Radiotherapy. Malignant melanoma is traditionally

regarded as a radioresistant tumour. Radiotherapy has little part to play in the management of primary tumours, although it has been recorded in the past that the lentigo maligna melanoma variant is relatively radiosensitive, and radiotherapy has been used to treat elderly and infirm patients with these lesions [1,2].

Radiotherapy can be of considerable value in the palliation of metastatic disease in relieving pain from bony metastases. Intracerebral metastases can also be palliated by radiotherapy used in combination with systemic steroids [3,4]. Radiobiological studies have indicated that there is a large 'shoulder' effect when melanoma cells are irradiated. This term describes the observation that, if a given dose of radiation is divided into several small fractions, only a small proportion of the cells are killed and the remainder quickly proliferate. In contrast, if the same total dose of radiation is divided into a smaller number of larger fractions, a higher proportion of the cells are killed each time and the end result is more favourable.

Melanoma, pregnancy and female sex hormones

Several large case–control studies and a meta-analysis suggest that oral contraception will not affect the outcome for women who have had stage 1 or 2 melanoma excised [1]. A recent prospective observational study of hormone replacement therapy (HRT) in women who have had melanoma shows no adverse effect of HRT, which can therefore be prescribed according to clinical need [2].

Primary melanoma diagnosed during pregnancy does not carry a worse prognosis than melanoma diagnosed in the non-pregnant state, although two studies show that melanomas diagnosed in pregnancy are significantly thicker than melanomas diagnosed in non-pregnant age-matched females [3,4]. Patients who develop stage 3 or 4 melanoma while pregnant require to be managed by an expert team. There is no evidence that termination of the pregnancy will alter the prognosis for the mother, but there is the possibility that the infant may have in its circulation melanoma cells transmitted from the mother through the placenta.

There is no evidence to suggest that pregnancy after melanoma therapy alters the prognosis, which continues to be determined mainly by tumour thickness.

Prospects for primary and secondary prevention of melanoma

Melanoma is currently increasing rapidly in incidence in most countries for which adequate data are available. In some parts of the world there appears to be stabilization of the incidence rate in younger females. Mortality rates are not rising as rapidly as incidence rates and in some sections of the population are relatively static. This implies that patients are seeking medical help and thus receiving surgical excision earlier in the growth phase of their primary melanoma when the lesion is thinner and thus associated with a better prognosis.

Secondary prevention of melanoma is prevention of deaths from melanoma and thus is aimed at earlier diagnosis. Campaigns to encourage earlier presentation for treatment have been associated with a significant reduction in patient delay prior to seeking medical advice about a new or changing pigmented lesion, and also in a significant reduction in thickness of primary melanomas excised [1].

Primary prevention of melanoma is prevention of new cases developing and depends on knowledge of the aetiological agent and the capacity to avoid that agent. Although the exact relationship between melanoma and UV exposure is not fully established, cancer societies in many countries are introducing campaigns advocating a reduction in sun exposure, particularly for those who have the established risk factors, which include large numbers of banal naevi, dysplastic naevi and a family history of melanoma [2]. In view of the epidemiological evidence that excess sun exposure in early life leads to a greater risk of melanoma in adult life, much of this publicity is currently aimed at children and those responsible for their care.

Chapter 39

Disorders of Skin Colour

S.S. Bleehen & A.V. Anstey

The colour of the skin [1–3]

Normal skin colour is dependent on haemoglobin (in both the oxygenated and reduced state), carotenoids and melanin pigment. The major colour determinant is melanin, and racial and ethnic differences in skin colour are related to the number, size, shape, distribution and degradation of melanin-laden organelles called melanosomes. These are produced by the melanocytes (Fig. 39.1) and are transferred to the surrounding epidermal keratinocytes. The wide variety of skin colour occurring in humans can be objectively measured by reflectance spectrophotometry [1,4].

Two types of melanin pigmentation occur in humans [2]. The first is *constitutive* skin colour, which is the amount of melanin pigmentation that is genetically determined in the absence of sun exposure and other influences. The other is *facultative* (inducible) skin colour or 'tan', which results from sun exposure. Increased pigmentation can also be due to endocrine causes, such as occur in pregnancy, and to interaction of light and hormonal effects, as seen in melasma (chloasma) and Addison's disease.

Variations in the degree of pigmentation occur in various regions of the body and are different in the various ethnic groups. In black people, the abdomen is the darkest and the lumbar region the lightest. In white people, the darkest area is the upper thigh and the lightest the lumbar region [5]. Females are generally lighter than males. In some ethnic groups, a sharply demarcated linear border is seen between more and less pigmented skin. This occurs in the Japanese [6] and black Americans [7], and is most noticeable on the anterior aspect of the arm between a dark lateral portion and a more lightly pigmented medial area. It is also seen in the lower legs and on the chest [5].

A blue colour is seen in the Mongolian spot that can occur on any part of the body, although most commonly in the sacral region. These spots fade after birth, but can persist in certain sites as in the naevus of Ota (see p. 39.42). The blue colouration of the skin is due to an optical effect and the presence of brown pigment in the dermis. It results from decreased spectral reflectance in the 'red' region compared with normal skin, and there is a subtractive mixing of colours [8]. Dermal melanocytes and pigmentation are commonly found in mammals and are seen in primates such as the vervet monkey [9] and the mandrill. The function of such blue coloration in sociosexual communication is explained in Chapter 4. Its development is dependent on androgens [10].

The carotenoids are yellow pigments that are exogenously produced and can be obtained only from plants in

the diet. These are to be found in the epidermis as well as the subcutaneous fat.

The evolution of pigmentary systems and their variety throughout the animal kingdom are reviewed in Chapter 2.

The melanocyte [1–4]

Epidermal melanin unit

Melanin pigmentation in the skin in humans is a dual process, which involves not only the production of melanosomes within the melanocyte, termed *melanogenesis*, but also the distribution and transfer of these pigment granules to surrounding epidermal keratinocytes. Each epidermal melanocyte is surrounded by a group of keratinocytes with which it maintains functional contact, the whole being an epidermal melanin unit [1,5]. Although the number of active epidermal melanin units varies considerably in the different regions of the body (Fig. 39.2), the number of keratinocytes served by each melanocyte remains constant [6]. A single melanocyte supplies melanosomes to a group of about 36 keratinocytes.

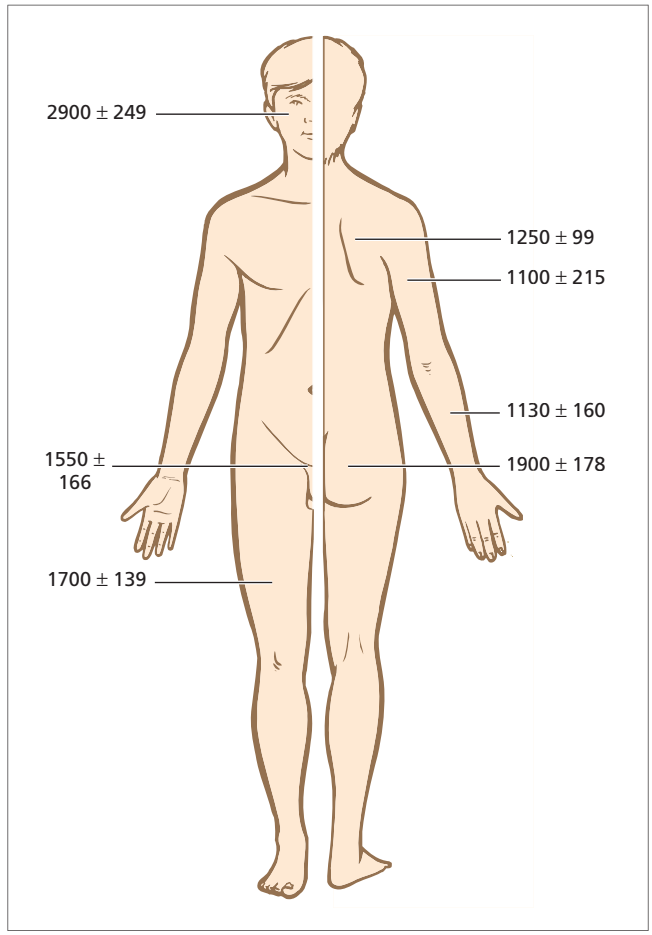

Fig. 39.2 Regional variation in the distribution of epidermal melanocytes. The figures are mean values per mm^2 ± standard error of the mean. (From Rosdahl & Rorsman [8].)

The concept of the epidermal melanin unit as a structural and functional unit, like the nephron of the kidney, has proved useful in the understanding of disorders of melanin pigmentation in humans. This concept has also been extended to classes of vertebrates other than mammals, and has been applied to reptiles and amphibia [7]. The epidermal melanocytes of frogs possess the capacity not only to produce melanin but also to rearrange the melanin granules within the cell and to produce an adaptation of skin colour to the background—a melanophore action [7]. In addition, fish, amphibia and reptiles have specially large pigment cells called chromatophores or melanophores, which lie in the dermis and have the capacity to disperse or aggregate the pigment granules which they contain [3]. The skin remains light when the pigment is aggregated in the centre of the melanophores and dark when it is dispersed to their periphery.

Three different mechanisms may be involved in the control of colour change. First, the pigment cell may act as an independent effector and respond directly to the stimulus of light; there is evidence that this can occur in some fish and amphibia [3] and the tanning processes of human skin, both immediate and delayed, can be considered to be analogous. Second, the movement of pigment within a melanophore may be under nervous control. The melanophores of fish are innervated by postganglionic sympathetic fibres, which are undoubtedly able to mediate contraction of the pigment and thus lighten the skin. A similar mechanism accounts for the rapid colour change of the chameleon. It has been claimed, but is not commonly accepted, that nervous mechanisms also play a part in the darkening of chromatophores in fish. Third, the activity of pigment cells may be under humoral influence [3]. Pituitary hormones that cause expansion of melanophores or promote the formation of melanin in epidermal melanocytes occur in fish, amphibia, reptiles and mammals. There is evidence of a lightening hormone in the amphibian pituitary, and a substance of similar function, known as melatonin, occurs in high concentration in the mammalian pineal body.

Distribution of melanocytes

Melanocytes can be found in nearly every tissue but are most common in the epidermis, hair follicles, dermis, eye, around blood vessels, peripheral nerves and the sympathetic chain, and in the lining of the coelomic cavity. They are also present in the leptomeninges and inner ear. It is estimated that the total epidermal melanocyte population in a person is about 2×10^9 cells. The melanocyte mass forms a tissue with a volume of 1.0–1.5 cm^3 [1]. The distribution of epidermal melanocytes in different parts of the body varies, the population density in the face and genital areas being greater than in the trunk (Fig. 39.2) [1,2]. The range is from $2900 \pm 249/mm^2$ for the face to $1100 \pm 215/mm^2$ for the upper arm [1]. There are no significant sexual or racial differences. The differences in colour between white, oriental and black skin are due to the amount and arrangement of the melanosomes produced by the melanocytes. Ultrastructural studies [3–5] indicate that skin colour in the different races is largely determined by the size, packaging, distribution and degradation of melanosomes within the keratinocytes.

A reduction in the number of melanocytes occurs with ageing [6–8]. The melanocyte density decreases by 6–8% per decade. The density of melanocytes is about twofold higher in exposed than in non-exposed skin [2].

Embryology and affinities

Melanocytes are remarkable in that in spite of their ubiquity they all arise from the neural crest [1]. This is a region of the embryonic ectoderm that originates from the margins of the neural plate at the time when it sinks in to form the tubular central nervous system. The neural crest gives rise also to some of the dorsal root and cranial ganglia and other miscellaneous structures. The dependence

of melanin formation on melanocytes of neural crest origin has been demonstrated experimentally in both amphibia and mammals [2,3].

Ultrastructural studies on early human embryos have shown the presence of melanocytes in the epidermis by the eighth week of gestation; by the 10th week these cells contain melanosomes showing early melanization [4]. Dendritic melanocytes have been identified in the black fetus at the 10th week using the silver impregnation technique [5].

The position and differentiation of melanocytes in the epidermis are influenced by keratinocytes. In cultured fetal skin equivalents, the melanocytes are grouped and distributed both basally and suprabasally, whereas in neonatal skin equivalents they are singly distributed among basal keratinocytes only [6].

It is generally accepted that melanocytes in the skin and hair continue to reproduce themselves by cell division, although mitotic melanocytes are rarely seen *in vivo*. Mitotic non-neoplastic melanocytes have been observed in the skin of mice and humans [7]. Stimulation of the mitosis of melanocytes occurs following UV irradiation [8]. The mitotic index of these cells is much lower than that of the keratinocytes.

Okun and co-workers presented morphological, enzymatic and histochemical evidence to support a histogenetic relationship between melanocytes and mast cells [9,10]. However, most pigment-cell biologists believe that these cells are quite distinct and of different embryonic lineage, the mast cell being of mesenchymal origin whereas the melanocyte is derived from the neural crest. For a long time, the Langerhans' cell was thought to be related to the melanocyte [11,12], but this dendritic cell is of bone marrow origin [13]. Langerhans' cells have been found in mouse skin deprived of its neural crest component [14].

Fine structure of melanocytes

Melanocytes form a network of dendritic cells in the basal layer of the epidermis (see Fig. 39.10). They are also found in the external hair root sheaths and in the bulbs of hair follicles. These secretory melanocytes behave as unicellular glands producing melanosomes that are transferred to surrounding epidermal keratinocytes—a cytocrine activity [1]. Some do not transfer their melanosomes but redistribute them from the perinuclear zone into the dendrites and then back again. These non-secretory melanocytes are melanophores. Melanocytes may also be found in the dermis, particularly in some mammals.

The donation of pigment has been studied *in vivo* by electron microscopy [2,3] and *in vitro* using time-lapse cinematography (Fig. 39.3) [4,5]. The transfer of melanosomes involves the active participation of keratinocytes. Cell cultures have shown that melanocytes are rather inactive and non-mobile, and become dendritic in relation to keratinocytes. The tip of the dendrite of the melanocyte becomes embedded in the cytoplasm of the keratinocyte and the end becomes pinched off. A package of melanosomes is transferred to the keratinocyte, which acts as a phagocyte [6].

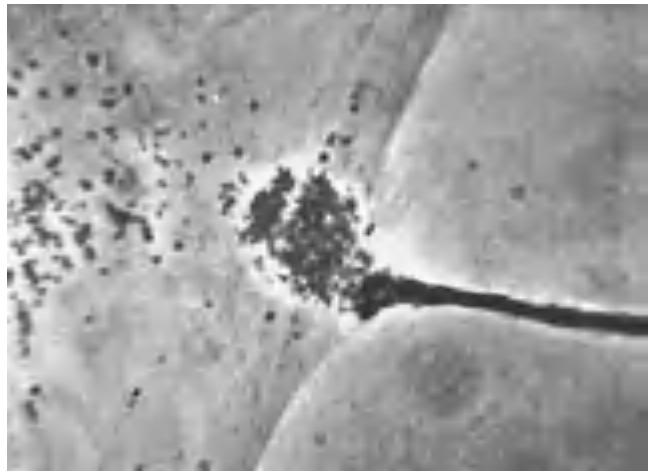

Fig. 39.3 Transfer of melanin granules from a melanocyte to an epidermal cell in a guinea-pig ear skin culture. (From Cruickshank & Harcourt [5].)

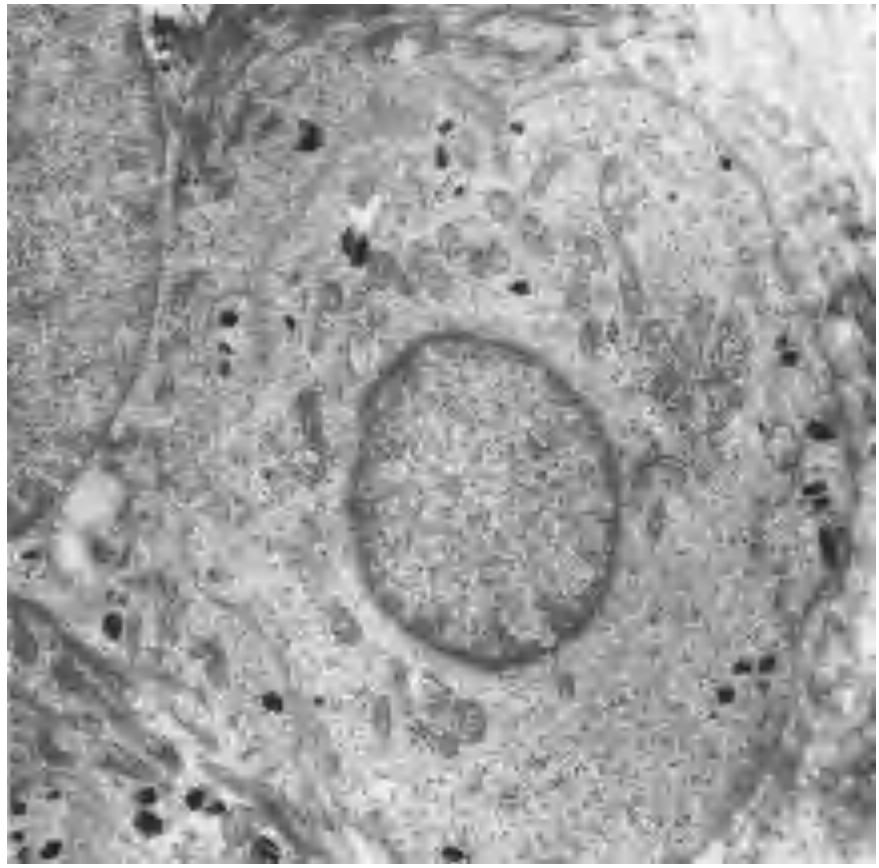

Fig. 39.4 Melanocyte in the basal layer of the epidermis. × 12 000.

Several theories have been suggested for the post-transfer digestion of melanosome complexes within the keratinocytes and their subsequent packaging. Experimental studies indicate that the melanosomes are packaged according to size, the larger ones as single units, the smaller ones as complexes of two or more [7].

On electron microscopy, the melanocyte is readily distinguishable from the keratinocyte by the lack of desmosomes and tonofibrils and by a more lucent cytoplasm (Fig. 39.4) [8].

The characteristic feature of the cell is the presence of special cytoplasmic organelles, the melanosomes, on which melanin is formed by the action of the enzyme tyrosinase. The developing melanosomes show varying degrees of electron density, the more fully melanized being very dense. Four stages of melanosomal development are recognized (Figs 39.5–39.7) [9]. Stage 1 is a membrane-bound, spherical vesicle derived from the Golgi apparatus. This vesicle may show tyrosinase activity or contain filaments that have a periodicity of particles along their length of 7 nm, characteristic of melanofilaments.

How the structural proteins and the enzyme tyrosinase are organized in these early melanosomes is uncertain, but according to the classical theory tyrosinase is produced on membrane-bound ribosomes and transferred via the endoplasmic reticulum to the Golgi apparatus,

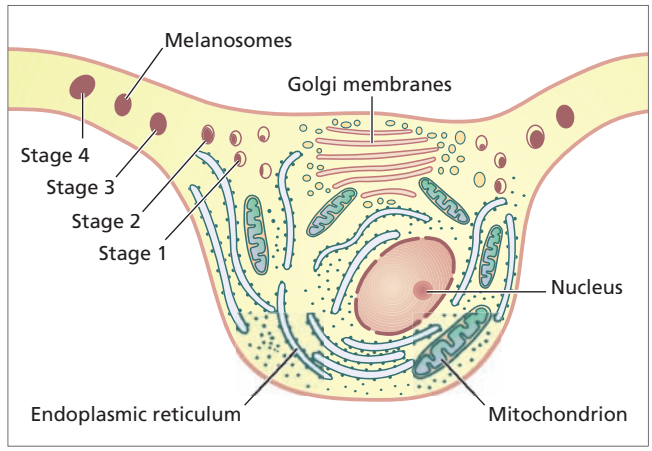

Fig. 39.5 Fine structure of a melanocyte. (From Jimbow *et al.* [12].)

where it accumulates in vesicles derived from the Golgi apparatus [10]. Stage 2 melanosomes are oval in shape and show numerous melanofilaments with and without cross-linking. In stage 3, the internal structure of the melanosomes is partially obscured by the deposition of melanin. By stage 4, the mature melanosome appears electron dense. Ultrastructural studies have shown that the fully melanized melanosomes are not as amorphous as

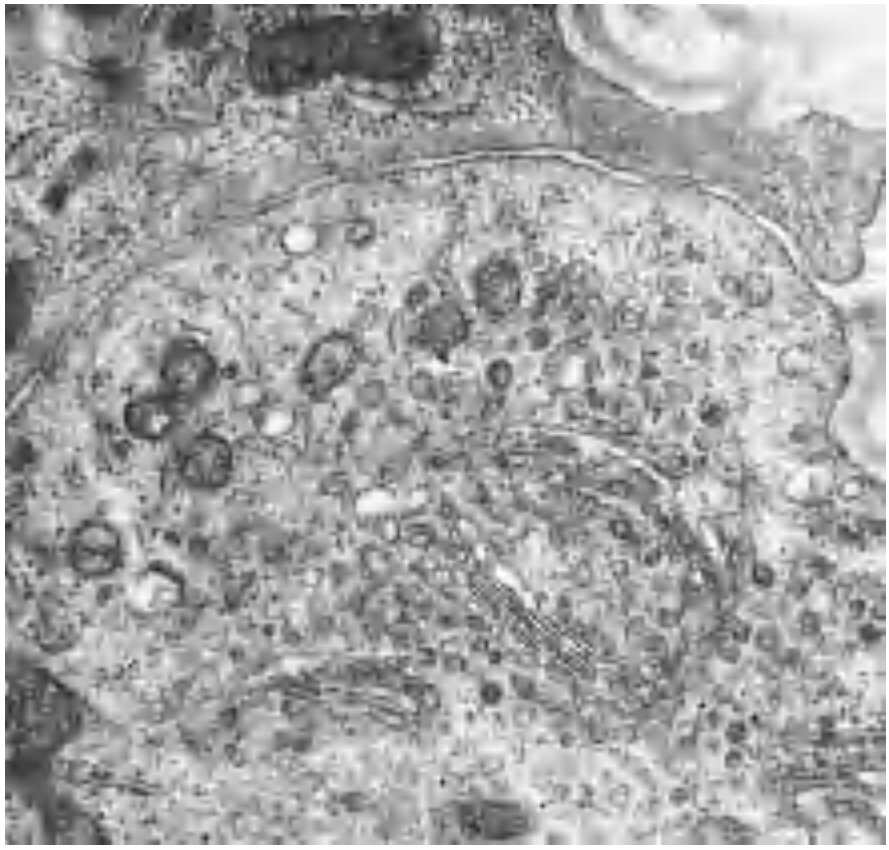

Fig. 39.6 Portion of a melanocyte in the basal layer of the epidermis of a tyrosinase-negative albino. Early stages of development of melanosomes in relation to the Golgi apparatus. Fine cytofilaments within cell. × 28 000.

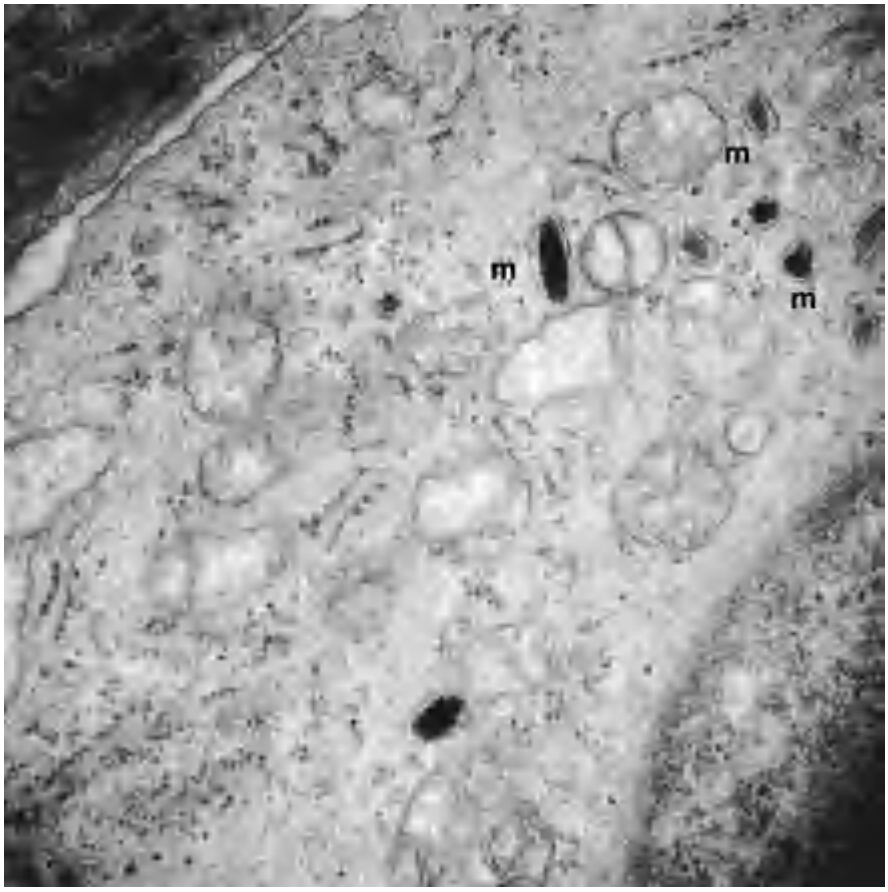

Fig. 39.7 Portion of a melanocyte in the basal layer of normal skin showing melanosomes (m) in various stages of development in the cytoplasm. × 28 000.

previously considered but contain spherical microvesicles called vesiculoglobular bodies [11]. These are involved in the organization of the melanosomes and are to be found in both the ellipsoidal filamentous eumelanosomes and the spherical phaeomelanosomes of human red hair [12]. The vesicular bodies are the key unit for the development of macromelanosomes [13,14].

The subcellular components of melanocytes have been isolated by density-gradient ultracentrifugation and the various fractions examined by electron microscopy and analysed for enzyme activity. The proof that melanosomes are the site of melanogenesis came from these studies, which also showed that the smooth and rough membranes as well as the melanosomes of the cells have tyrosinase activity [15,16].

Melanocytes also contain fine cytoplasmic filaments about 100 nm in diameter (Fig. 39.6). These are particularly prominent in the melanocytes of the pale skin of freckled and albino subjects [8]. Studies on tanning reactions in human skin indicate that they are concerned with the movement of dendrites and melanosomes within the melanocyte and the transfer of these organelles to the epithelial cells [17,18].

Culture of human melanocytes

The culture of human pigment cells was at first frustrated by the problem of separating them from keratinocytes, which enjoyed the proliferative advantage, and by the fact that melanocytes would not multiply *in vitro* without the presence of mitogenic factors [1,2]. Selective plating of melanocytes was achieved by the addition of 12-*O*-tetradecanoyl phorbol 13-acetate (TPA) to culture media containing a mixed population of skin cells, and cholera toxin was shown to potentiate their mitogenic activity [3].

Melanocytes derived from both newborn foreskin and adult facial or truncal skin have been maintained in a tissue culture medium supplemented with epidermal growth factor, triiodothyronine, transferrin, insulin, cholera toxin and bovine hypothalamic extract dialysed to remove a keratinocyte growth factor present in the crude extract. After 3–4 weeks, pure melanocyte populations could be harvested and serially passaged up to six times over several months, with successive doubling of the cell numbers 10 or more times [4]. Such cultures have been used to study melanogenesis. For example, it has been shown that UV radiation from a solar simulator directly induces pigment formation in human melanocytes *in vitro*. There is a dose-related increase in melanin per cell and in uptake of ^{14}C-dopa, but an inhibition of growth. There are increases in the length and number of dendritic processes and in the number of melanosomes [5].

Melanocytes from melanomas and naevi have also been successfully maintained *in vitro* [6]. The melanocytes from uninvolved skin of subjects with vitiligo proved very difficult to culture [7], but they have been successfully isolated and seeded by adding the enzyme catalase to the medium and thereafter keeping the concentrations of calcium and TPA low [8].

Large-scale cultivation of human pigment cells appears possible by using collagen-coated Sephadex beads (Cytodex 3) as a microcarrier surface [2].

Biochemistry of melanogenesis

Melanins are usually classified into two main groups: the black and brown eumelanins, which are insoluble, and the yellow and reddish-brown phaeomelanins, which are alkali soluble (Table 39.1). Eumelanins arise by oxidative polymerization of 5,6-dihydroxyindoles; phaeomelanins are chemically distinct, in that they contain sulphur in addition to nitrogen and are formed from cystein-*S*-yl-dopas (Fig. 39.8). However, the situation is complicated by the fact that some phaeomelanin-like pigments may be structural variants of eumelanins [1]. Thus, in the presence of metal ions, black insoluble eumelanin may be oxidized chemically or photochemically to a soluble form (melanin-free acid), which is light in colour [2,3]. A further complication is that red human hair contains, in addition to phaeomelanins, small amounts of intensely coloured pigments known as trichochromes [1,4], which were originally isolated from the red feathers of New Hampshire hens. Trichochromes are sulphur-containing pigments of a well-defined structure, of which six variants have so far been identified (Fig. 39.9).

Both eumelanins and phaeomelanins are derived from tyrosine, by the same initial steps. Tyrosine is oxidized to 3,4-dihydroxyphenylalanine (dopa) by the copper-containing enzyme tyrosinase, which also catalyses the further oxidation to dopaquinone (Fig. 39.8). Three distinct forms of active tyrosinase have been isolated from mouse melanoma. Two, T_1 and T_2, with similar molecular weights of 66 600 and 56 700, are soluble; one, T_3, is insoluble [5]. Recently, it has been found that not only tyrosinase is involved in melanogenesis but also the tyrosinase-related proteins TRP-1 and TRP-2 [6,7]. It has also been proposed that a peroxidase is involved in the initial conversion of tyrosine to dopa [8].

Table 39.1 Main types of epidermal melanin pigments. (Courtesy of Prota [1].)

Eumelanins	Black or brown nitrogenous pigments, insoluble in all solvents, which arise by oxidative polymerization of 5,6-dihydroxyindoles derived biogenetically from tyrosine via dopa
Phaeomelanins	Alkali-soluble pigments, ranging from yellow to reddish-brown; most of them contain sulphur in addition to nitrogen and arise by oxidative polymerization of cystein-*S*-yl-dopas via 1,4-benzothiazine intermediates
Trichochromes	A variety of sulphur-containing phaeomelanic pigments with a well-defined structure, characterized by a $\Delta^{2,2'}$-bi(1,4-benzothiazine) chromophore

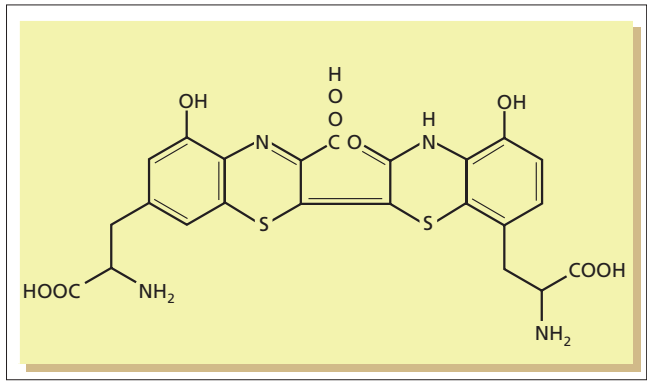

Fig. 39.9 Structure of trichochrome B, one of six trichochromes so far identified.

From dopaquinone the eumelanin and phaeomelanin pathways diverge. Eumelanins arise by oxidative polymerization of 5,6-dihydroxyindoles. In the classical Raper–Mason scheme, dopaquinone undergoes cyclization to cyclodopa (leukodopachrome), which is rapidly oxidized to dopachrome [9,10]. Dopachrome then becomes rearranged to form 5,6-dihydroxyindole (Di) or, in smaller amounts, 5,6-dihydroxyindole-2-carboxylic acid (DiCA). It was proposed that 5,6-indolequinone then polymerized by repeated condensations at the 3 and 7 positions.

The process is now believed to be more complicated [1,4,11,12]. Certain metal ions, such as copper, zinc and iron, are found in high levels in pigmented tissues and have long been thought to be involved in melanin pigmentation. It appears that zinc, copper, cobalt, nickel, and to a lesser extent iron, manganese and calcium, all catalyse the rearrangement of dopachrome to form DiCA rather than Di. The ratio of DiCA to Di determines the extent to which these intermediates take part in the subsequent polymerization process to form eumelanins. The final stages of conversion of Di, DiCA or mixed oligomers to eumelanins is little understood.

Most of the knowledge of the chemistry of the phaeomelanins comes from study of red hen feathers, although the pigments in human red hair are similar. Phaeomelanins have a complex structure made up of benzothiazole and tetrahydroisoquinoline units (Fig. 39.8) linked together by carbon bonds.

The biosynthesis of phaeomelanins and trichochromes involves the addition of the SH group of cysteine to dopaquinone to form cysteinyldopa, of which two forms have been characterized: 5-cystein-*S*-yl-dopa (5-cysdopa) and 2-cystein-*S*-yl-dopa (2-cysdopa). Dopaquinone will also link with glutathione to form colourless glutathione-dopa. The addition of cysteine or glutathione to quinones

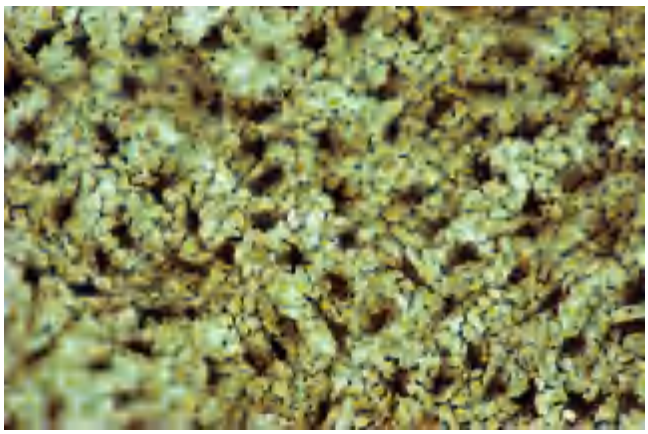

Fig. 39.10 Epidermal sheet of forearm skin incubated in dopa to show melanocytes.

are each fast non-enzymatic reactions that, in a sense, sidetrack the metabolic pathway leading to eumelanin formation. Glutathionedopas may be enzymatically converted to cysteinyldopas. Cysteinyldopa can be detected in the plasma and urine of patients with melanoma [13]. Prota [1] has reviewed these pathways and discussed their significance.

Melanocytes can be demonstrated by incubation of the skin in dopa (Fig. 39.10). Incorporation of labelled tyrosine into the cytoplasm of melanocytes has been shown by autoradiography [14]. Eumelanosomes and phaeomelanosomes appear to be morphologically different [14,15].

Endocrine and paracrine influences

In many vertebrates, α-melanocyte-stimulating hormone (α-MSH) is the major hormone controlling melanin pigmentation [1]. This peptide is derived from a large precursor protein produced by the pituitary, pro-opiocortin [2]. In mammals, including humans, so-called 'β-MSH' is an extraction artefact [1,3] and is derived from β-lipotrophin, a precursor molecule for the opiate peptides (Fig. 39.11). Both α-MSH and β-MSH contain the same heptapeptide sequence

. Met . Glu . His . Phe . Arg . Trp . Gly .

which has a melanogenic effect. For maximal melanocyte-stimulating activity, the whole sequence is necessary [4]. γ-MSH, which has five of the amino acids in the sequence, has been shown to have some activity.

There is considerable evidence from studies with mouse melanoma cells [5,6] that MSH interacts with membrane receptors [7], leading to activation of adenylate cyclase (and formation of cyclic AMP) and increase in tyrosinase and melanin formation. The peptide β-endorphin and its derivatives met-enkephalin and melanotrophin-potentiating factor (MPF), which all lack the heptapeptide, do not activate this second messenger in mouse melanocytes [4]. In lizard skin, MPF potentiates the effect of α-MSH [8].

The mode of action of MSH on human melanogenesis is far less clear. Pigment formation in response to MSH has not been achieved *in vitro*. There is, however, evidence

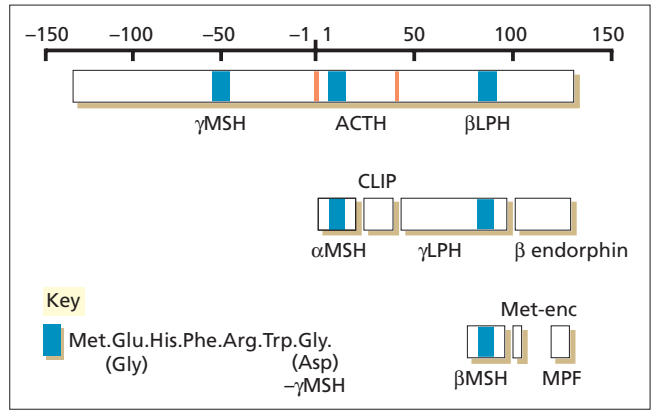

Fig. 39.11 Schematic representation of adrenocorticotrophic hormone (ACTH)/β-lipotrophin (β-LPH) precursor. MPF, melanotrophin-potentiating factor; MSH, melanocyte-stimulating hormone.

that MSH receptors are present, since cyclic AMP can be elevated [9]. The demonstration that an analogue of diacylglycerol (DAG) increases both the melanin content of cultured human melanocytes [10] and the incorporation of dopa suggests that DAG and the receptors linked to phospholipase C are also implicated in the intracellular signals [5,11]. Calmodulin antagonists both increase melanogenesis and decrease cell proliferation in cultured melanoma cells [12].

The culture of melanocytes *in vitro* has made it possible to investigate the possible role of local as well as systemic factors. In this respect, it is important to differentiate an effect on melanocyte proliferation from actions on the synthesis of melanin and its transfer to surrounding keratinocytes, which are mainly responsible for pigmentation.

As well as α-MSH, which can be synthesized not only by the pituitary but also within normal and abnormal pigment cells [13], basic fibroblast growth factor (bFGF) [14–16] is a naturally produced mitogen. Of a range of membrane-derived mediators of inflammation, only leukotrienes C_4 and D_4 have proved capable of stimulating melanocyte proliferation; arachidonic acid, prostaglandins D_2 and E_2, and leukotrienes B_4 and E_4 are ineffective [17]. The cytokines interleukin (IL)-1α, IL-6 and tumour necrosis factor-α (TNF-α) inhibit both melanocyte proliferation and melanogenesis [18].

The addition to melanocyte cultures of media in which keratinocytes have been incubated has been shown to increase melanocyte yield, total melanin and melanocyte dendricity. Because the addition of bFGF or other known mitogens has no effects in this system, it seems probable that other keratinocyte-derived factors influence melanocyte behaviour [19].

Many amphibians are able to adjust the colour of their skin rapidly to the external environment. Frogs placed on a dark background respond by the skin darkening due to dispersal of melanosomes within the melanophores. Later, there is an increase in melanogenesis. When they are placed on a light background, there is an aggregation of pigment granules within the melanophores. The epidermal melanocytes and dermal melanophores of frogs and other amphibians are extremely responsive to α-MSH and other melanotrophic hormones [20].

In humans, MSH stimulates melanogenesis, and an increase in the pigmentation of the skin is seen in a number of disorders where there are elevated levels of this polypeptide. Marked hyperpigmentation of the skin occurs in Nelson's syndrome (Fig. 39.12) and in Addison's disease. A darkening of black skin has been detected within 24 h of injection with MSH [21,22].

Evidence from animal experiments suggests that oestrogens, but not androgens, increase skin pigmentation. In mammals, pituitary and ovarian hormones are potent stimulators of melanogenesis [23].

Melatonin

The aggregation of melanin within the chromatophores and consequent lightening of the skin in the frog can be achieved by 5-methoxy-*N*-acetyl-tryptamine, known as melatonin [1]. This substance has been isolated from bovine pineal glands, although it is also present in much lower concentration in the hypothalamus and peripheral nerves [2]. Its action on frog chromatophores resembles that of epinephrine (adrenaline), norepinephrine (noradrenaline), acetylcholine, serotonin and triiodothyronine, but melatonin is by far the most potent, being 10^5 times as effective as norepinephrine [3].

There is conflicting evidence about the action of melatonin on mammalian epidermal melanocytes. On the one hand, a visible lightening of the skin has been produced within 2 days in melanotic dogs by treatment with 1 mg/day of the hormone [4]. On the other hand, large doses of melatonin have failed to alter the skin pigmentation of a human subject [5] or to cause any change, macroscopic or microscopic, in guinea-pig epidermis [6].

It is now unequivocally established that in seasonally breeding mammals the daily pattern of melatonin secretion by the pineal gland provides an endocrine measure of daylength and mediates its effect on reproductive function. Humans show a clear daily rhythm, and a fall in nocturnal serum melatonin occurs during prepuberty and pubescence [7,8]. Melatonin has been advocated for alleviating jet lag. A hypothesis that a decrease in melatonin secretion initiates puberty is discussed in Chapter 69.

Biological significance of melanin

Melanin is widespread throughout the animal kingdom, where it appears to serve a variety of functions concerned with the protection of tissue and the gross coloration of animals. It is generally assumed that its major function in humans is protection of the lower layers of the skin against UV light. As keratinizing epidermal cells move outwards to become the stratum corneum, they carry with them melanosomes, which they have received from the melanocytes. The stratum corneum of oriental and black people is flecked with melanin, although this is not ordinarily so in white people.

If human pigment has such adaptive significance, we might expect to find that, among the races of the world, pigment is geographically distributed in relation to solar intensity. It appears to be generally true that pigmentation is greatest in the tropics and reduced in temperate zones, reappearing to some extent in northern races subjected to prolonged snow glare [1]. However, there are exceptions, for example native Americans are not notably different in skin colour throughout the whole continent, and Tasmanians are dark even though they live in a temperate climate.

The damaging role of UV light is well illustrated by the high incidence of epidermal carcinoma in Europeans exposed to the tropical sun. The evolutionary usefulness of pigmentation may be twofold. On the one hand, it protects against damage by sunburn. On the other, since it efficiently absorbs UV radiation and is readily activated to a free radical by incident light, it may serve to eliminate genetically damaged cells by a phototoxic mechanism.

Not all the effects of pigmentation are advantageous. There is no doubt that pigmentation increases the heat load in hot climates, so that black people absorb 30% more heat from sunlight than do white people, although this factor may be offset by more profuse sweating [2,3]. In addition, in cold climates pale skin has the advantage that heat loss by radiation is reduced.

A further disadvantage of pigmentation is that it vitiates against the synthesis of vitamin D, so that in areas of poor nutrition black children are more liable to rickets than white children. Thus, loss of pigmentation may facilitate vitamin D synthesis in temperate climates. It might be presumed that the retention of pigment in Arctic

latitudes, while providing a protection against snow glare, is only permitted by natural selection because of the high-fat diet in these areas.

Since pigmentation appears to be not entirely advantageous to life in the tropics, other hypotheses about its biological significance have been advanced. For example, Wassermann [4,5] has suggested that the major adaptation of black people to tropical Africa is in the ability to survive malaria, multiple parasites and tropical diseases under the hazards of intense solar radiation and, more often than not, poor nutrition. He suggests that diseases, not climatic conditions, are the primary selective factors, and lists evidence that black Africans, in comparison with white people, show increased reticuloendothelial activity and increased serum γ-globulin fractions. These features are inversely related to the size and activity of the adrenal cortex. Because of their primary decrease in adrenocortical function, black people show increased MSH and adrenocorticotrophic hormone (ACTH) activity, which enhances melanogenesis. Pigmentation might thus be a secondary phenomenon.

One of the most important properties of melanin is its free radical character. Electron spin resonance (ESR) studies show that melanin belongs to a class of so-called stable free radicals [6,7]. Skin irradiated with UV light shows an increase in free radicals, and ESR studies have shown that following irradiation a different type of signal is produced that is more apparent in white than in pigmented human skin [8]. Other studies also indicate that melanin acts not only in an optical fashion by diffusing and absorbing light, but also as a trap for electrons and possibly free radicals. Melanin can oxidize reduced NADH *in vitro* and can also participate in other oxidation–reduction reactions [9].

Because melanin is phagocytized by leukocytes, it can be circulated around the body. Melanin granules can be found in about 75% of the skin-draining lymph nodes in Bantu, but in only about 20% of similar nodes in white people. Thus, melanin circulating through the body may influence intracellular metabolism, and on these grounds could be regarded as a hormone [4,5].

Pathogenesis of disorders of melanin pigmentation

Disorders of melanin pigmentation can be divided on morphological grounds into two types. The first is hypermelanosis, where there is an increased amount of melanin in the skin. This excess may be confined to the epidermis, when the skin appears browner than normal, or it may be present in the dermis, producing a slaty-grey or blue appearance. The second type is hypomelanosis, where there is a lack of pigment in the skin, which therefore appears white or lighter than the normal colour. Amelanosis is the term applied when there is a total lack of melanin in the skin. Hypermelanosis and hypomelanosis can be generalized and diffuse, or may be localized and circumscribed. Sometimes, localized areas may have a segmental or dermatomal pattern. The term 'depigmentation' is used to describe a loss of pre-existing pigment from the skin. Leukoderma is a white skin that may be congenital or acquired and can be due to a variety of aetiological factors. Examination of the skin with a source of long-wave UV light, for example Wood's lamp, is often helpful in localizing abnormal variations in melanin pigmentation in the skin and as an aid to the diagnosis of various disorders [1].

Changes in pigmentation can arise in a number of ways and can be due to a variety of genetic and environmental factors. Abnormalities may involve:

1 formation of melanosomes in melanocytes;
2 melanization of melanosomes;
3 secretion of melanosomes into keratinocytes;
4 transport of melanosomes in keratinocytes with and without degradation in lysosome-like organelles.

It is also pertinent to consider non-melanin pigmentation as a cause of cutaneous colour changes, as discussed at the end of this chapter.

Light and electron microscopy studies have considerably advanced our knowledge as regards the pathogenesis of many disorders of melanin pigmentation in humans. Only a few examples of pigmentary disorders are given here. In vitiligo, there is an absence of secretory melanocytes in the amelanotic areas. In piebaldism, in the amelanotic areas there is a complete lack of melanocytes. This probably results from a failure of migration of melanoblasts derived from the neural crest. Alternatively, it could be due to a failure of the cells to differentiate into melanocytes. In the hyperpigmented areas of human piebaldism, abnormalities are found in the formation and melanization of melanosomes. As with many of the disorders of pigmentation, more than one of the biological processes may be affected. Genetic studies carried out on mice show that white spotting is related to the action of approximately 70 genes at 40 loci [2,3]. It is therefore not surprising that there are so many genetically determined disorders of pigmentation in humans, with various modes

of inheritance. Genetic factors are involved in the migration of melanoblasts and their development and differentiation in the skin. The morphology of the melanocytes, the structure of the melanosome matrix, tyrosinase activity and the type of melanin synthesized are all under genetic control. Also, the patterns of melanosome transfer and of their subsequent degradation are determined by different genes. Melanosomal abnormalities occur in a wide variety of disorders. Giant spherical pigment granules (macromelanosomes) are found in the skin of patients with neurofibromatosis [4,5], naevus spilus [6], lentiginoses, X-linked recessive ocular albinism and Hermansky–Pudlak syndrome [7]. Abnormal giant melanosomal complexes due to a fusion of melanosomes are found within melanocytes in Chédiak–Higashi syndrome [8].

