in young adults, with a slight predilection for females.

Clinical features. The primary form presents as a slowly-growing single asymptomatic or slightly painful bluish nodule less than 20 mm in diameter. The site of predilection is the head and neck, followed by the hand (particularly the fingers). Multiple lesions are exceptional [5].

Pathology. The pathology is that of a widely dilated vascular channel in the dermis or subcutis, containing an organizing thrombus and prominent papillary projections with a hyalinized collagenous core. The papillae are lined by a single layer of usually bland endothelial cells with few mitotic figures. The presence of hyalinized collagen lined by endothelial cells produces an appearance similar to the 'dissection of collagen bundles' described in angiosarcoma. Distinction from angiosarcoma, however, is easy, as the latter is only exceptionally purely intravascular; it also displays cytological atypia, multilayering and mitotic figures. In secondary forms of Masson's tumour, the changes are seen within one or several vascular channels of a vascular tumour, usually a cavernous haemangioma or a vascular malformation.

Diagnosis. The clinical diagnosis suggested usually is that of a vascular tumour.

Treatment. Simple excision is usually curative and there is no tendency for local recurrence.

Reactive angioendotheliomatosis [1–3]

Definition. A reactive vascular proliferation, which is usually multifocal and which is associated with a number of systemic diseases. In the past, it was divided into a reactive and a malignant form. With the advent of immunohistochemistry, it became apparent that the malignant form is a variant of aggressive intravascular lymphoma (see Chapter 54).

Incidence and aetiology. This condition is rare and involves adults, with a wide age range and no sex predilection. Most cases present with cutaneous involvement only and are idiopathic. It has been described in association with systemic diseases, including bacterial endocarditis, peripheral vascular atherosclerotic disease, cryoglobulinaemia [2], liver and renal disease, antiphospholipid syndrome [4] and amyloidosis [5]. It is not clear how systemic diseases induce this vascular proliferation.

Clinical features. Most patients present with multiple erythematous and/or haemorrhagic macules, papules and plaques on the trunk and limbs. Patients with fewer, more localized, lesions may also be seen. In the latter cases, the association with systemic disease is not usually present. In patients with antiphospholipid syndrome or cryoglobulinaemia, ulcerated lesions may be present.

Pathology [6]. The dermis and, in some cases, the subcutis show a multifocal proliferation of clusters of capillaries lined by plump endothelial cells with little or no cytological atypia. A layer of pericytes surrounds each capillary. In some areas, dilated capillaries appear to contain smaller vascular channels within their lumina. Patients with cryoglobulinaemia show thrombosis of capillaries by hyaline eosinophilic globules.

Treatment. There is no treatment available, but the condition is usually self-limited and resolves spontaneously within a few weeks.

Glomeruloid haemangioma [1,2]

Definition. This is a distinctive multifocal vascular proliferation that occurs in association with POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M* protein and *s*kin changes) or with multicentric Castleman's disease. This condition is best considered as a form of reactive angioendotheliomatosis in the setting of POEMS syndrome.

Incidence and aetiology. This is a rare disease that presents exclusively in the context of POEMS syndrome and multicentric Castleman's disease. It presents in adults, with no sex predilection.

Clinical features. Patients present with multiple vascular papules on the trunk and limbs. Only a minority of these vascular lesions have the histological appearance of glomeruloid haemangioma; most have the histological appearance of cherry angiomas, or overlap with other vascular lesions, including cirsoid aneurysm (p. 53.19).

Pathology. The histological appearances in a typical case are striking, consisting of a multifocal dermal proliferation of clusters of closely packed dilated capillaries with a striking similarity to renal glomeruli. A layer of pericytes surrounds each capillary. Vacuolated cells are focally present and, in some cases, there are eosinophilic hyaline globules within the lumina of capillaries. These globules represent deposits of protein.

Treatment. The lesions do not tend to regress spontaneously. Individual lesions can be removed surgically, but because of their numbers this is not generally a practical option.

Pyogenic granuloma [1,2]

SYN. LOBULAR CAPILLARY HAEMANGIOMA; GRANULOMA TELANGIECTATICUM

Definition. A vascular nodule that develops rapidly, often at the site of a recent injury, and which is composed of a lobular proliferation of capillaries in a loose stroma.

Fig. 53.11 Clinical appearance of a pyogenic granuloma on a typical site at the tip of the finger.

Incidence and aetiology. This is a common lesion affecting both sexes with a predilection for females. It may occur at any age, and is seen quite often in children and young adults but is unusual in the elderly [3]. In a minority of cases, a minor injury, usually of a penetrating kind, has occurred a few weeks before the nodule appears. In other cases, no injury can be recollected, but this is likely on the basis of the patient's occupation or the body site affected. The balance of evidence indicates a reactive lesion.

Granuloma gravidarum is a variant of pyogenic granuloma that presents in the oral cavity during pregnancy.

Clinical features. The tumour is vascular, bright red to brownish-red or blue-black in colour. It is partially compressible, but cannot be completely blanched and does not show pulsation. The surface of early bright-red lesions is usually thin, intact epidermis. Older and darker lesions are frequently eroded and crusted, and may bleed very easily. Occasionally, the surface is raspberry-like or even verrucous. The size is commonly between 5 and 10 mm, but may reach 50 mm. The outline is rounded. The base is often pedunculated and surrounded by a collar of acanthotic epidermis; the lesion may be sessile. The common sites are the hands, especially the fingers (Fig. 53.11), the feet, lips, head and upper trunk, and the mucosal surfaces of the mouth and perianal area. The initial evolution is rapid, but growth ceases after a few weeks. Spontaneous disappearance is rare. Lesions are not painful; patients mainly complain of the appearance or of recurrent bleeding. There is a recent report of multiple pyogenic granulomas developing after exfoliative dermatitis [4]. Eruptive forms of this tumour have rarely been described [5]. In this setting, distinction from bacillary angiomatosis is crucial, as the latter often presents with multiple lesions that can be clinically and histologically difficult to distinguish

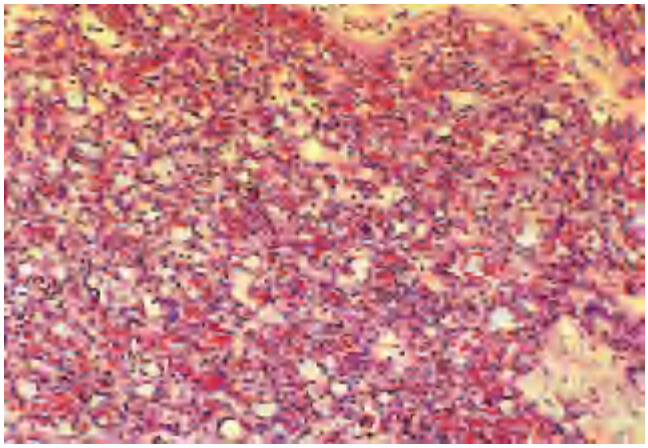

Fig. 53.12 Typical lobules of capillaries in a myxoid background, in a case of pyogenic granuloma.

from pyogenic granuloma. Multiple lesions closely resembling pyogenic granulomas have been reported after systemic [6] and topical [7] treatment with retinoids. Subcutaneous [8] and intravascular [9] variants are rarely seen and do not have distinctive clinical features.

Pathology. There is a lobular proliferation of small blood vessels, which erupt through a breach in the epidermis to produce a globular pedunculated tumour. The epidermis forms a collarette at the base of the lesion and covers part, or all, of the tumour in a thin layer. The proliferating vessels are set in a myxoid stroma, lacking in collagen in the earlier stages and relatively rich in mucin. The endothelial cells are plump, as in new granulation tissue, lining the vessels in a single layer. They are surrounded by a mixed cell population of fibroblasts, mast cells, lymphocytes, plasma cells and, where the surface is eroded, polymorphonuclear leukocytes (Fig. 53.12). Mitotic figures may be prominent. Older lesions tend to organize and partly fibrose. Late lesions can display focal degenerative atypia, raising the possibility of malignancy. In rare instances, particularly in children, and sometimes following treatment, satellite lesions which have a similar pathology to the primary lesion may develop around a pyogenic granuloma. These respond to simple destructive measures, thus ruling out malignancy [10]. Bacillary angiomatosis shows an almost identical histology to that of pyogenic granuloma [11]. However, in bacillary angiomatosis, pale epithelioid endothelial cells are prominent, neutrophils and nuclear dust are seen throughout the lesion and violaceous amorphous aggregates of bacilli which are positive with either Giemsa or Warthin–Starry stains are easily identified.

Diagnosis. In most cases, the history and clinical appearance leave little doubt about the diagnosis, and microscopic confirmation is straightforward. In 38% of one case series, the clinical diagnosis of pyogenic granuloma proved to be wrong [12]. The errors included keratoacanthoma and other epithelial neoplasms, inflamed seborrhoeic keratoses, melanocytic naevi, juvenile and malignant melanoma, virus warts, molluscum contagiosum, angioma, glomus tumour, eccrine poroma, Kaposi's sarcoma and metastatic carcinoma.

Treatment. The pedunculated lesions are easy to treat by curettage with cauterization or diathermy coagulation of the base. A considerable proportion of pyogenic granulomas recur after such treatment, because the proliferating vessels in the base extend in a conical manner into the deeper dermis. In some areas—for instance in the nail fold or on the palmar aspect of a finger—it may be reasonable to carry out curettage and hope for the best. Wherever possible, it is desirable to excise a narrow, but deep, ellipse of skin beneath the lesion and close the wound with sutures.

Cirsoid aneurysm [1–3]

SYN. CUTANEOUS ARTERIOVENOUS HAEMANGIOMA; ACRAL ARTERIOVENOUS TUMOUR

Definition. Cirsoid aneurysm is a small vascular proliferation characterized by small to medium-sized channels with features of arteries and veins. As opposed to deeper tumours showing similar features, shunting is absent.

Clinical features. Most lesions present on the head and neck region of young adults, with no sex predilection, as a small blue/red asymptomatic papule.

Pathology. The dermis contains a mixture of scattered blood vessels with thick walls and features of veins and arteries.

Treatment. As there is no associated shunting or deep component, simple excision is the treatment of choice.

Epithelioid haemangioma [1,2]

SYN. ANGIOLYMPHOID HYPERPLASIA WITH EOSINOPHILIA; PSEUDOPYOGENIC GRANULOMA; HISTIOCYTOID HAEMANGIOMA

Definition. A benign, locally proliferating lesion composed of vascular channels lined by endothelial cells with abundant pink cytoplasm and vesicular nuclei. Kimura's disease is distinct from angiolymphoid hyperplasia with eosinophils. In Kimura's disease, the lesions occur in younger patients, are deeper-seated, are associated with lymphadenopathy, have no initial overlying skin lesions and do not contain epithelioid endothelial cells [3,4]. Furthermore, peripheral blood eosinophilia is much more common in Kimura's disease.

Incidence and aetiology. These lesions have now been reported from many parts of the world. The cause is unknown, but most studies suggest a reactive process [5].

Clinical features [6–10] (Fig. 53.13). Affected individuals are commonly young adults who present with a cluster of small, translucent nodules on the head and neck, particularly around the ear or the hairline. The lesions may also involve the oral mucosa [11]. Less frequently, lesions can involve the trunk and extremities. Involvement of deeper soft tissues and internal organs, including bone, can be seen. Both sexes are equally affected. Individual nodules rarely exceed 2–3 cm in diameter, but occasionally deeper extension and larger subcutaneous lesions occur. Spontaneous regression is seen in the majority of cases after a variable period of time. Peripheral blood eosinophilia may be present but only in less than 10% of patients.

Pathology [2,12]. A poorly circumscribed lobular lesion is seen. It is composed of clusters of proliferating capillaries and, often, thicker blood vessels lined by plump, epithelioid endothelial cells with little cytological atypia and rare mitotic figures. Around the blood vessels there is a cellular inflammatory infiltrate composed mainly of lymphocytes and large numbers of eosinophils. However, only less than half of cases contain a prominent infiltrate. Older lesions show sclerosis of the stroma and the endothelial cells become more prominent. A frequent finding, particularly in larger lesions, is the involvement of larger blood vessels. Rare cases are entirely intravascular [13]. The endothelial cells stain for vascular markers including CD34, von Willebrand factor and CD31. In cutaneous cases, endothelial cells are negative for pan-keratin.

Fig. 53.13 Epithelioid haemangioma, or angiolymphoid hyperplasia with eosinophilia. (Courtesy of Dr R.H. Champion, Addenbrooke's Hospital, Cambridge, UK.)

Treatment. The natural history of the lesion is such that if a confident diagnosis is made on a small lesion, it is reasonable to observe the lesion for 3–6 months and await spontaneous regression. Both surgery and radiotherapy are effective, but local recurrences are common.

Hobnail haemangioma [1–4]

SYN. TARGETOID HAEMOSIDEROTIC HAEMANGIOMA

Definition. This is a benign vascular dermal proliferation characterized by small channels lined by endothelial cells with little cytoplasm and a prominent dark nucleus (hobnail cells). Formation of small papillae is also often seen. The original name proposed for this condition was based on a distinctive targetoid clinical appearance produced by bleeding and haemosiderin deposition. However, only a minority of lesions present with this typical appearance and therefore, the alternative name of hobnail haemangioma has been proposed.

Incidence and aetiology. It is relatively uncommon and occurs mainly in young to middle-aged adults with a slight predilection for males. Trauma may play a part in its pathogenesis [4].

Clinical features. This entity presents as a rapidly developing, asymptomatic, solitary red or brown lesion, which in some cases has a central raised violaceous papule and is surrounded by a paler brown halo (targetoid appearance) [1]. Any body site may be affected, but it has predilection for the lower limbs and trunk. The oral mucosa may also be affected [3].

Pathology. Pathological examination shows dilated vascular channels in the papillary and high reticular dermis, with a single layer of endothelial cells lining intraluminal papillary projections. These cells give a hobnail ('matchstick') appearance. They may occasionally be more numerous and appear to fill the lumen of the vessel. The vascular channels tend to disappear in the mid and lower reticular dermis, and the endothelial cells become less prominent and loose the hobnail appearance. Haemosiderin deposition is prominent and can be highlighted with a Perl's stain. The pathological appearance may resemble Kaposi's sarcoma, but this differential diagnosis can usually be resolved by clinicopathological correlation, as hobnail haemangioma is a solitary entity, whereas Kaposi's sarcoma is usually composed of multiple lesions. Histological distinction can be made if attention is paid to the symmetry of the lesion, the presence of hobnail endothelial cells with papillary projections and the absence of inflammation in hobnail haemangioma.

Diagnosis. It is usually suspected clinically if lesions have a targetoid appearance. The diagnosis is otherwise made histologically.

Treatment. Simple surgical excision is the treatment of choice; there is no tendency for recurrence.

Microvenular haemangioma [1–3]

Definition. This is a benign dermal vascular lesion characterized by proliferation of small vascular channels with features suggestive of venules.

Incidence and aetiology. It is relatively rare and presents mainly in young adults, with no sex predilection. Presentation in children is very rare [4]. Although the histological appearances suggest a venular differentiation, this has not been proven.

Clinical features. It presents as a solitary red/brown or bluish papule, nodule or plaque with predilection for the limbs. Most lesions are less than 10 mm in diameter.

Pathology. There is a superficial and deep dermal proliferation of angulated, thin-walled, vascular channels, all of which are surrounded by a single layer of pericytes. These channels are lined by flat, bland, endothelial cells and are surrounded by somewhat hyalinized collagen. A frequent finding is the infiltration of arrector pili muscles by vascular channels. Inflammation is not usually a feature.

Treatment. Simple surgical excision is the treatment of choice; there is no tendency for local recurrence.

Sinusoidal haemangioma [1]

Definition. This is a benign dermal and/or subcutaneous variant of cavernous haemangioma composed of thin-walled dilated vascular spaces in a typical sieve-like distribution.

Incidence and aetiology. Lesions are rare and present in adults, with a slight predilection for females.

Clinical features. Sinusoidal haemangioma presents as a solitary blue asymptomatic nodule, particularly on the trunk or upper limbs. The dermis and subcutaneous tissue overlying the breast is not uncommonly involved and may suggest a diagnosis of angiosarcoma (see below).

Pathology. The lesion is usually well circumscribed, but several lobules of subcutaneous tissue may be focally affected by the tumour. A striking feature is the presence of back-to-back dilated and congested thin-walled vascular channels. These channels are interconnected, and transverse sectioning is in part responsible for the distinctive sinusoidal appearance. Pseudopapillary projections are focally present and thrombosis with dystrophic calcification may also be seen. Focal cytological atypia secondary to degenerative changes may be seen. Distinction from angiosarcoma, particularly in tumours presenting in the breast, is based on the fact that the latter occurs in the breast parenchyma and only invades the dermis and subcutis secondarily. Tumour cells in angiosarcoma also display cytological atypia, multilayering and mitotic figures.

Treatment. Simple surgical excision is the treatment of choice, and there is no tendency for local recurrence.

Spindle cell haemangioma [1–5]

SYN. SPINDLE CELL HAEMANGIOENDOTHELIOMA

Definition. This is a benign vascular tumour, initially described as a low-grade malignant lesion with high tendency for local recurrence and minimal potential for metastasis. Further studies, however, demonstrated that it is a benign multifocal process often associated with a vascular malformation [3–5]. Confirmation of its benign nature has led to the change of the name 'haemangioendothelioma' for 'haemangioma' as the former implies low-grade malignant potential [6].

Incidence and aetiology. Spindle cell haemangioma is relatively rare. Males and females are affected equally, and the age range is wide. Often, lesions present in childhood or early adulthood and tend to be long-standing. The process appears to be reactive, and it is often associated with lymphoedema, Maffucci's syndrome (multiple enchondromas) [7], early onset varicose veins or Klippel–Trenaunay syndrome.

Clinical features. The majority of cases present in the distal limbs, particularly the hands and feet, as multiple cutaneous or subcutaneous red or bluish nodules. Deeper tumours are rare. Lesions continue to appear over many years, indicating multifocality rather than true recurrences. Most nodules are less than a few centimetres in diameter; they may occasionally be painful.

Pathology. Low-power magnification reveals single or multiple, fairly well-circumscribed, haemorrhagic nodules. Origin from a pre-existing blood vessel is often seen, and individual lesions may be entirely intravascular. Dilated, thin-walled, congested, cavernous-like vascular spaces are intermixed with more cellular areas composed of bland, short, spindle-shaped cells, with formation of slit-like spaces. Scattered more epithelioid cells, with pink cytoplasm and prominent vacuolation, are also seen. The spindle-shaped cells are a mixture of endothelial cells, pericytes and fibroblasts. Focal degenerative cytological atypia may be present. Immunohistochemistry reveals staining for CD31 and CD34 and focal staining for smooth muscle actin.

Diagnosis. The clinical appearances usually suggest a vascular process, but the final diagnosis usually requires histological confirmation.

Treatment. Single lesions are easily treated with simple excision. Treatment is more difficult in the presence of multiple lesions, as new lesions are more likely to appear over time.

Kaposiform haemangioendothelioma [1–5]

SYN. KAPOSI-LIKE INFANTILE HAEMANGIOENDOTHELIOMA

Definition. Kaposiform haemangioendothelioma is a locally aggressive vascular neoplasm, which occurs mainly in the abdominal cavity [1] but can affect primarily the skin or deeper soft tissues.

Incidence and aetiology. This tumour is rare and presents mainly in young children under the age of 2 years, with no sex predilection. Some lesions are congenital [6]. Rare cases occur in older children and adults. In 20% of cases, there is an association with lymphangiomatosis [3]. It appears clear that this lesion is truly neoplastic. Although it is not malignant, it causes morbidity and mortality due to its location and the frequent occurrence of Kasabach–Merritt syndrome.

Clinical features. The most common presentation by far is that of a large retroperitoneal infiltrative mass. Involvement of neighbouring organs and the very common association with consumption coagulopathy (Kasabach–Merritt syndrome) may lead to death. This complication is less common in more superficial tumours, particularly those located in the dermis and subcutaneous tissue [5,7,8].

Pathology. The growth pattern is lobular and infiltrative. Multiple nodules with haemorrhage and surrounding fibrosis are seen. Tumour lobules are composed of bland spindle-shaped cells with poorly defined pink cytoplasm. Cleft-like spaces are often seen between spindle-shaped cells, and a resemblance to Kaposi's sarcoma can be striking. However, numerous capillaries, often associated with microthrombi, are also present in tumour lobules. Epithelioid endothelial cells with focal vacuolation are also present. These features, along with the striking lobular architecture of the tumour, allow distinction from Kaposi's sarcoma.

Treatment. Complete excision is desirable as local recurrence is frequent, but this may be difficult to achieve when involvement is extensive. Spontaneous regression does not occur.

Atypical vascular proliferation after radiotherapy [1–3]

These lesions usually present a few years or months after radiotherapy for breast cancer (by comparison, post-irradiation angiosarcomas tend to present many years after radiotherapy) [1–3]. The clinical lesions are not distinctive and vary from macules to papules. Occasional cases may mimic lymphangioma circumscriptum. Irregular lymphatic-like vascular channels, lined by a single layer of endothelial cells, are seen in the dermis. The endothelial cells can have a hobnail appearance, and papillary projections can also be found. Careful examination of multiple sections is recommended to make sure that there are no mitotic figures or cytological atypia, as distinction from a well-differentiated angiosarcoma can be very difficult.

Giant cell angioblastoma [1,2]

This is a very rare distinctive congenital vascular tumour of which only a few cases have been reported, situated on the hand, the palate and the scalp. The tumour is diffusely infiltrative and slowly growing. Two of the reported cases showed no progression after incomplete excision. The

tumour is composed of infiltrative vascular channels lined by a single layer of bland endothelial cells and intermixed with solid nodules composed of spindle-shaped cells, histiocyte-like cells and osteoclasts. A plexiform growth pattern is often seen.

Retiform haemangioendothelioma [1–3]

SYN. HOBNAIL HAEMANGIOENDOTHELIOMA

Definition. Retiform haemangioendothelioma is a rare variant of low-grade angiosarcoma with a tendency for local aggressive behaviour. It is characterized by arborizing vascular channels lined by endothelial cells with a hobnail morphology.

Clinical features [1–3]. Retiform haemangioendothelioma presents mainly in young adults, with no sex predilection, as a slowly growing, asymptomatic, dermal and subcutaneous plaque or nodule. Exceptional cases present with multiple lesions [4]. Rarely there is an association with lymphoedema or radiotherapy. Local recurrence occurs in up to 60% of cases. So far, only one tumour has metastasized to a regional lymph node, and a further lesion has spread to locally to soft tissues [5]. No tumour-related deaths have been reported.

Pathology. Scanning magnification is distinctive and reveals arborizing, thin-walled narrow vascular channels with a striking resemblance to the rete testis. The growth pattern is infiltrative, and the vascular spaces are lined by bland hobnail endothelial cells with prominent nuclei and scanty cytoplasm. Intravascular papillae with collagenous cores, similar to those seen in papillary endolymphatic angioendothelioma, are sometimes seen. The surrounding stroma often appears hyalinized; a prominent mononuclear inflammatory cell infiltrate is common. The endothelial cells stain for vascular markers. There is no relationship to human herpesvirus 8 (HHV8).

Treatment. Wide local excision is the treatment of choice.

Papillary intralymphatic angioendothelioma [1]

SYN. ENDOVASCULAR LYMPHATIC ANGIOENDOTHELIOMA; DABSKA'S TUMOUR

Definition. Defining this entity is difficult because, since its original description in 1969, few further convincing cases have been described [1–4]. Furthermore, the original series included some examples of what it is now known as retiform haemangioendothelioma. Recently, the tumour has been better characterized under the preferred name of 'papillary endolymphatic angioendothelioma' [5]. It belongs to the family of tumours with hobnail endothelial cells, and it is characterized by dilated, cavernous-like lymphatic spaces with frequent papillary projections.

Clinical features. It presents mainly in infants and children, with 25% of the cases occurring in adults. There is no sex predilection. Presentation is as a slowly growing asymptomatic plaque or nodule with a predilection for the limbs. Although in the original series of six cases, a tendency for local recurrence and metastasis to regional lymph nodes was reported [1], in a recent series of 12 cases, none of the eight cases with follow-up recurred locally or metastasized [5]. It therefore seems likely that the behaviour of this tumour is benign.

Pathology. This tumour is composed of dilated, thin-walled channels simulating a cavernous lymphangioma. These channels are lined by bland hobnail endothelial cells with very rare mitotic figures. A striking feature is the formation of intraluminal papillary tufts with hyaline cores. Aggregates of mononuclear inflammatory cells may be seen around the vascular channels.

Treatment. Until the issue regarding the biological behaviour of this tumour is resolved, complete excision is recommended.

Kaposi's sarcoma [1–3]

SYN. KAPOSI'S DISEASE; GRANULOMA MULTIPLEX HAEMORRHAGICUM; IDIOPATHIC MULTIPLE PIGMENTED SARCOMA

Definition. A multifocal endothelial proliferation predominantly involving the skin and other organs and associated with formation of vascular channels and proliferation of spindle-shaped cells. It is not clear whether Kaposi's sarcoma is a reactive vascular proliferation or a neoplastic process. The recent demonstration of clonality tends to favour a neoplastic process [4].

At present, there are four recognized clinical subsets of Kaposi's sarcoma. These are:

1 Classic
2 Endemic
3 Iatrogenic
4 Human immunodeficiency virus (HIV)-related (Chapter 26).

Recent work has clearly identified a new type of herpesvirus, HHV8, in all Kaposi's sarcoma patients, both those with and those without additional HIV infection [5–7]; additionally, seroconversion to positivity against Kaposi's sarcoma-associated herpesvirus nuclear antigens has been observed [8]. This gives further support to the belief that this virus, along with genetic, immunological and environmental factors, is closely involved in the pathogenesis of Kaposi's sarcoma [9].

Classic Kaposi's sarcoma [10–12] is as described originally by Kaposi. It is found mainly in elderly males, particularly from Southern Europe or Jews of Eastern European origin. The lesions begin slowly and insidiously around the ankle and slowly spread up the leg (Fig. 53.14). Lymphoedema can occur as a complication. Lesions in other locations, including the oral mucosa, are very rare. Involvement of internal organs is not usually seen. The disease is very rarely responsible for the death of the patient. An association with haemopoietic malignancies may be seen.

Endemic Kaposi's sarcoma [13,14] is found in equatorial Africa, mainly in Zaire, Uganda [15,16] and Rwanda. In adults, males predominate, but this form is also seen in children. Crops of cutaneous vascular lesions develop, and may be associated with gross oedema. Visceral lesions may also occur; the prognosis is poor if there is extracutaneous involvement. The condition responds to chemotherapy.

Iatrogenic Kaposi's sarcoma [10,17,18]. This is seen in transplant patients and after cytotoxic chemotherapy for lymphomas. In transplant patients, it is 150 times more common than expected, and affected patients may be younger than those with other types of Kaposi's sarcoma (excepting those with HIV infection). Both systemic and cutaneous involvement may occur, and the progress of the disease may be aggressive, causing the death of the patient. If it is possible to remove the immunosuppression, the lesions will regress.

Kaposi's sarcoma associated with HIV infection [19–21]. This variant was first recognized in 1979 [22–24] when an epidemic of Kaposi's sarcoma was identified in the homosexual community in New York. Since that time, it has become firmly associated with the later stages of HIV infection [25–28]. However, it is much commoner in homosexuals than in others at risk, such as drug abusers or haemophiliacs. Kaposi's sarcoma usually develops in the later stages of the disease and is rarely a presenting feature of HIV infection. However, because of an awareness of the association between Kaposi's and HIV infection, both clinicians and pathologists may be called on to diagnose, or more often to exclude, Kaposi's sarcoma in its very early stages in 'at-risk' individuals. At this stage, only one or two flat macules may be present (Fig. 53.15). In the later stages, however, the lesions may occur anywhere on the body, develop with explosive rapidity and become

Fig. 53.16 Early lesion of Kaposi's sarcoma in an HIV-positive patient.

large nodules. The face and mucous membranes such as the soft palate are relatively frequently involved (Fig. 53.16). Involvement of lymph nodes, lungs and gastrointestinal tract is common. While both radiotherapy and chemotherapy may offer worthwhile temporary benefit, the prognosis is poor.

Clinical features [2,29–31]. Kaposi's sarcoma tends to occur in males. The lesions have a dark-blue or purplish colour. Initially, they may be almost macular and when they become tumid, pressure may produce partial blanching to reveal a brown tinge. The process usually begins on the extremities, most commonly on the feet and occasionally on the hands, ears or nose. Individual tumours enlarge to a diameter of 10–30 mm and stop growing. The process is multifocal, and adjacent areas may fuse to form a plaque or tumour. Oedema of the limb may follow, or at times precede, the appearance of the tumour. There are few subjective symptoms; pain may be felt in nodules on pressure areas. The lesions may involute to leave pigmented scars, or may become eroded, ulcerated or fungating. New lesions may appear along the course of superficial veins, and in time most patients have more or less symmetrical lesions. The rate of spread is remarkably variable. It tends to be slow in Europeans and more rapid in Africans, where oedema is often the first sign. Lymph nodes, mucosal surfaces and internal organs, particularly the small intestine, may all be involved as the disease

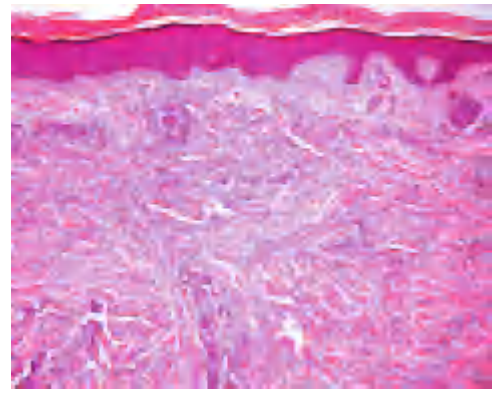

Fig. 53.17 Patch-stage Kaposi's sarcoma. Note the dermal proliferation of small, thin-walled, irregular lymphatic-like channels around pre-existing normal blood vessels and adnexal structures.

progresses. Kaposi's sarcoma may at times start in other organs and run its course without skin manifestation. Visceral involvement is the common pattern in African children, with lymph nodes as the main tissue involved.

Patients presenting with Kaposi's sarcoma associated with severe immunodepression have subtle lesions, which may well be missed by the unwary [2]. They may have only one or two lesions scattered over the body, and these may resemble slight areas of trauma or a simple bruise. The lesions are therefore quite dissimilar from the classic florid lesions developing on the lower limbs of the older patients from central Europe.

Pathology [31–35]. The cutaneous lesions of Kaposi's sarcoma can generally be divided into patch, plaque and nodular stages. These stages often overlap clinically and histologically. In the patch stage of the disease, there is a proliferation of jagged, irregular, lymphatic-like vascular channels lined by a single layer of bland endothelial cells, surrounding pre-existing blood vessels and adnexal structures (Fig. 53.17). Normal pre-existing capillaries and even adnexal structures seem to be floating within the newly formed channels, the so-called 'promontory sign' (Fig. 53.18). From the early stages a patchy, variably prominent, mononuclear inflammatory cell infiltrate containing plasma cells is seen. This is associated with extravasation of red blood cells and haemosiderin deposition. In some cases, numerous irregular, widely dilated, lymphatic-like channels impart a prominent lymphangiomatous appearance (lymphangiomatous Kaposi's sarcoma) [36].

The plaque stage is an exaggeration of the patch stage (Fig. 53.19). The vascular channels increase in number, and a network of bland spindle-shaped cells with pink cytoplasm develops. Dilated vascular channels in a back-to-back pattern may also be seen. Intra- or extracellular hyaline PAS-positive eosinophilic globules are common, and probably represent degenerate red blood cells [36].

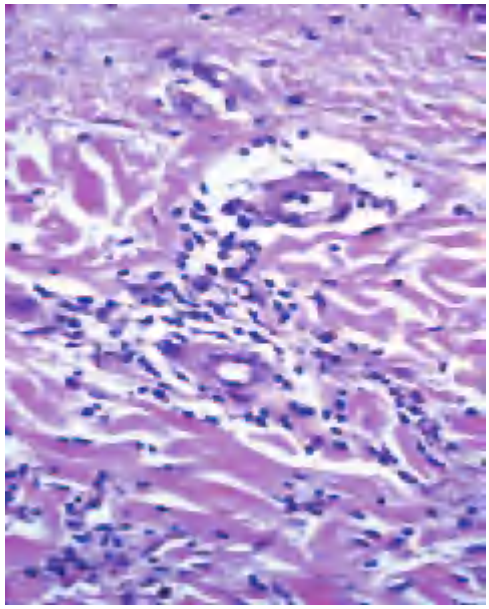

Fig. 53.18 Patch-stage Kaposi's sarcoma. Small irregular vascular channels lined by bland endothelial cells. Note the promontory sign, in which a normal pre-existing capillary seems to be floating in a newly formed channel.

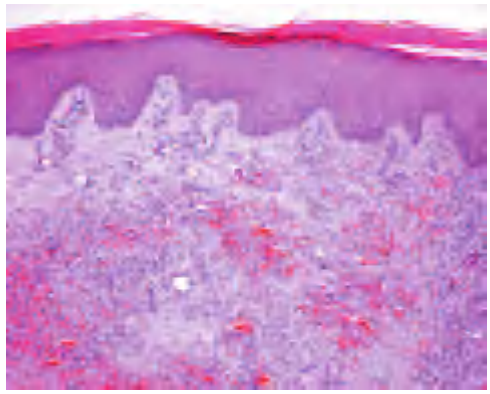

Fig. 53.19 Plaque-stage Kaposi's sarcoma. More diffuse proliferation of vascular channels with prominent haemorrhage.

Involvement of the whole dermis and superficial subcutis is frequent.

In the nodular stage, there are fairly well-circumscribed nodules of generally bland, spindle-shaped cells forming frequent cleft-like spaces that impart a typical sieve-like appearance (Fig. 53.20). Extravasated red blood cells are plentiful, as are hyaline globules. Mitotic figures are common. The periphery of the nodules may display a more angiomatous appearance.

Very rare examples of Kaposi's sarcoma display a high degree of cytological atypia and behave in an aggressive fashion.

A useful aid in the histological diagnosis of Kaposi's sarcoma is a newly developed monoclonal antibody against HHV8, which stains tumour cells in all cases of the disease. *In-situ* hybridization may also be used to demonstrate the virus, but this more expensive and time-consuming technique is not widely available.

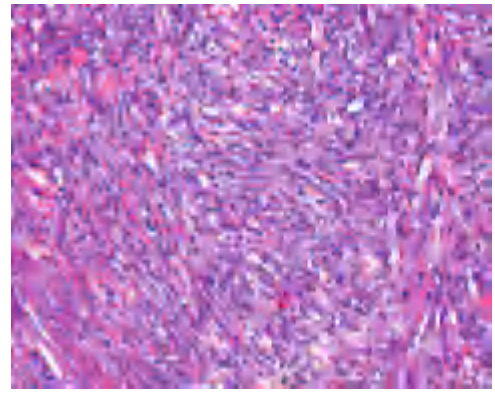

Fig. 53.20 Nodular Kaposi's sarcoma. Note the typical sieve-like appearance, with blood cells between the cleft-like spaces.

The pathological differential diagnosis includes many benign vascular tumours or reactive proliferations, including spindle cell haemangioma, tufted angioma, microvenular haemangioma, hobnail haemangioma, progressive lymphangioma and, on the lower legs, a 'venous' dermatitis (acroangiodermatitis). Angiosarcoma is also often considered in the differential diagnosis, but in the latter there is clear evidence of cytological atypia and multilayering.

Diagnosis [28]. The early lesion is most likely to be confused with a wide variety of benign vascular proliferations (see above) [31,34,35]. It must also be distinguished from histiocytoma or from other types of sarcoma. Its evolution from a macular lesion and its characteristic colour, slow development and multifocal distribution make the diagnosis likely in most instances. Cases in which the tumour is preceded by oedema may cause difficulty, as lymphangiosarcoma may arise in chronic lymphoedema. In prolonged venous hypertension of the lower legs, or in association with underlying vascular malformations, nodules with a close resemblance to Kaposi's sarcoma may develop (acroangiodermatitis, pseudo-Kaposi's sarcoma); they differ, however, in lack of progression, and a spindle cell proliferation is not seen in the histological sections.

Treatment [30,31]. Where a small area is involved, excision or radiotherapy can be used. Superficial radiotherapy is rapid and effective, and is the treatment of choice for the majority of patients with nodular disease of the extremities. Extensive disease can be treated by cytotoxic drugs such as chlorambucil [38], cyclophosphamide, vinblastine or actinomycin [39]. Cases related to acquired immune

deficiency syndrome (AIDS) may respond to intralesional vinblastine or vincristine, interleukin-2 or interferon [40] (Chapter 26).

Angiosarcoma [1–4]

SYN. MALIGNANT HAEMANGIOENDOTHELIOMA; HAEMANGIOSARCOMA; LYMPHANGIOSARCOMA

Definition. A malignant vascular tumour, arising from both vascular and lymphatic endothelium. Except for the pure epithelioid variant of angiosarcoma (see below), cutaneous angiosarcoma almost exclusively occurs in three settings: idiopathic angiosarcoma of the face, scalp and neck [2–4], angiosarcoma associated with chronic lymphoedema (Stewart–Treves syndrome) [5–9] and postirradiation angiosarcoma [10–12]. In this chapter, the terms 'angiosarcoma' and 'lymphangiosarcoma' are used interchangeably.

Incidence. This is a rare tumour in any form.

Stewart–Treves syndrome occurs in 0.5% of patients who survive mastectomy for more than 5 years. The mean age at appearance of the angiosarcoma is 62 years, and the mean interval between mastectomy and the appearance of the tumour is 10.5 years [9]. Two cases have been reported in men following mastectomy [13]. Not all patients have received radiotherapy in association with the mastectomy, and not all have had axillary nodes removed. Lymphoedema is not invariably present, or it may be late in appearing and antedate the tumour by only a short time. The incidence and cause of postmastectomy lymphoedema have been reviewed [14]. In the majority of cases, the clinical course and autopsy findings have shown that the treatment of the breast carcinoma was successful and that patients have had less frequent involvement of the axillary nodes than usual [9]. A small number of cases have arisen in lymphoedema of the lower limb, or in the upper limb without breast cancer and mastectomy [15]. Most of these patients were women.

Multiple primary malignancies have occurred in 8% of cases of Stewart–Treves syndrome [6] and a systemically acting carcinogen has been suggested [8,9]. There is no evidence to support this.

Fig. 53.21 Typical haemorrhagic appearance of an angiosarcoma.

Clinical features [3,4,16,17]. In all types of angiosarcoma, the first sign may be an area of bruising, often thought by the patient to be traumatic (Fig. 53.21). Dusky blue or red nodules develop and grow rapidly, and fresh discrete nodules appear nearby. In some cases, haemorrhagic blisters are a prominent feature. As the tumours grow, the oedema may increase and older lesions may ulcerate. Multifocality is a very frequent finding; this makes surgical excision very difficult, particularly in those cases occurring on the face and scalp. Dissemination occurs early, with the first visceral deposits usually being in the lung and pleural cavity.

Angiosarcoma in children is exceptional and mainly occurs in deep soft tissues. Several cases have arisen in vascular naevi some years after treatment [21].

Most studies reporting outcome have confined their attention to idiopathic angiosarcoma of the face, neck and scalp, in which the reported 5-year survival is low, at between 12% and 33% [3,22]. A recent study combining angiosarcomas of the face and scalp with those in soft tissue reported a 5-year survival of 24% [1]. Angiosarcomas arising in the setting of chronic lymphoedema and after radiotherapy appear to be equally aggressive.

Pathology [4,19–21]. In the well-differentiated tumour, vascular channels infiltrate the normal structures in a disorganized fashion, as if trying to line every available tissue space with a layer of endothelial cells. The collagen is characteristically lined by tumour cells in a pattern that has been described as 'dissection of collagen' (Fig. 53.22). Tumour cells may be plumper than normal, double-layered in places and form solid intravascular buds. The pattern of growth is more suggestive of lymphatic vessels than blood vessels, but both are probably involved. Haemorrhage is often prominent. Less well-differentiated tumours show more atypical pleomorphic endothelial cells, often with a spindle cell morphology, which may be heaped into several layers or become syncytial. Advancing malignancy may be associated with loss of vascular pattern and proliferation of cell masses.

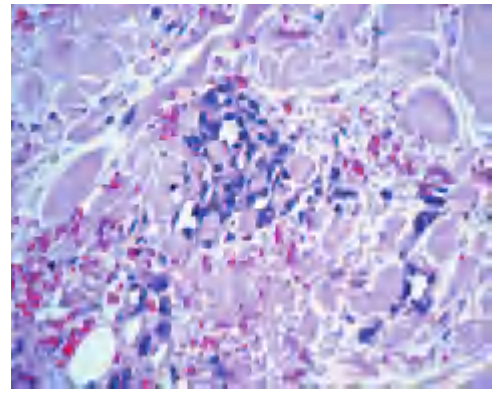

Fig. 53.22 Well-differentiated angiosarcoma, with thin-walled irregular vascular channels lined by atypical endothelial cells. Note the dissection of collagen pattern.

Immunohistochemical studies have indicated that the antibodies to CD31 are the most reliable markers for routine use, compared with antibodies against factor VIII and CD34 [7]. However, a panel of antibodies including the three markers is recommended in difficult cases as positivity to the various markers varies.

Treatment [3]. All angiosarcomas, regardless of the setting in which they occur, have a bad prognosis. In the less malignant types, wide excision and grafting has controlled some cases. The response to radiotherapy is disappointing and is usually only palliative. In the early stages of angiosarcoma of a limb, radical amputation may offer a hope of cure. It has been suggested that a high mitotic count correlates with poor prognosis and that a heavy mononuclear inflammatory cell infiltrate correlates with good prognosis [3,5,16]. In our experience, however, histological features do not seem to correlate with prognosis. Tumour size and completeness of excision appear to be more reliable factors to predict outcome [16].

Epithelioid haemangioendothelioma [1–3]

Definition. Epithelioid haemangioendothelioma is a distinctive tumour characterized by epithelioid endothelial cells arranged in strands or individual units in a myxoid or hyalinized stroma. It was initially described as a low-grade malignant tumour, but it has recently been proposed that it should be classified as a fully malignant neoplasm, in view of the associated morbidity and mortality [3].

Clinical features [1–3]. This tumour may occur in many internal organs, and it is more commonly seen in deeper soft tissues. Involvement of the skin may occur primarily or as a result of direct extension from a deep-seated primary. Less than 10% of cases occur primarily in the skin. Tumours present in middle-aged adults, with an equal sex incidence. Cutaneous tumours are usually small, but deeper lesions are often several centimetres in diameter. Pain is a frequent complaint, probably due to angiocentricity. Involvement of other organs, including the lung, liver and bone may be seen in some cases, and it is not clear whether this represents multicentricity or metastatic spread.

Pathology [1–3]. The neoplasm is infiltrative and is composed of strands, cords and nests of endothelial cells in a hyaline or myxoid stroma. Dermal lesions often consist of a fairly well-defined nodule. The tumour cells have epithelioid morphology and consist of pink cytoplasm, vesicular nuclei and inconspicuous nucleoli. Angiocentricity is commonly seen. Formation of vascular channels is not readily apparent but a common finding is the presence of intracytoplasmic vacuoles with or without red blood cells. A small number of cases display cytological atypia, which may be prominent, and a high mitotic count. There is no clear correlation between cytological grade and behaviour. Occasional tumours overlap with epithelioid angiosarcoma. Staining for endothelial cell markers, especially factor VIII-related antigen and CD31, is usually positive, and 20% of cases are focally positive for keratin [3,4].

Prognosis and treatment. Purely cutaneous tumours appear to have a benign behaviour, but there is some tendency for local recurrence. Deeper tumours have a recurrence rate of up to 15% and a mortality rate of 20%. Complete excision with clear margins is therefore necessary.

Epithelioid angiosarcoma [1–3]

Definition. A distinctive variant of angiosarcoma composed almost exclusively of endothelial cells with an epithelioid morphology, often mimicking a carcinoma. This tumour represents the malignant end of the spectrum of tumours with epithelioid cell morphology.

Incidence. This is a rare tumour that mainly occurs in deep soft tissue, but may present primarily in the skin or other organs.

Clinical features [1–3]. Cutaneous tumours present in young to middle-aged adults, mainly in males, with a predilection for the extremities. The typical presentation is that of solitary, or more rarely multiple, asymptomatic papules or nodules which are often haemorrhagic. It is not

clear whether multiple lesions represent multifocality or metastatic disease. Occasional cases have been reported in association with a foreign body [4], radiotherapy [1] or an arteriovenous fistula [5].

Pathology [1–3]. Sheets of atypical epithelioid cells with abundant pink cytoplasm, vesicular nuclei and a single eosinophilic nucleolus occupy the dermis and/or subcutis. Haemorrhage and haemosiderin deposition is often seen. Formation of vascular channels is not readily apparent, and the main feature is the presence of intracytoplasmic vacuoles with or without red blood cells in variable numbers of tumour cells. Mitotic figures are common. Tumour cells are variably positive for vascular markers including CD31, CD34 and von Willebrand factor. In 50% of cases, there is positivity for cytokeratin. Focal positivity for epithelial membrane antigen is also seen in some cases.

Prognosis and treatment. Although it was initially suggested that cutaneous epithelioid angiosarcoma has a relatively good prognosis, this was based on only very few cases with limited follow-up [2]. The behaviour of these tumours appears to be aggressive, and complete excision and close follow-up are therefore indicated.

Lymphatic tumours

Cavernous lymphangioma, cystic hygroma and lymphangioma circumscriptum are described in Chapter 51.

Progressive lymphangioma

SYN. BENIGN LYMPHANGIOENDOTHELIOMA

Definition. This is a benign dermal tumour composed of irregular lymphatic channels dissecting between collagen bundles.

Clinical features [1–4]. Most cases present in middle-aged adults, but the age range is wide and children may be affected. The tumour presents as a slowly enlarging red macule, usually several centimetres in diameter with predilection for the limbs. Males are slightly more affected than females. Multiple lesions are exceptional [3].

Pathology [1–4]. Low-power examination reveals an ill-defined, often pan-dermal, proliferation of irregular thin-walled lymphatic channels dissecting between collagen bundles. These channels tend to be orientated parallel to the epidermis and are lined by a single layer of bland endothelial cells. Involvement of the subcutaneous tissue is rare. Distinction from the lymphangiomatous variant of Kaposi's sarcoma is often very difficult, but in the former there are aggregates of inflammatory cells including plasma cells, and the cells lining the vascular channels are usually positive for HHV8. Distinction from a well-differentiated angiosarcoma is based on the absence of cytological atypia and mitotic figures.

Treatment. Excision is all that is required; there is no tendency for local recurrence.

Tumours of perivascular cells

Glomus tumour [1–3]

SYN. GLOMANGIOMA; GLOMANGIOMYOMA

Definition. A tumour of the myoarterial glomus composed of vascular channels surrounded by proliferating glomus cells. The tumours have variable quantities of glomus cells, blood vessels and smooth muscle. According to this finding, they are classified as solid glomus tumour, glomangioma and glomangiomyoma.

Incidence and aetiology. Glomus tumours are comparatively uncommon. Some are present at birth; they rarely appear during infancy, but from the age of 7 years onwards the incidence increases gradually. Multiple tumours are 10 times more frequent in children than in adults [3,4]. The occurrence of familial cases with autosomal-dominant inheritance [1,5,6], and the association of multiple tumours with malformation of the same limb, suggest that genetic factors may be involved [7]. There may be a history of trauma preceding the tumour.

Clinical features. A solitary glomus tumour is a pink or purple nodule varying in size from 1 to 20 mm; it is conspicuously painful (Fig. 53.23). Pain may be provoked by direct pressure or a change in skin temperature, or may be

Fig. 53.23 Clinical appearance of a glomus tumour.

spontaneous. There is an equal sex incidence; adults present mainly during the third or fourth decades of life. The commonest site is the hands, particularly the fingers, followed by other sites on the extremities including the head, neck and penis. Tumours beneath the nail are particularly painful, and patients present for treatment while the lesions are still very small. The affected nail has a bluish-red flush. Glomus tumours may also involve internal organs.

Multiple glomus tumours are larger and usually dark blue in colour, and are situated deep in the dermis. They are less restricted to the extremities, may be widely scattered and are not usually painful [8–11]. In some cases, grouped multiple tumours may be painful, and pain, intermittent discoloration and sweating of a limb may precede the development of a palpable tumour.

Pathology. The tumour is round, well-circumscribed and situated in the dermis. The proportion of glomus cells to vascular spaces varies. The smaller, painful lesions tend to be mainly cellular. The larger, multiple and often painless lesions are angiomatous, with only a band of cells around the dilated vascular channels. The glomus cell is cuboidal, with a well-marked cell membrane and a round central nucleus. The cells align themselves in rows around the single layer of endothelial cells of the vascular spaces and in a somewhat less orderly fashion further out. Numerous non-myelinated nerve fibres course through the cellular masses. More than 50% of tumours can be classified as glomangiomas, and a minority (less than 15%) are classified as glomangiomyomas. Electron microscopy [12–14] suggests that glomus cells are transversely cut smooth muscle cells and that there are many mast cells around the tumour, but that nerve fibres are not associated with the glomus cells. Tumour cells are universally positive for smooth muscle actin and are usually negative for desmin. An oncocytic variant has been described [15], and also variants developing within a cutaneous nerve [16] and within a vein [17]. Malignant glomus tumour (glomangiosarcoma) is exceedingly rare. Even tumours that are histologically malignant rarely metastasize, but they have a potential for local recurrence [18,19].

Diagnosis. The solitary tumour is to be distinguished from other painful tumours such as leiomyoma and eccrine spiradenoma. Distinction is usually only possible on histological examination. The multiple glomangioma may be indistinguishable clinically from a cavernous haemangioma, and is possibly identical to 'blue rubber bleb' naevus [5].

Treatment. Surgical excision is usually curative. Local recurrence is very rare and occurs mainly after incomplete excision. Most recurrences are seen in deeper lesions with an infiltrative growth pattern. These lesions have been described as infiltrating glomus tumours [18].

Neuromuscular hamartoma [1,2]

SYN. TRITON TUMOUR

Definition. These lesions appear to be combined hamartomas of both muscular and neural tissue.

Clinical features. The clinical appearance is of a subcutaneous mass.

Pathology. Multinodular masses of skeletal muscle are mixed with both myelinated and unmyelinated nerve fibres. Malignant triton tumours, composed of a mixture of schwannoma-like material and rhabdomyosarcoma, are very much commoner than the benign variety of triton tumour.

Management. Surgical excision is required.

Multiple mucosal neuromas [1]

SYN. SIPPLE'S SYNDROME

In Sipple's syndrome, multiple neuromas of the oral mucosa may be associated with phaeochromocytoma, parafollicular thyroid cysts secreting calcitonin, medullary thyroid carcinoma and opaque nerve fibres on the cornea (Chapters 12 and 59).

REFERENCE

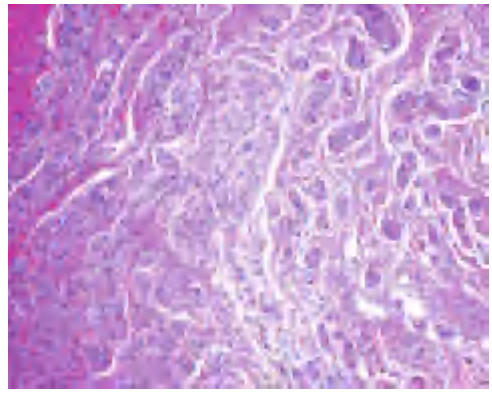

Fig. 53.24 Histological appearance of an amputation neuroma. Small nerves proliferate in the dermis in a background of fibrosis.

Amputation stump neuroma [1]

SYN. TRAUMATIC NEUROMA

Definition. This is a benign response of nerve tissue to injury.

Clinical features. A small, tender nodule is found in a scar site.

Pathology. Foci of proliferating nerve tissue surrounded by scar tissue are typically seen (Fig. 53.24). Accessory digits may show a very similar pattern of tissue involvement.

Management. Surgical excision is usually required. The problem can be prevented by apposing ends of nerves at sites of injury.

Morton's neuroma [1,2]

SYN. MORTON'S METATARSALGIA

Definition. This is the result of damage to the plantar digital nerve, followed by fibrosis. The condition has been associated with the use of high-heeled footwear.

Clinical features. It is most common in women, who complain of severe pain, usually between the third and fourth metatarsals, especially when walking.

Pathology. On pathological examination, there is very prominent perineurial, endoneurial and epineurial fibrosis. Perivascular fibrosis and intimal thickening are also seen.

Management. Excision is the recommended therapy and is curative.

Solitary circumscribed neuroma

SYN. PALISADED ENCAPSULATED NEUROMA

Definition. This is a distinctive variant of cutaneous neuroma composed of variable proportions of the normal components of nerve tissue.

Clinical features [1–3]. It is fairly common and presents mainly on the face of adults as a small asymptomatic papule, which may resemble a naevus. There is an equal sex incidence.

Pathology [1–3]. Examination reveals a well-circumscribed, partially encapsulated dermal nodule, often associated with a nerve in the deep dermis. It is composed of uniform cells with pink cytoplasm in a collagenous background and with artifactual clefting between bundles. The capsule displays epithelial membrane antigen-positive perineurial cells. Most of the cells within the nodule are S100-positive, and special stains may demonstrate axons.

Treatment. Simple excision is curative.

Schwannoma

SYN. NEURILEMMOMA

Definition. A tumour of nerve sheaths composed of Schwann cells.

Incidence. The tumour is relatively uncommon. It arises most frequently from the acoustic nerve. Bilateral acoustic schwannomas are characteristic of neurofibromatosis type 2. There is no association with neurofibromatosis type 1. In the peripheral nervous system, it is usually found in association with one of the main nerves of the limbs, usually on the flexor aspect near the elbow, wrist or knee, the hands or the head and neck [1]. It may be seen on the tongue. Other sites include the wall of the gastrointestinal tract and the posterior mediastinum. It may occur at any age, but is most common in the fourth and fifth decades. Females are affected more often than males [2].

Clinical features [3]. They are rounded or ovoid, circumscribed nodules varying in size up to 5 cm, usually firm (but sometimes soft and cystic) in consistency, and sometimes painful. The colour is pink-grey or yellowish. Small lesions may be intradermal, but larger ones are subcutaneous. They usually grow slowly. Malignant transformation of a schwannoma is exceedingly rare and may contain areas of epithelioid angiosarcoma [4,5].

Pathology [1,6]. The tumour is rounded, circumscribed and encapsulated. It is situated in the course of a nerve, usually in the subcutaneous fat. The cells are spindle shaped with poorly defined cytoplasm and elongated wavy basophilic nuclei. Variable amounts of collagen are seen in the background. Cells are arranged in bands, which stream and interweave. The nuclei display palisading and are arranged in parallel rows with intervening eosinophilic cytoplasm in a typical appearance known as Verocay bodies. Cellular areas known as Antoni A are intermixed with areas showing prominent myxoid change known as Antoni B [7]. The latter areas are likely to be the result of degeneration. In some tumours, there is mucous secretion, producing a vacuolated stroma. Scattered mononuclear inflammatory cells are often seen. In some cases, the nerve of origin may be found associated with the capsule. Electron microscopy shows that tumour cells have typical features of Schwann cells [8]. There is no proliferation of nerve fibrils. S100 protein staining is strong and uniform [9].