Defective melanization of melanosomes occurs in oculocutaneous albinism. In this group of inherited disorders, melanocytes are present but there is decreased or absent synthesis of tyrosinase and marked diminution in the biosynthesis of melanin. In tyrosinase-positive albinism, melanin synthesis can be induced *in vitro* when the skin or hair bulbs are incubated in tyrosine and dopa. In the tyrosinase-negative type this does not occur. There are various possibilities why there is defective melanization and it is possible that in the tyrosinase-positive type there is active inhibition *in vivo* of tyrosinase. Defective melanization occurs in untreated patients with phenylketonuria because of what is believed to be competitive inhibition of tyrosinase by the elevated levels of phenylalanine. Darkening of the hair is seen when these patients are put on diets that are low in phenylalanine.

Melanocytes can be lost from the skin as a result of such physical causes as thermal burns and ionizing radiation. Certain chemicals, particularly substituted phenols [9], have a selective destructive effect on functional melanocytes. Many of these compounds, for example the monobenzylether of hydroquinone, can produce in humans a permanent depigmentation of the skin, such as seen in vitiligo (Fig. 39.13). Acquired hypomelanosis may be due to a number of inflammatory disorders of the skin in which melanocytes may be lost and destroyed. Also, failure of the transfer of melanosomes from the melanocyte to surrounding keratinocytes can occur and probably accounts for the hypomelanosis seen in lesions of psoriasis and in eczema.

Hypermelanosis similarly can be due to many factors, both genetic and acquired. It can be due to an increased number of melanocytes in the skin such as occurs in the dermal melanocytoses: the naevus of Ota, the naevus of Ito and the Mongolian spot. Many of the hypermelanotic disorders are due to an increase in melanogenesis due to genetic factors. Some may be induced by UV light, hormones and chemical compounds. Rarely, patients with metastatic malignant melanoma develop a generalized hypermelanosis of the skin and mucous membranes due to numerous pigment-containing cells in the dermis [10,11].

Fig. 39.13 Occupational vitiligo due to tertiary-butylphenol.

An ultrastructural study [12] has shown that in some white patients with diffuse hypermelanosis there is a tendency for the melanosomes to be dispersed singly in the keratinocytes rather than aggregated in melanosomal complexes. Large non-aggregated melanosomes, as seen in black skin, are found in tanned white skin treated with trimethylpsoralen and exposed to long-wave UV radiation [13].

Finally, the degradation of melanosomes may vary in different disorders of pigmentation. Autophagocytosis of melanosomes occurs in melanocytes in Chédiak–Higashi syndrome [8] and is seen in naevus depigmentosus [14].

Normal pigmentation, racial variation and response to sun exposure

Genetic factors play the primary role in determining the degree of pigmentation that is normal for the individual, i.e. *constitutive* skin colour, as well as the response to exposure to sunlight, i.e. *inducible* skin colour [1]. Considerable variation in skin colour exists among humans, the main racial groupings being Caucasoid (white), Mongoloid (oriental), Negroid (black) and Australoid (aboriginal) (see Chapter 69). It has been estimated that three to four gene pairs account for the variation in colour between black and white people in the USA. Racial differences in melanocyte morphology are apparent, but the population density of melanocytes in a particular skin site remains relatively constant. The main cytogenetic differences lie in the size, shape and distribution of the melanosomes, particularly their packaging within the keratinocytes. Ultrastructural studies have shown that in white people the melanosomes are small and tend to be in membrane-bound complexes containing three or more within the keratinocytes [2,3]. The ellipsoidal melanosomes of aboriginals and black people are larger, about 1 μm in length, and tend to be distributed as singlets rather than being aggregated. These larger melanosomes can be found intact in the stratum corneum. The melanosomes in the complexes in white people show degradative changes even in the basal layer of the epidermis and are presumably broken up by lysosomal enzymes [4]. Whether melanosomes are individually dispersed or aggregated in melanosomal complexes appears to depend on the size of the melanosome [2].

The melanin in the skin has a photoprotective role [5]. Melanin acts as a neutral density filter reducing all the wavelengths of light. The superior photoprotection of the black epidermis is due not only to its increased melanin content but also to the packaging and distribution of the melanosomes [4].

A classification of sun-reactive skin types based on sunburn and tanning history is now in general use and has stood the test of time (Table 39.2) [6].

Two types of pigmentation of the skin in humans occur in response to sun exposure [1,7]. The first is immediate pigment darkening, referred to as the Meirowsky phenomenon. This is best observed in those with hyperpigmented skins and is most effectively induced by long-wave UV light (UVA). It is transient and, although rapidly induced, soon fades. The second is the increased pigmentation that follows the erythemal response. This is the delayed tanning reaction and can be seen 48–72 h after the exposure of the skin to UV light.

Hypermelanosis

Familial progressive hyperpigmentation (MIM *145250) [1]

Familial progressive hyperpigmentation has been reported in a black family where diffuse macular areas of hyperpigmentation were present at birth and increased in size and number with age. Pigmented macules also involved mucosal surfaces. Four individuals in two generations were affected. Skin biopsy revealed increased melanin pigment, but normal melanocyte density in the epidermis. Ultrastructural examination revealed an

Table 39.2 Classification of sun-reactive skin types.

Skin type	Sun sensitivity	Pigmentary response
I	Very sensitive, always burn easily	Little or no tan
II	Very sensitive, always burn	Minimal tan
III	Sensitive, burn moderately	Tan gradually (light brown)
IV	Moderately sensitive, burn minimally	Tan easily (brown)
V	Minimally sensitive, rarely burn	Tan darkly (dark brown)
VI	Insensitive, never burn	Deeply pigmented (black)

increased number of melanin granules that were larger than normal [1].

REFERENCE

Periorbital melanosis

Some darkening of the skin around the eyes is not uncommon. Familial periorbital hyperpigmentation is characterized by dark circular areas around the eyes, and is determined by an autosomal dominant gene [1]. Increased pigmentation is first noted below the lower eyelids at the approach of puberty. There is wide variation in its ultimate extent and intensity.

Lentiginosis

The histological and clinical features of lentigo, together with other lesions in which the number of melanocytes is increased, are fully described in Chapter 38. A lentigo is a benign pigmented macule in which there is an increased number of melanocytes. The term 'lentiginosis' is applied when lentigines are present in exceptionally large numbers or in a distinctive distribution. The following clinical syndromes can usefully be differentiated.

Generalized lentiginosis. Lentigines are commonly multiple but appear singly or in small crops at irregular intervals from infancy onwards. Their pathogenesis is unknown and in the great majority of cases no genetic factor is demonstrable.

Unilateral lentiginosis (zosteriform lentiginosis). Lentigines may occur on one side of the body [1]. Cases have been reported with and without associated neurological abnormalities [2–4]. The lentigines can be zosteriform and occur in a dermatomal-like distribution [5–7]. These cases are usually without central nervous system abnormalities and are of a naevoid nature. Lentigines have also been reported within naevoid hypopigmentation [8]. A case of unilateral lentiginosis with contralateral naevus depigmentosus has been reported [9].

Eruptive lentiginosis [1–3]. Lentigines increase in number with age [4]. Very large numbers of lentigines may develop rapidly over the course of a few weeks, usually in adolescents and young adults. The lesions may be telangiectatic at first, but rapidly become pigmented and subsequently evolve as cellular melanocytic naevi.

Multiple lentigines syndrome (LEOPARD syndrome, MIM #151100) [5–9]. A syndrome has been characterized in which multiple lentigines are associated with a wide range of developmental defects. It is determined by an autosomal dominant gene with variable expressivity.

Lentigines are present at birth or first appear early in life and increase in number until puberty. They are most numerous on the neck and upper trunk, but occur all over the body, including the scalp, genitalia, palms and soles. Cardiac abnormalities are frequent—sometimes pulmonary or subaortic stenosis but more commonly conduction defects [10].

Several patients with this syndrome have died at an early age from obstructive cardiomyopathy [7]. Growth tends to be retarded. Ocular hypertelorism and mild mandibular prognathism are the most usual of a variety of skeletal abnormalities. Inconstant features are deafness and genital abnormalities. The deafness, which may be profound, is of sensorineural type. The genital abnormalities include gonadal hypoplasia, hypospadias and delayed puberty. This very variable syndrome has been named LEOPARD syndrome, comprising *l*entigines, *e*lectrocardiographic abnormalities, *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormalities of the genitalia, *r*etardation of growth and *d*eafness.

Histological studies of the lentigines show an increase in pigment in the epidermis with an increased number of melanocytes that are glutted with melanosomes [6]. Macromelanosomes are found in the multiple lentigines syndrome [11].

Many case reports of hereditary generalized lentiginosis are insufficiently detailed to allow their precise classification. In one family, fixation nystagmus is mentioned as an associated defect. It is possible that some such cases are examples of the very variable LEOPARD

syndrome, but the existence of more than one genotype for generalized lentiginosis is not excluded.

Centrofacial lentiginosis (MIM 151000) [1–3]. This uncommon syndrome is apparently determined by an autosomal dominant gene. Small brown or black macules appear during the first year and increase in number up to the age of 8 or 10 years. Their distribution is restricted to a horizontal band across the centre of the face. The mucous membranes are not involved.

Associated defects include coalescence of the eyebrows, a high-arched palate, absent upper median incisors, sacral hypertrichosis, spina bifida and scoliosis. Mental retardation is frequent and many affected individuals are epileptic.

A somewhat similar disorder of multiple lentigines in a centrofacial distribution, sparing the mucosae, but also with lesions on the buttocks, palms and soles, has been reported in black people [4]. Inheritance is dominant. There have been no systemic changes.

Peutz–Jeghers syndrome (MIM 175200)

SYN. PERIORIFICIAL LENTIGINOSIS

Aetiology. Peutz–Jeghers syndrome is an autosomal dominant disorder characterized by lentigines on the lips, buccal mucosa, fingers and toes in association with intestinal polyps [1–3]. Study of a large pedigree [4] demonstrated the variability of the manifestations; clinically normal carriers and monosymptomatic cases are recognized. Peutz–Jeghers syndrome is caused by mutations in a novel serine threonine kinase; the gene has been mapped to chromosome 19p13.3 [5].

Pathology. The pigmented macules show an increase in the amount of melanin in the basal layer of the epidermis. Polyps are found throughout the gastrointestinal tract. They are most numerous in the jejunum and ileum and less frequent in the colon, rectum, stomach and duodenum. In general, the polyps are benign hamartomas. They may show histological rather than biological evidence of malignancy [1,6]. The true malignant potential of the polyps is not as great as in some other genetically determined syndromes with colonic polyps but is not negligible. Malignancies, usually fatal, have involved mainly the gastrointestinal tract (stomach, duodenum, jejunum, colon, rectum, pancreas). There also seems to be an increased incidence of malignancy in other organs (breast, ovary and also some less common types). In one series, there were 16 fatal malignancies in 72 cases with an average age at death of 36 years [7,8]. In another series, 15 of 31 cases had malignancies [9].

Clinical features [1,2,4,6]. Both sexes and all races may be affected. About 40% of cases have no family history and are presumed to be new mutations. The pigmented macules usually appear in infancy and early childhood, but may be present at birth or may develop later in life. The oral mucous membrane is almost constantly involved. Round, oval or irregular patches of brown or almost black pigmentation 1–5 mm in diameter are irregularly distributed over the buccal mucosa, gums, hard palate and lips, especially the lower lip. The pigmented macules on the face are smaller, often under 1 mm, and darker, and are concentrated around the nose and mouth. Larger macules may be present on both aspects of the hands and feet and may be conspicuous on palms and soles. The oral pigmentation is usually permanent, but the macules on the lips and skin may fade after puberty. Rarely, the nails may be pigmented, diffusely or in longitudinal bands. In one case, new pigmented lesions appeared preferentially in areas that had previously had psoriasis [10].

Symptoms attributable to the polyps usually occur between the ages of 10 and 30 years, but may occur in early childhood or be delayed until later adult life. The most common symptoms are repeated attacks of abdominal pain caused by intestinal obstruction. Rectal bleeding is common and haematemesis may occur with gastric or duodenal polyps. Many patients are anaemic. Although there have been several reports [9] of an association with intestinal cancers, the risk is small and the prognosis is similar to that of the general population [11].

Mucosal and facial pigmentation without evidence of intestinal polyposis may be found in relatives. Indistinguishable pigmentary changes beginning in adult life also occur sporadically in individuals without intestinal involvement. In three generations of one family, facial and mucosal lentiginosis occurred without polyposis [12].

Associated abnormalities. Clubbing of the fingers has been noted in many cases. Of women with this syndrome, 10% have ovarian tumours. A granulosa–theca cell tumour of the ovary has been associated in several cases. Precocious puberty in both sexes has been associated with hormone-secreting tumours [8,13]. Lentiginosis of Peutz–Jeghers distribution has been found in association with intestinal haemangiomatosis, which was the source of recurrent severe haemorrhage [14].

Diagnosis. The mucosal pigmentation is the most constant feature of the syndrome. It may require differentiation from that of Addison's disease, in which there is also diffusely increased pigmentation elsewhere. Freckling occurs in those of fair complexion, but the macules are light-influenced, are not periorificial in distribution and do not involve the mucous membranes.

In Cronkhite–Canada syndrome (see below) the volar aspects of the fingers are diffusely pigmented but the mucous membranes are spared. Examination of relatives may assist the diagnosis. At a stage when the polyps are already giving rise to symptoms they may not always be radiologically detectable.

Treatment. In many cases, it may be appropriate to undertake regular endoscopic examinations of the upper gastrointestinal tract and of the whole colon, together with barium follow-through studies of the small intestine every 2 years or so. A pelvic examination should also be done. In view of the generally benign nature of the polyps, routine radical surgery is not required. Individual polyps may require endoscopic or surgical removal. Prophylactic colectomy has sometimes been advocated for cases with numerous colonic polyps.

Cronkhite–Canada syndrome (MIM 175500) [1–6]

Cronkhite–Canada syndrome is a rare syndrome of unknown origin, in which diffuse pigmentation of the palms and the volar aspects of the fingers and macular pigmentation of the dorsa of the hands are associated with gastrointestinal polyposis [1–4,6] (see Chapter 59). The skin changes are assumed to be the result of malabsorption associated with the protein-losing enteropathy.

Diarrhoea, abdominal pain and weight loss, beginning in adult life, are the presenting manifestations. Alopecia, patchy at first but becoming total, begins a few months later, and dystrophic changes in the nails develop at the same stage. The nail dystrophy is distinctive but not pathognomonic and could be explained by the formation of ventral nail in the absence of normal nail production by the matrix [4]. Exceptionally, the nail changes may precede gastrointestinal symptoms by months or years [5].

Hyperpigmentation is present in more than 85% of patients [2]. It consists of light to dark brown lentigo-like macules ranging in size from a diameter of a few millimetres to 10 cm. These hyperpigmented macules are scattered but are most numerous on upper and lower extremities, face, palms and soles. The mucosal surfaces are usually spared, although the buccal mucosa is occasionally affected. In some patients hyperpigmentation is generalized. Treatment of the malabsorption leads to reversal of hyperpigmentation in most cases.

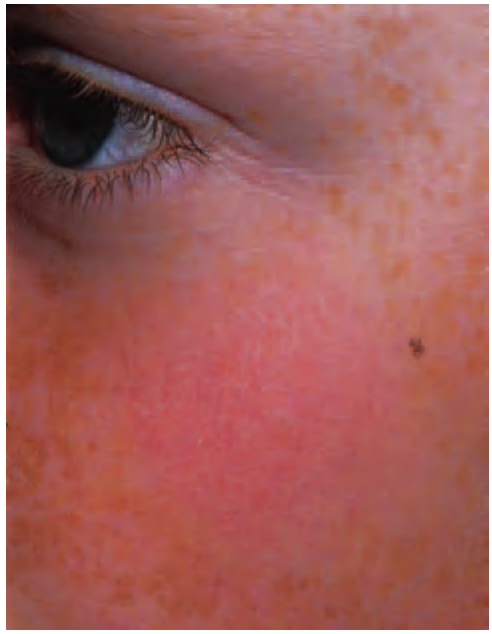

Fig. 39.14 Freckles, one area of which has been bleached by a superimposed patch of pityriasis alba.

Ephelides

SYN. FRECKLES

Freckling is probably determined by an autosomal dominant gene [1]. It is most frequent in individuals with red or blonde hair and blue eyes, particularly in those of Celtic extraction. Red-haired individuals with fair skin (and freckles) have a significantly higher incidence of the gene encoding melanocortin receptors [2,3].

Pathology [4]. There is no increase in the number of melanocytes in the pigmented macules but their melanosomes are long and rod-shaped, like those found generally in dark-skinned people. They form melanin more rapidly after exposure to sunlight than do those in the surrounding pale skin, which are spherical and often granular, and are of the type usually found in fair- and red-haired individuals. With the light microscope, the only abnormality detectable is an increase in the quantity of melanin in the epidermis.

Clinical features (Fig. 39.14). Freckles first appear at about the age of 5 years as light-brown pigmented macules on light-exposed skin. They increase in number, size and depth of pigmentation during the summer months and are smaller, lighter and fewer in number in the winter. They may be cosmetically disfiguring or may enhance appearance, but are not otherwise of significance.

The incidence of melanocytic naevi is increased in freckled individuals.

Treatment. Freckles seldom require treatment and may sometimes be regarded as a desirable cutaneous feature. However, they are amenable to removal by laser for those who desire it [5,6]. Solar lentigines may be improved in appearance by topical treatment which includes retinoic acid [7].

Freckles in various syndromes. Freckles are a feature of a number of inherited and acquired disorders described in this chapter. These include xeroderma pigmentosum [8], neurofibromatosis, Moynahan's syndrome and progeria. The lesions in the various forms of lentiginosis (see above) must also be differentiated. Their distribution and the lack of relationship to light exposure should be noted.

Cutaneous lentiginosis with atrial myxomas (MIM 160980) [1–4]

SYN. NAME SYNDROME; LAMB SYNDROME

This is a rare syndrome comprising various cutaneous pigmented lesions, particularly freckles, cutaneous myxomas, atrial myxomas, which are sometimes bilateral, other cardiac lesions (see Chapter 59) and cerebral artery aneurysms. NAME syndrome comprises *n*aevi, *a*trial myxomas, *m*yxomas of the skin and *e*phelides. Blue naevi occur in LAMB syndrome [4].

Laugier–Hunziker syndrome [1,2]

This rare syndrome of unknown aetiology has no known genetic basis. It is characterized by macular pigmentation of the lips and buccal mucosa together with linear black streaks of the nails. Onset is usually in adult life. There have been no systemic changes. The differential diagnosis of striate melanonychia is considered in Chapter 62.

Penile melanosis/vulvovaginal melanosis [1–3]

Acquired, irregular, brownish or slaty-brown discoloration of the glans or shaft of the penis or of the vulva and vagina may give rise to fears of malignant potential. Histologically, there is only an increase of pigment without any increase or atypia of the melanocytes.

Incontinentia pigmenti (MIM #308300)

SYN. BLOCH–SULZBERGER SYNDROME; BLOCH–SIEMENS SYNDROME

Definition. Incontinentia pigmenti is a complex hereditary syndrome in which vesicular, verrucous and pigmented cutaneous lesions are associated with developmental defects of the eye, skeletal system and central nervous system [1].

Aetiology. The condition is not excessively rare and cases have been reported from many countries [2].

Most pedigrees are small, but from the accumulated genetic data [2–5] it appears that this syndrome is due to an X-linked dominant trait that is usually lethal in males. More than 95% of the reported cases are females, the few males being probably the result of spontaneous mutations and mosaicism of the X chromosome [6,7]. Initial studies indicated that the gene was on chromosome Xp11.2 [8], but subsequent studies confirmed the locus to be on Xq28 [9,10].

Incomplete forms of the syndrome are found in some female relations [4].

Pathology [2]. The bullae are situated beneath the horny layer or within a spongiotic epidermis. The dermis shows non-specific inflammatory changes with a cellular infiltrate, including numerous eosinophils. The infiltrate extends into the epidermis, and the contents of the bullae may consist predominantly of eosinophils (Fig. 39.15). The lichenoid papules show hyperkeratosis, acanthosis and oedema of the basal layer, many cells of which are degenerate. Macrophages laden with melanin are present in the upper dermis. In the warty lesions, the hyperkeratosis is further increased, and within the irregularly acanthotic epidermis are hyaline bodies representing individual cell keratinization. The epidermal changes at this stage may suggest pseudoepitheliomatous hyperplasia. The pigmented patches show diminution or absence of pigment in the basal cells and large quantities of melanin in melanophages in the upper dermis. The epidermis may be normal or slightly acanthotic.

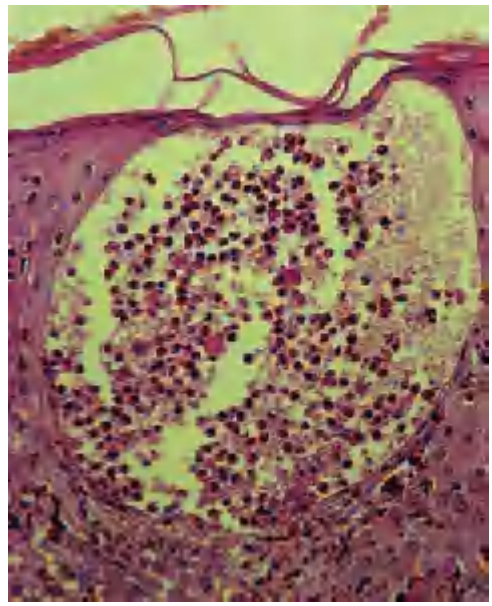

Fig. 39.15 Incontinentia pigmenti. Intraepidermal vesicle containing eosinophils. The spongiotic epidermis has been invaded by an inflammatory infiltrate that includes many eosinophils. Dyskeratotic cells are present.

Ultrastructural studies [11,12] show that, particularly in the early stages, there are many dyskeratotic cells in the epidermis. In addition to eosinophils, there are activated lymphocytes, basophils and mast cells, especially in the upper dermis [13]. In all three stages, melanophages are present.

Clinical features [2,14–16]. The skin changes are often present at birth, have usually developed before the end of the first week and rarely appear after the first 2 months. Three clinical stages are recognized: (i) bullae, (ii) papular and warty lesions, and (iii) pigmentation. However, their sequence is irregular, their duration variable and they

(a)

(b)

Fig. 39.16 Incontinentia pigmenti: (a) linear groups of blisters in a child aged 3 weeks; (b) linear warty lesions on the lower leg of the same child aged 3 months.

Fig. 39.17 Slate-grey pigmentation on the abdomen of a woman who had blistering lesions in childhood and who gave birth to a child with typical incontinentia pigmenti.

may overlap. It is possible that the earlier inflammatory stages can occur *in utero* and not progress after birth.

Clear tense bullae, often in linear groups (Fig. 39.16), develop on the limbs in recurrent crops; less often they are generalized. The crops continue for a few days or for a month or two. They are accompanied or followed by smooth red nodules or plaques, often irregularly linear, on the limbs and trunk. The plaques may be extensive and may precede the bullae. They may be bluish-purple in colour and may ulcerate. Linear warty lesions may appear on the dorsa of hands and feet, particularly on the fingers and toes. Warty lesions around the nails with underlying lytic bone lesions have occurred in adolescence [17]. The pigmentation, which may be the only abnormality, may be present from the outset or may appear as the inflammatory lesions are subsiding, although not necessarily in the same sites; inflammatory lesions can develop in areas that are already pigmented. Activity may rarely persist into adult life [14]. The pigmentation, ranging in colour from blue-grey or slate to brown (Fig. 39.17), is characteristic of the syndrome, and the bizarre 'splashed' or 'Chinese figure' distribution is diagnostic. Multiple, linear and macular telangiectases have occasionally been present [18].

Peripheral eosinophilia, up to 50%, is usual when acute inflammatory skin changes are present. There is evidence of both neutrophil and lymphocyte dysfunction, and altered immunological reactivity is observed in some patients [3,19].

The inflammatory lesions are uncommon after the age of 6 months but may be followed by atrophy or sclerosis. The pigmentation persists for many years, slowly fading until it is imperceptible by the second or third decade. Hypopigmented and atrophic streaks are not uncommonly found in the later stages of incontinentia pigmenti. They may also occur in young children. They may be anhidrotic [13]. Such lesions may be the only remaining sign of childhood disease and may then be of importance in counselling parents who already have an affected child. The hair is usually normal, but in about 25% of cases patches of cicatricial alopecia, resembling pseudopelade, are present from birth or develop in infancy at or near the vertex. The nails are usually normal but may be small and dystrophic. A case of keratoacanthoma developing within a pigmented area of incontinentia pigmenti was speculated to represent a late manifestation of the disease [20].

In over half the reported cases, organs other than the skin have also been involved.

Dental defects are frequent: delayed dentition, partial anodontia and cone- or peg-shaped teeth are the most usual. The absence of teeth, especially the upper lateral incisors and premolars, has been recorded in otherwise unaffected siblings and in the mother who may likewise appear normal.

Ocular defects [2,21] are found in about 30% of cases, many patients being blind. The defects include strabismus, cataract, uveitis, optic atrophy, retinal vascular abnormalities

and a condition resembling retrolental fibroplasia. Microphthalmia also occurs.

Central nervous system disorders [2] occur in about 25% of cases. These include mental retardation, slow motor development, spastic tetraplegia and diplegia, microcephaly and epilepsy.

Skeletal abnormalities [2] are less common and are usually minor, although skull and palatal defects are reported.

Diagnosis. The combination of bullae with linear nodular or warty lesions in a female infant is pathognomonic. During a purely bullous phase, infantile pemphigoid must be excluded. Both conditions present with blood and tissue eosinophilia, but in infantile pemphigoid the eruption remains monomorphic and the bullae, in irregular clusters, commonly develop on the hands, feet, face and genitalia and are not followed by the characteristic pigmentary changes. Epidermolysis bullosa and other bullous eruptions of infancy should not cause difficulty. At a later stage when only the splashed pigmentation is present, it has to be differentiated from post-inflammatory pigmentation of other types and from other genetically determined pigmentary disorders. Incontinentia pigmenti achromians (hypomelanosis of Ito) is a completely separate disease (see p. 39.52). Biopsy of the skin in the blistering phase is often of help in establishing the diagnosis (see Fig. 39.15) with the presence of many eosinophils in the epidermis and dermis.

Treatment. Usually no treatment is necessary other than the control of secondary infection. Systemic therapy with corticosteroids or sulfapyridine (sulphapyridine) is usually unsuccessful. Skilled dental supervision will minimize the cosmetic disability. As with other serious genetically determined disorders, family counselling should be offered.

Fanconi's syndrome (MIM #227650) [1–9]

SYN. PANCYTOPENIA WITH CONGENITAL DEFECTS

Fanconi's syndrome is a rare autosomal recessive condition characterized by widespread mottled skin pigmentation, petechiae, microcephaly, genital hypoplasia, generalized hyperreflexia, internal strabismus and normal intelligence [1,2,8]. The full syndrome occurs more frequently in boys than in girls.

Chromosome breakages occur in a high proportion of phytohaemagglutinin-stimulated lymphocytes in most of the patients studied. A DNA-repair defect is implicated [4].

Clinical features [1,2,8]. The age of onset is usually between 4 and 10 years, and either cutaneous or haematological abnormalities may be the presenting manifestation. In 85% of cases, there is generalized, dusky or olive-brown pigmentation, often most intense on the lower trunk, in the flexures and on the neck. Scattered over the dusky areas are often depigmented macules of 'raindrop' type and macules of darker pigmentation. Rarely, only café-au-lait macules are present.

A constant feature is progressive hypoplastic anaemia with neutropenia and thrombocytopenia, usually presenting as an increased bleeding tendency [7]. The haematological manifestations appear earlier in males. The pancytopenia usually causes death in 2–5 years. In recent years, treatment with anabolic steroids has improved survival, and histocompatible bone marrow transplantation is also to be considered. Haematological defects may be

present in otherwise normal siblings. There is an increased incidence of acute leukaemia and other neoplasms [3].

Affected children are usually of slender build with short broad hands with tapering fingers. The thumbs are often rudimentary, with aplasia of the radii. Microcephaly, mental retardation and hypogonadism are frequent and other developmental defects occur. Few patients survive to adult life, although this is recorded [2].

Diagnosis. The diagnosis of Fanconi's anaemia is made on clinical grounds and by haematological assessment. The association of pigmentation of very similar type with pancytopenia is seen only in dyskeratosis congenita. Prenatal diagnosis is now possible by demonstrating increased spontaneous and induced chromosomal breakage in cultured fetal amniocytes or chorionic villous cells [9].

Albright's syndrome (MIM #174800) [1–7]

Albright *et al*. [1] described a syndrome in 1937 characterized by polyostotic fibrous dysplasia, skin pigmentation and (in females) precocious puberty.

Aetiology. The cause is unknown. Simple monostotic and polyostotic fibrous dysplasia affects the sexes equally and is relatively common. Fibrous dysplasia with associated pigmentation is unusual and is more frequent in females than in males. The full syndrome with precocious puberty occurs only in girls [2,3].

Pathology [4]. In the majority of patients, the number of melanocytes is not increased either in the lesions or in normal skin, and in split-skin preparations the giant pigment granules characteristically seen in Malpighian cells and melanocytes in neurofibromatosis are rarely to be found.

Clinical features [1,4–7]. Cutaneous pigmentation usually develops between the ages of 4 months and 2 years,

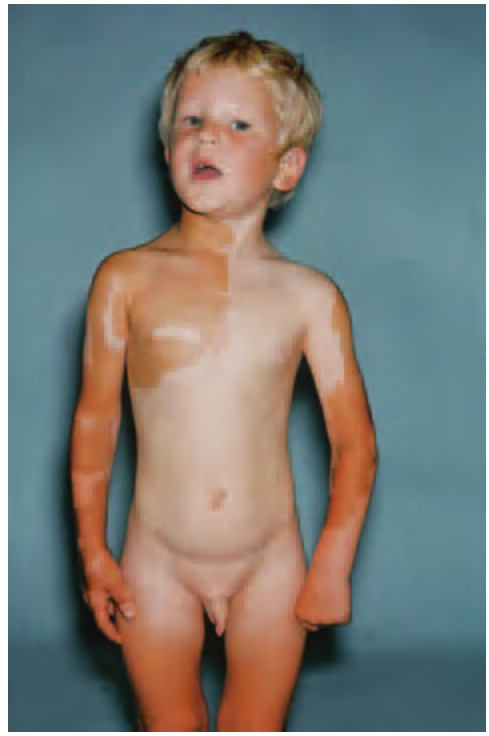

Fig. 39.18 Large pigmented macules in a child with Albright's syndrome. (Courtesy of Professor N.R. Rowell, Leeds General Infirmary, Leeds, UK.)

but may be present at birth. Extensive light-brown patches, often with an irregular or serrated margin, occur mainly on the trunk, buttocks and thighs, but may rarely involve the face and neck. They tend to be asymmetrical and to be most extensive on the side showing the most severe bone involvement (Fig. 39.18).

The bone lesions usually reveal themselves during the first decade by aching pain, pathological fractures and secondary deformities [3]. Bony overgrowth at the base of the skull may produce defective vision or proptosis. Serum calcium and phosphorus are normal but alkaline phosphatase may be elevated if the bone lesions are numerous. In females, precocious puberty, manifested by breast enlargement or by vaginal bleeding and growth of pubic hair, occurs below the age of 5 years in about 50% of cases and between 5 and 10 years in 30%. Growth in childhood is accelerated but the epiphyses unite prematurely.

Other developmental abnormalities may be associated. The prognosis for life is good and the pathological fractures unite normally.

Diagnosis. There is no single clinical feature of the pigmented lesions that reliably differentiates Albright's syndrome from neurofibromatosis, in which bone lesions and endocrine disturbances may also occur. The presence of many café-au-lait macules, freckles in the axillae and Lisch nodules on the iris are diagnostic for neurofibromatosis.

Giant pigment granules may also rarely be found in Albright's syndrome.

Other hereditary disorders with hypermelanosis

Increased pigmentation is an incidental or inconstant feature of many other genetically determined syndromes characterized predominantly by ectodermal dysplasia or diffuse connective-tissue defects. Such conditions are described in other chapters but are briefly mentioned below in differential diagnosis. There are also a number of unusual syndromes of which pigmentation is the most conspicuous or the only manifestation. The interrelationships, classification and nomenclature of some of these syndromes, of which few examples have been reported, are not reliably established [1,2].

Naegeli–Franceschetti–Jadassohn syndrome (MIM *161000) [3–11]

SYN. NAEGELI SYNDROME

This rare syndrome, inherited as an autosomal dominant condition, is known in one large Swiss family [3]. A very similar condition with associated onychodystrophy is described in an English family [4].

Reticulate pigmentation develops during the second or third year in a previously normal child. It may become very extensive and is not preceded by any inflammation. Often the neck and axillae are particularly affected. The fine network of hyperpigmentation differs from the irregular splashes and whirls seen in incontinentia pigmenti. Keratoderma of the palms and soles is usual. Hypohidrosis with intolerance to heat is common. The hair and nails are normal, except in the English family where the fingernails and toenails are of almond shape. The teeth may be normal or defective, with yellow discoloration of the enamel. Mental and physical development is normal. In addition to pigmentary incontinence, varying amounts of colloid–amyloid bodies have been found in the superficial dermis [5].

A number of cases have been described that show a combination of some of the features of Naegeli–Franceschetti–Jadassohn syndrome and of incontinentia pigmenti [6–8].

Reticulate hyperpigmentation may be associated with alopecia, nail changes and growth retardation [7] and there may be a history of blisters [9]. There may or may not be sweating defects [10]. Reticular pigmentation with milia has also been described as a variant of Naegeli–Franceschetti–Jadassohn syndrome [11].

Mendes da Costa syndrome (MIM *302000) [1,2]

SYN. DYSTROPHIA BULLOSA; TYPUS MACULATUS

This rare syndrome, determined by a sex-linked recessive gene, is known only in a single family in Amsterdam [1,2]. The affected individuals, all boys, are normal at birth. They develop tense bullae, irregularly scattered on trunk and limbs, between the ages of 2 months and 3 years. Soon after the bullae begin to appear the hair is lost, and conspicuous coarsely reticulate pigmentation develops on the face and limbs in association with macular atrophy. Some patients are physically and mentally retarded and the expectation of life is poor.

Cantú's syndrome (MIM 114620) [1]

This is inherited as an autosomal dominant. Brown macules develop in adolescence on the face, forearms and feet. The palms and soles are hyperkeratotic.

REFERENCE

1 Cantú JM, Sánchez-Corona J, Fragoso R *et al*. A 'new' autosomal dominant genodermatosis characterized by hyperpigmented spots and palmoplantar hyperkeratosis. *Clin Genet* 1978; **14**: 165–8.

Dyskeratosis congenita (MIM #305000) (see Chapter 12) [1–4]

Reticulate hyperpigmentation, most conspicuous on the neck, chest and thighs, develops between the ages of 5 and 13 years [1]. It is usually preceded by nail dystrophy and accompanied or followed by leukoplakia of the oral, ocular and anal mucous membranes [2,3]. The skin has a poikilodermatous appearance with atrophy and prominent telangiectasia. Haematological abnormalities are common [4].

The condition is inherited as a sex-linked recessive, although autosomal dominant pedigrees are described. There is an increased risk of malignant disease [2,3].

Dermatopathia pigmentosa reticularis (MIM *125595) [1–5]

Since the first description in 1958 [1], 10 cases have been reported [2,3]. The condition is probably inherited as an autosomal dominant [4]. Onset is usually in early childhood or from birth. The most striking change is widespread reticulate pigmentation with pigmentary incontinence and sometimes liquefaction degeneration of the basal layer. Associated findings have included a variable combination of alopecia, nail changes, palmoplantar hyperkeratosis and loss of dermatoglyphics. The genetics of the disorder are uncertain. An isolated case from the Netherlands also presented ainhum-like constrictions of the digits [5].

Becker's syndrome [1–4]

This is different from Becker's naevus (see Chapter 15). It consists of discrete or confluent brown macules on the neck and forearms, present from early infancy in three sisters. There was no atrophy or telangiectasia. In another case, somewhat similar mottled pigmentation of neck and elbows appeared at the age of 10 years [2].

Two other syndromes defy classification: diffuse pigmentation of the trunk and neck, beginning in the first year, with later development of small white macules in the pigmented areas [3]; and diffuse pigmentation with conspicuous macular depigmentation on the trunk, associated with macular and reticulate pigmentation of the neck [4].

Acromelanosis [1–12]

Diffuse hyperpigmentation of the dorsal aspects of fingers and toes is not uncommon in individuals of dark complexion [1]. It has been reported in mulattos and white, black and oriental people. A simple dominant gene is implicated. There may be more than one genotype. The pigmentation begins in infancy or childhood and increases in depth and extent. There may be increased pigmentation in the flexures of the finger joints and in the larger joint flexures. The condition must be differentiated from hyperpigmentation induced by repeated trauma. Sporadic cases presenting in infancy with progressive hyperpigmentation of the fingers and toes are reported as 'acromelanosis progressiva' [2] and acromelanosis [1,3]. Some examples of acropigmentation show a reticulate pattern [4].

Reticulate acropigmentation of Kitamura [5–9]

Previously reported only in Japan, this is now recognized to be worldwide [5–8]. The condition is inherited as an autosomal dominant and in the first two decades a network of freckle-like areas of pigmentation develops on the dorsa of the hands. They may subsequently involve most

Fig. 39.19 Reticulate acropigmentation of Kitamura. (Courtesy of Dr W.A.D. Griffiths, St John's Institute of Dermatology, London, UK.)

parts of the body (Fig. 39.19). Palmar pits and breakages of epidermal ridge pattern are found. Several individual cases and families have been reported with features of both Kitamura's disease and reticulate pigmented anomaly of the flexures (Dowling–Degos disease) [9–11]. Histologically, the pigment macules show epidermal atrophy and an increased number of melanocytes.

Symmetrical dyschromatosis of the extremities (MIM *127400) [12–14]

SYN. ACROPIGMENTATION OF DOHI

This has been reported mainly from Japan, where it is not uncommon. It appears to be determined by an autosomal dominant gene. An identical or closely similar syndrome has been described in European [12], Afro-Caribbean and Indian patients [13]. During infancy or early childhood, mottled pigmentation with areas of depigmentation develops on the dorsa of the hands and feet and sometimes on the arms and legs. The face is spared, apart from a few scattered, small, discrete, pigmented macules.

A symmetrical acroleukopathy reported in a Japanese mother and daughter [14] began soon after birth around the nail folds and reached the distal interphalangeal joints by adolescence.

Hereditary universal melanosis [1–4]

A number of rare or even unique clinical pictures have been reported with such names as melanosis diffusa congenita, universal acquired melanosis (carbon baby) [4], familial progressive hyperpigmentation, familial diffuse melanosis, generalized pigmentation and dyschromatosis universalis. The relationship between these various entities and their inheritance is often in doubt. Pigmentation is usually present from early infancy but it may be progressive. It is often diffuse and generalized but may later become rather mottled.

Reticulate pigmented anomaly of the flexures (MIM 179850) [1]

SYN. DOWLING–DEGOS DISEASE

This disorder of pigmentation combined with epidermal changes is considered in Chapter 12. Cases showing features of this and of reticulate acropigmentation, suggesting that there is some overlap in pathogenesis, are discussed above [1].

REFERENCE

Schimke immuno-osseous dysplasia (MIM #242900) [1]

Schimke immuno-osseous dysplasia is a rare autosomal recessive spondylo-epiphyseal dysplasia characterized by short stature, unusual facies, hyperpigmented macules, proteinuria with progressive renal failure, lymphopenia with recurrent infections and cerebral ischaemia. There is no effective treatment for patients suffering from this syndrome other than supportive measures.

Neurofibromatosis (MIM *162200) (see Chapter 12)

Café-au-lait marks are present in 90% of patients with neurofibromatosis, particularly in those with NF-1, and may appear early. They are round or oval patches of light-brown pigmentation. They are also found in 10% of normal subjects. The presence of one or two is not diagnostic in the absence of other signs of the disease but if six or more are present, with a diameter of 5 mm or more, the probability of neurofibromatosis is high.

Extensive melanotic macules can also occur and resemble those seen in Albright's syndrome; however, these tend to be confined to a particular site and are on either side of the midline. Axillary freckling is common in neurofibromatosis and is an aid to the diagnosis. Lisch nodules and iris hamartomas are present in most patients over the age of 6 years (Fig. 39.20). Giant pigment granules (macromelanosomes) are found in the café-au-lait macules (Fig. 39.21).

NF-1 accounts for 85% of all neurofibromatosis. The NF-1 gene has been identified on the proximal long arm of chromosome 17 [1,2]. It is inherited as an autosomal dominant trait with variable penetrance and expression, and a spontaneous mutation rate of around 50%. NF-2 has the same mode of inheritance, high spontaneous mutation rate, high penetrance and variable expression as NF-1. The NF-2 gene is located near the centre of the long arm of chromosome 22 [3].

Werner's syndrome (MIM #277700) [1–3]

Werner's syndrome is a rare autosomal recessive disorder characterized by primary growth retardation, features of premature ageing and an increased prevalence of malignancy [1]. Localized or diffuse hyperpigmentation is commonly seen [1–3]. Less commonly, depigmented spots with greying of the hair are present [1–3]. The gene for Werner's syndrome (*WRN*) has now been cloned and sequenced, and mutational analysis has confirmed that most cases are caused by one of three major mutations in the *WRN* gene [4].

Gaucher's disease and Niemann–Pick disease (see Chapter 57)

Pigmentation of two types occurs in adults with Gaucher's disease: brown patches of chloasma type on the face, neck and hands; and symmetrical pigmentation of the lower legs with a sharp lower margin and an irregular upper margin. There may also be a brown wedge-shaped thickening of the bulbar conjunctiva.

In the acute infantile form of Gaucher's disease, the skin is not pigmented, but in Niemann–Pick disease there is diffuse brown pigmentation, most marked on the face.

Xeroderma pigmentosum (see Chapter 12) [1]

Freckle-like pigmentation of the face and other exposed skin begins in infancy or early childhood. The light- or dark-brown macules are associated with telangiectases, small white atrophic spots and later with keratoses and tumours. The freckled sun-exposed skin with associated severe photosensitivity in a young child is a striking clinical phenotype not easily overlooked.

Hypermelanosis in endocrine disorders

Some of the mechanisms by which endocrine glands influence melanogenesis are discussed on pp. 39.10–39.11. Here are considered clinical syndromes showing endocrine-induced pigmentary changes (see also Chapter 59).

Addison's disease [1–3]

Pigmentation is rarely absent in Addison's disease, but may be slight in cases of rapid onset. It is diffuse but is most intense on areas exposed to light, and is accentuated in the flexures, at sites of pressure and friction, and in the creases of palms and soles. Normally pigmented areas, such as the nipples and genital skin, darken. Pigmentation of the buccal mucous membrane is almost invariable, and the conjunctival and vaginal mucous membranes may also be involved. However, less distinctive patterns of pigmentation are not exceptional [2], and in any unexplained melanosis adrenal function should be carefully evaluated. Vitiligo-like lesions may also occur in Addison's disease [3].

The hypermelanosis is the result of increased secretion of melanotrophic hormones by the pituitary. Affected patients have elevated plasma levels of β-MSH-like immunoreactivity.

Acromegaly

Pigmentation of addisonian pattern is present in some cases of acromegaly, and may be a striking feature.

Cushing's syndrome [1–4]

Pigmentation of addisonian pattern has been noted in 10% of reported patients with Cushing's syndrome. It is an indication of secretion of ACTH and β-MSH by the pituitary and should suggest the probable presence of a pituitary tumour. After adrenalectomy, progressive hypermelanosis develops in a proportion of patients, about 10%, in spite of adequate hormone replacement therapy. Only in half of these patients is the sella turcica enlarged [1,2]. These patients with Nelson's syndrome [3] show marked hypermelanosis, with the mucous membranes also being involved. The hair is often darker and there are sometimes multiple lentigines and longitudinal pigmented bands in the nails. Very high levels of both β-MSH and ACTH are found in the plasma [4].

4 Abe K, Nicholson WE, Liddle GW *et al*. Normal and abnormal regulation of β-MSH in man. *J Clin Invest* 1969; **48**: 1580–5.

Hyperthyroidism

Pigmentation occurs in about 10% of patients with primary thyrotoxicosis [1]. It is usually diffuse and is broadly of addisonian pattern, although involvement of the mucous membranes is uncommon and pigmentation of nipples and genital skin is less striking. The eyelids are occasionally conspicuously pigmented (Jellinek's sign). Some patients show chloasmal rather than diffuse pigmentation. The incidence of vitiligo is increased. Diffuse pigmentation was present at birth in the infant of a thyrotoxic mother [2].

Pregnancy and menstruation

Increased pigmentation is almost invariable in pregnancy and is most marked in brunettes. A blotchy hypermelanosis of the face involving the cheeks, forehead and chin is frequently seen. This was called chloasma, but the term 'melasma' is now preferred (see p. 39.40). The pigmentation may involve the neck and is associated with darkening of the nipples, the linea alba to form the linea nigra, and the anogenital skin. The pigmentation usually fades after parturition, but may persist for months and years. The same pigmentation can be idiopathic and familial and is particularly seen in those who tan readily when exposed to bright sunlight [1,2]. It is noted by some women to be more apparent just prior to menstruation [3].

Oral contraceptives

Melasma (chloasma) (see p. 39.40) is frequently seen in women on oral contraceptives. No one oral contraceptive appears to be more liable than any other to cause pigmentation in predisposed subjects. The hypermelanosis is made more apparent with sun exposure. These patients also develop the same pigmentation when pregnant [4]. The pigmentation takes a long time to fade after discontinuing oral contraception and, as after pregnancy, it may never fade completely.

The mechanism is not fully elucidated and although MSH may be involved it plays a minor part. Oestrogens and progesterone are involved in the increased pigmentation but other factors are also implicated [2]. In a study of idiopathic melasma it was suggested that some of the patients had mild ovarian dysfunction [5]. Plasma concentrations of MSH are normal in patients with idiopathic melasma [5] and in those on oral contraceptives [6].

Phaeochromocytoma

Pigmentation of addisonian pattern occurs in some cases of malignant phaeochromocytoma. Hypertension, headaches, profuse sweating, palpitation and apprehension will suggest the diagnosis, which is established by the abnormal plasma catecholamines.

Carcinoid syndrome

Hyperpigmentation of the skin has been noted in a number of patients with this syndrome.

ACTH administration [1,2]

A small proportion of patients treated with ACTH in high dosage (120 units/day) develop pigmentation of addisonian pattern. The pigmentation, which is accompanied by a combination of addisonian and Cushingoid manifestations, fades when the dose is reduced.

The incidence of melanosis appears to be rather higher in patients treated with tetracosactrin [2].