There are several variants of schwannoma, which may be confused histologically with other benign or malignant tumours.

Ancient schwannoma [10] often occurs in a deep location and is characterized by prominent degenerative changes, which often result in cytological atypia. There is loss of Antoni A areas, which makes histological diagnosis difficult.

Cellular schwannoma [11] also tends to have a predilection for deep soft tissues. It is characterized by high cellularity, with almost complete absence of Antoni B areas. This, coupled with the presence of mitotic figures, often leads to a misdiagnosis of malignancy.

Plexiform schwannoma [12,13] tends to occur in younger patients, may be painful and has a predilection for the dermis. Multiple cellular nodules composed of bland Schwann cells are seen in the dermis. Distinction from plexiform neurofibroma is important, as these tumours are not usually associated with neurofibromatosis type 1.

Melanotic schwannoma [14] only exceptionally occurs in the skin; it has a predilection for spinal nerve roots. Tumour cells are epithelioid and melanin pigment is prominent. The importance of this variant is that they are

capable of malignant behaviour and may be a marker of Carney complex (Chapter 59).

Pacinian schwannoma is a rare variant composed of structures closely resembling the Pacinian corpuscles.

Glandular schwannoma [15] represents in most cases an ordinary schwannoma with entrapment of normal sweat glands.

Diagnosis. Of the various nodular dermal and hypodermal tumours, schwannoma is most likely to be mistaken for a glomus tumour when painful, and for a lipoma, epidermoid cyst, synovial ganglion, juxta-articular node or neurofibroma when asymptomatic. The diagnosis can be suspected when it is in the course of a nerve; otherwise, histological examination is necessary.

Treatment. Simple excision is curative.

Solitary neurofibroma [1–4]

Definition. An isolated lesion probably arising from the endoneurium and composed of a mixture of Schwann cells, fibroblasts and perineurial fibroblasts. It is not related to neurofibromatosis type 1. Although it appears to be hamartomatous in nature, the demonstration of clonality suggests a neoplastic origin [5].

Fig. 53.25 Multiple soft papules, typical of neurofibroma in a patient with neurofibromatosis type 1.

Clinical features. Both sexes and any body site may be affected. It usually appears during the third decade as a slow-growing, small polypoid lesion. Multiple neurofibromas are rare outside the setting of neurofibromatosis type 1 (Fig. 53.25).

Simple excision is curative. Malignant change is said not to occur outside the setting of neurofibromatosis type 1.

Pathology. These lesions differ from neurilemmomas in that they do not have a capsule, they are only focally positive for S100 protein, and they do not usually have well-defined Antoni A and Antoni B areas. Instead, they are composed of bland spindle-shaped cells with wavy nuclei in a myxoid or collagenous stroma. Mast cells are usually prominent. Degenerative changes are sometimes seen but mitotic activity is absent. Less than 50% of the cells in these lesions are S100-positive. There is also focal positivity for CD34 and epithelial membrane antigen.

Several histological variants of neurofibroma have been described, including epithelioid neurofibroma and granular cell neurofibroma [3].

Plexiform neurofibroma

This tumour is considered to be pathognomonic of neurofibromatosis type 1 (see Chapter 12). It presents in

Fig. 53.26 Clinical appearance of a plexiform neurofibroma.

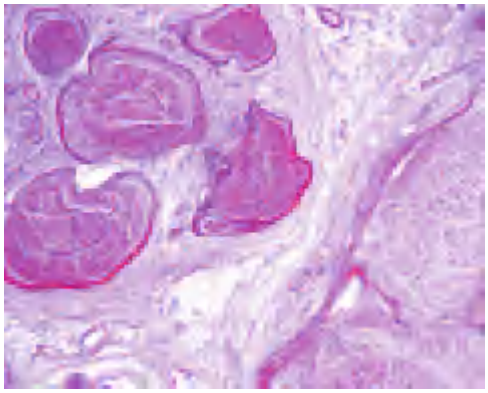

Fig. 53.27 Irregular, poorly formed nerves in a plexiform neurofibroma.

children and young adults of either sex, with predilection for the lower limbs and the head and neck. Tumours are large and located in the dermis, subcutis and even deeper soft tissues (Fig. 53.26). The overlying skin is folded and hyperpigmented and the lesion is described as having an appearance like a 'bag of worms'. This reflects the typical histological appearance of nerve trunks of different size randomly distributed throughout the involved tissues (Fig. 53.27). Careful histological examination of these lesions is necessary because the presence of any mitotic activity usually indicates malignant transformation.

Surgical removal of these lesions is usually very difficult because of the extensive involvement. When planning the surgical removal of these tumours, surgeons should remember that there is a tendency for haemorrhage within the tumour that may lead to morbidity or mortality.

Diffuse neurofibroma

This lesion presents as a diffuse, poorly-defined induration of the skin and subcutaneous tissue in children or young adults, with a predilection for the trunk and head and neck area. Only a minority of cases are associated with neurofibromatosis type 1. The histological features are identical to those of a solitary neurofibroma except for the fact that there is diffuse replacement of involved tissue by the tumour.

Perineurioma [1–3]

SYN. STORIFORM PERINEURAL FIBROMA

Definition. Perineurioma is a tumour originally described in soft tissues. It is relatively common in the skin and it is composed of cells showing differentiation towards perineural fibroblasts.

Clinical features. The lesion has predilection for the lower limbs of young females. Tumours are small and asymptomatic. A distinctive sclerosing variant affecting, almost exclusively, the hands has been described recently [3].

Pathology. Tumours are well-circumscribed and composed of bipolar and slender bland, thin, spindle-shaped cells with scanty cytoplasm and wavy nuclei. They are often arranged in a storiform pattern. Cellularity varies and is low in the sclerosing variant where hyalinized collagen predominates. Tumour cells are distinctively positive for epithelial membrane antigen. Focal positivity for factor XIIIa and CD34 may also be seen.

Treatment. Lesions are entirely benign, and simple excision is the treatment of choice.

Dermal nerve sheath myxoma [1–3]

SYN. NEUROTHEKEOMA

Definition. This is a myxoid tumour that is thought to display nerve sheath differentiation.

Clinical features [1,2]. It presents most commonly on the upper limbs or face of young individuals, with a predilection for females. Lesions are small, skin-coloured and asymptomatic.

Pathology [1–3]. The dermis shows a well-defined tumour composed of lobules that vary in size and shape and separated by fibrocollagenous stroma. Each lobule is composed of slender stellate or spindle-shaped cells

with bland nuclei and indistinct cytoplasm margins in the background of prominent myxoid change. Mitotic figures are very rare. Occasional cases display more cellular areas [4]. Tumour cells are uniformly positive for S100.

Treatment. Simple excision is curative. There is no tendency for local recurrence.

4 Rosati LA, Fratamico CM, Eusebi V. Cellular neurothekeoma. *Appl Pathol* 1986; **4**: 186–91.

Cellular neurothekeoma [1–4]

Definition. Despite its name, this tumour is not likely to be related to dermal nerve sheath myxoma, and its line of differentiation has not been established. It should not be confused with ordinary nerve sheath myxomas showing focal cellular areas [1–3].

Clinical features. The tumour presents as a small, asymptomatic papule in children and young adults, with a predilection for the trunk and face and neck [4].

Pathology. In the dermis, there is an ill-defined tumour composed of nests and fascicles of epithelioid or spindle-shaped cells with vesicular nuclei and a single small eosinophilic nucleolus. Mitotic figures are relatively common and scattered multinucleated cells may be seen. Tumour cells resemble melanocytes, and this often leads to the lesion being confused with a melanoma. However, there is no junctional activity, and cells are negative for S100. Some tumours have larger size, more cytological atypia and increased mitotic count, and these tumours have been classified as atypical cellular neurothekeoma. However, this does not seem to be related to a more aggressive behaviour. Tumour cells are often positive for smooth muscle actin, NKI-C3, neurone-specific enolase and PGP 9.5.

Treatment. Simple excision is curative, and there is no tendency for local recurrence.

Granular cell tumour [1–4]

SYN. ABRIKOSSOFF'S TUMOUR

Definition. A tumour composed of cells with characteristic granular cytoplasm. The histogenesis of the classic granular cell tumour seems to be neuroectodermal. However, it is worth remembering that many tumours of different histogenesis may show granular cell change, due to the cytoplasmic accumulation of secondary lysosomes.

Incidence. This is a rare tumour, occurring in the tongue as well as in the skin, and also in a variety of deeper locations including internal organs. Females are slightly more affected than males, and it is common in the third to fifth decade of life. It can occur in childhood [5,6].

Clinical features. The tumour is usually solitary, situated in the skin, the gingiva [7], or beneath the epithelium of the tongue. It is firm and rounded but with rather indefinite margins, sessile or pedunculated, and between 5 and 20 mm in diameter, although larger tumours may be seen. The colour may vary from flesh colour to pink or greyish-brown. It is most common in the tongue, where the epithelium over it may be thickened. On the skin surface, the epithelium covering the tumour is usually normal, although it may thicken or at times ulcerate. There is no particular site of predilection. Multiple tumours may occur, and several have been reported in children, one of whom also had axillary freckling [5]. The tumour grows slowly.

A malignant type of granular cell myoblastoma that metastasizes has been reported [8,9].

Among the internal sites reported are muscle, lip, jaws, parotid gland, pharynx, larynx, trachea, bronchus, lung, chest wall, breast, lacrimal sac, orbit, heart, oesophagus, common bile duct, urinary bladder, spermatic cord, male urethra, perineum, anal region, vulva and ovary [6,10].

Pathology [11,12]. Large polyhedral cells arranged in sheets, which infiltrate the dermal connective tissue and subcutaneous fat, form the tumour. The cytoplasm is pale and contains brightly acidophilic granules. The nuclei are relatively small and round, and tend to be vesicular. The epithelium over the area may show pseudoepitheliomatous hyperplasia. The original suggestion that the cells are myoblasts probably arose from examination of tumours of the tongue in which infiltration between the striated muscle bundles gave the impression of origin from the muscle. The general belief now is that the cells are of neural or nerve sheath origin [13–18].

Diagnosis. Histological examination is usually necessary to separate this tumour from other tumours of the deeper dermis.

Treatment. Local recurrence, mainly due to incomplete excision, is uncommon, and simple excision is therefore the treatment of choice.

Meningothelial heterotopias [1–8]

SYN. CUTANEOUS MENINGIOMA

Lesions with meningothelial elements presenting in the skin and soft tissue were divided into three groups by Lopez *et al*. [4]. The first two groups of lesions represent meningothelial heterotopias or hamartomas. The main differences between both groups reside in the fact that affected patients are children in the first group and adults in the second group. The third group consists of intracranial meningiomas that extend secondarily into the skin or soft tissues. This group will not be discussed in more detail here.

A small number of cases of meningothelial heterotopias have been associated with von Recklinghausen's disease [1]. The tumour occurs over the scalp or in the paraspinous region of the trunk of children and young adults. Occasionally it appears to be familial [6]. The lesions resemble 'soft naevi'. On the scalp, the area may be bald. The skin is adherent to the mass, which is dermal or subcutaneous, and there may be a central depression with epidermal atrophy or ulceration. A connection with the cranial cavity is not usually demonstrated. The size ranges from 2 to 10 cm.

Pathology [6–8]. Low-power examination often reveals a lesion with a striking resemblance to a lymphangioma. Irregular dilated spaces are seen dissecting between collagen bundles. The spaces are partially lined by plump epithelioid cells, which are also seen in clusters in the surrounding stroma. Focal formation of psammoma bodies may be present. The dermal collagen and blood vessels also appear to be increased. Some lesions contain more solid areas. The presence of meningothelial cells can be demonstrated by positive staining for epithelial membrane antigen.

Glial heterotopic nodules [1,2]

SYN. NASAL GLIOMA

Definition. This represents the presence of heterotopic mature glial tissue in the dermis or subcutis, predominantly on the central face. It may be considered to be a developmental defect in the closure of the neural tube. However, rare cases occur away from the midline, suggesting a different unexplained mechanism for its occurrence [3].

Clinical features. Most lesions present in infants or children as a subcutaneous mass on the bridge of the nose. Presentation in adults is exceptional. Communication with the cranial cavity is present in up to 20% of cases.

Pathology. Nodules of astrocytes in a neurofibrillar background are characteristic. Less commonly, oligodendrocytes are seen; neuronal elements are exceptional.

Treatment. Excision is curative, but it is very important to make sure that an underlying communication with the cranial cavity is ruled out, as failure to do so may result in complications such as meningitis or cerebrospinal fluid leakage.

Pigmented neuroectodermal tumour of infancy [1]

SYN. MELANOTIC PROGONOMA; RETINAL ANLAGE TUMOUR

For many years, there has been a debate as to whether this tumour is of neural or melanocytic origin [2–4]. Recent evidence seems to indicate that this tumour recapitulates the early stages of development of the retinal epithelium [5].

Clinical features. This tumour occurs most frequently in the anterior part of the maxilla, usually in infants less than 6 months old, and often presents as a pigmented oral mass [6]. It has been reported also in the anterior fontanelle, the shoulder, epididymis and mediastinum. There is a slight predilection for males. It may cause a high urinary excretion of vanillylmandelic acid [2]. This benign tumour has been mistaken in the past for malignant melanoma, and could also be confused with a cellular blue naevus.

The clinical appearance is that of a rapidly expanding nodule in the jaw, which may affect dentition. Although classified as benign, the lesions may cause considerable local destruction, and around 5% of cases may metastasize and prove fatal [7].

Pathology [8,9]. A mass of irregular alveolar spaces surrounded by fibrous stroma is seen. Two types of cells are easily recognized: small round blue cells with scanty cytoplasm in a fibrillary matrix, and large epithelioid cells with pink cytoplasm and vesicular nuclei. These cells often contain melanin. Both types of tumour cells stain for synaptophysin and neurone-specific enolase, and are negative for S100. The large cells are positive for cytokeratin and HMB45.

Treatment. Complete surgical excision is the treatment of choice.

Malignant peripheral nerve sheath tumour [1,2]

SYN. NEUROFIBROSARCOMA; MALIGNANT SCHWANNOMA

Definition. A malignant tumour arising from the nerve sheath.

Aetiology. Cutaneous tumours usually arise in patients with neurofibromatosis type 1 from a plexiform neurofibroma [3]. Deep-seated lesions arise *de novo* or in association with neurofibromatosis type 1. Patients with this disease develop malignancy in 30–50% of cases.

Incidence. It is an uncommon tumour. It occurs in young adults, or even children, when it complicates multiple neurofibromatosis. Sporadic cases occur in older individuals.

Clinical features [4]. The diagnosis should be suspected when a previously static tumour in a patient with neurofibromatosis begins to enlarge or becomes painful. The pain may become radicular as the lesion progresses but the tumours are not always associated with nerve trunks. The commoner sites are the flexor aspects of the limbs. A minority of cases occur as a complication of radiotherapy.

Pathology. The basic pattern is that of fascicles of tumour cells, often with a herringbone pattern and resembling a fibrosarcoma. Tumour cells tend to concentrate around blood vessels and myxoid change is common. The degree of pleomorphism and the number of mitotic figures varies.

Treatment. Wide local excision or amputation is necessary because of the aggressive behaviour of the tumour, and even then the prognosis is not good. Systemic metastases particularly to the lungs are common. The prognosis is

worse in cases associated with radiotherapy. The tumour is not radiosensitive.

Clear cell sarcoma [1–4]

Definition. Clear cell sarcoma is a distinctive malignant soft-tissue tumour that displays melanocytic differentiation.

Clinical features. Most cases occur on the lower limbs, with a predilection for the foot. The upper limb is affected in about 25% of cases. There is a predilection for females. Tumours tend to grow around tendons, are usually less than 3 cm in diameter and are often painful.

Pathology. The lesion has a lobular growth pattern. Tumour cells are fairly homogeneous and contain clear or pale pink cytoplasm and a prominent eosinophilic nucleolus. Mitotic figures are not prominent, but multinucleated giant cells with a wreath-like arrangement of the nuclei are often identified. Loose thin bands of collagen surround tumour cells. Secondary involvement of the dermis is relatively common. Necrosis is sometimes seen. Melanin is sometimes identified, and S100, HMB45 and melan A are usually positive. Electron-microscopic examination of tumour cells reveals the presence of melanosomes.

Cytogenetic analysis often reveals a translocation between chromosomes 12 and 22; this translocation is not found in melanoma [5].

Prognosis and treatment [1–4]. About 50% of patients develop metastatic disease, often many years after the initial diagnosis. Wide excision is the treatment of choice. Chemotherapy does not seem to be effective in the treatment of disseminated disease.

Peripheral primitive neuroectodermal tumour [1,2]

SYN. PERIPHERAL NEUROEPITHELIOMA; EXTRAOSSEOUS EWING'S SARCOMA

Primary cutaneous or subcutaneous peripheral primitive neuroectodermal tumour is extremely rare, and only a handful of cases have been reported in the literature. The tumour presents in children and has no distinctive clinical features, although it is often confused with a vascular tumour. It has been suggested that superficial tumours have a better prognosis than those presenting in deeper soft tissues, but the number of cases reported and their follow-up is too limited for this to be certain. The histological diagnosis includes tumours composed of small blue round cells and immunohistochemistry plays an important role in diagnosis. Tumour cells are diffusely positive for CD99. This tumour usually presents a reciprocal chromosome translocation t(11;22)(q24;q12) that is an important aid in diagnosis.

Tumours of muscle

Congenital smooth muscle hamartoma

This lesion is described in Chapter 15.

Leiomyoma [1–3]

Definition. A benign tumour of smooth muscle derived from the arrector pili muscle, from the media of blood vessels, or from smooth muscle of the scrotum, labia majora or nipples (genital leiomyoma) [4,5].

Incidence. The tumour occurs in three main types, all of which are relatively uncommon.

Pilar leiomyoma (leiomyoma cutis) originates in the pilomotor muscle and is the most frequent. It can occur at any age from birth onwards, but appears usually in early adult life. It has been reported in identical twins, in siblings and in several generations of a family [6–8]. The cases with a familial background have all had multiple tumours. The sexes are affected equally.

Fig. 53.28 Clinical appearance of multiple leiomyomas.

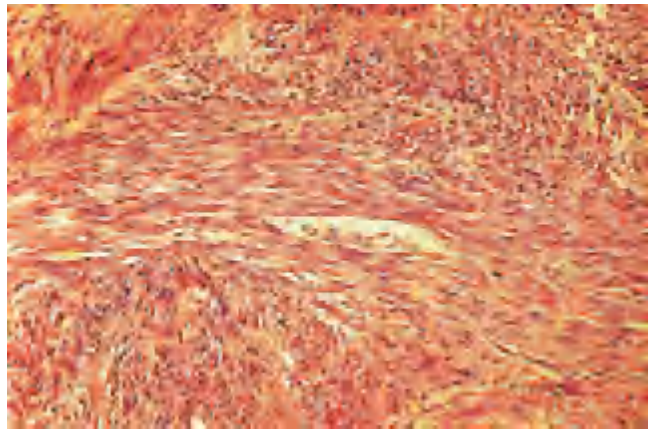

Fig. 53.29 Pathology of leiomyoma, showing large, spindle-shaped cells with eosinophilic cytoplasm.

Genital leiomyoma (dartoic myoma) arises in the smooth muscle of the genitalia and areola of the nipple [9,10]. It can occur at any age. The cutaneous variety is about six times more frequent than the genital type [11].

Angioleiomyoma arises from the muscular coat of veins, and is seen mainly in middle age or later as a solitary nodule on a limb. It is rather more prevalent than glomus tumour in published series [6,12,13]. Females are more commonly affected than males.

Clinical features [6,14]. Pilar leiomyoma generally presents as a collection of pink, red or dusky brown, firm dermal nodules of varying size but usually less than 15 mm diameter (Fig. 53.28). The nodules are often subject to episodes of pain and may be tender. The pain can be provoked by touching or chilling the skin, or by emotional disturbance. It is often worse in winter. Some lesions contract and become paler when painful [12,15]. The condition usually begins with the appearance of one small nodule, which gradually increases in size, and further similar lesions appear nearby or at some other area. Adjacent tumours may coalesce to form a plaque. The areas most commonly affected are the extremities, with the proximal and extensor aspects somewhat favoured. The trunk is involved more often than the head and neck. Multiple lesions may be regional and unilateral, or more than one region can be affected. Solitary lesions may occur, apart from the dartoic type. The gene that predisposes to multiple pilar leiomyomas has been mapped to chromosome 1q 42.3-q43 [16].

Genital leiomyoma is a solitary dermal nodule occurring most commonly in the scrotum, but also appearing on the penis, labia majora and nipple area. Scrotal tumours are often large. Pain is less frequent than with leiomyoma cutis. Contraction in response to stimulation by touch or cold can occur.

Angioleiomyoma is usually a solitary, flesh-coloured, rounded, subcutaneous or deep dermal tumour up to 40 mm in diameter. It is more frequent on the lower limb than the upper and may appear on the trunk or face. About half the reported cases have been painful [6,12]. Lesions are long-standing and present between the fourth and sixth decades of life. Pain may be triggered by changes in temperature, pregnancy or menses.

Pathology [12,14,17,18]. The smooth muscle cells proliferate to produce interweaving bundles of spindle-shaped cells, which are strongly eosinophilic (Fig. 53.29). The nuclei are long and thin, and the general appearance of the mass in ordinary sections may suggest a hypertrophic fibrous reaction. The smooth muscle cells can be distinguished from collagen by their different reaction with trichrome stains, and by the presence of myofibrils, which stain with phosphotungstic acid haematoxylin, and by their blunt-ended nuclei. Tumour cells are positive for actin and desmin.

The tumour of pilomotor origin (leiomyoma cutis, multiple cutaneous leiomyomas) is usually composed of numerous dermal nodules with vague margins where the cells penetrate the surrounding collagen bundles, and an upper border that approaches the papillary body. Associated epidermal hyperplasia is common. Focal nuclear atypia likely to be degenerative in origin and very low mitotic activity (up to one per 10 high-power fields) may be seen without this being indicative of malignant degeneration [19]. Genital leiomyomas are nodular tumours with a similar appearance. Scrotal tumours are less circumscribed and more cellular than those developing in the vulva. The angiomyomas are related to veins in the subcutaneous tissue, and are rounded and well-circumscribed [20]. Vessels of variable thickness are intermixed with bundles of mature smooth muscle. Focal degenerative cytological atypia may be seen, but mitotic figures are absent. Calcification, hyalinization and thrombosis of vessels are often seen.

Diagnosis. The multiple type should cause little difficulty, and even without pain it is fairly distinctive. The solitary painful lesion may be mistaken for a glomus tumour or an eccrine spiradenoma, and a history of contraction is helpful. In practice the diagnosis can be elusive.

Treatment. Surgical excision cures the solitary tumour. The severity of the pain may make the patient demand treatment, and extensive lesions require plastic surgery. Excision of an area containing multiple tumours is often followed by their appearance in the neighbourhood of the treated area. Medical treatments that may relieve pain include calcium-channel blockers and gabapentin.

Leiomyosarcoma [1–3]

Definition. A malignant tumour displaying smooth muscle differentiation. Tumours are divided into those occurring in the subcutaneous tissue and those arising in the dermis. Pure dermal lesions have a very different behaviour from those arising in the subcutis and it is therefore important to separate them (see below).

Incidence. This is a rare tumour. Dermal leiomyosarcoma presents predominantly on the lower limbs of young adults, with a predilection for males. Subcutaneous leiomyosarcoma affects middle-aged to elderly patients with slight predilection for males.

Clinical features [4,5]. The tumour may be situated in the dermis, when it is reddish in colour and may bleed on trauma. It is usually larger than a leiomyoma and dermal lesions may be painful. The majority of tumours have, however, arisen in the subcutaneous or deeper tissues as nodular tumours, ulcerated plaques [6] or diffuse swellings [7]. It may invade underlying muscle fascia. It is most common on the thigh, followed by the head and neck, arm and trunk, and may arise from the penis [8] or vulva. It is unlikely to be diagnosed clinically. Dermal leiomyosarcomas have a 40% recurrence rate, but they almost never metastasize [9]. Subcutaneous tumours metastasize in up to 50% of cases and they are associated with a mortality of about 30%.

Pathology [3,9–13]. The lesion is distinguished from other dermal malignant tumours composed of spindle-shaped cells by the presence of fascicles of eosinophilic spindle-shaped with vesicular cigar-shaped nuclei. The degree of differentiation varies and necrosis tends to be present in deeper tumours, but not in those arising primarily in the dermis. Most tumours are actin- and desmin-positive, but staining for the later may be lost in poorly differentiated variants. About 30% of leiomyosarcomas are positive for keratin, but this is less commonly seen in cutaneous examples.

Treatment. Wide surgical excision is necessary, as local recurrence follows inadequate excision.

Skeletal muscle tumours

Rhabdomyosarcomatous congenital hamartoma

This lesion is described in Chapter 15.

Rhabdomyoma

Rhabdomyomas are divided into adult, fetal and genital types. They mainly occur in soft tissues, vulva or vagina, upper respiratory tract and internal organs. Presentation in the skin is almost never seen, and they will not be discussed further in this chapter.

Cutaneous rhabdomyosarcoma

Malignant tumours with skeletal-muscle differentiation are classified into two large groups, namely embryonal and alveolar types. Although rhabdomyosarcomas represent up to 8% of tumours in children, primary involvement of the skin by this tumour is very rare. Much more common is involvement of the skin by direct extension from deeper soft tissues. Only 16 cases of primary cutaneous rhabdomyosarcoma have been reported in the literature so far, and only five of these have occurred in adults [1,2]. The most common subtype occurring in the skin is the alveolar variant. The majority of cases have presented on the face. The prognosis is difficult to estimate because of the rarity of these cases and the limited follow-up available.

Tumours of uncertain histogenesis

Superficial angiomyxoma [1,2]

Definition. Superficial angiomyxoma is a dermal or subcutaneous tumour composed of a mixture of small blood vessels and sparse spindle-shaped cells in a prominent myxoid stroma.

Clinical features [1,2]. Most cases occur in adults as an asymptomatic solitary papule or nodule with equal sex incidence. Lesions are usually less than 3 cm and have a wide anatomical distribution with a predilection for the trunk, head and neck and genital skin. In patients with multiple lesions, the possibility of Carney complex should be considered (see Chapter 59) [3].

Pathology. Tumours are multilobulated, with copious myxoid stroma, numerous delicate small blood vessels and spindle-shaped or stellated bland cells probably representing fibroblasts. Aggregates of inflammatory cells, mainly neutrophils, are frequent. In up to 30% of cases epithelial structures, probably representing hyperplastic trapped adnexal structures (particularly hair follicles), are identified.

Treatment. Local recurrence is seen in up to 30% of cases [3], but the behaviour is benign and therefore excision is the treatment of choice.

Digital myxoma [1]

SYN. CUTANEOUS MYXOID CYST

Digital myxoma is relatively rare and presents mainly on the fingers as a small, solitary painful nodule. Females are much more commonly affected than males and there is a tendency for local recurrence. Lesions are poorly circumscribed and consist of abundant myxoid stroma with only scattered bland spindle-shaped cells.

'Aggressive' angiomyxoma [1,2]

Definition. 'Aggressive' angiomyxoma is a distinctive tumour occurring in the genital region and pelvis predominantly of females. It is characterized by bland

spindle-shaped cells in the background of a prominent myxoid stroma and frequent thick-walled blood vessels.

Clinical features. This tumour occurs almost exclusively in females of reproductive age, but rare lesions have been described in males [3]. Tumours are slowly growing and by the time of presentation they are large and ill-defined, often measuring 10 cm or more. The most commonly affected sites are the vulva and perineum. Extension into deeper soft tissues is often found.

Pathology. The lesion is infiltrative and is composed of spindle or stellate-shaped, bland, cells with scanty cytoplasm, surrounded by prominent myxoid stroma. Small to medium-sized thick-walled blood vessels are seen throughout the tumour. Mitotic figures are very rare. Interestingly, tumour cells are positive for actin and desmin.

Prognosis and treatment. Local recurrence is observed in up to a third of cases, and complete surgical excision is usually difficult because of the infiltration of surrounding tissue. However, recurrences are not usually destructive, and radical surgical procedures are therefore not indicated.

Epithelioid sarcoma [1,2]

Definition. A distinctive malignant soft-tissue tumour composed of cells with epithelial differentiation. It is not clear whether this tumour represents a primary soft-tissue carcinoma or a sarcoma with epithelial differentiation.

Incidence. It is an uncommon tumour, affecting males more often than females and tending to begin in early adult life.

Clinical features [3,4]. The presenting sign can be a dermal nodule that grows outwards and may ulcerate early, a nodule or lobular subcutaneous tumour that is painless and grows slowly, or a tumour attached to deeper structures that is rather poorly defined and causes pain, paraesthesiae or muscular wasting when growing along a large trunk nerve. As a result of prominent perineurial and perivascular extension of tumour cells, multiple nodules in a sporotrichoid distribution may be seen. The distal extremities are the usual situation for the tumour, particularly the flexor aspect of the finger and the palm. It may grow at a deceptively slow rate.

A distinctive variant of epithelioid sarcoma previously described as 'extrarenal rhabdoid tumour' has been reported in older patients who present with a large mass on the proximal limbs, genitalia, buttocks, trunk or head and neck [5]. This variant is known as 'proximal-type epithelioid sarcoma'.

Pathology [6,7]. The tumour is composed of firm nodules 5–50 mm or larger in diameter surrounded by fibrous tissue and fat. It is often closely associated with fascia, periosteum, tendon or nerve sheaths. The cut surface is greyish-white and flecked or mottled with yellow or brown, reflecting the presence of areas of necrosis. Microscopically, there are masses of large, round, polygonal or spindle cells with acidophilic cytoplasm. Spindle cells are often present and may predominate. The larger nodules have necrotic centres and show so-called 'geographical necrosis', which may be mistaken on scanning power microscopy for a granuloma. Mitotic figures are common, and binucleate cells occur. Variable cytological atypia is always present and may be prominent. Intercellular hyalinized collagen increases the acidophilia, while calcification, with osteoid or bone formation, may take place in the necrotic areas. The tumour spreads along dense fibrous structures and may ulcerate in areas with little subcutaneous fat. Local recurrence after excision is common, and metastasis, principally to lymph nodes, lung and pleura, may occur. Tumour cells show clear histological, ultrastructural and immunohistochemical evidence of epithelial differentiation.

The proximal type of epithelioid sarcoma shows a similar multinodular growth pattern but tumour cells are larger and with a more rhabdoid appearance consisting of abundant cytoplasm and large nuclei with or without a prominent eosinophilic nucleolus.

Immunohistochemically, tumour cells in both variants of epithelioid sarcoma have the same profile. They are positive for keratin and epithelial membrane antigen. They also express vimentin, and in 50% of the cases they are positive for CD34 [8].

Diagnosis. Superficial lesions can easily be mistaken for an ulcerating squamous cell carcinoma, deeper ones are usually regarded as inflammatory in nature. Histological diagnoses have varied, with granulomatous inflammation and synovial sarcoma being the commonest benign and malignant diagnoses, respectively.

Prognosis and treatment. Complete removal by surgical excision is essential if local recurrence and eventual metastasis are to be avoided, and the earlier this is done the less likely is the process to spread along fascial planes. Surgical excision followed by radiotherapy is often

recommended. Involvement of regional lymph nodes is associated with distant metastasis and death [9]. Local recurrence and metastasis may occur years after the original diagnosis. The survival rate has been estimated at between 65% and 70% [6,9]. Features associated with poorer prognosis include male sex, older age at diagnosis, proximal location, tumour size, mitotic rate, necrosis, vascular invasion and local recurrence and lymph node metastasis [6,7,9].

Tumours of fat cells

Lipoma, angiolipoma and hibernoma

These lesions are described in Chapter 55.

Lipoblastoma and lipoblastomatosis

Definition. Lipoblastoma is a tumour that occurs almost exclusively in infants and children. It is characterized by a proliferation of immature fat cells in a myxoid stroma and intermixed with mature adipocytes [1]. Lipoblastoma is a well-circumscribed subcutaneous tumour; lipoblastomatosis refers to a deeper lesion or those that have an infiltrative growth pattern.

Clinical features [1–3]. Most cases present during the first few years of life, with a predilection for males. The majority of tumours occur on the limbs as an asymptomatic mass no more than a few centimetres in diameter. Lipoblastoma is much more common than lipoblastomatosis.

Pathology [1–3]. Tumours have a characteristic lobular appearance. Each tumour lobule is separated by fibrous septae and consists of a mixture of small univacuolated signet-ring cells, spindle-shaped or stellate cells and scattered mature adipocytes. In the background, there are prominent myxoid changes and numerous small vessels in a typical 'crow's-feet' distribution, mimicking a myxoid liposarcoma. Distinction from the latter may be very difficult, especially in small biopsies. The clinical information is therefore crucial, as myxoid liposarcoma is vanishingly rare in children and almost never occurs before the age of 10 years [4]. Furthermore, lipoblastoma tends to be less cellular than myxoid liposarcoma and has a lobular architecture. Over time, maturation occurs, and in some cases most of the tumour is composed of mature fat cells.

Cytogenetic studies in lipoblastoma have shown rearrangements on chromosome 8q [5].

Treatment. The tumour is benign, and simple excision is the treatment of choice. Deeper lesions have some tendency for local recurrence.

Spindle cell and pleomorphic lipoma [1–5]

Definition. Spindle cell lipoma is composed of mature adipocytes and variable numbers of short bland spindle-shaped cells with indistinct cytoplasm. Pleomorphic lipoma is composed of mature adipocytes, cells with hyperchromatic nuclei and frequent multinucleation, and collagen bundles. Both types of tumour may overlap, and they are therefore considered to be part of the same spectrum.

Clinical features [1,2,4,5]. Spindle cell lipoma usually presents as a small subcutaneous nodule on the upper back and nape of the neck of middle-aged to old patients, with marked predilection for males. Occasional purely dermal examples may be seen. Multiple lesions, and familial cases, occur rarely [3]. Pleomorphic lipoma has a similar clinical presentation.

Pathology [1,2,4]. Spindle cell lipoma presents as a well-circumscribed tumour composed of mature adipocytes intermixed with short spindle-shaped cells with wavy nuclei. Hyalinized collagen bundles and focal myxoid change are prominent. Pseudovascular spaces are

prominent in some cases. The spindle-shaped cells stain for CD34 and the adipocytes are positive for S100. Pleomorphic lipoma is also well-circumscribed and composed of mature adipocytes intermixed with uninucleated or multinucleated cells with hyperchromatic nuclei. The nuclei in the multinucleated cells are often arranged in a circle (floret cell).

Cytogenetic studies of both tumours have shown variable abnormalities, most commonly in chromosome 16q and rarely in chromosomes 13q and 6p [6,7].

Treatment. There is little tendency for local recurrence, and simple excision is therefore the treatment of choice.

Atypical lipomatous tumour [1–4]

SYN. WELL-DIFFERENTIATED LIPOSARCOMA

Definition. This is a lesion composed of lobules of mature adipose cells, with scattered larger cells with variation in nuclear size and hyperchromatism. The term 'atypical lipomatous tumour' is usually used for neoplasms occurring in the subcutis or within skeletal muscle. Similar tumours occurring in the abdominal cavity are regarded as well-differentiated liposarcomas, in view of the fact that they have a potential to cause death as a result of extensive growth. Only subcutaneous lesions will be discussed here.

Clinical features [1–3]. Subcutaneous atypical lipomatous tumours occur in middle-aged to old adults with predilection for the lower limbs. Tumours may be large, are asymptomatic and have the same clinical appearance as a lipoma.

Pathology. Typically, lobules of mature adipose tissue, with or without fibrous tissue and myxoid change, are seen. Focal variation in the size and shape of adipocytes is seen and this is associated with nuclear enlargement and hyperchromatism. Vacuolated cells may also be found. Atypical cells are often present in the fibrous tissue.

Cytogenetic studies of these neoplasms have found chromosomal abnormalities in most cases. About a third of the cases show supernumerary ring chromosomes affecting chromosome 12q 13–15 [4].

Prognosis and treatment. There is a tendency for local recurrence, but metastases are not seen unless the tumour undergoes dedifferentiation [5]. Complete surgical excision is indicated.

Liposarcoma [1]

Myxoid and round cell liposarcoma and pleomorphic liposarcoma are vanishingly rare in the skin. Only a few cases of primary cutaneous liposarcoma have been described. Follow-up is limited, but the behaviour seems to be better than that of their deeper counterparts, probably reflecting early detection and treatment and the easy accessibility to the skin. Liposarcoma will not be discussed further in this chapter.

Ossifying lesions in the dermis [1]

A wide range of subcutaneous lesions may occasionally show partial ossification. The most common are pilomatricomas and melanocytic naevi. Other soft-tissue lesions, such as soft-tissue chondromas and fibromyxoid tumours, may show metaplastic bone formation.

REFERENCE

1 Fletcher CDM. Calcifying and ossifying soft tissue lesions presenting in the skin. *J Cutan Pathol* 1996; **23**: 297.

Osteoma cutis [1]

Definition. A true bony new growth arising within the skin from bone-forming tissue and showing no tendency to invade.

Incidence and aetiology. Osteoma cutis is a rare tumour. Most osseous nodules in the skin are not true neoplasms, but result from metaplastic ossification, which usually occurs in a focus of calcification; the initiating lesion is frequently an inflammatory granuloma or scar. The majority of these lesions are best classified as dystrophic ossification rather than as osteomas. Dystrophic ossification has been reported in scleroderma, in old acne cysts and at sites of puncture of the skin or of haematomas. They may be found in melanocytic naevus, pilomatricoma, histiocytoma and chondroid syringoma, and may be secondary to basal cell carcinoma [2,3]. Another cause is Albright's hereditary osteodystrophy, in which cutaneous ossification has recently been recognized with increasing frequency [4–6]. Rarely, multiple miliary osteomas of the skin can occur after acne [7,8], sometimes with neurotic excoriations or after dermabrasion [9]. There remain a minority of reported cases that appear to be primary osteomas, the majority of which are multiple and on the face or scalp [9–11].

There is no point in trying to estimate the age and sex incidence for a group as heterogeneous as individuals with dystrophic calcification of the skin. It seems likely that primary osteomas will become even more rare if hereditary osteodystrophy and other causes are sought.

Clinical features. Metaplastic osteomas are frequently small and clinically undetectable in the primary lesion. They are usually situated deep in the dermis or subcutaneous tissue. They may be seen when radiographs of the area are taken, but are most commonly first noticed by the histology technician as a hard body that damages the knife edge. The distinguishing feature, if the tumour is found clinically, is the stone-hard texture on palpation, similar to pilomatricoma. A case of osteoma cutis associated with diaphyseal aclasis has been reported [12].

Pathology [3]. Whether metaplastic or primary, the microscopic picture is of a small circumscribed nodule of osseous tissue with trabeculae enclosing fat and, occasionally, marrow cells.

Treatment. If required, simple excision is curative.

Cutaneous calculus [1,2]

SYN. SUBEPIDERMAL CALCIFIED NODULE

This small tumour, which is not very uncommon, has a characteristic yellowish white colour and is situated in the subepidermal tissue. It is seen most commonly on the face in children; it varies in size up to 10 mm or so, but may occasionally be larger and plaque-like, and it has a hard consistency. The epidermis over it may be verrucose. Episodes of inflammation and shedding of a portion of the lesion may occur. Microscopic examination shows calcareous bodies in the superficial part of the dermis. A histiocytic or foreign-body reaction often surrounds some of the calcified bodies. The exact histogenesis is uncertain. Calcification of naevus cells has been suggested. The lesion can be removed easily by curettage.

Progressive osseous heteroplasia

This is discussed in Chapter 46.

Chapter 54

Cutaneous Lymphomas and Lymphocytic Infiltrates

S.J. Whittaker & R.M. MacKie

Introduction

For many years, the terms cutaneous reticulosis and mycosis fungoides (MF) were the only two used to describe a wide range of clinical and histological presentations of malignant cutaneous lymphocytic infiltrates, many of which appeared to have a very unpredictable prognosis. Over the past 20 years, advances in the classification of lymphoid cells have greatly improved our understanding of the cutaneous lymphomas. Various node-based classifications of lymphomas, including the Kiel classification first introduced in 1980 and updated in 1988 [1], were of relatively little value for cutaneous lymphoma as they were based purely on detailed pathological assessment of nodes with no clinical correlation. Current classifications are based on clinical, pathological, immunopathological, molecular and cytogenetic findings [2,3], and the classification of cutaneous lymphomas in turn has a critical influence on the therapeutic approach.

In 1975, it was demonstrated that the great majority of lymphoid infiltrates associated with the skin were of T-cell type and Edelson introduced the term cutaneous T-cell lymphoma (CTCL) [4]. In Europe, the work of the Dutch Cutaneous Lymphoma Working Party (DCLWP) clearly identified different subsets both of CTCL and of primary cutaneous B-cell lymphomas [5]. MF is the most common of the CTCL subsets, but other subsets with clearly identifiable clinicopathological features and varying prognoses have also been described. These data formed the basis for the European Organization for Research on Treatment of Cancer (EORTC) classification of cutaneous lymphomas in 1997 [2]. In contrast, human T-lymphotropic virus type 1 (HTLV-1)-associated cutaneous lymphoma [6] is relatively rare in Europe but much more common in Japan and usually occurs as secondary cutaneous involvement. At the present time, there is no clear evidence that other CTCLs are directly associated with HTLV or other related viruses. A critical observation has been the realization that lymphomas with a similar pathology arising in different organs carry very different prognoses. Nodal CD30+ lymphoma can be associated with a poor prognosis, whereas primary cutaneous CD30+ lymphomas are generally associated with a good prognosis [7]. It is also now clear that primary cutaneous B-cell

lymphoma is not as rare as was previously believed [5]. Extensive studies from the DCLWP suggest that primary cutaneous B-cell lymphomas are about one-third as common as primary CTCLs, and that the majority of these B-cell lymphomas have a good prognosis. This is in contrast to earlier reports, many of which concerned B-cell lymphomas arising in other body sites and only involving the skin at a late stage. The recent World Health Organization (WHO) classification has encompased most of the EORTC primary cutaneous lymphoma categories with the exception of distinct cutaneous B-cell lymphomas, although the WHO classification does acknowledge the presence of a primary cutaneous follicle centre cell lymphoma which is pathogenetically distinct from primary nodal follicular lymphoma [3].

The concept of a subset of circulating lymphocytes with a special avidity or affinity for the skin has been supported by the identification of T cells expressing the cutaneous lymphocyte antigen, CLA (HECA 452), which binds to its ligand, E-selectin, on dermal endothelial cells [8]. These subsets of T cells are thought to traffic through the skin comprising skin-associated lymphoid tissue (SALT), and contribute to the skin immune system (SIS), in a similar manner to other mucosal sites such as the gut mucosa-associated lymphoid tissue (MALT). The expression of the chemokine receptor CXCR3 by tumour cells may also contribute to epidermotropism in CTCL [9]. In early stage disease, the identification of T-cell clones in skin using T-cell receptor (TCR) gene analysis has critically established both the neoplastic nature and lineage of a wide variety of cutaneous lymphoproliferative entities during the last decade, and both TCR and immunoglobulin gene analysis are now a standard part of the assessment of cutaneous lymphoid infiltrates [10]. The presence of a T-cell clone is not synonymous with malignancy and the significance of T-cell clones in benign cutaneous lymphoid infiltrates is unclear at present. It is unclear whether these techniques will also provide prognostic information but they do complement existing staging approaches, particularly for analysis of lymph node and peripheral blood in MF and Sézary syndrome. The underlying molecular pathogenesis of CTCL is still unknown but various abnormalities have been identified including a high frequency of tumour-suppressor gene inactivation involving particularly genes controlling the cell cycle such as the *p53* and *p15/16* genes [11,12]. These abnormalities appear to be associated with disease progression and may contribute to treatment resistance. In addition, several novel molecular cytogenetic techniques have detected a consistent pattern of chromosomal abnormalities indicating the location of putative genes that may have a fundamental role in the pathogenesis of CTCL [13,14].

Several novel therapies have been developed specifically for CTCL: a retinoid, bexarotene, that binds to the RXR receptor and a diphtheria interleukin-2 (IL-2) fusion toxin, Denileukin Diftitox (Onzar; Ontak) [15–17]. Both have been assessed in rigorous clinical trials and offer promising alternatives to existing therapies.

Primary cutaneous T-cell lymphomas

Mycosis fungoides

Definition. The most common variant of primary CTCL, generally associated with an indolent clinical course and characterized by well-defined clinicopathological features.

Aetiology. The aetiology of MF is not yet established. The HTLV-1 retrovirus was first isolated from a patient with CTCL and subsequently it was appreciated that this

patient had adult T-cell leukaemia–lymphoma (ATLL). Because of clinical and pathological similarities to cutaneous involvement in ATLL, there has been an intensive search for HTLV-1 and related viruses in MF. However, although an association with HTLV-1 has been suggested, subsequent extensive investigations have failed to identify conclusively any of the currently recognized HTLV-associated viruses in MF [1–5]. For over 20 years, one of the theories associated with the development of MF has been that this is a disease of antigen persistence associated with chronic lymphocyte stimulation and eventual transformation of benign lymphocytes to a low-grade malignant T-cell lymphoma [6]. This is a plausible and attractive theory, but as yet the antigen or antigens responsible for this transformation have not been identified.

A number of case–control studies have investigated the possibility of environmental agents precipitating or aggravating early CTCL. One study from the east coast of North America [7] recorded a significantly higher incidence of allergies and of fungal and viral infections in patients who developed CTCL compared with healthy controls, and also reported that a higher proportion of CTCL patients had worked in the petrochemical, textile, machine and metal industries. A study from the UK did not confirm these observations but did record a significantly higher incidence of atopic disease in MF patients and there have been subsequent reports of CTCL developing in patients with severe atopic dermatitis [8]. A more recent study from North America has failed to confirm any clear occupational or environmental exposure but has observed a higher than expected prevalence of other malignancies including non-lymphoma cutaneous malignancies in patients with MF [9]. Further reports have also suggested that there is a possible increased incidence of non-melanoma skin cancer, melanoma and also lung cancer in MF but whether or not this is related to prior therapy remains to be clarified [10].

Clinical features. Classical MF is characterized by typical cutaneous stages of disease consisting of patches and plaques involving less than 10% of the body surface area (stage T1/IA), more than 10% of the body surface area (stage T2/IB), tumours (stage T3/IIB) and erythrodermic disease (stage T3/III). Patients may progress from having limited patches and plaques to extensive plaques or tumours and even erythroderma [11]. However, many patients do not show any evidence of progression. Patch stage MF is characterized by subtle fine scaly and often slightly atrophic erythematous patches on the trunk (Fig. 54.1), usually involving the limb girdle areas and breast and particularly the buttocks. There may be mild pruritus but patients are often asymptomatic. At this stage, the clinical differential diagnosis includes pityriasis rosea, fungal infection, mild dermatitis or even a rather atypical form of psoriasis. Plaques are more obvious persistent polymorphic erythematous lesions with a similar distribution but, with the development of stage T2/IB, there is usually involvement of the head, neck and limbs as well as the trunk (Figs 54.2 & 54.3). Individual plaques may become very large, and there may be some degree of regression, giving rise to unusual arcuate and horseshoe-shaped lesions that can show considerable variation in colour, degree of scaling and border definition. Striking psoariasiform scaling can sometimes be a feature. There is some evidence that the overall thickness of plaques in stage T2/IB may have prognostic significance [12]. Once again patients may complain of pruritus or be asymptomatic. Rarely, individual plaques may become eroded or ulcerated and painful, which is often associated with secondary bacterial infection and such patients may have a very poor quality of life and high morbidity despite having an early stage of disease. Tumours can show considerable variation in size (Fig. 54.4), and if there are only a few small tumours it may be difficult to decide if this is truly stage T3/IIB disease. Many patients with early

Fig. 54.1 Early mycosis fungoides showing plaques in the buttock area.

Fig. 54.2 More advanced mycosis fungoides showing typical polycyclic plaques.

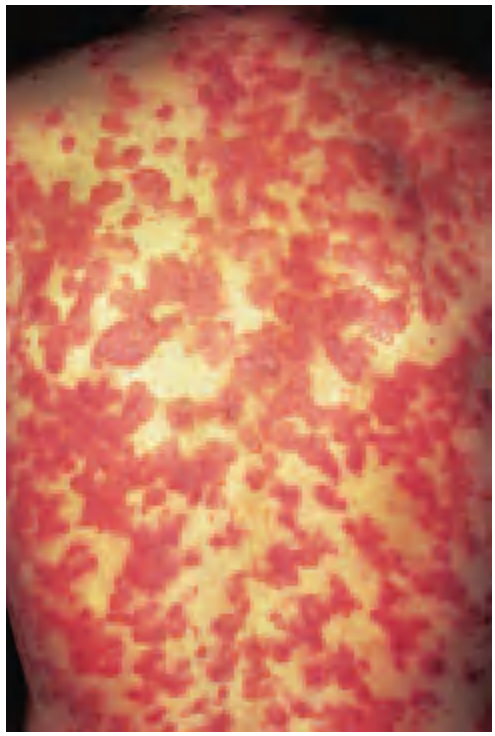

Fig. 54.3 Further stage of mycosis fungoides showing plaques involving more than 10% of the body surface.

Fig. 54.4 Nodular mycosis fungoides showing striking nodules on the back of the neck. Similar lesions were present on all four limbs.

stages (T1/IA–T2/IB) of disease do not progress but rarely patients may gradually develop an *erythroderma* (stage T3/III), which is usually associated with severe pruritus. A *tumeur d'emblée* form of MF, in which patients rapidly develop large nodules and tumours without the prior presence of patches and plaques, has been described in the past [13], but many of these patients have other CTCL variants, which should be excluded on the basis of a critical assessment of the histological and immunophenotypical features. Patients may also rarely present with erythrodermic stages of disease and the differential diagnosis for these patients includes inflammatory dermatoses and Sézary syndrome.

The development of peripheral lymphadenopathy in MF alters the staging regardless of the cutaneous stage of disease [14]. Although the great majority of patients with early stage disease do not develop overt clinical involvement of lymph nodes or other organs (see prognosis), a small proportion do eventually show generalized systemic spread and may exhibit typical 'B' symptoms with fever and weight loss. Histological involvement of lymph nodes and other organs is a very poor prognostic sign. Any systemic organ can be involved but apart from liver, spleen and bone marrow, pulmonary, skeletal and central nervous system (CNS) involvement is well documented.

There are a large number of clinical variants of MF. Some plaques have a rather verrucous [15] or hyperkeratotic appearance, and bullae may rarely develop in the course of progression of individual plaques [16]. Rare icthyosiform variants have been described. An important subset of patients have MF that appears to be associated with pilosebaceous follicles, giving rise to a follicular clinical pattern often with alopecia (pilotropic or folliculotropic MF; see below) and there is some recent evidence that these patients may be resistant to treatment and have a poorer prognosis independent of their stage of disease. Rarely, younger patients present with a purpuric eruption not unlike the pigmented purpuric dermatosis associated with capillaritis but with histological features of MF [17]. Non-white younger adult patients may also present with a hypopigmented variant of MF [18,19], characterized by striking hypopigmented scaly patches often involving the trunk and especially the pelvic girdle area rather than the limbs. Histologically, these lesions tend to show marked epidermotropism, in contrast to the subtle clinical features. In *poikilodermatous* MF, patients develop clinical lesions characterized by either widespread or isolated poikiloderma, which may or may not be associated with typical patches and plaques of MF. The trunk is usually involved and the breasts and pelvic girdle area may also be affected (Fig. 54.5). The poikiloderma is typically characterized by atrophy, pigmentation and telangiectasia and must be distinguished from poikiloderma resulting from other disorders by appropriate histology. Rarely, patients may have extensive poikiloderma as a feature

Fig. 54.5 Poikilodermatous mycosis fungoides showing involvement of both breasts.

of erythrodermic disease. These clinical variants do not have any prognostic significance with the exception of pilotropic MF.

Clinical differential diagnosis. In the early stages of MF, the clinical differential diagnosis may include such diverse conditions as allergic contact dermatitis, atopic dermatitis, psoriasis and fungal infection. Any patient with persistent polymorphic plaques, particularly involving the pelvic girdle area, should have a skin biopsy and histological confirmation of the disease. Multiple biopsies may be required to confirm a clinical suspicion of MF in early stages of disease.

Staging. There are two staging systems in current use that have prognostic significance [1–3]. The TNM classification and the staging system suggested by the North American MF Cooperative Group are given in Tables 54.1 and 54.2. All patients should have a defined stage so that appropriate advice can be given regarding prognosis and treatment.

All patients with MF should have a full clinical examination and adequate diagnostic biopsies for histology and immunophenotypic and preferably molecular studies as, even for stage IA disease, studies suggest that patients with a detectable T-cell clone have a shorter duration of response and a higher rate of failure to respond [4]. Occasionally, multiple skin biopsies and the opinion of experienced dermatopathologists are required to make a diagnosis. Peripheral blood samples should be taken for routine haematology, biochemistry, serum lactate dehydrogenase (LDH), Sézary cells, lymphocyte subsets, CD4 : CD8 ratio, HTLV-1 serology and, ideally, TCR gene analysis of peripheral blood mononuclear cells. These tests are necessary to distinguish patients with ATLL and those patients with peripheral blood T-cell clones who may have a poor prognosis. Any palpable and bulky peripheral nodes should be biopsied but the practice of 'blind' lymph node biopsy of non-palpable nodes is not essential, although histological evidence of lymphoma can very rarely be detected in the absence of palpable lymphadenopathy. Chest X-ray should be performed [5]. Staging CT scans of the chest, abdomen and pelvis are indicated in all those patients with stage IIA, IIB, III and IV MF, but not in those with stage IA or IB MF [4]. Bone marrow aspirate and trephine biopsies may be indicated in patients with stage IIB, III and IV MF and patients with peripheral blood involvement, as indicated by the presence of Sézary cell counts representing more than 5% of the total leukocyte count, although the overall positive yield will be low [6,7].

Table 54.1 TNM classification of mycosis fungoides (MF).

Cutaneous involvement (T)	
T_0	Lesions clinically and/or histologically suspicious but not diagnostic
T_1	Plaques involving less than 10% of skin
T_2	Plaques involving more than 10% of skin
T_3	Tumours present
T_4	Erythroderma
Lymph nodes (N)	
N_0	Clinically and pathologically normal
N_1	Palpable; pathologically not involved
N_2	Clinically non-palpable; pathologically MF
N_3	Clinically enlarged; pathologically MF
Viscera (M)	
M_0	No visceral spread
M_1	Visceral spread present
Peripheral blood (B)	
B_0	No atypical circulating cells
B_1	Atypical circulating cells present

Table 54.2 A staging system for mycosis fungoides related to TNM classification.