Hypermelanosis in other systemic disorders

Increased pigmentation is an inconstant feature of a wide variety of systemic disorders and may be associated with malignant disease. In most instances, the mechanism is

obscure although, in some, elevated levels of β-MSH-like immunoreactivity are found. A genetic predisposition may be present in those affected. The hypermelanosis may be diffuse or localized. It may be confined to the epidermis, when the skin appears brown in colour, or it may be in the dermis, when often the skin is a slaty-grey or blue colour. Pigments other than melanins may also be present.

Chronic infections [1]

Pigmentation may occur in many chronic infections, but it is difficult to determine the relative responsibility of the infection and of malnutrition and other factors. It has been associated particularly with malaria, kala-azar, schistosomiasis and tuberculosis, but is occasionally seen in other chronic infections. Diffuse, light-brown pigmentation is a feature of the later stages of subacute bacterial endocarditis. It has been suggested [1] that the activity of the reticuloendothelial system is inversely related to adrenocortical activity. With stimulation of the reticuloendothelial system by these chronic infections and consequent reduced adrenocortical activity, this would lead to enhanced pigmentation of the skin.

REFERENCE

Neoplastic disease [1–5]

In cachectic states there may be diffuse hyperpigmentation of the skin as in Addison's disease. The mechanism is uncertain. In the ectopic ACTH syndrome, which may occur in patients with oat cell carcinoma of the bronchus, pigmentation is usual. The tumour has been shown to produce a distinct MSH-like compound [1].

In an adult, acanthosis nigricans (see Chapter 34) is associated usually with internal malignancy, almost invariably an adenocarcinoma. The hypermelanosis affects the axillae, nipples and umbilicus, which also show a warty papillomatosis. These skin changes may later become generalized. The mucous membranes are frequently involved.

A diffuse dermal melanosis, having a slaty-blue colour, can occur secondary to melanoma and melanogenuria [2,3]. Ultrastructural studies on this rare condition have shown in one patient [4] single-cell metastases disseminated widely through the skin; in another [5] the dermal histiocytes contained many lysosomal bodies containing electron-dense granular material, presumably melanin.

Lymphomas [1–3]

Pigmentation is an uncommon manifestation of lymphomas, occurring in 10% of cases of Hodgkin's disease and in 1 or 2% of cases of lymphosarcoma and lymphatic leukaemia. The pigmentation is of addisonian type, but allegedly without involvement of the mucous membranes. Malnutrition may be a factor and post-inflammatory pigmentation after scratching may modify the clinical pattern. Diffuse progressive hyperpigmentation can also be a manifestation of mycosis fungoides [1,2]. A number of different clinical patterns for early mycosis fungoides have been described, including pigmented purpura-like lesions [3] (see Chapters 48 & 54).

Several of the cytostatic drugs used for the treatment of these disorders can also produce increased pigmentation of the skin (see Chapter 73).

Diseases of the nervous system [1–3]

Pigmentation, usually conforming to the addisonian pattern, occurs in some diseases of the nervous system, particularly those involving the diencephalon and the substantia nigra. Intense pigmentation is a feature of Schilder's disease [1] but some increase in pigmentation is not uncommon in hepatolenticular degeneration [2] and in ependymomas. It is occasionally noted in chronic schizophrenia. In post-encephalitic parkinsonism, it may be diffuse but may be melasmal. Pigmentation may sometimes develop after intense and prolonged emotional stress [3].

Fig. 39.22 Generalized pigmentation in a woman aged 33 years with systemic sclerosis.

Rheumatoid arthritis and Still's disease [1,2]

Pigmentation, usually generalized, is occasionally observed in rheumatoid arthritis and is a more frequent feature of Still's disease. It may sometimes be caused by medication taken to treat the rheumatoid arthritis, such as minocycline [1] or methotrexate [2].

REFERENCES

Systemic sclerosis, scleroderma and morphoea [1–9]

Generalized pigmentation in systemic sclerosis and scleroderma may be intense and diffuse or of addisonian type, but without mucous membrane involvement [1]. It may involve predominantly the face and limbs but is often far more extensive than the scleroderma (Fig. 39.22). Hyperpigmentation in systemic sclerosis is seen most commonly in patients with pigmented skin, and is less common in whites [2]. Keratinocyte endothelin-1 production has been implicated as playing a central role in the pathogenesis of cutaneous hyperpigmentation in systemic sclerosis [3], as has local expression and systemic release of a stem cell factor [4]. Levels of soluble cell surface L-selectin are elevated in systemic sclerosis with diffuse hyperpigmentation [5].

Pigmentation may also be a conspicuous feature of morphoea [6] and is occasionally the presenting symptom (Fig. 39.23). Hyperpigmentation is sometimes a feature of atrophoderma of Pasini and Pierini [7], and has also been reported in the linear atrophoderma of Moulin [8]. Prominent post-inflammatory hyperpigmentation has been reported in a case of porphyria cutanea tarda with idiopathic myelofibrosis and CREST syndrome [9].

Fig. 39.23 Morphoea. Hyperpigmentation was the presenting symptom.

Dermatomyositis and lupus erythematosus [1,3]

Diffuse pigmentation may accompany or follow the cutaneous lesions of dermatomyositis [1]. Acanthosis nigricans has also been reported in association with dermatomyositis [2]. In systemic lupus erythematosus, diffuse pigmentation of light-exposed skin occurs in about 10% of cases. It may gradually darken, although the disease is controlled by treatment. Longitudinal melanonychia may occasionally be a feature of systemic lupus erythematosus [3].

Multiple organ failure [1]

Patients with multiple organ failure who survive for long periods are susceptible to hyperpigmentation. Renal failure, hepatic failure and polypharmacy may all contribute to this. An unusual case of intense green colour in a patient with multiple organ failure was attributed to dyes in the liquid tube feeds [1].

Renal failure [1–4]

Chronic renal disease with nitrogen retention is frequently accompanied by increased pigmentation of the skin. This hypermelanosis is diffuse and brown in colour. It is most intense on the hands and face. Hyperpigmented macules are common on the palms and soles [3]. Elevated levels of β-MSH are found in the plasma of these patients [1,2] and cause the excess production of melanin in the skin. The increased levels of β-MSH-like immunoreactivity are due to slow clearance by the kidney rather than increased production by the pituitary. Lipochromes and carotenoids deposited in the skin may also play a part. Paradoxically, hypopigmentation with acquired lightening of hair is sometimes a feature of chronic renal failure [4].

Anaemia [1–8]

Hyperpigmentation of the skin occurs in vitamin B_{12} deficiency and is more common in dark-skinned races [1]. A diffuse brown pigmentation is also seen occasionally in patients with folic acid deficiency [2,4]. Pigmentation of the fingertips and nails of a patient with B_{12} deficiency has been reported [5]. The pigmentation seen in association with B_{12} deficiency often has a rather dappled and mottled appearance, and particularly affects the face, hands and feet [3,5,7]. Sometimes, only the fingers are affected. Treatment with vitamin B_{12} reverses the pigmentation of the skin to normal [7,8]. Pigmentation also occurs in megaloblastic anaemia associated with pregnancy [2]. In the haemolytic anaemias, hypermelanosis and haemosiderosis may develop on the lower legs.

Hepatic cirrhosis

A diffuse hypermelanosis is seen in patients with cirrhosis due to many aetiological factors. It is particularly striking in patients with primary biliary cirrhosis, when it may occur at an early stage. The excess melanin is dispersed widely in the epidermis [1]. No significant difference from normal controls is observed in the levels of MSH-like peptides. Lichen planus may be associated with primary biliary cirrhosis [2], and as lesions resolve they leave slaty-brown hypermelanotic macules.

Haemochromatosis (see Chapter 57)

Pigmentation, bronzed or slaty-grey in colour, involves first the exposed skin but later generalizes [1]. It is present in some 90% of cases [2], but may not be conspicuous. The diagnosis should be suspected when pigmentation of this pattern occurs in middle-aged men, is supported by the finding of an enlarged liver and diabetes, and is confirmed by the high level of serum iron [1–3]. Hyperpigmentation

is reversible with phlebotomy [3], and a single case with high serum ferritin showed no post-inflammatory hyperpigmentation with sclerotherapy for spider veins [4].

Amyloidosis (see Chapter 57)

Localized pigmentation, often symmetrical, is seen in both lichen and macular amyloidosis [1,2]. The macular type of amyloidosis is often mistaken for banal post-inflammatory hyperpigmentation, but the lesions often have a distinctive 'ripple' pattern, and microscopic studies reveal the presence of amyloid. Melanophages are found in the papillary dermis. The melanin contained in these dermal cells is derived from degenerating basal keratinocytes and melanocytes [1,3]. Macular amyloidosis is seen most commonly on the upper back (interscapular areas), chest, buttocks, forearms and shins.

Vitamin A deficiency (see Chapter 57)

Severely malnourished patients with the pathognomonic ocular lesions of vitamin A deficiency also show cutaneous changes. In children, dry skin is the main manifestation of vitamin A deficiency and may be associated with hyperpigmentation of the face and limbs. In adults there is dryness and scaling of the skin with abundant desquamation associated with generalized hyperpigmentation. Conjunctival pigmentation has been noted particularly in the oriental races and may be striking, especially in the lower fornix and bulbar conjunctiva.

Pellagra (see Chapter 57) [1]

Hyperpigmentation is frequent in pellagra, and is confined to sun-exposed sites. It follows the onset of the dermatitis that characterizes this condition. Following erythema and sometimes bullae on sun-exposed skin, the skin becomes mildly oedematous with brown scales and haemorrhagic crusts. The exposed skin becomes hard, dry and cracked and in extreme cases is black in colour. The sites of involvement are the face, neck, dorsa of hands and feet, and sometimes the forearms. These changes are seldom seen elswhere.

Malabsorption syndromes

In sprue and other malabsorption syndromes, pigmentation is of common occurrence and may sometimes be prominent [1,2]. It may be of addisonian type but without involvement of the mucous membranes, or may occur in well-defined patches on the face and neck and occasionally on the trunk. The scaly inflammatory plaques (see Chapter 57) that may develop in these syndromes are usually followed by intense pigmentation.

Vagabond's disease

This classically occurs in those in whom lack of food is combined with lack of cleanliness, and heavy infestation with pediculi. The pigmentation is basically of addisonian pattern and the mucous membranes may be involved.

The pathogenesis is uncertain, but the hypermelanosis is probably post-inflammatory and related to the scratching from the pediculosis infestation. Areas of hypomelanosis occur and there is a decrease in the number of melanocytes that show degenerative changes [1]. Adrenal function is in most cases normal [2].

SYN. CROW–FUKASE SYNDROME; SHIMPO'S SYNDROME; PEP SYNDROME; POEMS SYNDROME

This multisystem disorder characterized by polyneuropathy, dysglobulinaemia, anasarca, pigmentation,

scleroderma, hypertrichosis, endocrinopathy, hepatosplenomegaly and lymphadenopathy is discussed in Chapter 57.

Hypermelanosis of drug origin [1–6]

Pigmentation may be induced by a wide variety of drugs [1,2]. Several mechanisms are involved in drug-induced changes of pigmentation of the skin. These include increased melanin synthesis, increased lipofuscin synthesis, deposition of drug-related material and post-inflammatory hyperpigmentation [6]. For example, the phenothiazines, particularly chlorpromazine, react with melanin to form drug–pigment complexes, probably due to a 'charge transfer reaction'. In contrast to melanin, the chlorpromazine–melanin complexes are not metabolized by the body. Imipramine hyperpigmentation is thought to be produced by a similar mechanism [7]. Many drugs induce hypermelanosis as a non-specific post-inflammatory change in predisposed subjects. The pigmentation following fixed drug eruptions is of this type. Other drugs induce pigmentation more directly: in the case of arsenic it is believed that it combines avidly with sulphydryl groups in the epidermal cells and promotes the action of tyrosinase. A post-inflammatory hyperpigmentation of the skin is seen following the resolution of drug-induced lichenoid reactions. Oestrogens stimulate melanin production, and drug-induced hyperpigmentation may be seen with the combined oral contraceptive [5]. Hyperpigmentation in AIDS patients may occur as a complication of drug therapy, most notably with zidovudine which causes pigmentation of nail, skin and oral mucosa.

Chlorpromazine and related phenothiazines [1–10]

Bluish-grey pigmentation of the sun-exposed areas of the skin is seen in a small percentage of patients receiving high doses of chlorpromazine for long periods [1,2]. The pigmentation is cumulative and some develop a purplish tint. Related phenothiazines may cause a similar effect, but chlorpromazine is usually implicated [3]. Some of those affected also develop cataracts, corneal opacities and pigmentation of the conjunctivae [4]. The nail beds are also affected in severe cases [2]. Sun exposure is a factor. The mechanism is uncertain, as discussed above, but probably involves drug–melanin complexes. There is extensive deposition of melanin-like material throughout the reticuloendothelial system and involving the parenchymal cells of internal organs. The pigment found in the cells of the dermis stains as for melanin [1,2]. Electron microscopy studies [5] show increased melanin in the epidermis and perivascular macrophages in the dermis that contain electron-dense particles. Radioactively labelled chlorpromazine is found to localize in tissues containing melanin [6]. It is believed that this drug or some metabolite is bound to melanin in the tissues [9]. The level of immunoreactive β-MSH in the plasma of these patients is within the normal range [7].

The administration of penicillamine as a copper-chelating agent has diminished the pigmentation in some cases [8]. It ultimately slowly fades after phenothiazine therapy is stopped.

A blue-grey pigmentation of the sun-exposed areas of skin has been reported following treatment with low-dose trifluoperazine [10].

Hydantoin [1,2]

Phenytoin (diphenylhydantoin) is the prototype of the hydantoin derivatives. Some 10% of patients receiving hydantoin preparations develop pigmentation of the face and neck, resembling chloasma, which fades in a few months when the drug is stopped. It has been suggested that hydantoin exerts a direct action on the melanocytes; it has been shown to expand melanophores in amphibian larvae.

A patient on this drug developed pigmentation of addisonian type and other evidence of hypoadrenalism [2].

Arsenic (see Chapter 73)

Prolonged ingestion of inorganic arsenic may result in diffuse pigmentation, most intense on the trunk, where macular areas of depigmentation within areas of hyperpigmentation produce the distinctive 'raindrop' appearance [1]. Many cases also show arsenical keratoses, but the severity of the two manifestations of arsenic poisoning is not necessarily proportionate and either may be present alone.

Antimalarial drugs [1–5]

About 25% of patients receiving chloroquine or hydroxychloroquine for several years develop bluish-grey pigmentation on the face and neck and sometimes the lower legs and forearms. With continued therapy, the areas darken, particularly oval patches on the shins, which increase in size. A blue-black colour may develop. Also, these patches are more pigmented in the light-exposed areas. The nail beds may be affected diffusely or in transverse bands and the hard palate may be bluish-grey. Bleaching of the colour of the hair occurs and when associated with pigmentation of the skin should suggest the diagnosis [4]. Corneal and retinal changes may develop following pigmentation of the skin due to antimalarials [3]. Chloroquine has been shown to have an affinity for dermal melanin [4]. A yellowish pigmentation of the skin is common with mepacrine [5]. Pigmentation appears to result from complexes of melanin, haemosiderin and mepacrine, in combination with sulphur [5]. Quinine and quinidine may also produce a generalized pigmentation [3,6].

Antitumour agents [1–7]

Long-term administration of busulfan (busulphan) produces a diffuse brown pigmentation, particularly in non-white people with a dark complexion. Less commonly, Addison's disease is simulated [2,3]. Light and electron microscopy studies suggest that busulfan has both a stimulatory and a toxic effect on melanocytes [4]. Both busulfan and doxorubicin cause mucous membrane pigmentation. Other cytostatic drugs that may produce hyperpigmentation include cyclophosphamide, bleomycin, fluorouracil, hydroxyurea, daunorubicin, methotrexate, mithramycin, mitomycin, thiotepa and Adriamycin [6,7]. Topical cytostatic drugs that produce localized hyperpigmentation include carmustine, mechlorethamine and fluorouracil. Patients on cyclophosphamide [5], bleomycin, daunorubicin, doxorubicin and fluorouracil can develop banded or diffuse pigmentation of the nails. Hair pigmentation may be induced by methotrexate, and pigmentation of the teeth may be seen with cyclophosphamide.

Fixed eruptions [1–6]

Circumscribed areas of slate-brown pigmentation commonly follow the erythematous and bullous stages of fixed eruptions (see Chapter 73) but almost universal brown pigmentation has followed the long-continued ingestion of phenolphthalein [3]. Fixed eruptions are particularly frequent in black people. More or less symmetrical, discrete patches are usually seen but the melanosis may be diffuse or melasmal, and the mucous membranes may be involved [4,5].

The slate-brown colour in fixed drug eruption is due to pigmentary incontinence with melanophages in the upper dermis [6].

Post-inflammatory hypermelanosis

Hypermelanosis commonly follows acute or chronic inflammatory processes in the skin. The intensity and persistence of the hypermelanosis are greater in dark-skinned subjects. The degree of inflammation appears to be of less significance in determining the pigmentary response than the nature of the dermatosis, for it may be frequent and severe after some conditions and slight after others [1]. Disorders where there is disruption of the basal layer of the epidermis, such as lichen planus or lupus erythematosus, frequently develop areas of slate-brown hypermelanosis. Similarly, in fixed drug eruptions, hyperpigmentation occurs owing to damage of cells in the basal layer. There is pigmentary incontinence with melanophages in the upper dermis [2]. In the late phase of chronic graft-versus-host reaction, there is a poikilodermatous appearance with hyperpigmentation [3].

Hypermelanosis of the epidermis may also occur in inflammatory disorders, but more frequently there is hypomelanosis of the skin. This results from an increased mitotic rate of keratinocytes and diminished transfer of melanosomes from the melanocyte to these cells, which also exhibit a reduced transit time from the basal layer to being shed on the skin surface. Very frequently in inflammatory disease in the skin, hypermelanosis and hypomelanosis occur together, often with a slaty-blue colour due to the presence of melanophages in the upper dermis. There may be an associated loss of functional melanocytes in the skin [4].

The cause of the pigmentation is usually obvious, although the preceding lesions have sometimes not been noticed by the patient or have been transitory or clinically imperceptible. The pattern and distribution of the pigmentation will sometimes allow a retrospective diagnosis, as in lichen planus, herpes zoster, dermatitis herpetiformis and papular urticaria. Pigmentation is often conspicuous after lichenoid drug eruptions, and is a feature of lipomelanic reticulosis.

An unexplained, but not excessively rare, clinical syndrome has been reported in some dark-skinned white people [5]. A small irregular patch of hypermelanosis of the interscapular skin is often intensely pruritic. It seems likely that this condition is in fact notalgia paraesthetica [6,7] (see Chapter 60).

Reticulate pigmentation following the vascular network is characteristic of erythema ab igne (see Chapter 22), which may occur at any site regularly exposed to the heat of a fire or a hot-water bottle. A reticulate pigmentation is also seen in prurigo pigmentosa, a dermatosis mostly occurring in Japan [8].

Post-inflammatory hyperpigmentation may occur following trauma to the skin. It can occur following dermabrasion and particularly in those who are racially pigmented. Unusual patterns may declare their origin, for example the tooth-mark pattern on an ill-treated child [9] or the symmetrical pigmentation of the sides of the chin in a patient who, as a nervous tic, chews the buccal mucosa [10].

In late secondary syphilis, especially in women, so-called syphilitic leukoderma is occasionally seen. Diffuse hypermelanosis of the sides and back of the neck and the shoulders is mottled with depigmented macules 1–2 cm in diameter. The Wassermann reaction is always positive. A deep-blue or slate-grey hyperpigmentation is seen in late pinta (see Chapter 30).

Tanning and specific effects of UV light [1–9]

The increased melanin pigmentation of human skin following exposure to sunlight or UV light from various sources is known as 'tanning'. Two separate reactions are recognized: immediate pigment darkening and delayed tanning reaction. Immediate pigment darkening is induced by UV light, particularly UVA (320–400 nm). Visible light

(400–700 nm) is less effective. The reaction is rapid and can be induced in a matter of a few minutes. It reaches a maximum 1–2 h following irradiation and slowly decreases between 3 and 24 h [1]. Ultrastructural studies have shown that in this reaction there are alterations in the distribution of pre-existing melanosomes within the keratinocytes and melanocytes [2–4]. Delayed tanning involves the formation of new melanosomes and is a gradual process that occurs 48–72 h following irradiation of the skin. Alterations in the distribution of 10-nm cytofilaments in the melanocytes are seen in both types of reaction to UV light [2,3]. In delayed tanning, the dopa reaction and tyrosinase activity are markedly increased, and the melanocytes are increased in number and have well-developed dendrites. The minimal UV dose required for the stimulation of melanogenesis varies in the three spectral regions [5].

Tanning and DNA damage are closely associated. Repeated suberythemal doses of UV light induce tanning but have also been shown to induce DNA damage. Skin phototypes II and IV develop similar degrees of DNA damage, but repair is faster for skin type IV [6]. Tanning salon exposure has also been demonstrated to induce cyclobutane pyrimidine dimers and p53 protein expression in epidermal keratinocytes, changes linked with the early stages of cutaneous carcinogenesis [7]. It is widely believed by lay people that a tan provides good protection against sunburn. However, tanned skin has been shown to be less effective against formation of DNA photoproducts than constitutive pigmentation [8] and has a sun protection factor of 3–5 at best. Population-based surveys reveal that tanning is still popular, particularly with the young, but that episodes of sunburn remain common [9,10].

Photodynamic and phototoxic reactions [1–5]

Drugs and other chemicals with photodynamic and phototoxic activity potentiate the pigmentogenic effect of UV light. Tanning follows the sunburn-like reactions to drugs such as demethylchlortetracycline and imipramine, but does not occur after photoallergic reactions [3].

If the photodynamic agent is applied directly to the skin, the intensity of the pigmentary response is greatly enhanced. Transient hyperpigmentation has been reported due to photodynamic therapy in acne [4] and localized scleroderma [5]. Hypermelanosis may sometimes be heavy and persistent following photodynamic and phototoxic reactions. The more or less diffuse patterns of pigmentation so induced are considered below, together with other facial melanoses. Two distinctive clinical syndromes are Berloque dermatitis and phytophotodermatitis.

Phytophotodermatitis [1–3]

SYN. MEADOW DERMATITIS; STRIMMER DERMATITIS; WEEDWACKER DERMATITIS

This is an inflammatory and pigmentary reaction of the skin to light, potentiated by furocoumarins in plants (Fig. 39.24). All the plants reliably recorded as inducing this reaction in humans have been shown to contain furocoumarins, including cow parsley (*Anthrisus sylvestris*) and giant hogweed (*Heracleum sphondylium*) [1,2]. The reaction occurs in those exposed to sunlight after these plants have been crushed on the skin. There is some individual variation in susceptibility but with adequate exposure most will react. If the inflammatory phase is severe, bullae are formed, but in milder cases only the pigmentary changes are conspicuous and follow the irregular pattern of the points of contact of the plant stems and leaves with the uncovered skin. Serial dilutions of psoralens may, in exceptional cases, be needed to distinguish photoallergy from phototoxicity [3].

Common clinical patterns for phytophotodermatitis include a bizarre network of pigmented streaks on the legs

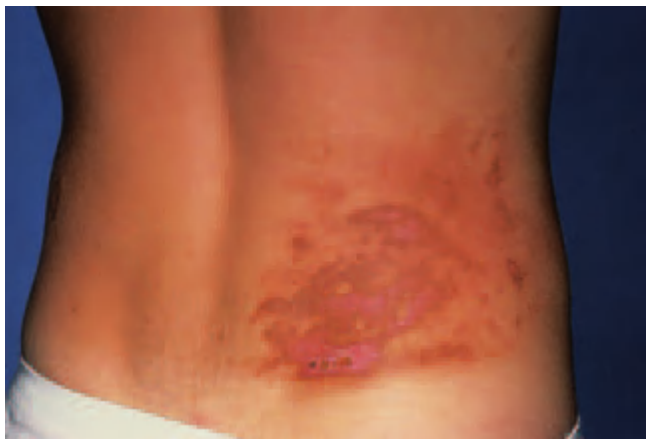

Fig. 39.24 Phytophotodermatitis. Linear, streaky pigmentation following an acute blistering reaction caused by giant hogweed and sunlight.

or arms (meadow dermatitis), and much finer spots and small streaks on forearms and legs from contact with plant material during strimming (strimmer dermatitis). Squeezing limes outside when preparing cold drinks can cause blistering of the hands if carried out on sunny days. Handling celery either at harvest or when it is sold can cause phytophotodermatitis of the fingertips if it takes place in direct sunlight.

Berloque dermatitis (Fig. 39.25) [1–8]

Berloque dermatitis results from the potentiation of UV-stimulated melanogenesis by 5-methoxypsoralen (bergapten) in bergamot oil contained in perfumes. The term arose from the method of applying perfume to the sides of the neck and upper chest in a pendant shape (*berloque* is French for pendant). The action spectrum for this reaction includes wavelengths of UV light above 320 nm. There is wide individual variation in susceptibility, and the reaction occurs in only a small proportion of those exposed [5]. This variation depends on the readiness with which the bergapten is absorbed, the quantity applied, and the intensity and duration of exposure to UV light. Susceptibility is increased by stripping the horny layer [6]. Hot humid conditions favour absorption.

The pigmentation occurs in susceptible subjects who have been exposed to light after the application of perfume. The distribution of the lesions is therefore variable but their configuration is usually distinctive. Deep-brown

Fig. 39.25 Berloque dermatitis.

pigmentation follows the pattern formed by the trickle of the droplets of perfume over the skin from their points of application. The pigmentation fades after weeks or months. The condition is now much less frequent, although it is a continuing cosmetic problem [7].

Following the application of psoralens to the skin and irradiation with long-wave UV light, there is an increase in the number of functional melanocytes. These cells are more dendritic and more dopa-positive. There is an increase in melanogenesis and in white skin the distribution pattern of the melanosomes in the keratinocytes is changed from the aggregated to the non-aggregated form [4,8].

PUVA lentigines [1–6]

These pigmented macules develop in all the treatment-exposed areas in patients who are on long-term photochemotherapy with psoralens and UVA (PUVA) [1]. They vary in appearance and may be numerous in number and small in size. Occasionally, larger irregular lentigines are seen, some with a stellate configuration [2] (Fig. 39.26). PUVA lentigines are usually permanent and show little tendency to remit. A less common clinical pattern is localization of lentigines to sites previously affected by psoriasis, creating an appearance not unlike a naevus spilus [3]. The histology is that of a lentigo. The melanocytes are hypertrophic and some may be cytologically atypical [4]. Similar melanocytic macules have been reported following use of a sunbed [5]. PUVA has also been reported to cause hyperpigmentation of the nails [6].

Erythema dyschromicum perstans [1]

SYN. ASHY DERMATOSIS OF RAMIREZ; LICHEN PIGMENTOSUS

This clinical syndrome of unknown origin was reported first from El Salvador in 1957, then from Venezuela [2], and subsequently from many other countries. It is sometimes called lichen pigmentosus. Ramirez observed a cutaneous eruption in Salvadorians that caused ashy discoloration of the skin, such that affected individuals were called *los cenicientos* (the ash-coloured ones). The exact relationship to lichen planus is uncertain but there are close similarities and both conditions may coexist [3,4]. It has occurred in both sexes from childhood to old age, and is not uncommon.

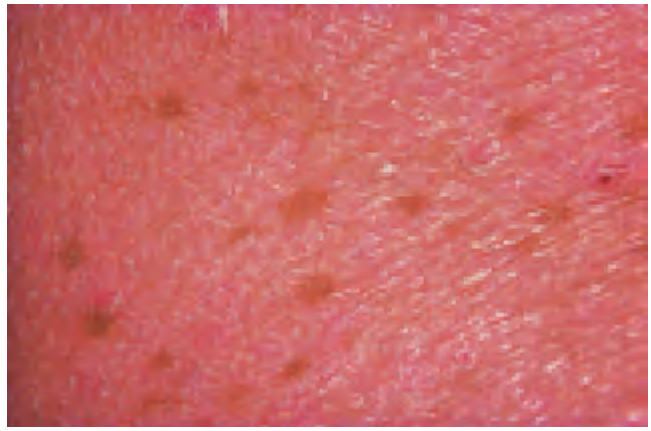

Fig. 39.26 Psoralen and UVA (PUVA)-induced freckles in a patient on long-term treatment.

Histologically, the active border shows vacuolar degeneration of the basal cells. The epidermis contains much pigment and there is pigmentary incontinence; the dermal vessels are sleeved with an infiltrate of lymphocytes and histiocytes, and there are many melanophages [5]. Ultrastructural studies [5,6] show vacuoles within the cytoplasm of basal and suprabasal keratinocytes that contain many melanosomal complexes. One study found IgM cytoid bodies on direct immunofluorescence [7].

Clinically, the condition is characterized by numerous macules of varying shades of grey with a red, slightly raised and palpably infiltrated margin. They vary in size and tend to coalesce over extensive areas of the trunk, limbs and face. Against the general greyish background are macules of hypomelanosis or hypermelanosis. The condition is persistent and slowly extends, but causes no symptoms.

The pigmented macules resemble very closely the lesions of late pinta, but the negative dark-field examinations, negative serological tests for syphilis and lack of response to penicillin are important features that allow the dermatologist to exclude this treponematosis.

Facial melanoses

Hypermelanosis involving predominantly the face and

the neck is relatively common and often presents a complex diagnostic problem. Several more or less well-defined clinical syndromes can be recognized, but many transitional forms defy classification. The causes of the pigmentation are often obscure.

Genetic and racial factors are important, the increased pigmentation occurring more frequently in those with dark skins, especially oriental people. Endocrine factors play a major role in melasma and are implicated to some degree in other melanoses. External agents (light and photodynamic chemicals) are essential factors in the occupational melanoses but are also concerned in Riehl's melanosis, erythrosis and poikiloderma of Civatte. Other unknown factors are certainly implicated, and wide individual variation in susceptibility must be postulated.

Cosmetics may occasionally cause facial melanosis. Facial melanosis is, of course, also a conspicuous feature of addisonian pigmentation.

Melasma (Figs 39.27 & 39.28) [1–3]

SYN. MASK OF PREGNANCY; CHLOASMA

This common acquired hypermelanosis is seen mainly in women, and occurs exclusively on the sun-exposed skin of the face. The majority of cases are attibuted to pregnancy or the combined oral contraceptive pill. In the context of pregnancy melasma is regarded as a normal physiological change, along with darkening of the nipples and linea nigra. It is not uncommon at any time during the years of reproductive activity and has been attributed, without acceptable proof, to a variety of ovarian disorders. The rarity of melasma in post-menopausal women on oestrogen-containing hormone replacement therapy and the fact that men are occasionally affected suggests that oestrogen alone is not the causative agent. Thus, an endocrine mechanism is postulated but its nature is unknown.

The hypermelanosis affects the upper lip, cheeks, forehead and chin and becomes more apparent following sun exposure. The areas are brown in colour and are bilateral and frequently symmetrical. In some women it may be noticeable premenstrually. After pregnancy or after stopping oral contraceptives the condition may fade but is often persistent. Melasma-like hyperpigmentation has been reported from use of phenytoin or mephenytoin (hydantoins).

Up to 10% of cases of melasma are seen in men, particularly Latin Americans and those from the Middle East or Asia.

A variety of topical treatments are effective at lightening melasma [4,5], but these treatments should be combined with assiduous sun-protection measures if the reduced pigmentation is to be maintained.

Riehl's melanosis

SYN. MELANODERMATITIS TOXICA; PIGMENTED COSMETIC DERMATITIS; FEMALE FACIAL MELANOSIS

A distinctive pattern of pigmentation was common in Vienna between 1916 and 1920 [1]. It was again frequently seen in Europe and Asia during and after the Second World War. It has occurred in Argentina and in the South African Bantu [2]. The condition is more frequent in women, and tar derivatives and fragrances are suspected to be the cause [3]. Patients in Japan and elsewhere may show positive patch tests to cosmetics or their ingredients; the disease is then called 'pigmented cosmetic dermatitis' [4,5]. Nutritional and other factors may be involved, for some cases occur in children and in others there is no history of contact with cosmetics. Workers handling coal-tar products, such as pitch, asphalt and creosote or mineral oils, may develop diffuse melanosis of exposed skin through the photodynamic action of anthracene, phenanthrene and other substances [4].

Histologically, in the early stages, there is liquefaction degeneration of the basal layer of the epidermis and a perivascular or band-like dermal infiltrate. There is pigmentary incontinence. Later, the epidermis appears normal but many melanophages are present in the upper dermis [6]. Ultrastructural studies show intercellular and intracellular oedema of keratinocytes and a multilayered basal lamina, as well as many melanophages in the dermis [4].

Brownish-grey pigmentation develops quite rapidly over the greater part of the face but is more intense on the forehead and temples. Smaller pigmented macules, often perifollicular, lie beyond the indefinite margin. The pigmentation may extend to the chest, neck and scalp, and occasionally involves hands and forearms. Horny plugs fill the follicles and there may be some scaling. Unexplained constitutional symptoms are occasionally noted [1]. Where a contact cause can be implicated, removal of the cause leads to slow improvement over many months.

Poikiloderma of Civatte (Fig. 39.29) [1]

This occurs in middle-aged women. The milder forms are common and patients often do not seek medical advice. The distribution implicates exposure to light, and it is probable that photodynamic substances in cosmetics are an important factor. The age incidence suggests that an unknown endocrine factor or age change may also play some part. Reddish-brown reticulate pigmentation with telangiectasia and atrophy develops in irregular, more or less symmetrical patches on the lateral cheeks and the sides of the neck but spares the area shaded by the chin. Treatment with a tuneable dye laser is effective at clearing the telangiectasia of poikiloderma of Civatte, but care is needed as it may also cause scarring and may even worsen the appearance.

Fig. 39.29 Poikiloderma of Civatte on side of neck.

Erythrose péribuccale pigmentaire de Brocq [1–4]

SYN. ERYTHROSIS PIGMENTATA FACIEI

This syndrome occurs predominantly in middle-aged women but has been reported in men. A photodynamic substance in cosmetics is probably responsible. Diffuse brownish-red pigmentation develops more or less symmetrically around the mouth but spares a narrow perioral ring. It may extend up the centre of the face to the forehead and in some cases there are well-defined patches of pigmentation over the angles of the jaw and the temples [3]. The erythematous component, and hence the intensity of the pigmentation, may fluctuate over short periods. The pigmentation is usually persistent but tends gradually to fade if the cause is eliminated.

A similar post-inflammatory hyperpigmentation is seen in some patients with perioral dermatitis and may be the result of topical steroid therapy [4].

Erythromelanosis follicularis of the face and neck [1–5]

This syndrome, of unknown origin, was originally described in Japan but may not be uncommon in white people. The affected individuals have been men, young or middle-aged at the time of onset [1–3], although it has been reported in adult females [4,5].

Histologically, there is slight hyperkeratosis. The hair follicles are enlarged and contain lamellar horny masses. The sebaceous glands are also enlarged. The epidermis overlying the affected follicle is flattened and contains excess melanin. In the dermis, an inconspicuous lymphocytic infiltrate surrounds dilated vessels.

The clinical picture is distinctive. A background of reddish-brown pigmentation with telangiectasia is studded with pale follicular papules. The hairs are lost from the majority of affected follicles in the vellus region, but less conspicuously from the terminal hair of scalp or beard. The pigmentation involves the skin in front of, beneath and behind the ear, extending to the side of the neck. It spreads slowly, is persistent and is not influenced by treatment.

The distribution and lack of clinical follicular keratosis or scarring readily distinguish erythromelanosis from the various forms of keratosis pilaris and from other facial melanoses.

Dermal melanocytosis

SYN. CERULODERMA

Hyperpigmentation of the skin may be due to the presence of functional fusiform and dendritic melanocytes that lie in the dermis [1]. Although dermal melanocytes are common in other mammals, they are not often seen in humans. These cells have failed to reach their proper location in the basal layer of the epidermis in their migration from the neural crest of the developing embryo. Several conditions are grouped under the term 'dermal melanocytosis'. In all of them, the affected areas have a slate-brown or blue colour (ceruloderma) due to an optical effect from the pigment lying in the dermis.

Mongolian spot (Fig. 39.30) [1–4]

Mongolian blue spots are seen in 90% of oriental babies and less frequently in black babies. The usual site of involvement is the lumbosacral region. The spots are poorly circumscribed areas of slate-brown or blue-black pigmentation that are sometimes extensive and may be mistaken for bruises. A case of generalized dermal melanocytosis of the newborn has been described [2]. Mongolian blue spots usually fade in early childhood, although the aberrant extrasacral spots can persist [3]. The dermal melanocytes in persistent Mongolian spots have an extracellular sheath [4], as also seen in the naevus of Ito.

Naevus of Ota

SYN. NEVUS FUSCOCAERULEUS OPHTHALMOMAXILLARIS; OCULODERMAL MELANOCYTOSIS

In naevus of Ota, the hyperpigmentation affects one side of the face in the area supplied by the ophthalmic and maxillary divisions of the trigeminal nerve [5,6]. Occasionally, it is bilateral. It is usually congenital but may appear later in life. It is more prevalent in the Japanese but is observed in other races. The colour is variable, but is usually either slate-brown or blue. The sclera is involved and there may be hyperpigmentation of the cornea, iris, retina, ocular muscles and orbit [7] (Fig. 39.31). Sometimes, there is pigmentation of the hard palate. An ipsilateral sensineural deafness occurring in a patient with naevus of Ota has been reported [8].

Naevus of Ota does not improve with time. Malignant change in the cutaneous lesions of naevus of Ota is extremely rare. However, melanomas are more common in the choroid, iris, orbit and brain of these patients [9]. A bilateral acquired dermal melanosis of the face resembling naevus of Ota has been described [10]. Promising results with the Q-switch ruby laser have been reported in the treatment of naevus of Ota, with multiple treatments increasing the response rate [11].

Naevus of Ito (Fig. 39.32) [4,12]

In this condition, the increased pigmentation affects the area supplied by the posterior supraclavicular and lateral brachial cutaneous nerves. It is common in the Japanese.

Fig. 39.32 Naevus of Ito.

Blue naevus (see Chapter 38) [1]

These commonly occur on or near the dorsa of hands and feet, usually early in life. Malignant transformation does not occur in the common blue naevus. However, the cellular blue naevus may rarely undergo malignant change.

Hypermelanosis associated with other cutaneous lesions

Hypermelanosis is a characteristic feature of urticaria pigmentosa (see Chapter 47) but the mechanism of its production is unknown. The possible relationship between melanocytes and mast cells is discussed on p. 39.4. Tyrosinase-positive cells have been found in the upper dermis in some cases. In the childhood type, the light-brown macules often exceed 2 cm in diameter and the lesions are frequently nodular. In the adult types, the smaller and more numerous macules are purplish-brown in colour and not palpably infiltrated, and often fail to urticate on friction. They are usually widely distributed over the trunk and limbs.

The differential diagnosis of hypermelanosis

The very large number of conditions associated with widespread or localized hypermelanosis cannot readily be classified. The present classification is based on the colour of the skin and on various causative factors. The hypermelanosis may be due to genetic and naevoid factors (Table 39.3) or it is acquired and due to a variety of factors (Table 39.4).

The areas of hypermelanosis may be circumscribed or may be diffuse with intensification of the normal pattern of pigmentation. Hypermelanosis confined to the face and neck is considered on pp. 39.39–39.42. In acquired circumscribed patches of hypermelanosis, a post-inflammatory origin should be considered (see p. 39.45).

Treatment of hypermelanosis

Hypermelanosis, particularly affecting areas on the face, can be the cause of marked cosmetic disability and give rise to much mental distress. Treatment depends essentially on establishing the cause and if possible reversing the conditions that have given rise to the hypermelanosis. In the majority of cases, topical therapy has no place,

although some who are perturbed about their cosmetic disability will demand treatment with a skin-bleaching preparation. Because in many cases exposure to sunlight intensifies the pigmentation, a photoprotective preparation should be prescribed and applied during sunny weather. Cosmetic camouflage may also be indicated.

A number of compounds have been used in skin-bleaching preparations and of these hydroquinone is the most safe. Preparations containing 2% hydroquinone, although not very effective, are of help in producing cutaneous depigmentation [1]. Although higher concentrations of hydroquinone are more potent, these preparations frequently irritate the skin and may produce, if used for long periods of time, an exogenous ochronosis and pigmented colloid millium [2,3]. A formulation of hydroquinone and retinoic acid has some effect in depigmenting human skin and is of use in the treatment of hypermelanotic conditions such as melasma [4–6]. It is not very effective for post-inflammatory hyperpigmentation. Topical tretinoin has been found to be effective in the treatment of actinic lentigines ('liver spots') in photodamaged skin [7] and also improves melasma [8]. The monobenzylether of hydroquinone is responsible for many therapeutic and cosmetic disasters and the compound should be used only to bleach away the remaining pigmented areas in patients with extensive vitiligo [9]. Several other substituted phenols, such as 4-isopropylcatechol, can produce cutaneous depigmentation; however, this compound and others are irritant and may produce sensitization [10].

Hypomelanosis

Genetic and naevoid disorders

A number of genetically determined or naevoid conditions are characterized by localized and/or generalized hypomelanosis of the skin. These are listed in Table 39.5.

Albinism [1–10]

There are many distinct types of oculocutaneous albinism (OCA), each of which is characterized by partial or complete failure to produce melanin in the skin and the eyes. The classification is rapidly changing with the advent of advances in molecular genetics (e.g. rufous OCA is now TRP-1 gene-related OCA or type III OCA). Melanocytes are present in normal distribution but fail to synthesize melanin adequately. These conditions are inherited as autosomal recessive disorders; one rare type with apparent autosomal dominant inheritance is now felt to be due to quasi-dominant pedigree patterns or to partial expression of OCA II in OCA I heterozygotes (Table 39.5). The gene encoding tyrosinase has been localized to chromosome 11 [3] and many different mutations are now recognized for OCA [4]. The gene for type II OCA has been mapped to chromosome 15q11.13 [5]. Tyrosinase-negative albinism is characterized by hair bulbs that, after plucking and incubation with tyrosine, fail to produce darkening. In tyrosinase-positive albinism, the hair bulbs do darken in this test and the precise metabolic defects have yet to be ascertained. The tyrosinase-positive types are the most common. Ultrastructural studies of skin and hair show that in tyrosinase-negative albinos most of the melanosomes are stage 1 and stage 2 without any melanization. Other types may show up to stage 3.

In ocular albinism, only the eyes are clinically involved, although careful investigation of the melanocytes in the skin does show some changes. There are four different types, two X-linked, one dominant and one recessive. Carrier females of the X-linked types may show irregular retinal pigmentation. In two types there is an associated deafness, the melanocytes apparently failing to play a protective role in the ear. In most albinos this defect leads to little or no change in ear function.

Incidence. Albinism is found in all races and the prevalence varies considerably. In the UK, the incidence is

* Brown OCA is currently included as a type of OCA II.
† Platinum OCA may be an alleleic variant of minimal pigment OCA.
‡ Dominant OCA probably does not exist: instances appear to be due to quasi-dominant pedigree patterns or to partial expression of albinism II in OCA I heterozygotes.
§ The term 'albinoidism' is applied to both pigmentary dilution (MIM *126070) and OCA II.

(a) (b)

Fig. 39.33 (a) Tyrosinase-positive oculocutaneous albinism in a black woman aged 40 years. (b) Dark-brown freckles on light-exposed areas.

estimated at 1 in 20 000. In the USA, the incidence of albinism is estimated at 1 in 39 000 in Caucasians and 1 in 28 000 in Afro-Caribbeans. In some countries it is more common, particularly where there is a tendency towards inbreeding and especially in isolated communities. The Cuna tribe on the San Blas islands off the coast of Panama have the highest incidence of albinism in the world (63 per 10 000). In Nigeria, the incidence of albinism is much higher in the south [6]. There are no adequate studies of the incidence of the different genotypes of OCA in the different races.

Clinical features. In all races there is marked dilution of the pigmentation of the skin, hair and eyes. In tyrosinase-negative OCA the skin is pink in colour, the hair is white and the patients show a prominent red reflex. This is the most severe variant of OCA.

In tyrosinase-positive OCA, some pigment is formed and with increasing age is to be found in the iris, skin and hair, the latter often developing a flaxen-yellow colour. These patients may also tan and in black people the skin has a yellowish-brown colour that with age develops dark-brown freckles, particularly in sun-exposed areas (Fig. 39.33). Also in this type, the iris is less translucent and in black people may be brown in colour.

In both types, patients have photophobia; often they have a characteristic facial expression due to apparent squinting. Errors of refraction are common, especially in the tyrosinase-negative type (OCA IA), and almost all patients have horizontal or rotatory nystagmus, sometimes with head nodding. In the tyrosinase-positive type, visual acuity may improve as patients get older and they may have less severe nystagmus [7]. There are abnormalities of the optic pathway. Foveal hypoplasia occurs in the tyrosinase-negative type [7].

In the yellow mutant type of albinism, the newborn resembles the tyrosinase-negative type, but by the age of 1 year the hair is yellow-red in colour. Hair bulbs incubated in tyrosine plus cysteine produce an intensification of the yellow-red phaeomelanin. This type of albinism is prevalent in the Amish communities in the USA [8].

The other types of albinism listed in Table 39.5 have pigment changes described by their names. Each has a rather distinctive racial predisposition.

In temperate climates, the prognosis for the albino is good, the visual defects constituting the greatest disability. In the tropics the fate of albinos is grim. At an early age [9] most of them develop in solar-exposed skin many actinic keratoses, squamous cell carcinomas and, occasionally, melanomas. Some die young from these tumours [6].

Treatment. No treatment is possible other than prescribing photoprotective preparations and limiting sun exposure, vigorous enforcement of which from early childhood can be very helpful. The regular examination of all albinos for the early detection and treatment of premalignant and malignant conditions of the skin is advisable,

especially in the tropics. Prenatal diagnosis of albinism has been reported [10].

*Albinoidism (MIM *126070)*

Albinoidism is the name applied to families where there is some partial defect in melanin production in the skin but only minimal changes in the eyes. The biochemical basis of this is uncertain. Several families are described with this type of albinism [1,2]. Although there is hypopigmentation of the skin and hair, it is not as marked as in OCA. Slight tanning is reported and the hair-bulb test is positive. A diffuse punctate pattern of iris transillumination is seen. The eyes are usually normal, but there may be photophobia. In one large Swiss pedigree there was high-grade myopia [2]. The condition appears to have autosomal dominant inheritance, but in some families it is recessive.

Hermansky–Pudlak syndrome (MIM #203300)

Hermansky–Pudlak syndrome is a rare type of OCA associated with a haemorrhagic diathesis [1]. About 250 cases have been reported, most of whom are from Puerto Rico or the south of the Netherlands [1]. Two different mutations in the gene for Hermansky–Pudlak syndrome have been identified. Tyrosinase-positive OCA occurs in association with a bleeding tendency and deposits of a ceroid-like pigment in the cells of the reticuloendothelial system [2]. The bleeding tendency is attributed to a storage-pool platelet defect. The platelets have decreased numbers of dense granules and reduced levels of serotonin and ADP [3]. Pulmonary fibrosis, granulomatous colitis and lupus nephritis have been associated [4]. There is no defect in circulating lymphocytes or neutrophils [5]. Two cases of Hermansky–Pudlak syndrome have been complicated by systemic lupus erythematosus [6].