Stage	T	N	M
IA	T_1	N_0	M_0
IB	T_2	N_0	M_0
IIA	$T_{1–2}$	N_1	M_0
IIB	T_3	$N_{0–1}$	M_0
III	T_4	$N_{0–1}$	M_0
IVA	$T_{1–4}$	$N_{2–3}$	M_0
IVB	$T_{1–4}$	$N_{0–3}$	M_1

Prognosis (Table 54.3). Multivariate analysis has established that age at onset (over 60 years), skin stage and the presence of nodal (IVA) or visceral (IVB) disease are independent prognostic factors in MF [1–5]. Recent findings have confirmed that a patient's life expectancy is not adversely affected in stage IA disease [6]. Patients with stage IB–IIA disease have a 73–86% or 49–73% overall 5-year survival, respectively, while patients with stage IIB disease have a 40–65% 5-year survival [7–9]. The 5-year survival of patients with erythrodermic stage III disease is 45–57%, for those with stage IVA 15–40% and for stage IVB disease 0–15% [7,10,11]. The presence of a peripheral blood T-cell clone may indicate which patients with early stage disease are likely to develop disease progression [12]. The development of lymph node disease has a significant impact on prognosis [13]. Sézary syndrome patients by definition are staged as T4 N1–3 M0 B1 and have a poor prognosis, with an overall median survival of 32 months from diagnosis [14]. Recent studies of erythrodermic CTCL have shown that the presence of peripheral nodal disease is the most important prognostic factor in a multivariate analysis, although the peripheral blood tumour burden is also very close to significance [15]. In addition, prognostic data on a large series of patients have suggested that patients with thick plaques may have a worse prognosis than those with thin or patch stage disease and this has formed the basis for a suggested modification of the staging system, although the reproducibility of this histological assessment has not been confirmed [16].

A high incidence of second malignancies in MF patients, notably non-melanoma skin cancer and pulmonary small cell lung cancer, and also of malignancies in relatives of patients, mainly lymphomas and leukaemias, have been reported [17,18]. Other types of lymphoma–leukaemia and Hodgkin's lymphoma have also been described in association with MF and Sézary syndrome [19–21].

DSS, disease-specific survival; FFR, freedom from relapse; FU, follow up; NR, not reached; OS, overall survival.
* Some cases assumed to be dermatopathic.
Comments:
(1) All actuarial survival curves calculated according to method of Kaplan-Meier and based on stage at diagnosis.
(2) In the study by Doorn *et al*. [7] (and in a subsequent publication: van Doorn *et al*. *Arch Dermatol* 2002; **138**: 191–8), the presence of follicular mucinosis was an independent poor prognostic feature possibly related to depth of infiltrate in patients with stage IB disease (DSS of 81% and 36% and OS of 75% and 21% at 5 and 10 years respectively). A lack of a complete response to initial therapy was also associated with a poor outcome ($P<0.001$) in a multivariate analysis as well as increasing clinical stage and the presence of extracutaneous disease. A different staging system was used in this study (based on Hamminga *et al*. [2]) but for the purposes of this table the staging has been altered to be consistent. This study is the only one to provide comprehensive DSS data for different stages of mycosis fungoides. Only 3 patients had stage IVB disease and only 18 patients each had stage IIA and IVA disease. Therefore the results for these stages must be interpreted cautiously.
(3) In the study by Zackheim *et al*. [9], black patients had a relatively more advanced stage of disease than white patients. The TNM classification was used in this study. Lymph node stage had an unfavourable impact on survival but this trend did not reach significance for each individual T stage because of a lack of sufficient power (an estimated 1700 subjects required) and IIA/IVA patients were not designated separately. Similar considerations apply to peripheral blood involvement. Similar outcomes for patients with stage IIB (T3) and III (T4) disease is consistent with other studies but this might reflect a lack of lymph node staging data included in this study.
(4) The study by Kim *et al*. [6] primarily included data on 122 patients with stage IA disease but survival data on 556 patients with all stages was also included to give the figures in brackets. The FFR data at 5 and 10 years is confusing because the text states that the FFR at 10 years was 25% but the figure indicates that it remains at approximately 50% as for FFR at 5 years. The median survival for stage IA patients was not reached at 32.5 years.
(5) In the study by Kim *et al*. [8], overall survival at 20 years for stage IB and IIA patients was 27%. DSS was better for patients <58 years of age ($P<0.03$). In 23 of the 56 patients with palpable lymphadenopathy, no histological assessment was made and these patients were assumed to have reactive/dermatopathic nodes (IIA). This might account for the lack of difference in OS at 5 years* between stage IB and IIA patients, although there appears to be an apparent difference in OS at 10 years*.
(6) In the study by Kim *et al*. [11], the overall and median survival data was calculated from the date of initial treatment which was usually within 3 months of diagnosis. This study also stratified patients into 3 groups according to the presence of none, one or two to three poor prognostic parameters, namely age at presentation (>65 years), the presence of clinical adenopathy and B1 stage producing varied median survivals of 10.2 years (0 factors), 3.7 years (1 factor) and 1.5 years (2/3 factors), $P<0.005$.
(7) The study by Coninck *et al*. [10] included 112 patients with extracutaneous disease at presentation or with progression and 434 patients with only cutaneous disease giving the 546 patients listed in the table for median survival and disease progression.

Pathology [1–3]. The features of MF vary according to the clinical stage. The earliest pathological features of MF are the presence of a moderate, predominantly lymphocytic infiltrate in the papillary dermis. Many of the small lymphoid cells may be hyperchromatic and show a tendency to 'line up' just below the dermal–epidermal junction. Even at this early stage, the affinity of these T lymphocytes for the epidermis and papillary dermis is apparent, as there is rarely significant involvement in the underlying reticular dermis. As the disease progresses with the development of thicker plaques, prominent epidermotropism (Fig. 54.6) is seen. This describes the selective colonization of the epidermis by these atypical T cells and is characterized by single-cell colonization often along the basal layer, or by clusters of atypical lymphocytes in the epidermis—

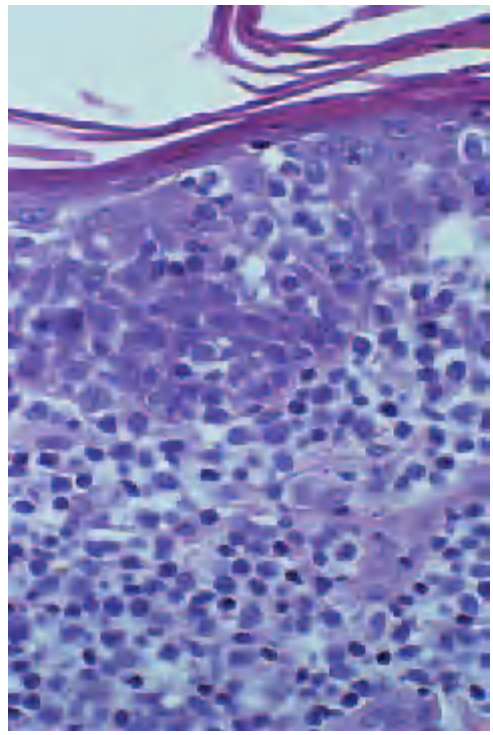

Fig. 54.6 Histology of mycosis fungoides showing striking epidermotropism with the presence in the epidermis of cytologically atypical small dark cells proven on marker studies to be $CD4^+$ helper T lymphocytes.

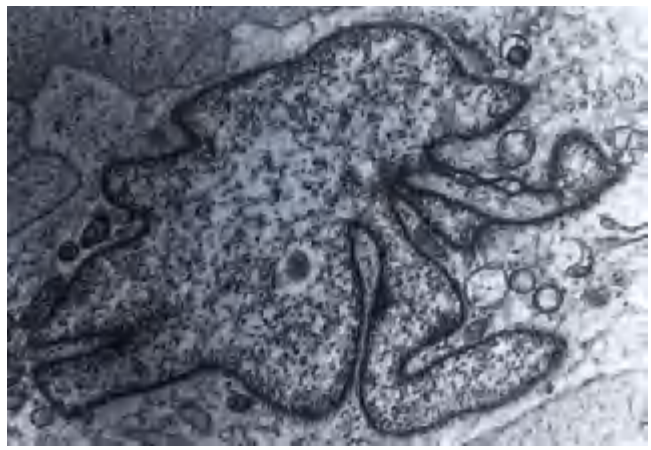

Fig. 54.7 Electron micrograph of T cell infiltrating the epidermis in mycosis fungoides, showing the striking cellular contours of the typical cell of Lutzner with a typical high nuclear contour index.

so-called *Pautrier microabscesses*. The lymphocytes in the epidermis are often strikingly cerebriform (Fig. 54.7), with a very irregular nuclear outline and heavy nuclear staining. If these cells are examined either under high power or with thin sections, the cerebriform and irregular nature of the nuclei can be better appreciated in three dimensions. In early MF, the T-cell lymphocytic infiltrate may be associated with a number of other cell types including

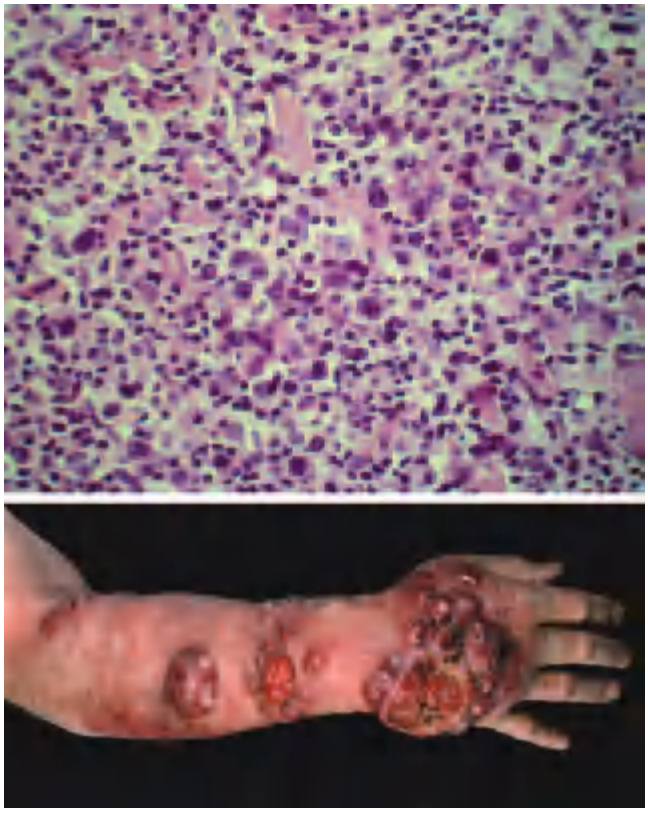

Fig. 54.8 High-power view (a) of large cell transformation in mycosis fungoides (b).

small numbers of plasma cells or eosinophils, but as the infiltrate becomes more intense and more epidermotropic, the infiltrate becomes monotonous and monomorphic. Granulomatous features may be rarely present and a prominent histiocytic infiltrate can be seen [4].

In more advanced stages of disease (IIB–IVB), the striking epidermotropic quality of the lymphocytic infiltrate may be lost, with scattered larger tumour cells showing marked cellular atypia. Large cell transformation may also occur and is a poor prognostic feature on univariate analysis, although this does not appear to be independent of age and stage of disease on multivariate analysis [5]. An earlier study showed no difference in survival for stage IIB patients showing histological features of large cell transformation compared to those without, but there was a significant difference in survival from diagnosis [6]. Large cell transformation (Fig. 54.8) is defined as the presence of more than 25–50% of large cells (either CD30 positive or negative) within the dermal infiltrate or the development of microscopic dermal nodules consisting of larger cells with pleomorphic and occasionally anaplastic morphology [5]. It is important to distinguish large histiocytic cells from large $CD30^+$ tumour cells and occasionally the presence of reactive germinal centres in MF can also cause histological confusion.

A further problem is the differentiation between large cell transformation in MF and the association with a primary cutaneous $CD30^+$ lymphoproliferative disorder such as lymphomatoid papulosis or anaplastic large cell lymphoma, which have a good prognosis. The development of large tumours on patches or plaques of MF would suggest large cell transformation if the histological criteria were fulfilled. In contrast, the presence of very large numbers (more than 75%) of $CD30^+$ large cells in only one or a few isolated tumours developing at sites distant from patches and plaques can present a very difficult diagnostic problem.

Immunopathology. The tumour cells in MF are $CD3^+$, $CD4^+$, $CD45RO^+$ and usually $CD7^-$ T cells. This is the phenotype of a mature helper T cell of memory type [7]. The tumour cells are CLA^+, consistent with a skin homing T cell [8]. In rare cases, the tumour cells are $CD3^+$ and $CD8^+$ and these cases may be hyperpigmented [9]. $CD8^+$ MF must be distinguished from an epidermotropic cytotoxic variant of CTCL with a poor prognosis (see below). Occasionally, there is a very prominent infiltrate of reactive tumour infiltrating $CD8^+$ T cells expressing cytotoxic proteins, which may indicate a good prognosis [10,11]. The dermal infiltrate often consists of a prominent population of $CD1a^+$ dendritic cells and $CD68^+$ histiocytic cells. In advanced disease, tumour cells may express an aberrant phenotype with either loss of T-cell surface antigens 'null-cell phenotype' or expression of the CD30 antigen either by scattered larger tumour cells or by prominent dermal nodules consisting of large pleomorphic or anaplastic tumour cells [5,7]. The latter feature may be associated with large cell transformation but CD30 expression does not appear to have any prognostic significance [5]. The tumour cells usually express the αβ T-cell receptor [12] and only rarely express cytotoxic proteins with disease progression [13].

Pathological differential diagnosis. In early MF, the main differential diagnosis includes a dermatitis reaction. The epidermotropic quality of the T-cell infiltrate in MF may be helpful, as may the cytology of the individual T cells, as in MF these intraepidermal lymphocytes tend to be larger than surrounding keratinocytes and have intensely stained nuclei with a very irregular outline. Spongiosis, if present in association with epidermotropic T cells or Pautrier microabscesses, is minimal, whereas this tends to be more striking in dermatitis reactions. A useful clue may be the characteristic basal layer colonization and the larger size of the intraepidermal T cells compared to the dermal mononuclear cells.

The pathological diagnosis of early MF can still, however, be extremely subjective and is best made in full collaboration with the clinician and only after careful correlation with the clinical features. It is often wise to take several biopsies from separate lesions, and if necessary to

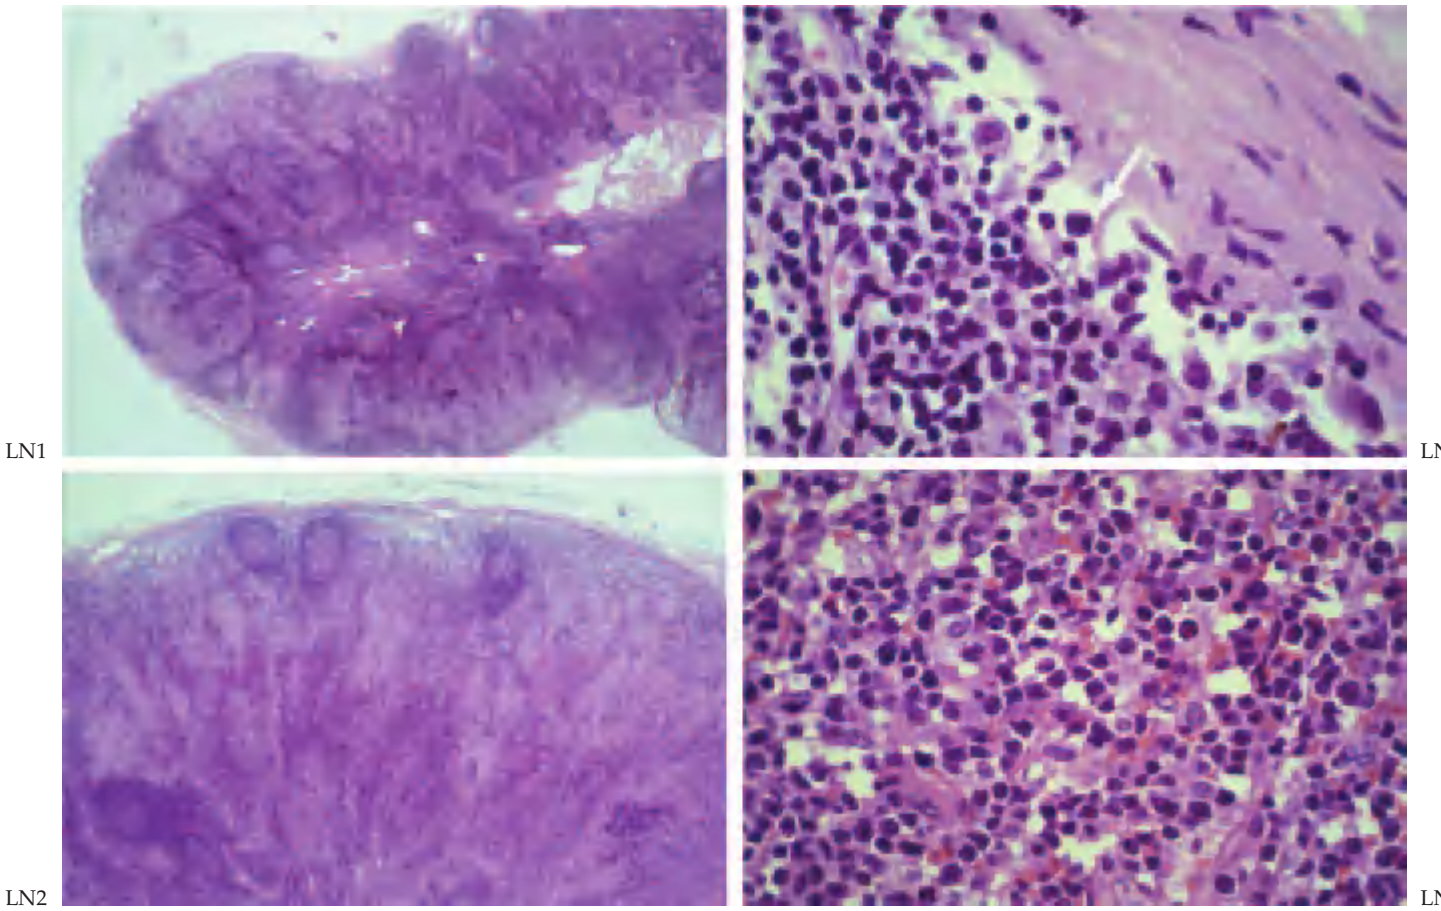

Fig. 54.9 Composite photomicrograph showing features of dermatopathic lymphadenopathy. LN1 is characterized by dermatopathic changes with melanin deposition and occasional atypical lymphocytes. LN2 with paracortical expansion of T-cell areas. LN4 showing a high-power view of lymph node effacement by small and medium sized atypical convoluted cells.

arrange for repeat biopsies to be carried out as the clinical picture evolves over a period of months or even years.

Immunophenotypic studies are usually of minimal value in differentiating early MF from other cutaneous lymphocytic infiltrates, as the majority of these cells will also be $CD3^+$, $CD4^+$ although a predominance of larger $CD4^+$ cells within the epidermis compared to the mixed population of smaller cells within the dermis can sometimes be helpful [12].

The differential diagnosis of early MF from conditions such as arthropod bites and lymphomatous drug eruptions can also be difficult, and good clinicopathological correlation is essential. In general, reactions to arthropod bites tend to show a higher proportion of eosinophils, and the disposition of the infiltrate in lymphomatous drug reactions will be perivascular rather than epidermotropic. In a proportion of cases, however, the diagnosis is suspected on clinical grounds but cannot confidently be made with certainty on histological examination. In these cases, sequential biopsies at 3–6-month intervals may be needed.

Pathology of extracutaneous disease. The usual pattern of extracutaneous spread is from the skin to the draining peripheral lymph nodes and thereafter to other organs such as the liver and spleen, but pulmonary, skeletal and CNS involvement have been documented. The histological assessment of peripheral nodes is based on the study by Scheffer *et al*. [14]. Those biopsies with no abnormalities are recorded as LN0 while those with dermatopathic changes are designated LN1 (*dermatopathic lymphadenopathy*), which is characterized by enlargement of the paracortical area of the lymph node because of the presence of large numbers of macrophages and pale dendritic (interdigitating reticulum) cells. The macrophages contain aggregates both of melanin and lipid material, giving rise to the older term 'lipomelanic reticulosis'. Histological evidence of possible involvement (LN2) is characterized by the additional presence of small clusters of larger atypical mononuclear cells within the expanded paracortical areas (Fig. 54.9). In contrast, partial (LN3) or complete effacement (LN4) of the lymph node architecture is consistent with definite lymphomatous involvement (Fig. 54.9).

An NCI classification system was proposed in 1985 that, although similar, has subtle differences [15]. In this system, lymph node architecture is preserved in LN1–3 in which dermatopathic changes may predominate. LN1 is characterized by single infrequent atypical cells, LN2 shows small clusters of atypical lymphocytes and LN3 shows larger clusters of atypical cells in paracortical areas. LN4 is characterized by partial or complete effacement by atypical cells [15].

A comparison of these systems has shown that both have a poor prognosis for partial or totally effaced nodes with non-effaced nodes showing no difference in survival [16]. In the recent WHO classification system, a modification of these classifications has been proposed whereby LN1 and LN2 have been grouped together as grade I (no histological involvement), with LN3 as grade II and LN4 as grade III, both representing definite histological involvement, although this system has not yet been validated [17]. However, there is a subtle difference in this system because in the WHO proposal grade I can be characterized by scattered but not clusters of atypical cerebriform cells, whereas nodes showing clusters of atypical cerebriform cells are graded as II (LN3).

T-cell receptor gene analysis. TCR gene analysis consists of analysis of DNA from tissue samples for the detection of clonal rearrangements of the TCR genes as a marker of a monoclonal T-cell population. A similar approach can be used to identify a B-cell clone using analysis of immunoglobulin genes. A clonal lymphoid population is usually synonymous with a neoplastic proliferation but this does not signify malignancy. In contrast, the malignant potential of a lymphoid clone is related to the underlying molecular abnormalities. Analysis of TCR genes in MF is now a standard approach that has diagnostic, prognostic and therapeutic implications. Originally, Southern blot analysis of the β TCR gene was employed but this approach is time-consuming, requires large amounts of high-quality DNA and is relatively insensitive [1,2]. Consequently, most studies are now based on more sensitive PCR techniques and several different methods are employed including denaturing gradient gel electrophoresis (DGGE), temperature gradient gel electrophoresis (TGGE), single-strand conformational gel electrophoresis (SSCP) and gene scan methods for analysis of the γ TCR gene [3–8]. Although MF tumour cells usually express an αβ TCR, the γ TCR gene is rearranged in lymphocytes expressing both a γδ and an αβ TCR and this gene is much easier to analyse comprehensively than the β TCR gene. These different approaches have not been compared adequately but most results are broadly consistent.

T-cell clones can be detected in a proportion (approximately 70% overall) of patients with early stage disease and are almost invariable in patients with later stages of disease [5,6]. The lack of T-cell clones in all patients with early stages of disease almost certainly reflects a lack of sensitivity of the technique, although studies have shown that those early stage patients without a T-cell clone achieve a higher complete remission rate with skin-directed therapy than those with a T-cell clone [9]. This suggests that the proportion of non-tumour cells in the infiltrate, possibly reflecting the host immune response, may also be critical. Identical T-cell clones can be detected in peripheral blood of patients with all stages of disease and this may have independent prognostic significance [7,10]. In contrast, non-identical peripheral blood T-cell clones can also be detected and may not be pathological, emphasizing that results from all samples must be carefully compared [11]. In patients with both MF and lymphomatoid papulosis or $CD30^+$ large cell anaplastic lymphoma, identical T-cell clones can be found, suggesting a common pathogenesis [1,2,12]. T-cell clones identical to those in the skin can be detected in dermatopathic lymph nodes (LN1–LN2) but whether this has any pro-

gnostic significance is unclear at present [13–16]. Because of the sensitivity of these PCR-based techniques, T-cell clones have rarely been detected in non-neoplastic inflammatory disorders and therefore it is critical that the presence or absence of a clonal TCR gene rearrangement must always be interpreted in conjunction with the clinical and pathological features. Recent PCR-based studies have also detected T-cell clonal proliferations in some cases of pityriasis lichenoides acuta, small and large plaque parapsoriasis and pityriasis lichenoides chronica [17–21]. The clinical significance of these findings is unclear at present. Although these results would appear to support clinical impressions that large plaque parapsoriasis probably represents early stage MF, small plaque parapsoriasis has been thought to be a separate inflammatory condition that is not related to MF. The findings in pityriasis lichenoides acuta support previous suggestions that this represents part of a spectrum with lymphomatoid papulosis and, intriguingly, lesions resembling pityriasis lichenoides chronica can be associated with MF.

Molecular features. The underlying molecular pathogenesis of MF is currently unknown. No disease-specific translocations have been identified [1], but various abnormalities of tumour-suppressor genes have been detected including overexpression and mutation of *p53* in advanced stages of disease [2–5]. In one study, UVB-type *p53* mutations were found, although this has not yet been confirmed in other studies [4]. *p53* abnormalities are not found in early stages of disease, suggesting that inactivation of *p53* is related to disease progression, similar to findings in other nodal and extranodal lymphomas. At present, it is unclear if *p53* abnormalities are associated with treatment resistance and a poor prognosis as seen in other non-Hodgkin's lymphomas.

Inactivation of both *p15* and *p16* genes has also been detected in MF [6–8]. Unlike *p53*, this is usually a result of hypermethylation of promoter sequences rather than mutation, but it is unclear whether this is restricted to late-stage disease [8]. Frequent allelic losses on 10q have been detected predominantly in late stages of disease, suggesting that this region harbours a gene that is involved in the pathogenesis of MF [9]. In this study, a tumour-suppressor gene on 10q, *PTEN*, was homozygously deleted in a proportion of patients [9]. Recent studies have identified loss of Fas protein expression in later stages of disease and infrequent mutations of the *Fas* gene on 10q have also been detected in early stages of disease, providing a further mechanism by which tumour cells in MF may escape apoptosis [10]. Therefore, it is possible that biallelic inactivation of the *Fas* gene may be a consequence of mutation and deletion on 10q in MF. A specific pattern of chromosomal losses and gains has also been found in MF using allelotyping and comparative genomic hybridization [11–13]. Deletions on chromosomes 1p, 13, 19, 17p and 10q and gains of 4 and 17q are characteristic, with an identical pattern seen in Sézary syndrome suggesting a similar pathogenesis. 17p loss may be associated with biallelic inactivation of *p53* through a combination of deletion and point mutation. These results suggest that

abnormalities of genes in these chromosomal regions are critical to the pathogenesis of MF.

Follicular mucinosis [1–4]

SYN. ALOPECIA MUCINOSA

Definition. Boggy cutaneous plaques showing follicular prominence and histological evidence of mucinous degeneration of hair follicles that is often associated with an atypical pilotropic T-cell infiltrate and clinical features of MF (pilotropic or folliculotropic MF).

Clinical features. There appear to be two distinct forms of follicular mucinosis, one associated with MF and an entirely separate benign inflammatory form of follicular mucinosis, which is not associated with the development of MF. The clinical features of these two types of follicular mucinosis are identical: follicular papules and plaques often associated with severe pruritus and with a predilection for the face and scalp but the trunk and limbs can be affected and the classic patches and plaques of MF may also be present. A younger age group is affected by inflammatory forms but there are no satisfactory criteria for distinguishing this from MF-associated follicular mucinosis, suggesting that both may represent forms of MF. Prominent giant comedones are often a feature with acneiform lesions (Fig. 54.10), and significant alopecia may be present, rarely with mucinorrhoea [5].

Fig. 54.10 Clinical appearance of follicular mucinosis showing boggy mucin-secreting plaques on the trunk.

Pathology. There is degeneration of involved hair follicles, associated in MF with a prominent pilotropic atypical T-cell infiltrate. In MF there may also be associated interfollicular epidermotropism. Although these histological features distinguish follicular mucinosis from pilotropic MF, both conditions may simply represent points on a spectrum [5]. Mucin stains such as alcian blue show the presence of large quantities of mucin (Fig. 54.11). In MF, a pilotropic or folliculotropic infiltrate may also occur without mucinosis. In contrast, the inflammatory form of follicular mucinosis does not show a prominent atypical pilotropic T-cell infiltrate, although repeated biopsies may be required to fully exclude MF and it may be impossible to distinguish these two forms with confidence [6]. Follicular mucinosis can also occur as an incidental histological feature in the context of a variety of inflammatory dermatoses [7].

Immunophenotype. The tumour cells in both follicular mucinosis and folliculotropic/pilotropic MF are usually $CD3^+$, $CD4^+$ and $CD8^-$. Prominent $CD30^{+/-}$ blast cells may be associated with a poor prognosis [5,6]. TCR clonal gene rearrangements can be detected in both MF-associated follicular mucinosis and so-called benign forms of

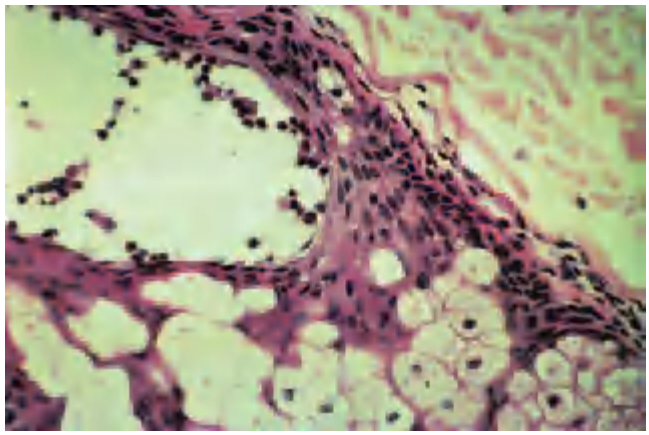

Fig. 54.11 Histology of lesion illustrated in Fig. 54.10 showing degeneration of the hair follicle.

inflammatory follicular mucinosis, consistent with suggestions that both may represent MF variants [6,8].

Pathogenesis. It is likely that follicular mucinosis represents a follicular (pilotropic) variant of MF with mucinous degeneration of the hair follicle, although the reason for mucin deposition is not currently known. This is supported by the presence of this clinical and histological pattern in patients with typical features of MF. The poor prognosis of folliculotropic variants may relate to the poorer efficacy of skin-directed therapies because of the depth of the associated T-cell infiltrate or a currently unknown pathogenetic difference.

Treatment. There is emerging evidence that follicular variants of MF have a worse prognosis, with disease-specific survival rates of 81% at 5 years and 36% at 10 years [5]. MF associated with follicular mucinosis is treated with skin-directed therapy as for early stages of MF, but patients may also require systemic treatment with IFN-α or retinoids. Total skin electron beam therapy may be appropriate for resistant cases. Dapsone can be effective for inflammatory forms of follicular mucinosis. However, if the hair follicles have been destroyed, scarring alopecia will be present and the hair loss permanent.

Pagetoid reticulosis

SYN. WORINGER–KOLOPP DISEASE

Definition. A localized solitary variant of CTCL, which histologically shows intense epidermotropism.

Clinical features. This entity was first described in 1939 [1] and is rare but appears to affect younger adults [2]. It is characterized by an isolated persistent scaly plaque, commonly involving an acral site (Fig. 54.12). The lesion may be asymptomatic and slowly expands, but no further plaques develop on other body sites. A more generalized variant with multiple plaques at other sites has also been described (*Kettron Goodman*), but it is likely that this represents an epidermotropic variant of MF or the more recently described $CD8^+$ epidermotropic CTCL variant [3; and see below].

Pathology. Biopsies show very striking colonization of an acanthotic epidermis [4,5] by atypical large pale mononuclear cells, which usually either fail to express lymphoid markers or express an aberrant T-cell phenotype. Originally there was controversy over whether these cells were derived from histiocytes, Langerhans' cells or Merkel cells. However, the detection of an aberrant T-cell phenotype in some cases and clonal TCR gene rearrangements has clearly established that this entity represents a CTCL variant [6–8].

Pathogenesis. This entity may either represent a localized epidermotropic variant of either MF [9] or the more

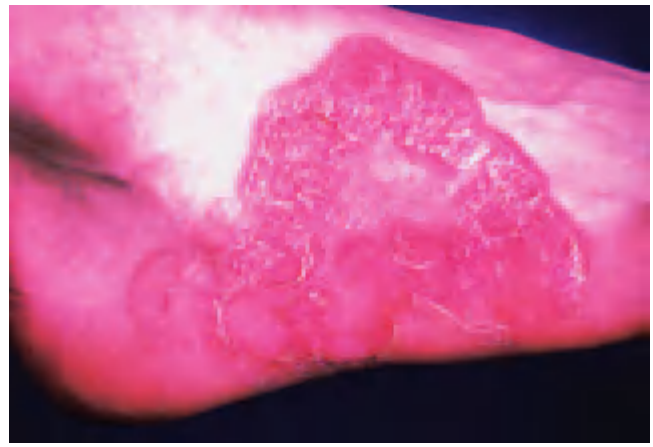

Fig. 54.12 Pagetoid reticulosis. Striking solitary scaling lesion on the side of the foot of a young male.

recently described $CD8^+$ epidermotropic CTCL [3]. However, the underlying pathogenesis will not be understood fully until the fundamental biology of MF has been clarified.

Treatment. The natural history of this lesion is of very slow local extension with an excellent prognosis. Successful remission and probable cure has been reported with both surgical excision and low-dose superficial radiotherapy.

Granulomatous slack-skin disease

Definition. A rare disease characterized clinically by the slow development of pendulous folds of lax erythematous skin and histologically by dermal granulomas and elastolysis.

Clinical features. The lesions develop slowly, usually in middle-aged adults, and then progress over several years, [1]. They are typically flexural in distribution. This condition appears to be caused by cutaneous elastolysis provoked by an underlying lymphoma. Several patients have died of Hodgkin's disease or non-Hodgkin's lymphoma [2–4] and the otherwise unaltered epidermis may show lymphocytic epidermotropism, similar to that seen in MF. The condition must be distinguished from other forms of cutis laxa.

Pathology. Histology reveals a dense granulomatous dermal infiltrate with destruction of dermal elastic tissue (elastolysis) [5–7]. The destruction appears to be mediated by histiocytic giant cells [8]. Similar granulomas may occasionally be found in the spleen and lymph nodes [4]. The lymphocytic infiltrate in the dermis has an aberrant T-cell phenotype, which is suggestive of a lymphomatous proliferation. TCR gene analysis has confirmed that there is a T-cell clone present suggesting CTCL, but whether this condition represents a variant of MF or a different type of CTCL is currently unclear [9].

Treatment. No effective therapy has yet been identified.

Sézary syndrome [1–4]

Definition. The presence of a clinical triad consisting of erythroderma, peripheral lymphadenopathy and atypical mononuclear cells (Sézary cells) comprising 5% or more of peripheral blood lymphocytes on a buffy coat smear (B1), or more than 20% of total lymphocyte count or a total Sézary count of more than 1000×10^9/L (B2). The presence of a peripheral blood T-cell clone as indicated either by a CD4 : CD8 ratio greater than 10, aberrant expression of pan T-cell antigens, cytogenetics or TCR gene analysis is now also required to confirm that the patient has a malignant disease, Sézary T-cell lymphoma–leukaemia [5].

Clinical features. The majority of patients are elderly males and may develop the syndrome either *ab initio* or as progression from classical MF. Many patients describe a prolonged history of 'dermatitis'. Patients present with a generalized exfoliative erythroderma, and may have systemic problems because of shunting of blood through grossly dilated cutaneous vasculature, and resulting high-output cardiac failure. There may be associated ectropion, scalp alopecia, palmoplantar hyperkeratoses and fissuring and the nails often show gross subungual hyperkeratoses (Fig. 54.13). Peripheral lymphadenopathy is often

Fig. 54.13 Sézary syndrome showing erythroderma with palmoplantar hyperkeratoses and prominent nail dystrophy.

present. The distinction from erythrodermic MF (T4 N0–3 M0/stage III–IVA) is based on the degree of peripheral blood involvement (more than 5% Sézary cells per 100 lymphocytes (T4 N0–3 M0B1/stage III–IVA) as suggested in the original National Cancer Institute (NCI) staging system) [6]. However, there has been a debate about the diagnostic and prognostic relevance of the proportion of peripheral blood Sézary cells. In 1988, the NCI originally published a revised staging system, with over 20% Sézary cell count (per 100 lymphocyes) as the B1 rating [7], based on previous studies showing that this figure had prognostic significance in Sézary syndrome [8,9]. However, this has been shown to include some patients with benign disorders and may also actually represent a larger tumour burden (B2). An absolute Sézary cell count of over 1000/mm^3 has recently been proposed as a criterion for the diagnosis of Sézary syndrome, which most closely represents the B2 rating for peripheral blood involvement, but this figure may exclude those patients with a lower tumour burden (more than 5% per 100 lymphocytes; B1), who nevertheless have a neoplastic form of Sézary syndrome [5,10]. A recent study suggests that the presence of lymph node disease in Sézary syndrome is an independent prognostic factor while the degree of peripheral blood involvement also has some prognostic significance [11]. The prognosis for patients with Sézary syndrome is poor, with a median survival of 35 months from diagnosis. Most die of opportunistic infection. However, with improved earlier diagnosis the prognosis may now be better.

Immunopathology. Skin biopsies can show large numbers of atypical mononuclear cells in the dermis with epidermotropism, but it has been shown that non-diagnostic and lymphomatoid histology is frequently seen in proven cases of Sézary syndrome [12]. The presence of atypical (Sézary-like) peripheral blood cerebriform mononuclear cells has also been reported in a variety of inflammatory conditions including actinic reticuloid, erythroderma associated with dermatitis and psoriasis, and severe drug reactions, but in general the percentage of atypical cells in such conditions is fewer than in the Sézary syndrome (Fig. 54.14) [13,14]. In addition, T cells with the morphological and ultrastructural features of Sézary cells can be identified in the peripheral blood of normal healthy individuals [15,16]. However, it is important to realize that the total lymphocyte count does not have to be raised for the diagnosis to be made, and the presence of a normal total white cell count without careful morphological examination of the 'tail' of a blood smear or of a buffy coat preparation may mask this diagnosis. Consequently, it can be difficult to conclusively distinguish cases of T-cell leukaemia–lymphoma from inflammatory dermatoses. Large Sézary cell variants (over 16 μm diameter) are easier to recognize but small Sézary cell variants (12–14 μm) are more common and are more difficult to distinguish from activated lymphocytes [4]. Sézary cells are usually CD3$^+$, CD4$^+$, CD7$^-$, CD26$^-$ T cells but CD7$^+$ and CD8$^+$ variants have been reported [17–21]. Absolute CD4 counts and CD4 : CD8 ratios are elevated. A CD4 : CD8 ratio greater than 10 distinguishes most cases of T-cell leukaemia–lymphoma from inflammatory dermatosis associated with Sézary cells but is not pathognomonic. A consensus has now been agreed that diagnostic criteria should include the clinical triad of features plus the presence of a peripheral blood T-cell clone detected either by expression

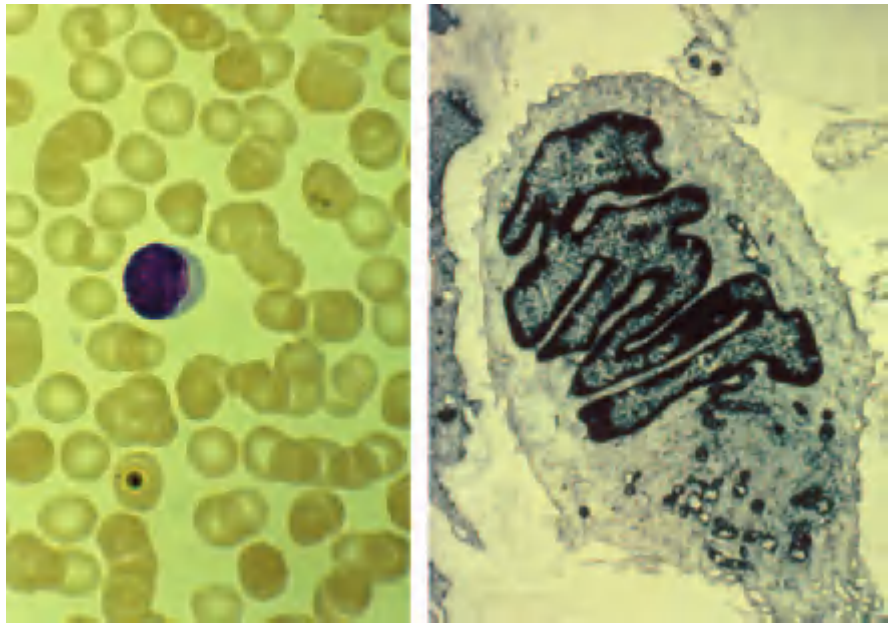

Fig. 54.14 High-power view of Sézary cells in peripheral blood showing large cell with very large nucleus and minimal cytoplasm, and ultrastructural features of a typical cerebriform nucleus.

of aberrant pan T-cell antigens, cytogenetics or TCR gene analysis [5]. Those patients without evidence of a T-cell clone may have a benign inflammatory dermatosis with an excellent prognosis [22]. Sézary syndrome should also be distinguished from other T-cell malignancies such as T-prolymphocytic leukaemia, which can present with cutaneous involvement including rarely erythroderma, although this is usually apparent on the basis of clinicopathological and immunophenotypic features [23].

Molecular features. Conventional G-banded karyotypes reveal multiple, often clonal, complex chromosomal abnormalities consisting of numerical and structural changes in approximately 50% of cases of Sézary syndrome and an abnormal karyotype is a poor prognostic factor [24,25]. No disease-specific recurrent translocations have been detected as yet, despite intensive studies with multicolour fluorescent in-situ hybridization (M-FISH) [26]. Extensive comparative genomic hybridization (CGH) studies have revealed similar chromosomal gains and losses to MF, suggesting a similar pathogenesis [27].

Epidermotropic $CD8^+$ cytotoxic lymphoma

Definition. A primary cutaneous $CD8^+$ T-cell lymphoma that expresses cytotoxic proteins and shows a prominent epidermotropic infiltrate [1]. Although there are currently few reports of this entity, the distinctive pathological and immunophenotypic features and poor prognosis suggest that it represents a distinct subtype of CTCL [1,2].

Clinical features. These patients rapidly develop generalized papules, plaques, nodules and/or tumours which may show ulceration and necrosis [1]. Mucosal involvement may occur. The characteristic distribution of MF, namely involvement of the limb girdle areas, is usually not a feature. The prognosis is very poor, with a 5-year survival of 0%.

Pathology. These lymphomas show a prominent epidermotropic band-like infiltrate with nodular infiltrates of large or small- to medium-sized atypical T cells. These cutaneous lymphomas must be distinguished from MF, $CD30^-$ small to medium pleomorphic and $CD30^-$ large T-cell lymphomas.

Immunophenotype. The tumour cells are $CD8^+$ and usually $CD45RA^+$ and $CD3^+$ [1,2]. The tumour cells also express cytotoxic proteins such as T-cell intracellular antigen-I (TIA-I), granzyme B and perforin. Epstein–Barr virus (EBV) is not detected, in contrast to nasal-type natural killer (NK)/T-cell lymphomas [3].

Pathogenesis. Although the number of cases reported is small, many of these cases express the γδ TCR and show clonal rearrangements of the γ TCR gene with the β TCR gene in a germline configuration, consistent with an origin from a cutaneous γδ T cell [4]. These lymphomas may previously have represented disseminated pagetoid reticuloses (Ketron Goodman). In the EORTC classification this subtype is defined as either $CD30^-$ small to medium pleomorphic or large T-cell lymphomas, while in the WHO classification these lymphomas are defined in the peripheral T-cell lymphoma category.

Treatment. These patients have a very poor prognosis and responses to radiotherapy and chemotherapy are limited.

Large cell $CD30^-$ cutaneous lymphoma (peripheral T-cell lymphoma—unclassified)

Definition. In the EORTC classification a separate category of primary cutaneous $CD30^-$ large cell lymphoma is defined on the basis of a lack of prior or concurrent clinicopathological features of MF and the presence of $CD30^-$ large pleomorphic or immunoblastic cells [1,2].

Clinical features. The characteristic presentation is the sudden appearance of solitary or multiple nodules or tumours on the skin with no preceding plaques or patches of typical MF. In the past, this subgroup of T-cell lymphomas may have been called tumeur d'emblée type of MF. The lesions can be localized or generalized. Patients are HTLV-1 negative. The prognosis is poor, with a 5-year survival of 15% reported [1].

Pathology. Prominent nodular or diffuse infiltrates are characteristic with medium to large pleomorphic T cells and immunoblasts. This CTCL variant must be distinguished from $CD30^-$ small to medium pleomorphic CTCL. Epidermotropism is usually absent. Although an angiocentric pattern was originally reported [1], it is likely that $CD30^-$ cutaneous angiocentric lymphomas represent extranodal NK/T-cell lymphomas (nasal type).

Immunophenotype. The tumour cells usually express T-cell antigens such as CD4 but the pattern may be aberrant with loss of most pan T-cell antigens. By definition, these cells are $CD30^-$ and $CD56^-$. Clonal TCR gene rearrangements are usually present. Epidermotropic cytotoxic $CD8^+$ variants almost certainly represent a separate entity (see above). Similarly, $CD56^+$ cases represent either extranodal NK/T-cell lymphomas (nasal type) or blastic NK-cell lymphomas (see below).

Pathogenesis. This CTCL variant must also be distinguished from transformed MF, HTLV-1 positive ATLL, cytotoxic $CD8^+$ epidermotropic CTCL and blastic NK-cell or extranodal NK/T-cell lymphomas (nasal type). The remaining group of $CD30^-$ CTCL, which are classified as peripheral T-cell lymphoma in the WHO classification, require further study to clarify the pathogenesis.

Treatment. Superficial radiotherapy and multiagent chemotherapy are usually required but the overall prognosis is poor.

Pleomorphic (small to medium) $CD30^-$ cutaneous lymphoma (peripheral T-cell lymphoma—unclassified)

Definition. This subtype of CTCL defined by the EORTC classification must be distinguished clinically from MF and is characterized by small to medium pleomorphic tumour cells [1]. In the WHO classification these lymphomas are classified as peripheral T-cell lymphomas.

Clinical features. Several erythematous or purple nodules or tumours without typical patches or plaques of MF. Patients are HTLV-1 negative. The estimated 5-year survival is 62–80%, but this is only based on small series [1–3]. Systemic involvement is unusual.

Pathology. There are dense nodular or diffuse infiltrates of small to medium pleomorphic T cells within the dermis, often extending into the subcutis [1–3]. This subtype can be distinguished from large cell $CD30^-$ CTCL because in the latter more than 30% of the tumour cells are large pleomorphic cells. Epidermotropism may be present.

Immunophenotype. The tumour cells are usually $CD4^+$ and $CD3^+$ but loss of some T-cell antigens is common [1–3]. It is now appreciated that cases with a $CD8^+$ phenotype and marked epidermotropism represent a different entity, namely cytotoxic epidermotropic $CD8^+$ CTCL (see above), which has a worse prognosis. Clonal TCR gene rearrangements are present.

Pathogenesis. Currently, little is known about the underlying aetiology and pathogenesis of this rare group of primary cutaneous lymphomas. Cases must be distinguished from MF and pseudo T-cell lymphomas. In the WHO classification these lymphomas are classified as peripheral T-cell lymphoma and further studies are required to characterize this group in more detail.

Treatment. In view of the excellent prognosis, superficial radiotherapy is appropriate for solitary lesions. Single-agent chemotherapy and IFN-α have been reported to be effective [3].

Treatment of mycosis fungoides and Sézary syndrome

Current therapy of MF and Sézary syndrome includes:

1 Topical steroids
2 Topical chemotherapy—mechlorethamine (nitrogen mustard) and carmustine (BCNU)
3 Phototherapy—both UVB and psoralen with UVA (PUVA) and UVA-1
4 Radiotherapy, including total skin electron beam therapy (TSEB)
5 Immunotherapy (IFN-α, IFN-γ and IL-12)
6 Retinoids
7 Combination therapies
8 Systemic single and multiagent chemotherapy
9 Photopheresis
10 Toxin therapies
11 Monoclonal antibodies.

The choice of initial treatment for the MF patient will depend on the stage of the disease as well as the general condition and age of the patient (performance status). At present, there are very few published studies that could form the basis for evidence-based therapy, mainly because of the rarity of the condition and also because of the variation between individual patients in disease pattern and progress. A large proportion of patients with MF are frail, elderly and likely to succumb either to other general medical problems or to the side effects of overenthusiastic therapy. These points and the patient's quality of life should always be considered when selecting a treatment regimen. One of the few randomized trials of treatment of MF reported on 103 patients who received either TSEB (3000 cGy total skin electron beam) together with cyclophosphamide, daunorubicin, etoposide and vincristine (a rigorous 'treat to cure' regimen) or sequential topical therapy consisting of topical nitrogen mustard, superficial radiotherapy and TSEB, progressing to PUVA

if required (a 'gentle palliative' regimen). After a median follow-up time of 75 months, there was no difference in disease-free or overall survival between the 52 patients who received TSEB plus chemotherapy and the 51 who received sequential palliative topical therapy [1]. This study established a consensus that therapy in MF should be based on stage of disease and aimed at disease palliation rather than an aggressive intent to cure. The role of novel therapeutic approaches, such as photodynamic therapy, remains to be established.

Topical steroids

For patients with limited early stage MF, life expectancy may not be adversely affected and it is acceptable to simply use emollients with or without moderate potency topical steroids. Potent topical corticosteroids can produce a clinical response, although this is usually short-lived [1].

Topical chemotherapy—nitrogen mustard (mechlorethamine) and carmustine (BCNU)

Topical mechlorethamine (nitrogen mustard) 0.01% or 0.02%, either as an aqueous solution (normal saline) or ointment base (emulsifying ointment), is effective for superficial disease with response rates of 51–80% for IA, 26–68% for IB and 61% for IIA disease [1–4]. The aqueous solution is relatively unstable, and the ointment base—more commonly than the aqueous solution—can cause irritancy or an allergic dermatitis in sensitized individuals (35–58%), but efficacy is similar. This product must not be used in pregnancy and there are rare reports of non-melanoma skin cancer in patients treated with topical mechlorethamine. There is no consensus as to whether mechorethamine should be applied to individual lesions or the whole skin, daily or twice weekly, or about the duration of topical therapy after a clinical remission has been produced; responses can be sustained for prolonged periods.

Topical carmustine (BCNU) is an alternative topical chemotherapeutic agent in MF, with similar efficacy to mechlorethamine as indicated by response rates of 86% in stage IA, 47% in stage IB and 55% in stage IIA patients [5]. Alternate day or daily treatment with 10 mg BCNU in 60 mL dilute alcohol (95%) or 20–40% BCNU ointment can be used. Hypersensitivity reactions occur less often (5–10%) than with mechlorethamine. All patients treated topically with carmustine should have regular monitoring of their full blood counts and treatment is normally given for only 2–4 weeks to avoid myelosuppression; maintenance therapy is contraindicated.

Topical retinoids

Recently, a novel retinoid, 1% Targretin (bexarotene) gel, has been approved by the Food and Drug Administration (FDA) for topical therapy in stage I MF in patients who are resistant or intolerant of other topical therapies [1]. In open uncontrolled studies, response rates of 63% with 21% complete response rates have been reported in 67 patients with early stage (IA–IIA) disease. Median time to and duration of response were 20 and 99 weeks, respectively.

Other topical therapies

There has only been one randomized placebo-controlled trial of topical therapy in MF. Topical peldesine cream (BCX-34—an inhibitor of the purine nucleoside phosphorylase enzyme) showed no benefit, compared to vehicle, with complete responses of 28% and 24%, respectively, emphasizing the difficulties in interpretation of uncontrolled studies of topical therapy in early stages of MF [2].

Phototherapy and photochemotherapy

The clinical benefit of PUVA (photochemotherapy) was noted over 20 years ago and response rates of 79–88% in

stage IA and 52–59% in stage IB disease have been reported [1–5]. Flexural sites ('sanctuary sites') often fail to respond completely and the duration of response varies. There is no significant response in tumour (IIB) stage disease. Maintenance therapy is rarely effective at preventing relapse and therefore should be avoided if possible so as to limit the total cumulative dose, as patients will often require repeated courses over many years. One study has shown that 56% of stage IA and 39% of stage IB complete PUVA responders had no recurrence of disease after 44 months follow-up without maintenance therapy [6]. PUVA is an ideal therapy for patients with stage IB–IIA disease who are intolerant of or fail to respond to topical therapies such as mechlorethamine, although both therapies can be complementary for some patients. Treatment regimens have varied in reported studies of PUVA in CTCL with twice to four times weekly and different protocols for incremental dosage, but usually 2–3 times weekly treatment is acceptable until disease clearance or best partial response. Many patients will inevitably have a high total cumulative UVA dosage and the risks of non-melanoma and melanoma skin cancer are consequently increased for these patients. Efforts should be made to restrict the total PUVA dosage to less than 200 treatment sessions or a total cumulative dose of 1200 J/cm^2. In some circumstances patients may receive a greater total dosage if clinically justified and with the consent of the patient. PUVA remains one of the most effective therapies for patients with early stage disease but there are surprisingly no data to establish if PUVA can improve overall survival. PUVA therapy is rarely tolerated in erythrodermic (stage III) disease but occasional patients will respond repeatedly.

Broad- and narrow-band UVB and high-dose UVA-1 phototherapy have also been used in MF with success [7–9]. There have been no adequate comparative studies of different phototherapy regimens in CTCL.

Radiotherapy and electron beam therapy

MF and other CTCL variants are very radiosensitive malignancies and individual thick plaques, eroded plaques or tumours can be treated successfully with low-dose superficial orthovoltage radiotherapy often administered in several fractions (e.g. two or three fractions of 400 cGy at 80–120 kV). Large tumours may require a different energy source. Radiotherapy is often used with other therapeutic modalities such as PUVA, and closely adjacent and overlapping fields can often be re-treated because of the low doses used [1].

Whole body TSEB therapy has been evaluated extensively in CTCL [2,3]. Different field arrangements have been used in an attempt to treat the whole skin uniformly to a depth of 1 cm with various total dosage administered and additional radiotherapy to shielded areas. A meta-analysis of open uncontrolled and mostly retrospective studies of TSEB as monotherapy in 952 patients with CTCL has established that responses are stage-dependent, with complete responses of 96% in stage IA, IB and IIA disease but disease relapse rates are very high, indicating that this approach is not curative even in early stage disease [4]. In stage IIB disease, complete responses are less common (36%), but erythrodermic (stage III) disease shows complete responses of 60%. Greater skin surface dose (32–36 Gy) and higher energy (4–6 MeV electrons) are associated with a higher rate of complete response and 5-year relapse-free survivals of 10–23% were noted [4]. A retrospective study of erythrodermic disease has also shown 60% complete responses with 26% progression-free at 5 years [5]. In this study, the overall median survival was 3.4 years with a median dose of 32 Gy given as five weekly fractions over 6–9 weeks. Patients with stage III disease did best compared to those with significant nodal or haematological (IVA–B) disease. The duration of response was also longer for those who received more than 20 Gy using 4–9 MeV [5].

A comparative study of TSEB versus topical mechlorethamine in early stage MF showed similar response rates and duration of response, suggesting that TSEB therapy should be reserved for those who fail first- and second-line therapies [6]. Adverse effects of TSEB include temporary alopecia, telangiectasia and skin malignancies, and the treatment is only available in a limited number of centres [7]. Although TSEB is usually only given once in a lifetime, several reports have documented patients who have received two or three courses, although the total dosage tolerated and duration of response have been lower with subsequent courses [8,9].

Immunotherapy

Different forms of immunotherapy have been evaluated in CTCL, with the intention of enhancing antitumour host immune responses by promoting the generation of cytotoxic T cells and Th1 cytokine responses. Studies of IFN-α have shown overall response rates of 45–74%, with complete responses of 10–27% [1–3]. Various regimens have been employed (from 3 MU three times weekly to 36 MU/day) and it appears that response rates are higher for larger dosage regimens (overall responses of 78% compared to 37% for the lower dosage regimen) [2]. Overall response rates are also higher in early (IB–IIA 88%) compared to late (III–IV 63%) stages of disease [2].

Other small pilot studies have shown that both IL-12 and IFN-γ can produce clinical responses in CTCL but their therapeutic value remains to be established [4,5]. Ciclosporin has been used in CTCL, particularly in erythrodermic variants, to relieve severe pruritus but there is some evidence that treatment may actually cause rapid disease progression and its use in CTCL is not recommended [6].

Retinoids

Oral retinoid therapy has been used both as a single agent and in combination with interferons and PUVA in the management of MF (see below). A non-randomized study comparing acitretin and isotretinoin in MF and Sézary syndrome has shown no obvious differences, with complete responses of 21% in both groups [1].

Phase II and III studies of a novel synthetic retinoid in CTCL have recently been published [2,3]. Bexarotene (Targretin) is the only retinoid that selectively binds and activates the RXR receptor. Bexarotene has been shown to promote apoptosis and inhibit cell proliferation. It is relatively selective and therefore should have little effect on the RAR receptor involved in cell differentiation. In phase II and III studies of 152 patients with CTCL, response rates from 20% to 67% have been reported [2,3]. The most effective tolerated oral dosage is 300 mg/m^2/day, although responses improve with higher dosage. Side effects are transient and generally mild but most patients while on therapy require treatment for hyperlipidaemia and central (hypothalamic) hypothyroidism. At a dosage of 300 mg/m^2/day in early stage disease (IA, IB, IIA), response rates of 54% have been noted [2], while advanced MF patients (stage IIB–IVB) have shown response rates of 45% with a notable reduction in pruritus in stage III disease [3].

Combination therapy

Combined IFN-α and retinoids produce similar response rates to IFN alone and are not recommended [1]. Studies comparing PUVA and IFN-α with IFN-α and acitretin in early stage disease have shown complete response rates of 70% and 38%, respectively, but there are no data on duration of response [2]. Uncontrolled studies of combined PUVA and IFN-α (maximum tolerated dosage 12 MU/m^2 three times weekly) in MF and Sézary syndrome have shown overall responses rates of 100%, with 62% complete response rates [3]. This combination may also be useful in patients with resistant early stage disease such as those with thick plaques and folliculotropic disease. Open studies comparing PUVA with combined PUVA and acitretin have shown a similar complete response rate (73 and 72%, respectively), although the cumulative dose to

best response was lower in patients receiving the combination therapy [4]. Current randomized controlled studies are comparing: (i) PUVA versus PUVA and IFN-α in early stage MF; (ii) the role of maintenance IFN-α after induction of a complete response with PUVA and IFN; and (iii) PUVA alone compared to PUVA combined with bexarotene. At present there are few data on the impact on disease-free and overall survival.

Systemic chemotherapy

MF and Sézary syndrome are relatively chemoresistant and responses are usually short-lived [1]. This may partly reflect the low proliferative rate of tumour cells and a high prevalence of inactivating *p53* mutations, which produce a relative resistance to tumour cell apoptosis. A systematic review of published data on different regimens has shown complete response rates of 33% in 526 patients treated with single-agent chemotherapy with a median duration of 3–22 months [2]. Combination chemotherapy in 331 patients produced complete response rates of 38%, with a median duration of 5–41 months [2]. CTCL patients are prone to infection and septicaemia is a common preterminal event.

Chemotherapy should not be used in patients with early stage IA, IB or IIA disease. However, treatment of stage IIB and IVA disease remains problematic. Individual tumours and effaced peripheral lymph nodes will respond to superficial radiotherapy and additional chemotherapy should be considered in patients with a good performance status (WHO 0–2). However, responses are likely to be short-lived and patients should be entered into ongoing clinical trials. Single-agent chemotherapy that has been shown to produce a clinical response in stage IIB–IVB disease includes oral chlorambucil (4–6 cycles of 0.15–0.2 mg/kg/day for 2 weeks every 28 days), methotrexate and etoposide, and the intravenous use of the purine analogues 2-deoxycoformycin, 2-chlorodeoxyadenosine and fludarabine [2]. Open studies of 2-deoxycoformycin in MF and Sézary syndrome have reported response rates of 35–71%, with complete response rates of 10–33% [3,4]. Methotrexate has been reported to produce a complete response rate of 41% in 29 patients with erythrodermic (stage III/T4) disease, with a median survival of 8.4 years with single weekly doses of 5–125 mg. However, this study was uncontrolled and it is unclear if the patients included represented an usually good prognostic group [5]. Recently, liposomal doxorubicin and gemcitabine have been used in CTCL [6,7].

Recent pilot studies assessing the use of TSEB and/or total body irradiation (TBI) combined with high-dose conditioning chemotherapy prior to autologous stem cell transplantation in patients with stage IIB–IVA disease have shown good clinical responses [8,9] but high relapse rates and there are no data available at present to indicate if this approach affects disease-free or overall survival. Allogeneic stem cell or bone marrow transplantation has only been used in a few patients with encouraging results [10,11], but the associated mortality suggests that this approach is difficult to justify. However, a graft-versus-lymphoma effect may be therapeutically important and in the future non-myeloablative miniallografts may have a role for selected CTCL patients.

Photopheresis

Extracorporeal photopheresis (ECP) involves administration of oral psoralen, followed by *ex vivo* collection of an

enriched buffy coat preparation using a cell separator. These leukocytes are then passed through thin polythene tubing with exposure to UVA and the cells thereafter returned to the patient. This regimen is repeated on 2 successive days and the 2-day cycle repeated monthly or fortnightly in an accelerated regimen. A specially designed photopheresis apparatus is required for this technique. The underlying theory is that a proportion of the UVA-exposed leukocytes, including some tumour lymphocytes, undergo apoptosis and that dendritic cells are activated during the *ex vivo* circulation with induction of a host antitumour immune response after the treated cells are returned to the patient. Different models of autoimmune disease support this suggestion [1,2] and recent evidence has also shown activation of dendritic cells during an expanded period of *ex vivo* incubation overnight (transimmunization) [3].

ECP is licensed by the FDA for the treatment of CTCL but there are no randomized studies to clarify whether ECP has any impact on overall survival. The original open study of ECP in 29 patients with erythrodermic CTCL reported a response rate of 73% but response rates in patients with earlier stages of MF were much lower (38%) [4]. Subsequently, a median survival of 62 months was reported in the original cohort of 29 erythrodermic patients, which compares favourably with historical controls (30 months) [5]. A study of 33 patients with Sézary syndrome treated with ECP reported a median survival of 39 months, which was similar to historical controls from the same institution [6]. Other studies have shown more prolonged median survival data [7]. An accelerated regimen consisting of nine collections rather than six for each cycle and an increase to treatment every 2 weeks has shown overall response rates of 50%, with 18% complete responses in erythrodermic disease [8]. A systematic review of response rates in erythrodermic disease (stage III–IVA) with ECP has shown overall responses of 35–71%, with complete responses of 14–26% [9]. Other studies are more difficult to interpret because they have either involved small numbers, patients with earlier stages of disease and in most studies many of the patients have been on other concurrent therapies [10,11]. Preliminary non-randomized studies suggest that the combination of IFN-α and ECP is more effective than ECP alone but this has yet to be confirmed in randomized studies [12,13]. There are isolated case reports of combined ECP and IFN-α that have induced complete clinical and molecular responses [14,15].

Randomized controlled trials of ECP are required to establish an effect on disease-free and overall survival. There have been claims that the CD8 count is critical in predicting whether patients will respond to ECP [5], although others have provided evidence that the total baseline Sézary count is the only predictor of response [16].

Toxin therapies

Recently, Denileukin Diftitox, a DAB_{389}–IL-2 fusion toxin (Ontak USA/Onzar Europe), has completed phase I–II studies and has received provisional FDA approval for the treatment of resistant or recurrent CTCL. Onzar is a recombinant fusion protein consisting of peptide sequences for the enzymatically active domain (389) of diphtheria toxin and the membrane translocation domain of IL-2 that is capable of inhibiting protein synthesis in tumour cells expressing high levels of the IL-2 receptor resulting in cell death. Phase III studies of 71 heavily pretreated patients with stage IB–IVA, and more than 20% $CD25^+$ lymphocytes, showed an overall response rate of 30%, including 10% with complete responses [1]. Patients

were assessed with a rigorous skin scoring system and documented responses were defined as lasting at least 6 weeks. The median duration of response was 6.9 months (range 2.7–46.1 months). The optimally tolerated intravenous regimen is 18 μg/kg/day for 5 days, repeated every 21 days for 4–8 cycles. Adverse effects include fever, chills, myalgia, nausea and vomiting, and a mild increase in transaminase levels. Acute hypersensitivity reactions occurred in 60%, invariably within 24 h and during the initial infusion. A vascular leak syndrome characterized by hypotension, hypoalbuminaemia and oedema was defined retrospectively within the first 14 days of a given dose in 25% of patients. Myelosuppression is rare. Five per cent of adverse effects are severe or life-threatening. The clinical relevance of antibody responses to Denileukin Diftitox is unclear. The duration of clinical response has not yet been established and current studies are comparing different regimens of Onzar and are also assessing the use of this therapy in $CD25^-$ tumours. This therapy is not likely to be appropriate for early stage disease but may be useful in advanced disease.

Monoclonal antibody therapy

A humanized chimeric anti-CD4 monoclonal antibody has been used to treat eight patients with CTCL of whom seven showed a clinical response but this was of short duration [1]. A radiolabelled anti-CD5 antibody has also been used in MF with some objective results [2] and CAMPATH (anti-CD52/alemtuzumab) has also been administered to CTCL patients (stage III) with demonstrable but short-lived clinical responses [3].

CD30+ cutaneous lymphoproliferative disorders

In the skin, $CD30^+$ lymphoproliferative disorders are invariably of T-cell origin although nodal $CD30^+$ lymphomas can be derived from B, T or null cells. By definition, primary cutaneous $CD30^+$ disorders do not have any systemic or nodal involvement [1–3]. CD30 positivity was originally identified on Reed–Sternberg cells in Hodgkin's disease, but has since been found on a proportion of activated T and B lymphocytes. In general, cutaneous lymphomas that are $CD30^+$ *ab initio* are associated with a good prognosis, in contrast to $CD30^+$ lymphomas in other anatomical sites such as the lymph nodes where CD30 positivity is more commonly associated with a poor prognosis. In the skin, the situation in which tumour cells acquire CD30 expression, during the course of disease, is associated with a poor prognosis [4].

Molecular studies show the presence of the Epstein–Barr genome in a proportion of $CD30^+$ infiltrates in Hodgkin's disease, but this has not to date been found in patients with lymphomatoid papulosis [5]. Recent work indicates that CD30 is a cell-surface receptor for tumour necrosis factor-α and -α-like cytokines [6], and it has been demonstrated that CD30 expression can be up-regulated by EBV.

Specific disease entities described in this section include:

- Lymphomatoid papulosis
- Primary cutaneous $CD30^+$ (anaplastic) large T-cell lymphoma
- CD30 large T-cell lymphoma with regional nodal involvement
- Regressing atypical histiocytosis
- Secondary cutaneous $CD30^+$ large T-cell lymphoma.

However, it should be remembered that there is overlap between these conditions and that one may transform into another during disease progression.

Lymphomatoid papulosis

Definition. This term was first used in 1968 by Macaulay to describe a 'self-healing rhythmical paradoxical papular eruption, histologically malignant but clinically benign' [1–6].

Fig. 54.15 Lymphomatoid papulosis. Note multiple scars on the upper chest area of this patient, with a small number of fresh papular lesions.

Clinical features. Affected patients have recurrent crops of papular lesions predominantly affecting the trunk, although any body site can be involved and regional localized patterns may occur (Fig. 54.15) [7]. These lesions grow rapidly over a few days and develop ulcerated necrotic centres. Healing occurs slowly, with fine atrophic circular or varioliform scars, but the cycle recurs every few months, with no obvious initiating factor. The lesions generally occur first in adult life and may recur in crops for up to 40 years. Over time, every individual skin lesion will resolve and there may eventually be a persistent remission. A small number of cases have been reported in children [8,9].

The original description of lymphomatoid papulosis suggested a benign and non-progressive chronic pattern of the disease, but there are well-documented cases both of patients with lymphomatoid papulosis developing $CD30^+$ large cell anaplastic T-cell lymphoma or MF, and of patients with pre-existing MF developing lesions indistinguishable from those of lymphomatoid papulosis [10,11]. A follicular variant of the condition has also been described [12]. A proportion of patients also go on to develop Hodgkin's disease, or develop lymphomatoid papulosis-like lesions in the course of established Hodgkin's disease [13–15].

Pathology. The histological features of the papules are a relative lack of epidermotropism and Pautrier abscesses, but the presence in the dermis of a mixed infiltrate composed of atypical lymphocytes with large nuclei and frequent abnormal mitoses, eosinophils, neutrophils, free red cells and large histiocytic cells [16]. Some of these cells may show gross cytological atypia (Fig. 54.16). The epidermis may be ulcerated and the infiltrate may extend deeply into the reticular dermis. True vasculitis is rarely seen.

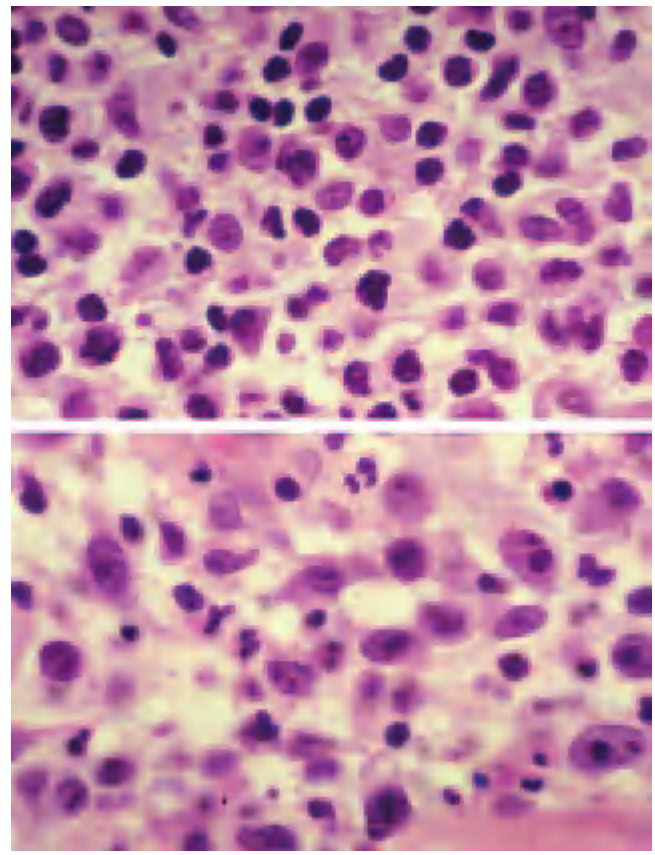

Fig. 54.16 Composite high-power view of atypical cerebriform cells in type B lymphomatoid papulosis (top) and large 'Reed–Sternberg-like' ($CD30^+$) cells in type A histology (bottom).

Lymphomatoid papulosis can be divided on histological grounds into types A, B and C subgroups [17]. In the A subgroup there appears to be a predominance of large, strikingly atypical $CD30^+$ cells similar to those seen in Hodgkin's disease [18]. In the B subgroup, smaller atypical T lymphocytes with convoluted nuclei similar to those seen in MF predominate. Group C lesions have large clusters of $CD30^+$ cells and an overall pattern suggestive of an anaplastic $CD30^+$ large cell lymphoma. Many cases, however, have all types of lesions coexisting simultaneously or a mixed pattern of A and B. Some patients with clinical lesions resembling pityriasis lichenoides acuta (PLEVA) show a lymphomatoid histology and this probably represents a form of lymphomatoid papulosis (type B) [19,20].

Clonal TCR gene rearrangements can be identified and are identical in different lesions from the same patient, but some biopsies may not show a clonal pattern either because of an inability to detect a small clonal T-cell population as a result of a lack of sensitivity, or because of a non-T-cell lineage in type A lesions [4,21]. Identical T-cell clones can be detected in patients with both MF and lymphomatoid papulosis [21].

Treatment. There is no current treatment that alters the natural history of the disease but some therapies appear to accelerate healing and may reduce or prevent the frequency and severity of new crops of lesions for a short time. There is absolutely no evidence that intensive combination chemotherapy alters beneficially the course of lymphomatoid papulosis, and indeed there are individual case reports suggesting that high-dose intensive chemotherapy may cause transition to a more virulent CD30+ lymphoproliferative disorder. Topical or intralesional steroids and topical nitrogen mustard applied to developing lesions may accelerate clearance, but have little effect on well-developed lesions. Narrow-band UVB therapy and PUVA both appear to benefit individual patients for short periods of time. Low-dose oral methotrexate appears to be the most useful systemic therapy, and there are reports of a beneficial effect with oral dapsone [22,23].

Long-term follow-up is necessary in all cases because of the risk of progression to a more aggressive lymphoma such as CD30+ anaplastic large T-cell cutaneous lymphoma, MF or Hodgkin's disease in less than 5% of cases. The prognosis in patients with both MF and lymphomatoid papulosis appears to be excellent [10]. There appear to be no currently available clinical or pathological prognostic markers to indicate whether such progression is likely.

An excellent recent review of 118 patients with lymphomatoid papulosis followed for many years suggests that approximately 4% will develop extracutaneous disease within 10 years [24].

Primary cutaneous (anaplastic) CD30+ large cell lymphoma

Definition. A rare anaplastic large T-cell CD30+ lymphoma originating in and confined to the skin.

Clinical features. These lymphomas are usually seen in adults and present as large solitary or multiple and often ulcerated nodules, most often on the trunk (Fig. 54.17) [1]. There are no patches or plaques of MF elsewhere, and some individual lesions may regress spontaneously, although new lesions will also develop. Some individuals develop disease localized to a limb. Progression to extracutaneous sites is rare but has been recorded in approximately 10% [1,2]. Careful staging consisting of bone marrow and CT scans are required. Disease-related 5-year survival rates of 90% have been reported [1].

Pathology. Biopsy shows a dense lymphocytic infiltrate of large atypical cells with an anaplastic morphology and mitoses, but usually no epidermotropism as seen in MF (Figs 54.18 & 54.19). The tumour cells variably express T-cell antigens and the vast majority will be CD30+. Some tumour cells show a very lymphomatoid-like morphology, while others are more anaplastic [3–5]. Clonal TCR gene rearrangements are detected in almost all cases consistent with a T-cell origin.

Treatment. Both excision and localized radiotherapy are acceptable methods of treating isolated lesions. The recurrence rate on the treated site is very low, but new lesions may develop over time elsewhere on the skin. Spontaneous clearance of even quite large lesions is recorded, and

Fig. 54.17 CD30$^+$ cutaneous lymphoma showing typical ulcerated lesion on shoulder.

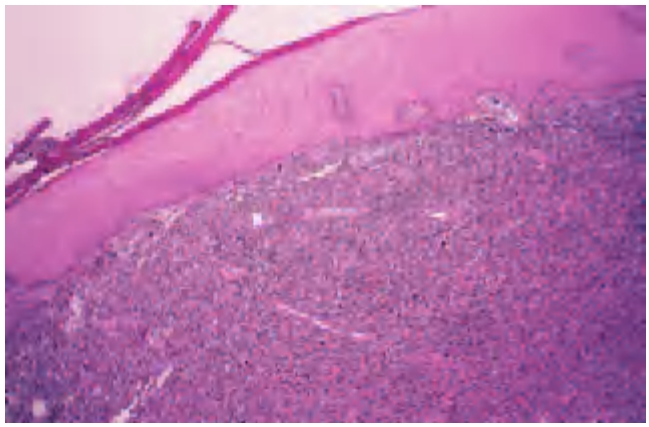

Fig. 54.18 Low-power view of CD30$^+$ infiltrate showing lack of epidermotropism but dense infiltrate in the underlying dermis.

therefore a short period of observation after the diagnosis is made is also acceptable [6]. Systemic chemotherapy including CHOP may be effective but cutaneous recurrence is likely, and chemotherapy is therefore not the treatment of choice for disease confined to the skin. Low-dose methotrexate may also be effective.

CD30$^+$ large cell cutaneous lymphoma with regional nodal involvement

Clinical features. This is a relatively rare variant described by the Dutch Lymphoma Group, who identified 11 cases with either solitary or multiple ulcerated cutaneous tumours, involving one anatomical site and associated with palpable and pathologically involved regional lymph nodes, but no evidence of lymphoma beyond the regional nodal basin [1]. The limited evidence to date on treatment and prognosis suggests that this lymphoma is similar if not identical to primary cutaneous CD30$^+$ large cell lymphoma, with a 5-year survival of over 90%.

Pathology. This is identical to that found in primary cutaneous CD30$^+$ anaplastic large cell lymphoma.

Treatment. If a patient has biopsy proven CD30$^+$ large cell lymphoma in both skin and local nodes, full staging including CT scan and bone marrow aspirate should be carried out. If these investigations show no spread beyond the local draining nodes, then local radiotherapy to the skin lesions is a useful first-line treatment. Low-dose methotrexate may also be helpful. Use of either of these modalities may coincide with resolution of the draining

nodes. It is suggested that treatment should be based on the extent and severity of the cutaneous lesions, as patients treated with chemotherapy including CHOP show good initial clearance of lesions but relatively rapid cutaneous relapse.

Regressing CD30$^+$ large cell cutaneous lymphoma (regressing atypical histiocytosis)

Definition. A rare primary cutaneous CD30$^+$ T-cell lymphoma associated with nodulo-ulcerative lesions of the skin. This entity was first described in 1982 by Flynn *et al*. [1] who considered it to be 'a cutaneous proliferation of atypical neoplastic histiocytes with unexpectedly indolent biologic behaviour'. However, it has now been identified as being of T-cell derivation rather than histiocytic [2].

Clinical features. The clinical features are of large, rapidly developing, ulcerative nodules, often on the thighs and buttocks (see Fig. 54.15). The lesions may be solitary or multiple and the patient is not generally unwell. If untreated, a proportion of these lesions will heal spontaneously. There is thus a striking clinical and pathological similarity to lymphomatoid papulosis [3], although individual lesions are larger, and this entity almost certainly represents a variant of primary cutaneous CD30$^+$ anaplastic large T-cell lymphoma.

Pathology. The pathology is that of a confluent dermal infiltrate that is not angiocentric and has overlying epidermal ulceration in virtually all cases. Large and strikingly atypical mononuclear cells are present with associated inflammatory cells including eosinophils and neutrophils. Focal tumour cell necrosis and perilesional fibrosis are both common. T-cell antigen expression is variable but the tumour cells are CD30$^+$. A recent report has detected the presence of clonal rearrangements of the TCR gene, confirming the T-cell origin [4].

Treatment. As the majority of these lesions regress spontaneously, treatment should be expectant and conservative. Low-dose radiotherapy may accelerate shrinkage of lesions. Methotrexate may be effective.

Secondary cutaneous CD30$^+$ anaplastic large cell lymphoma

Definition. A systemic CD30$^+$ anaplastic large T-cell proliferation in which there is secondary cutaneous involvement. These rare patients generally have a known CD30$^+$ anaplastic large cell lymphoma (ALCL) involving multiple lymph node basins, liver, spleen and other organs. In the course of their disease they may also develop cutaneous papules, nodules and ulcerated lesions.

Clinical features. Patients with CD30$^+$ systemic ALCL are usually systemically unwell with weight loss and other symptoms. Cutaneous lesions may develop at a relatively late stage in disease progression. Crops of large painful ulcerated lesions may develop rapidly, and there is usually palpable lymphadenopathy and hepatosplenomegaly.

Pathology. The histology is usually indistinguishable from primary cutaneous CD30$^+$ ALCL.

Treatment. These patients have a poor outlook. A small series of 11 patients reported by the Dutch Lymphoma Group reported a temporary complete remission in two of seven patients given systemic chemotherapy, but subsequently six patients died within 13 months. Combined chemotherapy and radiotherapy are appropriate [1].

Secondary cutaneous lymphomas

Subcutaneous panniculitis-like T-cell lymphoma

Definition. This is a rare cytotoxic lymphoma, representing less than 1% of all non-Hodgkin's lymphomas, which usually affects younger adults with an equal sex incidence [1].

Clinical features. Patients present with indolent, slowly expanding, subcutaneous nodules usually involving the limbs, which may initially be misdiagnosed as panniculitis (Fig. 54.20) [2–5]. Occasional cases present with more diffuse erythematous induration mimicking a cellulitis, and necrotic lesions can develop. Lymphadenopathy is usually absent at presentation. Systemic symptoms may occur, particularly in those patients who develop a haemophagocytic syndrome consisting of fever, pancytopenia and hepatosplenomegaly [3,6]. The prognosis is

Fig. 54.20 Subcutaneous panniculitis-like T-cell lymphoma: indurated and eroded deep plaque on the thigh.

poor, although there is often a prolonged indolent phase before the diagnosis is established [7].

Pathology. There is a diffuse infiltrate extending throughout the subcutis without epidermotropism [3,7,8]. The degree of cellular atypia can be minimal but large hyperchromatic cells are usually present (Fig. 54.21). Rimming of the tumour cells around fat cells is a useful diagnostic feature. A prominent reactive histiocytic infiltrate is common and the tumour cells may show vascular invasion with angiocentricity. In patients with the haemophagocytic syndrome, erythro- and lymphophagocytosis may be present. Indolent cases were previously diagnosed as benign cytophagic histiocytosis (Weber–Christian disease) [9,10].

Immunophenotype. Tumour cells have a mature T-cell phenotype and are usually $CD8^+$ [8,11]. They express cytotoxic molecules including granzyme B, perforin and TIA-I. Clonal rearrangements of the TCR genes are present and most express an αβ TCR. However, in 25% of cases, tumour cells express a γδ TCR and are $CD4^-$, $CD8^-$ and $CD56^+$, with a possible worse prognosis [8,11,12].

Pathogenesis. There is no evidence for an association with EBV, and the underlying molecular pathogenesis remains to be established.

Treatment. Superficial radiotherapy and combination chemotherapy can be associated with successful clinical responses and resolution of haemophagocytic syndrome, although these remissions are usually short-lived and the overall prognosis is poor.

Adult T-cell leukaemia–lymphoma (HTLV-1-associated)

Definition. ATLL is a pleomorphic peripheral T-cell leukaemia–lymphoma caused by the human retrovirus HTLV-1. HTLV-1 infection is prevalent in certain parts of the world, including Japan, central Africa, the Caribbean and south-eastern states of the USA, and consequently ATLL is endemic in these regions. Sporadic cases are found throughout the world. The disease has a long latency and the incidence of ATLL among HTLV-1 carriers has been estimated to be 2.5% [1]. The virus can be transmitted in breast milk and in blood products. There is a slight male predominance and the median age of onset is 55 years [1].

Clinical features. Patients with ATLL often have extensive lymph node and peripheral blood involvement but the skin is the most common extranodal site of disease and primary cutaneous disease can occur [2]. Other extranodal sites of disease include bone, lung, liver, gastrointestinal tract and CNS. Cutaneous involvement is characterized by widespread or solitary papules, nodules, tumours or erythroderma often associated with intense pruritus (Fig. 54.22) [3,4]. Patients may present with patches and plaques that are clinically indistinguishable from MF [5]. Several clinical variants have been defined [6]: an acute variant is characterized by a leukaemic phase with generalized lymphadenopathy and hepatosplenomegaly often associated with cutaneous involvement and hypercalcaemia with lytic bone lesions. Opportunistic infections are common because of a relative T-cell immunodeficiency. A lymphomatous variant is similar but with the absence of peripheral blood involvement. A chronic variant is typically characterized by cutaneous disease and a peripheral blood lymphocytosis without hypercalcaemia. The smouldering variant is also characterized by prominent cutaneous disease without overt peripheral blood involvement. Pulmonary lesions may occur. Progression from the chronic and smouldering variants to acute disease occurs in at least 25% of cases but often only after a long duration [5]. HTLV-1 serology is invariably positive [6].

Pathology. In the skin, a prominent epidermotropic infiltrate consisting of medium to large cells with a pleomorphic nuclear morphology is usually found, particularly in the acute and lymphomatous variants (Fig. 54.23) [4–6]. Blast-like cells may be present. Pautrier-like microabscesses and a cerebriform nuclear morphology can be

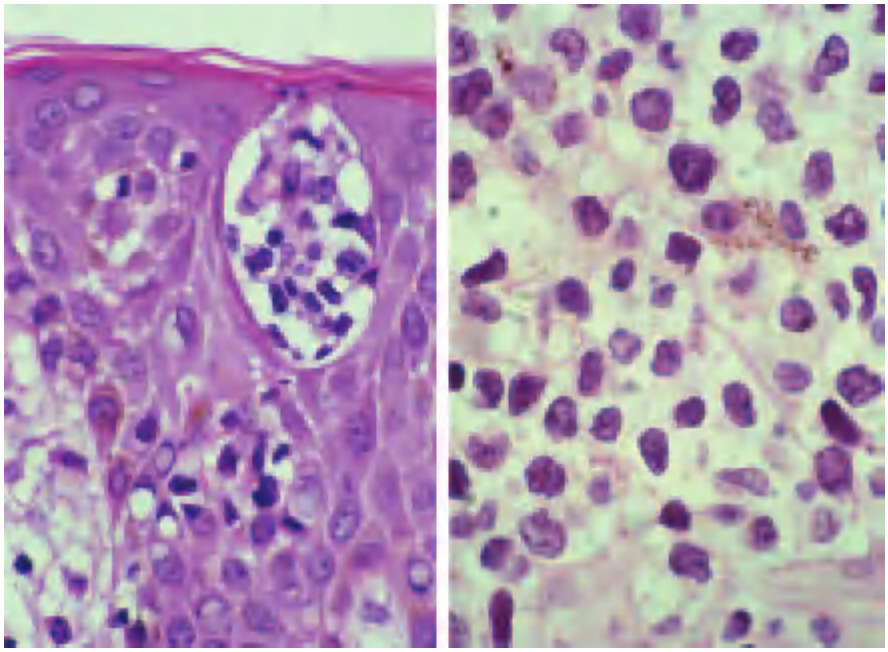

Fig. 54.23 Adult T-cell leukaemia–lymphoma: prominent atypical cells forming a Pautrier micro-abscess and large pleomorphic cells within the dermis.

seen simulating MF. However, the degree of cellular atypia may also be mild, causing diagnostic difficulties. Eosinophilia is often present. Granulomatous features have been rarely described [5]. In the peripheral blood, the tumour cells are polylobulated ('flower cells'). Lymph nodes usually show a leukaemic pattern of infiltration, with preservation and dilation of lymph node sinuses containing tumour cells. Rarely, Hodgkin-like features are present within an expanded lymph node paracortex containing a diffuse infiltrate of small, mildly atypical lymphocytes and scattered $CD30^+$, $CD15^+$ Reed–Sternberg-like EBV-positive cells resulting from expansion of EBV-positive cells as a consequence of a relative T-cell immunodeficiency [7].

Immunophenotype. Tumour cells are $CD2^+$, $CD3^+$, $CD5^+$ and $CD7^-$. Most cells are $CD4^+$, although $CD8^+$ and $CD4^-$, $CD8^-$ variants also occur [8]. CD25 expression is almost universal. Large blast-like cells can be $CD30^+$ but are ALK^-. Cytotoxic proteins are not expressed. Analysis of TCR genes shows clonal gene rearrangement.

Pathogenesis. HTLV-1 is the underlying cause of ATLL. The virus is randomly integrated into the host genome following expression of viral reverse transcriptase, and the viral tax protein is a potent transactivation factor that induces expression of numerous host genes. Additional molecular abnormalities produce a malignant phenotype. The HTLV-1 provirus is clonally integrated, confirming a pathogenetic role for the virus in individual cases [8].

Treatment. Cutaneous disease can respond to skin-directed therapy but patients with the acute and lymphomatous variants have a poor prognosis (less than 10% 5-year survival) and require combination chemotherapy. In contrast, patients with the chronic (30% 5-year survival) and smouldering (65% 5-year survival) variants can have a prolonged course although disease transformation eventually occurs for most patients [6].

Blastic NK-cell lymphoma

Definition. This is a rare lymphoma, which is derived from NK cells and shows a predilection for extranodal sites and particularly the skin [1]. There is no racial pre-

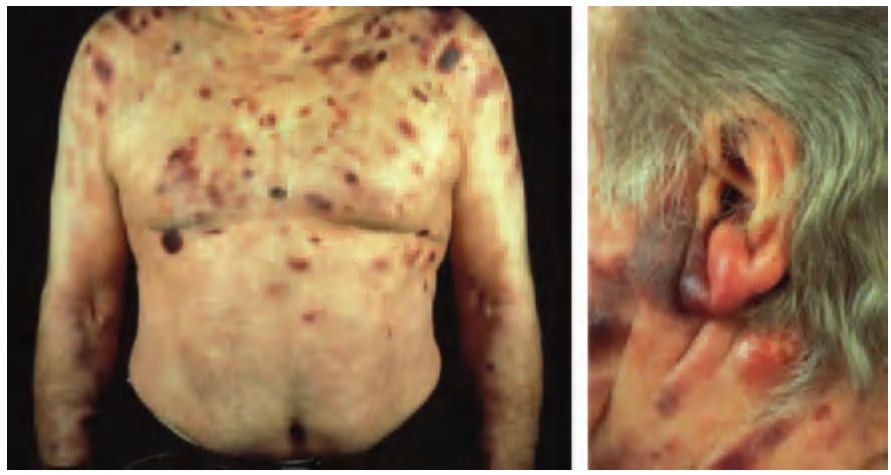

Fig. 54.24 Typical clinical presentations of blastic lymphoma in the skin with large mauvish and pigmented dermal plaques involving the head/neck and trunk.

disposition. Elderly patients are mostly affected and the prognosis is poor.

Clinical features. Patients usually present with multiple and rarely solitary large dusky mauve dermal tumours, which can become ulcerated (Fig. 54.24). There is no specific site predilection. Primary cutaneous disease is common but lymphadenopathy and systemic dissemination is likely during the course of disease [2–5].

Pathology. A dense monomorphic infiltrate of medium-sized tumour cells with a fine chromatin resembling lymphoblasts is seen throughout the dermis with a well-defined grenz zone (Fig. 54.25) [4,5]. Occasionally, tumour cells show a rosette pattern. Necrosis and angiocentricity are usually absent.

Immunophenotype. Tumour cells are $CD56^+$ with variable expression of CD4, and CD43 but do not express surface CD3. CD2, CD7 and cytoplasmic CD3ε are usually negative [3–5]. Cytotoxic proteins may be rarely expressed. Rare cases are $CD34^+$ and TdT^+ and, because of a morphological resemblance to myeloblastic and precursor T-lymphoblastic leukaemia which also express CD56, it is important to confirm that the tumour cells are negative for surface CD3 and myeloperoxidase. TCR gene analysis reveals a germline pattern for all TCR genes consistent with an NK-cell origin [4–6]. Markers of myelomonocytic lineage are usually negative but, intriguingly, a recent study suggests that these tumours may actually be derived from very rare peripheral blood $CD68^+$, $CD123^+$ plasmacytoid monocytes rather than NK cells [7].

Pathogenesis. EBV has not been detected in tumour cells and no disease-specific cytogenetic abnormality has been detected [5,6].

Treatment. Combination chemotherapy and radiotherapy can produce a partial remission, which is invariably short-lived, and the prognosis is very poor. Patients with localized cutaneous disease may have a better prognosis.

Extranodal NK/NK-like T-cell lymphoma (nasal type)

Definition. This rare type of extranodal EBV-positive angiocentric lymphoma preferentially involves the nasal cavity and nasopharynx but also shows a predilection for the skin and used to be referred to as polymorphic reticuloses or angiocentric immunoproliferative lesion [1–4]. The disease is more prevalent in Asia and Central and South America. Most cases are derived from NK cells but rare cases have a cytotoxic T-cell phenotype.

Clinical features. Involvement of the nasal cavity, nasopharynx, paranasal sinuses, orbit and oropharynx is associated with tissue destruction ('lethal midline granuloma'). Secondary involvement of other extranodal sites

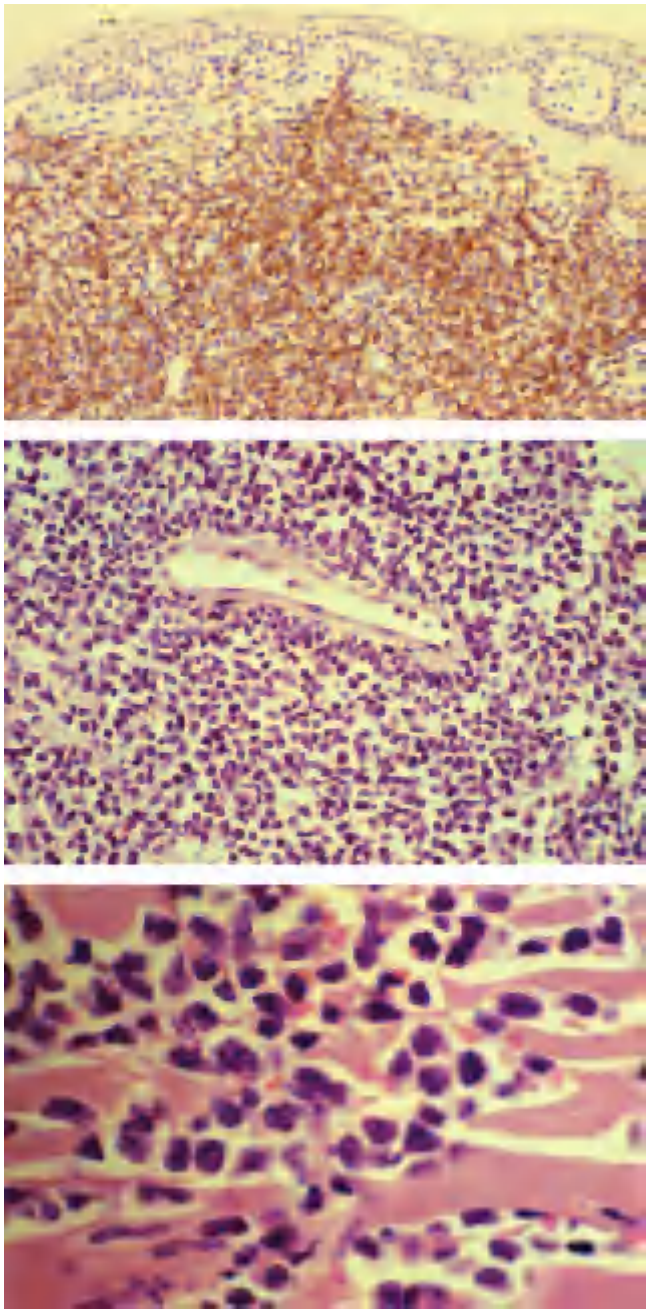

Fig. 54.25 Blastic NK-like lymphoma in the skin: CD56 positivity; rosetting of blood vessels; large atypical mononuclear cells.

including the skin and gastrointestinal tract occurs but primary cutaneous disease is rare. Cutaneous nodules and tumours may ulcerate and become necrotic. Purpura, bullous lesions and diffuse maculopapular rashes have been described [5–8]. A haemophagocytic syndrome can develop rarely and systemic symptoms are common. Bone marrow and peripheral blood involvement is rare but such cases can be indistinguishable from aggresive NK-cell leukaemia–lymphoma.

Pathology. There is a diffuse infiltrate that is angiocentric and angiodestructive [1–4,6]. Extensive necrosis is common. Tumour cells can show a variable morphology with small, medium and large anaplastic cells described. An associated heavy mixed inflammatory infiltrate is common and pseudoepitheliomatous hyperplasia may be found, which can lead to diagnostic confusion.

Immunophenotype. Tumour cells are $CD56^+$, $CD2^+$, surface $CD3^-$, cytoplasmic $CD3\varepsilon^+$. Most cases express cytotoxic proteins, namely granzyme B, perforin and TIA-I [1–4,6]. Rare cases are $CD30^+$ and this may confer a more favourable prognosis [6]. TCR genes are in a germline configuration consistent with an NK-cell origin. However, rare cases of extranodal NK/T-cell lymphomas have a $CD56^-$, $CD3\varepsilon^+$ cytotoxic phenotype and show a clonal TCR gene rearrangement consistent with a cytotoxic T cell [4,7].

Pathogenesis. EBV is present in almost all cases of extranodal NK/T-cell lymphoma, whether $CD56^+$ or $CD56^-$ [3]. EBV is present in clonal episomal form, suggesting that the virus has a critical pathogenetic role. No disease-specific cytogenetic abnormality has been identified but deletions of 6q and isochromosome 6q are common [9].

Treatment. The prognosis is poor despite aggressive chemotherapy, particularly for those patients with disease outside the nasal cavity [4]. The multidrug resistance phenotype is often expressed in cutaneous cases and the median survival for patients presenting with cutaneous disease is 15 months [6].

Primary cutaneous B-cell lymphomas

Primary cutaneous B-cell lymphomas constitute approximately one-quarter of all primary cutaneous lymphomas [1]. There is still controversy about the precise classification of cutaneous B-cell lymphomas, illustrated by the differences between the EORTC classification which is an organ-specific system, and the recent WHO classification which only recognizes that primary cutaneous follicular lymphomas may occur rarely [2,3]. Full staging investigations are essential for all patients with a cutaneous B-cell lymphoma because most primary cutaneous B-cell lymphomas are indolent with an excellent long-term prognosis [4]. Other types of systemic B-cell non-Hodgkin's lymphomas such as small cell lymphocytic lymphoma and mantle cell lymphomas are only found within skin as secondary cutaneous involvement associated with underlying nodal disease [5–7], although very rarely mantle cell lymphomas can be restricted to skin [7,8].

Follicle centre cell lymphoma

SYN. CROSTI'S LYMPHOMA

Definition. An indolent primary cutaneous B-cell lymphoma derived from follicle centre cells (PCFCCL) consisting of a mixture of centrocytes and centroblasts.

Clinical features. Patients present with clinically non-specific solitary or grouped papules, nodules or tumours, most commonly on the head and neck or trunk [1–3], although any body site may be involved (Figs 54.26–54.28). A gradual increase in size of pre-existing lesions and the appearance of new nodules over a period of years is likely without treatment [1–3]. Staging investigations including CT scans of the chest, abdomen and pelvis, and bone marrow aspirate and trephine biopsies are negative

Fig. 54.27 Typical clinical presentation of primary cutaneous follicle centre cell lymphoma on the scalp.

Fig. 54.28 Primary cutaneous follicle centre cell lymphoma. Cutaneous presentation of a systemic follicular t(14;18) lymphoma on the trunk with subtle dermal papules and plaques.

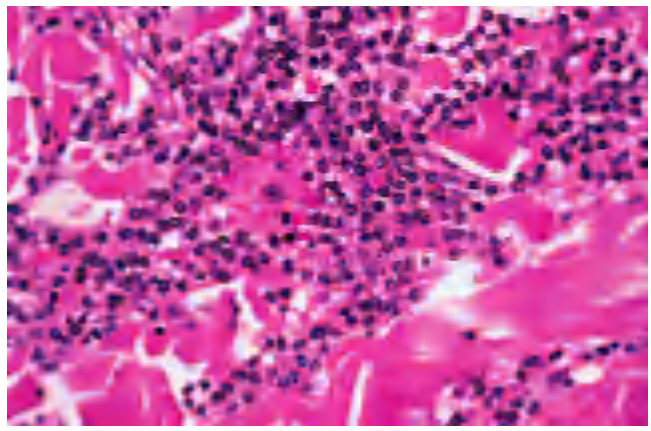

Fig. 54.29 Primary cutaneous follicle centre cell lymphoma, pathology. B-cell lymphoma. H&E section showing characteristic lymphoid infiltrate.

at the time of diagnosis. The estimated 5-year survival of PCFCCL is 94–97% [3].

Pathology. The histology of PCFCCL is variable but the infiltrate shows no epidermotropism and there is a clear grenz zone in the papillary dermis. In the reticular dermis and subcutaneous fat, there is a 'bottom-heavy' lymphocytic infiltrate composed of a mixture of centrocytes, centroblasts and a prominent infiltrate of reactive T cells with the remnants of poorly formed germinal centres [1–3]. This pathology has to be distinguished from marginal zone lymphomas with follicular colonization of reactive germinal centres. Prominent larger tumours tend to show a diffuse infiltrate of larger centrocytes, centroblasts and immunoblasts with fewer reactive T cells and no evidence of follicular structures [3]. Individual patients may show both histological patterns in biopsies from the same group of lesions. A subset of PCFCCL shows neoplastic follicular structures with an expansile growth pattern, a thin poorly formed mantle zone and an absence of tingible body (starry sky) macrophages similar to nodal follicular lymphoma although the phenotypic and molecular features are distinct [4]. In the WHO classification, the diffuse pattern of PCFCCL would be classified as a diffuse large B-cell lymphoma (DLBCL; Figs 54.29–54.31).

Immunophenotype. The tumour cells express B-cell-associated markers such as CD19, CD20, CD22 and CD79a but are $CD5^-$ [3,5,6]. CD10 and both cytoplasmic and surface immunoglobulin is variably expressed by the neoplastic cells [7]. Follicular structures can be more clearly defined by identifying networks of $CD21^+$ and $CD23^+$ follicular dendritic cells. The tumour cells are also mostly Bcl-2 negative, in contrast to systemic follicular lymphoma and DLBCL in which a significant proportion of the tumour cells are $CD10^+$ and Bcl-2 positive [5]. In contrast, Bcl-6 is usually expressed by tumour cells with

Fig. 54.30 Primary cutaneous follicle centre cell lymphoma, pathology. B-cell lymphoma stained with L26 (B-cell marker) showing striking positive staining.

evidence of somatic mutation as also seen in follicular lymphoma and DLBCL consistent with lymphomas derived from germinal centre cells [8]. Clonal immunoglobulin gene rearrangements are present in most cases. False-negative cases are common, caused by somatic hypermutation affecting the primer binding for PCR immunoglobulin gene analysis [9]. Extensive somatic mutation of variable region genes has been identified, which is also consistent with an origin from germinal centre cells [10,11].

Pathogenesis. The relationship between PCFCCL and both systemic follicular lymphoma and DLBCL remains unclear. While there are morphological similarities, PCFCCL follows an indolent clinical course, the immunophenotypic features (CD10 and Bcl-2 often negative) are usually distinct and the t(14;18), which is characteristic of systemic follicular lymphoma and a significant proportion of DLBCLs, has not been consistently detected in

Fig. 54.31 Primary cutaneous follicle centre cell lymphoma.

most European studies of PCFCCL [6,12,13]. Cases with a diffuse pattern are classified as a diffuse large B-cell lymphoma in the WHO classification. In addition, rare PCFCCL cases with a distinctive follicular growth pattern show $CD10^+$ and Bcl-6 positive tumour cells. Microdissection of tumour cells has confirmed the follicular origin of these tumour cells, which are usually Bcl-2 negative and do not show evidence of the t(14;18) translocation, suggesting a different pathogenesis to nodal follicular lymphoma [4]. However, studies from the USA have detected the t(14;18) in a high proportion of $CD10^+$ and Bcl-2 positive PCFCCL with a follicular growth pattern, suggesting that there might be some unexplained geographical distinction although there are no obvious prognostic differences [14,15]. Inactivation of both the cyclin-dependent kinase inhibitors, namely the *p15* and *p16* genes, by promoter hypermethylation has been detected in a proportion of cases but the clinical significance is not yet clear [16]. CGH studies have also identified a consistent pattern of chromosomal gains and losses associated with specific oncogene abnormalities in PCFCCL [17]. However, a detailed characterization of the molecular abnormalities in PCFCCL is required to clarify the pathogenetic relationship between PCFCCL and systemic follicular and DLBCLs.

Treatment. Superficial radiotherapy is the treatment of choice for solitary, recurrent and multifocal cutaneous disease, except in rare cases with very extensive cutaneous disease or systemic involvement when single-agent treatment with chlorambucil or combination chemotherapy may be indicated. Solitary lesions may be excised, although subsequent radiotherapy is probably advisable to reduce the risk of local recurrence [18–20].

Marginal zone lymphoma (immunocytoma)

Definition. An indolent cutaneous B-cell lymphoma derived from post-germinal centre cells and characterized by a proliferation of small lymphocytes, lymphoplasmacytoid cells and plasma cells with monotypic cytoplasmic immunoglobulin.

Clinical features. These lymphomas present as asymptomatic solitary or multiple dermal papules, plaques or nodules on any body site, although the trunk is most often involved (Fig. 54.32) [1–4]. Full staging investigations are indicated. Benign monoclonal paraproteinaemia may be present. There is a slight male predominance. Anetoderma associated with individual lesions has been described [5]. The estimated 5-year survival is 98–100% [4,6,7].

Pathology. The histology is characterized by nodular or diffuse dermal infiltrates of small- to medium-sized lymphocytes, lymphoplasmacytoid cells and plasma cells, often with a reactive T-cell infiltrate [2–4]. There is no epidermotropism. Reactive follicular structures are often present and tumour cells present within expanded marginal zones and interfollicular areas may colonize these follicular structures (Fig. 54.33). This pattern has to be distinguished immunophenotypically from rare follicular patterns of PCFCCL [4]. Occasional scattered centrocytes, centroblasts and immunoblasts may be present. The tumour cells, characterized by monotypic κ or λ expressing larger paler lymphoplasmacytoid cells, are concentrated at the periphery of the cellular aggregates or residual follicular structures. PAS-positive intranuclear or intracytoplasmic inclusions may be present [2–4].

Fig. 54.32 Marginal zone primary cutaneous B-cell lymphoma: typical urticated dermal erythematous papules and plaques predominantly situated on the trunk.

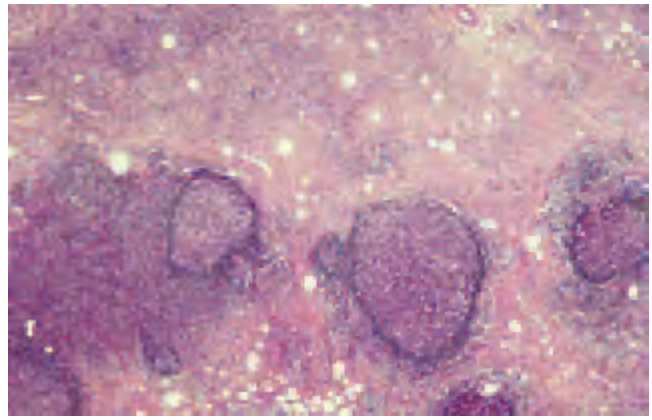

Fig. 54.33 Marginal zone primary cutaneous B-cell lymphoma: reactive germinal centres with a non-epidermotropic monomorphic infiltrate of lymphoplasmacytoid cells and mature plasma cells.

Immunophenotype. The tumour cells show either κ or λ light chain restriction (although this can often be difficult to detect in cutaneous sections because of non-specific staining of collagen) and express CD20 and CD79a but are Bcl-6, CD5 and CD10 negative [4]. The tumour cells are Bcl-2 positive but the t(14;18) is not present [3,4]. Marginal zone lymphomas of the skin should be distinguished from cutaneous infiltrates of B-chronic lymphocytic leukaemia, which are $CD5^+$. Clonal immunoglobulin gene rearrangements are detected in most cases. There is a high false-negative rate because of somatic hypermutation, which interferes with primer annealing in the analysis of immunoglobulin genes as for follicle centre cell lymphomas [8].

Pathogenesis. Marginal zone lymphoma was first described in the stomach (MALT lymphoma) and has since been described in the thyroid, salivary gland, orbit and lung as well as the skin. Although not recognized as a distinct entity in the EORTC classification, primary cutaneous marginal zone lymphomas have since become more clearly defined. At present it is not clear if these primary cutaneous lymphomas have a similar pathogenesis to other extranodal marginal zone lymphomas. The demonstration of light chain restriction and/or a clonal immunoglobulin gene rearrangement represents a critical technique for distinguishing these low-grade cutaneous lymphomas from reactive B-cell infiltrates. The distinction between primary cutaneous marginal zone B-cell lymphoma and immunocytoma is based on the predominance of a monomorphic plasma cell infiltration in immunocytoma but, in view of similar clinical behaviour, the two subtypes are grouped together. In the WHO classification, immunocytoma is recognized in the skin only with sec-

ondary cutaneous involvement. There are no disease-specific cytogenetic abnormalities in cutaneous cases, although a consistent pattern of chromosomal gains and losses have been identified using CGH techniques [9]. In extranodal marginal zone B-cell lymphoma of MALT, trisomy 3 (involving up-regulation of the Bcl-6 gene) and t(11;18) are present in most cases [10]. The t(11;18) produces a fusion protein involving the *AP12* gene and the *MALT-1* gene. In addition, a t(14;18) involving the *IgH* gene locus and the *MALT-1* gene has also been recently identified in a subset of MALT lymphomas including some cutaneous marginal zone lymphomas [11]. Other subsets show a t(1;14) involving the Bcl-10 gene on 1q [12].

Development of immunocytomas has been reported in areas of acrodermatitis chronica atrophicans and has led to speculation about the role of *Borrelia burgdorferi* producing chronic antigen stimulation leading to neoplastic transformation (see below). The detection of *Borrelia* DNA in some cutaneous lesions of immunocytomas and marginal zone B-cell lymphomas using PCR has provided support for this role, but the frequency of positivity varies considerably in different geographical regions with positive results in central Europe and Scotland [13,14] but no evidence of an association in the USA [15].

Treatment. Radiotherapy is appropriate and some patients may simply be observed in view of the excellent long-term prognosis [16]. The role of IFN-α has not been established but it may be effective either systemically or intralesionally [17]. In cases associated with *Borrelia burgdorferi* antibiotic therapy is appropriate [16,17].

Large B-cell lymphoma

Definition. Large B-cell lymphoma (LBCL) is characterized by a diffuse proliferation of large B cells consisting of centroblasts and immunoblasts. This (i.e. diffuse LBCL) is the most common form of non-Hodgkin's lymphoma, derived from germinal and post-germinal centre cells, which usually develops as a primary nodal lymphoma but rarely may present as an aggressive primary cutaneous B-cell lymphoma. Common extranodal sites include the gastrointestinal tract.

Clinical features. As primary cutaneous lymphomas these tumours affect an elderly population with a female predominance. These lymphomas tend to develop on the lower limbs, predominantly as large dermal nodules or tumours, which are either solitary or multifocal (Fig. 54.34) [1]. This has led to the EORTC classification of these lymphomas as LBCL of the leg, although primary cutaneous LBCL can also rarely occur at other sites [2]. The prognosis of primary cutaneous LBCL is poor, with a 5-year survival of 52–58% [1,3]. Full staging investigations are critical to exclude systemic involvement.