Chédiak–Higashi syndrome (MIM #214500)

Chédiak–Higashi syndrome is a rare autosomal recessive disorder characterized by hypopigmentation of the skin and eye [1]. The skin is fair, the retinae are pale and the irides translucent. The hair is light blonde or silvery grey. These children are very susceptible to bacterial and viral infections, and intractable respiratory and cutaneous infections usually prove fatal before the age of 10 years. Longer survival is possible but later the lymph nodes, spleen and liver are enlarged and a malignant lymphoma develops. A similar condition is seen in Aleutian mink [2], Hereford cattle [3] and the beige mouse [4].

The hereditary defect concerns membrane-bound organelles of various cell types and is due to mutations in a gene encoding a protein known as lysosomal trafficking regulator. The melanocytes contain giant pigment granules (Fig. 39.34), which arise by autophagocytosis and fusion of large melanosomes that show degradative changes within the cells [5]. Similar defects of granules and other organelles occur in white cells and platelets. Cytoplasmic inclusions are present in a variety of cells of neuroectodermal origin. The white cells are defective in combating infection and if these children survive infancy, they usually die later from a malignant lymphoma.

Griscelli syndromes type I (MIM #214450) and type II (MIM #607624)

Griscelli syndrome type I comprises partial albinism with neurological deficiency due to mutations in the myosin type V gene.

Griscelli syndrome type II, due to mutations in the *RAB27A* gene, combines partial albinism and immunodeficiency [1], but is distinct from Chédiak–Higashi syndrome. It is inherited as an autosomal recessive condition. In addition to pigmentary dilution, there is immune deficiency and the affected children are prone to recurrent pyogenic infection. There is hypogammaglobulinaemia and defective cell-mediated immunity with lymphohistiocytosis and haematophagocytosis.

Prader–Willi syndrome (MIM #176270) and Angelman syndrome (MIM #105830) [1]

Both syndromes are associated with mental retardation, abnormal behaviour and hypopigmentation. In both there are deletions of the same region of chromosome 15, with deletion on the paternal chromosome in Prader–Willi syndrome and the maternal in Angelman syndrome.

*Cross' syndrome (MIM *257800)*

SYN. OCULOCEREBRAL SYNDROME WITH HYPOPIGMENTATION

Cross' syndrome is one of the 'silvery hair' syndromes and is characterized by generalized hypopigmentation associated with ocular anomalies, mental and physical retardation, ataxia and spasticity [1]. It is probably determined by an autosomal recessive gene [2,3]. The pigmentary and ocular defects are manifest from birth. The hypopigmentation resembles albinism: blood tyrosine levels are normal and the light-coloured hair pigments poorly in tyrosine solution. The ocular defects include microphthalmos, a small opaque cornea and coarse nystagmus. Spasticity soon becomes evident, and physical and mental development is retarded [3].

Piebaldism (MIM #172800) [1–11]

Piebaldism is a rare autosomal dominant condition characterized by stable areas of vitiligo-like amelanotic skin associated with a white forelock [2,3]. The incidence of piebaldism is estimated at less than 1 in 20 000. Both sexes are affected equally, and no race is spared. A similar condition of 'white spotting' is seen in mice and results from deletion or mutation of the c-*kit* proto-oncogene that codes for an embryonic growth factor called Steel factor [4]. Missense and frameshift mutations of the *kit* proto-oncogene, which encodes the cellular receptor tyrosine kinase for the mast cell/stem cell growth factor, are responsible for a range of phenotypes with piebaldism [5,6].

The plurality of defects revealed by electron microscopy suggests that a number of different gene loci are concerned. Ultrastructural studies have shown either an absence of melanocytes and melanosomes in the hypomelanotic areas or sometimes reduced numbers of abnormal large melanocytes. In the hypermelanotic islands in the areas of hypomelanosis, melanocytes are present that produce normal melanosomes but also abnormal spherical and granular melanosomes [9]. When transferred to the

Fig. 39.35 Piebaldism. The lesions had been present from birth.

keratinocytes, these show abnormal degradation and fusion.

Clinical features. Patches of skin totally devoid of pigment are present at birth and usually remain unchanged throughout life. Most common is a frontal median or paramedian patch, associated with a mesh of white hair (white forelock); rarely, this may be the only lesion. Often, white patches occur on the upper chest, abdomen and limbs, bilaterally but not necessarily symmetrically (Fig. 39.35). Occasionally, they are found on the face, particularly the chin. The hands and feet, as well as the back, remain normally pigmented. Islands of normal or hypermelanotic skin occur in the white areas, or less often on normal skin.

Piebaldism can easily be distinguished from vitiligo where the lesions are acquired later in life and their configuration and distribution are quite different. In piebaldism, there is almost invariably a white forelock and the pattern of arrangement of the lesions is quite characteristic. Also the presence of islands of normal pigmented skin in the hypomelanotic areas is typical. If the interpupillary distance is increased or the patient is deaf, the diagnosis of Waardenburg's syndrome (see below) must be considered. The patterns of hypomelanosis as seen in the localized and systematized types of naevus depigmentosus differ from piebaldism. Microscopy of the skin in naevus depigmentosus reveals normal numbers of melanocytes with sometimes rather stubby dendrites [9]. A progressive variant of piebaldism has been described in association with a novel mutation in the *kit* gene [11].

Treatment. Photoprotective preparations should be prescribed to protect the amelanotic areas from burning with sun exposure. Cosmetic camouflage or skin dyes may be helpful for some patients. Skin grafts, minigrafts and grafts of autologous cultured melanocytes have some promise [12,13]. PUVA therapy is generally disappointing, as are topical corticosteroids.

Tietz's syndrome (MIM #103500)

Tietz reported a six-generation pedegree with the constant association of total absence of pigment in the skin and hair, normal eyes, complete deaf-mutism and hypoplasia of the eyebrows [1]. An autosomal dominant gene appeared to be implicated. There is some doubt that this syndrome is a distinct entity.

The analogy with a syndrome in cats, in which severe deafness is associated with total absence of skin pigment but normal eye colour, suggests that Tietz's syndrome probably represents a 'generalized white spot' rather than albinism.

REFERENCE

Waardenburg's syndrome (MIM #193150) [1–11]

Waardenburg's syndrome (WS) is a rare autosomal dominant condition characterized by lateral displacement of the inner canthi and the lacrimal puncta, prominent nasal root and medial eyebrows, congenital deafness and heterochromic irides. The pigmentary changes are a 'dappled' appearance of the skin, a white forelock, which may be conspicuous or only a few strands, and premature greying of hair, eyebrows and cilia. A few patients show piebaldism; pigment-free patches may be large and multiple or small and inconspicuous.

WS has been reported in both black and white people. The incidence has been estimated at 1 in 42 000 in the general population and 1–2% among the congenitally deaf. Variable expression and penetrance explain milder or incomplete phenotypes. The skin lesions so clearly resemble those of piebaldism that a similar pathogenetic mechanism is likely. Some abnormality of the development of neural crest derivatives is postulated.

Four variants of WS have been described. Type I is the classic form, while type II lacks dystopia canthorum but has a high incidence of congenital sensorineural deafness and heterochromia. Type III resembles type I but is associated with limb abnormalities in addition to dystopia canthorum. Type IV, like type III, is autosomal recessive and is characterized by associated Hirschsprung's disease and, in some cases, by more extensive hypopigmentation [7].

A number of different mutations of the *PAX*-3 gene on chromosome 2q35 have now been reported in different forms of type I and type III [4]. None of the cases of type II have been linked to 2q markers but type IIA is now known to be due to mutations in the *MITF* gene. Mutations in the endothelin-3 gene [10] and in endothelin-B genes have been reported in type IV, and mutations in the *SOX10* gene have also been implicated as causing WS [11]. Types IIB and IIC are further subdivisions linked to genes mapping to chromosomes 1p and 8p, respectively. Ultrastructural studies on the amelanotic skin show an absence of melanocytes [5]. In the pigmented areas, there are abnormalities of the melanocytes and melanosomes.

Ziprkowski–Margolis syndrome [1,2]

Ziprkowski–Margolis syndrome is a rare X-linked recessive syndrome that occurs in males. It was first reported in 14 members of an Egyptian–Jewish family with males showing deaf-mutism, heterochromic irides and piebald-like hypomelanosis of skin and hair. The skin appears completely amelanotic at birth, but pigmented macules develop on the extremities, trunk and scalp. The hair usually remains white. Linkage studies indicate the gene locus to be on Xq, probably in the region Xq13–26 [3].

Hypomelanotic macules of tuberous sclerosis

In this neurocutaneous disorder (see Chapter 12), transmitted as an autosomal dominant trait, hypomelanotic macules are found in about 90% of affected babies [1–3]. These macules are usually multiple, irregularly scattered and frequently have a lance–ovate shape: the configuration of an ash leaf (Fig. 39.36). The macules are the earliest manifestation of this disorder and are of diagnostic significance in a baby with fits, especially infantile spasms [1]. They are best identified in the fair skinned with the aid of a Wood's lamp. Electron microscopy of the macules shows the presence of normal or reduced numbers of

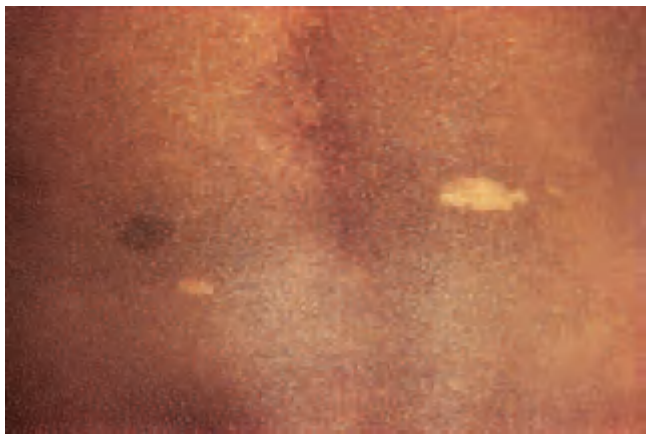

Fig. 39.36 Ash-leaf-shaped hypopigmented macules in tuberous sclerosis.

melanocytes that have poorly developed dendrites and contain fewer and smaller melanosomes than normal [2]. The gene responsible for tuberous sclerosis has been localized to 9q34 (*TSC1*) and 16p13.3 (*TSC2*) [4,5].

Naevus depigmentosus

SYN. ACHROMIC NAEVUS

This is a circumscribed area of depigmentation, usually present at birth and changing little thereafter. The lesions are often single but may be multiple, circumscribed [1], and rounded, dermatomal or in whorls and streaks resembling incontinentia pigmenti achromians of Ito (see below). Histology may show either normal or reduced numbers of melanocytes. A functional defect in melanocytes, with morphological abnormalities of melanosomes, has been identified [2]. Apart from a few reports of associated findings, this is an isolated naevoid abnormality of the skin.

Incontinentia pigmenti achromians of Ito (MIM *300337) [1–7]

SYN. HYPOMELANOSIS OF ITO

This neurocutaneous disorder is characterized by bizarre whorled areas of depigmented skin that are variable in extent and may be unilateral or bilateral. The areas of hypomelanosis occur along Blaschko's lines [6] (Fig. 39.37). The appearances resemble the late stages of incontinentia pigmenti, but this is clearly a quite separate disease without the preceding inflammatory stages and without the sex-linked inheritance of incontinentia pigmenti. There is no basal layer damage and no pigmentary incontinence. Most cases are sporadic, although familial cases have been reported. Mosaicism involving the X chromosome has been found [6]. The white streaks are usually present at birth but may progress thereafter. Eventually, they may repigment. There may be associated disorders in the musculoskeletal system, teeth, eyes and central nervous system [2]. Convulsions and mental deficiency occur commonly in the reported cases [4]. The skin lesions have to be distinguished from the more bizarre-shaped depigmented naevi and from focal dermal hypoplasia where the skin also shows atrophic changes.

Vogt–Koyanagi syndrome

SYN. HARADA'S DISEASE

Aetiology. This complex syndrome affects the skin, eyes, inner ears and meninges. It is rare but widely distributed. Most cases occur in the third and fourth decades but children may be affected. The cause is unknown but an abnormal response to a virus and immunological mechanisms have been postulated. Of interest is the report of the condition occurring in a patient following an operation for metastatic malignant melanoma [1]. In one study, cellular hypersensitivity to uveal pigment was confirmed by leukocyte migration tests [2].

Pathology. Electron microscopy of depigmented skin shows an absence of melanocytes, with replacement by Langerhans' cells and by indeterminate dendritic cells, as in vitiligo [3,4]. Colloid–amyloid bodies are also found at the dermal–epidermal junction [3]. Inflammatory skin lesions are characterized by a chronic, mixed inflammatory cell infiltrate [5].

Clinical features [6,7]. A prodromal febrile episode, which may be trivial or severe with encephalitic or meningitic symptoms and lymphocytosis of the cerebrospinal fluid, is followed after a week or two by bilateral uveitis, often with choroiditis and optic neuritis. Shortly after the establishment of uveitis, deafness and/or tinnitus of labyrinthine origin develops in over 50% of cases. As the uveitis begins to subside, and usually within the first 3 months, vitiligo, poliosis and alopecia may develop. Poliosis, which occurs in 80% of cases, may be limited to the brows and lashes or may involve scalp and body hair extensively. Vitiligo, present in about 60% of cases, is usually symmetrical. Rarely, it may precede the uveitis, even by as much as 3 years. Two cases of vitiligo following a plaque-type inflammatory erythema have been reported [8]. Halo naevi may be present [9]. Alopecia areata occurs in 50%; occasionally the hair loss is diffuse.

The pigmentary changes tend to be permanent. The uveitis, which may take a year or more to clear, may result in total blindness, but most cases show some recovery of visual acuity, although it is seldom complete [10]. Hearing is usually completely restored.

Diagnosis. The association of vitiligo with loss of pigment in brows and lashes and with the residual ocular defects should clearly differentiate this syndrome from any other.

Alezzandrini's syndrome [1,2]

Alezzandrini's syndrome has only been reported in a small number of cases. The syndrome is characterized by unilateral facial vitiligo associated with unilateral retinal degeneration, white hair, poliosis and deafness.

Vitiligo [1–3]

Aetiology. Vitiligo affects all races and has a long history [4]. It is stated that it occurs in 1% of the world's population [2]. An epidemiological survey on the island of Bornholm in Denmark [5] found the prevalence to be 0.38%. It is likely that this figure applies also to other countries in north-west Europe. The incidence of vitiligo in those with racially pigmented skins is higher (and the social impact greater), although reliable figures are not available. There is a preponderance of females in most series based on outpatient attendances, but the frequency in the population is probably the same in both sexes [5].

* Autoantibodies demonstrable.

Fig. 39.38 Vitiligo. Epidermal sheet of marginal depigmented area showing marked reduction in number of melanocytes.

Between 30 and 40% of patients have a positive family history [2], and a genetic factor is undoubtedly involved. Inheritance may be polygenic or determined by an autosomal dominant gene of variable penetrance. Vitiligo has been reported in monozygotic twins [6].

Various theories have been suggested for the aetiology of vitiligo; the same mechanism may not apply to all cases.

- *Autoimmune hypothesis*: this is based on the clinical association of vitiligo with a number of disorders also considered to be autoimmune (Table 39.6). Organ-specific autoantibodies to thyroid, gastric parietal cells and adrenal tissue are found in the serum more frequently in patients with vitiligo than in the general population [11,12]. A complement-fixing antibody to melanocytes has been found in the serum of several patients who in addition to vitiligo had alopecia areata, mucocutaneous candidiasis and multiple endocrine insufficiencies [11]. Antibodies to normal human melanocytes have been detected using a specific immunoprecipitation assay [13,14], and have a cytolytic effect [15]. T-cell profiles are abnormal in vitiligo, with a decrease in T-helper cells [16–18].
- *Neurogenic hypothesis* [19]: this suggests that a compound is released at peripheral nerve endings in the skin that may inhibit melanogenesis and could have a toxic effect on melanocytes. Although vitiligo may sometimes occur in a dermatomal distribution and electron microscopy shows abnormalities of terminal portions of peripheral nerves, there is little support for this hypothesis. However, recent studies on neuropeptide and neuronal markers in vitiligo suggest that neuropeptide Y may have a role [20].
- *Self-destruct theory of Lerner* [2]: this suggests that melanocytes destroy themselves due to a defect in a natural protective mechanism that removes toxic melanin precursors. This hypothesis is based on the clinical features of vitiligo and on experimental studies of cutaneous depigmentation by chemical compounds that have a selective lethal effect on functional melanocytes [21]. These compounds can produce a leukoderma indistinguishable from idiopathic vitiligo.

It has been suggested that defective keratinocyte metabolism plays a major role, with low catalase levels in the epidermis of vitiligo [22]. A new hypothesis involving defective tetrahydrobiopterin and catecholamine biosynthesis has been put forward to explain the pathogenesis of this disorder [23].

Pathology. There is a marked absence of melanocytes and melanin in the epidermis. Histochemical studies [24] show a lack of dopa-positive melanocytes in the basal layer of the epidermis (Fig. 39.38). Recent immunohistochemical studies with a large panel of antibodies show only an occasional melanocyte in lesional skin [25]. Electron microscopy studies [9,26,27] confirm the loss of melanocytes, which appear to be replaced by Langerhans' cells. In the epidermis of areas around the margins of vitiligo are abnormalities of keratinocytes [9] as well as degenerating melanocytes. There is increased cellularity of the dermis and occasional colloid amyloid bodies are found. In inflammatory vitiligo, where there is a raised erythematous border, there is an infiltrate of lymphocytes and histiocytes. This infiltrate is also found in the marginal areas of some biopsies [27].

Clinical features [2,3]. Vitiligo can begin at any age, but in 50% of cases it develops before the age of 20 years. The condition is gradually progressive, sometimes extending rapidly over a period of several months and then remaining quiescent for many years.

Hypomelanotic macules are usually first noted on the sun-exposed areas of skin, on the face or on the dorsa of hands (Fig. 39.39). These areas are prone to sunburn. Rarely, itching in the absence of sunburn may occur. Damage to the 'normal' skin frequently results in an area of depigmentation—an isomorphic or Koebner phenomenon (Fig. 39.40).

Fig. 39.39 Vitiligo.

Fig. 39.40 Isomorphic or Koebner phenomenon at site of a scratch in a patient with vitiligo.

The amelanotic macules in vitiligo are found particularly in areas that are normally hyperpigmented, for example the face, axillae, groins, areolae and genitalia. Areas subjected to repeated friction and trauma are also likely to be affected, for example the dorsa of hands, feet, elbows, knees and ankles. The distribution of the lesions is usually symmetrical, although sometimes it is unilateral and may have a dermatomal arrangement (Fig. 39.41). Rarely, there is complete vitiligo, although a few pigmented areas always remain.

Fig. 39.41 Segmental vitiligo.

The pigment loss may be partial or complete, or both may occur in the same areas (trichrome vitiligo) (Fig. 39.42).

The macules have a convex outline, increase irregularly in size and fuse with neighbouring lesions to form complex patterns. The hairs in the patches frequently remain normally pigmented, but in older lesions the hairs too are often amelanotic. The margins of the lesions may become hyperpigmented. The main symptom is the cosmetic disability, although some patients present because of sunburn in the amelanotic areas. Vitiligo commonly starts in children, who are more likely to show segmental vitiligo, autoimmune diseases or to have a family history of canities [28].

Spontaneous repigmentation is noted in about 10–20% of patients, most frequently in sun-exposed areas. It is usually seen in younger patients, the repigmentation being quite trivial and mainly perifollicular.

In addition to premature greyness of the hair, uveitis also rarely occurs [29]. Careful examination of the ocular fundus may show abnormalities [30]. There have also been suggestions of an increased incidence of deafness [31].

Associated disorders. A number of conditions occur in association with vitiligo and are listed in Table 39.6. Halo naevi [2,3] occur not infrequently and often antedate the onset of vitiligo. Areas of depigmentation sometimes develop in patients with malignant melanoma [10].

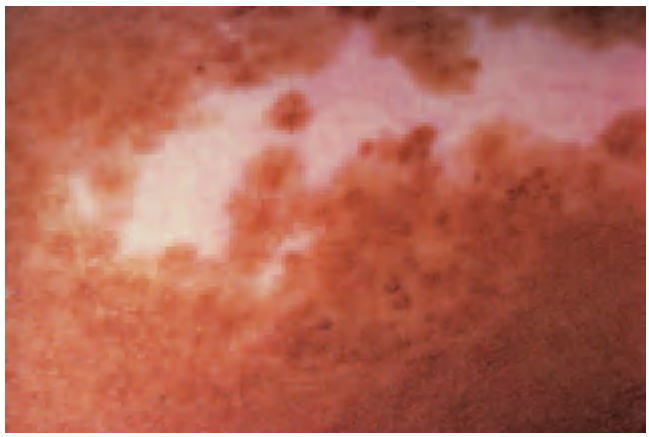

Fig. 39.42 'Trichrome' vitiligo.

Vitiligo with uveitis, central nervous system involvement and premature greying of the hair occurs in the Vogt–Koyanagi syndrome (see p. 39.53).

Diagnosis. The distribution, age of onset and hyperpigmented border will suggest the diagnosis. In piebaldism, the lesions are present at birth, are usually confined to the head and trunk, and rarely show a hyperpigmented border. Careful examination of the texture of the unpigmented skin should exclude lichen sclerosus and scleroderma. Post-inflammatory leukoderma, which is frequent in the darker races, shows an irregular mottling of hyperpigmented and hypopigmented blotches. Hypomelanosis of the affected skin is commonly seen in pityriasis alba, producing slightly scaly areas with rather ill-defined edges on children's faces. Hypopigmented slightly scaly macules are seen in pityriasis versicolor. These areas often fluoresce a golden yellow when examined under a Wood's lamp. The hypomelanotic macules in leprosy are anaesthetic.

Treatment. The treatment of vitiligo is unsatisfactory and in most cases the patient is best advised to seek effective cosmetic camouflage for the lesions on exposed skin. In sunny climates, the prescription of sunscreens is often necessary.

Treatment with systemic psoralens, 4,5',8-trimethylpsoralen, 8-methoxypsoralen or 5-methoxypsoralen, combined with exposure to sunlight or to light sources providing high-intensity long-wave UV light, is effective in a proportion of cases [3,32,33]. The patient is instructed to take the psoralens in a dose of 0.6 mg/kg 2 h before carefully controlled graduated exposure to sunlight, preferably around midday. Therapy is continued for at least 6 months and in some for several years. In the majority of patients, the areas retain the pigment long after psoralen therapy has been discontinued. The use of topical applications of psoralens is hazardous and may result in untoward blistering of the skin. Khellin has also been used with UVA [34].

Narrow-band UVB phototherapy has been found to be effective and safe for vitiligo [35].

In some patients, the more potent topical corticosteroid preparations, 0.1% betamethasone valerate and 0.05% clobetasol propionate, are effective in producing repigmentation of areas of vitiligo, but often at the price of some atrophy [36].

In those patients with extensive vitiligo and only a few residual areas of hyperpigmentation, skin-bleaching creams, such as 20% monobenzylether of hydroquinone, are of use [37].

The use of grafting techniques, minigrafts and autologous cultured melanocytes is interesting but may be limited by the Koebner phenomenon [38–40]. Minigrafting has been carried out with success in some patients with more widespread vitiligo [41]. A systematic review of autologous transplantation methods in vitiligo has recently been performed [42].

Halo naevus [1,2]

SYN. SUTTON'S NAEVUS; LEUKODERMA ACQUISITUM CENTRIFUGUM

Definition and aetiology. Leukoderma acquisitum centrifugum designates the development of a halo of hypomelanosis around a central cutaneous tumour. This tumour is usually a benign melanocytic naevus but may be a neuroid naevus, a blue naevus, a neurofibroma, or a primary or secondary malignant melanoma [1]. The phenomenon, which is not uncommon, is usually seen in children or young adults of either sex.

Halo naevi occur with increased frequency in patients with certain organ-specific autoimmune disorders, as does vitiligo (see above), with which it is often associated. An immunological association of halo naevus with cutaneous malignant melanoma exists. Antibodies against the cytoplasm of malignant melanoma cells are found in the serum of patients with halo naevi [3]. Multiple halo naevi may occur in patients with melanoma.

Pathology [1,4]. Most halo naevi are compound naevi. There is frequently a lymphocytic infiltration of the naevus and the constituent cells may show damage. Ultrastructural studies show the apposition of mononuclear cells with naevus cells that show cytotoxic changes [5]. In the depigmented halo, there is an absence of melanocytes, but Langerhans' cells are present [6]. Melanophages are often present in the dermis.

Clinical features [1,7]. Circular areas of hypomelanosis occur around pigmented naevi, particularly on the trunk, less commonly on the head and rarely on the limbs. Multiple lesions are common, the halos being about 0.5–1.0 cm wide and developing simultaneously or at intervals around several, but not all, naevi (Fig. 39.43). The condition is usually seen in young people. The naevus tends to flatten and may disappear completely. The depigmented areas often persist, but may pigment after many years. Eczema around naevi (Meyerson's naevi) is discussed in Chapter 38.

Treatment. Normally none is required. The usual diagnostic criteria must be applied if there is any possibility that the central tumour is a melanoma. It should be remembered that a halo around a benign naevus is relatively common, whereas malignant melanoma is rare, and a melanoma surrounded by a halo is extremely rare. Mutilating surgery must never be undertaken without preliminary histological examination by an experienced pathologist.

Chemical depigmentation

A number of chemicals can produce cutaneous depigmentation when applied to the skin [1,2]. Several substituted phenols produce an occupational leukoderma in workers coming in contact with them (see also Chapter 21). Of these, *p*-tertiary-butylphenol is the most important [2–4]. Occupational leukoderma occurs in workers in contact with the monobenzylether of hydroquinone [5]; this compound is used in the treatment of hypermelanosis and can produce confetti-like areas of depigmentation in the treated areas [6] (Fig. 39.44). The monomethylether of hydroquinone can induce a similar leukoderma [7]. Several phenolic germicidal preparations can produce depigmentation of the skin [4]. 4-Tertiary-butylcatechol is also a cause of occupational leukoderma [8], and this may follow contact sensitization [9]. The areas most likely to be affected in occupational leukoderma are the dorsa of the hands (see Fig. 39.13), but other areas are involved, not necessarily in contact with the chemicals. The depigmented areas frequently enlarge, and new ones appear

Fig. 39.44 Depigmentation on the face following treatment of melasma with monobenzylether of hydroquinone. (Courtesy of St John's Dermatology Centre, London, UK.)

even after the patient is no longer in contact. The areas may or may not repigment. Treatment with psoralens is usually ineffective. In the hypomelanotic and amelanotic areas, there is often an almost complete absence of melanocytes [3,4]. Experimental studies [1,10] indicate that these substituted phenols have a selective lethal effect on functional melanocytes.

Post-inflammatory and infections

Hypomelanotic areas occur following the resolution of areas of eczema and psoriasis (Fig. 39.45). These are also seen in pityriasis lichenoides and cutaneous T-cell lymphoma [1].

Fig. 39.45 Hypopigmentation in a girl with resolving psoriasis.

Fig. 39.46 Pityriasis alba. (Courtesy of St John's Institute of Dermatology, London, UK.)

The superficial eczema known as pityriasis alba (see Chapter 17) commonly presents with white, somewhat scaly, and not so well-defined areas of skin, which are most noticeable on the cheeks of racially pigmented children (Fig. 39.46).

Hypopigmented macules occur in the superficial fungal infection pityriasis versicolor, a condition frequently mistaken for vitiligo. Hyperpigmented areas are also present. It is suggested that the fungus forms oxidation

products of unsaturated fatty acids of skin surface lipids that inhibit the tyrosinase activity of melanocytes [2]. Other mechanisms are suggested, including the fungus acting as a sun barrier in a thickened stratum corneum. Light and electron microscopy studies of hypopigmented macules [3,4] and of hyperpigmented areas [5] have been unhelpful in determining the mechanisms involved and are confusing. The lack of sunburn in the pale areas may be explained by the fact that the causative yeast produces pityriacitrin, an indole compound that has a broad spectrum of ultraviolet absorption [6].

In a number of inflammatory disorders of the skin, there are areas of hypomelanosis and in these there may be a loss of functional melanocytes. This loss is seen in lupus erythematosus and lichen planus. Hypopigmentation is seen in sarcoidosis [7,8] and leprosy [9]. A leukomelanoderma occurs in syphilis.

Idiopathic guttate hypomelanosis [1–3]

This clinical entity, also known as disseminate lenticular leukoderma [4], can be mistaken for vitiligo. It is common. The lesions in white people most frequently occur in sun-exposed areas of the limbs. Solar damage is a factor in these cases. Non-actinic lesions occur in black people and may be on the trunk in unexposed areas [1].

Clinically, the lesions are porcelain-white macules, usually 2–6 mm in size but sometimes much larger. The borders are sharply defined, often angular and irregular. The skin markings are normal. Histologically, there is a decrease in pigment granules. Histochemical and ultrastructural studies [5,6] show a reduction in the number of melanocytes, many of which lack mature melanosomes. It has been suggested that this disorder results from an age-related somatic mutation of melanocytes.

Symmetrical progressive leukopathy [1]

This has been reported from Japan and Brazil, where it is relatively common. Punctate leukoderma develops in young adults, symmetrically on the front of the shins and on the extensor aspects of the arms, and less often on the abdomen and interscapular region. It is persistent.

REFERENCE

Cutanous lymphoma [1,2]

Cutaneous T-cell lymphoma may sometimes show prominent hypopigmentation. In poikilodermatous mycosis fungoides, clinical lesions are characterized by widespread poikiloderma rather than plaques or nodules. On clinical examination there is alternating increase and decrease in pigmentation associated with epidermal atrophy. In hypopigmented mycosis fungoides, the areas of hypopigmentation are more prominent than in poikilodermatous mycosis fungoides [1,2].

Endogenous non-melanin pigmentation [1]

A variety of substances that are normal constituents of the body may, if present in excess or in an abnormal form or site, give rise to alterations in skin colour. Other substances formed only by patients with certain metabolic defects may also produce pigmentary changes. Special stains of histological specimens, or techniques such as spectroscopy, may help to identify the nature of exogenous and other non-melanin pigments.

Haemosiderosis (see Chapter 48)

The deposition in the tissue of the iron-containing pigment haemosiderin is commonly the result of the local destruction of red blood cells, but also occurs in haemochromatosis. The presence of haemosiderin stimulates melanogenesis, and hypermelanosis may dominate the clinical and histological picture. Such is the case in haemochromatosis (see Chapters 57 & 59). In the much more frequent conditions in which haemosiderin is derived locally from red blood cells, the pigmentation is orange–red at first, later fading through ochre and tawny shades.

Hypostatic haemosiderosis

Haemosiderosis of the lower legs is extremely common in the presence of venous insufficiency. Recently involved areas show grouped points of reddish pigment, but recurrent extravasation of red cells combined with increasing hypermelanosis soon produce a more or less uniform deep brown or coppery colour. The pigmentation usually persists even if the venous insufficiency is relieved.

Sickle-cell anaemia and congenital haemolytic anaemia

Haemosiderosis and melanosis may give rise to conspicuous pigmentation of the lower leg in the third decade or earlier.

Schamberg's disease and related disorders [2] (see Chapter 48)

Haemosiderosis without clinically evident hypermelanosis is seen in Schamberg's disease and other types of capillaritis. Reddish-brown plaques with cayenne-pepper points beyond their margins are present on the legs and thighs and sometimes on the arms.

Small patches of haemosiderosis, most numerous on the lower legs but progressively involving thighs and buttocks, are characteristic of drug reactions to ureides. Haemosiderosis of the trunk is a feature of some reactions to clothing.

Jaundice

Jaundice results from the staining of the skin with bilirubin, which has a great affinity for elastic tissue, hence the early involvement of the sclerae. The range of yellow shades produced by bilirubin may be modified by the presence of biliverdin, which adds a greenish hue. Bronzing is the effect of added melanin pigmentation and is often seen in jaundice of long duration. The sclerae are not involved in carotenaemia or in mepacrine pigmentation.

Bronze baby syndrome [1–3]

This striking grey-brown discoloration of the skin of neonates follows phototherapy for hyperbilirubinaemia and is often associated with evidence of liver dysfunction. The serum is also brownish. The nature and origin of the pigment are uncertain. The changes are reversible unless there is some underlying liver disease.

Riboflavinaemia [1]

Yellow skin and hair have been described in a patient with myeloma, due to riboflavin being avidly bound by a monoclonal antiflavin antibody.

REFERENCE

1 Farhangi M, Osserman EF. Myeloma with xanthoderma due to an IgG monoclonal anti-flavin antibody. *N Engl J Med* 1976; **294**: 177–83.

Carotenaemia [1]

Carotene, a lipochrome, contributes a yellow component to the colour of normal skin. In the presence of excessive blood carotene levels, this yellow component is increased, and is most conspicuously accentuated where the horny layer is thick on the palms and soles. The sclerae are not discoloured. The most striking coloration is seen in food faddists who overindulge in oranges or carrots. Some increased yellowness is seen in conditions with hyperlipaemia, diabetes, nephritis and hypothyroidism, and where conversion of carotene to vitamin A is impaired by an inborn metabolic error [2] or by hepatic disease. However, it is now more commonly seen in young women drastically reducing their weight and eating foodstuffs with high carotene content [3,4].

Carotenaemia is seen in patients on oral supplements of β-carotene as a photoprotective agent in erythropoietic protoporphyria [5,6] and in those taking carotenoids that contain canthaxanthin.

Ochronosis (see Chapter 57)

In alkaptonuria, a deficiency in homogentisic acid oxidase causes accumulation of homogentisic acid throughout the body. Ochronosis is the term used to describe the pigmentary changes that occur in connective tissue in patients with alkaptonuria [1]. The term was coined by Virchow in 1866 for the ochre-like (pale yellow) colour of the connective tissue when viewed down a microscope. Ochronosis is present in about 75% of patients with alkaptonuria, and the majority show some pigmentation. Most frequent is darkening of the ear cartilages and of the sclerae and conjunctiva. Less often the axillary skin is pigmented and there is brown mottled pigmentation of the face, sometimes in butterfly distribution, and of the neck and trunk. Rarely, pigmentation of the palmar and plantar skin is seen [2]. Examination of the urine establishes the diagnosis.

Exogenous pigments

A wide variety of chemicals either from industrial or medicinal exposure can produce discoloration of the skin. Some of these may not only produce an alteration of pigmentation by being deposited in the dermis but may also result in an increase in the amount of melanin in the skin. Of importance are the metals silver, gold, mercury and bismuth, which are cumulatively deposited in the dermis and can produce permanent disfiguring pigmentation. A number of drugs can cause discoloration of the skin. These include the antimalarials, the phenothiazines, clofazimine and minocycline. Of less importance is the transient staining of the skin produced by picric acid, dinitrophenol and chemical dyes.

Fig. 39.47 Occupational argyria.

Metals

Argyria [1–8]

Silver may be deposited in the skin either from industrial exposure or as a result of medication with silver salts [2–4]. Blue macules have appeared at sites of acupuncture needles [6]. Cases have followed the use of silver salts for the irrigation of nasal, oral and urethral mucous membranes and the excessive use of an oral smoking remedy containing silver acetate [2,7]. 'Food supplements' may also contain colloidal silver [8]. The pigmentation is usually a slate-grey colour and may be clinically apparent after a few months, but usually takes many years to develop and depends on the degree of exposure. The hyperpigmentation is most apparent in sun-exposed areas of skin, especially the forehead, nose and hands (Fig. 39.47). In some patients, the entire skin has a slate blue-grey colour. The sclerae, nails and mucous membranes may become hyperpigmented. Light and electron microscopy studies [1,5,6,8,9] show silver granules in the dermis that are most numerous in relation to the basal lamina of the eccrine sweat glands, and in the dermal elastic fibres. Furthermore, silver particles may be seen lying free within the cell cytoplasm of epithelial cells of the secretory segment of eccrine sweat glands and in mast cells [8,9]. Silver granules are readily visible with dark-field illumination. X-ray-dispersive microanalysis confirms that the granules contain silver [1,6]. Silver is widely deposited in the tissues as well as in the skin. The diagnosis of argyria is established by skin biopsy. The pigmentation is permanent; treatment with depigmentary preparations is not effective.

Chrysiasis [1–5]

Chrysiasis and chrysoderma are terms used to describe permanent pigmentation of the skin due to parenteral administration of gold salts. Excessive administration of gold leads to its deposition in connective tissue. Chrysiasis has not been observed in any patient who has received less than 50 mg/kg of gold thiosulphate, and it has not failed to develop in any patient receiving more than 150 mg/kg. It may first develop after a few months or after a long latent period. The pigmentation is blue-grey or may show a purplish hue, and is limited to light-exposed skin and to the sclerae [3]. The oral mucous membrane is not affected. The diagnosis is confirmed histologically on microscopy with dark-field illumination and on electron microscopy with electron probe microanalysis [4]. The granules of gold are larger and more irregular than those of silver. The pigmentation is permanent [5].

Mercury [1–4]

Repeated applications of mercury-containing compounds can produce localized hyperpigmentation of the treated areas [1–3]. Systemic administration of mercury results in gingival hyperpigmentation. The pigment is observed in the upper dermis around capillaries and associated with collagen and elastic fibres. Electron microscopy shows an increase in melanin pigmentation and the metal is present as granules in dermal macrophages [1,3]. A case report of homicidal subcutaneous injection of metallic mercury resulted in widespread skin lesions, remote from the radiologically visible mercury; these appeared at 40 days and began to clear at 6 months [4].

Bismuthia

The administration of bismuth at regular intervals over a period of years has often been practised, yet generalized pigmentation is extremely rare. The diffuse grey pigmentation resembles that of argyria and involves also the sclera and the oral and sometimes the vaginal mucous membrane [1].

A distinctive blue-black line occurs at the gingival margin. This is due to deposition of bismuth that reacts with hydrogen sulphide formed by bacteria in the mouth [2].

Drugs

Mepacrine [1,2]

Pigmentation of the skin is first noticed a few days after the administration of mepacrine commences and may persist for several weeks after it ceases. The dye is deposited in the skin. A bright-yellow or greenish-yellow colour develops first and remains most prominent on the face, hands and feet, but occurs diffusely with accentuation in the skin flexures. The sclerae are sometimes affected, which may mimic jaundice [2]. The melanin-containing pigment induced by antimalarials is discussed in Chapter 73.

Clofazimine (Lamprene) [1–4]

This synthetic riminohenazine dye used in the treatment of leprosy produces an initial redness of the skin due to an accumulation of the drug. Later, with prolonged treatment, a violaceous brown colour develops that is most noticeable in lesional areas [1]. Histochemical studies indicate a ceroid-lipofuscin pigment as well as clofazimine inside macrophage phagolysosomes [2,3]. Reddish-blue pigmentation has been reported within scarred areas of lupus erythematosus in one patient [4].

Hydroxyurea [1]

Nail pigmentation has been reported in association with use of hydroxyurea and most commonly consists of longitudinal melanonychia. Occasionally all 20 nails are affected and there is associated hyperpigmentation of the skin.

REFERENCE

Minocycline [1–8]

Long-term therapy with minocycline may result in pigmentation, but this is generally agreed to be rare. Three types of cutaneous pigmentation are seen in patients treated with minocycline [6] (Fig. 39.48):
1 a focal type with well-demarcated blue-black pigmentation at sites of previous inflammation as first described in acne scars [1];
2 a more diffuse and generalized pigmentation that is most apparent in sun-exposed areas of skin and nails [2], but may also involve the sclera [5];
3 a more persistent brown-grey change most prominent on sun-exposed sites.
The pigmentation usually occurs following prolonged courses and high doses of this drug. Histological studies show the presence of brown-black granules in the upper

dermis that stain for iron [1,3]. Electron microscopy reveals electron-dense material in dermal macrophages and X-ray microanalysis confirms the presence of iron [4]. Partial resolution of the pigmentation occurs after the drug is stopped [6]. Similar blue-black pigmentation of the legs has resulted from treatment with the 4-quinolone antibiotic pefloxacin [7] and the tetracycline antibiotic methacycline [8].

Amiodarone [1–5]

Amiodarone is a drug used for prolonged periods in the treatment of ventricular tachycardia. It induces photosensitivity in more than 50% of patients; however, fewer than 5% develop cutaneous hyperpigmentation [1–5]. A grey-blue pigmentation of the face and other sun-exposed areas is a rare late effect of this drug, and may also involve non-exposed sites (Fig. 39.49) [1]. Yellow-brown granules are present in dermal histiocytes. Ultrastructural studies show membrane-bound dense lysosomal bodies in macrophages that probably contain degradation products of the drug bound to lipofuscin [1,2]. Dose reduction or withdrawal of amiodarone can lead to complete disappearance of the pigmentation [5].

Picric acid, dinitrophenol and other chemicals

Picric acid, self-administered by malingerers to simulate jaundice, stains the skin yellow. Dinitrophenol, formerly used in industry and as a metabolic stimulant, also produces yellow staining of the skin and of the sclerae. Trinitrotoluene, santonin and acriflavine also stain the skin yellow.

Tattoos

Accidental tattoos

Pigmented particles may be accidentally introduced as contaminants of wounds or may, at high velocity, penetrate previously intact skin.

Superficial abrasions contaminated with chemically inert particles may be followed by disfiguring tattoos. Such irregularly spattered pigmentation is quite commonly seen after road accidents and blast injuries. Some particles may eventually be extruded, but the disfigurement is often permanent. Small lesions may be excised and larger areas treated by dermabrasion, the results of which depend on the depth to which the particles have penetrated.

Collier's stripes [1]

These are a very distinctive occupational mark in coalminers. The bluish grey, linear or angular stripes develop at the sites of abrasions. The commonest sites are the forehead, bridge of the nose, wrists and elbows. Histologically, particles of coal dust up to 100 μm in diameter are

seen at all levels in the dermis. They tend to be grouped around blood vessels.

Therapeutic agents

Iron salts. The use of solutions of ferric sulphate and ferric chloride in the treatment of dermatitis has been followed by a reddish-brown tattoo [2,3]. The pigmentation may disappear after a few months or may persist indefinitely [4].

Occupational contact with iron salts [5] produced red-brown punctate perifollicular pigmentation of the forearms in a man employed in pickling metal in hydrochloric acid.

Gentian violet (pararosaniline chloride). This has, exceptionally, given rise to a tattoo when applied to a wound of the face [6].

Decorative tattoos (see also Chapter 22) [1–5]

History and prevalence. From ancient origins the practice of tattooing has developed along more or less parallel lines in most countries. Tattoos have been used to accentuate beauty, as a permanent adornment, or to make a statement. Occasionally tattoos serve to accentuate aggression or ugliness in order to make the wearer more intimidating. Tattoos with words or a name as a symbol of dedication or devotion have always been popular. Tattoos have also been used for more sinister motives. Tattoos were used as a means of identification by the Nazis in the Second World War for members of concentration and labour camps as well as for members of the SS. Formerly associated with religious ceremonies, fertility and marriage rites, tattooing in contemporary westernized civilizations thus fulfils a number of diverse functions and in so doing it survives and flourishes.

Contemporary life finds tattooing more popular than ever [1], even among the elite [2]. Tattoos are no longer the exclusive preserve of street gangs, prisoners and members of the armed forces [1,2]. Not all who submit to tattooing are emotionally unstable, immature individuals. Indeed, tattooing is viewed by many as an acceptable fashion accessory like any other, and is increasingly popular in Western societies with the young and with women, as well as the more traditional male stereotypes [1,2]. Tattooing and body piercing are now so common that health care workers are advised to maintain a non-judgemental attitude to tattoos [1], even in the face of the unexpected [4]. The decision to have a tattoo may be taken when an individual is in no position to make such a life-long commitment, for example when intoxicated, under peer pressure or when mentally unwell [5]. Tattoos may also be a manifestation of deliberate self-harm [6].

Another contemporary trend is the use of temporary black henna 'tattoos' [3,7]. These are not true tattoos but represent application of a black dye to produce a tattoo-like appearance that lasts for a few days. Unfortunately, a high concentration of the well-known contact sensitizer paraphenylenediamine is usually present in these 'tattoos', which results in a risk of contact allergy [3,7].

Techniques and materials. The professional tattooist uses an electric needle to introduce particles of pigment into the dermis; the amateur, often a child, pricks particles of soot or Indian ink into skin with any pointed object. The individual's choice of design may be motivated by subconscious psychological factors. The pigments commonly employed include:

- blue-black (carbon);
- red (cinnabar and vegetable dyes);
- light blue (cobaltous aluminate);
- green (chromic oxide or chromium sesquioxide);
- yellow (cadmium sulphide);
- brown (ochre, iron oxides).

Complications of tattoos

Unhappiness with the tattoo. Many regret having a tattoo, which may cause a significant psychological, social and financial burden [8].

Introduction of infection. Significant infection of tattoos is now unusual, and pyogenic infection, although the most frequent, is seldom serious. Erysipelas and gangrene, necessitating amputation, are mentioned in the older literature. Syphilis and tuberculosis have been inoculated by the tattoo needle, and small outbreaks have been traced to an infected operator. The tattooing of many people in rapid succession has been suspected of transmitting infective hepatitis. Also there is the risk of transmitting retrovirus infection. The transmission of leprosy is suspected [9]. Both vaccinia and warts have developed in recently inflicted tattoos.

Allergic reactions to pigment. Once the initial inflammatory changes have subsided, by far the most frequent reaction observed in tattoos is the development of allergic sensitivity to one of the pigments.

Fig. 39.50 Lichenoid reaction in red areas of a tattoo.

In most cases, the tattoo pigment itself, or a derived compound formed locally in the tissues, provokes the development of hypersensitivity, which is manifest clinically by the sudden onset of irritation, swelling and redness in a part of the tattoo a few weeks or many years after its infliction. In recent years, lichenoid tattoo reactions have been reported; these appear to be confined entirely to the red areas (Fig. 39.50) [10]. These resemble the reactions to cinnabar (mercuric sulphide); although this pigment has now been replaced by vegetable dyes, cases do still occur [11].

The allergic reaction can remain localized but may become generalized as a patchy eczematous eruption or an exfoliative dermatitis. In some cases, the primary sensitization is induced by some other contact with the metal, and the reaction in the tattoo accompanies or follows an attack of contact dermatitis.

Mercury [12]. The red areas of the tattoo are affected. The reaction may eventually subside spontaneously, but the risk of a generalized eruption is high. The tattoo reaction may be accompanied by erosions of the oral mucosa in contact with amalgam dental fillings [13]. Patch tests are positive to mercuric chloride and ammoniated mercury but not necessarily to cinnabar.

Chrome [14]. The green areas are affected. The patient is often primarily sensitized by exposure to cement. Patch tests with 0.5% potassium dichromate are positive.

Cobalt [15]. The light-blue areas are affected. In three patients, the tattoo reaction was accompanied by the simultaneous development of uveitis [16]. Patch tests are positive with 2% cobalt chloride.