Pathology. There is a diffuse non-epidermotropic infiltrate of large cells with morphological similarity to centroblasts and immunoblasts (Fig. 54.35). There are relatively few associated inflammatory cells but a reactive T-cell infiltrate may be present. Germinal centres are not apparent and mitoses are prominent. Several morphological variants have been defined in nodal disease including an anaplastic variant [4]. Morphological variants in cutaneous disease have also been recognized including cleaved and round cell types but the reproducibility of this distinction may be poor [3]. However, the presence of a round cell morphology has been shown to be an

Fig. 54.34 Clinical presentation of primary cutaneous large B-cell lymphoma on the legs.

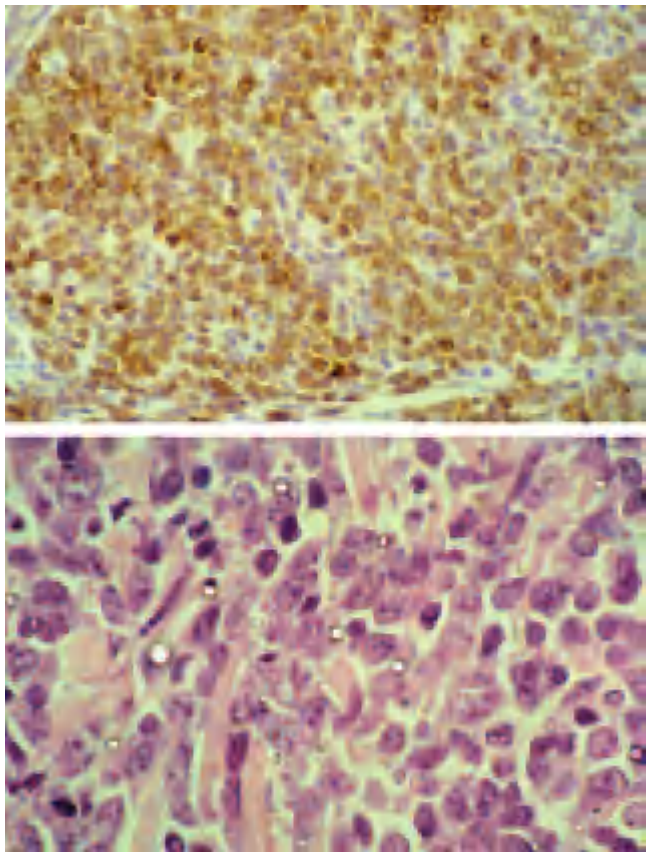

Fig. 54.35 Primary cutaneous large B-cell lymphoma showing a diffuse pattern of large mononuclear cells and strong Bcl-2 positivity.

independent adverse prognostic feature in multivariate analysis [3]. The cleaved cell type showing a predominance of large centrocytes and multilobated cells with few exceptions represent diffuse PCFCCL (Crosti's lymphoma).

Immunophenotype. The tumour cells are CD19, CD20, CD22 and CD79a positive with monotypic expression of surface and/or cytoplasmic immunoglobulin in some cases [5]. Tumour cells are usually strongly Bcl-2 positive [5], except for cases involving sites other than the leg, although most of these cases have a predominance of large cleaved cells [6], and Bcl-6 is also expressed by most cases with evidence of Bcl-6 gene mutations [5,7]. CD30 can be expressed in nodal cases with an anaplastic morphology but this has not been described in primary cutaneous cases. In nodal cases, CD5 (cyclin D1 negative) and CD10 have only rarely been detected and CD10 expression can also be rarely detected in primary cutaneous disease [5].

Pathogenesis. Although LBCLs usually arise *de novo* in the skin, they may also occur resulting from high-grade transformation of a low-grade primary cutaneous B-cell lymphoma such as PCFCCL [8]. These lymphomas are derived from germinal or post-germinal centre B cells. At present it is unclear whether primary cutaneous LBCL has the same pathogenesis as the more common primary nodal DLBCL, although this would seem likely. The EORTC classification of cutaneous cases as large B-cell lymphoma of the leg has caused controversy although there are a number of examples of site-specific lymphomas. However, the disease can rarely occur at sites

other than the leg. It may be difficult to distinguish this type of lymphoma from diffuse forms of PCFCCL, but the excellent prognosis of the latter suggests that this distinction is clinically relevant [8]. In addition, cases with a predominance of large cleaved (centrocyte) and multilobated cells invariably represent diffuse forms of PCFCCL.

Clonal rearrangements of immunoglobulin genes are present in most cases with false-negative results resulting from somatic hypermutation [9]. No disease-specific cytogenetic abnormalities have been identified. The t(14;18) translocation has not been identified in Bcl-2 positive cutaneous cases although this is a common feature of nodal DLBCL [5,6,10]. Chromosomal amplification of the *bcl-2* gene may account for bcl-2 overexpression in some cutaneous cases and, unlike PCFCCL and primary cutaneous marginal zone lymphoma (PCMZL), 6q loss and 18q gain are characteristic CGH findings [11]. In addition, inactivation of *p15* and *p16* genes by promotor hypermethylation has been detected and array CGH studies have identified specific oncogene abnormalities [11,12]. Recent studies in nodal DLBCL using microarray technology have detected at least three distinct expression profiles: one characteristic of germinal centre cells; one with an expression profile consistent with activated peripheral blood B cells; and one with an indeterminate profile [13]. Moreover, these patterns have prognostic and therapeutic significance [14]. As yet there are no data on cutaneous cases.

Prognosis. The prognosis for primary cutaneous LBCL, excluding cases of diffuse PCFCCL, is poor, with a 58% 5-year survival, but this is generally better than for nodal DLBCL [1]. Studies have previously suggested that Bcl-2 expression is site-related (lower limbs and multifocal lesions are more frequently bcl-2 positive) and possibly associated with a worse prognosis [3,6], although other studies have disputed the prognostic significance of bcl-2 expression [15]. A recent study of 145 cases has shown that multifocal disease, location on the leg and a round cell morphology are associated with a worse prognosis in a multivariate analysis (5-year survival of 52% vs 94%) [3]. However, this study included a significant number of cases with a diffuse pattern of large cleaved cells representing diffuse forms of PCFCCL. Unfortunately, tumour Bcl-2 expression was not included in this analysis and the possibility that Bcl-2 expression is a poor prognostic feature requires further study.

Treatment. In elderly patients with solitary tumours, radiotherapy may be appropriate but multiagent chemotherapy is usually required, especially for multifocal disease [16,17]. The role of rituximab (a chimeric mouse/human anti-CD20 antibody which induces antibody-dependent cytotoxicity) in cutaneous disease has yet to be determined [18,19], but this has proved effective in relapsed nodal DLBCL with or without chemotherapy. Intralesional rituximab may prove to be effective [20].

Cutaneous plasmacytoma [1–3]

Definition. Plasmacytomas are clonal proliferations of plasma cells without evidence of multiple myeloma. These

are usually localized tumours either in bone (osseous) or extramedullary sites. A variety of sites may be affected including the skin (4% of all extramedullary plasmacytomas). Extraosseous lesions in association with multiple myeloma are not uncommon, and the skin is infiltrated in approximately 10% of cases [4]. However, primary involvement of the skin without evidence of bone involvement is extremely rare, with less than 30 cases recorded to date in the world literature.

Clinical features. Patients usually present with solitary or multiple, slowly growing violaceous dermal or subcutaneous nodules with no specific site predilection. Full staging investigations and skeletal surveys are required to exclude underlying myeloma, although a proportion of patients may have a benign monoclonal gammopathy. The prognosis is excellent, although patients may rarely develop myeloma.

Pathology. Nodular or diffuse dermal infiltrates consisting of mature plasma cells with some abnormal forms and occasional multinucleated forms. Occasionally, it can be difficult to distinguish plasmacytoma from immunocytoma (marginal zone B-cell lymphoma).

Immunophenotype. Tumour cells are $CD38^+$ (usually $CD19^-$ and $CD20^-$) and show κ or λ light chain restriction with clonal immunoglobulin gene rearrangements. These findings help to distinguish plasmacytoma from benign reactive plasma cell infiltrates (plasmacytosis).

Pathogenesis. There are few studies in cutaneous plasmacytoma in view of the rarity of the disease, but the underlying pathogenesis of extramedullary and osseous plasmacytoma is related to plasma cell myeloma.

Treatment. There are excellent responses to excision and/or radiotherapy.

Borrelia burgdorferi-associated lymphomas

In 1982, Burgdorf *et al*. suggested that Lyme disease was caused by the tick *Ixodes ricinus*, and since that time the spirochete *Borrelia burgdorferi* has been recognized as being the vehicle responsible for carrying infection from the tick to human [1]. Cutaneous manifestations of Lyme disease are fully described in Chapter 27, but prior to the publication by Burgdorf *et al*. it was recognized in the German literature that patients with acrodermatitis chronica atrophicans, now recognized as part of the spectrum of Lyme disease, could develop cutaneous B-cell lymphomas [2–4].

There have recently been descriptions of a number of patients with low-grade primary cutaneous B-cell lymphoma in association with chronic *Borrelia burgdorferi* infection [5]. These patients developed multiple plaques and nodules superimposed on lesions of acrodermatitis chronica atrophicans. In a small number of reported cases, the lesions of acrodermatitis chronica atrophicans clear with antibiotic therapy, but the nodules of B-cell lymphoma may or may not persist. In contrast, the role of *Borrelia* in the pathogenesis of primary cutaneous B-cell lymphoma without clinical evidence of acrodermatitis is more controversial, with some studies detecting positive *Borrelia* serology and the presence of *Borrelia* in tumour DNA using PCR [6,7] while others have consistently shown negative results [8–10].

These lesions show a lymphoid proliferation characterized by an absence of epidermotropism, a grenz layer, and a fairly dense dermal and subcutaneous lymphocytic infiltrate. The cells express B-cell antigen and are monoclonal for either κ or λ light chains. To date, most cases reported have been κ-chain-positive. Immunoglobulin gene analysis can confirm the presence of a B-cell clonal proliferation. Extensive investigations have revealed no evidence of systemic involvement in most cases. The recognition of this entity suggests that chronic antigenic stimulation, in this case caused by the presence of *Borrelia burgdorferi* infection, may rarely encourage emergence of a neoplastic B-cell clone from a previously benign reactive proliferation of B lymphocytes [11].

Secondary cutaneous B-cell lymphomas

Intravascular large B-cell lymphoma [1–8]

SYN. MALIGNANT ANGIOENDOTHELIOMATOSIS; ANGIOTROPHIC LYMPHOMA

Definition. A rare extranodal B-cell lymphoma characterized by accumulation of large B cells within small blood vessels. This tumour usually involves multiple extranodal sites including the CNS and skin, which may be the presenting feature.

Clinical features. Patients present with diffuse, tender, hard, infiltrated plaques, commonly on the thigh (Fig. 54.36), and the clinical appearance may suggest a sclerotic connective tissue disorder or panniculitis. A variety of clinical features may occur as a consequence of occlusion of internal small vessels. The prognosis is poor, although rare cases with disease confined to the skin may have a better outlook.

Pathology. The tumour cells are large and show striking atypia with an occasional anaplastic morphology. These cells are situated entirely within vessel lumina (Fig. 54.37). Fibrin thrombi may be present.

Immunophenotype. The tumour cells are positive for B-cell-associated antigens consistent with origin from a peripheral post-germinal centre B cell. Clonal immunoglobulin gene rearrangements are present. Rare cases are derived from T cells and show a clonal TCR gene rearrangement. Rarely, factor VIII, an endothelial cell-related antigen, may be positive but this is thought to be caused by absorption of antigen by tumour cells rather than indicating an endothelial cell origin.

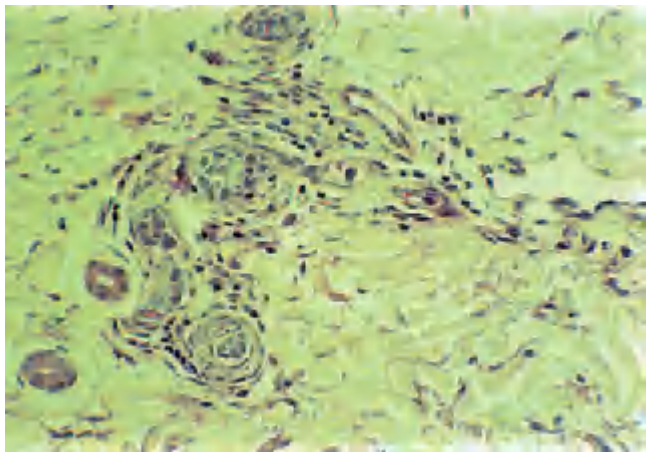

Fig. 54.36 Histology of angiocentric B-cell lymphoma showing B cells within small vascular channels in the dermis. These are stained with membrane markers for B cells, not with membrane markers for endothelial cells.

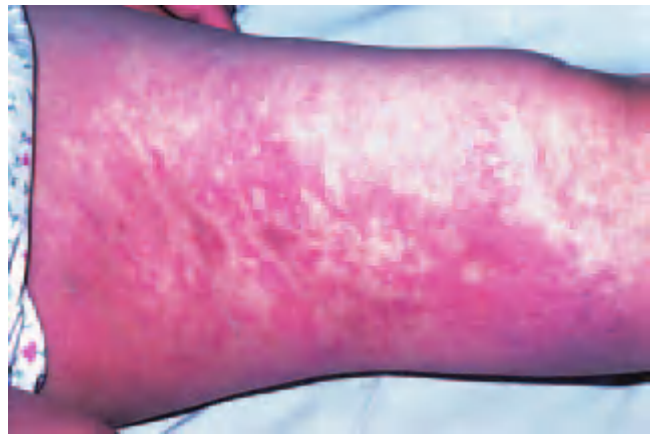

Fig. 54.37 Clinical illustration of patient illustrated in Fig. 54.36. Note marbled appearance of inner thigh which was woody hard on palpation. B-cell lymphoma showing lack of epidermotropism and clear grenz zone in the papillary dermis. (Courtesy of R.S. Lever, Western Infirmary, Glasgow, UK.)

Treatment. There are some reports of partial response to chemotherapy, but the disease has a poor prognosis and is usually fatal.

Lymphomatoid granulomatosis

Definition. An angiocentric and angiodestructive extranodal EBV-positive B-cell lymphoma, which invariably involves the lungs and may involve the skin [1–3].

Clinical features. Patients most frequently present with pulmonary symptoms associated with systemic malaise,

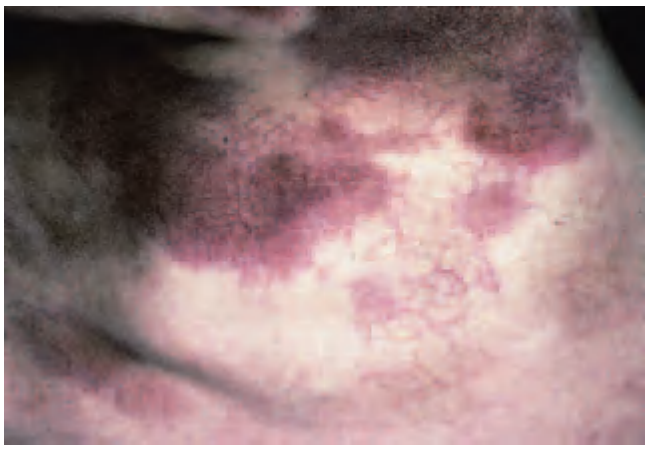

Fig. 54.38 Clinical features of lymphomatoid granulomatosis showing extensive purpuric, bruise-like lesions on the trunk.

arthralgias, weight loss and fever. The skin (50% of cases), CNS and kidneys are also often directly involved. The cutaneous lesions described are diverse but include subcutaneous nodules and plaques, more superficial plaques and a diffuse erythematous maculopapular eruption (Fig. 54.38) with epidermal atrophy and purpura [4–6]. Necrosis and ulceration may also occur [4]. Some patients have a fluctuating course with spontaneous remissions but eventually progressive disease develops.

Pathology. The striking feature is the angiocentricity of the infiltrate and the gross vessel destruction sometimes accompanied by fibrinoid necrosis (angiodestruction) [7]. The infiltrate is polymorphous and contains both lymphocytes and histiocytes with pleomorphic or immunoblastic tumour cells and often a prominent reactive T-cell infiltrate. Multinucleated cells may be present although well-formed granulomas are rare. The presence of large transformed cells is associated with a worse prognosis.

Immunophenotype. The tumour cells are EBV-positive, express CD20 and are variably CD79a$^+$. CD30 may be expressed but the cells are CD15$^-$. The reactive T cells are CD3$^+$ and CD4$^+$. Clonal immunoglobulin gene rearrangements can be detected in most cases and Southern blot analysis usually confirms the presence of clonal episomal EBV [8].

Pathogenesis. Lymphomatoid granulomatosis is an EBV-driven lymphoproliferative disorder that can be associated with immunodeficiency states. This lymphoma should be distinguished from extranodal NK/T-cell lymphoma (nasal type), which is also EBV-positive and characterized by an angiodestructive histology [8].

Treatment. Although some patients have spontaneous remissions, the development of high-grade disease is associated with a median survival of less than 2 years. Short-lived remissions with high-dose chemotherapy have been described. There are reports of responses to cyclophosphamide and IFN-α, particularly for patients with low-grade disease [9].

Pseudolymphomas

Definition. Benign but persistent lymphoid proliferations in the dermis, which may very rarely transform to true lymphoma in some cases [1–3]. The term cutaneous lymphoid hyperplasia has been suggested and both terms are more commonly used to describe a pathological than a clinical appearance. Confusion between pseudolymphoma and true lymphoma can easily arise if a biopsy is submitted to the pathologist without an adequate history of recent events such as drug ingestion or scabies infestation.

Aetiology. T-cell pseudolymphomas may arise as a form of adverse drug reaction. The range of drugs causing T-cell pseudolymphomas is wide but includes anticonvulsants, angiotensin-converting enzyme inhibitors, β-blockers, cytotoxics, antirheumatics, antibiotics, antidepressants and many others [4–8]. Persistent contact dermatitis may also produce a T-cell pseudolymphoma pathological picture [9]. Persistent nodular scabies and arthropod bites may also cause a T-cell pseudolymphomatous histology [10], possibly caused by retained foreign material stimulating a persistent antigenic reaction [11,12]. There are three reports in the literature of putative CTCL arising in association with silicone breast implants, which may be examples of this phenomenon [13].

Actinic reticuloid (see below) may resemble a T-cell lymphoma histologically, and in very rare cases may actually progress to true lymphoma. Jessner's lymphocytic infiltrate (see below) can also be classified as a T-cell pseu-

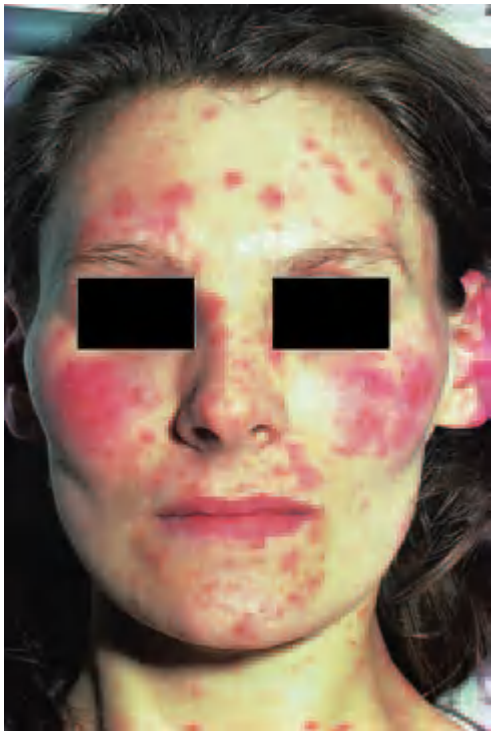

Fig. 54.39 Clinical appearance of a persistent photosensitive drug eruption induced by co-trimoxazole (Septrin).

dolymphoma, although there is a view that it is a variant of cutaneous lupus erythematosus.

B-cell pseudolymphomas may arise in the course of Lyme disease with *Borrelia burgdorferi* infection [14], in tattoos as a reaction to certain pigments [15,16], after vaccination and trauma [17], acupuncture [18] and within scars after herpes zoster infection [19]. The classic entity of lymphocytoma cutis also histologically resembles a B-cell pseudolymphoma, and is at present of unknown aetiology.

It is generally wise to be guarded in the diagnosis of pseudolymphoma, as in a number of cases clear progression from apparent pseudolymphoma to true lymphoma has been recorded. This appears to confirm the concept that chronic, initially benign, reactive inflammatory conditions may very rarely progress to frank lymphoma.

Clinical features. Both T- and B-cell pseudolymphomas may present as multiple cutaneous nodules (Fig. 54.39) as in persistent nodular scabies or lymphocytoma cutis. T-cell pseudolymphomas may also present as persistent erythema sometimes developing into an exfoliative erythroderma [20]. This is characteristic of T-cell pseudolymphomas caused by drug reactions or contact dermatitis. B-cell pseudolymphomas may also be associated with palpable lymphadenopathy, adding to diagnostic confusion.

Pathology [21–26]. It is vital to give the pathologist a good clinical history if the distinction between true lymphoma and pseudolymphoma is to be made, as the pathological, phenotypic and molecular differentiation is not absolute. The salient feature of a pseudolymphoma is the presence of T- or B-cell lymphoid proliferations. A few mitotic figures may be present, and there may also be subtle nuclear atypia. T-cell pseudolymphomas may be band-like or nodular in distribution, whereas B-cell pseudolymphomas are usually nodular. Germinal centre formation is usually absent in B-cell pseudolymphomas. Rarely, the lymphoid cells may be very bizarre and resemble mitogen-stimulated lymphocytes seen *in vitro* during the lymphocyte-transformation test [27]. In general, T-cell pseudolymphomas do not show epidermotropism or the presence of Pautrier's microabscesses.

Immunophenotypic studies show a normal T-cell phenotype and a mixed κ/λ expression. When germinal centres are present, Bcl-2 is not expressed in B-cell pseudolymphomas [28]. TCR and immunoglobulin gene analysis usually show evidence of a polyclonal proliferation, but rarely a monoclonal pattern has been detected, suggesting a neoplastic proliferation, but the significance of this finding is unclear at present [29–33].

Management. If the diagnosis of pseudolymphoma is considered likely, the presumed cause should be removed if possible. This is probably easiest in the case of an adverse drug reaction, but it may take weeks or even months for the cutaneous reaction to subside. In the cases of persistent nodular scabies or other pseudolymphomas that cause symptomatic itch, application of topical steroids will accelerate clearance.

Parapsoriasis

This term has caused confusion since its introduction in 1902 because of a lack of a universally agreed definition of the clinical entities to be included. For this reason, many dermatologists prefer not to use the term at all, and to substitute one of the many synonyms for clinical conditions that might be included in one of the parapsoriasis groups. There is unresolved controversy as to whether or not two of the parapsoriasis variants are either precursors to cutaneous lymphoma in the form of MF (so-called *premycotic eruptions*) or established but early MF from the outset. There is a broad division of parapsoriasis into small and large plaque variants, each with a number of synonyms. The evidence that the majority of cases of small plaque parapsoriasis are a chronic benign condition is reasonable.

Fig. 54.40 Typical chronic superficial scaly dermatitis showing linear plaques on the trunk that change little over time.

In the case of large plaque parapsoriasis, there is more evidence that, at least in some cases, from the outset it is a form of MF. Unfortunately, TCR gene rearrangement studies have not been conclusive, although the proportion of cases with evidence of monoclonality is lower in small plaque parapsoriasis. Future long-term follow-up of these cases is now required.

Small-plaque parapsoriasis [1,2]

SYN. CHRONIC SUPERFICIAL SCALY DERMATITIS; PERSISTENT SUPERFICIAL DERMATITIS; DIGITATE DERMATOSIS; XANTHOERYTHRODERMA PERSTANS

Definition. A chronic asymptomatic condition, characterized by the presence of persistent small scaly plaques, mainly on the trunk.

Clinical features. The lesions usually appear insidiously and asymptomatically on the trunk and, to a lesser extent, on the limbs of young adults. Individual lesions are monomorphic round or oval erythematous patches, 2.5–5 cm in diameter, with slight scaling (Fig. 54.40). Some have a slightly yellow, waxy tinge. The lesions persist for years or even decades, and may be more obvious in the winter months. There is sparing of the pelvic girdle area and the striking polymorphic appearance of individual patches in MF is lacking.

Pathology. This is non-specific. There are small focal areas of hyperkeratosis and parakeratosis, and in the underlying dermis there are small aggregates of morphologically normal $CD4^+$ T cells, mainly around the vasculature. There is no epidermotropism, and no Pautrier's microabscesses.

Immunophenotypic studies reveal a normal mature T-cell phenotype. One report has identified a 'dominant T-cell clone' in two out of five cases of small-plaque parapsoriasis, using PCR analysis [3]. The significance of this observation in terms of relationship to MF and disease progression is not yet clear. There is also a report of a higher frequency of clonal T cells in the peripheral blood of patients with small-plaque parapsoriasis [4] with no evidence of clonality in the skin, although the significance of this finding is now questionable because non-pathological T-cell clones can rarely be found in the peripheral blood of normal healthy volunteers.

Treatment. Often little treatment is needed. Emollients may help control the scaling, and a course of UVB phototherapy may result in temporary clearance of the lesions, but recurrence is invariable [5].

Large-plaque parapsoriasis

SYN. PARAKERATOSIS VARIEGATA; RETIFORM PARAPSORIASIS; ATROPHIC PARAPSORIASIS; POIKILODERMATOUS PARAPSORIASIS

Definition. A chronic condition characterized by the presence of fixed large atrophic erythematous plaques, usually on the trunk and occasionally on the limbs.

Clinical features. Patients present with persistent large yellow-orange atrophic patches and thin plaques on the trunk and limbs. Involvement of covered skin on the breast and buttock areas may suggest MF and in these cases patches and plaques may show striking polymorphism and poikiloderma with slow progression. Large series (129 cases followed for several years) have recorded the development of definite MF in 11% of cases [1].

Pathology [2,3]. There is frequently epidermal atrophy, and a lichenoid or interface reaction may also be seen at the dermal–epidermal junction. There is a band-like lymphocytic infiltrate in the papillary dermis, and there may also be free red cells present. The histology is not diagnostic for MF and most biopsies only show a mild dermatitis.

Immunophenotypic studies reveal a normal T-cell phenotype. TCR gene rearrangement studies have shown a clonal T-cell population in the skin in six of 12 patients, but progression to overt CTCL was only noted in one of the 12 patients [4].

Treatment. Topical emollients, UVB and PUVA are all helpful in offering symptomatic relief. Topical steroids should be used with caution because of the atrophic nature of the condition.

Actinic reticuloid [1,2]

Definition. This condition was first described by Ive *et al*. in 1969 [3]. The original description was of a group of elderly, exclusively male patients who developed a severe and very disabling photosensitivity involving reaction to light throughout the UVB, UVA and visible part of the spectrum. A number of these patients had a past history of contact dermatitis and a milder form of photosensitivity ('persistent light reactors'), but the true relationship between contact dermatitis, particularly to plants of the Compositae family [4], persistent light reactors (chronic actinic dermatitis) and actinic reticuloid is not yet established. The photosensitivity is very severe.

Clinical features. The clinical features are the symptoms of severe and persistent photosensitivity with erythema, oedema and striking 'leonine' thickening of the light-exposed skin of the face, neck and hands (Fig. 54.41) [5].

Patients with atopic dermatitis may be more likely to develop actinic reticuloid, and this should be considered in those with chronic atopic dermatitis who develop photosensitivity [6].

Pathology. The histological picture is that of an intense, superficial and deep lymphocytic infiltrate extending from the papillary dermis deep into the reticular dermis. Signs of actinic damage to collagen are present and some

Fig. 54.41 Actinic reticuloid showing marked infiltration of light-exposed skin of the face, with a striking change in skin texture at the collar area and normal skin on the area usually covered by clothing.

of the lymphocytic cells are large and atypical, hence the term 'reticuloid'. The majority of the lymphoid infiltrate consists of $CD8^+$ T cells.

TCR gene analysis does not show a clonal T-cell population [7], but the development of a T-cell clone has been reported in a single patient with a photosensitive dermatosis who developed MF [8]. One case has been reported of neutrophilic eccrine hidradenitis in actinic reticuloid [9].

Treatment. Treatment is based on light avoidance and the use of both the titanium dioxide-containing physical light barrier creams and the newer, more effective chemical UVA and UVB blockers. Low-dose systemic steroid therapy, ciclosporin, hydroxyurea [10] and azathioprine [11] may be effective in some patients.

The prognosis for recovery is poor and the majority of patients tend to have severe photosensitivity for the remainder of their lives.

Lymphocytoma cutis

SYN. SPIEGLER–FENDT SARCOID; LYMPHADENOSIS BENIGNA CUTIS OF BAFVERSTEDT

Definition. Lymphocytoma cutis is a benign cutaneous B-cell lymphoproliferative condition. It presents as nodules or plaques usually on the head and neck and pursues a chronic course [1–3].

Aetiology. This is at present unknown.

Clinical features. More cases are reported in females than males. Most patients show solitary or grouped asymptomatic erythematous or violaceous nodules or plaques, on the head, especially the ear lobes, and rarely the trunk or limbs (Fig. 54.42). Occasionally, they may have a translucent appearance. They are asymptomatic and not tender, painful or itchy. Lesions are often multiple and may be in all stages of development. They enlarge slowly and may reach a diameter of 3–5 cm. Associated sunlight sensitivity has been reported in some patients. Bafverstedt [4] has described an unusual form of lymphocytoma that presented as a solitary tumour of scrotal skin. Disseminated or miliary lymphocytoma cutis is also rare [5], and occurs in older patients on any body site.

Pathology [6,7]. The epidermis is usually unaffected and is often separated by a relatively acellular grenz zone from the dermis, which is replaced by a nodular dense infiltrate extending through the full thickness of the dermis. In classic cases, lymphocytes and histiocytes form a follicular arrangement resembling the appearance of a lymph node (Fig. 54.43). Mitotic figures may be visible in the cells of the follicles and occasional eosinophils may also be present. Appendages and blood vessels are spared. In some instances, there is no tendency for lymphoid follicle formation, although the histological appearance with normal

Fig. 54.42 Clinical presentation of a patient with lymphocytoma cutis.

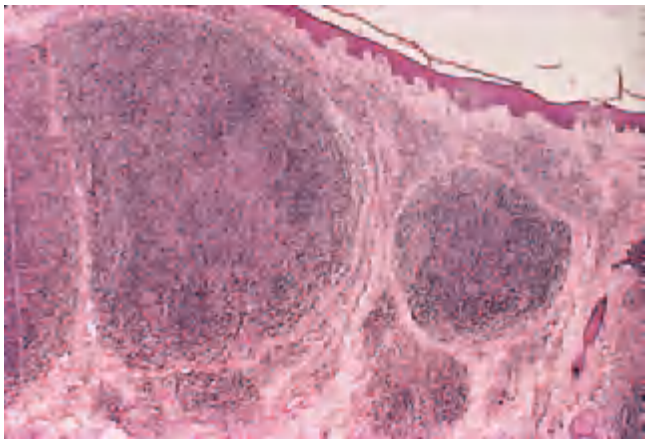

Fig. 54.43 Histology of Spiegler–Fendt sarcoid showing striking lymphoid follicles.

lymphocytes and histiocytes is otherwise similar. The histological differential diagnosis includes primary cutaneous lymphoma, particularly of marginal zone origin.

Immunopathology. The majority of lymphocytes in the dermis are B cells. Germinal centres are frequently seen in lymphocytoma cutis, and appropriate markers will confirm the morphological similarity of these structures to the germinal centres of lymph nodes. A cuff of reactive T cells may be seen around the periphery of the main B-cell aggregate.

Differential diagnosis. Histological examination should distinguish lymphocytoma cutis from granulomatous disorders including sarcoidosis, granuloma faciale and rosacea. Distinction from primary cutaneous B-cell marginal zone lymphoma (MZL) lymphoma is difficult, although the presence of atypical lymphoid cells would suggest a cutaneous MZL lymphoma. Insect bite reactions may also be impossible to distinguish with any confidence from lymphocytoma cutis.

Jessner's benign lymphocytic infiltration, tumid discoid lupus erythematosus (LE) and polymorphic light eruption can also cause difficulties. However, in Jessner's lymphocytic infiltrate, which characteristically waxes and wanes in severity, the dermal lymphocytic infiltrate is dominated by T cells. The presence of basal cell liquefaction degeneration and positive direct immunofluorescence helps distinguish LE.

Treatment. There is no treatment of proven value for lymphocytoma cutis. Penicillin and radiotherapy have been advocated in the past without adequate clinical trials. Intralesional steroids have also been advocated. Miliary lesions may partially respond to topical steroids. Hydroxycloroquine has also been effective.

Prognosis. Lymphocytoma cutis is a benign disorder in both localized and disseminated forms, although often running a very protracted course. Long-term follow-up of these patients suggests that a small proportion progress to cutaneous B-cell lymphoma and therefore the prognosis must be guarded [8–11].

Jessner's lymphocytic infiltrate [1]

Definition. A chronic benign T-cell lymphoproliferative disorder, usually of exposed skin.

Clinical features. Females are more often affected than males [2]. Both children [3,4] and familial cases [5,6] have been recorded. Benign lymphocytic infiltration of Jessner is characterized by the presence of red tumid nodules, usually on facial skin (Fig. 54.44). The lesions may involute spontaneously, but more commonly are persistent, and new lesions develop over time. There is variation in seasonal activity of the lesions, with winter exacerbations. The individual lesions are smooth raised non-scaling erythematous nodules or plaques and are commonly asymptomatic, although some patients complain of burning or pruritus.

Pathology [7–11]. Biopsies reveal a lymphocytic infiltrate predominantly in the lower dermis and concentrated tightly around blood vessels (Fig. 54.45). The epidermis and papillary dermis are relatively normal, and within the lymphocytic infiltrate there is no evidence of germinal centre or follicle formation. The great majority of these cells are $CD4^+$ T cells.

Fig. 54.44 Clinical appearance of a young woman with Jessner's lymphocytic infiltrate.

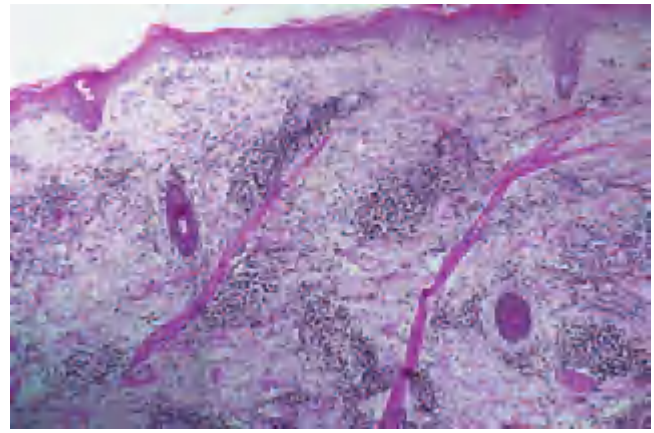

Fig. 54.45 Pathological pattern of Jessner's lymphocytic infiltrate. Note perivascular distribution and absence of epidermotropism.

Differential diagnosis. The clinical differential diagnosis includes a fixed drug eruption and cutaneous discoid LE. The lesions are usually more numerous than would be associated with a fixed drug eruption, although the histology is very similar. The individual lesions of Jessner's lymphocytic infiltrate are smooth and non-scarring, in contrast to the scaling atrophic scarring associated with chronic discoid LE. In addition, Jessner's lymphocytic infiltrate does not demonstrate a lupus band as seen at the dermal–epidermal junction in chronic discoid LE. However, there is a view that Jessner's lymphocytic infiltrate is a variant of LE.

Treatment. This is unsatisfactory, and lesions tend both to persist and to increase in numbers. There are individual case reports of successful therapy with topical steroids, systemic steroids, PUVA, radiotherapy, dapsone, hydroxychloroquine and gold [12].

Leukaemia cutis [1–3]

Diagnosis. The diagnosis of the specific type of leukaemia depends on detailed examination of the blood and bone marrow. The cutaneous infiltrate rarely indicates the type of leukaemia involved.

Specific cutaneous lesions occur more often in myelomonocytic leukaemia and T-cell prolymphocytic leukaemia than in other forms [4]. Specific lesions in the other forms of leukaemia are unusual as a presenting feature, and usually appear after the diagnosis has been established. There are a few cases where the diagnosis of leukaemia has been established first by analysis of the skin lesions [5]. These lesions usually consist of small reddish papules or nodules which may be fleeting or persistent. Clinically, they may resemble lesions of Sweet's syndrome, sarcoidosis, panniculitis, other granulomas or cutaneous lymphoma (Fig. 54.46). Ulceration, especially around the ankles, simulating gravitational ulceration, is seen most often in chronic lymphatic leukaemia and may represent the development of a leukaemic deposit in an area of low resistance.

Fig. 54.46 Specific deposits in a child with leukaemia. Note two large nodular lesions on the back.

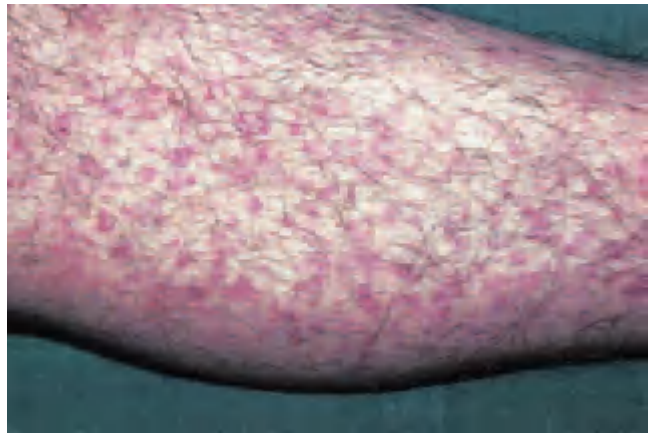

Fig. 54.47 Purpuric lesions in an adult patient with myelocytic leukaemia.

Although 'non-specific' lesions are said to be common, they are rarely reported by dermatologists. Generalized pruritus may be a presenting symptom and prurigo-like papules develop in some cases. Erythroderma has been recorded in association with an underlying T-cell leukaemia such as T-cell prolymphocytic leukaemia which must be distinguished from Sézary syndrome. There is usually marked exfoliation and the skin may be markedly thickened, especially over the face. The histological features in the skin may or may not be diagnostic.

Disseminated or unusually severe herpes zoster is common in association with all types of malignant disease. Specific infiltrations into herpetic scars may occur and bullous lesions have been recorded [6]. In multiple myeloma, both generalized and local amyloidosis is common. Anhidrosis has been recorded. Patients with myelomatosis may subsequently develop variants of acute myelogenous leukaemia [7,8] and it has been suggested that this complication is the result of treating the underlying disease with irradiation or alkylating agents [9].

Three cases of a perniotic syndrome associated with monocytosis and neutropenia have been described as a possible association with a preleukaemic state [10]. Sweet's disease and bullous pyoderma have also been associated with leukaemia (see Chapter 61).

Thrombocytopenic purpura is a characteristic symptom of the acute leukaemias and may occur on skin or mucous membranes, often as the presenting symptom (Fig. 54.47).

Beek [9] recorded 289 cases of lymphatic leukaemia with skin lesions and, in these, tumours were present in 50%, the head being the most common site. Erythroderma was present in 25%, herpes zoster in 26%, prurigo-like papules in 21%, bullae in 10%, varicelliform eruptions and urticaria in 3%. Haemorrhagic gangrene of the skin has also been recorded. The usual age at presentation of patients with lymphatic leukaemia is 45–54 years, but those

with cutaneous lesions tend to be older. Skin lesions in myelogenous leukaemia are much less frequent, with only 72 recorded cases. When the skin is involved the prognosis is poor.

A relatively specific picture is observed in a number of patients with chronic T-cell lymphatic leukaemia [6]. These patients are frequently elderly males and may present with diffuse generalized erythroderma, splenomegaly and lymphadenopathy. This may be caused by lymphokine release by the malignant T cells during their passage through the dermal vasculature, as skin biopsy of these lesions does not reveal a specific cutaneous infiltrate, or epidermotropism characteristic of MF.

Diagnosis. Diagnosis of all these conditions is based on pathological examination of material from blood, bone marrow, lymph nodes and skin [8,11–13].

Treatment. The treatment for leukaemia cutis is management of the underlying disease, with symptomatic measures for the skin lesions when required. Superficial radiotherapy may be useful, giving rapid symptomatic relief, and regression of specific cutaneous deposits.

Cutaneous Hodgkin's disease

The existence of a variant of Hodgkin's disease that begins in the skin is still debated, and it can be difficult if not impossible to differentiate from Hodgkin's disease beginning in the nodes, which spreads at an early stage to the skin [1–5]. Invariably, cutaneous Hodgkin's disease only occurs as direct extension from an underlying involved regional lymph node. Thus, careful clinical examination, followed if appropriate by node biopsy and CT scans, should be performed before a diagnosis of primary cutaneous Hodgkin's disease is made. In view of the cytological similarity between the cells of lymphomatoid papulosis and those of Hodgkin's disease, this differential diagnosis must be carefully considered and positively excluded.

Clinical features. One review of 1810 cases of Hodgkin's disease reports only nine (0.5%) with specific cutaneous lesions [6] but a more recent study records involvement in 16 of 465 cases (3.4%) [7]. They usually consist of small nodules, but ulcerative lesions have been recorded and rarely are the presenting symptom. There have been a number of reports of the first lesions appearing on the scalp.

Pathology [1,2,8]. To consider the diagnosis of Hodgkin's disease either involving the skin as a secondary process, or originating in the skin, the cutaneous infiltrate should consist of nodules of atypical lymphoid and histiocytic cells, including the presence of Reed–Sternberg cells that are $CD30^+$ and lymphoid cells that are $CD15^+$ [9–11]. CD15 positivity is not seen in lymphomatoid papulosis.

Cutaneous signs associated with Hodgkin's disease [5,12] are as follows:

Non-specific lesions. These are very common and occur in 3–50% of cases. These include pigmentation, pruritus, prurigo, atrophy, alopecia, exfoliative dermatitis and herpes zoster.

Pigmentation. This is melanin pigmentation and is very common. It resembles the pigmentation of Addison's disease, being most marked in areas that normally show some darkening such as the axillae, groins and around the nipples. Less often it is more widespread, and occasionally a bizarre pigmentation occurs. The mucous membranes are usually spared.

Pruritus. This often occurs together with pigmentation. Pruritus is not infrequently the presenting feature of the disease, and may precede the presence of palpable nodes by months or years. It tends to start on the legs. It is especially severe in patients who show other general symptoms such as fever and weight loss. Both pigmentation and pruritus occur in association with enlarged mediastinal or retroperitoneal glands, the presence of which should always be suspected when itching is severe.

Prurigo. This is a development from pruritus. In addition

to the widespread irritation, there are excessively itchy papules, which are scratched until the skin surface is removed and is replaced by a blood crust. The papules and crusts are usually found on the trunk. When present in association with enlarged superficial glands, this forms a very characteristic picture, often called *Hodgkin's prurigo*.

Ichthyosiform atrophy. An acquired ichthyosis occurring in the course of a chronic wasting disease is fairly common. Hodgkin's disease is probably the most common condition to be associated with this change. It usually starts on the legs and may remain restricted, but in severe cases progresses until it becomes universal. It resembles ichthyosis vulgaris, with thin, dry and rather firmly attached scales. It is not static and may regress for a time, only to return later. Red streaks are often visible between the scales. The patient is usually wasted and severely ill. Malabsorption from the gut may occur in some cases and contribute to this problem.

Alopecia. Hair loss is common in Hodgkin's disease. It can be caused by rubbing or scratching to relieve itching. It may also be part of the ichthyosiform atrophy or be caused by endocrine dysfunction, when specific infiltration occurs in organs such as the pituitary or adrenal. Rarely, it may be brought about by specific infiltration in the scalp.

Exfoliative dermatitis. Erythroderma and exfoliative dermatitis have been recorded as occurring in Hodgkin's disease on many occasions [4]. Most recorded cases would probably be more correctly included under ichthyosiform atrophy.

Herpes zoster. Herpes zoster is common in the course of Hodgkin's disease, but disseminated zoster is much less likely to occur in Hodgkin's disease than in chronic lymphatic leukaemia.

Miscellaneous conditions. Many other non-specific skin lesions have been described in association with Hodgkin's disease, but they are probably incidental. Erythema nodosum is seen occasionally and is apparently caused by the disease itself; in these cases, differentiation from sarcoidosis may be difficult, but the Kveim test or node biopsy should establish the diagnosis.

Lennert's lymphoma

Definition. A rare variant of systemic lymphoma with a characteristic histology, first described in 1968 as a variant of Hodgkin's disease [1].

Clinical features. Most patients have lymphadenopathy, fever, fatigue and weight loss. The skin is involved very rarely as a secondary event and this usually consists of clinically non-specific papules or nodules [2]. One patient presented with chronic cutaneous infection and pyoderma [3], and another simulating atypical granuloma annulare [4].

Pathology. The characteristic pattern is an infiltrate with a high content of epithelioid histiocytes, admixed with $CD4^+$ cells. If the skin is involved, there may be a subcutaneous infiltrate consisting of epithelioid histiocytes and T cells. Reed–Sternberg cells are rare [2,3].

Chapter 55

Subcutaneous Fat

M.M. Black & W.J. Cunliffe

Introduction

Subcutaneous fat (subcutis) occurs almost universally over the body surface between the skin and the deep fascia, but it is absent from the eyelids and the male genitalia. It varies in thickness with the race, age, sex, endocrine and nutritional status of the individual.

Subcutaneous fat acts as an insulating layer and a protective cushion, and also has an important role in thermogenesis, and as a store of readily available energy. In a normal person, fat constitutes about 10% of body weight, and provides about 40 days' reserve energy [1]. Brown fat has a very important thermoregulatory role and acts by increasing the basal metabolic rate [2]. This is particularly important in infancy, and heat production in response to cold exposure is maximal in neonates, who have large quantities of brown fat.

Fat also provides support and has a cosmetic function, for example in the contours of the face. It also has great social importance. Fat children may be bullied or ostracized at school [3], fat adults may find it harder to get certain jobs, and the contribution of fat to the shape of the breasts and buttocks as a secondary sexual development in the female has been known to influence social behaviour.

Embryology. The first fat-containing cell, the lipoblast, appears in the mesenchyme around the 14th week of fetal life. This cell matures to form the large unilocular lipocyte, the characteristic cell of adult fat. The primitive mesenchymal cell that forms the lipoblast is also capable of maturing to form a fibrocyte, a myocyte, a chondrocyte or an osteoblast. The distinction between adipocytes and fibroblasts is not always clear, and 'pre-adipocytes', which do not contain enough fat to be counted as fat cells by standard techniques, have been described [4].

Brown fat is a special type of granular fat that differs from white fat in its distribution, histology and function. It is multilocular and is metabolically very active, with many mitochondria, so that it is capable of producing heat. It is most prominent in the neck and upper thorax of the fetus, and it may be homologous to the hibernating gland fat found in some animals [5]. Brown fat is now known to persist into adult life [6], and it may have a role in preventing obesity [6]. Warm patches develop in the skin 1 h after taking ephedrine orally, and these warm patches may indicate the site of thermogenic brown fat.

Histology. The fat cells (lipocytes) form a specialized part of the reticuloendothelial system, which is capable of fat synthesis as well as fat storage. They are the largest connective tissue cells in the body, with a diameter of up to 100 μm. The mature fat cell has a characteristic signet-ring appearance, because the flat oval nucleus is displaced to the side by a single large intracellular vacuole, which contains fat. Groups of lipocytes are arranged in lobules, which are separated by interlobular septa composed of collagen and reticulin fibres. Fat tissue has an abundant blood supply, each individual lobule being supplied by an arteriole that runs along the septa, before breaking up to form capillaries which come into close apposition with the individual fat cells. The subcutaneous fat also contains a

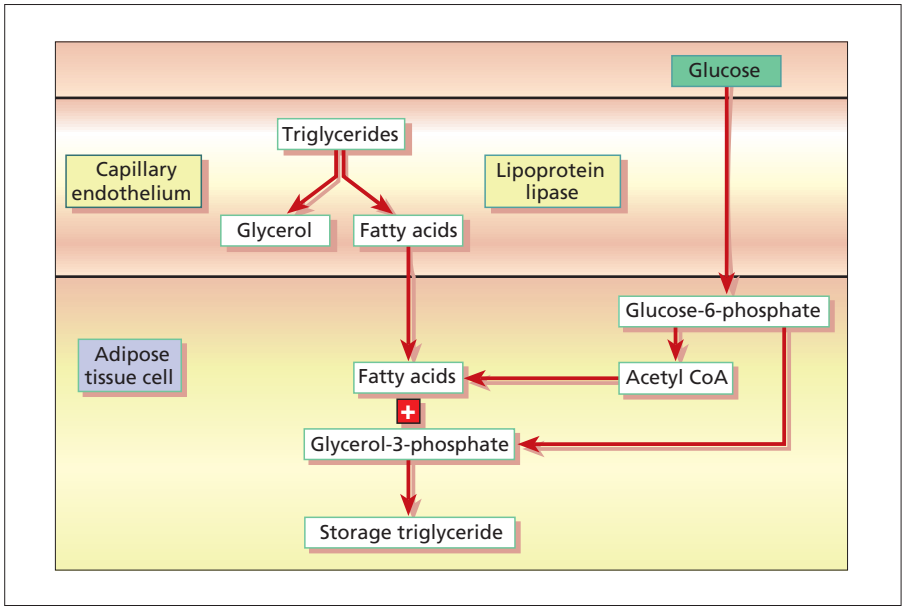

Fig. 55.1 The metabolic pathways related to adipose tissue.

rich lymphatic plexus, which receives vessels from the dermis. These lymph vessels traverse the subcutaneous layer parallel to the skin surface for some distance, before eventually penetrating the deep fascia and draining into the regional lymph nodes.

The nature of the lipocyte and its relationship to blood vessels and lymphatics has been reviewed in detail by Ryan and Curri [7].

The fat tissue and the fat organ. The fat tissue is composed of lobules of fat cells with their supporting connective tissue, blood and lymph vessels, and reticuloendothelial cells. In addition to forming subcutaneous fat, fat tissue occurs in the mediastinal and retroperitoneal tissues, the mesentery and the bone marrow. This tissue, although it is widely scattered throughout the body, forms a true organ as regards both structure and function [1]. The thickest subcutaneous fat deposits are found over large muscles such as the gluteal muscles, and the blood supply in these areas comes mainly from the underlying muscle.

Physiology [8,9]. The synthesis and catabolism of fat in the subcutaneous depot depends on many factors, including nourishment, endocrine and nervous activity. The role of the autonomic nervous system in regulating fat metabolism is now well established [10].

Hormones that may affect the metabolism of fat cells include insulin, cortisol, norepinephrine (noradrenaline) and several pituitary hormones, including somatotrophin, adrenocorticotrophic hormone (ACTH) thyrotrophin and lipotrophin.

The fats contained within the lipocytes are predominantly triglycerides, especially those of palmitic and stearic acids and the unsaturated oleic acid. All the fatty acids have an even number of carbon atoms, predominantly C16 and C18, with a few C14 and C12. Adipose tissue contains 10–30% of water with a small proportion of lipochromes, and less than 2% cholesterol. Fat-soluble substances are also present in varying amounts. These include fat-soluble vitamins and traces of chlorinated hydrocarbons (e.g. aldrin, dieldrin) ingested with the diet, as well as drugs such as acitretin. Adipose tissue *in vitro* has a metabolic rate similar to that of kidney tissue, and approximately half that of liver. Approximately half the triglyceride in the adipose tissue of rats and mice is catabolized and reconstituted in the course of a week or so.

The fat for storage enters the lipocyte as fatty acids, which combine with coenzyme A, using the energy of adenosine triphosphate (ATP), to form the corresponding acyl coenzyme A compounds. Some of these are then oxidized to provide energy for the regeneration of ATP, but most are converted to triglyceride by combination with glycerol-3-phosphate derived from glucose. Figure 55.1 shows the metabolic pathways related to adipose cells. When triglyceride is to be oxidized in the body for the provision of energy, it is converted to non-esterified fatty acids (NEFA) and conveyed in the blood to tissues such as liver and muscle, in which fatty acid oxidation readily takes place. In both tissues, the essential part of the process consists of the oxidation in the mitochondria of the long-chain fatty acids. The glycerol of the triglyceride molecule reacts with ATP to form glycerol phosphate, which is oxidized to glyceraldehyde-3-phosphate. This in turn may either be converted to glycogen by reversal of glycolysis, or it may be converted to pyruvate. Skeletal muscle readily oxidizes fatty acids but glucose, if available, is preferentially used. In cardiac muscle, fatty acids are a major source of energy.

Obesity

Obesity is a condition in which there is excessive fat in the body. It is a disease that is often neglected—indeed, frequently it is not even thought of as a disease but more as a self-inflicted condition, easily prevented and cured by self-control and determination. Unfortunately, this is not just the opinion of lay people but also of doctors. In truth, obesity is a worldwide epidemic. Obesity is given low priority as a medical illness. One reason for some negative attitudes is that, although a positive energy balance, which is the pathogenesis of obesity, should be easy to correct, in practice it is not. Most physicians know this from their own clinical experience—so why spend time and energy? Yet to be obese, or even slightly overweight, is these days totally unfashionable, especially among young women, and obese people may be insulted and bullied [1].

Obesity has been defined as a body mass index (BMI: body weight in kilograms divided by height in metres) above 30 kg/m^2. For example, to be considered as obese, a man whose height is 180 cm must weigh more than 100 kg and a woman of 160 cm more than 75 kg. With this cut-off, the prevalence of obesity in much of Europe is 15–20% of the middle-aged population. This means that countries such as the UK, France and Germany each have 5–10 million inhabitants who are obese and need treatment. A medical problem of this size is probably beyond the capacity of even the best health care system [1]. There has been a dramatic increase in obesity between the 1980s and 1990s in contrast to between the 1960s and early 1980s when the prevalence of obesity changed but little [2].

Obesity is accompanied by complications such as hypertension, non-insulin-dependent diabetes mellitus and atherosclerosis, which in turn cause ischaemic heart disease, stroke and premature death [2–4]. Other complications include certain malignancies such as prostate cancer, sleep apnoea, osteoarthritis and depression.

The alarming increase in diabetes is most probably a consequence of the current rapid rise in the prevalence of obesity. For example, in the UK, average body weight has risen by about 1 kg during the past decade.

Developing countries in other parts of the world are now seeing serious increases in obesity, for example in the Caribbean, South America and South-East Asia [5,6], while in Australian Aborigines and Polynesia figures approaching 80% have been recorded.

Obesity in children is of a special significance, because many obese children remain obese as adults. Observations indicate that the prevalence of childhood obesity is high where adult obesity is common [7,8].

Although precise methods for measuring the distribution of body fat, such as computed tomography (CT) and magnetic resonance imaging (MRI), are available, simpler measurements are required for clinical practice. Waist circumference divided by hip circumference (WHR) can be used for this purpose. The waist is measured, after an overnight fast, halfway between the lower costal margin and the iliac crest, and hip circumference is measured over the widest part of the gluteal region [9]. WHR should not exceed 1.0 in men and 0.85 in women—cut-offs based on Scandinavian data [10]. Waist circumference is another reasonable way of assessing obesity. Circumference values that indicate a significant increased relative risk are more than 88 cm for women and more than 102 cm for men [10].

Measurement of skinfold thickness with callipers is another alternative technique, but there are possible variations in the distribution of fat between subcutaneous areas and deep body fat. The typical female fat distribution (gynoid or 'pear-shape') over the hips, thighs and buttocks is related to energy needs during lactation, and is more healthy than the excess fat that accumulates over the upper trunk and abdomen in the male or android distribution [11–13].

Aetiology. Obesity is the result of genetic, behavioural, environmental, physiological, social and cultural factors that cause energy imbalance and promote excessive fat deposition. Although genes have an important role in the regulation of body weight, the World Health Organization consultation on obesity [6] concluded that behavioural and environmental factors, such as sedentary lifestyles combined with excessive energy intake, are primarily responsible for the dramatic increase in obesity in the last 10–20 years. The precise underlying mechanisms behind imbalance in energy intake and energy expenditure that lead to obesity are still controversial. Obesity is the result of a positive energy balance input that exceeds output. In most populations, obesity is more common among women than men and is a multifactorial phenotype, which may result from a complex network of

genetic and non-genetic factors. The relative importance of genetic factors for obesity is under debate [6,14]. Genome searches, using polymorphic markers in inbred mice with phenotypes that result in extreme obesity, and studies of human candidate genes, are being performed in an attempt to identify genes that contribute to obesity [15,16]. There is evidence that body weight is physiologically regulated [6,17,18], and it has been postulated that the storage of fat may provide signals to the brain that the body is obese, which in turn may make the subject eat less and burn more fuel [19]. One of the molecules that may be involved in such signalling is the obese (*ob*) gene product—leptin [20,21]. Mutations in *ob* result in profound obesity and type II diabetes in mice. The mouse *ob* gene and its human homologue have been cloned and sequenced [22]. The gene is expressed in adipose tissue and the product has features of a secreted protein.

Plasma leptin was found to be highly correlated with BMI [22] in rodents and in 87 lean and obese humans. In humans, there was variability in plasma leptin at each BMI, suggesting that there are differences in its secretion rate from fat. Weight loss because of food restriction was associated with a decrease in plasma leptin in samples from mice and obese humans.

One of the main effects of leptin may be to inhibit synthesis and release of the hypothalamic neuropeptide Y, which increases food intake, decreases thermogenesis and increases levels of insulin and corticosteroid in the plasma [23]. A particularly important effect may be to suppress ingestion of fat without affecting carbohydrate ingestion [23].

In aggregate, these data are consistent with the hypothesis that the size of the adipose tissue mass is in part regulated by a negative-feedback loop in which the level of leptin is a sensed parameter (Fig. 55.2) [24,25].

However, a word of caution on the *ob* gene story is necessary. The investigation of large numbers of obese individuals for abnormalities in the genes for both leptin production [26] and leptin receptors suggests that a genetically faulty system is rare. The raised concentrations of circulating leptin found in obesity are probably a consequence of an enlargement of the producing tissue, adipose tissue. Leptin may therefore be of limited interest for the pathogenesis of obesity in humans, and this may turn out to be true for other genes that are important for obesity in genetically obese animal models. This should not, however, diminish the importance of these discoveries for our understanding of the physiological regulation of energy balance, and they might even open up the study of the regulatory events that occur as a consequence of the leptin signal to the hypothalamus [1].

Genotype–environmental interreactions also have been implicated in the development of obesity [27]. Bouchard *et al*. [28] demonstrated that the amount of body weight and fat gained, as well as the distribution of fat gained in response to overfeeding, had greater similarity within identical twin pairs, further supporting the heritability of the tendency to become overweight or obese.

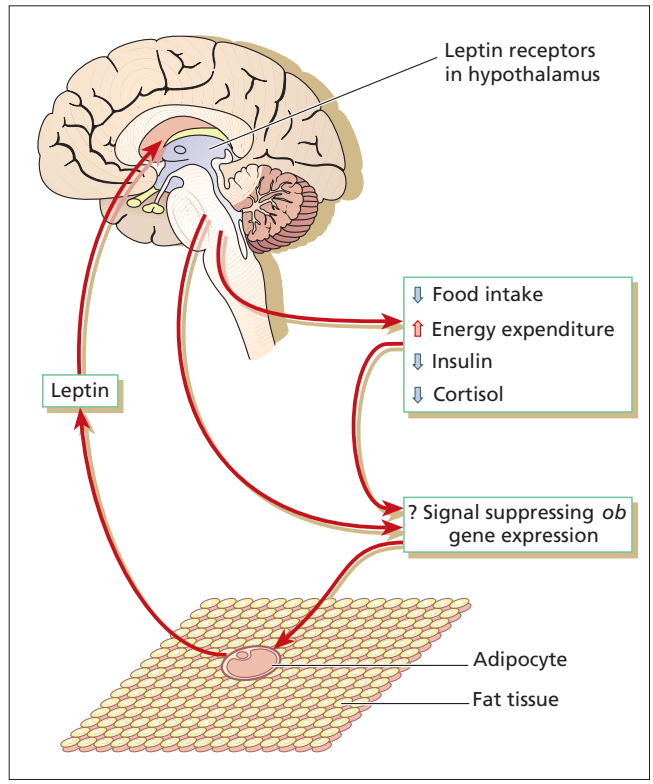

Fig. 55.2 Neurohormonal control of adipose tissue.

In accordance with the first law of thermodynamics (energy cannot be created or destroyed), excess energy is stored as tricyglcerols in adipose tissue. The primary functions of adipocytes are to store energy when calories are in excess, and to mobilize energy from this fatty source when energy needs exceed intake [29]. Weight gain during adulthood is characterized predominantly by adipocyte hypertrophy, a process by which adipocytes can increase their volume some several thousand-fold to accommodate large increases in fat.

Prevention and treatment. The aim of obesity treatment is to achieve and then maintain clinically meaningful weight loss, with the ultimate aim of reducing the risk for or severity of obesity-related diseases. Measures directed at improving public health awareness should be given high priority in national efforts; they include information campaigns, making exercise-sparing devices such as escalators less readily available, and establishing bicycle and walking lanes in cities. Despite an increased focus on nutrition, an increased awareness of the energy and fat content of foods, and the availability of various reduced-fat, fat-free and sugar-free food and beverages, obesity continues to increase [30].

Effective therapeutic regimens for treating obesity should incorporate multiple approaches to encourage behavioural change or modification and create strategies to facilitate consistent and long-term follow-through [30]. Numerous options are available [31,32], including reduced-energy diets, physical activity and exercise, behavioural modification, pharmacotherapy and surgery.

The principle for treatment, self-evidently, is to induce a negative energy balance. Short-term weight loss is easy, but long-term weight maintenance after that is unusual [30,33]. Powerful but insufficiently understood regulatory factors strive to induce regain of the weight lost. The body weight itself is often not the most important problem, unless it is affecting mobility. It is the morbidity associated with the metabolic complications that is of major concern, and this can improve rapidly even after a limited loss of weight. A normal body weight is not necessary, and is often unrealistic in the long term.

Reduced energy intake must be individually tailored to allow normal activities. A deficit of 500–600 kcal (0.210–0.251 mJ) per day is usually well tolerated. Emphasis should be placed on fat intake and on the energy density of food. Involvement of family is important [34]. A combination of exercise and diet is more effective than either alone [33], and long-term low-intensity exercise such as walking is as effective as high-intensity activities [35]. This is important because most obese patients are unaccustomed to sporting activities and will drop out of vigorous regimens.

Behaviour modification is an important component of all weight loss programmes [36,37]. Frequently, behavioural strategies are targeted toward identifying stimuli that signal unhealthy behaviours such as binge eating, learning about the role of readiness in initiating or continuing positive behaviours [38], and recognizing barriers that may compromise healthy pursuits.

Pharmacological agents may be used in conjunction with diet, exercise and behavioural strategies when non-pharmacological approaches have failed to produce a success. Several appetite-suppressant drugs are approved for weight loss and the reader is referred to authoritative sources on the subject [30].

Surgery is reserved for cases of extreme obesity (BMI over 40 kg/m^2). One of the most common procedures is gastric bypass surgery.

An excellent review on the aetiology prevalence and treatment of obesity is by Racette *et al*. [30].

Cellulite

Cellulite is an alteration of the topography of the skin that occurs mainly in women in the pelvic region, the limbs and abdomen. It is characterized by a padded or orange peel appearance.

Many authors confuse cellulite with obesity. However this is incorrect; in obesity only adipocyte hypertrophy and hyperplasia occurs [1], whereas in cellulite there are several structural alterations in the dermis, in the local microcirculation and within the adipocytes. These may result in further morphological, histochemical and biochemical modifications [2–5].

Cellulite may be classified in at least two ways. One classification divides cellulite into four stages according to the histopathological and clinical changes [1].

Grade 1. The patient has no symptoms and there are no clinical alterations. Histologically, there may be an increased thickness of the areolar layer, increased capillary permeability and microhaemorrhages.

Grade 2. There are no obvious changes in the skin at rest, but after skin compression or muscular contraction small dimples, local pallor, decreased temperature and decreased elasticity may be evident.

Grade 3. A padded skin or an orange peel appearance is evident at rest, and there is a slight feeling of granularity in the deeper parts of the skin on palpation, which may be associated with some pain. At this stage, there is the beginning histologically of fatty tissue destruction and the formation of micronodules.

Grade 4. This stage is characterized by changes seen in grade 3 but with more visible palpable and painful nodules and an obvious wavy appearance of the skin surface. Histopathologically, the lobular structure of the fatty tissue has disappeared and some nodules are encapsulated by dense connective tissue and there may be much fibrosis.

Cellulite may also be classified by the consistency of the skin—being hard, flaccid, oedematous or mixed [6]. Hard cellulite is observed in young women who perform regular physical activity. The appearance is of compact firm tissues and is not changed according to position. Flaccid cellulite is characteristically found in inactive women, especially if they have suddenly lost weight. In contrast, oedematous cellulite presents as an increased volume of the entire affected limb, and is associated with depression of the tissue to fingertip palpation, which persists when the finger is removed.

Aetiology. Just what precisely triggers the histopathological and clinical changes of cellulite is poorly understood. Hormonal factors may play a predisposing or aggravating part. Oestrogen is probably the most important hormone. Evidence for oestrogen involvement includes the fact that cellulite predominantly occurs in females, the onset of the disease after puberty, aggravation of the condition during pregnancy, menstruation and with oestrogen therapy [7].

A genetic predisposition may also be important. White women tend to be more prone to cellulite than Asian or black women and Latin women develop cellulite on the hips while Anglo-Saxon women develop cellulite on the abdomen.

Sedentary lifestyle contributes to the aggravation of cellulite as a consequence of a decrease in muscle mass, and the consequent decreased muscular pumping mechanism in the lower limbs inhibiting venous return. Obesity contributes to the problem by increasing the fatty mass. Factors that act as a mechanical barrier to the venous return are also likely to be important: tight clothes and pregnancy may be important in this context.

Treatment. Because of the multifactorial pathogenesis of cellulite, there are numerous therapeutic approaches—especially because many of the treatments are much less than optimal in their success. Treatments include reduction in aggravating factors, the use of physical and mechanical methods, and pharmacological agents.

Attempts to reduce weight, regular exercise and the use of non-hormonal contraceptives need to be encouraged. Physical therapies include ultrasound, thermotherapy, pressotherapy and lymphatic drainage. Several pharmacological agents have been tried, but adequate double-blind placebo-controlled studies are relatively lacking. The reader is referred to specialized texts on this topic [7]. A number of products for systemic and topical use have been developed but most have little scientific basis.

General pathology of adipose tissue: panniculitis [1–11]

Inflammatory disorders of the subcutaneous fat present an important diagnostic challenge to the dermatologist, because the lesions often develop as subcutaneous nodules or plaques. An adequate diagnostic biopsy is essential as a prerequisite to accurate diagnosis in almost all instances. A larger scalpel incisional biopsy is preferred, which obviously should extend deeply through the subcutis. Conventional punch biopsies (4 mm or smaller) are totally inadequate, as the tissue tapers down to leave little, if any, subcutaneous tissue. However, trephine punches are adequate and provide acceptable cosmetic results [10]. The pathologist may well need to cut serial sections, as some of the panniculitides are characterized by rather focal or even scattered pathological changes, and to look for evidence of damage to larger blood vessels.

Most panniculitides are persistent, lasting for weeks or months. For diagnostic purposes, the biopsy should be taken from an active earlier lesion: erythematous, indurated and usually tender. Although subcutaneous tissue has a rich capillary blood supply closely applied to fat cells, there are no lymphatics and very little intervening connective tissue [11]. Furthermore, the vasculature in the subcutis area is slow flowing. This renders the subcutaneous fat vulnerable to a variety of noxious insults [9]; for example, cold injury or enzymatic damage.

The sequence of cellular events following injury to the subcutis may take weeks or months to fully evolve, and is usually as follows [1,2]:

Neutrophils (eosinophils)
↓
Lymphocytes
↓
Histiocytes (granulomatous 'foamy macrophages')
↓
Fibroblasts (fibrosis)

The histological changes of the granulomatous stage are not necessarily diagnostic. When fat cells are damaged, the liberated lipid undergoes hydrolysis to glycerol and fatty acids, which usually provoke a foreign-body-type granulomatous reaction. Macrophages are attracted and foam cells are produced. After the phase of reaction to released lipocyte products, there is a period of reconstitution, the ease of repair depending on the extent of the initial lipocyte damage and the efficiency of the local circulation.

Atrophy of subcutaneous tissue (lipoatrophy) is a consequence of some types of inflammation in the fat lobules. In other instances, extensive fibrosis is inevitable after damage to subcutis, resulting in the formation of chronic subcutaneous fibrotic nodules.

In certain types of panniculitis, an ongoing slow chain reaction is set up, in which small foci of fat necrosis provoke a peripheral inflammatory reaction, which in itself leads to further peripheral fat necrosis, thus allowing the lesion to spread centrifugally. It is therefore clear that the histological findings will differ, depending on the age of the lesion biopsied.

In difficult cases of panniculitis, the author (MMB) recommends that it may well be helpful to submit more than one biopsy from lesions at different stages of their clinical evolution. Polarization of sections should be routinely performed to look for crystalline material, and in certain clinical situations extra tissue should be submitted for bacterial or fungal culture.

Classification of panniculitis [1–4]

1 Septal panniculitis:
- (a) erythema nodosum (see Chapter 49)
- (b) erythema nodosum migrans (see Chapter 49); (subacute nodular migratory paniniculitis)
- (c) eosinophilic panniculitis (this condition may overlap with lobular or mixed panniculitis)

2 Lobular panniculitis:
- (a) relapsing febrile nodular panniculitis (Weber–Christian syndrome)
- (b) idiopathic nodular panniculitis
- (c) lipoatrophic panniculitis (formerly Rothman–Makai syndrome)
- (d) panniculitis associated with crystal deposition—sclerema neonatorum (see Chapter 14), subcutaneous fat necrosis of newborn (see Chapter 14), gout or factitial panniculitis, poststeroid panniculitis
- (e) enzymic (pancreatic) panniculitis
- (f) α_1-antitrypsin deficiency panniculitis
- (g) fat necrosis—cold injury, nodular cystic fat necrosis, lipomembranous
- (h) lymphomatous panniculitis
- (i) cytophagic histiocytic panniculitis

3 Mixed panniculitis:
- (a) lupus erythematous profundus
- (b) scleroderma (fasciitis with eosinophilia)
- (c) connective-tissue panniculitis (overlaps with lipoatrophic panniculitis)
- (d) subcutaneous sarcoidosis (see Chapter 58)
- (e) subcutaneous granuloma annulare (see Chapter 57)
- (f) necrobiosis lipoidica (see Chapter 57)
- (g) infective panniculitis (e.g. opportunistic bacterial or fungal infections)
- (h) physical and factitious panniculitis (e.g. sclerosing lipogranuloma, oil granuloma)
- (i) sclerosing panniculitis (lipodermatosclerosis)
- (j) fasciitis—panniculitis syndrome

4 Panniculitis with vasculitis (see Chapter 49):
- (a) small-vessel vasculitis—leukocytoclastic vasculitis
- (b) large-vessel vasculitis—polyarteritis nodosa, thrombophlebitis, nodular vasculitis (erythema induratum)

(c) neutrophilic panniculitis
(d) oedematous scarring vasculitic panniculitis.

Inflammatory disorders of subcutaneous fat

Septal panniculitis

Erythema nodosum (see Chapter 49)

Although erythema nodosum is the prototype of a septal panniculitis, the inflammatory changes always involve the overlying dermis. In acute lesions, there is oedema of the septae with transudation of neutrophils, and sometimes eosinophils, into the septae and adjacent margin of fat lobules. In older lesions, the infiltrate becomes lymphohistiocytic and finally granulomatous, before the septae became thickened and finally fibrotic. Radial granulomas (Miescher) are often found in the interlobular septae in erythema nodosum [1]. There is still some debate as to whether *erythema nodosum migrans* (subacute nodular migratory panniculitis) [2–4] and the chronic and granulomatous forms of erythema nodosum [5] are variants of the same pathological process. Erythema nodosum migrans tends to be characterized by markedly thickened and fibrotic septae, marked capillary proliferation and a massive granulomatous reaction (with giant cells) along the borders of the widened septae [6].

Eosinophilic panniculitis

Eosinophilic panniculitis is characterized by a prominent infiltration of subcutaneous fat with eosinophils, and has been identified in patients presenting with a variety of associated clinical conditions [7–14].

The inflammatory infiltrate, including eosinophils, occurs principally within the septae but can involve the lobules. The overlying dermis is often involved, closely resembling eosinophilic cellulitis (Wells' syndrome) [9]. Fragmented eosinophilic granules (flame figures) are occasionally seen (Fig. 55.3). The current view of eosinophilic panniculitis is that it is not a disease entity, but it can be principally considered as a reactive process, often associated with a systemic condition [8].

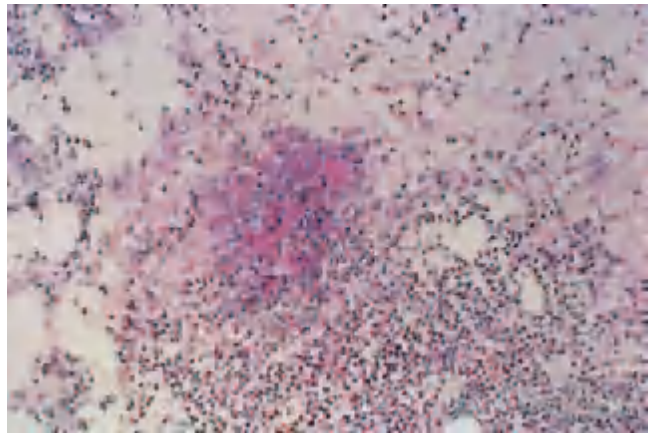

Fig. 55.3 Eosinophilic panniculitis. H&E, × 40.

More common causes of eosinophilic panniculitis include arthropod bites, atopic eczema, erythema nodosum, infectious causes (*Gnathostoma*, *Streptococcus*, *Toxocara*) and leukocytoclastic vasculitis [8]. The condition has also been associated with chronic recurrent parotitis [11], lupus panniculitis, morphoea profundus [12] and fasciola hepatica infection [13]. Fortunately, only very rarely is eosinophilic panniculitis associated with malignancy, either leukaemia [14] or a solid tumour [9].

Lobular panniculitis

Relapsing febrile nodular panniculitis

SYN. WEBER–CHRISTIAN SYNDROME

Relapsing febrile nodular panniculitis was first described by Pfeifer in 1892 [1]. The term Weber–Christian syndrome came to be used following the cases reported by Weber [2] and Christian [3]. Weber–Christian syndrome encompasses a febrile disease, characterized by the recurrent formation of single or multiple crops of tender inflammatory nodules in the subcutaneous fat. Because the range of clinical features differed, and the extent of systemic involvement varied, the concept of Weber–Christian syndrome never became popular and the view was put forward that it should not be considered to be a distinct entity [4–6]. The term nodular panniculitis was preferred [5]. Nodular panniculitis is essentially a lobular panniculitis in which fat necrosis develops in the absence of overt vasculitis.

Macrophages ingest fat released from damaged lipocytes, thus producing a characteristic foamy appearance. In some cases, liquefactive nodules appear, which ulcerate and discharge an oily yellow liquid [7]. In others, there is more systemic involvement, which may affect visceral fat or even the myocardium [8].

Nodular panniculitis can affect both adults and children, when it can occur in early infancy [9,10]. However, it must be stressed that nodular panniculitis or Weber–Christian syndrome may not be a distinct disease entity. On further investigation, many cases of nodular panniculitis can be subsequently reclassified depending on their cause; for example, pancreatic panniculitis, α_1-antitrypsin deficiency or cytophagic panniculitis. However, there are undoubtedly some cases of nodular panniculitis, in both children and adults, in which the aetiology remains to be determined.

Idiopathic nodular panniculitis

An idiopathic condition characterized by recurrent crops of nodular panniculitis. Some cases are accompanied by fever, malaise, abdominal pain and arthritis. As indicated, the term Weber–Christian syndrome is best avoided. Many cases of nodular panniculitis can now be attributed to specific causes (see below).

Pathology. The histological changes are non-specific but the panniculitis is mainly lobular [1] (Fig. 55.4). In the early stages, the fat lobules are infiltrated with acute inflammatory cells, producing a pseudopyogenic reaction. Later, lymphocytes and macrophages appear to ingest the fat released from damaged lipocytes. These lipophages develop a characteristic foamy cytoplasm, producing the typical appearance of a lipophagic granuloma (Fig. 55.5). Healing is by fibrosis, the fibrocytes invading the lobules from the fibrous septae and ultimately producing complete lobular fibrosis.

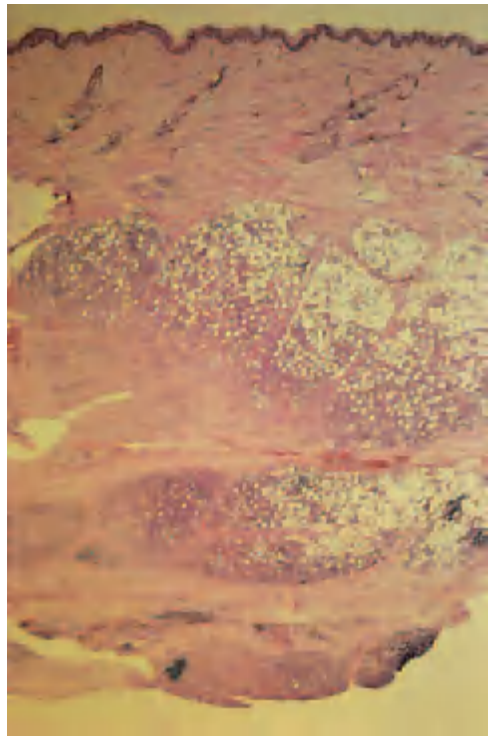

Fig. 55.4 Idiopathic nodular panniculitis. Low-power view showing lobular pattern of panniculitis. H&E, × 2.5.

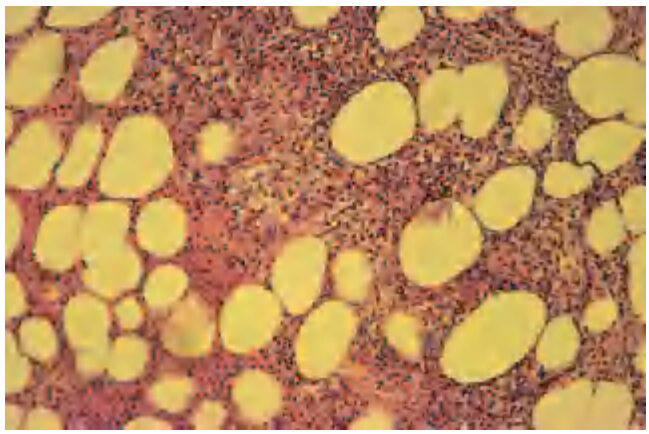

Fig. 55.5 Idiopathic nodular panniculitis: typical appearances of a lipophagic granuloma. H&E, × 40.

Fig. 55.6 Idiopathic nodular panniculitis.

Clinical features. Approximately 50% of cases of nodular panniculitis are idiopathic [2]. All ages may be affected, but the condition is very rare in childhood [3,4]. The majority of cases are young adult females who develop crops of dull-red tender subcutaneous nodules, usually about 1–2 cm in diameter. The lesions tend to be maximal on the lower limbs (Fig. 55.6), although the trunk and face can be affected.

Systemic features including fever, malaise, myalgia, arthralgia and weight loss are often present when there are multiple lesions. Many of the nodules eventually resolve, leaving a pigmented area or an atrophic depression. In a few cases, there may be overlying necrosis with drainage of oily brownish serous fluid (Fig. 55.7), eventually leading to scarring. Rarely, there may be involvement of visceral fat, including the heart, lungs, liver and kidneys, which may lead to death [5].

Fig. 55.7 Idiopathic nodular panniculitis: drainage of serous fluid.

The laboratory features are non-specific, but there may be anaemia, leukocytosis or leukopenia, thrombocytopenia and a raised erythrocyte sedimentation rate.

Diagnosis. Idiopathic nodular panniculitis has to be distinguished from other forms of panniculitis (see below). It is important to perform repeated laboratory tests for pancreatic disease, autoimmune disease, complement deficiency, α_1-antitrypsin deficiency, and to exclude cytophagic histiocytic panniculitis. The possibility of factitial or infective panniculitis must also be considered.

Prognosis. When only subcutaneous fat is involved, the prognosis is good [2]. Some cases recover after a few months, and permanent remission within 2–5 years is usual. Rarely, recurrences may continue for 10 years or longer, but without serious deterioration of the general condition. Exceptionally, the condition can be fatal if there is visceral involvement [5].

Treatment. Once the possibility of systemic disease has been excluded, the treatment is mainly symptomatic. Analgesics may be needed to alleviate pain, and ulceration may need bland aseptic dressings. In severe cases, systemic corticosteroids may be effective, provided adequate dosage (up to 80 mg/day prednisolone) is used for 7–10 days. The dosage should then be slowly tapered over a period of 4–6 weeks. Other treatments that have helped in some cases include antimalarials [6] and thalidomide [7].

Unusual causes of lobular panniculitis resembling idiopathic nodular panniculitis

Increasing numbers of case reports, usually isolated, are appearing that link nodular panniculitis to other illnesses

or events. Autoimmune diseases such as Sjögren's syndrome have been linked to a lobular plasma cell panniculitis [8], and ulcerative colitis and myopathy with nodular panniculitis [9].

Infections, for example hepatitis A [10] and *Borrelia burgdorferi* [11,12], have also been implicated in the causation of nodular panniculitis. Granulomatous panniculitis has been associated with crescentic glomerulonephritis [13]. Lobular panniculitis has been reported to develop at the site of interleukin-2 injections for treatment of metastatic carcinoma, and to be exacerbated by intravenous use of the same treatment [14]. Oral administration of the low-calorie artificial sweetener aspartame (NutraSweet®) has been implicated in the causation of lobular panniculitis [15].

Lipoatrophic panniculitis

SYN. CONNECTIVE TISSUE PANNICULITIS; AUTOIMMUNE PANNICULITIS

As the name implies, lipoatrophic panniculitis denotes the findings of prominent lipoatrophy. However, the development of lipoatrophy should be considered to be an 'end-stage' process, which is preceded by inflammation in the fat lobules and sometimes the fibrous septae. In the earlier literature, many cases of lipoatrophic panniculitis were considered to have Weber–Christian syndrome or Rothman–Makai syndrome [1]. As the aetiology of lipoatrophic panniculitis is unknown, it is perhaps not surprising that the nomenclature remains confused, and almost certainly there is considerable overlap in these clinical entities. 'Primary' lipophagic panniculitis has been described in adults (Fig. 55.8) [2] and children [3,4], either as an acute benign condition or as a chronic recurrent disabling disease. In children, a granulomatous histopathology can be seen prior to the development of lipoatrophy, for which the term lipophagic panniculitis is used [4]. Connective tissue panniculitis is a rare form of panniculitis, affecting septae and lobules, and leading to prominent lipoatrophy [5] (Fig. 55.9). The condition has been described in female adults and children [6]. Episodes of intense lymphocytic panniculitis lead to lipoatrophy. At various times in the illness, a circulating antinuclear antibody and/or SSB (La) antibodies may be detected [5,6]. A recent report has strengthened the view that the clinical spectrum of lipoatrophic panniculitis encompasses connective tissue panniculitis [7]. Histologically, in connective tissue panniculitis there is no evidence of hyalinization of fat and collagen, which is typical of lupus erythematosus profundus [8]. Various other autoimmune diseases have been reported in association with lipoatrophic panniculitis, including diabetes mellitus, rheumatoid arthritis and Hashimoto's thyroiditis [3]. Lipoatrophic

panniculitis has been reported in a very young child with a chromosomal abnormality on chromosone 10q26 [9].

Treatment. Systemic corticosteroids are effective, but usually only in higher doses. Antimalarial therapy, hydroxychloroquine or chloroquine, is the most effective acceptable treatment [10], but may not be sufficient alone [5,7]. Reconstructive surgery, in the form of vascular pedicles or alloplastic implants, has been successfully used in severe cases of lipoatrophic panniculitis [7].

Panniculitis associated with crystal deposition

Polarization of skin histology is important in the assessment of any inflammatory or granulomatous type of panniculitis, as it may be the only way to identify crystals readily [1].

Lipid-containing crystals are dissolved out during formalin fixation, but usually leave cleft-like spaces, which often produce a characteristic histology. Needle-shaped clefts are characteristically seen in subcutaneous fat necrosis of the newborn (see Chapter 14), sclerema neonatorum (see Chapter 14) and post-steroid panniculitis. Cholesterol crystals may cause panniculitis, but the crystals are only found in the lumen of smaller blood vessels.

Post-steroid panniculitis [2–5]

Post-steroid panniculitis is now undoubtedly very rare. All the reported cases have been in children, in whom subcutaneous nodules developed 1–13 days after stopping high doses of systemic corticosteroids quickly. The nodules vary in size from 0.5 to 4 cm, and tend to localize in those areas where there is the greatest accumulation of fat from steroid therapy. Although the nodules appear after the rapid discontinuation of steroids, they are not associated with systemic manifestations of the steroid-withdrawal syndrome. Resolution of the nodules is gradual, occurring over several weeks or months. There is no effective treatment.

The histology of post-steroid panniculitis is very similar to that of subcutaneous fat necrosis of the newborn, in that needle-shaped crystals may be found within lipocytes and histiocytes.

Calcifying panniculitis with renal failure [6]

In patients with chronic renal failure, a chronic alteration of calcium and phosphate metabolism often exists, and secondarily causes hyperparathyroidism. High parathyroid hormone levels lead to the processes of calciphylaxis and metastatic calcification [7,8]. The calcification is principally present within smaller and medium-sized arteries. Trauma to the subcutis can initiate a process of fat necrosis with sometimes distressing consequences. The process begins with erythematous tender nodules or plaques that progress to violaceous livedo-like areas, usually located on the thighs, abdomen or buttocks. These lesions tend to increase rapidly in size, progressing to large necrotic ulcers. Cutaneous necrosis mimicking calciphylaxis in renal failure has been reported resulting from oxalate crystal deposition [9]. Treatment should be aimed at preventing the hyperparathyroidism and secondary infection, but usually the disease has a high mortality.

Fig. 55.10 Ulceration of the thighs secondary to panniculitis caused by injections of pentazocine. (Courtesy of Dr R.F. Palestine, Mayo Clinic, Rochester, MN, USA.)

Gout

Urate crystals are inflammatory, and occasionally lobular panniculitis can be caused by deposition of crystals secondary to hyperuricaemia [10,11]. Urate crystals can be distinguished by their fine needle-like shape and tendency to form sheaves.

Drugs

Lobular panniculitis with crystals can occur following injection of drugs such as meperidine and pentazocine (Fig. 55.10) [12,13].

Crystal-storing histiocytosis

Crystal-storing histiocytosis is a rare condition in which tumorous deposits of histiocytes containing crystalline immunoglobulins are deposited in soft tissue. The condition has been reported to cause panniculitis of Weber–Christian type in a patient with lymphoblastic lymphoma [14].

Enzymic panniculitis

SYN. PANCREATIC PANNICULITIS [1]

Clinically, enzymic panniculitis overlaps closely with nodular panniculitis (Weber–Christian type) and leads to foci of subcutaneous fat necrosis. Systemic features are quite common, including arthritis, pleural effusions and ascites. The erythematous subcutaneous nodules tend to be present in the distal part of the extremities (often around periarticular areas). In milder cases, the nodule(s) can be single and resolve without ulcerating [2], but usually they evolve into sterile necrotic abscesses, which spontaneously ulcerate and exude a thick brown oily material, which represents adipose tissue that has undergone liquefaction necrosis (Fig. 55.11).

Subcutaneous fat necrosis affects 2–3% of all patients with diseases of the pancreas [3]. It appears that all three pancreatic enzymes (lipase, trypsin and amylase) are needed to induce fat necrosis [4]. In 40% of cases associated with pancreatic-induced subcutaneous fat necrosis, the skin lesions were the presenting feature [5]. Monoarticular or oligoarticular arthritic symptoms are common, and may also precede diagnosis of pancreatic disease [6]. The nature of the pancreatic pathology can vary widely. Surgical correction of an anatomical ductal

anomaly [7] or pancreatic pseudocyst [8] can result in complete resolution of panniculitis.

The syndrome has been described in post-traumatic pancreatitis [9], acute and chronic pancreatitis [10] and pancreatic carcinoma [1]. CT can be useful in delineating the pancreatic lesion, as well as outlining areas of subcutaneous fat necrosis [11]. Rarely, acute panniculitis can be associated with a high urinary amylase excretion in the absence of overt pancreatic disease [12]. The association of subcutaneous fat necrosis with pancreatic disease has been reported in systemic lupus erythematosus [13].

Pancreatic panniculitis has recently been reported in association with primary human immunodeficiency virus (HIV) infection and a haemophagocytic syndrome [14].

The histological changes of pancreatic panniculitis are unique but rarely encountered. Focal fat necrosis in the lobules occurs, which is probably initiated by circulating enzymes (Fig. 55.12). A characteristic coagulative necrosis of lipocytes ensues, which leads to ghosts of lipocytes and varying degrees of calcification [1]. In older lesions, fat necrosis and 'ghost' lipocytes become less prominent, and are replaced by a granulomatous infiltrate with Langhans' giant cells [1] (Fig. 55.13). In the very early stages of pancreatic panniculitis, a septal pattern of inflammatory involvement has been described [15].

The treatment of pancreatic panniculitis is primarily supportive and dependent on the underlying pancreatic pathology. Occasionally, complete resolution of symptoms occurs when gallstones are removed [16] or when an anatomical ductal anomaly has been divided [7]. Usually, the prognosis is gloomy. In a review of 27 patients with pancreatic panniculitis, all eight cases with pancreatic carcinoma and 42% of the 19 patients with pancreatitis died of their disease [17].

α_1-Antitrypsin-deficiency panniculitis

Subcutaneous panniculitis simulating Weber–Christian syndrome may be associated with deficiency of α_1-protease inhibitor (α_1-antitrypsin) [1].

Aetiology. Severe deficiency of this important inhibitor in the blood is inherited as the ZZ phenotype, which

occurs in about 1 in 2500 people [2]. Severe deficiencies of α_1-antitrypsin can be associated with emphysema, hepatitis, cirrhosis, vasculitis, urticaria, angio-oedema and panniculitis.

Homozygous deficiency with phenotype ZZ is the most commonly associated with panniculitis, although heterozygous deficiency with phenotype MZ has also been implicated [2,3].

α_1-Antitrypsin inhibits trypsin activity, but it is also active against neutrophil elastase, pancreatic elastase, serine proteases, collagenase, factor VIII and kallikrein [4].

The exact pathogenesis of the panniculitis is obscure, but deficiency of α_1-antitrypsin could accelerate the activation of lymphocytes and phagocytes, thus producing severe inflammation as well as tissue necrosis secondary to protease action.

Pathology. Characteristically, the panniculitis is severely necrotic and suppurative, involving lobules and septae. Vasculitis, haemorrhage or phlebothrombosis can occur in areas of severe inflammation. The end result can be extensive liquefactive necrosis of the dermis and fibrous septae in the subcutis, leading to transepidermal elimination of necrotic material. Even so, large areas of normal fat can be found adjacent to necrotic lobular and septal areas, which contain abundant polymorphonuclear leukocytes and macrophages [5]. In the earliest stage of inflammation, splaying of neutrophils between collagen bundles in the reticular dermis has been noted [6].

Clinical features. The age of onset of the panniculitis ranges from infancy to old age. Early lesions may resemble a cellulitis, as has been described in Marshall's syndrome (Sweet's syndrome leading to acquired cutis laxa), which has been reported to be associated with α_1-antitrypsin deficiency, and may represent part of the disease spectrum [7]. A clue to the diagnosis of α_1-antitrypsin deficiency is that the ulcerative lesions occur predominantly on the trunk and proximal extremities [2] (Fig. 55.14). The clinical findings of ulcerative panniculitis, combined with the histological findings of acute inflammation, necrosis and haemorrhage, certainly justify investigation of α_1-antitrypsin blood levels. Some of the lesions may be precipitated by trauma, and can be exacerbated by surgical débridement [5]. Even cryosurgery has been implicated [8].

Fig. 55.14 Severe suppurative panniculitis secondary to deficiency of α_1-antitrypsin. (Courtesy of Dr M.R. Pittelkow, Mayo Clinic, Rochester, MN, USA.)

Treatment. Dapsone [9] or doxycycline [10] can be very effective in controlling panniculitis [2,9] while systemic steroids, antimalarials and immunosuppressive drugs often give an inconsistent response. For patients with more severe manifestations of disease (e.g. emphysema, lung fibrosis and liver failure), replacement with α_1-antitrypsin offers a valuable treatment. Each patient requires approximately 10 g/month; the treatment is expensive. The creation of transgenic sheep to produce sufficient α_1-antitrypsin is being explored [11].

Fat necrosis

Fat necrosis is often an important accompanying feature in panniculitis, and can be prominent enough and sufficiently distinctive to merit separate description. Insults to the fat, including cold injury [1] or trauma [2], are well known to cause fat necrosis, often when there is accompanying venous insufficiency in the lower legs.

Cold panniculitis

SYN. ADIPONECROSIS E FRIGORE (HAXTHAUSEN) [1]

Cold panniculitis is a form of localized panniculitis that results from cold injury to subcutaneous fat.

Fig. 55.15 Cold panniculitis: erythematous nodular area on the malar region of a 6-month-old infant which developed after exposure to a very cold wind. (Courtesy of Dr D.J. Atherton, St John's Institute of Dermatology, London, UK.)

Clinical features. The condition has been reported in neonates [3], children [1,4] and adults, notably as a consequence to ice cubes [5], ice packs [3] or exposure to freezing air temperatures, particularly in adults with a chilblain-type of circulation [6].

Some 48–72 h after cold exposure, the affected areas become indurated with an ill-defined margin. The skin may be red or bluish and the area is usually cold to the touch (Fig. 55.15). The subject may complain of a cold sensation or a dull ache. If the area is kept warm, the subcutaneous plaques slowly soften and resolve over weeks without scarring. Cold panniculitis of the thighs or buttocks may occur in skiers or horse riders who wear inadequate clothing [6], although in this situation perniosis is more common than true panniculitis [7]. Children sucking ice lollies (popsicles) can induce cold panniculitis in the facial subcutaneous tissues [8].

Differential diagnosis. The clinical appearances may resemble other forms of panniculitis (especially erythema induratum) but can usually be distinguished by the location and history of prior cold exposure.

Treatment. Cold panniculitis resolves spontaneously if further exposure to cold injury is avoided. In horse riders, tight jeans should be replaced by several layers of looser and thicker clothing. If the limb becomes thoroughly chilled, rapid rewarming should be avoided. Vasodilators tend not to be helpful [9].

Nodular cystic fat necrosis [1]

SYN. ENCAPSULATED FAT NECROSIS [2]

The term denotes a characteristic form of encapsulated subcutaneous fat necrosis that presents as solitary or multiple subcutaneous nodules.

Aetiology. Early lesions begin as lobules of adipose tissue, which, because of compromised blood supply, often following trauma, become separated from the surrounding tissue [3]. These lobules subsequently become surrounded by thin fibrous tissue, and remain as encapsulated necrotic tissue or later undergo dystrophic calcification.

Clinical features. The painless lesions occur often on the lower legs of healthy adolescent boys or middle-aged women. The lesions can be solitary or multiple, often mobile, and varying from 2 to 35 mm in diameter. Preceding trauma is present in about 30% of cases. The nodules may be present for several weeks to years before excision. During surgical removal, a smooth-walled cyst within the subcutaneous fat containing solitary or multiple free-floating or attached nodules is usually found. Nodular cystic fat necrosis is probably not uncommon, but not readily recognized. Similar changes in the fat have been reported within the abdominal cavity [4] or within the abdominal wall [5]. Some authors take the view that encapsulated angiolipomas and encapsulated lipomas are variants of nodular cystic fat necrosis, with a variable degree of vascularity [2,6].

Histopathology. The lesions are totally or nearly totally encapsulated, showing massive fat necrosis with preservation of the outlines of non-nucleated adipocytes, usually with little in the way of inflammatory changes. Fibrous septae within the lesion, and dystrophic calcification, tend to be seen in older lesions. Focal lipomembranous changes may coexist [7].

Differential diagnosis. This includes lipoma, angiolipoma, pancreatic fat necrosis and membranous fat necrosis.

Lipomembranous fat necrosis [1]

SYN. MEMBRANOCYSTIC FAT NECROSIS

Lipomembranous fat necrosis is a striking and distinctive alteration in adipose tissue that was first described in Nasu–Hakola disease, a genetic disorder characterized by profound membranocystic degeneration of long bones and systemic adipose tissue, with associated progressive sudanophilic leukodystrophy of the brain [2]. Cystic areas of fat necrosis are lined by wavy hyaline acidophilic membranes (Fig. 55.16). Convoluted projections and arabesques of the membranes into the interior of the cysts are prominent [3]. The membranous structures stain brightly with periodic acid–Schiff but are resistant to diastase. Ultrastructurally, the membranes consist of two layers [4].

Changes of lipomembranous fat necrosis can occur as a non-specific reaction pattern in a wide range of autoimmune diseases including lupus erythematosus [3], diabetes mellitus [3], morphoea [5] and dermatomyositis [6]. In a clinical and pathological correlation of 1806 biopsies of panniculitis, lipomembranous fat necrosis was only identified in 13 cases [3]. It is now clear that venous stasis and ischaemia are important co-factors [1,3,7,8] in the development of lipomembranous fat necrosis. Most cases are seen in middle-aged obese women who develop venous stasis-associated chronic sclerotic plaques on the lower legs and ankles [1]. The condition therefore overlaps with or is a part of sclerosing panniculitis [9], lipodermatosclerosis; some consider it to be a non-specific finding [10].

Panniculitis caused by cellular proliferative disease

Subcutaneous T-cell lymphoma is a rare type of peripheral T-cell lymphoma, which clinically and histologically may mimic benign forms of panniculitis [1]. Erythematous subcutaneous nodules localized to the extremities appear in crops, often accompanied by fever and malaise [1,2]. The lymphoma may behave indolently for months to years, but in most cases it enters an acute aggressive phase in which the majority of patients develop fatal haemophagocytic syndrome [3] or sometimes acute leukaemia [4].

Although low-power histological appearances may resemble benign panniculitis, high-power examination reveals cytological atypia of the malignant lymphoid cells, and immunochemistry studies confirm the T-cell lineage [5]. Angiocentric lymphoma can also cause lobular granulomatous panniculitis [6,7].

Cytophagic histiocytic panniculitis [1,2]

Cytophagic histiocytic panniculitis is the term commonly used to refer to the specific cutaneous manifestation of haemophagocytic syndrome (HPS) [3].

In HPS, there is a histiocytic proliferation throughout the reticuloendothelial system. The proliferation and phagocytic activity of histiocytes in HPS is associated with a proliferation of lymphocytes [3]. Indeed, the primary abnormality in cytophagic histiocytic panniculitis may be a clonal T-cell proliferation [8].

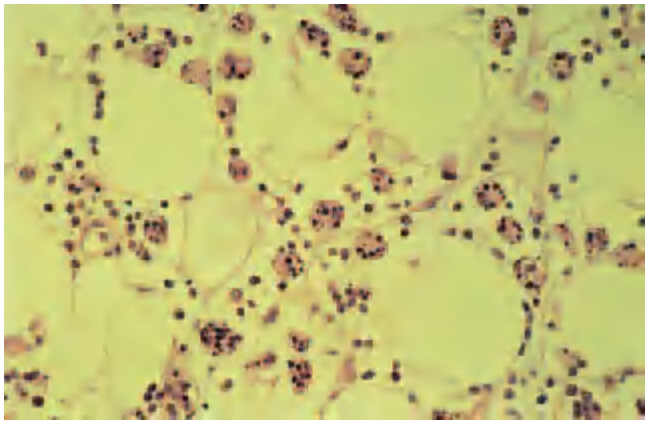

Fig. 55.17 Cytophagic histiocytic panniculitis: many histiocytes are present in the fat lobule, showing the characteristic 'bean-bag' appearance. H&E, × 25.

Aetiology. The proliferation of lymphocytes and histiocytes in HPS may be secondary to viral infections (e.g. Epstein–Barr virus [9], cytomegalovirus) or may be neoplastic in origin [2]. HPS has a higher rate of mortality when it is associated with a state of known immunosuppression, and has been reported in HIV-1 infections [2]. Indeed, lymphoma and infection may act as co-factors in the development of HPS. It has been postulated that in HPS cytokine production by the proliferating lymphocytes is important as a stimulus to activate macrophages [2].

Pathology [10]. Cytophagic histiocytic panniculitis may begin as a type of regional histiocytosis that primarily involves the subcutis [10]. In most cases, the condition spreads to involve the bone marrow, lymph nodes and reticuloendothelial system. The affected tissues are gradually replaced by a syncytium of histiocytic cells with associated T lymphocytes and plasma cells. The histiocytes are actively cytophagic, so that they become stuffed with white blood cells, red cells, nuclear fragments and platelets, thus giving them a characteristic 'bean-bag' appearance (Fig. 55.17).

The histiocytic proliferation is accompanied by lobular panniculitis with areas of fat necrosis, together with massive hyaline necrosis, oedema and haemorrhage [10]. Immunohistochemical studies tend to show that the histiocytic population is benign, whereas the lymphoid element, whether benign or malignant, is composed primarily of T cells [2].

Clinical features. This is a rare condition, which in the past has probably been labelled as systemic nodular panniculitis (Weber–Christian syndrome) [11,12]. The condition begins with crops of red tender nodules, associated with fever (Fig. 55.18). The nodules often develop a purpuric or bruised appearance (Fig. 55.19). The condition

Fig. 55.18 Cytophagic histiocytic panniculitis: early stage with recurrent crops of lesions. (Courtesy of the Mayo Clinic, Rochester, MN, USA.)

Fig. 55.19 Cytophagic histiocytic panniculitis: note the haemorrhagic nature of this early lesion on the thigh. (Courtesy of St John's Institute of Dermatology, London, UK.)

can be acute, or chronic with a febrile course associated with anaemia and pancytopenia. More severe cases tend to display weight loss, thrombocytopenia, raised liver enzymes, serosal effusions and hepatosplenomegaly [11–13].

Most patients have a progressive form of the disease, which is ultimately fatal. The fatal progression is usually determined by the development of severe anaemia, thrombocytopenia, coagulation defects, hypocalcaemia and liver failure [12,13]. At this stage, the development

of terminal T-cell lymphoma [14,15], B-cell lymphoma [16,17], histiocytic lymphomas [18] or sinus histiocytosis with massive lymphadenopathy (Rosai–Dorfman) [19] may also be evident. The complex coagulation defects are not fully understood. There may be a combination of thrombocytopenia or thrombocytosis, decreased factor VIII and fibrinogen levels, and an increase in excretion of fibrin degradation products.

It has been suggested that these abnormalities in coagulation may be caused by a circulating proteolytic enzyme other than thrombin, which may originate from proliferating lymphocytes [20]. The occurrence of cytophagic histiocytic panniculitis has been reported as a late complication of allogeneic bone marrow transplantation [21]. However, prolonged survival after combination-type chemotherapy has been reported, even in cases where the clinical features indicate a poor prognosis [22,23]. Monitoring of phagocytic activity may be of value in assessing disease activity [22].

Treatment. Many cases are ultimately fatal, and for the progressive forms combination cytotoxic chemotherapy should be tried [9,13]. Prolonged survival or even complete remission have been reported with this type of treatment schedule [23,24]. Ciclosporin has been reported to be effective in cytophagic histiocytic panniculitis [25], presumably by suppression of the abnormal T-cell activation and proliferation. Combinations of systemic corticosteroids and azathioprine have been reported to be effective [26], as has the use of intravenous immunoglobulins [27].

Mixed (septal and lobular) panniculitis

Lupus panniculitis

SYN. LE PROFUNDUS

Lupus panniculitis is a rare condition in which the inflammatory changes primarily affect the deep dermis and subcutaneous fat. The overlying skin may be associated with discoid lupus erythematosus (LE) in 20% of cases [1,2]. The serum antinuclear antibody is usually positive in approximately 70% of cases, but only 25–50% fulfil the American Rheumatism Association criteria for systemic LE [1,2]. However, there are a significant number of cases of lupus panniculitis that never meet the criteria for systemic LE, and some have no extracutaneous manifestations [3]. Many patients with lupus panniculitis tend to have a relatively mild but usually chronic disease course [3].

Clinical features. The lesions begin with subcutaneous nodules or plaques, where the overlying skin may appear normal, erythematous or may show changes characteristic

Fig. 55.20 Lupus panniculitis. (Courtesy of St John's Institute of Dermatology, London, UK.)

of discoid LE [2]. The lesions can be painful and may ulcerate, leading to atrophy and scarring after healing [4].

Common sites for nodules include thighs, buttocks, arms, breasts and face (Fig. 55.20). When breast tissue is involved (lupus mastitis), there may be difficulty in distinguishing lupus mastitis from breast carcinoma, even on mammography [5]. Indeed, lupus mastitis may account for 10% of all patients with lupus panniculitis [6]. Many cases of lupus panniculitis may have only mild extracutaneous features, but the coexistence of photosensitivity, arthritis, pericarditis, renal involvement [3] and even neuropsychiatric manifestations has been reported [6].

Perhaps not surprisingly, lupus panniculitis can overlap with morphoea-like lesions [7] or other forms of connective tissue panniculitis [4]. LE panniculitis is rare in childhood [8] but a linear variant has been described [9].

Pathology. The major histological criteria needed for a diagnosis of lupus panniculitis include hyaline necrosis of fat, lymphocytic aggregates or lymphoid follicle formation, periseptal or lobular lymphocytic panniculitis, and calcification [1] (Fig. 55.21). Minor changes (not necessary for diagnosis) include overlying changes of discoid LE, hyalinization of the subepidermal zone, mucin deposition, lymphocytic vascular inflammation and collections of plasma cells and eosinophils [10].

Treatment. Treatment can be difficult in chronic forms of lupus panniculitis. Local treatment in the form of potent corticosteroids under hydrocolloid dressings [11] or intralesional triamcinolone can be of benefit. Dapsone [12], oral hydroxychloroquine [8] and corticosteroids [5] can be effective in the management of lupus panniculitis. Low-dose thalidomide can be effective for antimalarial drug-resistant cases of discoid LE and LE profundus [13].

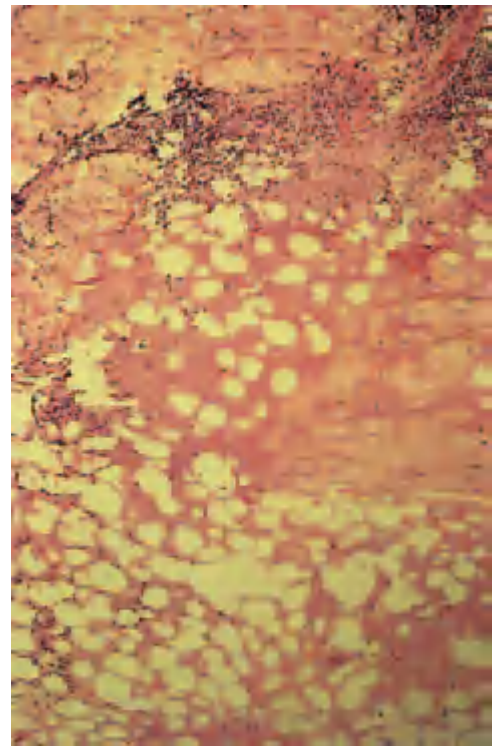

Fig. 55.21 Lupus panniculitis: extensive hyaline necrosis of fat with overlying lymphocytic aggregates are shown. H&E, × 4.

Panniculitis with complement deficiency

Although complement deficiencies are perhaps better known for their association with partial lipoatrophy syn-

dromes [1], they have also been reported in lobular panniculitis. The association of an immunoglobulin E (IgE) paraproteinaemia and severe acquired depletion of C1-esterase inhibitor with episodes of nodular panniculitis and hepatitis has been reported [2]. Nodular panniculitis has also been associated with a low serum complement, together with a systemic LE-like disease and circulating IgM immune complexes [3].

Infective panniculitis

Infective panniculitis (either through direct inoculation or as a manifestation of sepsis) is becoming an increasingly important cause of panniculitis [1]. This is particularly so for any immunocompromised patient, either as a result of steroid or immunosuppressive therapy [2] or brought about by HIV infection [3]. An association of acquired immune deficiency syndrome (AIDS) with cutaneous aspergillosis is developing, and some patients present with subcutaneous nodules [4].

Granulomatous panniculitis on the legs caused by *Candida albicans* has been reported in a diabetic who had not received immunosuppressive treatment [5]. Other occasional cases with infective panniculitis are not overtly immunosuppressed [1].

Clinical features [1]. Most cases of infectious panniculitis appear as inflamed subcutaneous nodules, plaques or ulcers [4] on the lower extremities. Other sites include the shoulders, arms, fingers, abdominal wall and gluteal region. The differential diagnosis includes erythema nodosum, abscess or other type of panniculitis.

A wide variety of organisms have been identified in infective panniculitis. These particularly include Gram-negative [3] and Gram-positive [1] bacteria, *Histoplasma* [2,6], *Mycobacterium tuberculosis* [7], atypical mycobacteria [8,9], *Actinomyces* and *Nocardia* species [1], *Candida* [4] and various fungi [1].

Histology. Classically, in infective panniculitis there is a mixed pattern of septal and lobular involvement. Neutrophilic involvement of the fibrous septae can occur [1], a feature that can rarely overlap with acute erythema nodosum [10]. Indeed, neutrophilic involvement in infective panniculitis can also overlap with other neutrophilic dermatoses (neutrophilic vasculitis and panniculitis) [11]. Certain morphological changes are found in infective panniculitis, whatever the identity of the infective organism. Epidermal involvement is common, as is papillary dermal oedema with diffuse neutrophilic infiltrate, vascular proliferation and haemorrhage [1]. Focal necrosis of sweat glands and discrete microabscess formation may be noted [1].