Manganese [17]. A reaction in the purple areas of a tattoo was due to manganese.

Carbon [18]. A case is reported of a reaction in the black areas of a tattoo, presumably to carbon particles.

Light-induced reactions [19]. A high proportion of yellow tattoos develop redness and swelling only on exposure to sunlight, and the same phenomenon is occasionally observed in red tattoos. The mechanism is uncertain, although the yellow pigment, cadmium sulphide, has photoconducting properties.

Localization of skin disease in tattoos

Some skin disorders show a predilection for tattooed skin, in which they may appear first or be accentuated. Syphilis in the secondary or tertiary stage has often been observed in tattoos but tends to spare the red areas, apparently deterred by the mercury. Lichen planus and psoriasis may be localized in tattoos but show no colour predilection. Lupus erythematosus is more rarely seen. A sarcoidal granuloma in a tattoo may be the presenting manifestation of generalized sarcoidosis [20]. Melanoma has been reported in a tattoo [21], although the association may be fortuitous. Foreign-body granulomas of sarcoid type are extremely unusual after decorative tattoos, but have been reported in ochre tattoos [22]; ochre has a high silica content.

Treatment of tattoos [1–9]. The removal of a tattoo may become essential on account of the development of one of the complications considered above, most commonly an allergic reaction within the tattoo. Some cases will settle with intralesional or even topical steroids, but more often excision of the offending area of tattoo, followed if necessary by grafting, is the only satisfactory treatment to secure elimination of all particles of pigment.

Far more frequently, removal of a tattoo is sought on aesthetic or cosmetic grounds, often only a few weeks after its infliction. If the area involved is small and simple or serial excision without grafting is practicable, this is undoubtedly the treatment of choice. If grafting is essential, the inevitable cosmetic imperfections of grafts are such that alternative procedures may be considered. Salabrasion using table salt is of use [6]. Some good results have been achieved with lasers, but scarring, at times quite troublesome, is likely to remain. The best results are with Q-switched red or near-infrared laser systems [7]. Infrared coagulation has also been used [8]. The keratotome [9] gives moderately good results and at least partially obliterates the design. For very extensive tattoos, dermabrasion or chemosurgery [4] have been advocated. The choice of technique should be influenced by personal predilections, and the experience of the plastic surgeon consulted. The patient should be warned that there is usually some residual pigment following superficial abrasion and there may be scarring.

Chapter 40

Genetic Blistering Diseases

R.A.J. Eady, J-D. Fine & S.M. Burge

Introduction

The hereditary blistering disorders described in this chapter, although uncommon, may have a dramatic impact on the patient and their family, and severe economic consequences for the relatives and health services. These diseases have been the subject of intensive study in recent years, and the discovery of the causative genes underlying Hailey–Hailey disease, and all the major types of epidermolysis bullosa (EB), has increased our knowledge not only of the pathogenesis of these disorders, but also of the normal biology of the skin. This is exemplified by the way the graded severity of the clinical features, and associated structural changes in the dermal–epidermal junction, of the dystrophic forms of EB can be explained by the nature of the mutations in the *COL7A1* gene encoding the structural protein, collagen VII [1]. The strategies used to track down the genetic causes of Hailey–Hailey disease and EB provide interesting contrasts. In most forms of EB, the candidate genes and proteins were flagged up by earlier ultrastructural and immunohistochemical studies of the skin of affected patients before linkage and mutation analysis pinpointed conclusively the locus and identity of the causative gene. There were no similar clues to discovering the causative gene, *ATP2C1*, in Hailey–Hailey disease. Indeed, before it was found that mutations in *ATP2C1* could result in Hailey–Hailey disease [2], most dermatologists or skin biologists were unaware of its existence.

Knowledge of the ultrastructure and molecular composition of the epidermis and dermal–epidermal junction is necessary for understanding the tissue and molecular pathology that underlies this group of disorders.

Epidermolysis bullosa

[R.A.J. Eady & J-D. Fine, pp. 40.1–40.32]

Definition and classification

EB comprises a group of genetically determined skin fragility disorders characterized by blistering of the skin and mucosae following mild mechanical trauma. The alternative term therefore is *mechanobullous diseases* [1]. The descriptive term *epidermolysis* is illogical because epidermal disruption is not the primary change in two of three main categories of EB. However, the name *epidermolysis bullosa*, as originally used by Koebner [2] in 1886, is now so well established in the literature that it is still the preferred term.

Classification of this complex and heterogeneous group of disorders is difficult, and not helped by the large variety of names and eponyms that have traditionally been used. Early classification was based largely on the mode of inheritance and clinical studies involving relatively few patients and families [3, reviewed in 4]. While these early observations were clearly important in establishing EB as an entity, a major step forward was made by Pearson [5] who used electron microscopy to show that the ultrastructural level of tissue cleavage (blister formation) in the skin is distinctive in the three major groups of EB: EB simplex, junctional EB and dystrophic EB. Other studies have revealed a number of associated ultrastructural abnormalities, which have also proved to be important in the diagnosis and classification of EB [6–9]. In addition, the application of immunohistochemical studies, particularly a specialized form of immunofluorescence microscopy,

has had a major role in differentiating certain forms of EB, and in helping to uncover the underlying molecular abnormalities by demonstrating specific antigenic changes in the dermal–epidermal junction of patients with different forms of the disease [10,11]. Since 1991, the molecular basis of virtually all subtypes of EB has been established [12].

The most comprehensive classification scheme, based on the recommendations of the Subcommittee of the National EB Registry (USA), and an international consensus group [13,14], has attempted to incorporate molecular and clinical findings, eliminate unnecessary eponyms, and combine certain phenotypes that cannot be distinguished by modern molecular analysis. It is still not clear whether a revised classification, based entirely or largely on the new molecular genetic findings, will provide a more practical or clinically useful alternative to the current one, although it is inevitable that this issue will be reviewed periodically. It is also possible that the concept of keeping all the currently recognized forms of EB under one umbrella could change. For example, a more genotypically based classification might reclassify most subtypes of EB simplex as part of a larger group of 'keratin diseases', and include the different subtypes of dystrophic EB with the group of inherited 'collagen diseases'. Nevertheless, the increasing knowledge of the molecular basis of EB will doubtless continue to be crucial for enabling accurate diagnosis, mainly for genetic counselling and prognosis.

A suggested working classification is shown in Table 40.1.

Table 40.1 Classification of epidermolysis bullosa (EB).

Type of EB	Inheritance
EB simplex (EBS) (intraepidermal blisters)	
More common forms	
EBS of hands and feet (Weber–Cockayne)	AD (rarely AR)
EBS herpetiformis (Dowling–Meara)	AD
EBS Koebner	AD (rarely AR)
Less common forms	
EBS associated with neuromuscular disease	AR
EBS with mottled pigmentation	AD
EBS superficialis	AD
EBS Ogna	AD
Junctional EB (JEB) (lamina lucida blisters)	
More common forms	
JEB gravis (Herlitz)	AR
JEB mitis (non-Herlitz; non-lethal; generalized atrophic benign EB)	AR
Less common forms	
JEB with pyloric atresia	AR
Inverse JEB	AR
Progressive JEB	AR
Cicatricial JEB	AR
Dystrophic EB (DEB) (sublamina-densa blisters)	
AUTOSOMAL RECESSIVE INHERITANCE	AR
More common forms	
Severe generalized, mutilating DEB (Hallopeau–Siemens)	
Mild, non-mutilating generalized/localized DEB	
Less common form	
Inverse DEB	
AUTOSOMAL DOMINANT INHERITANCE	AD
More common form	
Classical DEB (Cockayne–Touraine; Pasini)	
Less common forms	
Pretibial DEB	(may be AR)
EB pruriginosa	
Bart's syndrome	
Transient bullous disease of childhood	
Disorders of uncertain cause, possibly not EB	
Mendes da Costa disease	XR
Kallin's syndrome	?

AD, autosomal dominant; AR, autosomal recessive; XR, X-linked recessive.

Prevalence and incidence

The most accurate data available on the incidence and prevalence of EB are derived from the National EB Registry (USA) project, a longitudinal study of approximately 3300 patients within the continental USA [1]. The incidence and prevalence of EB are estimated to be 19.60 per million live births and 8.22 per million population, respectively. Similarly, the incidence and prevalence rates for EB simplex are 10.75 and 4.60; junctional EB 2.04 and 0.44; dominant dystrophic EB 2.86 and 0.99; and recessive dystrophic EB 2.04 and 0.92, respectively. Comparison of these data with those derived from two smaller populations (e.g. in Norway [2], Finland [3], Croatia [4], Northern Ireland [5] and Scotland [6]) suggests little if any differences reported across the major types and subtypes of EB (reviewed in [1]). These data suggest that there is no gender, racial, ethnic or geographical predilection for EB. It should be remembered, however, that these reported rates probably underestimate the true prevalence and incidence of EB, especially the clinically milder forms, because of recruitment or selection bias.

Epidermolysis bullosa simplex

EB simplex is the most frequent form of EB, accounting for at least 50% of patients enrolled by the National EB Registry (USA) [1]. Given the recognized underreporting of EB simplex, it is likely that at least two-thirds of all EB patients have this form of EB. The inheritance is chiefly autosomal dominant, and it is common to see affected individuals in three generations. Rarely, EB simplex may be transmitted as an autosomal recessive trait.

Molecular pathology [1,2]

In all forms of EB simplex, blister formation is intraepidermal and generally begins with the disruption of basal keratinocytes. Genetic linkage analysis [3] and transgenic mouse experiments [4] led to the discovery that mutations in the basal keratin pair, K5 and K14, could result in EB simplex. It was shown that expression of mutant keratins in cultured cells gave rise to dense keratin aggregates [5]. Similar aggregates or keratin filament clumps were seen in the basal epidermis (Fig. 40.1) [6,7] or cultured keratinocytes [8] of patients with the Dowling–Meara form of EB simplex. Immunoelectron microscopic studies labelled the abnormal filament clumps with K5 and K14 antibodies [9]. In general, a correlation exists between the position of the mutation on the *KRT5* or *KRT14* genes and the resulting phenotype (Fig. 40.2). For example, the most severe form of EB simplex, the Dowling–Meara subtype, is usually caused by missense mutations in the initiation or termination peptides of the rod domains [10,11], which are evolutionarily highly conserved and thought to have a critical role in keratin filament assembly and structural integrity. Mutations in *KRT5* and *KRT14* have also been described in Weber–Cockayne EB simplex [12–14]. In this

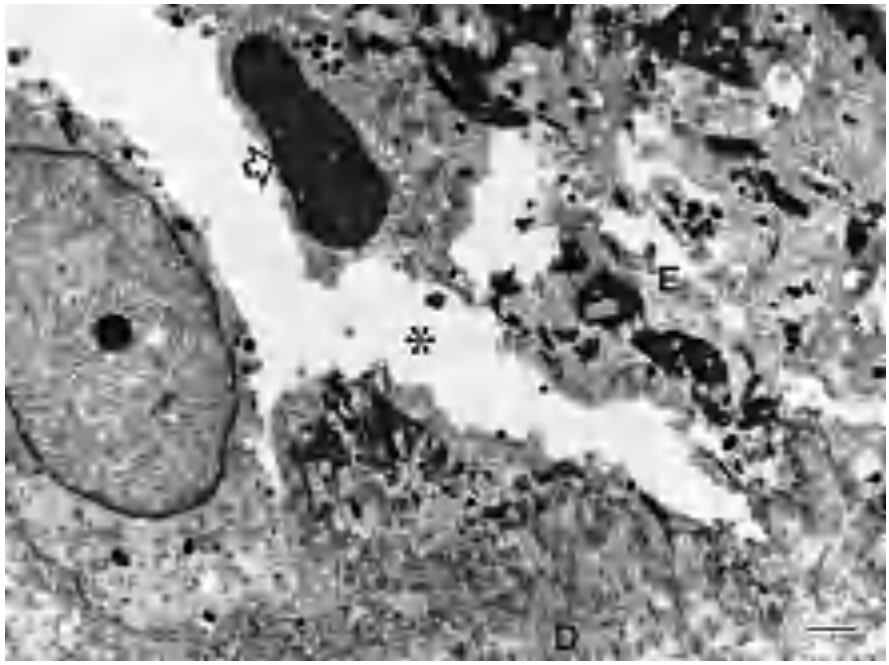

Fig. 40.1 Electron micrograph showing blister formation in epidermolysis bullosa simplex (Dowling–Meara). A split (*) is present in the epidermal basal layer (E), which contains electron-dense tonofilament (keratin) clumps (arrow). D, dermis; Bar = 1 μm.

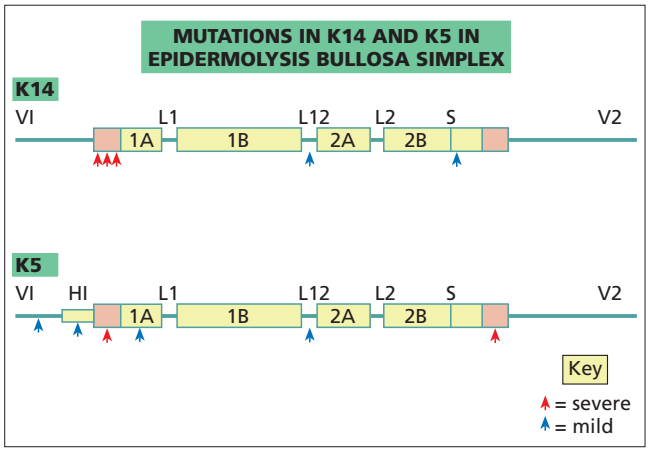

Fig. 40.2 Schematic representation of the type II (keratin 5) and type I (keratin 14) proteins, with position of mutations (arrowed). Each keratin has an α-helical rod domain (boxed areas) with head and tail domains at each end. The red boxes represent the highly conserved helix boundary sequence motifs. The mutations causing Dowling–Meara epidermolysis bullosa simplex occur in these boundary peptides and are known to be highly disruptive to keratin filament assembly. (Modified from a figure provided by Professor E.B. Lane.)

subtype of EB simplex, which is milder than the Dowling–Meara form, mutations occur outside the highly conserved boundary motifs, and chiefly in other parts of rod domain or the L12 linker region [13]. In the Weber–Cockayne or Koebner variants of EB simplex and in the form of EB simplex associated with mottled pigmentation, the basal cell keratin filaments are not consistently abnormal and do not show the major changes that characterize Dowling–Meara EB simplex. A heterozygous C to T transition at base position 71 in the non-helical VI domain of *KRT5*, causing a proline to leucine substitution, has been reported in three unrelated families with EB simplex and mottled pigmentation [15,16]. The cause of the pigmentary changes is unknown. Recessive forms of EB simplex would appear to be very rare; however, at least two families with autosomal recessive EB simplex with a Weber–Cockayne phenotype have been recognized [17,18]. In three cases with widespread blistering, more in keeping with a Koebner phenotype, normal keratin filaments were absent in the basal epidermal layer as was K14 protein expression [19–21]. However, K5 expression appeared normal. These cases were thought to represent the first functional knockouts of K14. Subsequently, a large kindred with EB simplex was described, also with ablation of K14, caused by a homozygous splice-site mutation [22]. A further autosomal recessive form of EB is associated with muscular dystrophy, and on occasion other abnormalities affecting the central nervous system. The ultrastructural level of tissue separation begins at a very low level in the basal cells, just above the hemidesmosomes and adjacent basal plasma membrane (Fig. 40.3) [23–28]. The level of cleavage in this form of EB may appear, in part, to be within the lamina lucida, therefore these ultrastructural findings, together with the clinical similarities of this form of EB with non-Herlitz junctional EB (see below), have led to the description of 'pseudojunctional EB' [28]. Immunofluorescence microscopy of skin from affected individuals shows diminished or absent staining for plectin [25–27], a 500-kDa protein, which is distributed among a variety of tissues, including

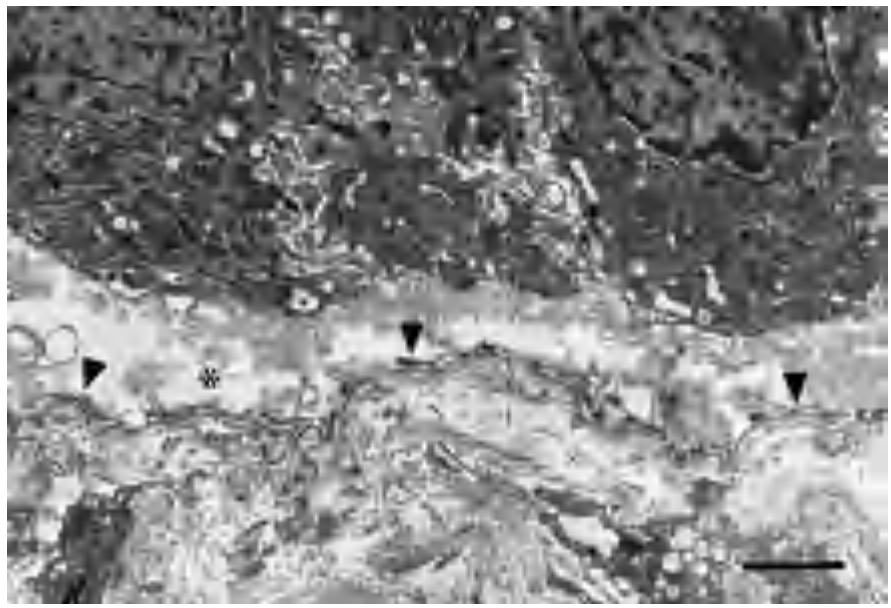

Fig. 40.3 Electron micrograph showing low level of intraepidermal blister formation in epidermolysis bullosa simplex associated with muscular dystrophy. The split (*) is above hemidesmosomes (arrowheads) and associated plasma membrane. Bar = 2 µm.

stratified squamous epithelia, nerve and muscle [29,30]. Homozygous mutations in the plectin gene, *PLEC1* on chromosome 8q24, have been described in several families with the disease [26,27, reviewed in 31] and in two unrelated children with EB simplex associated with mucosal lesions in the respiratory tract, but without evidence of concurrent myopathy [32]. The rarer, autosomal dominant, Ogna form of EB simplex has also been found to be caused by a *PLEC1* mutation [33].

Certain patients, who might otherwise have been diagnosed as having a form of junctional EB, by virtue of their clinical presentation or molecular findings, have been found to have an intraepidermal level of tissue cleavage in their skin, and have therefore been classified (or reclassified) as having EB simplex. This applies mainly to patients with EB associated with pyloric atresia [34,35], but has also been described in patients whose mutations result in deletions of the cytoplasmic domains of collagen XVII [36] or β4 integrin [37].

Clinical subtypes

The various clinical subtypes of EB simplex are as follows.

Epidermolysis bullosa simplex of hands and feet (Weber–Cockayne)

This is the most common type of EB. The palms and soles (Fig. 40.4) are mainly affected, with the exception of the sides of the toes, where blistering may be particularly painful. Many patients have blisters only on the feet, and a minority (approximately 10%) will have blisters at other sites, such as the waist or neck, especially in hot weather and after friction from clothing or other sources. In the large majority of patients, blistering starts in childhood,

Fig. 40.4 Blisters on a foot in epidermolysis bullosa simplex (Weber–Cockayne).

but there are reports of the onset being delayed until early adult life, and brought out by strenuous physical activity [1]. The condition is always worse in warm weather. Hyperhidrosis of the feet is common; this increases friction, which also exacerbates blistering. The blisters heal without clinically significant scarring or milia formation. Calluses on the balls of the feet and the heels are very common, especially in adults. Troublesome blistering or ulceration of the oral mucosa is rare, although infants may have occasional small intraoral lesions. The hair and teeth are normal; nail dystrophy is infrequent, and is usually localized and mild when it does occur.

REFERENCE

1 Lin AN, Carter DM, eds. Epidermolysis bullosa simplex: a clinical overview. In: *Epidermolysis Bullosa: Basic and Clinical Aspects*. New York: Springer, 1992: 89–117.

Koebner epidermolysis bullosa simplex [1,2]

This is one of the two major subtypes of generalized EB simplex. Although usually mild, approximately 60% of patients have localized scarring and approximately 16% have milia. Development of hair and teeth and nails is normal. The nails rarely may be involved by blisters, but are only temporarily shed. Blisters appear within the first year and may be present at birth. In infancy, they commonly appear on the occiput, back and legs, while in childhood, the hands and feet are often affected, although the palms and soles are not preferentially involved, as in Weber–Cockayne EB simplex. In common with other forms of EB simplex, blistering is worse in warm weather. Although blistering occurs throughout life, some patients are alleged to improve after puberty.

In the authors' experience, the Koebner subtype of EB simplex is rare in comparison with the Weber–Cockayne or Dowling–Meara forms of EB simplex. Approximately

Fig. 40.5 Extensive erosions in a neonate with epidermolysis bullosa simplex (Dowling–Meara). (Courtesy of Dr A. Highet, York District Hospital, York, UK.)

10% of patients with the Weber–Cockayne form of EB will at some time have experienced blistering at sites other than the palms and soles (see above). Such individuals were recognized by Cockayne [2]. In the autosomal recessive cases, oral blistering with dental caries may be a feature, and nail dystrophy is common.

Dowling–Meara epidermolysis bullosa simplex

SYN. EPIDERMOLYSIS BULLOSA HERPETIFORMIS

In 1954, Dowling and Meara [1] described four unrelated children (aged 3–7.5 years) with unusual trauma-induced or spontaneous blistering. The blisters healed without leaving scars, and tended to occur in groups that were reminiscent of those seen in dermatitis herpetiformis. Similar cases have since been described [2–10]. In infancy, blistering may be severe and extensive (Fig. 40.5) with involvement of the mucous membranes, shedding of nails and formation of milia. The differential diagnosis at this age may include both the junctional and generalized recessive dystrophic forms of EB. Therefore, a diagnostic skin biopsy is mandatory. After several months, blistering of the palms and soles becomes more frequent, as it does elsewhere. The distinctive feature of this condition is spontaneous herpetiform, annular or arcuate blistering on the trunk, limbs and neck (Fig. 40.6). However, when the blistering is severe and widespread, this pathognomonic grouping of lesions may not be obvious, so the correct diagnosis may be missed. Healing of the blisters may leave mild hyperpigmentation; localized atrophic scarring affects approximately 40% of patients, and milia are seen in approximately 20%. Irregular hyperkeratosis of the palms and soles, eventually developing into a confluent keratoderma (Fig. 40.7), first appears in childhood, and may rarely lead to a flexion deformity of the hands, associated with a severe keratoderma [5]. The general condition tends to improve with age [2]. Clearing of skin lesions has been noted in some patients with a fever, and after warm saline soaks [2].

Epidermolysis bullosa simplex Ogna (Gedde-Dahl)

This autosomal dominant condition was named after the village in Norway where the first affected family originated [1]. There is seasonal blistering of hands and feet, and occasionally elsewhere. This rare subtype of EB is distinguishable by a generalized bruising tendency, haemorrhagic bullae and onychogryphotic great toenails [1].

REFERENCE

1 Gedde-Dahl T. *Epidermolysis Bullosa: a Clinical, Genetic and Epidemiological Study*. Baltimore: Johns Hopkins University Press, 1971.

Epidermolysis bullosa simplex with mottled pigmentation

This rare condition can be distinguished from other forms of EB simplex by the associated pigmentary changes [1–5], which are present at birth or appear during infancy. There is a reticulate pattern of small tan-coloured macular lesions, which fade with age. They may cover the entire skin surface but preferentially involve the neck, upper trunk or extremities. Blistering may be localized, mimicking Weber–Cockayne disease, or become more generalized. Punctate keratoses on the palms and soles have been noted in some cases [2,3]. Mild localized skin atrophy and nail dystrophy are also features of the condition [5].

Autosomal recessive epidermolysis bullosa simplex with neuromuscular disease

Several families have been described in which skin fragility and blistering are associated with a neuromuscular disorder, chiefly muscular dystrophy [1–5], myasthenia gravis [3] or spinal muscular atrophy [6]. The blisters, which affect the skin and oral mucosa, are present at birth or soon afterwards. Muscle weakness and wasting may be severe and evident in early childhood, or milder and detectable later in life. Mental retardation has been reported [2], as has early death [1]. The widespread blistering is associated with atrophic scarring, milia, nail dystrophy and alopecia. Two children with homozygous null mutations developed supraglottic scarring and hoarseness; one required a tracheostomy [7].

Epidermolysis bullosa simplex superficialis

Epidermal cleavage is typically just beneath the stratum corneum. This autosomal dominant condition, reported in

seven patients [1], is characterized by the presence of superficial erosions rather than intact blisters, similar to those seen in pemphigus foliaceous. Healing results in localized atrophic scarring or post-inflammatory hyperpigmentation. The finding of mutations within the type VII collagen gene, *COL7A1*, in one kindred with EB superficialis [2], suggested that the diagnosis was an atypical form of dystrophic EB rather than EB simplex in these cases. Further molecular studies are needed to clarify whether other patients with EB superficialis also have mutations in *COL7A1*.

Kallin's syndrome

The single report on this disorder [1] included two sisters whose surname was Kallin. Both had blistering chiefly of the hands and feet, nail dystrophy, absent teeth and alopecia. One sister was partially deaf. Light microscopy showed a mid-epidermal cleavage in the skin of one sister, and a substratum corneal split in the other. From the limited information available, it is uncertain whether Kallin's syndrome is a distinct form of EB.

Lethal autosomal recessive epidermolysis bullosa simplex

A kindred of 13 Sudanese patients has been reported with the autosomal recessive form of EB simplex [1]. Blistering was present at or very shortly after birth and was generalized, with no associated scarring or milia, and with a predilection for the more distal portion of the limbs. The oral mucosa was only mildly affected, and the nails, teeth and hair were not affected. Most of the affected children died during the first 2 years of life; only one patient reached adolescence.

Electron microscopy of the skin of these patients was reported to reveal a paucity of tonofilaments in the basal epidermal cells. A published electron micrograph is reminiscent of the ultrastructural features seen in an unrelated case of North African origin whose autosomal recessive EB simplex was found to be caused by a homozygous null mutation in the keratin 14 gene [2].

Junctional epidermolysis bullosa

All the variants of this disorder are characterized by autosomal recessive inheritance and by blister formation at the level of the lamina lucida. Conventionally, junctional EB is divided into two main categories: the Herlitz (or lethal) and non-Herlitz (non-lethal) forms. The terms *lethal* and *non-lethal* are no longer recommended in this context because it is well recognized that non-Herlitz subtypes of junctional EB, or forms of dystrophic or simplex EB, may also have a lethal outcome, even in infancy. The term *indeterminate* junctional EB has been used to classify infants who have diagnostic biopsy evidence of junctional EB, but who have not lived long enough to allow clinical segregation into the Herlitz or non-Herlitz subtypes. The term *EB atrophicans* has also been used to describe patients with junctional blistering and atrophic scarring [1]. We do not recommend the use of this term because other forms of EB may be associated with atrophic scarring, and the abbreviation 'EBA' could potentially cause confusion with its more usual association with EB acquisita.

Molecular pathology [1,2]

Electron microscopy shows that the level of tissue separation in all forms of junctional EB is through the lamina lucida of the basement-membrane zone immediately beneath the plasma membrane of basal epidermal cells (Fig. 40.8a). The hemidesmosomes tend to be sparse and very small, especially in the more severe forms of the disease (Fig. 40.8b) [3–5]. In addition, the hemidesmosome subbasal dense plates may be indistinct or attenuated [4,5], and the association between hemidesmosomes and the basal keratinocyte keratin filament network is reduced [5]. Keratinocytes from junctional EB patients have shown similar ultrastructural changes *in vitro* [6,7] or after grafting on to nude mice [8]. These hemidesmosome abnormalities are most prominent in the Herlitz form of junctional EB and the subtype associated with pyloric atresia. Although the latter is normally classified as a form of junctional EB, the ultrastructural level of cleavage is not consistently restricted to the lamina lucida, and may occur intraepidermally at a level just above the basal plasma

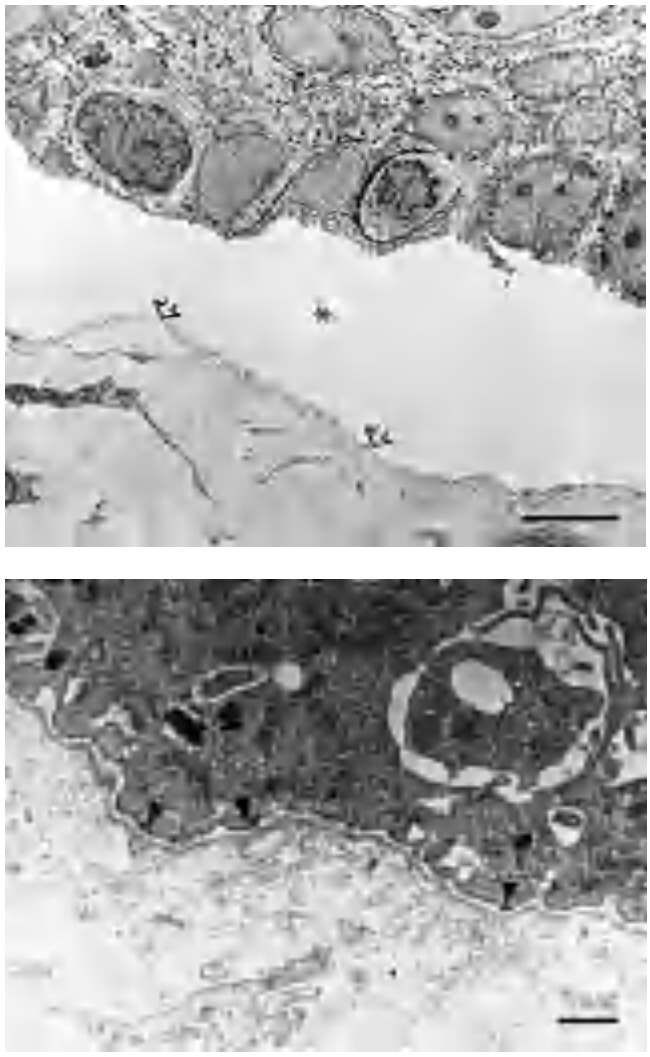

Fig. 40.8 Electron micrographs of dermal–epidermal junction in Herlitz junctional epidermolysis bullosa. (a) A clean split (*) is present at the level of the lamina lucida. A row of closely apposed basal keratinocytes is at the top of the split, and a continuous lamina densa (open arrowheads) is below. Bar = 5 µm. (b) In intact skin, hemidesmosomes (arrowheads) are sparse and much smaller than normal. Bar = 1 µm.

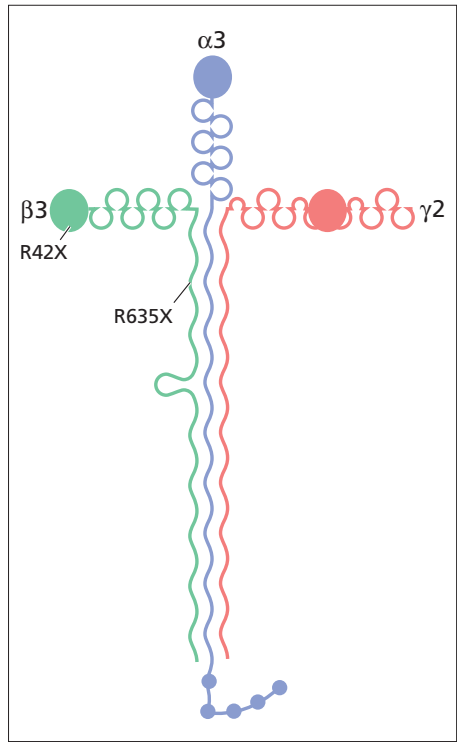

Fig. 40.9 Schematic representation of laminin 5, a heterotrimer comprising α3, β3 and γ2 chains encoded by the *LAMA3*, *LAMB3* and *LAMC2* genes, respectively. The relative positions of two premature stop codon mutations giving rise to R42X and R635X on the β3 chain are shown. These mutations together account for about 50% of all laminin 5 mutations underlying junctional epidermolysis bullosa. (Courtesy of Professor J.A. McGrath, St John's Institute of Dermatology, London, UK.)

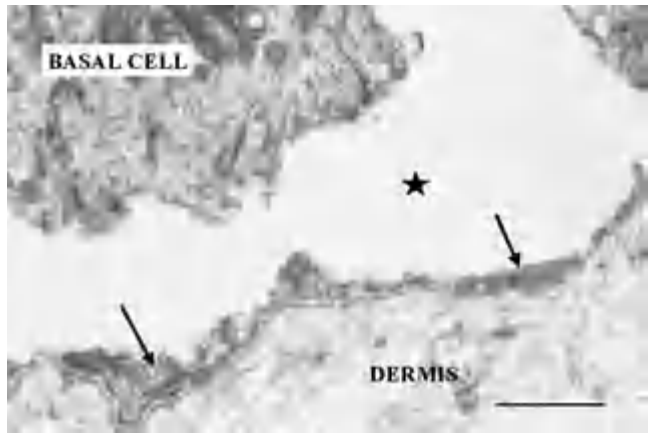

Fig. 40.10 Epidermolysis bullosa with pyloric atresia. A split (star) is present at a very low level in the basal epidermal layer, leaving fragments of basal cells at the base. Bar = 2 µm.

membrane of the basal keratinocytes (Fig. 40.9) [9]. This is similar therefore to the level of tissue disruption occurring in the skin of knockout mice with ablation of the β4 integrin subunit [10]. It may also resemble the ultrastructural abnormality seen in patients with autosomal recessive EB simplex resulting from defects in plectin (see p. 40.5) [11–13]. In the non-Herlitz forms of junctional EB, the hemidesmosome ultrastructure is variable, and individual hemidesmosomes may show little if any discernible abnormality [4].

Immunofluorescence microscopy indicated an abnormality in the expression of the anchoring filament protein laminin 5 in the skin of patients with Herlitz junctional EB and in certain patients with non-Herlitz phenotypes [14–16]. Molecular analysis subsequently showed that the Herlitz form of the disease may be caused by mutations in any of the three laminin 5 genes, *LAMA3*, *LAMB3* and *LAMC2* (Fig. 40.10), encoding the α3, β3 and γ2 polypeptide

chains, respectively, which co-polymerize to form the heterotrimeric laminin 5 protein. The mutations reported so far in Herlitz junctional EB have been homozygous or compound heterozygous premature termination codon mutations [17–20]. These would be expected to result in the production of unstable RNA transcripts and a severely truncated non-functional protein, leading to reduced adhesion at the dermal–epidermal junction and marked skin fragility. The majority of mutations have been found in the *LAMB3* gene, with evidence for mutational hotspots leading to recurrent mutations R42X and R635X [21]. The mutation R635X was found in seven of 24 (29%) mutant alleles in a study of 12 British families with Herlitz junctional EB [22]. The mutation represents a C-to-T transition at a CpG dinucleotide and probably results from deamination of 5-methylcytosine to thymine, a recognized cause of human genetic disease [22].

Non-Herlitz junctional EB (also known as generalized atrophic benign EB; GABEB) may also result from laminin 5 gene pathology [23,24]. In a family with non-Herlitz EB, there was a premature termination codon mutation in exon 3 of one *LAMB3* allele and a missense mutation in exon 7 in the other allele. Exons 3 and 7 encode part of the domain VI on the short arm of the β3 chain. Because this globular domain is thought to be involved with the interaction between laminin 5 and other basement-membrane proteins, such as laminin 6, these mutations might therefore cause destabilization of the macromolecular network involved in adhesion at the dermal–epidermal junction [23].

Other patients with non-Herlitz junctional EB may instead have mutations in the *COL17A1* gene encoding another anchoring filament component, collagen XVII (also known as the 180-kDa bullous pemphigoid antigen [BP180] or BPAG2) [25,26]. The strong similarity in the clinical phenotype of non-Herlitz junctional EB patients with either collagen XVII or laminin 5 gene pathology suggests that the attribution of GABEB is not specific to a particular genotype. Evidence for the role of collagen XVII in odontogenesis is provided by the finding of a combination of a glycine substitution mutation in the helical domain of one *COL17A1* allele, and an internal duplication in the other allele, in a patient with fairly mild skin changes but severe dental abnormalities [27]. The patient's offspring inherited the glycine substitution mutation but had normal second *COL17A1* alleles. Interestingly, although their skins were clinically normal, they had inherited the dental anomaly.

Patients with the subtype of junctional EB associated with pyloric atresia may have a reduced expression of the α6β4 integrin in their skin, as shown by indirect immunofluorescence [28–30]. Staining for other antigens, including laminin 5, is usually normal. The α6β4 integrin is a hemidesmosome-associated heteropolymer and receptor for laminin 5. Knockout mouse experiments with targeted removal of the β4 and α6 subunits showed that homozygous (–/–) mice manifested widespread epithelial separation from the underlying stroma and major ultrastructural changes in the hemidesmosomes [10,31,32]. Mutations in genes for the β4 and α6 integrin chains, *ITGB4* and *ITGA6*, have been shown to underlie this form of EB [33–36] and, in some cases, the phenotype may be predicted by the nature of the mutations.

Clinical subtypes

Junctional EB has the following subtypes.

Herlitz junctional epidermolysis bullosa [1,2]

SYN. EPIDERMOLYSIS BULLOSA LETALIS; EPIDERMOLYSIS BULLOSA ATROPHICANS GENERALISATA GRAVIS

Blistering and erosions are present at or soon after birth and rapidly become generalized. The absence of blistering at birth is consistent with the diagnosis. The whole skin is extremely fragile and lifting or turning the baby may cause extensive blistering or peeling away of the epidermis. Eroded areas are often very slow to heal. Healing may result in atrophic scarring. Milia are not generally seen, although they may occur after secondary infection.

Fig. 40.11 Facial erosions in junctional epidermolysis bullosa (Herlitz).

Fig. 40.12 Junctional epidermolysis bullosa (Herlitz).

Involvement of the oral and pharyngeal mucosa is frequent and may be severe; hoarseness and stridor may indicate laryngeal or supraglottic involvement [3,4]. Vesicles have been reported in the trachea and bronchioles post-mortem [5,6]. Many infants die early in infancy with overwhelming infection, but those surviving the first few months will often develop distinctive lesions characterized by non-healing crusted erosions containing exuberant granulation tissue [1,7]. These typical lesions occur symmetrically around the nose and mouth (Fig. 40.11) but also in other sites including the neck, trunk and buttocks (Fig. 40.12). The combination of chronic infection and loss of protein and iron from the skin, in addition to poor feeding, contributes to impaired healing and refractory anaemia [8]. The teeth show abnormal enamel formation, but normal dentine [9], and as a result are malformed, pitted and lost prematurely. Following blistering and erosions, the formation of granulation tissue on the nail folds and nail bed leads to shedding of the nails and bulbous changes of the fingertips (Fig. 40.13).

Fig. 40.13 Nail changes in junctional epidermolysis bullosa (Herlitz).

Fig. 40.14 Pitting and discoloration of teeth in non-Herlitz junctional epidermolysis bullosa.

Generalized non-Herlitz junctional epidermolysis bullosa

SYN. EPIDERMOLYSIS BULLOSA ATROPHICANS GENERALISATA MITIS; GENERALIZED ATROPHIC BENIGN EPIDERMOLYSIS BULLOSA (GABEB)

Hashimoto *et al.* [1] first described this condition in 1976. Hintner and Wolff [2] coined the acronym GABEB. The early clinical course may be similar to the Herlitz form of junctional EB with generalized skin fragility and blistering, but the patients usually survive to adulthood [2–8]. Although blistering persists, there is gradual lessening in severity of the disease with age. Mucous membranes are involved, but less severely than in the Herlitz form of junctional EB. The teeth show severe enamel defects (Fig. 40.14) and may fail to erupt normally. The nails are dystrophic and frequently missing, especially on the toes. Approximately 3–5% of patients may develop a degree

Fig. 40.15 Atrophic scarring on lower legs and toenail dystrophy in non-Herlitz junctional epidermolysis bullosa.

of pseudosyndactyly, clinically suggestive of dystrophic EB. These patients were originally said to have 'cicatricial' junctional EB (see below). Typically, the lesions in non-Herlitz junctional EB heal with atrophic scarring, which can easily be mistaken for the scarring seen in dystrophic EB, especially on the lower legs (Fig. 40.15) or backs of the hands. An important sign of this form of EB is the poor hair development; the alopecia affects the scalp (Fig. 40.16),

Fig. 40.16 Alopecia in non-Herlitz junctional epidermolysis bullosa.

eyebrows and eyelashes, and body hair is also sparse or absent. Pigmented naevi, or acquired macular hyperpigmented lesions with irregular borders, are common [2–4]. Oesophageal stricture [2], laryngeal involvement [3], oral erosions [2,3,6], corneal ulcers [6] hypoacusis [1,2] and urethral stricture [9] have all been reported.

A more localized form of non-Herlitz junctional EB has been recognized [10,11]. Typical clinical manifestations include nail dystrophy, dental enamel changes and blistering involving the lower legs and feet only [9]. In a second report of two affected sisters, the skin was generally fragile, but the atrophic changes were most noticeable on the lower legs and dorsa of the feet. The nails were dystrophic, but hair and teeth appeared normal [11]. Chronic painful erosions associated with hyperkeratosis were present on the soles. In the rare form of 'inverse' non-Herlitz junctional EB [12,13], the whole skin is fragile and blistering starts during the neonatal period. Later, the lesions affect chiefly the groin, perineum and axillae (inverse sites). Healing may result in small atrophic white streaks. Dysplastic teeth, erosions of the cornea and feet (Fig. 40.17) and nail dystrophy, are all features. Squamous cell carcinoma, similar to that occurring in dystrophic EB (see below), may also occur in non-Herlitz junctional EB [14–16], at times with a fatal outcome. Keratoacanthoma has also been reported [17].

Fig. 40.17 Hyperkeratosis with erosions on soles in non-Herlitz junctional epidermolysis bullosa.

Junctional epidermolysis bullosa with pyloric atresia

This rare disorder is normally included as a subtype of junctional EB, although, not uncommonly, the true level of blistering has been found to be in the cytoplasm of basal keratinocytes, just above the plasma membrane, rather than within lamina lucida. These cases therefore might more appropriately be classified as EB simplex (see p. 40.10). Over 50 patients with this disorder have been reported [1], yet only a few have survived beyond the first few months of life. Blistering is usually present at birth, following a pregnancy complicated by polyhydramnios. The lesions are usually widespread and can result in atrophic scarring. The teeth are hypoplastic, lacking normal enamel, and the nails are dystrophic. Early attempts at feeding result in vomiting, which is not bile-stained. In a series of five patients [2], four died at the age of 1–2 months; the fifth survived for over 4 years, but had constant haematuria and dysuria and recurrent urinary tract infections. Hayashi *et al.* [1] have made a strong case for surgical correction of the congenital pyloric atresia. Of the five patients in their report, four (aged 17 months to 16 years) were moderately well, despite complications such as retarded growth and hydronephrosis. The fifth patient died of respiratory distress, probably caused by aspiration, and had renal complications. The variable clinical outcome in this disorder will probably be explained, to some degree, by the nature of the mutations affecting either the α6 or β4 integrin subunits [3].

Progressive junctional epidermolysis bullosa

SYN. EPIDERMOLYSIS BULLOSA PROGRESSIVA

This condition was originally named EB dystrophica–neurotrophica by Gedde-Dahl because of the association of partial deafness [1]. The onset is delayed until childhood or adolescence, and nail dystrophy is a common presentation. Blistering occurs on the hands and feet. Later, knees and elbows are involved. Progressive atrophic changes lead to early loss of fingerprint patterns and mild finger contractures. The tooth enamel may be defective and the tongue papillae may disappear [2]. The oral mucosa is sometimes involved. The ultrastructural changes are said to be distinctive and show widening of the lamina lucida with deposition of amorphous material. The hemidesmosomes are ultrastructurally normal [2–4]. The molecular basis is unknown.

Cicatricial junctional epidermolysis bullosa

Three patients have been reported in whom blistering had healed with scarring and resulted in loss of nails, alopecia, syndactyly and contractures. The oral mucosa was involved and there was stenosis of the anterior nares [1]. Based on more recent findings [2], this rare phenotype is included under the heading of non-Herlitz junctional EB. The evidence that this form of EB has a distinct genotype awaits confirmation.

Dystrophic epidermolysis bullosa

The dystrophic forms of EB are characterized by skin fragility, blistering, scarring, nail changes and milia formation. Unlike the other types of EB, there are both major autosomal recessive and autosomal dominant subtypes. Recent studies have shown a number of genotypic and phenotypic differences between these two major subtypes of dystrophic EB, and a number of newer clinical variants have emerged. However, the definition of the subtypes of dystrophic EB is somewhat arbitrary, representing more quantitative than qualitative phenotypic differences [1].

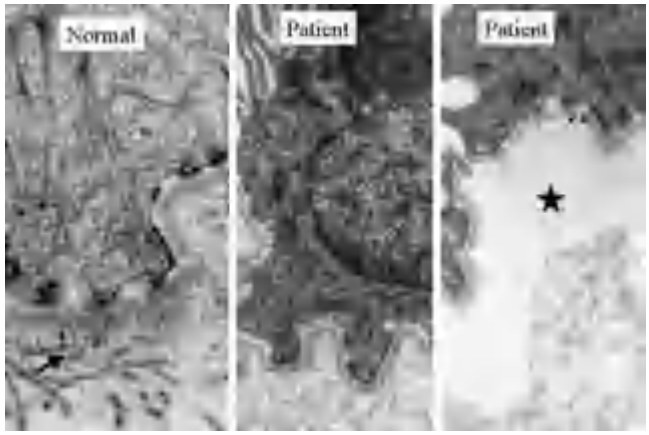
Molecular pathology [1–3]

In contrast to EB simplex or junctional EB, in which



(a) (b) (c)

Fig. 40.18 Electron micrographs demonstrating blister formation in dystrophic epidermolysis bullosa. (a) Anchoring fibrils (arrow) are present in the dermal–epidermal junction in normal skin, (b) but are absent in patient's skin. (c) Early blister formation (star) beneath the lamina densa (double arrows).

several genes are now recognized in the pathogenesis of these disorders, both autosomal dominant and recessive forms of dystrophic EB are caused by mutations in a single gene, *COL7A1*, which encodes the anchoring fibril protein, type VII collagen.

Ultrastructurally, the level of blistering or tissue cleavage in all dystrophic forms of EB is immediately below the lamina densa of the epidermal basement membrane, at a site normally occupied by anchoring fibrils (Fig. 40.18) (see Chapter 3 for a fuller description of these and other structures in the basement-membrane zone) [3].

Quantitative electron microscopy and immunoelectron microscopy have shown that anchoring fibrils in dystrophic EB are reduced in number, morphologically altered or completely absent [4,5]. Immunofluorescence staining of the skin of patients using antitype VII collagen antibodies showed that the normal bright linear staining is absent in severe generalized recessive dystrophic EB, but present in dominant dystrophic EB [6–8]. In the milder or more localized form of recessive dystrophic EB, the immunoreactivity may be attenuated or normal in intensity. In the 'inverse' form of recessive dystrophic EB, type VII collagen is normally expressed, but the anchoring fibrils are structurally abnormal [9]. These ultrastructural and immunohistochemical findings indicated that type VII collagen was the candidate gene for at least the recessive forms of dystrophic EB and probably for the dominant form too. These clues were supported by genetic linkage of both dominant and recessive forms of dystrophic EB with the type VII collagen gene locus [10–13], which had been mapped to chromosome 3p21 [14]. Other studies showing abnormalities of collagenase in skin and dermal fibroblasts from patients with recessive dystrophic EB indicated that the collagenase gene was also a candidate [15]. However, this was not borne out by subsequent linkage analysis [16,17].