It is important to stress that infection should be suspected in virtually any case of panniculitis when it is known that the patient is immunocompromised. Extra biopsy material submitted for tissue culture is highly desirable, if not essential [3], as special stains may fail to demonstrate the organisms [1].

Factitial panniculitis [1]

Factitial panniculitis is a rare condition in which the panniculitis is self-inflicted. Its importance lies in the fact that some cases may masquerade as systemic disease or idiopathic Weber–Christian syndrome. The causes and clinical features of factitial panniculitis may vary widely depending on the type of insult to the subcutaneous fat. Factitial panniculitis may result from blunt trauma to the skin, usually on the forearm and hand (l'oedème bleu) [2]. Histologically, such cases may show an organizing haematoma in the fat, together with haemosiderin and amorphous polysaccharide masses [2]. Cupping and acupuncture techniques for relief of pain may rarely lead to factitial panniculitis on the limbs [3]. More commonly, however, factitial panniculitis is induced by injected materials (e.g. drugs and silicone materials). Injected drugs such as morphine, pentazocine, meperidine or tetanus toxoid can all cause chronic ulcerative panniculitis

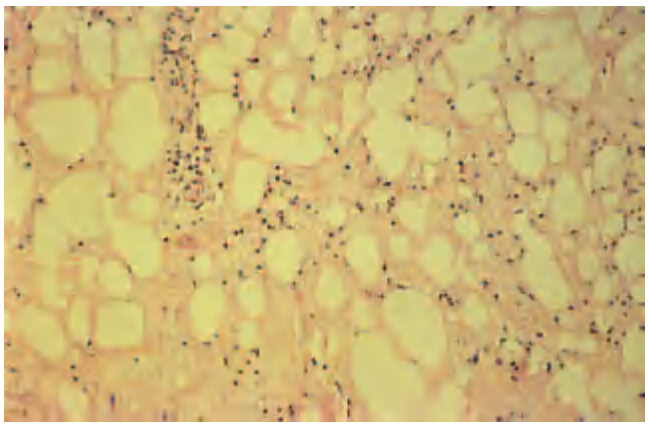

Fig. 55.22 Paraffinoma: showing typical 'Swiss-cheese'-like pseudocystic spaces. H&E, × 25.

Fig. 55.23 Paraffinoma: firm indurated areas present on the malar areas, following paraffin oil injections many years before for cosmetic purposes. (Courtesy of St John's Institute of Dermatology, London, UK.)

on the thighs and buttocks, associated with 'woody-hard' fibrotic induration (see Fig. 55.10) [4,5]. Silicone injections (used by some patients to augment the size of breasts or genitalia) can cause panniculitis [6], as can the accidental injection of various oily vehicles for therapeutic agents. Povidine, a synthetic polymer used as a dispersing or suspending agent for drugs, has also been reported to cause panniculitis associated with fever [7]. The injection of mineral oil into tissues may induce a granulomatous foreign body reaction (sclerosing lipogranuloma) or 'paraffinoma' [8]. Histologically, paraffinomas show multiple 'Swiss-cheese-like' pseudocystic spaces (Fig. 55.22), which are surrounded by fibrosis and inflammation. Most paraffinomas occur on the head and neck area in women who have the injections for cosmetic reasons [9] (Fig. 55.23).

Rarely, however, paraffinomas are not factitial in origin. The development of orbital and palpebral paraffinoma has been reported to ensue after ethmoidectomy for chronic sinusitis, when the nasal cavity was packed with gauze containing a petrolatum-based antibiotic ointment [10]. Mentally disturbed patients have been known to inject milk or faeces, which produces a severe cellulitis or suppurative panniculitis.

Factitial panniculitis simulating pyoderma gangrenosum has also been reported in Münchausen syndrome [11].

Histology. The histology will obviously vary according to the type of noxious injury to the fat. Blunt trauma tends to produce deeper haematomas [2]. Polarization is essential to reveal the possibility of injected crystals [4,5]. The presence of vacuoles or pseudocystic spaces favours the injection of silicone [6] or paraffin [9,10].

The use of scanning electron microscopy or energy-dispersive spectroscopy techniques can aid in the identification of injected materials [6]. In general, factitial panniculitis is a mixed septal and lobular panniculitis that is associated with a prominent degree of inflammatory or granulomatous infiltrate, with fibrosis ensuing.

Differential diagnosis. The diagnosis may be suggested by the personality of the patient, the chronic and recurrent nature of the panniculitis and by its focal or bizarre site. In some cases, there may be fever or systemic symptoms and the condition may then be mistaken for systemic nodular panniculitis (Weber–Christian syndrome).

Oil granuloma

SYN. OLEOGRANULOMA; OLEOMA; PARAFFINOMA; SCLEROSING LIPOGRANULOMA

Definition. A granulomatous reaction to the injection of a relatively bulky oily fluid into the tissues. In many cases the condition overlaps with that of factitial panniculitis, but in some cases it may represent an industrial injury.

Aetiology. Many years ago, mineral oils, particularly liquid paraffin and soft paraffin, were in vogue for improving the contour of the body (breasts, face, genitalia) [1]. Oil granulomas are now less common since the development of less toxic silicones and bovine collagen for tissue replacement, or the use of liposuction techniques.

Grease-gun injuries can cause sclerosing lipogranulomas [2].

Histology. A massive injection of oil tends to provoke an initial acute inflammatory response, but some mineral oils will remain in the tissue for a considerable time without producing any marked inflammatory reaction. Larger oil droplets become encysted by fibrosis ('onion-skin cysts'). The classical 'paraffinoma' shows multiple small cystic areas ('Swiss-cheese effect') associated with very little inflammatory change but a prominent degree of fibrosis. Certain animal fats produce a tuberculoid granuloma, whereas vegetable oils, by virtue of irritant substances liberated by hydrolysis, often provoke inflammatory changes and lipophagic granuloma.

Differential diagnosis of a mineral oil granuloma from idiopathic sclerosing lipogranuloma may be very difficult, although the use of scanning electron microscopy and energy-dispersive spectroscopy techniques can be of help [3].

Clinical features. The nodules or plaques usually appear several months after injection, but their onset can be delayed for up to 42 years [4]. Once initiated, the lesions tend to persist indefinitely. Firm non-tender nodules or plaques form, which may be fixed to both skin and deeper fascia. Ulceration occasionally occurs. The common sites following cosmetic procedures are the face and breasts of women. Nodules on the thighs and buttocks are the result of injections of therapeutic agents in oily vehicles. It is not rare for some patients to strenuously deny any history of earlier injections for cosmetic or therapeutic purposes.

The grease-gun injury characteristically affects the dorsum of the left hand and appears as a nodule, plaque or sinus [2,5]. The onset is more rapid, the patient usually being unaware of the injury, but there may be an anaesthetic period before the gradual onset of swelling, pain and ischaemia. Rapid referral to a plastic surgeon or hand specialist is necessary. Perianal oil granulomas have been reported to follow injections for haemorrhoids [6]. Factitial panniculitis (dermatitis artefacta) can be caused by self-injection of mineral oils or silicones. An analysis of the lipid content in 23 cases of sclerosing lipogranuloma of the male genitalia demonstrated the presence of paraffin hydrocarbons in all specimens [7].

Prognosis. In chronic cases, the lesions remain essentially unchanged almost indefinitely, although the coexistence of sarcoma has been reported [8]. With acute grease-gun injuries, ischaemic changes may rapidly develop.

Treatment. Xeroradiology can be helpful, as is a knowledge of the offending material. Decompression and clearing of the affected area are needed in grease-gun injuries [2]. Tetanus toxoid may be needed along with high-dose systemic steroids if there has been a delay in diagnosis of grease-gun injuries [2]. If there is any doubt about the diagnosis of chronic oil granuloma, a deep surgical biopsy should be performed. No effective treatment exists other than complete excision.

Idiopathic sclerosing lipogranuloma

An idiopathic form of sclerosing lipogranuloma has also been reported [9], but the lack of recent reports may indicate that it really represents an oil granuloma in which the history is concealed [6,7].

Sclerosing panniculitis [1–4]

SYN. LIPODERMATOSCLEROSIS [3]; HYPODERMATITIS SCLERODERMAFORMIS [3]

There is growing evidence that the term sclerosing panniculitis encompasses both lipodermatosclerosis and hypodermatitis sclerodermaformis, perhaps appearing in different stages [2]. The patients, usually women, gradually develop well-circumscribed indurated inflammatory plaques around the lower extremities, which lead to hyperpigmentation. Histologically, there is a combination of fat necrosis, sclerosis and a lobular panniculitis. Lipomembranous changes can coexist [5]. Not all cases are overtly associated with chronic venous stasis, although the condition may show some gradual response to elastic compression stockings [2]. It has been postulated that there may be overlap in the pathogenesis between lipodermatosclerosis and eosinophilic fasciitis [6].

Infective cellulitis may also have a role in exacerbating lipodermatosclerosis and the fasciitis–panniculitis

syndrome [7]. It is likely that the pathogenesis of lipodermatosclerosis is multifactorial [8]. The condition may be initiated by venous stasis, which may lead to leukocyte plugging and endothelial injury to the microcirculation. Perivascular cuffing by fibrin deposits may activate fibroblasts, endothelial cells and mastocytes, which ultimately lead to fibrous thickening of the fascia and fibrous septae in the subcutis [5]. Elevated matrix turnover has also been implicated in lipodermatosclerosis [9].

Fasciitis–panniculitis syndromes [1]

In eosinophilic fasciitis and related syndromes, the inflammation often extends to involve the fibrous septae and fat lobules [1]. It has become increasingly recognized that a histological picture similar to eosinophilic fasciitis, involving the subcutaneous fat, can occur in a variety of diseases, including morphoea profunda [1], lupus panniculitis [1], toxic oil syndrome [2], L-tryptophan-induced eosinophilia–myalgia syndrome [3], graft-versus-host reaction [4], post-irradiation injury [5], infections [6] and cancer-related (paraneoplastic) syndromes [7,8].

Panniculitis in other connective tissue diseases

As already indicated, panniculitis in connective tissue diseases may overlap with lupus panniculitis [1] and also lipoatrophic panniculitis [2]. Deep morphoea (morphoea profunda) may show lipoatrophy, scleroderma-like lesions and deeper subcutaneous nodules or plaques. They may also share some histological features, notably lymphocytic panniculitis, lymphoid nodular areas in the fat, widening of the fibrous septae and lymphocytic vasculitis [3–5]. The association of panniculitis with dermatomyositis is very rare but well documented [6–8]. The parallel course of panniculitis and muscular involvement, and their response to treatment, suggest that panniculitis may be an inherent part of dermatomyositis [6–8].

Subcutaneous nodules or plaques develop on the arms, buttocks, thighs and abdomen, or features of multifocal lipoatrophy may be present [9].

Partial lipoatrophy may also coexist with dermatomyositis [10,11]. The association of panniculitis and dermatomyositis has been reported to respond to a combination of low-dose methotrexate and prednisolone [9], or high-dose intravenous immunoglobulins [12].

Fig. 55.24 Scarring of lower abdominal folds secondary to panniculitis and/or vasculitis following jejuno-ileal bypass for gross obesity.

Panniculitis with vasculitis

Because the vasculature of the subcutis is 'housed' in the fibrous septae that divide up fat lobules, it is obvious that most deep vasculitis syndromes (particularly large-vessel vasculitis) begin as a septal panniculitis and involve the fat lobules later.

Nearly all cases of leukocytoclastic vasculitis in the subcutis zone also affect the overlying dermis. Nodular forms of vasculitis affecting the fat are primarily dealt with in Chapter 49, together with larger vessel vasculitis syndromes (e.g. polyarteritis nodosa).

This section covers a series of miscellaneous entities that may overlap with vasculitis, or may in some way be associated with them.

Panniculitis has rarely been reported in association with relapsing polychondritis, and histologically was characterized by septal and lobular involvement with vasculitis [1,2]. The association of granulomatous lipophagic panniculitis with temporal arteritis and chronic active hepatitis has been reported, and perhaps represents three-organ manifestations of an underlying aberration of the immune defence mechanism [3].

Unusual forms of vasculitis-associated panniculitis include that resulting from the complications of jejuno-ileal bypass surgery for obesity (Fig. 55.24) [4,5].

Neutrophilic panniculitis

Subcutaneous neutrophilic infiltrates are a rare accompaniment in atypical Sweet's syndrome and bullous pyoderma gangrenosum [6]. Recent case reports have highlighted the association of neutrophilic panniculitis with myelodysplastic syndromes [7,8]. The neutrophilic infiltrates spread out from the septa to the lobules, without evidence of necrotizing panniculitis. It has been postulated that neutrophilic panniculitis belongs to the spectrum of atypical neutrophilic dermatoses associated with myelodysplastic syndromes [7]. Septal forms of neutrophilic panniculitis can occur in classical Sweet's syndrome, and may present as erythema nodosum-like eruptions [9].

A pustular neutrophilic form of panniculitis has been associated with rheumatoid arthritis [10]. Clearly, in all forms of neutrophilic panniculitis it is necessary to exclude an infective organism, particularly in an immunocompromised patient [11].

Oedematous scarring vasculitic panniculitis

A condition termed oedematous scarring vasculitic panniculitis has been identified in children, which is described as a novel multisystemic disease with a mortality rate of 35.7% [12]. The cutaneous lesions may intially resemble hydroa vacciniforme, but later disfiguring involvement affects both covered and sun-exposed areas. The lesions develop as oedematous vesicles, which progress to deep ulcerations and varicelliform scars. Histologically, panniculitis and vasculitis coexist with a heavy nodular lymphohistiocytic infiltrate. In cases with systemic involvement, malaise, fever, failure to thrive, leukopenia, thrombocytopenia, hepatosplenomegaly and increased levels of serum C3 have been frequently observed [12]. Several of the patients ultimately developed cutaneous lymphoma, after an interval of 5–8 years [12]. Other patients with 'hydroa vacciniforme' have also been reported to develop malignant lymphoma [13–15]. Currently, it is not clear whether oedematous scarring vasculitic panniculitis is a disease entity, whether it is in any way related to hydroa vacciniforme or whether it represents an evolutionary process in the development of malignant lymphoma in children.

Wells' syndrome [1–4]

SYN. EOSINOPHILIC CELLULITIS; RECURRENT GRANULOMATOUS DERMATITIS WITH EOSINOPHILIA

Definition. This is a syndrome with an impressive and distinctive clinical picture resembling cellulitis, and with a typical histology characterized by tissue eosinophilia, oedema and 'flame' figures.

Aetiology. A good example of this is the association of eosinophilic cellulitis with idiopathic hypereosinophilic syndrome [5]. Eosinophilic cellulitis has also been reported with herpes simplex virus type 2 infections, in which antiviral therapy led to a complete remission of the eosinophilic cellulitis [6]. Some cases may be associated with malignancy [7].

Pathology. Early on, there is an infiltrate of polymorphs and especially of eosinophils, with considerable oedema. Flame figures are noteworthy—clusters of eosinophils and histiocytes around a core of collagen and eosinophilic debris. The flame figures may disappear after the acute stage. Blood eosinophilia is usual but not invariable.

Clinical features. Wells' syndrome is rare. It can affect either sex, usually in adult life, but some congenital [8], neonatal [9] or childhood cases [10] have occurred. Any site may be involved, with single or multiple lesions. The disease evolves over a few weeks, and recurrences are common. Initially, the lesions are itchy erythematous plaques with features resembling both urticaria and cellulitis. Unusual nodular variants [11] and lesions that followed the lines of Blaschko [12] have been described. After a week or two they become flatter, and sometimes go through a greenish colour change before resolving without scarring. The general health is usually unimpaired, but fever has been reported.

Differential diagnosis. Clinically, cellulitis and urticaria are the main differential diagnoses. *Toxocara* infections may be similar, both clinically and histologically. Flame figures can be found in many other diseases, including insect-bite reactions, dermatophyte ide eruptions and pemphigoid. There may also be features resembling the Churg–Strauss syndrome [13].

Treatment. Often no specific treatment is needed. Low-dose systemic steroids can provide symptomatic relief in severe cases [14].

Lipodystrophy

The terms lipoatrophy and lipodystrophy are sometimes used interchangeably and without precise definition. Perhaps it is best to define lipodystrophy as an abnormality of fat that is usually associated with atrophy (lipoatrophy), or infrequently hypertrophy of the adipose tissue. Lipoatrophy refers specifically to loss of fat. However, the lipoatrophy may be part of a local panatrophy affecting all mesodermal layers [1]. Lipodystrophies are a rare and heterogeneous group of the disorders characterized by selective and variable reduction in and, more often, loss of adipose tissue from different parts of the body; in all but the more very localized varieties they are often associated with metabolic complications of insulin resistance, in particular insulin-resistant diabetes mellitus [2]. Over the last 5 years, there has been a much better understanding of the aetiology of these disorders. The loss of adipose tissue can have a genetic, immunological, infectious or drug-associated aetiology [3]. The age of onset may also determine the nomenclature of the disease. Some patients may develop the disease very early on in life—such patients are

then sometimes referred to as having congenital lipodystrophy. In other patients, the disease occurs later on in life—so-called acquired lipodystrophy. The lipodystrophies can also be classified according to the extent of the disease into three major clinical entities: localized, partial body and whole body distribution. The atrophy may be localized (e.g. to the thighs); it can be widespread, involving the upper part of the trunk (partial lipodystrophy); or it may affect the whole body (generalized lipodystrophy).

Nevertheless, the aetiology and clinical presentation are not always clear-cut. For example, cases of partial lipoatrophy have been reported that have evolved into generalized lipoatrophy, suggesting some common link between these uncommon disorders.

Localized lipoatrophy

Localized atrophy may be seen in insulin-dependent diabetics, induced by insulin; following certain inflammatory conditions, such as panniculitis and morphoea; or as primary idiopathic lipoatrophy. Failure to perform a biopsy in the early phases of the atrophy may explain why some of the cases are labelled as idiopathic in origin. It has been suggested that many cases may be preceded by an inflammatory reaction in the fat (see also lipoatrophic panniculitis) [1].

Insulin lipodystrophies

This is a cosmetically distressing complication of insulin administration. Both atrophy and hypertrophy of the fat tissue can occur. It occurs in various degrees in up to 37% of insulin-dependent diabetics [2].

Aetiology. Insulin lipoatrophy is usually seen in women and children, rarely in men. The mechanism remains speculative but local changes induced by insulin or impurities are probably important [3] as are antibodies to insulin [4]. Most cases are associated with high levels of insulin requirement and/or an increased insulin-binding capacity.

Cross-reaction of insulin antibodies with cells thus changed could result in further damage [5]. It was thought that the introduction of highly purified insulin would make a significant impact in reducing the frequency of this disorder. There is evidence to support this view because the subcutaneous damage is reduced if highly purified insulins are used, resulting in clinical improvement and a reduction in insulin requirements and insulin-binding capacity [5–7]. However, localized lipodystrophies in insulin-requiring patients are still very common, affecting up to 40% of patients.

A recent publication investigated a cross-sectional study of 112 children and adolescents with type 1 diabetes mellitus and related the presence of insulin antibodies to the clinical features of insulin lipodystrophies [4]. The antibodies against insulin increased significantly after diabetes manifestations and initiation of insulin treatment, while β-cell-specific antibodies did not. Severe lipohypertrophy was seen in four children, severe lipohypertrophy in 18 and moderate lipohypertrophy in 27 children. Among clinical and immunological parameters investigated, insulin antibodies were significantly associated with hypertrophy or atrophy of injection sites. It was concluded that lipodystrophies in diabetics are significantly associated with insulin antibodies, and that these may have a role in the development of the disease.

Histopathology. There is a loss of fat tissue and inflammatory changes are conspicuously absent. In lipohypertrophy, there may be replacement of mid-dermal collagen by hypertrophic fat cells.

Clinical features. Although both features can occur in the same patient, recent publications suggest that insulin fat hypertrophy is more common than atrophic changes [4]. Most cases present 6 months to 2 years after the start of insulin administration. Lesions may vary from only a small dimple to an extensive disfiguring area with much local loss of fat or firm fatty induration. The changes are usually found only at the sites of injection, but loss of fat may occur elsewhere. There is a definite tendency to spontaneous recovery at the involved site when the site of injection is changed.

Treatment. A change to a purified insulin, particularly the new human insulin, is not necessarily curative [8]. Prevention is either by constant alteration of the site of injection, so that no two injections are given in exactly the same area more frequently than once a month, or by the use of the more purified insulins [5,9]. Liposuction may help the hypertrophic variety [10]. In one very resistant case of progressive lipoatrophy, continuous subcutaneous infusion with human insulin was required to control the atrophy [9].

Localized lipohypertrophy has also been reported in a 51-year-old female patient with panhypopituitism during growth hormone replacement therapy [11].

Localized 'idiopathic' lipoatrophy

This group of disorders predominantly affects the thighs, ankles or abdomen, and all cases may possibly be variants of the same process.

Histopathology. Two histological subsets exist: involutional and inflammatory [1]. Sixty per cent can be termed involutional; the adipocytes are small and embedded in hyaline connective tissue with many capillaries. Such patients usually have a single lesion and only one-third show immunoreactants. Forty per cent can be classed as inflammatory [2]; the lipocytes are normal and there is a sparse infiltrate of lymphocytes, histiocytes and plasma cells; all show immunoreactants [1]. The epidermis is normal. The appearance should not be confused with the striking lipomembranous (membranocystic) changes seen occasionally in morphoea, panniculitis and other inflammatory dermatoses.

Clinical features. Two clinical groups, based on the localization of the atrophy, have been described.

Lipoatrophia semicircularis [3–5]. These patients show lesions on the anterolateral aspects of the thighs, characterized by a band-like circular depression, 2–4 cm in width. Patients have also been described with lipoatrophy of the ankles which can extend up the legs (Fig. 55.25) [6]. The overlying skin is normal. An association with osteodystrophy of the hands and feet has also been reported [7].

The loss of fat develops rapidly within several weeks, usually without associated symptoms, although rheumatic-like pains within the involved areas were reported by two women. Trauma is a possible triggering mechanism—a series of seven cases has been reported in individuals working in the same office. The exact position of the indentations corresponding to the height of the desks strongly supports the hypothesis that in some patients this condition is caused by repetitive trauma to the upper thighs [8].

Fig. 55.25 Extensive lipoatrophy of the legs.

Primary inflammatory vascular changes in the subcutaneous tissue have been demonstrated in these patients, and also during the early period of other lipoatrophies [9]. There is no treatment, but considerable improvement may occur after the activity of the disease settles.

Centrifugal lipodystrophy. Lipodystrophia centrifugalis abdominalis infantalis is rare and has been seen predominantly in Japanese children [10–14], affecting the subcutaneous fat, usually of the abdomen and upper groin. Patients of Chinese and English ancestry have been reported [15]. The condition spreads in a centrifugal fashion with a central large bluish depressed area and slight erythema of the edge. Further experience has shown that the original name is inappropriate, because the condition may affect other areas and may occur outside infancy and not affecting the abdomen [16,17]. The condition may be strikingly unilateral [18,19]. One case is reported to have lasted over 40 years, and was associated with angioblastoma, which occurred at the same site at the age of 46 years [11]. Regional lymphadenopathy may occur [13]. A 10-year-old boy with a centrifugal lipodystrophy also developed serpiginous erythema of the scalp with

scarring alopecia [20]. Ulceration may also be a complication [21].

Histology shows a decrease in the subcutaneous fat with an inflammatory infiltrate in the lower dermis and subcutis. Immunocytochemistry has more recently suggested the possible involvement of apoptosis as a factor responsible for fatty tissue degeneration [22]. A patient has been reported who showed characteristics of both centrifugal and progressive lipodystrophy [17].

Treatment. Treatment is disappointing, although after the disease activity has ceased there seems to be regrowth of fat in 75% of cases. Some improvement has been reported in most cases treated with oral and topical corticosteroids [10].

Partial or generalized lipoatrophies [1–4]

In these rare syndromes there is extensive absence or progressive loss of subcutaneous fat. Several syndromes are described: congenital generalized lipodystrophy, acquired generalized lipodystrophy, partial (cephalothoracic) lipodystrophy and partial face-sparing lipodystrophy [5]. Genetic explanations for the disease are increasingly being reported.

Congenital generalized lipodystrophy

SYN. LIPOATROPHIC DIABETES; LAWRENCE–SEIP SYNDROME; BERARDINELLI–SEIP SYNDROME

A rare congenital generalized lipoatrophy, sometimes familial, with loss of the subcutaneous and visceral fat, hepatomegaly, increased bone growth, hyperlipaemia and, later, diabetes mellitus [1,6,7].

Aetiology. The inheritance is probably autosomal recessive, and it is suggested that patients with the full syndrome are homozygous; heterozygous subjects manifest hyperlipaemia only. Gene alterations on chromosome 11q13 have been reported [8,9]. The pathogenesis is unknown, but a defect in the diencephalon or hypothalamus has been suggested [10], because some patients have an increased level of hypothalamic releasing factors. A defect in the insulin receptor gene has been reported [11].

Histopathology. There is complete loss of subcutaneous and visceral fat.

Clinical features. There is complete loss of subcutaneous and other fat, noticeable at birth or before the age of 2 years. Detailed metabolic and radiological studies have shown poor metabolically active adipose tissue, whereas mechanical adipose tissue is well preserved [12]. Hepatomegaly (occasionally with splenomegaly), hyperlipaemia and sometimes cutaneous xanthomas, hypertrichosis, hypermetabolism and excessive bone growth are characteristic. Younger patients show glycosuria only when given large amounts of glucose. Hyperglycaemia with excessive thirst and polyuria usually develop only after the age of 10 years. The diabetes is insulin resistant. Although there is complete loss of fat, the skin retains its elasticity. The loss of fat is usually quite widespread, but can be localized to the legs [13]. There is often generalized hypertrichosis, even at birth, and the scalp hair becomes abundant and often curly with the onset of disease. The scalp hair is frequently luxuriant, almost reaching the eyebrows. There is precocious enlargement of the genitalia, and in females marked enlargement of the clitoris.

As a result of increased bone growth, the children are tall for their age; the somatic musculature is increased and the abdomen markedly protuberant, often with an

umbilical hernia. All patients have a remarkably similar facial appearance, most have a dolichocephalic skull. The loss of facial fat gives a very characteristic gaunt appearance. The joints, particularly of the hands and feet, are enlarged. Widespread pigmentation, particularly of the axillary and inguinal folds, may be associated with linear epidermal thickenings, giving the appearance of acanthosis nigricans [1,7].

A proportion of congenital cases have progressive hypertrophic cardiomegaly [14], renal anomalies such as nephrotic syndrome, nephromegaly, medullary hyperechogenicity [15] and neurological disorders (including mental deficiency and hemiplegia). Pregnancy in such patients is most unusual, but can be associated with a successful outcome.

Some patients may have increased plasma levels of corticotrophin-releasing factor, follicle-stimulating hormone-releasing factor and melanocyte-stimulating hormone-releasing factor, presumably caused by neurological dysfunction [10].

X-rays show focal bone lesions, which on MRI can be shown to be caused by absence of marrow fat.

Acquired generalized lipodystrophy

When the onset is in the adult, excessive height is not a feature, muscularity is less obvious and abdominal protuberance not so marked. However, acromegaloid features with enlargement of the skin, hands and feet may precede the diabetes. The acquired type is frequently heralded by a febrile illness. Death from hepatic failure or haematemesis is usual.

Differential diagnosis. In congenital cases, differentiation from de Lange's disease may be difficult, especially if neurological features are present. In adult cases, the differential diagnosis is from acromegaly and thyrotoxicosis.

Insulin lipoatrophy in diabetics is focal, and usually confined to the sites of insulin injection.

Treatment. The response to treatment is poor. Pimozide, a selective dopaminergic blocker, may be helpful in restoring the fat and decreasing the levels of hypothalamic-releasing factors [10]. A diabetic diet may control glucose levels, and lipid-lowering agents and plasmapheresis may improve the hyperlipidaemia [16]. Specific anatomical defects can be improved, such as the repair of severe buttock deformities with bilateral gluteus maximus muscle flap advancements [17].

Partial lipoatrophy [1,2]

SYN. PARTIAL LIPODYSTROPHY; BARRAQUER–SIMONS DISEASE; PROGRESSIVE LIPODYSTROPHY

This rare lipoatrophy occurs either in childhood or in young adults as an incidental part of a widespread mesodermal atrophy. The partial lipodystrophy locus has been mapped to chromosome 1q with no evidence of genetic heterogeneity [3].

Aetiology. Most patients are children or young adults when the disorder begins, but onset in the first year and in middle age is reported. Females are affected four or five times more frequently than males [4], and the condition is sometimes familial. It may follow an acute specific fever such as measles, but the common occurrence of non-specific fevers makes proof of this observation difficult. Facial hemiatrophy associated with loss of subcutaneous fat in borreliosis has been reported [5]. Partial lipodystrophy has followed damage to the region of the mid-brain or diencephalon [6]. The association of lipodystrophy with immunologically related renal disease [4,7–10], systemic sclerosis [11], systemic lupus erythematosus [12] and high titres of thyroid antibodies supports the view of lipodystrophy being an immunological disorder in some patients [13], but one that requires more investigation.

Fig. 55.26 The typical cadaveric facies of a patient with partial lipodystrophy. She also has melasma.

It is difficult to explain the abnormal distribution of adipose tissue in partial lipodystrophy. Fatty tissue autotransplanted to an atrophic site lost fat, while atrophic tissue autotransplanted to a fatty site accumulated it, suggesting that local factors determine the distributions of fat [14]. The local factor may be neuronally mediated, as suggested by observations that there may be symmetrical segmental loss of fat, and the line demarcating dystrophic and normal tissue in partial lipodystrophy may correspond to a dermatome. Jensen [15] described increased adrenergic activity in a patient with partial lipodystrophy, and proposed that this was of significance, as adipocytes in the upper body are sensitive to the lipolytic effects of epinephrine (adrenaline) and those in the lower body are not.

Histopathology. There is usually complete loss of adipose tissue over the affected areas.

Clinical features. The disease is characterized by the relatively slow symmetrical disappearance of the facial fat, producing a cadaverous appearance (Fig. 55.26) and complete loss of the subcutaneous fat in the upper half of the body (Weir–Mitchell type). In some cases, there is a coincidental hypertrophy of the subcutaneous fat of the lower part of the body (Laignel-Lavastine and Viard type) [3]. Ten per cent may have 'hemilipodystrophy' involving half of the face or body. Up to 90% can develop progressive membranous mesangiocapillary glomerulonephritis [3,16,17] and this can be precipitated by the contraceptive pill, pregnancy (especially in the third trimester) or the use of ergot derivatives [4]. A successful outcome in pregnancy is uncommon [18]. Thus, such patients should be observed by a renal physician during pregnancy, and oral contraceptives are prohibited.

The association of hypocomplementaemia and mesangiocapillary glomerulonephritis is now well established [7,8]. Approximately half of the patients with this form of glomerulonephritis have a persistently low plasma concentration of the third component of complement (C3), while the concentration of the fourth component (C4) is normal. This is accompanied by the presence of a factor in serum that is capable of activating C3 without activation of the earlier components. This material has been termed 'C3 nephritic factor' or C3NeF [6]. Lupus, C3 nephritic factor and partial lipodystrophy are perhaps not as rare as previously thought [19,20]. Juvenile dermatomyositis is also a rare association [21].

The relationship between C3NeF, persistently low C3 and mesangiocapillary glomerulonephritis is not clear. It has been suggested that the C3NeF predisposes the glomerulus to the development of mesangiocapillary glomerulonephritis in response to some other agent. In a series of 12 patients, four died from renal failure 10–25 years after the onset of the partial lipoatrophy [4]. Transplantation in one case resulted in normalization of C3 and the disappearance of C3NeF [16].

Insulin-dependent diabetes mellitus develops in one-third of patients with partial lipodystrophy. Retinitis pigmentosa, acanthosis nigricans and hepatomegaly are rare associated features [2]. Chronic purpura resulting from leukocytoclastic vasculitis has been reported [22]. This patient had extensive and moderate hypertrophy of the subcutaneous fatty tissue, macroglossia, polyarthralgia and mononeuritis. Myopathy associated with muscle weakness has rarely been reported, and is caused by fat droplets between the myofibrils [23]. Mammography in patients with partial lipodystrophy reveals unusually dense breasts with homogeneous opacities and ectopic fat depositions. These changes are possibly diagnostic, but confusing to the ill-informed radiologist [24].

Treatment. There is little effective treatment, other than the prevention and treatment of kidney disease. New plastic surgical techniques, including free radial forearm adipofascial flaps, can markedly improve the facial appearance [25,26].

Partial face-sparing lipodystrophy

SYN. KOBBERLING–DUNNIGAN SYNDROME

This even rarer form is a genetically heterogeneous set of disorders characterized by a widespread but partial absence of subcutaneous fat usually sparing the face and neck; it can be easily missed because of the normal facial appearance [1]. Insulin-resistant diabetes, hypertriglyceridaemia and pancreatitis may coexist, but renal disease as yet has not surfaced. An autosomal dominant inheritance has been reported in some patients with the so-called Dunnigan subtype, who have a chromosomal abnormality on 1q21-22 [2,3]. As new reports appear, more types of lipodystrophy are likely to be reported, as is evidenced by a report of a patient with mental retardation, generalized lipodystrophy, diabetes and dysmorphic traits [4,5]. These patients do not at all fit into previously reported lipodystrophies.

Lipodystrophy associated with protease inhibitors

Lipodystrophy has been reported in HIV-infected patients taking protease inhibitors, which have been recommended since 1996 as standard therapy for such patients in combination with nucleoside analogues. In these cases, lipodystrophy consists of an association of peripheral lipoatrophy with central adiposity [1]. The incidence of such lipodystrophy, lipodystrophy with subcutaneous lipoatrophy, and lipodystrophy with central obesity were 11.7 in 100 patient-years. An increased risk for any lipodystrophy is found among women as compared with men, heterosexuals and homosexuals as compared with intravenous drug users, with increasing age, and with the duration of exposure to antiretroviral therapy but not with any individual antiretroviral agent [2]. Reversion of the lipodystrophy does not occur after withdrawal of protease inhibitors [3].

In a further study on 614 patients, 20 months after initiation of protease inhibitor therapy, a cross-sectional study demonstrated that 23% of patients had abnormal glucose metabolism, 20% had hypertriglyceridaemia and 57% hypercholesterolaemia [4]. Cardiovascular problems in such patients not surprisingly occur with significant frequency.

This syndrome associated with protease inhibitors also occurs in children but less so if they received a lower dose of the protease inhibitor [5].

Treatment simplification approaches in which protease inhibitors are replaced by nevirapine have been shown to improve the lipid profile of these patients [6]. Treatment with dehydroepiandrosterone and indometacin can improve the lipid abnormalities, the abnormalities of glucose metabolism and the lipodystrophy. The mechanism of action of this combination may relate to the underlying peroxisome dysregulation induced by protease inhibitors.

Summary of the metabolic abnormalities in lipodystrophies

It has been suggested that reduced synthesis and secretion of adipose-specific proteins may relate to the metabolic complications of lipodystrophies [1]. The authors measured fasting serum concentrations of adiponectin and leptin in patients with a variety of lipodystrophies. Patients with congenital generalized lipodystrophy and acquired generalized lipodystrophy had markedly reduced serum adiponectin levels compared to those with familial partial lipodystrophy. The same trend was noted for serum leptin levels. Serum adiponectin levels correlated negatively with fasting serum triglycerides and insulin levels, and positively with serum high-density lipoprotein cholesterol levels. These results indicated that adiponectin and leptin levels are extremely low in patients with generalized lipodystrophies, and may be related to the severe insulin resistance and its metabolic complications in such patients.

Further support for this link comes from the fact that chronic leptin treatment (recombinant mathionyl human leptin) improves insulin-stimulated hepatic and peripheral glucose metabolism in severely insulin-resistant lipodystrophic patients [2,3]. This therapy also influences, directly or indirectly, menstrual regularity. Of five patients so treated, only one female was cycling normally before therapy; all had normal menses by the fourth month of leptin therapy [4].

Lipomas

Lipomas are benign tumours composed of mature fat cells. They are found in the subcutaneous tissue and less commonly in internal organs.

Aetiology. The metabolic changes associated with benign tumours are varied but include fundamental defects responsible for the altered growth properties of the tumour. It has been demonstrated that loss of negative-feedback control regulatory enzymes (by citrate or phosphofructokinase) may be an early feature in the development of lipoma [1].

Histopathology. Fat cells in groups slightly larger than the normal lobule are typically enclosed within a capsule of connective tissue, but the capsule may be deficient and the tumour then appears locally invasive. Relatively large blood vessels are seen traversing the connective tissue septa. Primitive fat cells may be found in clinically benign lipomas in children [2]. Xanthomatous and mucinous changes appear in many lipomas. Lipomas exhibit, like many other solid tumours, distinctive cytogenic abnormalities (karyotypic aberrations affecting mainly 12q,6p,13q). Such distinctive changes may be of help in histologically borderline or difficult cases [3]. There are also a variety of rare lipomatous-like tumours; the reader is referred to specialized texts [4].

Clinical features. A lipoma is a subcutaneous nodule, often lobulated, with a characteristic soft putty-like consistency. The overlying skin is normal and moves freely over the tumour, and feels cooler than the surrounding skin. The tumour grows very slowly to reach a diameter that is usually between 2 and 10 cm but may be considerably greater. The most common sites are the neck, shoulders and upper arms, back and thighs. There are rarely any subjective symptoms, but pain from pressure on the nerves is sometimes experienced. Another rare event is infiltration of adjacent tissues in a particular muscle [5]. In these patients, there is a high recurrence rate after surgical intervention because of its diffuse infiltration; thus complete surgical excision is often impossible [6]. Fat necrosis may cause enlargement, pain and tenderness. A large lipoma on the exposed skin of the lower legs is susceptible to nodular perniosis.

There may be only one lipoma, or large numbers [7] may develop at intervals over a period of years. Seven per cent of patients with lipoma have multiple lesions [8,9]. Such lipomas may be randomly distributed, or more or less confined to one region of the body. In most patients,

the presence of multiple lipomas appears to have no special significance [2]. They may, however, be associated with neurofibromatosis, or with visceral lipomas in the respiratory, alimentary or genito-urinary tract. Tendon sheath lipomas are rare but usually associated with a mild disomfort [10]. They are an inconstant feature of Gardner's syndrome, in which they are associated with multiple sebaceous cysts, osteomas and polyposis of the colon.

Atypical lipomatous tumours are uncommon and occur predominantly in middle-aged patients; they often present as slow-growing masses in the extremity. Fifty-two per cent had a recurrence at an average of 4.7 years after resection, of which 39% required additional surgical procedures [11]. Occurrence of a deep lesion and positive margins at the time of the initial surgery correlated closely with the rate of recurrence and the need for additional surgical treatment. The differentiation into a high-grade liposarcoma developed in 13% of such patients [11]; such a malignant change is very rare.

Diagnosis. The diagnosis is usually easy, but in cases of doubt a biopsy should be performed. Angiolipomas are morphologically similar to lipomas, but are intermittently painful. Lipofascial herniae in the natal or perianal region simulate lipomas. Excision and suture are required to prevent recurrence. Mobile encapsulated lipomas are literally very mobile and can be moved from side to side over a range of up to 8 cm [12].

An epidermoid cyst can mimic a lipoma. However, the presence of the central punctum gives a clue to the correct diagnosis. The possibility of hibernoma should be considered when tumours appear in the neck and scapular region.

Treatment. This usually depends on the patient's desire for the lipoma to be surgically removed. Lipoma of the lumbar region may be associated with underlying spina bifida occulta, and removal of the tumour is dangerous without simultaneous exploration of the cauda equina. An MRI scan is essential in such patients; the spinal cord involvement is more frequent in girls than in boys, as is significantly associated with bladder dysfunction [13].

Angiolipoma

Angiolipomas are benign encapsulated lobulated tumours differing histologically from a lipoma in the excessive degree of vascular (capillary) proliferation. Fibrin thrombi are common. Approximately 10% of all lipomatous lesions examined pathologically are angiolipomas [1]. The age of onset is relatively young, and in one series of 288 patients averaged 17 years. Clinically, the lesions are from 0.5 to 5 cm in diameter and closely resemble lipomas. They are usually painful and tender and are sometimes bluish in colour [2]. The degree of pain varies with the degree of vascularization. They occur most frequently on the arms, legs and abdomen and are often multiple [3].

Angiolipomas are categorized into two groups: infiltrating and non-infiltrating [3]. The non-infiltrating angiolipoma is typically a soft well-encapsulated subcutaneous nodule. The non-infiltrating type occurs in younger individuals and is usually painful. Compression of nerve fibres that accompany the vascular channels may cause pain, which is usually dull. The infiltrating type, which is the less common type of angiolipoma, has a more aggressive behaviour, and can infiltrate osseous, muscular, neural and fibrocollagenous tissues. It may cause signs and symptoms that can simulate malignant neoplasms. The infiltrating type has the propensity to recur following local surgical excision; therefore the treatment for infiltrating angiolipoma is wide excision to include normal tissue surrounding the tumour. Associated features are rare; the association of multiple angiolipomas, multiple cerebral aneurysms and multiple meningomas has been reported [4].

Three cases of HIV-1 infected patients have been described who developed symptomatic angiolipomatous shortly after starting antiretroviral therapy, including protease inhibitors [5].

Painful lesions can be excised if single. Conventional analgesics usually do not help. Multiple lesions have been shown to respond to β-blockade with atenolol (50 mg/day). Pain relief was evident after 24 h. Therapy should be continued for a pain-free period of 2–3 months [6]. A double-blind study proved the benefit of intravenous

lidocaine (lignocaine) (5 mg/kg) in saline given over 45 min. The pain disappeared after 1–2 days but reappeared 3 weeks later [7]. Infiltrating angiolipomas need wide excision [8]. Liposuction has been successfully used in one patient [9].

Frontalis-associated lipoma [1,2]

This is a deeply placed lipoma of the forehead, which deserves special mention because it is often mistaken for an epidermoid cyst. The lipoma presents a smooth doughy dome-shaped mass, which appears relatively immobile and the skin glides over it. It arises either within the frontalis muscle or between the undersurface of the muscle and its deep fascia, and its removal requires greater surgical skill than is required for removing an epidermoid cyst or lipoma. A layered closure is essential to repair the severed frontalis muscle, and a pressure dressing is advisable to close the 'dead space'.

Fat-storing hamartoma of dermal dendrocytes

One patient has been described with a congenital reddish brown plaque over the lumbosacral area, which was composed of dermal dendrocytes that had phagocytosed lipid droplets [1]. There were no fat cells in the lesion and no associated metabolic abnormalities.

Hibernoma [1–3]

SYN. GRANULAR CELL LIPOMA

A rare benign tumour, which consists of primitive fetal brown fat. The histology is characteristic, showing masses of distinctive cells with fine granules and a solitary central nucleus [1–3]. The tumour is encapsulated and multilobular. It occurs in adults of either sex and presents as a firm non-tender nodule, with vascular dilatation of the overlying skin. The sites of predilection are the cervical, axillary and interscapular regions. Surgical excision is the only treatment. Local recurrence at excision is unusual [4].

Lipomatosis

Several different types of lipomatosis have been described.
1 Multiple symmetrical lipomatosis, characterized by a symmetric formation of fatty tumours, associated with signs of mediastinal location and neuropathy.
2 Pelvic lipomatosis, characterized by fat accumulation in the pelvic cavity with vesical and ureteral displacement, compression and occlusion.
3 Mediastino-abdominal lipomatosis, characterized by intrathoracic and intra-abdominal accumulation of fat, mimicking respiratory disease or ascites.
4 Mediastinal lipomatosis, frequently associated with long-term oral steroid exposure.
5 Renal sinus and perirenal lipomatosis, characterized by a tumour-like accumulation of fat in the renal and perirenal space inside the renal capsule.
6 Adiposis dolorosa, or Dercum's disease, a disease affecting women, characterized by the formation of painful para-articular lipomatous masses.

The cutaneous lipomatoses [1,2] are well-defined but rare syndromes of which two major types are identified: the symmetrical and non-symmetrical varieties. Both produce marked disfigurement. Except in the rare cases when they compress a vital structure, they usually present no physical threat to the patient. Both are benign and non-encapsulated, and represent progressive growth and extension of mature adipose tissue far beyond its normal proportions. The fat accumulation is caused by an increase in cell number rather than cell size by a zonal differentiation of adipoblasts into mature adipocytes [3].

Non-symmetrical lipomatosis

The most common albeit rare form of localized lipomatosis is the non-symmetrical subcutaneous lipomatosis. It is a benign entity and normally has no clinical significance except for the cosmetic disability. A localized form affecting the shoulder girdle [4,5] may infiltrate the deeper structures and produce distal symptoms. A case has been reported with tuberous sclerosis, but the association may be fortuitous [6]. It is not usually the result of any metabolic disturbance, and is not usually associated with abnormalities of lipid metabolism; in one case there was familial hyperlipidaemia [7]. It is familial and the mode of inheritance suggests an autosomal dominant trait [7]. Other associations include ipsilateral cranial and facial asymmetry, cranial and ocular manifestations, alopecia, spasticity and mental retardation. These associations occur with what is called encephalocraniocutaneous lipomatosis—a very rare syndrome [8,9]. It has been suggested that this syndrome is a variety of Proteus syndrome, in which such patients have hyperostoses of the skull, cutaneous lipomas outside the skull and visceral lipomatoses [10].

Multiple symmetrical lipomatosis

By contrast, multiple symmetrical lipomatosis (Fig. 55.27) is characterized by large symmetrical masses of fat, mainly in the neck and shoulder region in a horse-collar distribution. MRI can be used to characterize the nature and extent of disease [11,12]. It may be associated with hypertriglyceridaemia, elevated high-density lipoprotein cholesterol [13], hyperuricaemia, impaired glucose tolerance and renal tubular acidosis. The lipomatous tissue in these patients has been shown to have enhanced lipoprotein lipase activity [14], a possible explanation for the elevated high-density lipoprotein cholesterol levels displayed by these patients. The inheritance in this type is autosomal dominant. Specific chromosomal abnormalities have been reported [15]. Mitochondrial dysfunction is common in multiple symmetrical lipomatosis and may be based on identifiable defects in the mitochondrial genome [16].

These patients may also have severe peripheral and autonomic neuropathy [17], often alcoholism and mediastinal lipomas producing space-occupying symptoms [18]. Sebaceous naevus of Jadassohn has been reported in association with mediastinal lipomatoses [19]. Fifty per cent have alcohol-induced problems [2]. An unusual patient had benign symmetrical lipomatoses and giant rhinophyma producing a grotesque appearance [20]. Madelung's neck, probably the same condition, is a diffuse multilobular lipomatosis involving the back of the neck and the shoulders in a cape-like distribution. It classically afflicts wine porters and brewery workers. The disease may infrequently be sited in the upper thighs and lower abdomen [21]. Localization to the soles has been reported [22]. Localization of the symmetrical lipomatoses to the tongue results in macroglossia. Therapy is partial glossectomy [23].

Fig. 55.27 Multiple symmetrical lipomatosis. (Courtesy of M.C. Rodrîguez-Cerdeira, R. Trillo and X.C. Brana, Meixoerio Hospital, Vigo, Spain.)

The prominent fat deposits over the buttocks that constitute the steatopyga of the Bushmen and Hottentots may be regarded as a racial form of physiological lipomatosis. A distal form of acquired symmetrical lipomatosis of the hands has been reported in a chronic alcoholic Bantu male [24].

Treatment of lipomatosis is difficult. It includes classical lipectomy [25,26] but recurrence is common. Liposuction [27–29] has been reported to help considerably.

Congenital diffuse lipomatosis [1–4]

This has been infrequently recorded. Several syndromes that may involve a neuroectodermal defect have been described, in conjunction with various types of haemangioma or lymphangioma. Congenital lipomatosis may be associated with angiomatosis and macroencephalia (Bannayan's syndrome) [5]. The Proteus syndrome is very rare; the clinical features include hemihypertrophy, macrodactyly, exostoses, epidermal naevi, characteristic cerebriform masses involving the plantar or palmar surfaces, a variety of subcutaneous masses and scoliosis [6]. Histological examination of the subcutaneous masses has identified a variety of lipomatous and angiomatous tumours and hamartomas.

Treatment. Treatment is difficult but liposuction may help.

Dercum's disease

SYN. ADIPOSIS DOLOROSA

Dercum's disease is a rare progressive disease characterized by localized overgrowth of fat with painful subcutaneous plaques and ecchymoses.

Aetiology. The mechanism of Dercum's disease is not known. It most commonly affects menopausal women; they are usually obese at the time of onset of the disorder and severe emotional disturbance is common. In some families there is a dominant inheritance [1].

Histopathology. The changes are non-specific; there is a combination of fat cell necrosis and interstitial tissue proliferation.

Clinical features [2,3]. Dercum [4] coined the term 'adiposis dolorosa' to describe three cases of a syndrome characterized by painful deposits of adipose tissue occurring over multiple areas of the body (Figs 55.28 & 55.29). Adiposis dolorosa occurs predominantly in postmenopausal women (female : male ratio of up to 30 : 1) and is associated with weakness, fatigue and, frequently, emotional disturbances. Obesity is almost always present initially, but patients may lose weight and become asthenic as the syndrome progresses. The painful areas of fat may occur as subcutaneous 'lumps', which feel like a 'bag of worms' on palpation, or may be diffuse in a localized or generalized pattern. The juxta-articular areas are the most commonly involved site, but painful areas have been described over virtually all areas of the body. The pain occurs with palpation of the involved fat, but may also occur spontaneously. The disease usually begins gradually with only mild discomfort, but may progress to exquisite pain, particularly with movement, so that the patient is effectively immobilized. The pain tends to be cyclical with constant mild to moderate discomfort punctuated by episodes of severe pain, which is unresponsive to many or all analgesic agents.

Psychic disturbances are frequently observed, ranging from mild irritability to dementia. Depression, failure of memory and hypochondriacal complaints are quite common.

Fig. 55.28 Dercum's disease. (Courtesy of Dr R. Motley, University of Wales College of Medicine, Cardiff, UK.)

Diagnosis. This is not difficult when the classical triad is present: painful plaques, ecchymoses and obesity, appearing in women with amenorrhoea and neurotic symptoms.

Cushing's disease with diffuse deposition of fat, plethora and hirsutes must be distinguished from Dercum's disease. Amenorrhoea and ecchymoses are common to both disorders.

Treatment. Weight reduction and surgical excision of individual tumours may be helpful [5]. The pain is usually unresponsive to conventional therapy but several cases have been shown to respond to intravenous lidocaine [2,6–10]. Two studies were placebo controlled. The pain relief was from 3 to 52 weeks, and repeat therapy was associated with increasing duration of benefit [2,9]. The lidocaine effect is very specific, as other types of pain

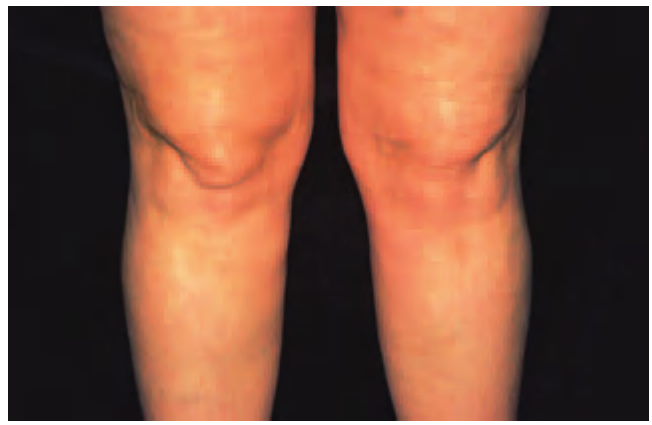

Fig. 55.29 Dercum's disease showing much improvement after liposuction. (Courtesy of Dr R. Motley, University of Wales College of Medicine, Cardiff, UK.)

(e.g. headaches) continued; the mechanism of action is unknown. Some response to mexiletine 150–750 mg orally has been reported [11].

Chapter 56

The 'Connective Tissue Diseases'

M.J.D. Goodfield, S.K. Jones & D.J. Veale

Introduction

Many single diseases can produce pathology in one or multiple organ systems. However, not all of the conditions that can affect multiple organ systems are related to each other, so what is it that determines the classification of diseases as 'connective tissue diseases'? We recognize that there are certain features common to all of them—the existence of autoimmunity in the form of autoantibody production or disordered cell-mediated immunity, vascular abnormalities characterized by Raynaud's phenomenon, occlusive vascular disease and vasculitis (although the pathology is not entirely a result of vascular inflammation), arthritis or arthralgia, and skin disease. However, dependence on clinical patterning is unreliable because similar patterns of disease may be seen with widely different pathologies. For instance, the primary vasculitides such as Wegener's granulomatosis or polyarteritis nodosa may share many systemic features of the connective tissue disorders, but so may sarcoidosis with a granulomatous pathology but without autoantibody production.

Despite this problem, it is still true that those disorders contained within the umbrella of the 'connective tissue diseases' share many clinical and pathological features. Indeed, it was this pathological similarity that first suggested that abnormalities of the connective tissue might be the common factor linking these conditions. In 1933, Klinge [1] was the first to propose that rheumatic fever and rheumatoid arthritis were disorders of the entire connective tissue. The changes in the intercellular components of the connective tissue, the presence of fibrinoid necrosis in collagenous tissue and the myxomatous swelling of ground substance were similar to those seen in experimental animals made hypersensitive to foreign protein, and for these reasons he concluded that the rheumatic diseases were caused by hypersensitivity. He included other conditions in which fibrinoid necrosis was a feature, such as polyarteritis nodosa, dermatomyositis and malignant hypertension. The presence of widespread fibrinoid change in the vessels led to the inclusion of systemic sclerosis by Masugi and Yä-Shu [2], and also of systemic lupus erythematosus. However, Klemperer *et al.* [3], with whose work the term 'collagen disease' is associated, struck a note of caution by pointing out that fibrinoid necrosis could be seen in the absence of hypersensitivity mechanisms, for example, in the base of peptic ulcers. It has been stated [4] that the presence of fibrinoid degeneration does not warrant the grouping of the conditions showing this change, nor does it imply an allergic mechanism. It is now recognized that there are various types of fibrinoid with somewhat similar staining properties. They have a multiple origin from the degeneration of collagen, from the ground substance, muscle and fibrin and other plasma proteins.

In 1950, Klemperer [5] stated: 'The term diffuse collagen disease was originally applied to acute and chronic maladies which are characterized anatomically by generalized alterations of the connective tissue, particularly by abnormalities of its extracellular components. In this case the term can include rheumatic fever, rheumatoid arthritis,

polyarteritis nodosa, acute lupus erythematosus, generalized scleroderma and dermatomyositis.' Klemperer emphasized his dissention from the widespread indiscriminate use of the term 'collagen disease' for disorders with unusual clinical or pathological features. He confirmed that his sole intention was to put forward the concept that, 'in certain diseases anatomical investigations reveal conspicuous alterations in the intermediary substances of the connective tissue in a systemic manner'. It is now realized that the connective tissue is not the only tissue involved in these disorders.