Cloning and sequencing of the human type VII collagen gene (*COL7A1*) and cDNA revealed that the gene is highly complex, containing a total of 118 exons within approximately 32 kb of genomic DNA [14,18–21]. Type VII collagen is a homotrimer ($\alpha_1[VII]_3$) in which each pro-α chain has a large amino-terminal non-collagenous domain (NC-1), a central collagenous domain of Gly-X-Y repeats with several interruptions, and a small carboxy-terminal non-collagenous domain (NC-2). The formation of antiparallel dimers involves cleavage of the NC-2 domain [22]. Anchoring fibrils consist of laterally associated aggregates of the dimers.

Numerous *COL7A1* mutations have been documented. The most severe (Hallopeau–Siemens) subtype of recessive dystrophic EB is caused by premature termination codon mutations on both *COL7A1* alleles [23–25]. Heterozygote carriers of these mutations are phenotypically normal, and it is presumed that a truncated polypeptide, encoded by the mutant allele, is unable to take part in triple helix formation without its collagenous domain, leaving the wild-type polypeptide free to form normal trimers [1]. Ultrastructural morphometric analysis has shown that the number of anchoring fibrils is reduced to about half the normal value in the heterozygotes [26]. In the milder forms of recessive dystrophic EB, typically a premature termination codon mutation on one allele combines with a missense mutation or in-frame deletion on the second allele [27]. The net result is thought to result in synthesis of type VII collagen molecules, which assemble into unstable and relatively weak anchoring fibrils.

Detailed studies correlating clinical, ultrastructural and immunofluorescence changes with different combinations of mutations in *COL7A1* have helped with the understanding of the phenotype diversity in recessive dystrophic EB [28,29]. Dominant dystrophic forms of EB have been shown exclusively to be associated with glycine substitutions within the triple helical collagenous domain of the type VII molecule, characterized by a Gly-X-Y repeating amino-acid sequence [1,30]. These mutations are thought to have a dominant negative effect on the processing or function of the normal gene product. The amino-acid substitutions are likely to destabilize the triple helix, impair the normal secretion of the molecules and make them susceptible to intracellular degradation. Assuming equal expression of both normal and mutant alleles, only approximately 13% of the triple-helical molecules will be normal [1]. This would help to explain the ultrastructural observations of reduced numbers of anchoring fibrils, some of which appear normal [4,5].

In the absence of a positive family history, it is often difficult to determine whether a single patient with mild to moderately severe dystrophic EB will have autosomal recessive or *de novo* dominant disease. Recent molecular

studies of *COL7A1* have established that the vast majority of such cases are recessive in nature. Nevertheless, a small number of *de novo* dominant patients have been documented. Three patients with *de novo* dominant disease were found to have the same glycine substitution mutation, G2043R in *COL7A1*. This mutation is the most common *COL7A1* mutation in dominant dystrophic EB throughout the world. These cases emphasize the importance of molecular analysis in providing accurate genetic counselling in patients with apparent sporadic dystrophic EB [31,32].

In addition to their occurrence in classical forms of dominant dystrophic EB, glycine substitution mutations have been demonstrated in rarer variants including Bart's syndrome [33], pretibial dystrophic EB [34] and EB pruriginosa [35,36]. Other types of *COL7A1* mutations may also occur in EB pruriginosa [36].

Clinical subtypes

Dystrophic EB has the following subtypes.

Fig. 40.19 Extensive lesions on the back in generalized recessive dystrophic epidermolysis bullosa.

Fig. 40.20 Scarring alopecia in generalized recessive dystrophic epidermolysis bullosa.

Fig. 40.21 Mitten hand deformity in generalized recessive dystrophic epidermolysis bullosa.

Autosomal recessive forms

Severe generalized recessive dystrophic epidermolysis bullosa (Hallopeau–Siemens) (syn. polydysplastic epidermolysis bullosa; epidermolysis bullosa dystrophica generalisata gravis) [1]. Bullae are present at birth or appear in early infancy. The clinical presentation may include localized absence of skin ('Bart's syndrome') especially affecting the hands, feet and lower legs in a glove or sock-like distribution [2]. The skin can be extremely fragile in this form of EB. Blisters develop spontaneously or after the mildest trauma on any part of the skin and may be haemorrhagic. Healing lesions leave atrophic scars like cigarette paper; thicker scars may occur particularly over the large joints, such as the knees. Milia formation is a constant feature. Although the whole of the skin is fragile and at high risk of developing blisters, the main sites of predilection are those subjected to repeated friction and other forms of physical trauma. These include the knees, elbows, hands, feet, back of the neck, shoulders and over the spine (Fig. 40.19). Ulcers over the spine or shoulders may heal extremely slowly. Chronic erosions and ulcers tend to become covered with a slough, often associated with heaped-up crusting and scaling, increasing the risk of secondary infection. Pruritus is frequent, and constant rubbing and scratching may induce blisters.

The scalp is often involved. Hair growth on the scalp and body is impaired and scarring alopecia may occur (Fig. 40.20). During childhood, repeated blistering with progressive scarring causes fusion of adjacent fingers and toes. If left untreated, the digits then undergo progressive contractures and gradually become encased in a cocoon-like covering of thin scar tissue (Fig. 40.21). Disuse of the hands results in bony resorption and muscle atrophy.

Non-cutaneous epithelia are also at risk of developing blisters, erosions and scars. Oral lesions may be severe, leading to ankyloglossia and microstomia. Patients are often unable to protrude the tongue outside the mouth, or to open the mouth normally. The gums are fragile, and gentle tooth brushing may induce epithelial disruption with bleeding. The lingual papillae are lost and the surface of the tongue becomes smooth, shiny and atrophic.

Fig. 40.22 Dental changes and blistering on lips in generalized recessive dystrophic epidermolysis bullosa.

Fig. 40.23 Squamous cell carcinoma arising in an area of chronic scarring in a patient with generalized recessive dystrophic epidermolysis bullosa.

Although the evidence for a primary abnormality of dental enamel is questionable, the teeth are at a high risk of developing caries (Fig. 40.22) because of prolonged exposure to food. This stems from a reduced ability to chew the food normally and diminished circulation of saliva. Oral secretory immunity may be compromised [3]. In one series, the frequency of caries in the recessive dystrophic form of EB was about five times greater than in dominant dystrophic EB [4]. The loss of dentition has several ramifications. First, the intake of solid food is impaired, with potential consequences affecting the patient's nutrition and tendency to suffer with constipation. Secondly, there is a secondary loss of bone within the alveolar ridges of the jaw, preventing later corrective dental treatment such as the use of tooth implants.

Oesophageal involvement is a serious and invariable complication of this form of EB [5–8]. It may occur very early in life, even in infancy, and by the age of 20–30 years will have affected most patients. Blistering in the oesophagus may cause acute pain and dysphagia, manifesting with difficulty in swallowing solids. With time, partial or complete obstruction may result from oesophageal stricture, caused by scarring and fibrosis; or from web formation [8]. Stricture occurs more frequently in the upper third of the oesophagus, and may be multiple. In time, the oesophagus is thought to shorten as a result of fibrosis and is then at additional risk from gastro-oesophageal reflux [6]. Rare complications of oesophageal involvement include spontaneous perforation [7] and bringing up an oesophageal cast. Oesophageal involvement is another cause of poor nutrition.

Perianal blistering, erosions and painful fissures are common in childhood. Later, anal stenosis from scarring may develop. These changes will contribute to a child's reluctance to defaecate, leading to faecal retention, abdominal pain and bloating. Chronic constipation and eventual faecal impaction are also common. A low-fibre diet adds to this complication [5,6].

The main ocular complications include symblepharon, which in its more severe form may involve joining of the lid margin to the peripheral cornea; limbal broadening, which is often asymptomatic; and corneal opacity, possibly resulting from recurrent corneal erosions [9,10].

General physical development is retarded. Most patients are very thin and have a short stature. Some blood vitamin and trace metal levels are low [11] and immune function may be impaired because of reduced natural killer cell activity [12]. Severe refractory multifactorial anaemia adds to management problems.

An important sequela of this form of EB is the development of squamous cell carcinomas. These are often multiple primary tumours which, histologically, are usually well differentiated. They may be difficult to identify clinically at an early stage, appearing as a non-healing erosion or crusted or hyperkeratotic lesion. In keeping with other scar carcinomas, these tumours behave aggressively and often metastasize, eventually with a fatal outcome. Life-table analysis from the National EB Registry [13,14] indicates the high probability of death within 5 years of diagnosis of the first squamous cell carcinoma. Patients as young as 13 years may be at risk of developing cancer [15]. These tumours usually arise in any chronically scarred area of skin (Fig. 40.23). Less frequently, they may occur in the oesophagus [16] and mouth. The large majority of carcinomas are on the limbs, often in areas of chronic non-healing ulceration [17]. The tumours tend to recur locally, despite primary treatment using an apparently wide-surgical excision. Recurrences and metastases are generally unresponsive to chemotherapy or radiotherapy. There is also an increased risk of developing malignant melanoma [13], but the incidence of other internal malignancies does not appear to be increased. Systemic amyloidosis is a

further complication [18,19] that may involve internal organs such as the heart or kidneys.

Most patients experience a delay in development of secondary sexual changes. Despite the severity of the skin disorder, sexual function may be sufficiently normal in some female patients to undergo an uncomplicated pregnancy with the vaginal delivery of a normal healthy child (R.A.J. Eady & S. Bewley, unpublished observations 1996) [20].

Fig. 40.24 Nails in localized recessive dystrophic epidermolysis bullosa.

Non-Hallopeau–Siemens dystrophic epidermolysis bullosa. The condition shares several cutaneous and extracutaneous features with the more severe, Hallopeau–Siemens form of recessive dystrophic EB, but is generally much milder. The skin and mucosae are very fragile, but lesions, including nail changes, milia and atrophic scarring, tend to be more localized, and similar to those seen in classical dominant dystrophic EB (Fig. 40.24). Growth retardation and anaemia are usually mild. Pseudosyndactyly, oesophageal involvement and squamous cell carcinoma may also occur, but these complications are usually milder or less frequent than in Hallopeau–Siemens dystrophic EB.

Inverse recessive dystrophic epidermolysis bullosa [1,2]. The primary areas of blistering and scarring include the groins, axillae, neck (Fig. 40.25) and lumbar area. Traumatic corneal erosions and oesophageal lesions are common. Nail dystrophy, mucous membrane involvement and dental changes are similar to those in the generalized form of the condition. Patients are also at risk of developing squamous cell carcinoma.

Autosomal dominant forms

Classical dominant dystrophic epidermolysis bullosa (syn. hyperplastic (Cockayne–Touraine) and albopapuloid (Pasini) variants). A problem with most classifications of EB, including a more recent one [1], is the convention of subdividing most cases of dominant dystrophic EB into the mutually exclusive Cockayne–Touraine or Pasini variants. In 1928, Pasini described a single family whose EB

Fig. 40.25 Scarring and erosions affecting the axilla and neck in the inverse form of recessive dystrophic epidermolysis bullosa.

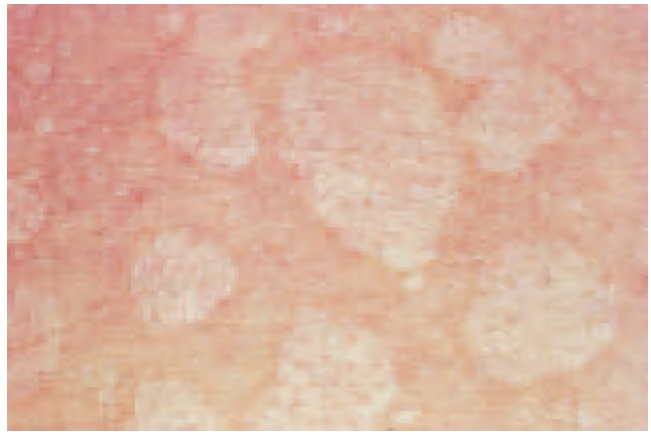

Fig. 40.26 Albopapuloid lesions on the lower back of a patient with dominant dystrophic epidermolysis bullosa.

Fig. 40.27 Nail changes and scarring of skin on backs of toes in dominant dystrophic epidermolysis bullosa.

was distinguished by the presence of numerous white papules that he called 'albopapuloid' lesions. In other respects, it is unclear how such individuals can confidently be distinguished from those with the so-called 'Cockayne–Touraine' phenotype. It has been said that one form tends to be more severe than the other, but the issue is clouded by the fact that albopapuloid lesions, which are most often seen on the trunk (Fig. 40.26), are probably not specific, and variations in the onset and severity of the disease have been described, even within the same kindreds [1,2]. Differences in ultrastructural and biochemical findings have also been reported (see [3] for review). The histogenesis of albopapuloid lesions is unclear, and reports have alluded to both epidermal and dermal abnormalities, including alterations of collagen and elastic tissue (reviewed in [2]). To avoid further confusion, the time has come to abandon these eponymous descriptions and to regard these so-called variants of dominant dystrophic EB as belonging to a continuum. The main feature of dominant dystrophic EB is that the skin is generally less fragile than in the Hallopeau–Siemens form of recessive dystrophic EB. Blisters usually follow sharp knocks or glancing blows rather than mild friction, and therefore can be difficult to induce for a diagnostic skin biopsy. They mainly occur in skin overlying bony prominences, such as the knees and ankles, and dorsa of the hands or feet. The most consistent findings are localized scarring with milia formation and dystrophic nails. Nail dystrophy is probably the most important diagnostic feature of the disease, especially in adults, because many patients have only limited scarring, which becomes less noticeable with age. The nail plates, particularly of the large toes, are often diminutive (Fig. 40.27) or entirely absent, where the normal nail is replaced by atrophic scar tissue. Blistering in the mouth is usually mild and the teeth are generally normal. However, perianal lesions may cause considerable pain, especially in children.

Clinically, it is often impossible to distinguish this form of dominant dystrophic EB from the localized recessive dystrophic forms, making genetic counselling impossible in the absence of a positive family history or accurate molecular diagnosis.

Congenital localized absence of skin (syn. Bart's syndrome). In 1966, Bart described a kindred with localized absence of the skin over the lower legs associated with cutaneous blistering and mucous membrane and nail involvement [1]. The condition, which appeared to follow an autosomal dominat mode of inheritance, was thought to be form of EB simplex [2]. However, localized absence of the skin has been reported by others in association with simplex [3], junctional [4,5] and dystrophic EB [6]. In view of these findings, congenital localized absence of the skin should be regarded now as a manifestation of EB, instead of a separate entity or syndrome. The original family described by Bart has since been shown to have dominant dystrophic EB, caused by a glycine substitution mutation in *COL7A1* [7].

Pretibial dystrophic epidermolysis bullosa and epidermolysis bullosa pruriginosa. In 1946, Kuske [1] reported a patient with itching, blisters, atrophy and scarring on the shins. There were further reports of similar patients [2,3]. In one family with a dominant transmission of the disease, the clinical features were variable [3]. Several authors have referred to this condition as pretibial EB [4–6], given the tendency for the lesions to develop in the pretibial areas.

In 1994, McGrath *et al*. [7] delineated a group of eight patients with a highly distinctive phenotype in which the overriding symptom is severe pruritus. The authors named the condition 'EB pruriginosa' to highlight this combination of clinical features. EB pruriginosa presents either at birth with mild acral blistering and erosions, or during infancy or childhood. Violaceous papular and nodular lesions, often in a linear arrangement, are mainly confined to the shins (Fig. 40.28) and forearms, although rare lesions may occur on the trunk. In adults, the lesions are chiefly lichenified plaques. Histologically, a split may be evident at the dermal–epidermal junction, although frank blisters are rarely seen. Apart from scarring with milia, toenail dystrophy is a consistent finding in adult patients.

Fig. 40.28 Violaceous lesions in a partly linear distribution in a patient with epidermolysis bullosa pruriginosa.

Most cases are sporadic. However, both autosomal recessive and dominant inheritance is recognized [8]. The cause of the severe pruritus is unknown; however, a number of patients have raised blood levels of immunoglobulin E (IgE) (R.A.J. Eady, unpublished observations 1997), suggesting a possible atopic background. Clinically, EB pruriginosa has to be distinguished from lichen simplex, hypertrophic lichen planus, Nékam's disease, cutaneous amyloidosis and dermatitis artefacta [9]. It shares several features with the pretibial form of dystrophic EB, but is clinically much more striking.

Transient bullous dermolysis of the newborn. In 1985, Hashimoto *et al.* [1] reported a newborn with blistering developing on the extremities soon after birth. The bullae quickly resolved and there was apparently no scarring or milia formation. The name 'transient bullous dermolysis of the newborn' was coined to describe this uniquely self-limited clinical course associated with a sublamina densa level of cleavage. Ultrastructurally, the basal epidermal keratinocytes were shown to contain electron-dense stellate bodies. The skin condition resolved completely and a year later there were only mild residual pigmentary changes. Later, Fine *et al.* [2] used immunofluorescence and immunoelectron microscopy to show that these intracellular inclusions contained type VII collagen, and that the underlying dermal–epidermal junction usually lacked normal anchoring fibrils and type VII collagen staining (Fig. 40.29). The phenotype of these patients resembled a mild dominant or localized recessive form of dystrophic EB, and included small numbers of tense blisters, milia and mild focal atrophic scarring. Fine *et al.* [2] further demonstrated that these immunohistochemical features tended to revert to that of normal non-EB skin, showing intense uniform linear immunostaining of the dermal–epidermal junction with antibodies to type VII collagen, at about the time most blister formation had ceased. It was thought that this phenomenon represents a transient secondary abnormality in packaging, transport or incorporation of a presumably mutated type VII collagen into the dermal–epidermal junction during early infancy in these patients.

The clinical and microscopic features were later confirmed by Schofield *et al.* [3] in other patients. Smith and Sybert [4], however, described similar ultrastructural and immunocytochemical findings in a patient with recessive dystrophic EB whose prognosis was poor. Phillips *et al.* [5] also showed that the presence of intraepidermal type VII collagen in infancy was not always predictive of a good clinical outcome.

One of the kindreds reported by Fine *et al.* [2] has since been shown to have a *COL7A1* mutation typical of dominant dystrophic EB [6]. *COL7A1* mutations have also been reported in other cases [7].

Diagnosis

Despite the impressive advances in the molecular genetics of different forms of EB, the initial diagnosis still relies largely on a careful clinical examination, enquiry into the family history and establishing the level of blister formation [1]. Because the clinical features may be unhelpful or even misleading, especially in a neonate, the diagnosis will often rely on microscopic analysis of a skin biopsy. Electron microscopy, performed in a laboratory with appropriate experience and skills, is still the best method for evaluating skin samples. Immunohistochemistry, particularly indirect immunofluoresence microscopy, is also important, if not essential. Ideally, tissue should be acquired at the same time for both electron microscopy and immunohistochemistry.

Skin biopsy

The main objectives of skin biopsy are first to establish the level of blistering or tissue separation and, secondly, to search for other clues that may be indicative of the underlying disorder and therefore helpful in the diagnosis. The importance of the correct biopsy technique cannot be overstressed. Most blisters that are clinically evident, and especially those with bloodstained contents, are often more than 12 h old and therefore too old for diagnostic purposes. Older blisters may cause severe diagnostic difficulty because false-negative immunostaining caused by proteolytic antigen degradation, re-epithelialization under the blister roof and multiple cleavage planes may all occur. A sample of non-blistered skin that has been gently rubbed to produce a mild erythema is preferable, because this will usually contain a cleavage plane with few if any secondary changes.

Because the diagnostic signs are mostly seen in and around the dermal–epidermal junction, shave biopsy samples are preferable to thicker specimens obtained by ellipse or punch biopsy methods. Care must be taken to ensure that a sufficient amount of dermis is present, to allow examination of the entire dermal–epidermal junction. It is often better to take two or three small pieces for different types of examination, such as electron microscopy and immunofluorescence. Attempts to subdivide a larger biopsy specimen can result in detachment of the epidermis from the dermis and spoil the sample for critical microscopic analysis. The samples should be immediately immersed in suitable fixative for electron microscopy, or in a freezing liquid, such as isopentane precooled with liquid nitrogen, after embedding in OCT Tissue-Tek Compound (Miles Inc, Diagnostics Division, IN 46515, USA), for immunofluorescence. The samples can then be stored in a –70°C freezer or in liquid nitrogen until required for analysis. Michel's transport medium can be used for both immunofluorescence and electron microscopy [2], although the ultrastructural preservation will be variable and often inadequate for detailed electron microscopic analysis.

Electron microscopy

The chief purpose is to demonstrate the level of tissue separation or blistering [1,2]. As indicated in the sections on molecular pathology of EB subtypes, the split is intraepidermal in EB simplex, in junctional EB it is through the lamina lucida, just below the lowermost plasma membrane of basal cells, and in dystrophic EB it is beneath the lamina densa. Other ultrastructural features important for diagnosis are that hemidesmosomes are generally sparse and small in the more severe forms of junctional EB [3,4] and anchoring fibrils are reduced in number, absent or structurally abnormal in dystrophic forms of EB [5–7]. A clear distinction cannot be made between the dominant and localized recessive dystrophic forms, even with morphometric analysis of anchoring fibrils [3]. Intraepidermal electron-dense stellate bodies are a marker of transient bullous dermolysis of the newborn (Fig. 40.29). In the Herlitz form of junctional EB and in the form of EB associated with pyloric atresia, hemidesmosome plaques are often minute, and subbasal dense plates are severely attenuated or absent.

In EB simplex, the most striking changes are seen in the Dowling–Meara form, where tonofilament clumping in basal keratinocytes (Fig. 40.1) is pathognomonic [8]. In the rare generalized or Koebner autosomal recessive forms of EB simplex, the tonofilaments may be severely depleted or absent from the basal cells. In EB superficialis, the cleavage level is usually subcorneal. Despite their value in diagnosis in most instances, the ultrastructural features in a given diagnostic biopsy sample can be difficult to interpret. Briggaman [9] has illustrated how the level of cleavage may appear to vary, not only between skin samples from the same patient but also within the same sample.

Antigen mapping

As an alternative to electron microscopy, the level of blister formation can be determined using indirect immunohistochemical staining [1–3]. The aim is not to look for reduced expression of skin antigens, but to stain the dermal–epidermal zone using antibodies to proteins that are strongly expressed in both normal skin and skin from patients with different forms of EB. For example, sera from bullous pemphigoid patients or, preferably, an anti-BP230 antibody can be used to stain the lower surface of basal cells (containing hemidesmosomes), and antikeratin 14 antibody to stain the cytoplasm of basal epidermal cells. Anti-type IV collagen antibody will stain the lamina densa of the epidermal basement membrane. In EB simplex, all antibodies (except antikeratin) stain only the base of the split. Antikeratin stains the roof and the floor (but this is difficult to see in low-level separations). In junctional EB, antikeratin and bullous pemphigoid antibodies stain the roof; whereas anti-type IV collagen staining is on the floor. In dystrophic EB, all antibodies stain only the roof of the split.

Use of specific antibody probes

This method can be very valuable in diagnosis when used together with electron microscopy or antigen mapping. The purpose is to demonstrate a reduction in or absence of expression of certain antigens in the dermal–epidermal junction, which may be indicative of specific abnormalities in either junctional or dystrophic forms of EB [1]. Several relevant studies have already been referred to under the sections on molecular pathology of EB subtypes.

In Herlitz and some non-Herlitz cases of junctional EB, caused by laminin 5 mutations, abnormal staining for laminin 5 can be shown using monoclonal antibodies GB3 [2] and K140 [3] (Fig. 40.30). In non-Herlitz junctional EB (generalized atrophic benign EB) with BP180 defects,

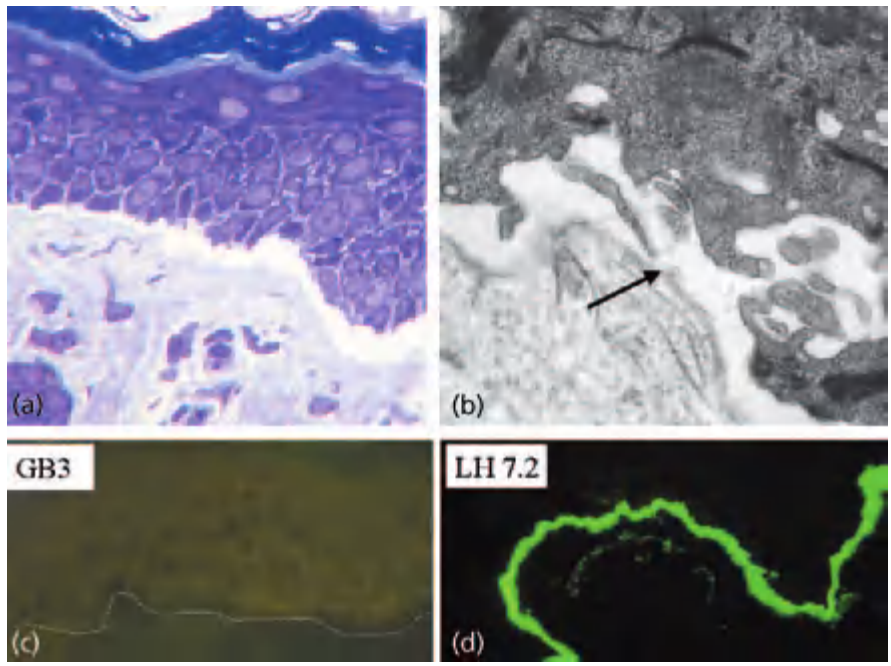

Fig. 40.30 Combined use of (a) light microscopy, (b) electron microscopy, and (c,d) indirect immunofluorescence microscopy for the diagnosis of Herlitz junctional EB. (a) A split in a semi-thin (1 μm thick) resin section has occurred in (b) the lamina lucida, just above the lamina densa (arrow). (c,d) In frozen sections, (c) GB3 (antilaminin 5) staining is negative, whereas (d) LH7.2 (anticollagen VII) staining is normal.

staining is reduced with anti-BP180, but not with anti-laminin 5 antibodies [4]. Antibodies to the α6 or β4 integrin chains will show reduced staining in the skin of patients with EB associated with pyloric atresia [5].

The monoclonal antibody 19-DEJ-1, recognizing 'uncein', an anchoring filament antigen possibly representing a protein with homology with a non-muscle myosin (J-D. Fine, unpublished data), shows reduced or absent staining in all forms of junctional EB and in approximately 25% of individuals with recessive dystrophic EB [6,7]. LH 7.2 monoclonal antibody, reacting with the amino terminal of the type VII collagen molecule is probably the most widely used antibody for the diagnosis of recessive dystrophic EB [8]. In cases of EB simplex associated with muscular dystrophy, reduced or absent staining will be found using antibodies to plectin, or HD1 (an antigen that is homologous with plectin) [9–11].

Molecular diagnosis

With the discovery of at least 10 distinct genes underlying different variants of EB, DNA-based techniques have had an increasingly important application in the diagnosis and prenatal diagnosis of EB. The information gained from molecular diagnosis is especially useful for genetic counselling and prognosis. When a patient is first seen in the clinic or neonatal unit, it is important to make provision for molecular diagnosis in the management plan, and obtain venous blood or cheek mucosa brushings (collected in ethylenediaminetetra-acetic acid tubes, and *not* in heparin or citrate) for subsequent DNA extraction and analysis in the laboratory.

An example of the power of moleular diagnosis is the ability to discover whether a patient has a dominant or recessive form of dystrophic EB, where neither the family history, a skin biopsy nor the clinical phenotype has been able to provide the information. In a cohort of some 180 families in which distinct *COL7A1* mutations had been identified, there was evidence of only one case derived from a *de novo* germ-line-dominant mutation in a parent [1]. This implies that the large majority of apparently sporadic 'new' cases, with no known family history of EB, are likely to have a recessive rather than a dominant form of dystrophic EB [1]. However, the presumptive *de novo* occurrence of a glycine substitution mutation has also been reported [2,3]. The possibility of germ-line mutations inherited in patients with 'sporadic' dominant dystrophic EB should also be considered [4]. Molecular diagnosis can be valuable in the differentiation of Herlitz from non-Herlitz EB (e.g. in a child) where the skin biopsy findings, including the immunofluorescence results, are equivocal.

The developments in the molecular genetics of the dystrophic and junctional forms of EB have already had a major impact on prenatal diagnosis. First trimester DNA testing is now an option for couples at risk of having affected children (see Chapter 13). Knowledge of mutation 'hotspots' within a population can reduce the time and expense of extensive screening for mutations that might otherwise be necessary [5]. The issue of mutation screening of family members of affected individuals, or unrelated partners, often arises during genetic counselling. In relatives not known to be at high risk of either being a carrier of a recessive gene and therefore of having an affected child, genetic screening may not be offered, or even encouraged. However, there are rare instances where prior screening may have averted an affected pregnancy [6].

Differential diagnosis

Differentiating EB from non-EB, or one form of EB from another, can be very difficult, especially in the neonatal period. At this stage, the following disorders may need to be included in the differential diagnosis of EB: bullous congenital ichthyosiform erythroderma; staphyloccocal scalded skin syndrome; bullous impetigo; incontinentia pigmenti; neonatal herpes simplex; autoimmune bullous disease, such as pemphigus or herpes gestationis, acquired transplacentally; aplasia cutis; focal dermal hypoplasia; Gunther's disease; and Kindler's syndrome.

In infants, older children or adults, some autoimmune bullous diseases, such as bullous pemphigoid, cicatricial pemphigoid or linear IgA disease may show overlapping features with junctional EB or Dowling–Meara EB simplex (e.g. EB acquisita may resemble dystrophic EB). Usually, however, the timing of the onset of blistering will allow inherited EB to be distinguished from the autoimmune immunobullous disorders. Pachyonychia congenita, skin peeling syndrome and ichthyosis bullosa of Siemens may rarely be confused with EB in older children or adults.

Shabbir's syndrome also has to be considered in the differential diagnosis of EB. This disorder, described by Shabbir *et al.* [1], included 22 patients from 13 mostly consanguineous Pakistani families. It starts in infancy and affects both sexes. Chronic erosive lesions affect the face, mainly around the nose and mouth, and, to a lesser extent, the limbs, trunk and genitalia. The nails are also involved and the third constant feature is hoarseness. The teeth may be notched. In a detailed study of three children with Shabbir's syndrome (or laryngo-onychocutaneous syndrome), Phillips *et al.* [2] emphasized the additional feature of conjunctival lesions, which were also constant in their patients. They also thought that the condition may represent a distinctive form of junctional EB because two patients had transient blisters in the neonatal period, the ulcers appeared in sites of repeated rubbing or trivial trauma, and hemidesmosomes in some of their patients showed ultrastructural and immunohistochemical abnormalities consistent with junctional EB.

Another recently recognized disorder that must be distinguished from EB is an autosomal recessive form of ectodermal dysplasia associated with congenital skin fragility, caused by mutations in the plakophilin 1 gene [3,4]

Mendes da Costa disease [5] is often classified as a form of EB simplex. The pathogenesis of this rare X-linked disorder, reported in a Dutch family, is still poorly understood. Although blisters are seen, they are not trauma induced [6]. Without further evidence, the case for continuing to classify this disorder as a form of EB is questionable.

Treatment

There is no specific treatment for any form of EB, and the mainstay of clinical management is based on protection and avoidance of provoking factors. In the more severe forms of EB, it should be remembered that the whole skin and other stratified squamous epithelia, including the oral mucosa, are extremely fragile and vulnerable to blistering from the slightest friction or scrapes. In the milder forms, blistering may not always result from mild friction and may only follow sharp knocks to the skin. Major challenges include the treatment of the neonate with severe generalized disease and the older child, adolescent or adult with the chronic disability that accompanies the severe form of recessive dystrophic EB.

Management of neonates and infants

Because severe blistering and erosions may be associated with junctional, dystrophic or simplex forms of EB in the neonate, an early objective is to establish the diagnosis from an appropriate skin biopsy (see above). This may be particularly relevant for a newborn with Dowling–Meara EB simplex, where the clinical appearance may be confused with Herlitz junctional EB or even dystrophic EB, suggesting a much graver prognosis. The early management of neonates with EB should, where possible, be undertaken in a specialist neonatal or paediatric unit, which has the expertise, staff and resources to manage these vulnerable babies. A key to successful treatment is expert nursing care. Paediatric nurse specialists with experience of caring for babies and children with EB are often best placed to help with coordinating hospital treatment, training parents and non-specialist nurses at other centres to handle and treat the patients, and prepare for the child's return home. In these specialist centres [1], babies with EB are nursed on thick foam pads, which are covered by a silk sheet. This allows the babies to be held, fed and nursed without subjecting them to undue trauma. The erosions are cleaned with sterile normal saline and covered in comfortable non-adherent dressings. Some EB specialists may prefer to use a topical antiseptic such as stabilized hydrogen peroxide cream (Hioxyl, Quinoderm, UK) or 1% chlorhexidine cream, rather than topical antibiotics, chiefly because of the risk of emergence of antibiotic-resistant bacteria. Another preference is to treat open

wounds with 1% silver sulfadiazine cream (Flamazine, Smith and Nephew, UK) or an ointment containing polymyxin B or bacitracin. The topical antibiotic mupirocin is not recommended for regular use, especially in hospital practice, because of the emergence of mupirocin-resistant *Staphylococcus aureus* [2,3]. However, its use for short periods (up to 7 days) in the home, for localized infected areas, is normally safe and effective [4]. Among the newer dressings now favoured for use in children and older patients are Mepitel and Mepilex (Molynycke, Luton, UK). Mepitel is a porous, mildly adherent silicone-based material, which can be left in place for up to 7 days. Any exudate is usually able to pass through the holes in this dressing to be absorbed by a secondary gauze dressing, which can be changed more frequently. Mepilex has a foam backing which provides more protection where needed.

Management of severe generalized recessive dystrophic epidermolysis bullosa

Patients with the more severe forms of recessive dystrophic EB will often survive into middle age and will therefore require continuing care throughout life [5]. Ideally, they should be seen at 6-monthly intervals in a multidisciplinary clinic with expertise to help with the particular needs of these patients. Special precautions should be taken in the use of adhesive tapes, sphygmomanometer cuffs, tourniquets and any other instruments or appliances that might lead to blister formation or shearing of the skin or mucous membranes. The following systems require particular attention.

Oral and dental care [6,7]

Microstomia, intraoral fibrosis and tethering of the tongue make access and examination of the teeth and mucosa difficult. Treatment should start in early childhood, so the involvement of a paediatric dentist with specialist knowledge of the dental complications affecting children with EB is important. Wherever necessary, reconstructive measures should be applied to permanent and primary teeth, to maintain function. These include treatment of caries, and meticulous cleaning of tooth surfaces. Crown placement and even tooth implants (in adults) have been used succesfully in some patients. More frequent preventive measures include daily fluoride supplements and the use of a mouthwash containing sodium fluoride and aqueous chlorhexidine (G. Roberts, personal communication, 1996).

Gastrointestinal tract and nutrition [8–12]

Dysphagia and pain on swallowing are common. Oesophageal strictures may be demonstrated by X-ray examination (including barium swallow and cine radiography)

Fig. 40.31 Barium swallow radiograph showing constriction in the upper oesophagus in recessive dystrophic epidermolysis bullosa.

(Fig. 40.31) or by endoscopy. Oesophageal spasm, often accompanying an acute obstruction, can sometimes be relieved by administration of calcium-channel blocking agents. More permanent blockage requires an endoscopically guided balloon dilatation [8], which will usually have to be repeated, perhaps several times each year. More radical treatment has included surgical excision of the stricture followed by anastomosis, and colonic interposition [9]. Most patients have gastro-oesophageal reflux, which should be treated with a proton pump inhibitor to prevent further damage to the lining of the oesophagus with the risk of secondary scarring and oesophageal shortening. Constipation is inevitable and often chronic in these patients. The cause is complex and associated in some degree with inadequate fibre in the diet. A high-fibre diet is therefore important, and patients who have difficulty in eating sufficient fibre may benefit from nutritional supplements such as Enrich (Abbot Laboratories Ltd, Maidstone, Berks, UK). Osmotic and stimulant laxatives, as well as faecal softeners, may all have a role and be prescribed according to an individual patient's

needs. Lactulose is often the first choice of laxative to be used in treating constipation in children and adults.

Anal blistering and erosions contribute to the constipation and faecal retention, especially in children. Glycerol suppositories used in conjunction with a topical anaesthetic preparation may help. If faecal impaction occurs, more drastic measures, including manual removal of faeces under general anaethesia, may be required.

Trying to ensure adequate nutrition with a balanced diet is especially important to maintain growth in children [10,11]. A deficiency of vitamins and trace elements (including zinc and iron) is frequent [12]. Comprehensive nutritional supplementation is only partly effective in maintaining adequate growth, and controlling anaemia and wound healing. The advice of an EB dietitian is essential. Feeding through a gastrostomy allows appropriate nutrition in addition to the administration of supplements such as iron, zinc and multivitamins, which children may find difficult to take by mouth [13]. Gastrostomy feeding can be delivered overnight in the home [13]. Parenteral nutrition has also been used [10].

Eyes

External abrasions should be dealt with urgently; they usually require topical treatment with an antibiotic and anaesthetic. Scarring of the lids following blistering may result in inadequate lid closure and loss of normal protection to the eyes. Plastic surgical reconstruction may be indicated. Artificial tears are a useful lubricant.

Musculoskeletal system

Although early exercises and physiotherapy may be helpful, the progress of finger and hand contractures with eventual mitten-type deformity is virtually inevitable. Contractures and tight tethering by scar tissue may also affect elbows and knees. Surgical release of the contracted fingers is a highly specialized procedure and requires skin grafting and postoperative splinting [14–16]. The benefit from surgery is only temporary because most patients need further surgical treatment within a few years. The feet may be involved in a similar process, but a 'degloving' procedure is not recommended, because the foot deformities do not usually prevent the patients from standing or walking.

Anaemia

All patients with the more severe forms of recessive dystrophic EB are anaemic, and the picture is that of an anaemia of chronic disease. Despite the administration of oral iron supplements, the iron stores are usually low as assessed by serum ferritin levels. In patients with widespread lesions and secondary infection, the serum ferritin may not accurately reflect the need for supplementary iron. Instead, the serum iron level may be a better indicator of the requirement for iron replacement in these patients. Parenteral iron is painful if given intramuscularly, especially where the muscles are thin and wasted. Anaphylaxis is a potential risk of intravenous administration. Venofer (Synar-Med, UK), an iron hydroxide preparation, can be given intravenously, and has been used repeatedly in several dystrophic EB patients, with a good response and no serious side effects [17,18]. The haemogobin levels generally increased, and the patients' sense of well-being improved. Transfusion of packed red cells may be required, especially when the blood haemoglobin level falls below approximately 7.00 g/dL, or when the patient becomes short of breath and more easily fatigued than usual.

Bony abnormalities

Virtually all patients have bony changes, mainly osteoporosis [19]. The cause is multifactorial, and is related to poor nutrition, relative immobility in some patients and previous treatment with systemic glucocorticoids. This last point is especially relevant in older patients. Regular checking of bone density, especially of the hips and spine, usually by dual-energy X-ray absorptiometry, is now part of routine management. Treatment with calcium supplements and a biphosphonate may be indicated.

Systemic treatment

Long-term systemic corticosteroid treatment is not used now because of the high risk of complications, and phenytoin, which had appeared to control blistering in certain patients in an open study [20], did not prove to be more effective than placebo in a controlled trial [21]. Other systemic drugs that have been tried with mixed results in small numbers of patients include vitamin E [22,23], minocycline [24], ciclosporin [25,26] and retinoic acid [27]. Although, theoretically, the systemic use of a retinoid such as isotretinoin or acetretin might reduce the risk of squamous cell carcinomas in these patients, there is no evidence yet in support of this presumably lifelong treatment. In addition, in a recent phase 1 trial of low-dose isotretinoin in recessive dystrophic EB, many of the patients treated complained of increased mechanical fragility, blistering and/or itching as the dosage approached 0.5 mg/kg/day (J-D. Fine, unpublished data).

Skin grafting

Autologous split-thickness skin grafts have had short- to longer term beneficial effects in the treatment of chronic ulcers or erosions in patients with generalized recessive dystrophic EB [28] or pretibial EB [29,30]. The treatment

was found to be more effective when allogeneic keratinocytes were added to the split-skin grafts [30]. Cultured keratinocytes have also been used successfully in the treatment of junctional EB [31,32]. Repeated applications of autologous [31] or maternally derived [32] cells were used in the treatment of facial erosions in three children, and allogeneic keratinocytes were effective in promoting re-epithelialization of extensive erosions on the trunk and upper limbs of an infant [33]. Similar benefit was seen in a patient with recessive dystrophic EB [34]. The effects of applying allogeneic keratinoyctes to split-skin graft donor sites on the thigh were studied in 10 patients with severe recessive dystrophic EB [35]. There was no overall difference in the rate of wound healing, in comparison to similar non-treated sites. However, the treatment was effective in relieving pain in several patients.

Skin bioequivalents have also been used in the treatment of EB simplex [36], junctional EB [37,38] and dystrophic EB [37], with mixed results. Concerns have been raised about the relative efficacy, especially in the long term, of treatment with bioequivalents, including the commercially available Apligraf (Novartis), until more comprehensive data based on controlled trials become available [39]. Anecdotal evidence from the National EB Registry suggests that such treatments are often either ineffective or any benefits may be relatively short-lived (J-D. Fine, unpublished data).

Pain management

Patients with EB frequently experience severe pain, which is unresponsive to conventional treatment with non-opiate-based or non-steroidal anti-inflammatory agents. Unfortunately, systemic opiates are addictive and tend to exacerbate chronic constipation, making their chronic use highly undesirable. However, recent experience has found that the use of topical opiates, including diamorphine, may be effective in the treatment of pain in EB patients, reducing the need for powerful systemic analgesia (E. Pillay, F. Keane and R.A.J. Eady, unpublished data). Its use is particularly beneficial when chronic pain is associated with chronic ulcers and erosions, accompanied in some patients by squamous cell carcinoma. Amitriptylline is useful in pain management in both adults and children [40]. Amitriptylline and cognitive–behavioural techniques were effective in relieving chronic pain and discomfort in an 11-year-old child with junctional EB [41]. Oral midazolam 0.33 mg/kg administered 20 min prior to baths and dressing changes substantially improved the patient's tolerance of wound care [41].

Cancer and recessive dystrophic epidermolysis bullosa [42]

Squamous cell carcinomas are expected to occur in nearly every patient with Hallopeau–Siemens disease, as well as in a minority of patients with non-Hallopeau–Siemens and inverse forms of recessive dystrophic EB (Figs 40.32 & 40.33). Meticulous surveillance, preferably with the aid of serial photography, should be performed regularly (at

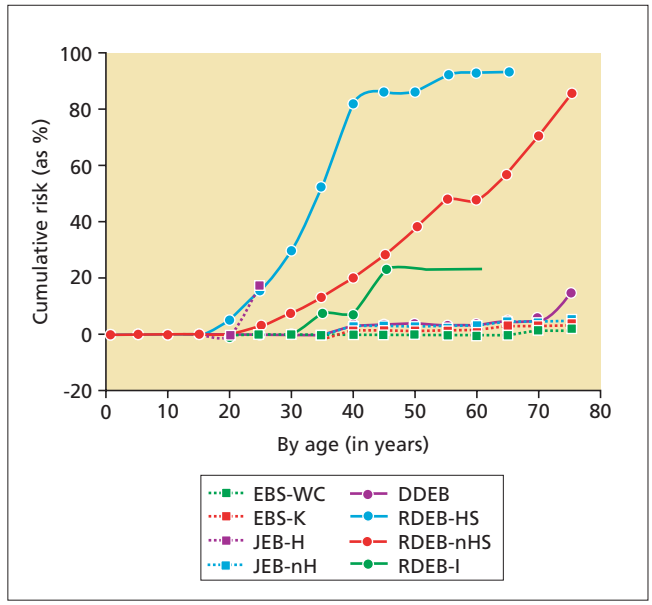

Fig. 40.32 Cumulative risk of death from squamous cell carcinoma in different forms of epidermolysis bullosa. EBS-WC, epidermolysis bullosa simplex (Weber–Cockayne); EBS-K, EB simplex (Koebner); JEB-H, junctional EB (Herlitz); n-H, non-Herlitz; DDEB, dominant dystrophic EB; RDEB-HS, recessive dystrophic EB (Hallopeau–Siemens); n-HS, non-Hallopeau–Siemens; RDEB-I, inversa. (J-D. Fine, unpublished data, 2002.)

least every 6 months), from the age of 10 years, and any suspicious lesion should be immediately biopsied. Those lesions that fail to reveal cancer histologically, and yet remain atypical in appearance or healing pattern, such as a non-healing erosion, should be re-biopsied, because it is possible to miss an early squamous cell carcinoma, given the tendency of these tumours to be well differentiated histologically and to show only focal areas of neoplastic change. Wide surgical excision is recommended, and careful serial follow-up examinations should be implemented, seeking possible local or regional recurrences. Although still unproven, there may be a role for sentinel node biopsy in the management of these patients. There is also no evidence yet in support of using Mohs technique instead conventional wide surgical excision. Regional metastases, even if extensive, may benefit from at least partial surgical debulking, to reduce the size of non-healing, painful, malodorous or chronically infected lesions. Neither chemotherapy or radiotherapy has been shown to provide lasting benefit in the treatment of primary or secondary tumours. However, radiotherapy, like surgery, may be used for reducing the tumour mass. It does not appear to make blistering worse (J-D. Fine, unpublished data, 2002).

Treatment of epidermolysis bullosa simplex

Heat and humidity lower the threshold for blistering in patients with EB simplex, and measures to reduce both these factors are therefore important. Patients with Weber–Cockayne or Dowling–Meara EB simplex should wear well-fitting well-ventilated shoes, preferably with a soft inner lining. Cotton socks are preferable to wool or synthetic fibres, and double-layer sports socks provide extra protection from friction and absorb sweat well. The application of aqueous solutions containing alcohol or glutaraldehyde [43] has been found useful, but is not necessarily recommended as glutaraldehyde is potentially irritant and toxic. Iontophoresis and the application of aluminium chloride hexahydrate [44] have also been used in attempts to suppress sweating. However, in a controlled trial of 20% aluminium chloride hexahydrate for the treatment of Weber–Cockayne EB simplex, there was no difference between the active drug and placebo in suppressing blistering [45]. The observation that oral tetracycline may have been effective in reducing the rate of blistering in two patients with EB simplex [46] requires further evaluation [47].

Newer forms of treatment, including gene therapy

Newer, specific, methods of treating EB have been slow to emerge. However, it is likely that genetically engineered growth factors and other cytokines that are able to influence wound healing will soon be available for clinical trials, or even clinical practice. Such advances could clearly have an important impact on the management of chronic erosions in junctional and dystrophic EB, although their potential role in the treatment of lesions in internal organs, such as the oesophagus, may be less clear. There is a pressing need for an effective means to halt and possibly reverse the relentless progression of digital fusion and hand contractures seen in recessive dystrophic EB.

Although currently unavailable, gene therapy [48–53] is nevertheless a realistic goal for the future treatment of more severe autosomal recessive forms of EB. There are numerous obstacles, but each is potentially surmountable, given time and sufficient resources. Different methods of introducing DNA into skin or skin cells *ex vivo* are currently being explored. The objective is to introduce one normal allele into somatic cells that, in recessive forms of EB, would have two mutant genes. The strategy includes finding effective and safe methods for targeting 'normal' genes into the right place (e.g. the nucleus of an epidermal stem cell) and keeping the gene activated under controlled conditions. The introduced gene must be able to undergo transcription and translation in the synthesis of an appropriate product, such as a basement-membrane protein, which then has to be secreted by the cells and incorporated into the extracellular matrix in a way that will allow it to be functionally effective. The gene may be at risk of being rapidly degraded, neutralized (by autoantibodies), shed (inside a differentiating keratinocyte) or being otherwise inactivated.

For autosomal dominant disorders, including dominant dystrophic EB or EB simplex, the strategy is different. Under these conditions, rather than introduce a further normal gene, the objective is to try to inactivate or nullify the action of the mutant gene, which usually exerts a 'dominant-negative' effect on its normal paired allele. A major approach involves antisense DNA and RNA strategies [54], which currently are being explored particularly for use in the treatment of cancer.

A direct result of the recent advances in the molecular genetics of different forms of EB has been the development of DNA-based first-trimester prenatal diagnosis. This has already been used for the benefit of many couples at high risk of having affected children (see Chapter 13). The introduction of preimplantation genetic diagnosis will broaden the available options in the overall management of those affected by EB.

Hailey–Hailey disease

SYN. FAMILIAL BENIGN CHRONIC PEMPHIGUS

[S.M. Burge, pp. 40.32–40.36]

Hailey–Hailey disease (McKusick No. 16960) is a rare intraepidermal blistering disease that is inherited as an autosomal dominant. The condition, which was described by the Hailey brothers in 1939, is characterized by recurrent vesicles and erosions usually affecting the neck, axillae and groins [1].

Aetiology. Hailey–Hailey disease is caused by mutations in *ATP2C1*, a gene on chromosome 3q21 that encodes a P-type calcium-transport adenosine triphosphatase (ATPase). This is the human homologue of an ATP-powered pump (PMR1) that sequesters calcium into the

Golgi in yeast. A number of mutations have been described but no phenotypic correlations identified [2–5]. An autosomal dominant pattern of inheritance has been confirmed in family studies [6,7]. Darier's disease, a condition that shares many clinical and pathological features with Hailey–Hailey disease, is caused by mutations in a gene that encodes another calcium ATPase located in the sarco-endoplasmic reticulum (SERCA) (see Chapter 34).

Pathogenesis. Calcium pumps have a key role in maintaining epidermal integrity, but it is not yet clear how loss of one functional allele of *ATP2C1* leads to the changes in adhesion that typify Hailey–Hailey disease. Calcium ATPases in the Golgi are important for protein sorting, processing and glycosylation, and cytosolic calcium is involved in cell signalling. The cellular processes that may be affected by the mutation in Hailey–Hailey disease include gene transcription, post-translational modifications of adhesion proteins, trafficking of adhesion proteins and the assembly of adhesion junctions.

The adhesion of cultured keratinocytes from patients with Hailey–Hailey disease is abnormal [8–10] and regulation of cytoplasmic calcium is impaired [2]. Plasminogen activation may potentiate acantholysis [11,12]. Acantholysis is reduced *in vitro* by corticosteroids, serine protease inhibitors and vitamin D_3 analogues, but not by retinoids [10,13].

UVB provokes acantholysis in patients and has been used to detect carriers of the disease gene [14]. The adhesion of cultured keratinocytes from Hailey–Hailey disease is impaired by UVB, but no more than the adhesion of keratinocytes from normal individuals. This suggests that other factors may be necessary for UVB to provoke acantholysis *in vivo* [15].

Sellotape stripping, friction, freezing, irritants, inflammation and suction induce acantholysis in the normal-looking skin of affected patients. Cutaneous bacterial or yeast infections may exacerbate disease [7,16].

Pathology. Acantholytic clefts and bullae form above the basal cells. The suprabasal cells separate partially from one another, so clusters of loosely coherent cells float in the bullae. Widespread partial acantholysis gives the epidermis the appearance of a 'dilapidated brick wall'. No intercellular deposits of IgG and complement are present in the epidermis.

The primary event appears to be dissolution of the desmosomal attachment plaque [17]. Tonofilaments separate from desmosomal plaques and aggregate in perinuclear whorls [18–20].

The components of desmosomes, adherens junctions, gap junctions and the cytoskeleton are distributed normally in uninvolved skin. Desmosomal components, E-cadherin and connexins are internalized in acantholytic cells [12,21–23] and extracellular epitopes of cadherins are lost [24]. P-cadherin, an adhesion protein expressed by basal cells in normal skin, is expressed by suprabasal acantholytic cells in Hailey–Hailey disease and other acantholytic conditions [25].

Clinical features. The condition usually presents in the third or fourth decade [1,2]. Flaccid vesicopustules, crusted erosions or expanding circinate plaques appear in areas exposed to friction such as the sides of the neck, axillae, groins and perineum. Involvement may be restricted to one site but can be generalized [3,4]. Lesions extend peripherally, healing in the centre (Fig. 40.34). Flexural disease may be hypertrophic and malodorous with soft, flat, moist vegetations and fissures (rhagades) (Fig. 40.35). Itch and pain are common and flexural disease may be disabling, particularly if the groins are affected [2]. Even mild disease may reduce quality of life [5]. Asymptomatic longitudinal white bands are present in the nails of some patients (Fig. 40.36) [2] and fine palmar pits have been documented in one patient [6]. Mucosal involvement is rare, but conjunctival, oral, oesophageal and vaginal involvement have been described [2,7].

Fig. 40.34 Hailey–Hailey disease: spreading annular plaque with a crusted rim.

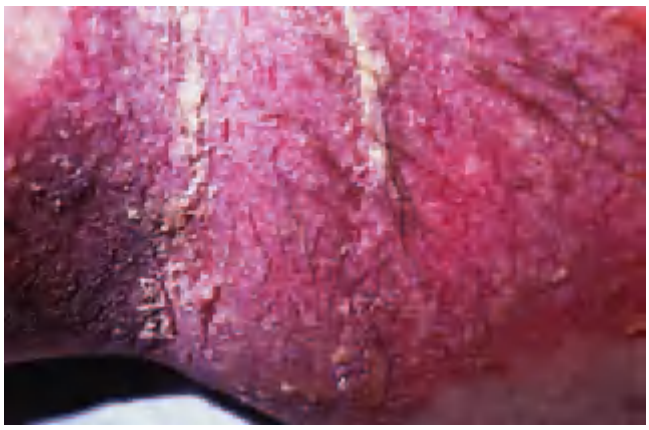

Fig. 40.35 Hailey–Hailey disease: typical hypertrophic malodorous axillary plaque with painful fissures (rhagades).

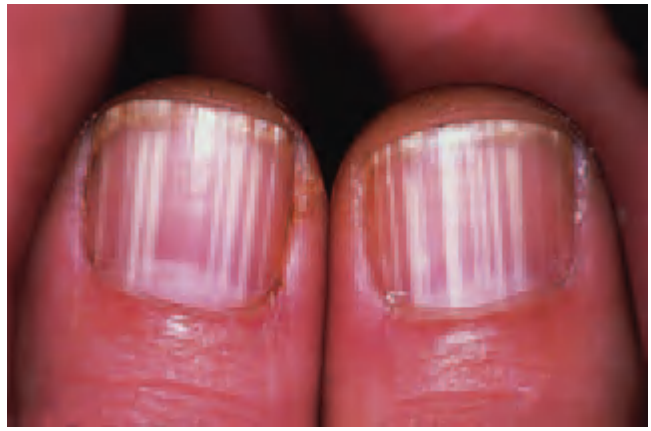

Fig. 40.36 Hailey–Hailey disease: longitudinal white bands in the nails may be a helpful diagnostic sign.

Complications. Herpes simplex virus causes painful exacerbations, which may be difficult to differentiate from vesicular Hailey–Hailey disease [8,9].

Contact dermatitis, both irritant and allergic, may exacerbate Hailey–Hailey disease [10,11], but the overall frequency of positive patch tests is probably not increased [12].

Rarely, carcinomas have arisen in skin affected by Hailey–Hailey disease, sometimes in association with human papillomavirus (HPV) [13–16].

Prognosis. Long remissions are common and many patients improve in old age [1,2].

Clinical differential diagnosis. Misdiagnosis is frequent [17,18]. Lesions may simulate impetigo, impetiginized eczema, *Candida* intertrigo or tinea corporis. Hypertrophic vulval lesions may suggest malignancy [2]. Diagnostic difficulties are compounded because Hailey–Hailey disease may respond to treatments such as antibacterials or topical steroids that are used for some of these conditions. Longitudinal white bands in the nails may confirm the diagnosis [2,19].

Vegetating flexural disease occurs in both pemphigus vegetans and Darier's disease. Oral lesions distinguish pemphigus vegetans. Darier's disease is characterized by hyperkeratotic papules as well as a distinctive nail dystrophy (see Chapter 34).

Localized perineal papules and plaques with an acantholytic histology have been reported in patients without other features of Hailey–Hailey disease [20–22]. The relationships between this condition, Hailey–Hailey disease and Darier's disease might be clarified by genetic studies.

Histological differential diagnosis. Hailey–Hailey disease must be differentiated from Darier's disease and pemphigus. Epidermal hyperplasia and suprabasal separation occur in both Darier's disease and Hailey–Hailey disease, but acantholysis tends to be more widespread in fully developed lesions of Hailey–Hailey disease, whereas dyskeratosis with corps ronds and grains is more prominent in Darier's disease [23]. In pemphigus, the acantholytic cells are less well preserved and immunoglobulin and complement are deposited between the keratinocytes.

Investigations. The diagnosis should be confirmed by skin biopsy. Skin swabs should be cultured if infection is suspected but herpes simplex virus may be difficult to culture and Tzank smears, biopsy, electron microscopy or polymerase chain reaction have been recommended if this infection is suspected [24,25]. Patch testing should be considered in patients with long-standing disease.

Treatment. Loose, cool clothing will reduce friction and sweating. Absorbent pads may be helpful to keep flexures dry and thus reduce bacterial overgrowth.

No controlled therapeutic trials have been performed.

Eighty-six per cent of 58 patients found combinations of moderate to potent topical corticosteroids with antibacterial agents effective in one series. Topical steroids were most effective if applied promptly to early lesions [2]. Very potent topical corticosteroids (clobetasol propionate) with antibiotics and/or antifungals controlled disease in seven patients, but the skin atrophied in four patients who had continued to apply the steroid [26]. Potent steroids may be required for severe disease, but the strength of steroid should be reduced if possible. Rarely, systemic corticosteroids may be required for widespread disease [3,18,27].

The role of antiseptics, antibiotics and/or topical antifungal agents as steroid-sparing agents is unproven, but long-term anti-staphylococcal treatment appears to be helpful [2,18,28]. Topical tetracycline, fusidic acid and imidazoles may be added to a topical corticosteroid. Low-dose oral tetracyclines, erythromycin or flucloxacillin should also be considered. Oral treatment of herpes simplex should be considered in patients with unresponsive painful disease.

Although ultraviolet light may exacerbate Hailey–Hailey disease, PUVA was effective in six patients [29,30] and suberythemal UVB controlled both psoriasis and coexisting Hailey–Hailey disease in one patient [31]. Superficial (grenz) rays produced remissions of several months in six patients [32].

Recommendations for many treatments have been made on the basis of individual cases and evidence for the efficacy of any of the following is poor: ciclosporin topically and orally (3–4 mg/kg/day) [33–35], dapsone [36], methotrexate [37], thalidomide [38], oral calcitriol [39] and a topical vitamin D_3 analogue [40]. Oral retinoids have been prescribed with variable outcomes [41,42]. Botulinum toxin [43] reduced axillary sweating and improved disease in one patient.

The long-term benefit of any surgical approach is equally uncertain, but many have been recommended for recalcitrant disease including cryosurgery [18], full-thickness excision with or without split-thickness grafting [44,45], dermabrasion [46], carbon dioxide laser vaporization [47], erbium:YAG laser ablation [48], electrodesiccation [49] and breast reduction [50].

Linear acantholytic dermatosis

A linear acantholytic dermatosis has been described affecting one side of the body and following the lines of Blaschko [1,2]. This pattern might be explained by cutaneous mosaicism for the *ATP2C1* mutation just as mosaicism for *ATP2A2* may underlie segmental Darier's disease [3].

A patient with a family history of Hailey–Hailey disease had mild generalized disease, but superimposed on this background she had pronounced erythema and blistering arranged in a unilateral pattern following the lines of Blaschko. The authors hypothesize that the individual has a germ-line mutation affecting one allele but, in addition, a post-zygotic mutation affects the other allele resulting in loss of heterozygosity. The linear manifestations may be more severe because keratinocytes in this area are homozygous for the mutation [4].

Chapter 41

Immunobullous Diseases

F. Wojnarowska, V.A. Venning & S.M. Burge

Introduction

The bullous diseases discussed in this chapter, although uncommon, have a dramatic impact on the patient and their family and have severe economic consequences for the family and health services. These diseases have been the subject of intensive investigation in recent years, and the study of both the genetic and autoimmune diseases has made major contributions to our knowledge of the biology of the skin. The identification of the target antigens for the autoantibodies in the autoimmune bullous diseases has led to the discovery of many components of the desmosome and the adhesion complex linking the epidermis to the dermis (Fig. 41.1; also see Fig. 41.11). In parallel with this work has been the realization that mutations of these same proteins are the basis of some of the genetic bullous diseases. The molecular biology of the genetic abnormalities is beginning to reveal how the fine structure of these proteins enables them to perform their function (see Chapter 40).

The immunological diseases are classified largely by their clinical presentation, histopathology and immunopathology. The increased use of immunoblotting and immunoelectron microscopy to define these diseases has revealed that the target antigens and the specific epitopes may be common to more than one clinical entity. Thus, the clinician is still the final arbiter for diagnosis.

A comprehension of the ultrastructural anatomy and composition of the areas under discussion greatly facilitates understanding the diseases that produce chronic blistering of the skin and mucous membranes (see Chapter 3).

The immunobullous diseases are characterized by pathogenic autoantibodies directed at target antigens whose function is either cell–cell adhesion within the epidermis, or adhesion of stratified squamous epithelium to dermis or mesenchyme. These target antigens are components of desmosomes or of the functional unit of the basement-membrane zone known as the adhesion complex and are shown in Figs 41.1 and 41.11. The clinical, immunopathological and immunogenetic features of these diseases are shown in Tables 41.2, 41.3, 41.5 and 41.6. Dermatitis herpetiformis is the one possible exception, as the relevant target antigen has not yet been identified.

The most important techniques for the investigation of patients with immunobullous disease are histopathology, and direct and indirect immunofluorescence. Research techniques such as immunoblotting and immunoelectron microscopy may refine the diagnosis in the individual patient but do not replace the clinician [1].

Intercellular adhesion in the epidermis

Adhesion between keratinocytes is mediated predominantly by cell adhesion molecules of the cadherin family localized in two specialized intercellular adhesion junctions: desmosomes (*maculae adherentes*) and intermediate or adherens junctions (*zonulae adherentes*). The desmosomes are small electron-dense structures that link the

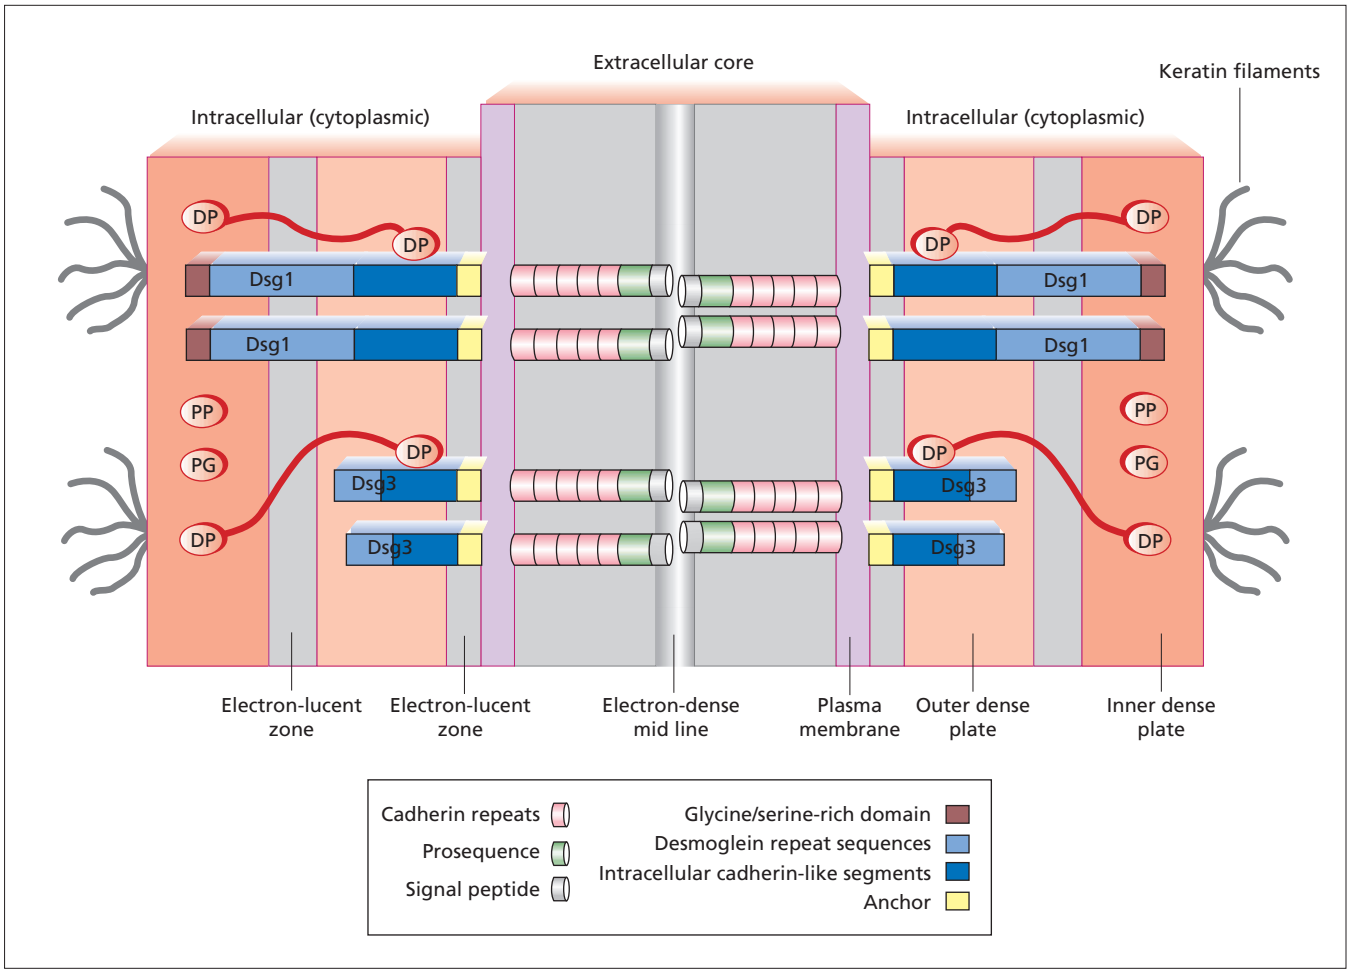

Fig. 41.1 Diagrammatic representation of the molecular components of the desmosome. DP, desmoplakin; Dsg1, desmoglein 1; Dsg3, desmoglein 3; N, amino terminal; PG, plakoglobin; PP, plakophilin. (Courtesy of Dr J. Allen, Oxford Radcliffe Hospital, Oxford, UK.)

intermediate filament within cells to the plasma membrane and to adjacent cells. The possible arrangement of desmosomal components is illustrated in Fig. 41.1. The major adhesion components of the desmosome are the desmosomal cadherins, desmogleins and desmocollins. The cadherins are transmembrane glycoproteins each having an extracellular domain, a transmembrane domain and a cytoplasmic domain that links to the cytoskeleton. Adhesion is probably regulated by complex interactions between the cytoplasmic domains of cadherins and cytoplasmic proteins such as catenins or plakoglobin [1–3]. For a detailed discussion see Chapter 3.

The desmoglein subfamily comprises at least three related proteins: desmogleins 1, 2 and 3. Desmoglein 1 is recognized by sera from patients with the autoimmune blistering disease pemphigus foliaceus and some with pemphigus vulgaris. It is also the target of protease-mediated damage by staphylococcal exotoxins [4]. Desmoglein 3 is the target antigen in pemphigus. The desmocollins are also a family of proteins that exist in more than one isoform. Desmocollin 1 is recognized by sera from some patients with immunoglobulin A (IgA) pemphigus.

The expression of desmosomal cadherins varies during differentiation, and expression in human skin differs from that in mucosal epithelium. Desmoglein 3 is expressed only in the basal and suprabasal layers of the epidermis whereas desmoglein 1 is found throughout the epidermis, particularly in the higher layers [5–7]. In mucosae, desmoglein 3 is strongly expressed throughout, whereas desmoglein 1 is expressed only weakly [8,9]. In neonatal epidermis, the distribution of desmogleins resembles that of the adult mucosa [10,11].

Desmosomes have well-defined submembranous plaques containing non-glycosylated proteins plakoglobin, desmoplakins 1 and 2 and plakophilin. Plakoglobin, present in both desmosomes and adherens junctions, may interact with cadherins to regulate adhesion [12,13]. Desmoplakins 1 and 2 belong to a multigene family of

intermediate filament organizing proteins, which includes the bullous pemphigoid antigen (BP230), present in the hemidesmosomes of the basement-membrane zone, and plectin, a widely distributed intermediate filament associated protein [12]. Less well-characterized plakins localizing to the desmosome are envoplakin and periplakin [14]. Plakin autoantibodies are present in the blistering disease, paraneoplastic pemphigus, a condition that is associated with lymphoid malignancies, thymomas or poorly differentiated sarcomas [15]. Keratin intermediate filaments insert into the desmosomal plaque, where their amino termini interact with the carboxy termini of desmoplakin. Desmoplakins and plakoglobin, and possibly also plakophilin 1, are attached to the desmosomal cadherins and to each other in a complex arrangement [16,17].

Adherens junctions

Epithelial cadherin (E-cadherin) is present in adherens junctions. Interactions between cytoplasmic domains on E-cadherin and cytoplasmic proteins called catenins are essential for normal adhesion. Plakoglobin, which is similar in structure to β-catenin, may also form complexes with E-cadherin [12]. Vinculin and α-actinin, cytoplasmic proteins present in adherens junctions, may link to bundles of actin microfilaments to influence the organization of the filaments. These are not currently identified as target antigens in immunobullous diseases.

Intraepidermal immunobullous diseases

Blisters form within the epidermis in the pemphigus group of immunobullous diseases. The antibodies in these diseases react with intercellular adhesion molecules. Immunoreactants are deposited between keratinocytes, intercellular bridges disappear and keratinocytes separate from one another, a change known as acantholysis.

Pemphigus

Definition. Pemphigus is derived from the Greek, *pemphix*, meaning blister or bubble. The term 'pemphigus' once covered most of the bullous eruptions of the skin, but diagnostic tests have improved and the bullous diseases have been reclassified. A number of distinct subgroups of pemphigus have emerged and many of the autoantigens have been identified. The antibodies are directed against epidermal cadherins, a family of calcium-dependent cell–cell adhesion molecules. The two major subtypes, pemphigus vulgaris and pemphigus foliaceus, are distinguished by the level of cleavage within the epidermis. Splitting is suprabasal in pemphigus vulgaris and its rare vegetating form, pemphigus vegetans. Blistering is more superficial in pemphigus foliaceus and related subtypes.

The classification of pemphigus, its clinical features, immunopathology and immunogenetics are summarized in Tables 41.1–41.3.

Table 41.1 Types of pemphigus.

Pemphigus vulgaris
variant: pemphigus vegetans
Pemphigus foliaceus
variant: pemphigus herpetiformis
variant: pemphigus erythematosus
Induced pemphigus
Intercellular IgA dermatosis
Paraneoplastic pemphigus

Table 41.2 The intraepidermal immunobullous diseases: clinical features.

Disease	Patients	Cutaneous distribution	Mucosal involvement	Lesions	Disease associations	Treatment	Prognosis
Pemphigus vulgaris	Middle age	Scalp, face, flexures, may be generalized	Always oropharynx, conjunctiva, genital	Flaccid blisters, erosions, flexural vegetations	Autoimmune disease, thymoma	Steroids, immunosuppressives, dapsone	Variable, may remit
Pemphigus vegetans	Middle age	Flexural	Oral	Vesicles, pustules, erosions, vegetating plaques		Steroids, immunosuppressives, dapsone	Variable, may remit
Pemphigus foliaceus	Middle age	Scalp, face, chest, upper back, rarely generalized 'seborrhoeic'	None	Scaly papules, crusted erosions, erythroderma		Steroids (topical, intralesional, systemic), immunosuppressives	Benign but chronic
Endemic pemphigus foliaceus	Children, young adults	Head, neck, generalized	Uncommon	Flaccid blisters, erosions, verrucous lesions, erythroderma		Steroids, immunosuppressives, antimalarials	Chronic mortality < 10%
Intercelluar IgA dermatosis	Adults children	Axillae, groins, face, scalp, proximal limbs	Uncommon	Flaccid pustules annular or circinate configuration	IgA monoclonal gammopathy	Dapsone	Chronic indolent
Paraneoplastic pemphigus	Adults, children	Upper body, palmo-plantar	Severe mucositis	Polymorphous, bullae, erosions, 'target lesions'	Lymphoproliferative disease, Castleman's, other malignancies	Tumour resection, steroids, immunosuppression	Very poor

Table 41.3 The intraepidermal immunobullous diseases: immunopathology and immunogenetics.

							Immunogenetics
Disease	Direct IMF	Isotype	Target antigens	Antigens (kDa)	Epitopes	Location	MHC class I and II
Pemphigus vulgaris/ pemphigus vegetans	Intercellular	IgG, (few IgM, IgA)	Desmoglein 3 Sometimes desmoglein 1 desmocollins	130	Amino-terminal of extracellular domain	Desmosome	DRB1*0402 DRB1*14
Pemphigus foliaceus	Intercellular	IgG	Desmoglein 1 Sometimes desmocollins	160	Amino-terminal of extracellular domain	Desmosome	HLA-DRB1*14
Endemic pemphigus foliaceus	Intercellular	IgG	Desmoglein 1 Sometimes desmocollins	160	Amino-terminal of extracellular domain	Desmosome	Several susceptibility alleles, all with same amino acid sequence in *DRB-1* gene DRB1*0102 DRB1*0404, *1402 or *1406
Paraneoplastic pemphigus	Intercellular and subepidermal	IgG	Plakins (desmoplakin, envoplakin BP230, periplakin)		Various	Desmosomes, BMZ; stratified, simple and transitional epithelia	Unknown

BMZ, basement-membrane zone; HLA, human leukocyte antigen; IMF, immunofluorescence; MHC, major histocompatibility complex.

Pemphigus vulgaris

Aetiology. Pemphigus vulgaris affects all races and both sexes [1]. It is a disease of middle age that affects children rarely, but patients are younger at presentation in India than in Western countries [2].

Pemphigus vulgaris accounts for approximately 70% of all cases of pemphigus and may be the most common autoimmune blistering disease in eastern countries, such as India, Malaysia, China and the Middle East [2,3]. The Jewish race, especially Ashkenazi Jews, have an increased susceptibility to pemphigus vulgaris [1]. In South Africa, pemphigus vulgaris is more common in Indians than in black or white races [4]. Pemphigus is less common in the West.

Predisposition to pemphigus is linked to genetic factors. First-degree relatives of patients with pemphigus vulgaris are more susceptible to the development of autoimmune diseases than controls [5,6] and have a higher incidence of circulating antidesmoglein antibodies [7]. Certain major histocompatibility complex (MHC) class II genotypes, in particular alleles of HLA-DRB1*04 and DRB1*14 subtypes, are common in patients with pemphigus vulgaris across racial barriers [8–11]. These alleles produce amino acid substitutions in the HLA-DRB1 peptide-binding sites, which may influence antigen presentation and recognition by T cells [11,12]. Susceptibility may also be determined by genes encoding immunoglobulins [13]. Pemphigus occurs in patients with other disorders characterized by immunological disturbances. Thymoma or myasthenia gravis have been reported in a number of patients; some have all three diseases [1]. Pemphigus may develop in patients with lupus erythematosus (see p. 41.16). Bullous pemphigoid (BP) and pemphigus have coexisted [14]. Pemphigus has been reported in patients with lymphoproliferative diseases such as Castleman's tumours (see p. 41.22). Viral DNA (herpes simplex, Epstein–Barr virus, human herpesviruses 6 and 8) has been detected in some skin biopsies or peripheral blood mononuclear cells from pemphigus patients [15,16] and pemphigus has coexisted with HIV infection [17].

Pathogenesis. Autoantibodies against the surface of keratinocytes occur in pemphigus and both clinical and experimental observations indicate that the circulating autoantibodies are pathogenic [1].

Pemphigus vulgaris antigen. The pemphigus vulgaris antigen, also known as desmoglein 3, is a desmosomal cadherin involved in mediating intercellular adhesion in the epidermis [2]. The antibody binds to an extracellular domain on the amino-terminal region of desmoglein 3 where it may have a direct effect on the function of the desmosomal cadherins [3,4].

Desmoglein 3 is found in desmosomes [4] and possibly elsewhere on the cell membrane of keratinocytes [5]. It is detected early in keratinocyte differentiation, primarily in the lower epidermis [6–9] and is expressed more strongly in buccal mucosa and scalp skin than in skin from the trunk [10]. This contrasts with the pattern of expression of the pemphigus foliaceus antigen, desmoglein 1, which is present throughout the epidermis, more intensely in the upper layers, but only weakly expressed in mucosae [11].

Where both desmogleins are expressed, one molecule is able to compensate for the loss of function of the other [12] and the distribution of lesions in different forms of pemphigus is consistent with the distribution of the desmogleins. Those pemphigus vulgaris patients with only desmoglein 3 antibodies tend to have lesions limited to the mucous membranes [13–15], where the relative lack of desmoglein 1 is unable to compensate and prevent

acantholysis. Pemphigus vulgaris patients with both desmoglein 3 and desmoglein 1 antibodies develop widespread mucocutaneous blistering [13,15,16] with skin blisters confined to the suprabasal epidermis, the location where both cadherins appear to be essential to maintain cell–cell adhesion. In cases evolving from mucosal dominant to mucocutaneous pemphigus vulgaris or from pemphigus vulgaris to pemphigus foliaceus, or more rarely vice versa, the shift in clinical features correlates with changes in the reactivity of the serum against the pemphigus antigens [17–21]. Although there is homology between desmogleins 1 and 3, the antibodies are not thought to be cross-reactive. One interpretation for this phenomenon is epitope spreading (tissue damage from a primary autoimmune or inflammatory response results in exposure of new epitopes on the same or another molecule to produce a secondary autoimmune response) [22]. However, a dual antibody response is not necessarily a feature only of late disease and may be present from the onset in mucocutaneous pemphigus vulgaris. Conversely, cases of antidesmoglein 3 mucosal pemphigus vulgaris may have neither clinical nor serological progression over many years of follow-up [23]. Antidesmoglein 1 antibodies are more common in Indian patients, suggesting that antibody profile does not simply reflect disease duration but is determined by other, possibly racial factors [23].

Pemphigus vulgaris sera may also contain autoantibodies to desmocollins [24,25]. Antibodies to non-cadherin antigens have also been reported. Antidesmoplakin in addition to antidesmoglein antibodies occurred in one patient but were not thought to be pathogenic [26]. Others report antibodies to cholinergic receptors and claim pathogenicity [27]. Although interesting, given the association of pemphigus with myasthenia gravis, this conclusion is disputed [28].

Antibodies. Patients with active disease have antibodies of both IgG1 and IgG4 subclasses, but the IgG4 antibodies are pathogenic [29,30]. Autoantibody production is T-cell dependent; autoreactive Th1 and Th2 cells specific for desmoglein 3 occur in pemphigus vulgaris [31]. Antibody–antigen complexes are found on desmosomes in early pemphigus lesions [32]. Immunohistological studies have revealed abnormalities in the staining pattern for desmosomal components, possibly secondary to the binding of the autoantibodies [12,33].

The pathogenicity of pemphigus vulgaris antibodies is suggested by several lines of evidence. Most studies have shown a correlation between disease activity and titre of antibody [34,35]. Transplacental transfer of maternal pemphigus vulgaris antibodies may cause transient blisters in the newborn [36]. In the neonatal mouse model, passive transfer of pemphigus vulgaris IgG causes suprabasal acantholysis [37]. Blistering is prevented by prior absorption of antibodies with the extracellular domain of the pemphigus vulgaris antigen [38]. Acantholysis can be induced in mice by antidesmoglein 3 antibodies alone but is greatly enhanced by addition of antidesmoglein 1 antibodies [39]. Pemphigus antibodies can induce acantholysis in mice deficient in complement, but the presence of complement amplifies blistering [40].

Complement and inflammatory mediators. Pemphigus IgG added to a skin organ culture or to cultures of epidermal cells induces acantholysis without requiring complement [41], but complement enhances pathogenicity. Pemphigus antibody fixes components of complement to the surface of epidermal cells [42]. Antibody binding may activate complement with the release of inflammatory mediators [43] and recruitment of activated T cells [44]. Complement activation in pemphigus is increased by interleukin-1α (IL-1α) and tumour necrosis factor-α (TNF-α) [45]. IL-1, thromboxane B_2 and leukotriene B_4 are present in blister fluid [43]. TNF-α and IL-6 are found in serum and lesional skin of pemphigus patients [46]. Their role in acantholysis is unknown.

Proteases. Several lines of evidence suggest that the plasminogen–plasmin system may be involved in the acantholytic process. Plasminogen activators and plasmin activity can be detected in the fluid taken from pemphigus blisters [47,48]. Keratinocytes in lesional epidermis may express tissue plasminogen activator when stimulated by contact with plasma [49]. Proteinase inhibitors, antibodies to plasminogen activators and inhibitors of plasminogen activators block the acantholysis induced by pemphigus antibodies in experimental models [47,50]. However, acantholysis induced by pemphigus antibodies occurs in plasminogen activator knockout mice, indicating that plasminogen activation is not a prerequisite [51]. The activity of plasminogen activator does not always correlate with disease activity in models of pemphigus [52], nor does proteolysis account for all the ultrastructural changes seen in epidermal cells injured by pemphigus vulgaris antibodies [53], but plasmin may amplify epidermal damage.

Pathology. The earliest changes consist of intercellular oedema with loss of intercellular attachments in the basal layer. Suprabasal epidermal cells separate from the basal

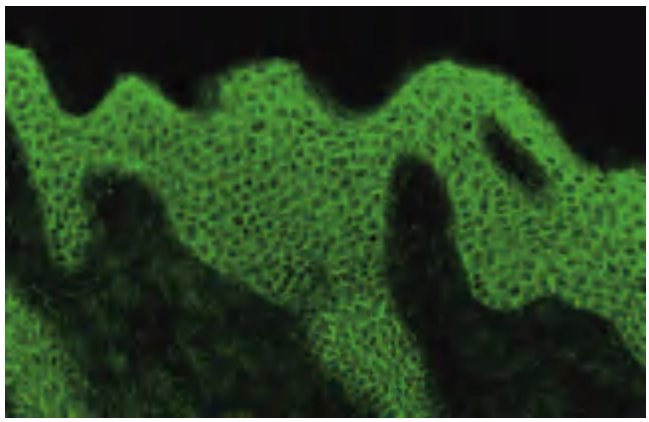

Fig. 41.2 Immunofluorescence showing intercellular IgG throughout the epidermis of a patient with pemphigus vulgaris.

cells to form clefts and blisters. Basal cells remain attached to the basement membrane but separate from one another and stand like a 'row of tombstones' on the floor of the blister. Blister cavities contain some acantholytic cells. A smear taken from the base of a blister or an oral erosion (Tzanck preparation) contains acantholytic cells. Clefting may extend into the walls of adnexae. Blistering is preceded by eosinophilic spongiosis in some cases. The superficial dermis has a mild superficial mixed inflammatory infiltrate which includes some eosinophils [1].

Electron microscopy has shown that widening of the intercellular space is followed by splitting of the desmosome junctions. When the cells separate from each other, the intracellular cytokeratin tonofilaments retract around the nucleus and the desmosomal plaques disappear. The attachment of basal cells to the basement membrane is not affected [2,3].

The diagnosis of pemphigus is confirmed by direct immunofluorescence, which shows IgG deposited on the surface of keratinocytes throughout the epidermis, in and around lesions (Fig. 41.2). IgG1 and IgG4 are the most common subclasses. Complement components (C3), IgM and IgA are present less frequently than IgG. Direct immunofluorescence may be the most sensitive method for diagnosing oral pemphigus (Table 41.5) [4].

Circulating pemphigus autoantibodies are detected by indirect immunofluorescence in over 80% of patients. The use of more than one substrate improves sensitivity, oesophageal substrate being preferable for the detection of desmoglein 3 antibodies [5]. A disadvantage of immunofluorescence methods is the difficulty distinguishing pemphigus vulgaris from pemphigus foliaceus on the staining pattern. Recombinant desmogleins (desmogleins 1 and 3) have been used recently to develop a sensitive and specific enzyme-linked immunoabsorbent assay (ELISA) for serodiagnosis of pemphigus [6,7]. Using ELISA, over 95% of pemphigus vulgaris patients have detectable antidesmoglein 3 antibodies and approximately 50% have antidesmoglein 1 antibodies. In appropriate dilutions, ELISA can be used to monitor disease activity [8].

Antibodies may be detected in patients without pemphigus [9]. Pemphigus-like circulating intercellular antibodies have been reported in conditions such as thermal burns [10], toxic epidermal necrolysis [9], penicillin reactions [11] and in first-degree relatives of relatives of pemphigus patients [12,13].

Clinical features. All patients have mucosal lesions, but pemphigus vulgaris presents with oral lesions in 50–70% of patients. These may precede cutaneous lesions by months or be the only manifestation of the disease [1–3]. Intact bullae are rare in the mouth. More commonly, patients have ill-defined, irregularly shaped buccal or palatal erosions, which are slow to heal (Fig. 41.3). The erosions extend peripherally with shedding of the epithelium [4]. Other mucosal surfaces may be involved including the conjunctiva [5], nasal, pharynx [6], larynx, oesophagus [7,8], urethra, vulva [9] and cervix [10].

Most patients develop cutaneous lesions. Involvement may be localized or generalized, but the disease has a predilection for the scalp, face, axillae, groins and pressure points (Figs 41.4 & 41.5). Flaccid blisters filled with

clear fluid arise on normal skin or an erythematous base. The contents soon become turbid or the blisters rupture producing painful erosions which extend at the edges as more epidermis is lost. At this stage, firm sliding pressure with a finger will separate normal-looking epidermis from the dermis producing an erosion (Nikolsky's sign). Nikolsky's sign is positive in pemphigus and more rarely in toxic epidermal necrolysis. Blisters can also be extended by vertical pressure, a phenomenon that occurs in many blistering diseases. Healing occurs without scarring but pigmentary change and acanthomas may occur in resolving lesions [11].

Fig. 41.5 Pemphigus vulgaris. Flaccid bullae and erosions on the forearm. (Courtesy of Dr R.J. Pye, Addenbrooke's Hospital, Cambridge, UK.)

Lesions in skin folds readily form vegetating granulations, and flexural pemphigus vulgaris merges with its variant pemphigus vegetans. Nail dystrophies, acute paronychia and subungual haematomas have been observed in pemphigus [12,13].

Severe pemphigus in pregnancy may be associated with fetal prematurity and death, but it is difficult to separate the effects of treatment from those of the disease. Generally the baby is healthy [14], although neonatal pemphigus may occur with mucosal or mucocutaneous lesions which are generally short-lived [15–17].

Prognosis. The severity and natural history are variable, but before treatment with steroids most patients with pemphigus vulgaris died [18]. Treatment with systemic steroids has reduced the mortality to between 5 and 15% [2,19], but some of these patients succumb to complications of therapy. Morbidity and mortality are related to the extent of disease, the maximum dosage of prednisolone required to induce remission and the presence of other diseases [2,18,20–22]. Disease activity generally decreases with time and most relapses occur in the first 2 years after diagnosis [23]. The outlook is worse in Jews [19] and in older patients [22].

Pemphigus vegetans

Definition. Pemphigus vegetans is a rare variant of pemphigus vulgaris that is characterized by vegetating erosions, primarily in flexures. Two subtypes are recognized: Neumann pemphigus vegetans and Hallopeau pemphigus vegetans. These may be considered to form a clinical spectrum from the severe Neumann type to the mild Hallopeau type [1].

Aetiology/pathogenesis. Antibodies react with the 130-kDa pemphigus vulgaris antigen and possibly other antigens in both types of pemphigus vegetans [2–6]. Antibodies in the Hallopeau type also react with desmocollins 1 and 2 [7].

Complement fixation might stimulate the marked infiltration of neutrophils and eosinophils that is so typical in pemphigus vegetans [3].

Pathology. The vegetating lesions are hyperkeratotic, papillomatous and acanthotic. Some suprabasal clefts may contain eosinophils but few acantholytic cells are present. Intraepidermal eosinophilic abscesses may be present in older lesions. Early lesions in the Neumann type show suprabasal acantholysis and intraepidermal vesicles without eosinophils. Eosinophilic spongiosis or eosinophilic microabscesses are common in the early pustular lesions of the Hallopeau type [8]. The dermis contains a heavy infiltrate of lymphocytes and eosinophils with a few neutrophils.

Direct immunofluorescence demonstrates intercellular IgG, sometimes with C3. Circulating intercellular antibodies can be detected in most patients by indirect immunofluorescence (Table 41.5).

Fig. 41.6 Pemphigus vegetans. Vegetations with no evidence of blistering. (Courtesy of Dr R.J. Pye, Addenbrooke's Hospital, Cambridge, UK.)

Clinical features. The disease starts at a slightly earlier age than pemphigus vulgaris. Involvement of the oral mucosa is almost invariable. Lesions are primarily flexural although vegetations may occur at any site (Table 41.4) [8].

Neumann type (Fig. 41.6). Vesicles and bullae rupture to form hypertrophic granulating erosions, which bleed easily. The lesions evolve into vegetating masses exuding serum and pus. The edges are studded with small pustules. Erosions at the edge of the lesions induce new vegetations. In time, the vegetations become dry, hyperkeratotic and fissured.

Hallopeau type (syn. pyodermite végétante, pyoderma vegetans). Pustules rather than vesicles characterize early lesions but these soon progress to vegetating plaques. As in the Neumann type, the vegetations are studded with pustules. In one patient, pemphigus foliaceus preceded the onset of pemphigus vegetans of Hallopeau [9].

Prognosis. The course of Neumann type of pemphigus vegetans is similar to pemphigus vulgaris but is generally prolonged. The Hallopeau type is more benign and spontaneous remission is possible.

Differential diagnosis of pemphigus vulgaris and pemphigus vegetans. Patients with mucosal lesions present to dental surgeons, oral surgeons and gynaecologists. Erosions may simulate acute herpetic stomatitis, erythema multiforme, aphthous ulcers or bullous lichen planus. Bullae are transient in the mouth and biopsies of erosions may not be diagnostic. Smears taken from the base of an erosion may show acantholytic cells (Tzanck's preparation). Direct immunofluorescence is the most accurate way to diagnose mucosal pemphigus [1]. Specimens may be posted to a suitable laboratory in Michel's medium if facilities for snap freezing and storage of the tissues are not available [2]. Indirect immunofluorescence may be a useful confirmatory test.

The diagnosis is less difficult when the patients have cutaneous blisters or erosions. Blisters in pemphigoid are tense and may be haemorrhagic. A smear taken from the base of a blister in pemphigoid (Tzanck's preparation) has no acantholytic cells. The diagnosis of pemphigoid is confirmed histologically by showing subepidermal bullae with immunoreactants in the basement-membrane zone.

Acute erythema multiforme is a short-lived disorder that may blister, but is easily differentiated from pemphigus histologically. Blistering in dermatitis herpetiformis is subepidermal and direct immunofluorescence of involved and uninvolved skin shows a granular deposition of IgA in the basement-membrane zone.

Vegetating pustular lesions in flexures must be differentiated from chronic infections or Hailey–Hailey disease (benign familial chronic pemphigus). Vegetating plaques mimicking pemphigus vegetans have been seen in IgA pemphigus [3] and paraneoplastic pemphigus [4]. The hyperkeratotic lesions of chronic pemphigus vegetans may simulate cutaneous tumours. The histology may be misinterpreted if immunofluorescence studies are not performed [5].

The histological differential includes Darier's disease, Hailey–Hailey disease and Grover's disease (transient acantholytic dermatosis). These conditions have distinctive clinical features in addition to negative immunofluorescence studies. Eosinophilic spongiosis may be an early histological manifestation of either pemphigus or bullous pemphigoid [6]. Immunofluorescence studies are needed to confirm the diagnosis.

Treatment of pemphigus vulgaris and pemphigus vegetans. The introduction of corticosteroids has greatly reduced mortality, but a significant morbidity remains [1]. Numerous steroid regimens, with and without immunosuppressive agents, have been recommended but sound clinical evidence for many of these regimens is lacking because the rarity of pemphigus has precluded controlled trials. Treatment has been the subject of a number of reviews [2–4].

Monitoring activity of disease. In the acute phase, the progress of the disease should be evaluated by the clinical findings. Once blistering stops and erosions heal, changes in the titre of circulating pemphigus antibody may be helpful in gauging the dosage of steroids [5,6]. Direct immunofluorescence studies of normal skin have also been recommended to predict remission or relapse [6].

Topical therapy. Patients who present with oral disease and mild cutaneous involvement may remain in this localized phase for months. Potent topical or intralesional steroids may reduce the requirement of oral steroids. Good oral hygiene, including treatment of periodontal disease, is important.

Opportunist infection is the major cause of death in patients with widespread blistering who are also immunosuppressed. Potassium permanganate and topical antiseptics may help reduce the risk of cutaneous infection,

while topical nystatin, amphotericin or one of the imidazoles will reduce the risk of oral *Candida*.

Systemic therapy. Prednisolone with an adjuvant is the preferred treatment for pemphigus vulgaris [3]. Prednisolone 1.0–1.5 mg/kg/day in combination with topical or intralesional steroids is sufficient to control disease in many patients. The dosage should be titrated to the clinical response [7] but it is important to stop oral steroids when the disease is inactive rather than maintain patients on a homoeopathic dose [8].