It has been customary to consider that systemic and discoid lupus erythematosus (SLE and DLE), systemic sclerosis, localized and generalized morphoea, dermatomyositis, rheumatoid arthritis and Sjögren's syndrome should be grouped together, and this has been supported by evidence of clinical, pathological and immunological overlap. The primary vasculitides, such as polyarteritis nodosa, Wegener's granulomatosis and giant cell arteritis, are sufficiently distinct to be considered separately, although there is much clinical overlap with these diseases too. However, these groupings may not be justified and may even hamper our understanding of these diseases. On the other hand, certain patients with evidence of clinical overlap can be distinguished by characteristic immunological abnormalities, associated with differences in outcome and response to therapy. With the passage of time, other conditions, sometimes newly described, such as eosinophilic fasciitis [6], may have to be added to the group.

There is an urgent need for precise and universally acceptable criteria for diagnosis. When adequate criteria and modern investigative techniques are used, it is apparent that each disorder can usually be distinguished as a separate entity. For example, evidence has been produced that DLE is a separate disorder and not a benign variant of SLE [7–9]. Often, subsets can be distinguished clinically, pathologically or immunologically. Immunological subgroupings are becoming more numerous and complex with the identification of new antigens and the reacting autoantibodies. Specific antibodies may be strongly associated with particular disease patterns, such as the antibody to extractable nuclear antigen found in mixed connective disease or anti-Ro or anti-La antibodies in a clinically distinctive type of lupus erythematosus called subacute cutaneous lupus erythematosus (SCLE; see p. 56.24). Moreover, certain diseases that appear clinically homogeneous may be genetically heterogeneous. The separate genotypes in DLE related to age of onset [8,9], the clinical subsets in SLE and the severity of disease in systemic sclerosis related to HLA-B8 [10] are good examples.

Despite these improvements in investigational techniques, diagnosis of these disorders is sometimes far from easy. Results have to be interpreted in the context of the clinical presentation. Patients are not helped by a diagnosis of 'collagen vascular disease' or 'collagenosis' when suffering from an illness with obscure symptoms and signs, possibly associated with an elevated plasma viscosity, and a weakly positive antinuclear antibody. It is the resort of the intellectually destitute and must be avoided. It is usually ultimately possible to make a precise diagnosis. This is very important for the patient and critical for research, both epidemiological and therapeutic. It is more than an academic exercise as, in the future, specific therapy may well depend on the precision of diagnosis.

Accurate naming of diseases is important for patients, but is also relevant to this chapter. Is the term 'the connective tissue diseases' [11] the most appropriate title for this contribution? We believe that it is because there seems to be no better alternative. Some authorities prefer the older term, 'collagen disease'; others [12] apply it to all inherited or acquired disorders of the connective tissue system. 'Collagen disease' is incorrect because there is no evidence that collagen is primarily at fault. 'Collagen vascular disease' conveys a little more detail, but is still incorrect. The increasing emphasis on immunological abnormalities in these conditions has brought the terms 'autoimmune disease' [13] and 'immunological disease' [14] some popularity, but both are overinclusive. To avoid the premature coining of a confusing new term we have preferred to continue to refer to 'connective tissue disease' wherever the use of a collective term is unavoidable.

Lupus erythematosus [1,2]

Lupus erythematosus (LE) is usually divided into two main types: DLE and SLE (defined on pp. 56.5 and 56.28

Table 56.1 Comparison of data on a series of patients with discoid and systemic lupus erythematosus seen by the authors.

	Discoid lupus erythematosus (n = 120) (%)	Systemic lupus erythematosus (n = 40) (%)
Rash	100	80
Joint pains	23	70
Fever	0	40
Raynaud's phenomenon	14	35
Chilblains	22	22
Poor peripheral circulation	26	32
ESR > 20 mm/h	20	85
Serum globulin > 3 g (%)	29	76
LE cells	1.7	83
Antinuclear factor(s)	35	87
Homogeneous	24	74
Speckled	11	26
Nucleolar	0	5.4
Precipitating autoantibodies	4	42
WR positive	5	22
Rheumatoid factor positive	15	37
Direct Coombs' test positive	2.5	15
Leukopenia	12.5	37
Thrombocytopenia	5	21

ESR, erythrocyte sedimentation rate; LE, lupus erythematosus; WR, Wassermann reaction.

respectively). Although some authors [3] would prefer the term cutaneous LE to DLE, we are continuing to use the term DLE in view of the long usage and to avoid confusion with SCLE. Others [4] suggest classifying LE into three groups—cutaneous LE, intermediate LE and SLE, but this is still controversial. DLE can be subdivided into a localized form in which lesions are confined to the face above the chin, the scalp and the ears, and a disseminated form in which lesions also occur elsewhere on the body [5,6]. Although haematological and serological abnormalities occur slightly more frequently in the disseminated form, the natural history of the two subgroups is similar, and it is likely that they are subsets of the same disorder. SCLE has been described as a subset intermediate between DLE and SLE [7].

The more controversial point is whether DLE and SLE are variants of the same disease. The evidence in favour of this may be summarized as follows:

1 The cutaneous lesions of SLE and DLE may be clinically and histologically indistinguishable.

2 Certain clinical features are found in both conditions (Table 56.1).

3 Similar haematological, biochemical and immunohistochemical abnormalities can be demonstrated in both conditions (Table 56.1), although the incidence of abnormalities is lower in DLE.

4 Patients with DLE occasionally develop evidence of overt SLE.

5 Patients with SLE may develop typical lesions of DLE when the active phase subsides [8].

6 Conditions such as lupus panniculitis, a recognizable clinical and pathological entity, occur in both DLE and SLE.

This seems to be formidable evidence, but the following observations require explanation.

1 The risk of a patient with DLE developing overt SLE is small. It varies from 1.3% [9] to about 6.5% [2,10–12]. The risk is higher in patients with disseminated DLE (22%) than in DLE confined to the head and neck (1.2%) [12]. In some series [13–15], such conversion was not encountered despite follow-up for nearly 30 years. A retrospective study [16] of 127 patients with SLE showed that eight patients had had discoid lesions from 2 to 29 years.

2 The presence of laboratory abnormalities in DLE does not in itself appear to predispose to the development of SLE [17], although they are common in disseminated DLE [12,18]. Haematological abnormalities were still present in 50% of 77 patients with DLE 5 years after initial assessment, yet none had developed SLE in the same period [14]. The same prognosis was found in a subgroup intermediate between discoid and SLE as in patients with uncomplicated LE [15].

3 Immunoglobulins and complement are present in uninvolved skin of patients with SLE and absent in patients with DLE [19].

4 Most patients with DLE exposed to UV radiation, stress, trauma, etc., do not develop the systemic disease.

5 The age and sex distribution of SLE [20,21] is strikingly different from that of DLE [15,22].

It has been proposed [2,21–24] that both SLE and DLE are initiated by the occurrence of somatic mutations in lymphocytic stem cells of predisposed individuals, and that they are genetically distinct. There are at least three genotypes related to age of onset in DLE [24] and the female/male ratios found in each disease suggest that

there is only one X-linked allele involved in genotype 2 and two in genotype 3. On the simplest interpretation, three 'forbidden clones' [25] of lymphocytes synthesizing cellular autoantibodies develop in SLE, whereas only one 'forbidden clone' is involved in DLE. Autosomal predisposing alleles are probably also present in all the genotypes in both SLE and DLE. The nature of these somatic mutations and the predisposing alleles remain unkown, but almost certainly include polymorphisms of genes determining the production of inflammatory cytokines [26].

6 Further evidence that DLE and SLE are genetically different disorders is now available from studies of histocompatibility antigens in the two diseases [27]. There is a significant difference in the incidence of HLA-B8 in female patients developing each disease between the ages of 15 and 39 years. It is considered that patients may have the predisposition to SLE, DLE or both. Those patients who 'convert' from DLE to SLE, and those patients with SLE who have discoid skin lesions, must be genetically predisposed to both conditions. Those patients with only a genotype for DLE will never convert, even when subjected to environmental factors, such as drugs, bacterial or viral infections, UV radiation and stress. More recent molecular genetic data give further support to this concept [28].

At present it is not possible to determine the genetic pattern of individual patients or to predict accurately the small proportion of patients with DLE-like lesions who will develop SLE, although the link with HLA-B8 has already been discussed [27]. Humoral autoantibodies are not the primary pathogen in these diseases [29], but they probably reflect the underlying cell-bound autoimmunity that causes the disease. Nevertheless, they may enhance tissue damage [30], and specific antibodies may be responsible for certain features such as the risk of neonatal LE (anti-Ro) and for thrombosis (the lupus anticoagulant). The ability to synthesize particular antinuclear antibodies may depend on additional genetic factors, and this could account for the absence of such antibodies in certain patients with active disease. If the possession of a serological abnormality in DLE implies a predisposition to transformation into systemic disease, we would expect the sex ratio of this group to be similar to that for SLE. This is not the case [11]. The sex ratio in patients with DLE and laboratory abnormalities is not significantly different from the sex ratio in patients without abnormalities.

From consideration of the clinical features, the natural history, the age and sex distribution, and studies of histocompatibility antigens, it is concluded that patients with DLE and haematological and serological abnormalities are not cases of SLE in disguise, but are cases of DLE, which is a separate entity from SLE, and has a different genetic background. Each of these entities, however, consists of several subsets, also genetically determined.

Discoid lupus erythematosus

SYN. CUTANEOUS LUPUS ERYTHEMATOSUS; CHRONIC DISCOID LUPUS ERYTHEMATOSUS

Definition. DLE is a benign disorder of the skin, most frequently involving the face, and characterized by well-defined red scaly patches of variable size, which heal with atrophy, scarring and pigmentary changes. The histology is characteristic. There are haematological and serological changes in approximately half of patients, and these changes, with other evidence, suggest an autoimmune aetiology.

Aetiology. This disorder has a characteristic age and sex pattern. The disease affects twice as many females as males, with a peak age of onset in the fourth decade in females and slightly later in males, although it can occur at any age. In a series of 1045 cases, 3% began under 15 years of age and 2.5% at over 70 years [1].

Genetic factors. Differences in the incidence of histocompatibility antigens [2–4] have supported the concept of multiple genotypes. Positive associations with HLA-B7, -B8, -Cw7, -DR2, -DR3 and -DQw1 are reported [5,6], but not always confirmed. The relative risk is increased with certain combinations of antigens—HLA-Cw7, -DR3 and -DQw1 and for HLA-B7, -Cw7 and -DR3. The extended haplotype—HLA*01, B*08, DRB1*0301—is associated with both SCLE and DLE, and the A*03, B*07, DRB1*15 haplotype has been associated with DLE alone [5]. Patients of both sexes developing lesions between the ages of 15 and 39 years have an increased incidence of HLA-B7, and females over the age of 40 years of HLA-B8, compared with controls [3]. Familial cases do occur [6]. A family history was found in 4% of one series [7]. Steagall *et al.* [8] reported the condition in identical twin sisters, and listed 25 families with two or more members who had DLE or SLE. Recent studies also indicated a striking relationship between polymorphic light eruption and DLE, first in twins [9] and then in a large cohort of patients and their relatives, suggesting a common genetic background for these disorders [10]. DLE has been noted in three consecutive generations [11].

It has been proposed that genetic factors, including somatic mutations, are implicated in the pathogenesis of the disease [11–13]. In a mathematical model based on the age of onset of the disease, there are at least three genotypes and probably a fourth corresponding to those 'transitory' cases [14] in which immunoglobulins are present at the dermal–epidermal junction of uninvolved skin. The relative size of these subgroups may differ between countries, because of differences in the frequency of the predisposing genes. The initiation of the disease may result from the occurrence of random events, either related to somatic mutation or to environmental factors. The model suggests that: (i) three mutations affecting autosomal genes; (ii) four mutations (one of which affects an X-linked gene); or (iii) five mutations (one involving an X-linked gene) could explain the three genotypes. As a result of the mutations, control of lymphocytes is lost and, after a latent period of approximately 4 years in females and 2 years in males, clinical signs of the disease become manifest. Normally, an endogenous defence mechanism appears to be directed against the uncontrolled lymphocytes. Environmental factors, by interfering with this defence mechanism, can precipitate or exacerbate the disease. Supporting this view, DLE-like lesions have occurred after allogeneic bone marrow transplantation [15].

Environmental factors. The onset of lesions may be precipitated by a variety of factors. At Leeds, lesions started with trauma in 11%, with mental stress in 12%, sunburn in 5%, infection in 3%, exposure to cold in 2% and pregnancy in 1%. The types of trauma included splashing with hot fat, a scratch on the nose and various types of wounds and scars. In the remainder (approximately two-thirds), lesions started apparently spontaneously. Once lesions had developed, exacerbations occurred particularly with exposure to sunlight and trauma.

Lodin [16] noted a lower incidence of trauma (2.2%) and included exposure to X-rays, diathermy and chemical burns, and lesions in scars of herpes zoster. DLE has developed in an old smallpox vaccination scar [17] and precisely in the field of radiation given for bronchogenic carcinoma [18]. DLE may have followed gas tungsten arc welding [19], psoralen and UVA (PUVA) therapy [20] and laser therapy [21]. Occasionally, drugs (e.g. isoniazid [22], penicillamine [23], griseofulvin [24] and dapsone [25]) may precipitate lesions of DLE. Patients with the primary antiphospholipid antibody syndrome may also develop DLE [26].

The finding of antibodies to reovirus RNA in 42% of patients suggests that viruses may have a role in DLE [27]. The significance of the finding of tubular structures, approximately 20 nm in diameter and similar to paramyxoviruses, in endothelial cells, perivascular histiocytes or fibroblasts [28,29], particularly of new lesions, is not yet known. They are found in the lesions of DLE but only occasionally in uninvolved skin [30]. A decrease in the frequency and size of these structures has been observed after chloroquine therapy [31]. It is possible that they are of viral origin.

Once lesions have developed, exacerbations may be associated with a variety of factors. In 120 patients at Leeds, a history of exacerbations with sunlight was found in 68%, but others have disagreed [32]. In those with photo-aggravated disease, both wavelengths shorter than 329 nm [33] and the whole range through UVB, UVA and visible light can produce lesions under experimental

conditions [34]. Skin lesions clinically and histologically compatible with lupus erythematosus (LE) were induced by UVB and UVA radiation in 42% of patients with DLE, 64% of patients with SCLE and 25% of patients with SLE [35]. Seventeen per cent of patients notice an exacerbation with cold, but more than half of patients note that the condition worsens in the summer, whereas 10% are worse in winter. Approximately 13% of patients notice a premenstrual deterioration. The effect of pregnancy is variable [36], as is the response to hormone replacement therapy [37].

There is no doubt that worry and anxiety play a part, and 16% of patients have noticed lesions deteriorating at such times.

Pathology [1]. The various clinical types of LE show an essentially similar histological picture (Figs 56.1 & 56.2) [2], and the subsets of LE cannot be distinguished histologically [3]. The salient features are as follow:

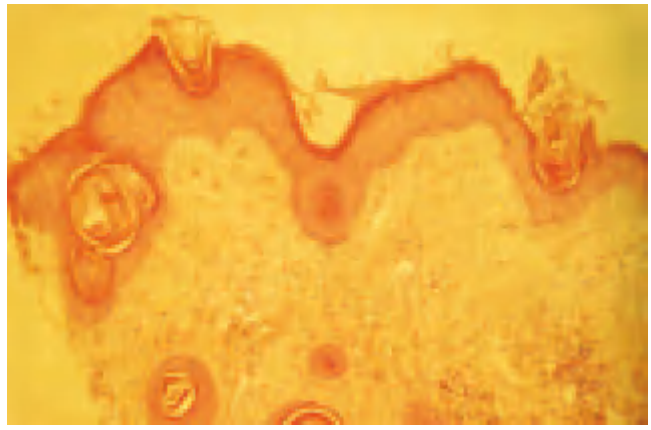

Fig. 56.1 Discoid lupus erythematosus: there is atrophy of the epidermis, keratotic plugging, liquefaction degeneration of the basal layer, oedema and hyalinization of the connective tissue below the epidermis and a marked inflammatory infiltrate.

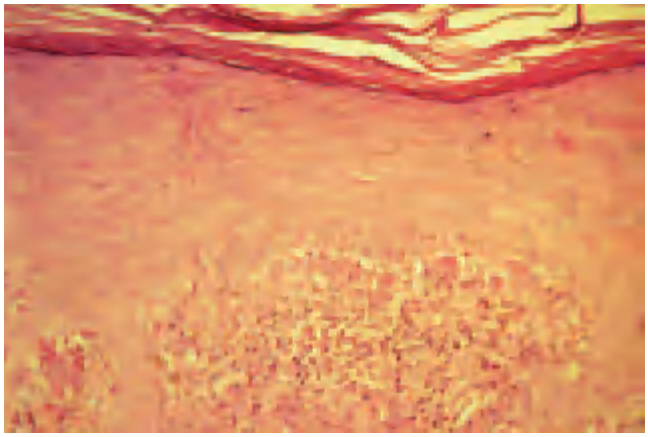

Fig. 56.2 Discoid lupus erythematosus: the degeneration of the basal layer and predominantly lymphocytic infiltration are well shown.

1 Liquefaction degeneration of the basal cell layer of the epidermis
2 Degenerative changes in the connective tissue, consisting of hyalinization, oedema and fibrinoid change, most marked immediately below the epidermis
3 A patchy dermal lymphocytic infiltrate with a few plasma cells and histiocytes, particularly around the appendages, which may be atrophic.

The presence of at least two of these is essential to the histological diagnosis of LE. The majority of infiltrating lymphocytes are T lymphocytes [4] and express Ia-like antigens, as well as the γ/δ T-cell receptor [5]. The following changes may also be found, but are less important:
1 Thinning and pallor of the epidermis with relative hyperkeratosis and plugging of the follicular mouths
2 Thickening of the basement membrane of the epidermis and sometimes of small vessels
3 Premature elastotic degeneration of collagen in light-exposed areas.
In tumid lesions the dermal infiltrate can be very dense, and sometimes almost granulomatous. Dermal deposits of mucin occur [6], which may be diffuse or localized, and form nodular lesions. Deposits may be very gross [7]. Occasionally, irregular hyperplasia of the epidermis occurs, and there may be clefts, or even bullae, between the dermis and epidermis. Although keratotic plugs are usually found in the openings of the hair follicles, they may also block the sweat ducts or occur independently of either structure. Sometimes, the hair follicles contain concentric layers of keratin instead of hairs. Pilosebaceous atrophy is a characteristic feature of DLE [8]. Atrophy of the prickle cell layer occurs to a variable extent, and sometimes there may be acanthosis. Melanin may be found in the upper dermis as the result of pigmentary incontinence. Blood vessels are dilated and the upper dermis is oedematous. Sections stained with the periodic acid–Schiff (PAS) technique show thickening of the basement membrane.

Table 56.2 Diseases associated with the presence of immunoreactants at the dermal–epidermal junction that may be confused with lupus erythematosus.

Mixed connective tissue disease
Systemic sclerosis
Dermatomyositis
Sjögren' syndrome
Myasthenia gravis
Porphyrias
Granuloma annulare
Necrobiosis lipoidica
Amyloidosis
Graft-versus-host disease
Psoriasis
Pyoderma gangrenosum
Sarcoidosis
Leprosy
Erythema multiforme
Pityriasis lichenoides acuta
Granuloma faciale
Keratoacanthoma
Scabies
Facial telangiectases
Bullous pemphigoid

Immunopathology. Immunohistology [9,10] shows the presence of immunoglobulins IgG, IgA, IgM and complement at the dermal–epidermal junction, in skin lesions present for 6 weeks or more, in approximately 80% of patients [11,12]. Homogeneous, granular or thready patterns occur, but the deposition is usually homogeneous in older lesions. They are more frequent on the face and in untreated lesions, but are rare on the trunk [13], and decrease after treatment with topical corticosteroids. They do not occur in uninvolved skin, unlike the majority of cases of SLE. For the diagnosis of DLE lesions, light microscopy is most valuable and should be carried out before direct immunofluorescence [14]. Immunoreactants are also found in oral mucosa and the conjunctiva [15]. C1q deposits are found in 29% of patients with immunofluorescent-positive DLE, compared with 90% in SLE, and the presence of such deposits implies an increased risk of eventual systemic disease [16]. Deposits at the dermal–epidermal junction are not specific to LE and have been found in many other circumstances (Table 56.2). However, in these diseases the deposits are less prominent at the dermal–epidermal junction and are more striking in the blood vessel walls. In LE, the deposits are heavy and contain several immunoglobulin classes, whereas in the other diseases only a single immunoglobulin class is usually present. In scarring alopecia caused by LE, the deposits occur around hair follicles, a feature not seen in other types of scarring alopecia [17].

Properdin has been demonstrated at the dermal–epidermal junction in 70% of lesions, usually in association with deposition of immunoglobulin, C3 and C4 [18]. It may also be found in non-lesional skin. Serum

properdin levels are raised compared with controls, as they are in patients with clinically active SLE [18]. In more acute forms there is less hyperkeratosis and dermal infiltration, but more dermal oedema, liquefaction necrosis and atrophy. Disruption of the elastic lamina and, rarely, endothelial proliferation and thrombosis of the deeper vessels of the dermis have been reported [19]. Biopsy material from lesions on the palms stained for alkaline phosphatase activity shows irregular capillary loops with branching, 'dead end' spurs and coiling [20]. In SLE, similar changes are found in involved and uninvolved skin.

Chronic DLE must be differentiated from five other conditions in which lymphocytic infiltrations of the dermis occur.

1 In Jessner's lymphocytic infiltration [21], the dermis shows large circumscribed aggregations of lymphocytes, often concentrated round the dermal appendages and blood vessels, with a normal epidermis. Sometimes, the infiltrate may extend into the fat of the subcutaneous tissues. Immunohistochemical studies show that the cells are predominantly T lymphocytes [22], as they are in DLE and SLE [23]. Monoclonal antibody studies show an increase in natural killer (NK) cells and activated cytotoxic T lymphocytes in Jessner's lymphocytic infiltration [24].

2 In polymorphic light eruption (PLE), the infiltrate is less prominent and more likely to occur around blood vessels than cutaneous appendages. Liquefaction degeneration is infrequent but, if present, it may be difficult to distinguish from that of DLE. There may be spongiotic changes in the epidermis and parakeratosis (the histology has some features of eczema, but the dermal infiltrate is usually denser). Lever and Schaumburg-Lever [25] believe that most cases of Jessner's lymphocytic infiltration and the plaque-type of PLE represent variants of chronic DLE, but immunoglobulin does not occur at the dermal–epidermal junction in either of the first two conditions [26,27].

3 Scattered patches of lymphocytes occur in the dermis in lymphocytic lymphoma, but there are no epidermal changes.

4 The infiltrate in lymphocytoma cutis (Spiegler–Fendt sarcoid; see Chapter 54) is usually separated from the normal epidermis by a band of normal collagen, and consists of lymphocytes and a few histiocytes. Sometimes, a follicular arrangement is present, with lymphocytes surrounding islands of histiocytes resembling lymph node follicles.

5 In benign lymphocytic infiltration, polyclonal T and B cells form aggregates in the dermis.

Sometimes, patients show clinical, histopathological and immunofluorescence overlap between DLE and lichen planus [28,29]. In such cases, a definite diagnosis cannot always be made, and it is likely that such patients have both diseases [30]. A major immunohistological finding is the presence of fluorescent ovoid bodies at the dermal–epidermal junction and in the dermis [29], which may be associated with a linear band of immunoglobulins, complement or fibrinogen.

Incidence. Because the condition is persistent, DLE appears to be more common than it really is. The incidence among new patients in the Department of Dermatology at Leeds is approximately 4 or 5 in 1000. It is said that it is only half as frequent in black people [1], although the distribution is worldwide.

Clinical features

Symptoms. The patient usually presents with a rash, but on questioning a history of Raynaud's phenomenon, chilblains or poor peripheral circulation is often obtained. In 120 patients at Leeds, 14% had Raynaud's phenomenon and 22% had chilblains; a poor peripheral circulation, without a definite story of Raynaud's phenomenon, was noted in a further 26% of patients. Joint pains are complained of by approximately one-quarter of patients, but this is similar to the incidence in controls [1]. Most patients have no symptoms of systemic upset, even with widespread cutaneous disease.

Most patients have disease limited to the head and neck (localized DLE), but a few have much more extensive disease, potentially affecting any area of the skin (disseminated DLE).

Localized disease. The face is most commonly affected, and the scalp, ears, nose, arms, legs and trunk to a lesser extent. The circumscribed or discoid type is the most frequent (Fig. 56.3), and occurs particularly on the cheeks, the bridge of the nose, the ears, the side of the neck and the scalp. Lesions may be bilateral, although not necessarily symmetrical, or unilateral. Alopecia occurs in the scalp lesions in approximately one-third of patients [2], and is usually permanent (Fig. 56.4). The eyebrows may be sparse, with erythema of the eyebrow skin. Usually, lesions occur as well-defined erythematous patches, varying in size from a few millimetres to 10–15 cm. There is adherent scale in many cases, and when this is removed its undersurface shows horny plugs which have occupied dilated pilosebaceous canals. This so-called 'tin-tack' sign can sometimes also be seen in localized pemphigus foliaceus [3]. When not obscured by scaling, these horny plugs can be seen on direct examination. The surface may present a dirty brownish yellow appearance that is rough to the touch, because of the follicular plugging. If hyperkeratosis is marked, a warty lesion with a red, slightly raised edge results. This warty type of LE is most commonly seen on the nose, temples, ears and scalp, but may also occur on the palms and soles and cause difficulty with walking (Fig. 56.5) [4].

Fig. 56.3 Discoid lupus erythematosus: the typical scaling is well shown.

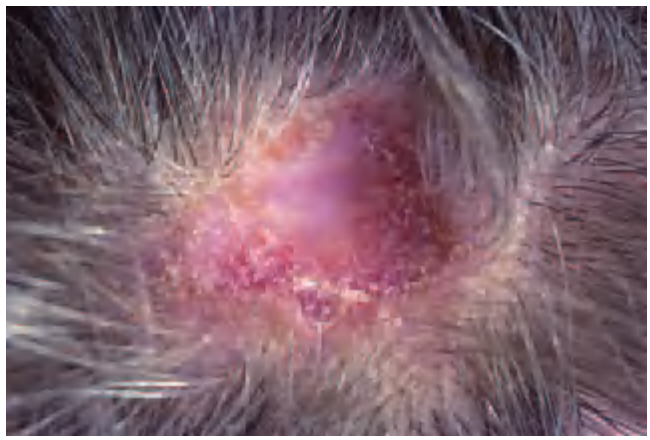

Fig. 56.4 Discoid lupus erythematosus of the scalp: note the follicular plugging.

Non-itching hyperkeratotic papulonodular lesions on the arms and hands, resembling keratoacanthoma, hypertrophic lichen planus or nodular prurigo, also occur [5]. Sometimes, the appearance resembles psoriasis. In other cases, there may be very little hyperkeratosis. Lesions

Fig. 56.5 Warty lesions of the feet in chronic lupus erythematosus.

Fig. 56.7 Discoid lupus erythematosus in a black person.

Fig. 56.6 Discoid lupus erythematosus: the pre-auricular type with pigmentation around the scarred area.

Fig. 56.8 Discoid lupus erythematosus in an Asian patient, showing marked hyperpigmentation at the border of the affected area.

then present as reddish, well-defined, almost smooth plaques with little or no scaling. Sometimes, these plaques may show prominent flattening in the centre, giving rise to annular lesions. Over the course of some months, particularly if treated, lesions flatten and may clear completely without much scarring. More frequently, a thin white scarred area, often with a slightly raised, red border or zone of hyperpigmentation, remains (Fig. 56.6). Localized cribriform scarring occurs, particularly on the face. Pigmentary disturbances are common, especially in dark-skinned people, and there is some evidence that DLE is more severe in black people (Figs 56.7 & 56.8) [6]. Patches of leukoderma may be interspersed with hyperpigmented areas. If relapse occurs, it usually starts in the reddish zone surrounding the scar. Calcification may occur in the plaques [7]. Lesions on the ear lead to considerable atrophy and scarring (Fig. 56.9). Wide follicular pits, sometimes containing scale or blackheads, occur mainly in the concha or triangular fossa of the ear (Fig. 56.10). They occur in up to one-third of cases [8] of DLE but they also occur in SLE. A pruritic chronic discrete umbilicated papular eruption may occur on the back, and results in acneiform hypertrophic follicular scars [9]. In approximately 7.5% of patients, the lesions on the face resemble rosacea, and differentiation can be difficult, particularly as in approximately 15% of cases patients with

Fig. 56.9 Discoid lupus erythematosus of the ear with scarring and atrophy.

Fig. 56.10 Discoid lupus erythematosus: characteristic pits in the ear.

Fig. 56.11 Discoid lupus erythematosus: a rosaceous pattern seen in 7.5% of patients.

true rosacea show exacerbation by sunlight. LE of this type presents with reddish nodular lesions on the nose, cheeks, forehead and sometimes chin, and is associated with a diffuse erythema of the face and easy flushing. Usually, there are no pustules as in true rosacea (Fig. 56.11) [10]. Low-titre antinuclear antibody in rosacea can be ignored [10]. Biopsy may be required to distinguish between LE and rosacea. Tumid lesions may occur, in which the tissues are swollen, brawny, warm and tense (Fig. 56.12). The surface shows a reddish, mottled appearance resulting from scarring. This type of lesion may be many centimetres in diameter and involve the whole of one cheek, or even the whole of a limb. Another clinical type of DLE results in annular atrophic plaques [11] on the face, neck and behind the ears. The centre of the plaques is depressed and sclerotic, and the lesions resemble morphoea, lichen sclerosus or 'annular atrophic plaques' [12]. Early lesions show IgG and complement at the dermal–epidermal junction [11], but repeated biopsies may be necessary to confirm the diagnosis.

Disseminated DLE (DDLE). Characteristic lesions of DLE may occur in a widespread pattern on the trunk and limbs, or may be localized to other body sites. This occurs almost always in women, and they are usually cigarette smokers. The appearance may be indistinguishable from the papulosquamous type of SCLE (see p. 56.24), but

Fig. 56.12 Discoid lupus erythematosus: tumid lesions of the face.

Fig. 56.13 Discoid lupus erythematosus: plaques on the back of the hands.

Fig. 56.14 Discoid lupus erythematosus: characteristic redness and scaling of the toes.

Fig. 56.15 Telangiectatic lupus erythematosus of the cheek.

scarring occurs in most patients. This variety tends to be persistent, resistant to therapy and associated with severe psychological upset. Lesions on the dorsa of the hands (Fig. 56.13), palms [4] or toes (Fig. 56.14) [13] occurred in 6% of patients at Leeds. Purplish plaques may occur on the front of the knees and on the back of the heels. Another disseminated variety results in a reticulate telangiectasia, usually seen on the arms, legs and the back of the calves. This type of telangiectasia is probably similar to 'lupus erythematosus telangiectoides', first described by Crocker [14]. Behçet [15] reviewed this clinical variant, which occurs in SLE as well as in DLE. The appearances are characterized by a persistent blotchy reticulate telangiectasia, which occurs on the face, neck, ears, dorsa of the hands, breasts, heels and on the sides of the feet (Fig. 56.15). Healing occurs with punctate atrophic scarring. The histology of this type of lesion shows an atrophic epidermis, with dilatation of the superficial vessels of the skin and slight infiltration of the papillary part of the corium. A further, more annular variant has been called 'lupus erythematosus gyratus repens' and consists of a migratory gyrate annular erythema with the histological features of LE, although the lupus band test is negative [16]. There may be an underlying carcinoma.

Fig. 56.16 Unusual spindling of the fingers and hyperextension of the distal phalanges in discoid lupus erythematosus.

Fig. 56.17 'Chilblain' lesions in a patient with Ro-positive systemic lupus erythematosus.

Occasionally, one or more fingers may show a curious atrophic spindling, sometimes with hyperextension of the terminal phalanges and dystrophy of the nails (Fig. 56.16). The fingers and toes may become markedly atrophic, with patchy erythema and tuft resorption on X-ray. Rarely, bullous lesions [17] may occur. Arteritic lesions resembling those of Degos' syndrome or disseminated atrophie blanche occasionally occur, and linear lesions following Blaschko's lines have been reported [18].

'Chilblain lupus' (Fig. 56.17) [19]. Approximately 6% of patients, predominantly female, develop chilblain-like lesions chiefly on the toes and fingers, but also on the heels, calves, knees, knuckles, elbows, nose and ears. Usually, but not always, the chilblain lesions occur some years after the development of discoid lesions on the face. It can be precipitated by pregnancy [20]. When the discoid lesions remit with treatment, the chilblains persist. Less commonly, discoid and perniotic lesions start simultaneously, and sometimes perniotic lesions occur alone. Histology and immunohistology is that of DLE, and the non-lesional skin gives a negative fluorescent band test. Some patients may have cryofibrinogenaemia or cold agglutinins. Patients are usually Ro antibody-positive [21]. They are also either smokers, or have markedly abnormal peripheral circulation with low resting blood flow [22]. Approximately 15% of patients develop SLE, and this occurs more frequently in those who develop both forms of cutaneous LE simultaneously and in those with the erythema multiforme syndrome.

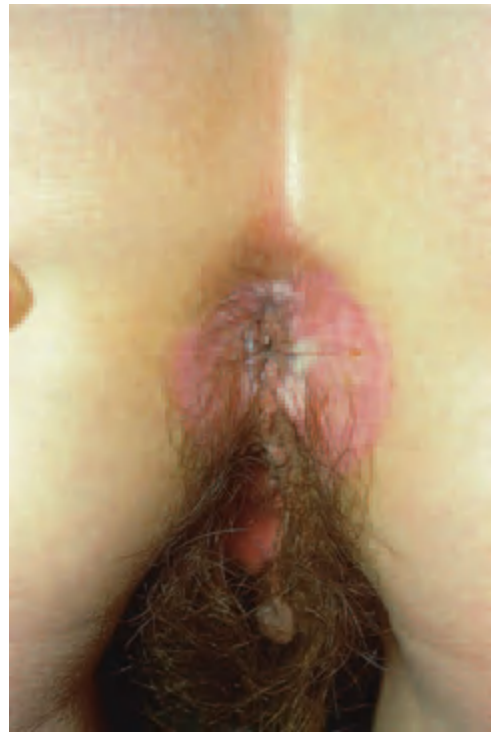

Fig. 56.18 Discoid lupus erythematosus of the perianal area.

Nail changes. Subungual hyperkeratosis is more common than the red-blue colouring of the nail plate with longitudinal striae and crumbling away of the nail [22]. The changes may respond to chloroquine.

Mucous membranes [23]. These are involved in approximately 24% of patients. Nasal mucosal lesions occur in 9% and hyperkeratotic lichen planus-like plaques on the buccal mucosa and palate in a similar number. The lips show slight thickening and roughness and redness, sometimes with superficial ulceration and crusting. Healing occurs with some scarring. Erythematous patches with a depressed centre and superficial ulceration occur on the inner cheeks, tongue and on the palate. Oral lesions may resemble leukoplakia [24]. Erythematous lesions occur on the vulva in 5% [23], or around the anus (Fig. 56.18) [25].

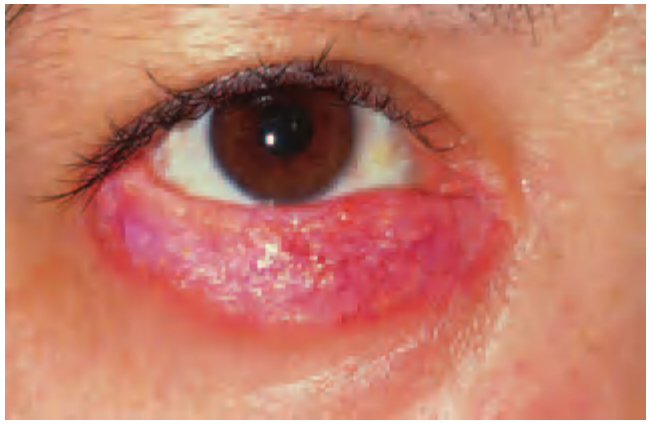

Fig. 56.19 Discoid lupus erythematosus of the lower eyelid.

Eye lesions. Velvety oedema and marked redness of the conjunctiva may occur. Palpebral lesions have been reported without lesions elsewhere on the face [26]. The eyelids are red, especially peripherally, and are slightly infiltrated and always scaly. The horny spikes of follicular plugging are seen on removal of the scale. They are most common on the lower eyelids, especially on the outer third. The free edge is rarely completely involved. Erythematous plaques on the lower eyelids occur in 6%, and may be associated with conjunctival scarring (Fig. 56.19), and symblepharon [27]. The lesions may itch, and are exacerbated by trauma and sunlight. Corneal involvement is rare. Superficial punctate keratopathy and stromal keratitis have been reported [28]. Acute mucinosis of the eyelids and periorbital skin can occur [29].

Lupus erythematosus and erythema multiforme-like syndrome (syn. Rowell's syndrome) [1–4]. The distinctive syndrome of cutaneous LE, either discoid or systemic, occurring with lesions resembling erythema multiforme on the face, neck, hands, chest and in the mouth (Fig. 56.20) was first

Fig. 56.20 Annular lesions of discoid lupus erythematosus resembling erythema multiforme and associated with characteristic immunological abnormalities (Rowell's syndrome).

described by Rowell in 1963 in patients with discoid LE, but may be seen in both subacute and systemic disease. Characteristically, it lasts from a few days to over a month, but episodes may occur at intervals over a period of 20 years. No precipitating factor can be elicited. The lesions are at first papular, but later a ring forms and the edge becomes vesicular. Bullae, necrosis and ulceration may develop if the reaction is intense, although sometimes healing occurs without scarring. Patients with this syndrome also frequently have perniotic lesions [5]. They show a characteristic pattern of serological abnormality, in that the speckled type of antinuclear factor is associated with rheumatoid factor and the same precipitating antibody to saline extract of human tissues (anti-SjT). Anti-SjT is now thought to be identical to anti-La (SS-B). The syndrome has been reported in identical twin sisters, one of whom had DLE and the other SLE [3]. In patients with SLE, the homogeneous type of antinuclear antibody may also be present in the serum. When the syndrome occurs in DLE, the dermal–epidermal band test is positive in the discoid lesions and negative in the erythema multiforme lesions. If the LE is systemic, the bullous lesions show positive findings comparable with those seen in the uninvolved skin of patients with SLE [2]. The syndrome may be confused with patients showing coincidental LE and erythema multiforme [6]. In one case, anti-SS-B antibody and rheumatoid factor only developed after the erythema multiforme-like lesions appeared, suggesting that these factors are not just incidental findings but may have a role in the clinical presentation [7]. A maintenance regimen of prednisolone may keep patients with SLE clear of lesions [8].

Childhood DLE [1]. DLE is uncommon in childhood. There appears to be no female preponderance, there is less photosensitivity and the frequency of progression to systemic disease is higher. The other clinical features are similar to those in adults.

Lupus erythematosus profundus (panniculitis) (Fig. 56.21) [1]. This is an unusual clinical variety of LE in which the cutaneous infiltrate occurs primarily (but not always exclusively) in deeper portions of the corium, with only microscopic epidermal changes, giving rise to firm, sharply defined nodules from one to several centimetres in diameter, lying beneath clinically normal skin [2]. The histopathology is sufficiently characteristic to make the diagnosis in the absence of other cutaneous or systemic lesions of LE [3]. LE profundus occurred in six out of 228 patients with DLE [4,5], and in four out of 86 in another series [6]. It can occur at any age and has been described in childhood [7]. The age and sex distribution of published cases is similar to that of DLE [8]. The earliest age reported is 3 months [9]. Familial cases have been reported [4]. One patient had four first-degree relatives with LE, and the condition also occurred in two sisters. It has been seen in three generations of one family [10].

Kaposi first described subcutaneous nodules in LE in 1883 [11], but Irgang [12] first used the term 'lupus erythematosus profundus' in 1940. Some authors [13] have considered the lesions to be sarcoid, but it is now usually accepted as a variant of LE [14], related more to DLE than SLE [15]. Although Arnold [2] considered that it was different from 'lupus erythematosus hypertrophicus et profundus' described by Behçet [16], this seems unlikely. In the latter, the overlying skin is abnormal, with raised scaly plaques, whereas in LE profundus it is usually normal. Subcutaneous nodules also occur in SLE [17], and sometimes antinuclear antibody and other immunological abnormalities can be demonstrated in LE profundus. Deep dermal and subcutaneous lymphocytic infiltrates

Fig. 56.22 Anetoderma secondary to lupus erythematosus profundus.

were found in 28 out of 100 histological sections of DLE, and in eight of these the infiltrate was extensive enough to be considered as LE profundus [14].

Histopathology. Microscopically [15], there may be epidermal atrophy, hydropic degeneration of the basal layer, follicular plugging and necrosis of the dermal collagen, suggesting LE. Collections of lymphocytes may occur around skin appendages and vessels in the mid-dermis. There is a striking lower dermal and subcutaneous necrobiosis, with some vasculitis and little cellular response. The collagen fibres in the lower dermis, in the septa and between the fat cells are swollen and poorly stained, and in some areas homogeneous masses and amorphous eosinophilic material replace the collagen. Immunofluorescence microscopy frequently shows linear staining at the basement-membrane zone [18]. Immune complexes can be demonstrated by direct fluorescence in small deep vessels in the dermis [19].

Clinical features. The nodular lesions are of varying size, but are usually one to several centimetres in diameter. They are usually firm, rubbery, sharply defined and persistent. The overlying skin usually appears normal, although histologically there are changes at the dermal–epidermal junction in 61% [20]. Typical lesions of DLE may be found elsewhere, most frequently on the cheeks, but they can occur on the face, arms, hands, breasts, buttocks, trunk or legs. Healing usually leads to the development of depressed areas, and rarely to soft, slightly pink areas of anetoderma (Fig. 56.22) up to 4 cm in diameter. Cutis laxa followed one case [21]. Lupus profundus confined to the breast has been called lupus mastitis and may herald SLE. It may be confused with carcinoma [22]. LE profundus may affect the periorbital tissues and cause severe localized oedema [23,24]. It may occur with eyelid plaques [25]. Wherever it occurs, the nodules are persistent, and lesions in the cheeks may lead to marked disfigurement.

LE hypertrophicus et profundus starts as a violaceous scaly tender lesion, which rapidly enlarges, developing a warty hypertrophic surface with coarse adherent scales, which form a hard brown-black tar-like plaque [19]. Patients with LE hypertrophicus et profundus may have extensive serological abnormalities [19], and antibodies to extractable nuclear antigen (ENA) may sometimes be present [26]. In the legs, it may initially resemble thrombophlebitis [27]. No characteristic immunological or genetic markers have been demonstrated in this subset [27]. Calcification can occur, and may be extensive, with the extrusion of thick, yellowish white material through ulcerated areas.

Associated diseases. LE profundus followed thrombocytopenic purpura in one case [13]. Lesions can occur after trauma or surgical biopsy [19], and have been precipitated by electromyography [28]. Monoclonal gammopathy has been reported in LE profundus [29].

Treatment. Clobetasol propionate cream (Dermovate) under a hydrocolloid occlusive dressing (Granuflex) is worth trying [30]. Antimalarial drugs are helpful [2,4,8], including in children [31]. Intralesional injections of triamcinolone (5 mg/mL) may be helpful [32]. Oral thalidomide has resolved resistant lesions, and this has been confirmed in a patient with associated partial C4 deficiency [33].

Associated features. Small telangiectases on the face occur in approximately 20% of patients. These dilated vessels may sometimes resemble spider naevi, but are usually small capillaries of irregular size and distribution, particularly on the cheeks. Dilated nail fold capillaries, similar to those seen in SLE and dermatomyositis, may be visible with the naked eye in 3%, and sometimes there may be erythema of the pulps of the fingers. More than half of patients state that they have a dry skin. Very occasionally, mild diffuse alopecia may occur, similar to that found in SLE, and alopecia areata has occurred in 10% of one series of DLE and mild SLE [1].

Bilateral enlargement of the parotids has been reported [2,3]. Histologically, there is lymphocytic infiltration of the parotid, which is said to be like that of LE profundus [3]. The parotid swelling may increase with exposure to sunlight and decrease during treatment with antimalarials and corticosteroids [3].

Livedo reticularis on the legs has been reported in DLE, and in one case cryoglobulins were intermittently demonstrated in the serum [4].

Porphyria cutanea tarda and, less commonly, variegate porphyria or acute intermittent porphyria may occur in patients with LE, including those showing discoid lesions [5,6]. Porphyria cutanea tarda may be precipitated by antimalarial therapy [7]. Erythropoietic protoporphyria may also occur [8]. The relation to pemphigus, myasthenia gravis and thymoma has been discussed [9].

DLE has also been associated with chronic lymphatic leukaemia, macroglobulinaemia [10], polychondritis [11], autoimmune thyroiditis [12], carpal tunnel syndrome [13], PLE [14], Sheehan's syndrome [15] and erysipelas [16]. Two siblings showing an autosomal form of chronic granulomatous disease with DLE-like lesions have been reported [17]. An illness resembling LE, especially of the discoid type, occurs in mothers of boys with X-linked chronic granulomatous disease. In these maternal carriers, a population of defective leukocytes can be demonstrated. Photosensitivity, chilblain LE of the fingers and toes, rosaceous lesions on the face, LE profundus and Jessner's lymphocytic infiltration-like lesions and stomatitis occur [18–20].

Hereditary C2 deficiency occurs in association with skin lesions resembling the discoid lesion of SLE [21]. Homozygous C2 deficiency in females is the most common association, but DLE has also been reported in heterozygous C2 deficiency [22]. Low levels of C4 have been demonstrated in two sisters [23]. Hereditary deficiency of the third [24] and of the fifth component of complement has also been associated with a lupus-like syndrome [25]. DLE has also occurred with C1q deficiency [26]. Identical twin boys have been reported with DLE skin lesions, immunological abnormalities of SLE and hereditary angio-oedema with low C1 inhibitor and C4 [27]. DLE is associated with classical hereditary angio-oedema with reduced levels of C1-esterase inhibitor [28]. Approximately 2% of patients with hereditary angio-oedema have LE-like disease [29]. A classic case of DLE with the less common variant form of hereditary angio-oedema has been reported [30], in which normal levels of C1-esterase inhibitor were present but activity was decreased.

Laboratory abnormalities in DLE. The incidence of laboratory abnormalities in 120 patients is shown in Table 56.1 [1]. Abnormalities were found in 55% of patients. Anaemia, leukopenia or thrombocytopenia can be found in approximately one-third of patients, and the erythrocyte sedimentation rate (ESR) is raised in 20%. The serum globulin is raised in 29% of patients, elevation of gammaglobulin being the most common abnormality. Higher mean IgG levels are associated with scarring [2]. Benign monoclonal gammopathy and multiple myeloma occasionally occur [3]. Chronic lymphatic leukaemia with macroglobulinaemia has been reported [4]. Occasionally, the Coombs' test may be positive, and cryoglobulins [5,6] and cold agglutinins may be detected in the serum. False-positive reactions for syphilis have been reported in 26% of cases [7]. Anticardiolipin antibodies (mainly IgM) in low titre occur in approximately 15% and are associated with antinuclear antibody, but do not seem to indicate an increased thrombotic tendency [8], although a case associated with the anticardiolipin syndrome has been reported [9]. Anticardiolipin antibody has also been reported in chilblain lupus [10]. Sometimes, the LE cell test may be positive (1.7%). Rheumatoid factor is present in approximately 17% of patients.

Antinuclear antibodies are found in 35%, the 'homogeneous' type of antinuclear factor being twice as frequent as the 'speckled' type. Antinuclear antibodies (ANA) are more common in older patients, in those who have had the disease for a long time and when there is extensive skin involvement. They are also more common in patients with chilblains, Raynaud's phenomenon and joint pains [11]. The incidence of antinuclear antibodies varies between series—5% [12], 13% [13,14], 50% [15] and 60% [16]—but such differences may be a result of the selection of patients or the sensitivity of the laboratory techniques. The incidence of anti-DNA antibodies varies from 0% [12,17] to 27% [18]. In the latter series, patients did not show any evidence of systemic involvement, and follow-up 3 years later showed no evidence of SLE [19], but it is possible that patients with DNA antibodies are more likely to develop SLE [20]. Antibodies to single-stranded DNA occur in nearly one-fifth and may indicate widespread and progressive disease [21]. DNA antibody titres fall with chloroquine therapy. One-fifth of patients have IgM antibodies to single-stranded DNA [17]. Antibodies to RNA occur in 42% [22]. Low-titre anti-Ro antibodies are found in 10% of patients with DLE, but are not related to photosensitivity and do not imply an increased risk of developing SCLE [23]. Serum complement levels are occasionally reduced [12]. DLE occurs with low levels of complement components [24–26], but there is no specific complement profile [27]. Antibody to extractable nuclear antigen is not found, but lymphocytotoxic antibodies have been demonstrated in 23% of patients in one series [28] but not found in another [12]. Precipitating autoantibodies are found in approximately 4% of patients. The SjT type of antibody (anti-La [SS-B]) is associated with 'speckled' antinuclear factor and rheumatoid factor in those patients with DLE and erythema multiforme [29]. Soluble interleukin 2 (IL-2) receptors may be found [30].

Antibodies to saline extracts of liver, blood vessels, skin, kidney, heart, spleen, leukocytes, gammaglobulin and deoxyribonucleoprotein have been detected by complement utilization [31]. The highest titres occur in the mildest non-scarring forms of the disease and the lowest

in the scarring type. It has been suggested that these antibodies may have a protective function [31].

A high incidence of antithyroid antibodies has been found in DLE, particularly in females [15]. Gastric parietal cell cytoplasmic antibodies occur in 13% of patients [15], but this incidence may not be higher than in controls.

Intradermal tests with autologous leukocytes [32] were positive in one-third of cases, but this test is not specific and the results do not differ from controls [33].

T-cell counts are significantly lower than in controls, although B cells are not reduced [34]. Kidney biopsy has shown silent lupus nephritis in patients with hypocomplementaemia [35].

Differential diagnosis. The relationship of DLE to SLE has been discussed elsewhere (see p. 56.2). The cutaneous lesions may be very similar, although patients with DLE of the face usually show more scaling, pigmentary disturbances, atrophy and scarring. In those with extensive DDLE, positive antibodies and mild systemic symptoms, it can be difficult to fit the patient into a precise diagnostic category. The annular atrophic plaque variety of DLE may resemble morphoea or lichen sclerosus [1]. Jessner's lymphocytic infiltration may be confused with the more acute localized oedematous lesions of LE, but the marked histological lymphocytic infiltration in the former should help to distinguish it from the latter, and immunoglobulin deposition does not occur at the dermal–epidermal junction in Jessner's infiltration [2]. Jessner's infiltration is rare in childhood [3] and has been reported in three members of one family [4], as well as in a mother and son, and father and daughter. Evidence has been produced from a study of 100 patients that Jessner's lymphocytic infiltration is a distinct entity, which does not seem to proceed to DLE, PLE or lymphoma [5], and studies of lymphoid infiltrates using the monoclonal antibody Leu-8 tend to confirm the difference between DLE and Jessner's lymphocytic infiltrate [6]; however, there is still disagreement on this point. Benign lymphocytic infiltration of the skin may be a further form of cutaneous LE as indicated by phototesting [7]. The distinction from PLE may be difficult, but the absence of antinuclear factor from the

serum [8] and of dermal–epidermal immunoglobulin deposits [9] in PLE may be helpful. PLE and DLE may coexist, or PLE may precede DLE by many years [10]. PLE is more common in the relatives of patients with LE; as many as 65% of patients with cutaneous LE have symptoms indistinguishable from those of PLE [11]. There may be an actinic factor in the reticular erythematous mucinosis (REM) syndrome (see Chapter 57), which can show clinical and histological features similar to DLE. The history and the presence of lesions elsewhere should exclude contact eczema, seborrhoeic eczema and psoriasis. Lupus vulgaris may resemble DLE, but the lesions of the former usually occur at an early age, are rarely symmetrical, may be ulcerated and usually show characteristic 'apple-jelly nodules'. Necrobiosis lipoidica can give facial lesions like DLE. The rosaceous type of LE can usually be differentiated from true rosacea by the absence of pustules.

Chronic DLE has been found in 12% of patients diagnosed as having scarring alopecia of the pseudopelade type [12]. Lesions on the lips, tongue and buccal mucosa may be confused with lichen planus, and the skin of some patients may show clinical, histological and immunological features of both diseases [13,14]. Overlap cases, in addition to LE-like lesions, have lichenoid papules, verrucous lesions, anonychia, and oral and vulval lesions resembling lichen planus. Patients with lichen planus do not have features of LE immunopathologically or by HLA typing [15]. Overlap cases either have both diseases or are variants of LE. In favour of the latter, the verrucous lesions show immunofluorescent findings of LE, and electron microscopy reveals tubuloreticular inclusions in endothelial cells of dermal blood vessels—which are found in LE but not in lichen planus [16].

LE of the legs and feet may resemble chilblains. Plaques of sarcoidosis and lesions of eosinophilic granuloma may cause diagnostic difficulties that can only be resolved histologically. Occasionally, lesions resembling DLE are caused by dermatophytes [17].

Infants may show sharply marginated, erythematous, finely scaling plaques on the cheeks and bridge of the nose, sometimes exacerbated by the sun [18], or a transitory rash with telangiectases on the face, particularly around the eyes, which clinically and histologically resembles LE [19]. These rashes probably are part of so-called neonatal LE (see p. 56.53). The annular erythemas of infancy have been reviewed [20].

An LE-like rash on the face with sun sensitivity occurs in Bloom's syndrome (see Chapter 12), which is thought to be caused by an autosomal recessive gene. A congenital telangiectatic erythema occurs in well-proportioned dwarfs, who look alike because of their bird-like facial appearance. The skin changes occur in infancy and may be associated with ectodermal and mesodermal defects.

Prognosis [1]. The untreated skin lesions of DLE tend to be persistent. With treatment, the more tumid lesions with little scaling may clear completely in the course of a month or two. Lesions of longer standing with much scaling and some scarring are slower to remit. Ultimately, scarring is found in 57%, with scarring alopecia in 35%; 35% also have pigmentary abnormalities [2]. Areas of activity at the edge of such scars may take years to settle. Twenty per cent of female patients notice a premenstrual flare, but there is no evidence of a deterioration of the condition on hormone replacement therapy [3]. Complete remission in the course of years can be expected in over 50% [1]. Long duration and lack of remission are related to Raynaud's phenomenon, scalp involvement and chilblain-like lesions

[4]. Relapses occurring with sunlight, cold, trauma or mental stress after months or years of remission are not infrequent. In spite of the chronic and relapsing nature of the condition, the patient usually remains in good health.

Despite the fact that over half of patients have haematological and serological abnormalities, the risk of developing overt SLE is only approximately 6.5% [4,5]. The risk is higher in patients with disseminated DLE (22%) than in DLE confined to the head and neck (1.2%). Females developing DLE before the age of 40 years, with HLA-B8 in their histocompatibility type, have an increased risk of 'converting' to SLE [6]. There is little clinical difference between those cases with or without abnormalities. Neither immunological nor biochemical abnormalities appear to alter the patient's progress [5,7]. Patients with active discoid skin lesions rarely have severe renal disease [8]. Patients with DLE showing signs of nephropathy, arthralgia and ANA titres of 1 : 320 or more should be carefully monitored [9].