Patients with generalized disease may require more aggressive immunosuppression to suppress blistering, but the major difficulty in managing these patients is achieving a balance between the adverse effects associated with high-dose steroid therapy and those of poorly controlled disease. High dosage of prednisolone of 120–240 mg/day has been recommended for severe pemphigus, but the risks are considerable [1,9,10]. Prednisolone 60–100 mg/day or intravenous pulses of either 1 g methylprednisolone or 100 mg dexamethasone are safer alternatives [8,11,12].

A number of immunosuppressive agents have been recommended as adjuncts to oral steroids [2–4]. Azathioprine is widely used in a dosage of 2.5 mg/kg/day. The combination of prednisolone and azathioprine is more effective than prednisolone alone, both in terms of mortality and remission [3,13,14]. Azathioprine may be an effective monotherapy in mild cases, although the therapeutic effect is delayed for 3–5 weeks.

Cyclophosphamide alone is not effective in pemphigus, but cyclophosphamide 1–3 mg/kg/day is an effective alternate to azathioprine in combination with steroids. The combination is more effective than steroids alone [3,4,15]. Monthly intravenous pulses of cyclophosphamide with dexamethasone combined with low-dose oral cyclophosphamide have been used with great success [11,14,16]. Remission was maintained with low doses of oral cyclophosphamide [11].

Tetracycline in combination with prednisolone has been reported as useful in an uncontrolled study [17]. A small controlled study showed superiority over prednisolone and azathioprine [18].

Oral or intramuscular gold in addition to steroids reduces mortality and increases the number of patients in remission [3,4].

Ciclosporin (cyclosporin) alone is not helpful in the acute phase of the disease. Ciclosporin 5 mg/kg/day has been used in combination with steroids, particularly in patients with haematological abnormalities [4,19–21]. However, a comparative study found no advantage over prednisolone alone [22]. Topical ciclosporin mouthwash has been helpful in severe oral pemphigus [23].

Dapsone has been advocated as an adjunct in some patients with mild disease [15,24].

Methotrexate is seldom used as there were concerns about toxicity with the high doses that were used [4]. One retrospective review of the literature suggested that methotrexate neither reduced mortality nor changed the number of patients in remission [3]. Others have found that moderate dosage of methotrexate (10–17.5 mg/week) permitted withdrawal of prednisolone in steroid-dependent patients [25].

Mycophenolate mofetil (2 g/day) has been found helpful as a steroid-sparing agent in some [26–28].

Plasmapheresis reduces the titres of autoantibody, but concomitant immunosuppression with steroids or cyclophosphamide is needed to prevent a rebound increase in the synthesis of antibody [4,29]. Sepsis is a serious complication.

Other unproven therapies tried for resistant cases of pemphigus include psoralen with ultraviolet A therapy (PUVA) and extracorporeal photophoresis [4]. High-dose intravenous immunoglobulin is capable of inducing rapid remission but the benefit is short-lived [30,31]. Acitretin has been used in conjunction with prednisolone in pemphigus vegetans [32].

Pemphigus foliaceus and its variants

Definition. Blistering in this group of autoimmune diseases is high in the epidermis, either in the granular layer or just beneath the stratum corneum.

Aetiology. Pemphigus foliaceus is less common worldwide than pemphigus vulgaris and in most parts of the world probably accounts for only 10–20% of cases of pemphigus [1–6]. One of the pemphigus vulgaris susceptibility alleles (HLA-DRB1*14) may also be associated with pemphigus foliaceus [7]. Endemic pemphigus foliaceus, also known as fogo selvagem ('wild fire'), is common in rural parts of South America, particularly certain states of Brazil [8]. It is probably triggered by an environmental factor (see below). Pemphigus foliaceus is also more common than pemphigus vulgaris in Mali, Libya and rural Tunisia and in South Africa, where it predominantly affects black races [6,9,10].

Pathogenesis. Experimental evidence suggests that autoantibodies in all forms of pemphigus foliaceus are pathogenic.

Pemphigus foliaceus antigen. Sera from all forms of pemphigus foliaceus recognize epitopes located in the extracellular aminoterminal domain of desmoglein 1, a 160-kDa desmosomal cadherin [11–14]. The epitopes recognized by autoantibodies in endemic pemphigus foliaceus may differ from those recognized in non-endemic pemphigus foliaceus [15]. Rare cases of pemphigus foliaceus evolving into pemphigus vulgaris develop antibodies to desmoglein 3 [16–21]. A small subset of pemphigus foliaceus sera have both desmoglein 3 and desmoglein 1 antibodies in the absence of clinical evolution [22]. Some sera, particularly from endemic pemphigus foliaceus, also contain autoantibodies directed against desmocollins 1 and 2 [23,24]. Cases of pemphigus foliaceus with antibodies to desmoplakin [25] and to keratinocyte cholinergic receptors [26] have also been reported. Their significance is unknown.

Localization of antigen. Immunoelectron microscopy has demonstrated that the antibodies bind exclusively to desmosomes [27,28]. Pemphigus foliaceus antigen (desmoglein 1) is expressed more strongly in skin from upper torso than in specimens from the lower torso or scalp [29]. In culture, the antigens are only expressed by stratified keratinocytes [30]. Although direct immunofluorescence may be positive around keratinocytes throughout the epidermis, pemphigus foliaceus sera bind to significantly more desmosomes in the upper epidermis than the lower epidermis, the reciprocal of the pattern with pemphigus vulgaris sera [31], so the pattern of binding correlates with the histological level of split in the epidermis. Antibody binding may have a direct effect on the function of the desmosomal cadherins in the upper epidermis, causing detachment of keratinocytes. Desmoglein 1 is present but only weakly expressed in mucosae [32], accounting for the lack of mucosal involvement in pemphigus foliaceus (Fig. 41.1).

Antibodies. A large epidemiological study of Brazilian pemphigus foliaceus found that only patients with disease had circulating autoantibodies. The titre correlated both with the extent and activity of the disease [33]. Recently, using more sensitive ELISA techniques, anti-desmoglein 1 antibodies have been detected in unaffected individuals living in an endemic area. Subsequent development of pemphigus foliaceus in some of these individuals was preceded by a marked increase in antibody titres [34]. The pathogenic autoantibodies in all forms of pemphigus foliaceus are predominantly in the IgG4 subclass [12,35,36]. Immunohistological staining for desmosomal components appears abnormal in skin from patients with pemphigus foliaceus, possibly altered by binding of autoantibodies (Table 41.5) [37,38].

Pathogenicity. Purified IgG fractions induce loss of cell adhesion in skin organ cultures and neonatal mice with

the typical histological findings of pemphigus foliaceus. Complement is not required. Antigen-specific immunoadsorption of the autoantibodies prevents blisters [39,40].

Proteases. Proteolysis may augment the acantholytic process as in pemphigus vulgaris (see above). High concentrations of plasminogen induce foliaceus-like acantholysis in cultured skin. Pemphigus foliaceus antibodies stimulate epidermal cells to secrete plasminogen activator, but secretion is reduced by corticosteroids. Antibodies against the plasminogen activator, urokinase, block acantholysis induced by pemphigus foliaceus IgG [41].

Pathology. In early lesions, vacuoles form in the intercellular spaces in the upper levels of the epidermis. These coalesce to form clefts and superficial bullae high in the granular layer or immediately below the stratum corneum. Bullae contain fibrin, some neutrophils and scattered acantholytic keratinocytes. Eosinophilic spongiosis [1] or neutrophilic spongiosis [2] may precede blisters. Frank neutrophilic pustules have been described [3]. Older lesions are acanthotic, papillomatous and hyperkeratotic with focal parakeratosis. Dyskeratotic cells in the granular layer of older lesions distinguish pemphigus foliaceus from pemphigus vulgaris [4]. A mixed inflammatory infiltrate of eosinophils and neutrophils occupies the superficial dermis.

Direct and indirect immunofluorescent findings are usually indistinguishable from pemphigus vulgaris with intercellular IgG and C3 throughout the epidermis. Occasionally, intercellular staining is restricted to the upper layers of epidermis, both on direct and indirect immunofluorescence [5]. Rarely, intercellular IgA is detected by direct immunofluorescence [6]. Indirect immunofluorescence is positive in over 85% of sera but immunoblotting is less sensitive (43%) (Table 41.5) [7].

Electron microscopy demonstrates loss of desmosomes, detachment of keratin tonofilaments and dyskeratosis [4].

Clinical features. Pemphigus foliaceus is less severe than pemphigus vulgaris. Most cases are idiopathic but penicillamine and other drugs containing thiol groups (e.g. captopril) have been implicated (see p. 41.18). The onset is usually insidious with scattered scaly lesions involving the 'seborrhoeic' areas: scalp, face, chest and upper back (Figs 41.7 & 41.8). Localized disease slowly extends. Blistering may not be obvious because the cleavage is superficial and the small flaccid blisters rupture easily. Scales separate leaving well-demarcated crusted erosions surrounded by erythema, sometimes with small vesicles along the borders. Erosions are both painful and offensive. Eventually, the patient may become erythrodermic with crusted oozing red skin (Fig. 41.9). Oral lesions are uncommon (Table 41.4) [1].

Fig. 41.7 Pemphigus foliaceus. Well-demarcated crusted lesions scattered over the chest.

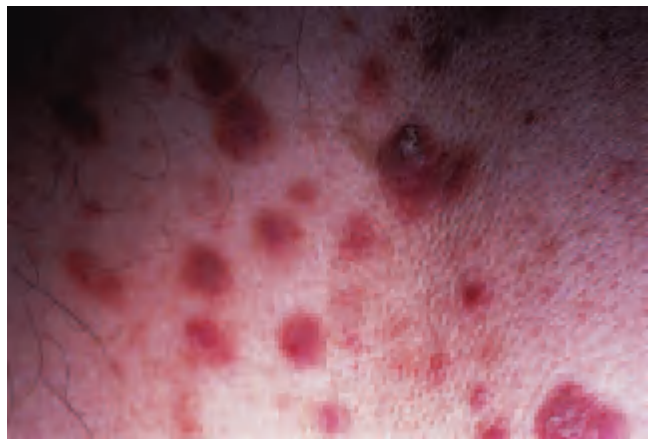

Fig. 41.8 Pemphigus foliaceus. Sharply demarcated areas of erythema, crusting and scaling with no obvious bullae.

Although the antibodies in pemphigus foliaceus can cross the placenta, the neonate is not usually affected [2]. In two cases in which the neonate did develop pemphigus foliaceus, both mother and neonate had very high antibody titres [3,4].

Clinical variants of pemphigus foliaceus

Pemphigus resembling dermatitis herpetiformis

A rare and atypical variant of pemphigus resembles dermatitis herpetiformis in its early phase (pemphigus herpetiformis) was first described by Jablonska and is the subject of a recent review [5]. Widespread clusters of pruritic papules and vesicles develop on an erythematous background. Biopsies show subcorneal pustules,

Fig. 41.9 Pemphigus foliaceus. This man became erythrodermic and then developed widespread painful erosions.

eosinophilic spongiosis or features of dermatitis herpetiformis without acantholysis, but immunofluorescence studies reveal intercellular staining. Patients possess circulating IgG intercellular autoantibodies which recognize either desmoglein 1 [6,7] or desmoglein 3 [7,8] or neither antigen [7]. The condition usually evolves into classical pemphigus foliaceus but has also been described preceding pemphigus vulgaris [6]. In general, the clinical course is benign.

Pemphigus erythematosus (Senear–Usher syndrome)

Pemphigus erythematosus is a variant of pemphigus foliaceus originally described by Senear and Usher [9–11]. Patients have immunological features of both lupus erythematosus and pemphigus (granular IgG and C3 at the basement-membrane zone, intercellular IgG and C3 in the epidermis and circulating antinuclear antibodies) [12]. The antibodies recognize the pemphigus foliaceus antigen, desmoglein 1 [13]. Progression to systemic lupus erythematosus is rare. Pemphigus erythematosus may be associated with myasthenia gravis or thymoma [12,14].

Erythematous scaly lesions over the nose and cheeks in a butterfly distribution simulate cutaneous lupus erythematosus or seborrhoeic dermatitis. Sunlight may exacerbate the disease. Lesions on the trunk, either localized or generalized, are similar to those in pemphigus foliaceus. Rarely, oral mucosa is involved.

Differential diagnosis. Pemphigus foliaceus may resemble seborrhoeic dermatitis or impetigo, but the histological and immunological features are diagnostic. Pemphigus erythematosus needs to be distinguished from both seborrhoeic dermatitis and chronic cutaneous lupus erythematosus. Pemphigus may simulate dermatitis herpetiformis both clinically and histologically, but immunopathological studies differentiate the diseases. Histological features may not be diagnostic in the early stages. Eosinophilic spongiosis may be an early manifestation [15]. Immunofluorescence studies should always be performed if pemphigus is suspected.

Treatment. These superficial forms of pemphigus usually respond to potent topical or intralesional steroids or, if control is inadequate, prednisolone 20–40 mg/day. Azathioprine or cyclophosphamide are effective adjuncts to oral steroids in severe cases. Hydroxychloroquine 200 mg twice daily has also been recommended as adjuvant therapy [16]. Intravenous immunoglobulin has been reported as effective in resistant cases [17,18].

Dapsone 100–300 mg/day may be effective as a monotherapy or given in combination with steroids [19]. Dapsone 100–300 mg/day is the treatment of choice for pemphigus with dermatitis herpetiformis-like lesions (pemphigus herpetiformis), but retinoids have been suggested as a second-line therapy in these patients [20,21]. Mycophenolate mofetil has been used as a steroid-sparing agent [22,23].

Nicotinamide 1.5 g/day, combined with either tetracycline 500 mg four times daily or minocycline 100 mg/day, appeared effective in superficial pemphigus in one uncontrolled study [24] but these results were not substantiated [25]. High-dose intravenous immunoglobulin has been successfully used in severe pemphigus foliaceus resistant to other therapies [18].

Prognosis. Pemphigus foliaceus is a benign but chronic disease that responds well to treatment and may remit. Prior to the introduction of steroids, the disease pursued a chronic course over many years [1]. There are rare reports of pemphigus foliaceus evolving both clinically and immunopathologically into pemphigus vulgaris [26–31]. Pemphigus erythematosus may persist for years as localized disease. The clinical course is often similar to pemphigus foliaceus.

Endemic pemphigus foliaceus

SYN. FOGO SELVAGEM (WILD FIRE); BRAZILIAN PEMPHIGUS FOLIACEUS

One form of pemphigus foliaceus is endemic to certain parts of South America. Histologically and immunopathologically it resembles the non-endemic form. It is distinguished by its unique epidemiological features, including geographical, temporal and familial clustering of cases, high prevalence in the young, and association with certain HLA haplotypes [1].

By 1987, more than 15 000 cases had been registered, clustered in certain states of Brazil [1–4]. Endemic foci have also been reported in Columbia, El Salvador, Paraguay and Peru [1,5]. An endemic focus has also been observed in rural Tunisia [2–4].

Aetiology. Epidemiological evidence suggests that endemic pemphigus foliaceus is precipitated by an environmental factor, possibly a biting insect. The disease is endemic in newly developed jungle areas of Brazil that are being used for agriculture, but endemic foci are eradicated by urbanization. Rural labourers are at greatest risk. The incidence of disease is greatest at the end of the rainy season when insects are most abundant. Black fly (family Simuliidae) bites are a risk factor for the disease [1]. Chronic exposure to black fly antigens may trigger the formation of antibodies that cross-react with epidermal antigens but this hypothesis has not been proved experimentally. Patients are exposed to numerous biting insects and infestations of parasites are common so other vectors may be important.

No infectious agent, chemical toxin or pollutant has been isolated.

A significant number of cases have an affected family member [1]. In one Brazilian population, the susceptibility allele was identified as HLA-DRB1*0102. In two other Brazilian populations different alleles of the HLA-DRB1 gene (DRB1*0404, *1402 or *1406) have been linked to the development of endemic pemphigus foliaceus [5,6]. All alleles involved in predisposition to disease share the same amino-acid sequence in the *DRB1* gene. Inheritance of this sequence may determine susceptibility when individuals are exposed to the appropriate environmental agent [1].

Pathogenesis. Passive transfer studies demonstrate the pathogenicity of the antibodies [7]. Like idiopathic pemphigus foliaceus, these are of the IgG4 subclass. Sera recognize epitopes located in the extracellular amino-terminal domain of desmoglein. The epitopes involved may be different from those in non-endemic disease [8]. Some sera also contain autoantibodies directed against desmocollins 1 and 2 [9,10]. Autoantibodies bind to oral mucosa as well as skin [11]. Mucosal involvement clinically is rare but there may be ultrastructural abnormalities (e.g. widening of the intercellular spaces and desmosomal changes [12]).

Using sensitive ELISA techniques, it is now clear that the prevalence of antidesmoglein 1 antibodies is high

among normal subjects living in an endemic area. The onset of the disease is preceded by a sustained antibody response. These findings support the concept that the production of antibodies against desmoglein 1 is initiated by exposure to an unknown environmental agent [13].

Clinical features. Endemic pemphigus foliaceus affects children and young adults, with a peak incidence in the second and third decades, whereas other forms of pemphigus foliaceus affect middle-aged adults (Table 41.4) [14,15].

Patients present with flaccid bullae, which rupture easily leaving superficial erosions. Nikolsky's sign is positive. The head and neck are involved at first. The burnt appearance and burning sensation, particularly on sun exposure, gives the disease its popular name, fogo selvagem, Portuguese for 'wild fire'. The disease slowly spreads acrally and may become generalized. Oral mucosa is usually spared.

Some patients develop widespread bullae with pyrexia, arthralgia and malaise. Generalized erythroderma may supervene. Chronic disease is frequent, with disseminated verrucous lesions that simulate prurigo nodularis. Plaques may vegetate. Hyperpigmentation is a feature of inactive disease.

Growth retardation, common in affected children, responds to treatment with oral corticosteroids. Adults who were affected in childhood may have azoospermia. Patients may show signs of chronic depression [14,15].

Although antibodies to desmoglein 1 cross the placenta, the disease is rarely transmitted from affected mothers to the neonate [16], except in rare cases with high-titre antibodies [17]. Desmoglein 3 is more highly expressed in neonatal than adult skin and this may be protective [18].

Treatment. Treatment is similar to other forms of pemphigus foliaceus. Topical steroids are effective in localized disease or as an adjunct to systemic treatment. Most patients respond to systemic steroids alone, but verrucous plaques may be resistant to therapy. Immunosuppressive agents, gold and antimalarials have been recommended [14,15].

Prognosis. Before the advent of corticosteroids, 40–60% of untreated patients died. Now less than 10% die, often as a result of the complications of treatment. Spontaneous remissions have been reported.

Induced pemphigus

Drugs may exacerbate or induce pemphigus. Drugs containing a sulphydryl group (thiol drugs) such as penicillamine and captopril are the best studied, but pemphigus can also been attributed to non-thiol drugs including other angiotensin-converting enzyme (ACE) inhibitors (e.g. enalapril [1], ramipril [2], fosinopril [3]) and other drugs such as nifedipine, the penicillins, cephalosporins, pyrazolon derivatives and rifampicin [4]. Patients treated with interferon may develop autoimmune pemphigus [5].

Pemphigus has also been induced by radiotherapy [6] and thermal burns [7]. Apparently dietary factors, particularly vegetables of the *Allium* group, have triggered pemphigus [8]. Human herpesvirus 8 DNA sequences

have been reported in peripheral blood mononuclear cells and skin from pemphigus patients [9,10]. Their significance is disputed [11].

Aetiology and pathogenesis. Alleles of HLA-DR4 predispose to pemphigus vulgaris and a susceptibility allele is also carried by individuals with drug-induced pemphigus [12]. Drugs may act to trigger disease in genetically predisposed individuals. Thiol drugs provoke acantholysis *in vitro*, possibly by increasing the activity of plasminogen activators. An active amide group in the molecule of non-thiol drugs may be responsible for inducing disease [4].

Clinical features. Pemphigus foliaceus or pemphigus erythematosus are the most common patterns induced by drugs. Drug-induced pemphigus vulgaris and pemphigus vegetans are rare. Most patients have circulating autoantibodies with the same antigenic specificities as in other forms of pemphigus [13,14].

Prognosis. Forty to 50% of patients with thiol-drug-induced pemphigus, but only 15% of the cases induced by non-thiol drugs recover spontaneously when the drug is withdrawn [4].

Intercellular IgA dermatosis and subcorneal pustular dermatosis

These conditions share clinical and histological features. Immunofluorescence studies were negative in classical subcorneal pustular dermatosis. Although there is overlap, the relationship between the diseases has not been defined so they are considered separately here.

Intercellular IgA dermatosis

SYN. IgA PEMPHIGUS FOLIACEUS; INTRAEPIDERMAL NEUTROPHILIC IgA DERMATOSIS; IgA HERPETIFORM PEMPHIGUS; INTERCELLULAR IgA VESICULOPUSTULAR DERMATOSIS

More than 50 cases have been reported of patients presenting with vesicopustular or vesicobullous eruptions with intraepidermal antikeratinocyte IgA detected in perilesional skin on direct immunofluorecence. These comprise a heterogeneous group clinically, histologically and immunologically. Some may be variants of subcorneal pustular dermatosis (see below), others may be a form of pemphigus, but the relationships between these conditions have still to be clarified [1,2].

Pathology. A neutrophil-rich polymorphonuclear infiltrate in the epidermis is observed. Two types are distinguished based on the level of pustule formation and IgA deposition [1]: the subcorneal pustular dermatosis type (subcorneal pustules) and the intraepidermal neutrophilic type (intraepidermal pustules). However, microabscesses at various levels have been observed and may depend on the age of the lesion [2]. Acantholysis is usually sparse or absent but is occasionally pronounced, mimicking either pemphigus vulgaris or pemphigus foliaceus histologically.

Pathogenesis. The hallmark of these disorders is the intercellular IgA deposition, present at many different epidermal levels or throughout the epidermis. Circulating IgA is either undetectable or present in low titre [2–4]. Desmocollin 1, a desmosomal component located mainly in the upper epidermis, has been identified as the target antigen in cases with subcorneal pustules [5–7]. In patients with the intraepidermal neutrophilic type, antigens resembling desmoglein 1 [5,8] or desmoglein 3 [7,9–11] have been implicated in a few cases. In others cases the target antigen could not be identified. Standard immunoblotting is frequently negative, probably because the target epitopes are conformation dependent [7,12].

Clinical features. The disease chiefly affects adults although childhood cases have been reported [1,2]. Patients with both types have flaccid vesicles or pustules

arising on either erythematous or normal skin. The lesions may be pruritic and show a circinate or annular configuration with central clearing and evolve to crusted or scaly erythematous macules. The sites of predilection are the axillae and groins. Other sites are elsewhere on the trunk, face, scalp and proximal limbs. In some cases, the flaccid pustules resemble subcorneal pustular dermatosis of Sneddon–Wilkinson (see below). Others may resemble pemphigus foliaceus or pemphigus herpetiformis [13–15]. Flexural oozing verrucous plaques mimicking pemphigus vegetans have been described in a child [16]. Nikolsky's sign is usually negative and mucosal involvement is unusual. Most run a chronic indolent course.

The most frequently reported association is monoclonal IgA gammopathy in the subcorneal type [17,18], a feature it has in common with classical subcorneal pustular dermatosis. Other cases have been linked with human immunodeficiency virus (HIV) infection, Crohn's disease, gluten-sensitive enteropathy, rheumatoid arthritis [2] and thiol drugs [19].

Treatment. These neutrophilic dermatoses respond well to dapsone [3,4,20] but poorly to steroids [3]. Other reported therapies are etretinate [3,20,21], isotretinoin [22], PUVA [21], immunosuppressives [14], plasmapheresis [23] and colchicine [10,24].

Subcorneal pustular dermatosis

SYN. SNEDDON–WILKINSON DISEASE

Definition. A chronic relapsing pustular eruption, mainly involving the trunk, which affects women over 40 years of age. Pustules are subcorneal.

Background. This disorder was separated from bullous impetigo in 1956 [1,2]. The exact nosological position of subcorneal pustular dermatosis remains controversial. Some cases may be a variant of pustular psoriasis, whereas others appear to overlap with the subcorneal pustular variant of IgA pemphigus.

Pathogenesis. The pathogenesis is obscure. The salient feature is subcorneal accumulation of neutrophils. Culture of the pustules is sterile. Subcorneal pustular dermatosis has been reported in association with various types of immune dysfunction. Monoclonal gammopathy, usually IgA (occasionally IgG), has been repeatedly reported. The paraproteinaemia is usually benign but IgA myeloma also occurs. Other reported associations are pyoderma gangrenosum, inflammatory bowel disease and rheumatoid arthritis [3–7]. The condition has also been observed at the injection site of recombinant human granulocyte–macrophage colony-stimulating factor in a patient with IgA myeloma [8]. Excess production of TNF-α has been implicated in the pathogenesis of neutrophil activation [9].

In classic subcorneal pustular dermatosis, immunofluorescence studies are negative. However, a possible subgroup with identical clinical and histological features to the 'classic' type have intercellular IgA deposition in

the upper epidermis [10,11]. Desmocollin 1 is the target antigen in these cases. There are also examples of 'classic immunofluorescence-negative' cases in whom intercellular epidermis IgA deposits were detected on repeat immunofluorescence testing [11], in one case after a latent period of many years [12]. The relationship between the intercellular IgA dermatoses, regarded as part of the pemphigus spectrum, and classic subcorneal pustular dermatosis remains unclear.

Pathology. Biopsies from early lesions show a perivascular inflammatory infiltrate with neutrophils and occasional eosinophils. Neutrophils migrate through the epidermis, without forming spongiform pustules, to collect beneath the stratum corneum in subcorneal pustules. The pustules sit on the surface of the epidermis rather than being an integral part of it. A few acantholytic cells may be found in old lesions [1]. Ultrastructural studies show cytolysis of single cells and invasion by neutrophils [13].

Both direct and indirect immunofluorescence studies are negative in classic cases [14], but recently some cases have been described with clinical features resembling classic subcorneal pustular dermatosis but with intercellular IgA within the epidermis [15–17].

Clinical features. The disease is more common in women and usually affects individuals between 40 and 50 years of age. The eruption occurs mainly in flexures and on the flexor aspect of the limbs [1,18,19]. The face is almost never affected, nor are the mucous membranes. The primary lesion is an oval pea-sized flaccid pustule, which arises on normal skin or a slightly erythematous base. Characteristically, pus accumulates in the lower half of a fully developed pustule, leaving clear fluid in the upper half (Fig. 41.10). Pustules rupture easily and tend to coalesce, forming annular or serpiginous patterns with a scaly edge. The eruption fades to leave faint hyperpigmentation, but successive waves of pustules pass across the previously affected areas. The intervals between active and quiescent phases varies from several days to several weeks.

Fig. 41.10 Subcorneal pustular dermatosis. Annular lesions with a scaly margin and surrounding pustules. Pus has accumulated in the lower half of the flaccid pustule leaving clear fluid in the upper half.

Prognosis. The condition is benign but chronic, with an average duration of 5.8 years [1]. Myeloma obviously worsens the outlook.

Diagnosis. The differential diagnosis includes impetigo, pustular psoriasis, pemphigus foliaceus, dermatitis herpetiformis, intercellular IgA dermatosis and acute generalized exanthematic pustulosis.

Pathogenic organisms are cultured from pustules in impetigo and the condition responds to antibiotics.

Pustular psoriasis, either of the acute von Zumbusch type with small pustules or the spreading annular type, may resemble subcorneal pustular dermatosis. Spongiosis is not a feature of subcorneal pustular dermatosis, but spongiform pustules that are an integral part of the epidermis are characteristic of pustular psoriasis [20]. Subcorneal pustular dermatosis, unlike pustular psoriasis, responds to dapsone. Some authors consider that subcorneal pustular dermatosis is part of the spectrum of pustular psoriasis [21]. 'Atypical cases' reported as examples of subcorneal pustular dermatosis may be unusual presentations of pustular psoriasis.

Biopsies from early lesions of pemphigus foliaceus may show subcorneal pustules with very little acantholysis. Direct immunofluorescence will show intercellular IgG in the epidermis in pemphigus.

Acute generalized exanthematic pustulosis is distinguished by its acute onset in a febrile patient with a history of exposure to a candidate drug. The histology shows spongiform pustules [22].

Treatment. Dapsone 50–150 mg/day is the treatment of choice. Although the response is slower than in dermatitis herpetiformis, most patients obtain partial, if not complete relief. Sulfapyridine and sulfamethoxypyridazine have been used as alternatives. Treatment can often be weaned or stopped without relapse. Some cases respond to potent topical corticosteroids [23] or oral steroids [9], but in general steroids are ineffective even in large doses. Etretinate [6,16,24] and acitretin [25] have been used. Isotretinoin was found ineffective at a dosage of 0.5 mg/kg/day [26]. Broad-band UVB [27], narrow-band UVB [28,29], PUVA [16,30] and Re-PUVA have also been reported as effective. Colchicine [31] and topical tacalcitol [32] have been recommended. In cases associated with myeloma, the skin lesions may improve when the paraprotein is reduced by chemotherapy [17].

Paraneoplastic pemphigus

A distinctive form of pemphigus has been described in association with a variety of underlying neoplasms [1], most commonly B-cell lymphoproliferative disorders but also thymoma, sarcomas and carcinomas [2,3]. Some cases have been linked with the use of fludarabine chemotherapy [4,5]. The clinical features overlap with erythema multiforme and lichen planus pemphigoides. Patients have severe mucosal erosions and polymorphous cutaneous signs including blisters, erosions particularly on the upper body and palmoplantar target lesions (Table 41.4) [1,2,6–10]. In two-thirds of cases, paraneoplastic pemphigus occurs with an existing neoplasm; in the remainder the neoplasm is detected after the mucocutaneous disease has occurred [2]. Biopsies show necrosis of keratinocytes or vacuolar interface dermatitis in addition to suprabasal clefting with acantholysis [11], but the specificity of these histological findings has been questioned [12].

Direct immunofluorescence reveals immunoglobulin and/or complement at the basement-membrane zone as well as on the surfaces of keratinocytes. Indirect immunofluorescence is positive in both non-stratifying (simple and transitional) epithelia and stratifying epithelia (Table 41.5) [13].

Antibodies are predominantly antiplakin antibodies of the IgG1 subclass. Their pathogenicity has been established by passive transfer studies. The autoantibodies recognize a complex of antigens on immunoblotting and immunoprecipitation. These are members of the plakin family of proteins and include desmoplakin 1 (250 kDa), envoplakin (210 kDa), the 230 kDa BP antigen and a 190-kDa antigen, thought to be periplakin [1,14–17] and plectin (500 kDa) [18]. Antiplakin antibodies are not specific to paraneoplastic pemphigus and have also been detected in patients with severe erythema multiforme [19], BP [20] and pemphigus foliaceous [21,22]. Antidesmoglein antibodies have been detected in paraneoplastic pemphigus in some [18,23–25] but not all cases [26]. Paraneoplastic pemphigus is a multisystem disease. Passive transfer of paraneoplastic pemphigus sera to mice produces autoantibody deposits in skin, upper digestive and respiratory tract epithelia, kidney, urinary bladder, smooth and striated muscle [27].

Paraneoplastic pemphigus is generally refractory to all treatments. Oral steroids, azathioprine, ciclosporin, mycophenolate mofetil and plasmaphoresis have been tried [1,2,8,9,28,29]. Most patients deteriorate inexorably, with death usually secondary to sepsis, gastrointestinal bleeding, multiorgan or respiratory failure [2,28]. Cases associated with benign or low-grade neoplasia such as thymoma or Castleman's disease [8,30–32] may remit partially after surgical removal of the neoplasm.

Structure of the dermal–epidermal junction

The basal keratinocytes of the epidermis are separated from the underlying dermis by the basement membrane, a two-layered structure on electron microscopy comprising the *lamina lucida*, the major components of which are laminins, and the *lamina densa*. Above the lamina lucida, straddling the plasma membrane of the epidermal basal cells are discrete electron-dense structures, the *hemidesmosomes*. Fine structures, the *anchoring filaments*, traverse the lamina lucida, particularly in the region of the hemidesmosomes, and appear to terminate in the lamina densa, rich in both laminin 5 and type IV collagen [1]. Beneath the lamina densa and appearing to embed in the upper dermis are curved structures, the anchoring fibrils, composed of type VII collagen (Fig. 41.11) [2].

The intracellular plaque of the hemidesmosomes contains a 230-kDa polypeptide, a member of the plakin family known as BP230 or BPAG1 as it binds to sera of patients with bullous pemphigoid (BP) [3]. Other components of the intracellular plaque are plectin (MW 500 kDa) and the less well-characterized antigens HD1, IFAP300 and P200. The intracytoplasmic keratin intermediate filaments (keratin types 5 and 14), organized into *tonofilaments*, loop down and insert into the hemidesmosomes where they interact with the carboxy-terminals of BP230 and plectin.

The transmembrane components of the hemidesmosome include BP180/collagen XVII or BPAG2 and $\alpha 6\beta 4$ integrin (Fig. 41.11). Collagen XVII (MW 180 kDa, also known as

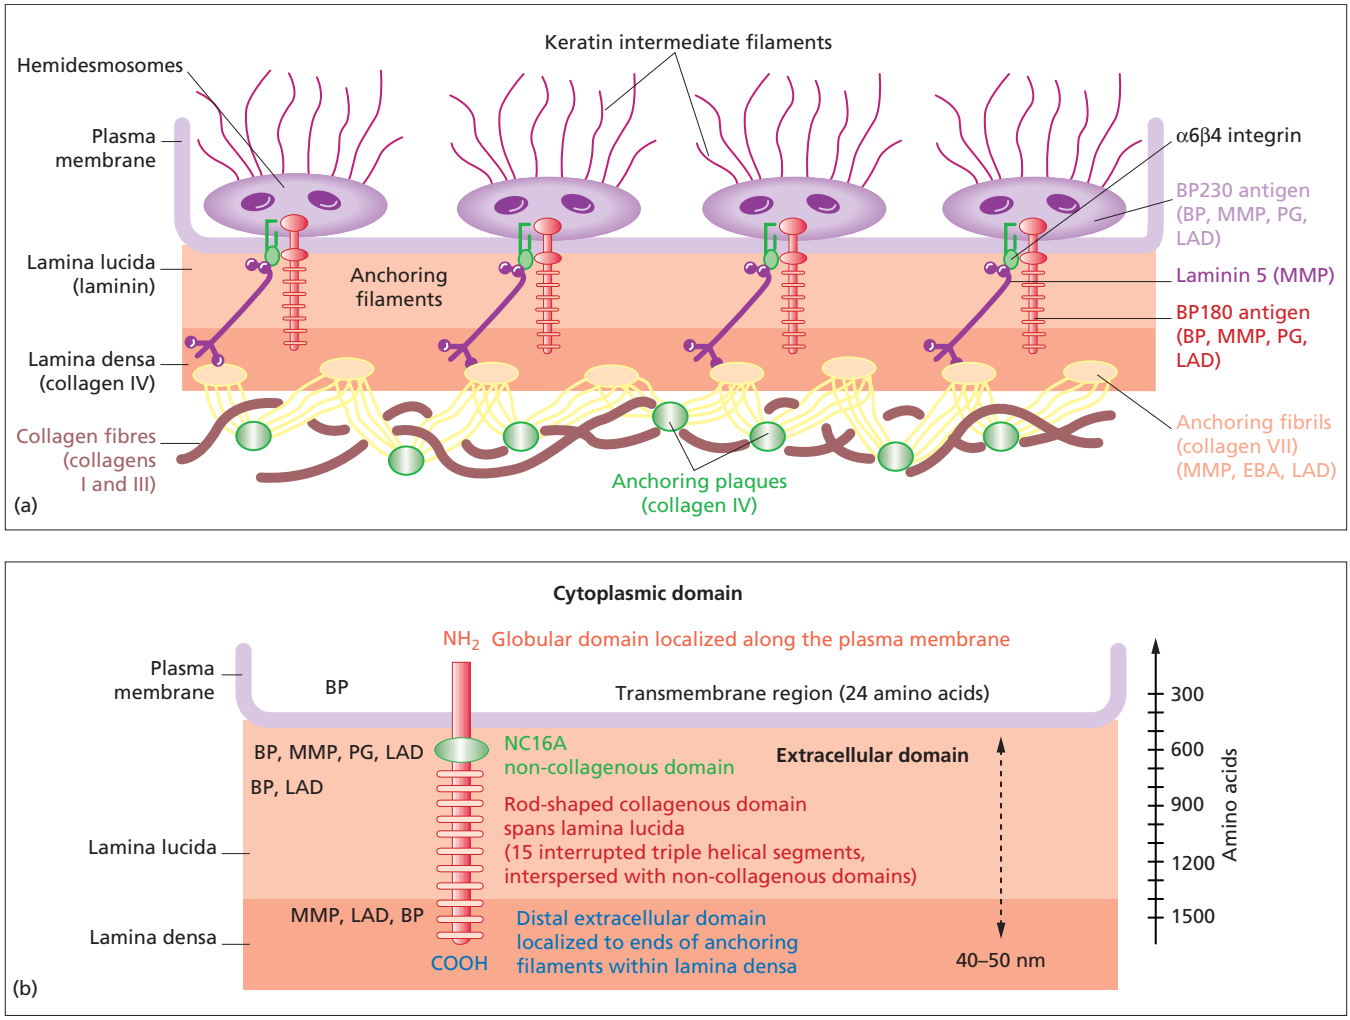

Fig. 41.11 The dermal–epidermal junction. (a) The structure of the adhesion complex of the basement-membrane zone. (b) The structure of BP180/collagen XVII, showing sites of antigen binding. BP, bullous pemphigoid; EBA, epidermolysis bullosa acquisita; LAD, linear IgA disease; MMP, mucous membrane pemphigoid; PG, pemphigoid gestationis. (Courtesy of Dr J. Allen, Oxford Radcliffe Hospital, Oxford, UK.)

BP180 as it binds BP sera) comprises an intracellular globular domain, where its NH_2 terminal interacts with the NH2 terminal of BP230 [4], with additional; stabilizing interactions with both plectin and β4 integrin [5]. The long extracellular collagenous domain of collagen XVII is shed by the physiological action of proteases [6] and interacts both with α6 integrin [5] and with the B3 chain of laminin 5 in the region of the anchoring filaments. Laminin 5 also interacts with other laminin isoforms, with both β4 and α6 integrin [5], as well as being the principal ligand for type VII collagen, the main component of the anchoring fibrils. Hence, laminin serves as a bridge between the transmembrane hemidesmosomal molecules and the dermal matrix molecules.

These structures collectively form the *adhesion complex* of the dermal–epidermal junction, with continuity running from the keratin filaments within the epidermal cells via the hemidesmosomes, the anchoring filaments and through to the anchoring fibrils embedded in the dermis. In normal skin, mechanical stability and adhesion between the epidermis and dermis depends on the integrity of the adhesion complex components. Mutations of these molecules produce skin fragility and blistering (see Chapter 40). Autoantibody-mediated diseases have been described in relation to BP230, BP180, laminin 5, type VII collagen and type IV collagen and these are considered in this chapter.

Subepidermal immunobullous diseases

These bullous diseases include a number of clinical entities (Table 41.4). However, there is clinical overlap and it is not uncommon for individual patients to be difficult to classify clinically (Fig. 41.12). Similarly, the histology and immunofluorescence are not always distinctive, and the identification of the target antigens for these diseases has demonstrated that not only are the antigens and their specific epitopes common to many of the entities, but also often multiple within a patient. In addition, new antigens are still being described. It seems likely that many as yet poorly characterized or undiscovered molecules within the anchoring complex of the basement-membrane zone can be the targets for autoantibodies in the subepidermal blistering diseases. The expectation that perhaps the immunogenetic constitution of the individual might determine the disease has been only partially fulfilled. Thus, the clinical overlap is reflected in immunopathological and immunogenetic overlap (Fig. 41.12) and is shown in Tables 41.5 and 41.6.

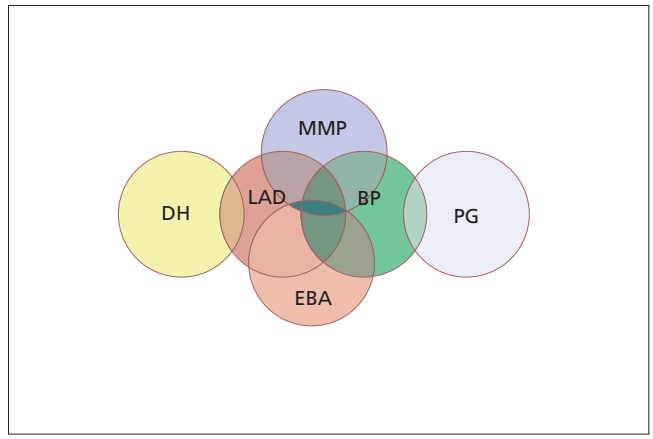

Fig. 41.12 The clinical and immunopathological overlap between the subepidermal blistering diseases. BP, bullous pemphigoid; DH, dermatitis herpetiformis; EBA, epidermolysis bullosa acquisita; LAD, linear IgA disease; MMP, mucous membrane pemphigoid; PG, pemphigoid gestationis.

The subepidermal autoimmune bullous diseases are, with the exception of dermatitis herpetiformis, characterized by autoantibodies directed against components of the adhesion complex (Fig. 41.11). The use of the patient's sera to identify these antigens and their genes has made a major contribution to cell and molecular biology. The mechanisms by which the autoimmune process is initiated and by which the combination of antibody with antigen results in blistering are in the process of being elucidated. However, evidence is accumulating that the autoantibodies are pathogenic.

Bullous pemphigoid

SYN. PEMPHIGOID

Definition. A blistering disease of elderly people, which often starts with pruritus and urticated and erythematous lesions; later large tense blisters develop both on erythematous and on normal skin and there may be mucosal involvement with blisters and erosions. The blisters are subepidermal and intact epidermis forms the roof. Autoantibodies, chiefly IgG, to the epidermal basement-membrane zone are found in the skin and blood [1].

The clinical features, immunopathology and immunogenetics are summarized in Tables 41.5 and 41.6.

Aetiology. Bullous pemphigoid is an affliction of elderly people, with onset usually after 60 years of age, but the condition can occur in those under 40 years, and more than 60 cases have been described in children, the three

Table 41.5 The subepidermal immunobullous diseases: clinical features.

Disease	Patients	Cutaneous distribution	Mucosal involvement	Lesions	Associations	Treatment	Prognosis
Bullous pemphigoid	Elderly (few infants and children)	Trunk, limbs, flexures	Common, minor	Urticated plaques, tense blisters, (milia)	Nil	Steroids, dapsone, immunosuppressives	3–6 years' duration
Mucous membrane pemphigoid	Middle–old age	Infrequent (30%)	Major, severe	Erosions, blisters, gingivitis, milia **Scarring**	Autoimmune disease	Steroids, dapsone, immunosuppressives	Chronic
Pemphigoid gestationis	Pregnant women	Umbilicus, generalized	Minor	Urticated plaques, tense blisters	Autoimmune thyroid disease	Steroids	Remits postpartum
Linear IgA disease							
Chronic bullous disease of childhood	Children	Perineum, face, trunk, limbs	Majority, (few severe)	Urticated plaques, annular lesions, tense blisters		Dapsone, sulphonamides	3–4 years' duration (few persist)
Adult linear IgA disease	Young adults to elderly	Trunk, limbs	Majority, (few severe)	Urticated plaques, tense blisters, papulovesicles	Ulcerative colitis, lymphoma	Dapsone, sulphonamides	3–6 years' duration (few persist)
Epidermolysis bullosa acquisita	Adults and children	Generalized, variable	Some, (few severe)	Urticated plaques, tense blisters, milia **Scarring**	Inflammatory bowel disease	Steroids, dapsone, immunosuppressives	Persists
Bullous SLE	Adults	Generalized, variable	Minor	Urticated plaques, tense blisters	SLE	Dapsone	Transient
Dermatitis herpetiformis	Young adults (some children and elderly)	Symmetrical, elbows, knees, buttocks	Minor	Papulovesicles	Gluten-sensitive enteropathy, lymphoma	Dapsone, sulphonamides, gluten-free diet	Persists

SLE, systemic lupus erythematosus.

youngest being 10 weeks or less at onset of their disease [1–4]. The risk of developing BP increases with age and is higher in men [5]. Bullous pemphigoid is the most common immunobullous disease in western Europe. In France and Germany, the incidence of BP is estimated to be 6–7 cases per million population per year and is similar in Singapore [6–8]. However, in other countries of the Far East, BP appears to be less common, and more likely to develop in Indians than Chinese [8–10]. Recent work suggests that in northern Europeans HLA-DQ7 may be associated with BP but only in men, not women [11,12]. This association does not exist in Chinese or Japanese patients [13,14].

Pathogenesis. Bullous pemphigoid provides one of the best models for an autoimmune disease. The disease is characterized by IgG autoantibodies to hemidesmosome-associated proteins within the adhesion complex (Fig. 41.11). The target antigens have been characterized and their genes cloned (see below). The autoantibodies have been shown to be pathogenic and complement to be necessary for blister formation [1,2].

The two major BP antigens are BP230 and BP180, which are associated with hemidesmosomes (Fig. 41.11) and are the products of genes located on different chromosomes [3].

BP230, also known as BPAG1, was the first to be characterized and has a molecular weight of 230 kDa [4,5]. BP230 is intracellular and localized to the dense plaque [6]. The gene for BP230 has been cloned and resides on the short arm of chromosome 6 [7,8]. The portions of BP230 antigen that are the target for the autoantibodies (immunodominant epitopes) are located chiefly at the carboxy terminal, which mediates the interaction of the keratin intermediate filaments with the hemidesmosome [9,10].

BP180, also known as BPAG2 and collagen XVII, has a molecular weight of 180 kDa [4,11] and is a transmembrane molecule with collagenous domains and a long extracellular portion, which is shed under physiological conditions (Fig. 41.11) [12,13]. The gene for BP180 has been cloned and is situated on chromosome 10 [3,12]. It is located in the hemidesmosome and the extracellular portion interacts with the anchoring filaments [6,14]. The extracellular region adjacent to the transmembrane portion, the NC16A domain, is the immunodominant epitope; however, other epitopes are found in many regions of the molecule, including the intracellular region, the shed collagenous ectodomain and the carboxy terminal (Fig. 41.11) [6,15–19]. This extracellular location makes it a likely candidate for pathogenic autoantibodies.

There are reports of other target antigens in individual patients, the most common being one of 200 kDa weight, which has been described associated with the epidermis and dermis [4,20].

Two animal models have demonstrated that the autoantibodies in BP are pathogenic. In the first model, injection of BP autoantibodies into rabbit cornea produced subepidermal blisters and immune deposits of IgG and C3 along the basement-membrane zone [1]. Other attempts were unsuccessful until molecular biology demonstrated that the chief epitope differed in mice and humans. Antibodies were raised to the immunodominant mouse epitope of BP180, and these antibodies produced immunopathological BP in neonatal mice [2].

The formation of blisters begins with autoantibody deposition, which binds C3 along the dermal–epidermal junction [21]. These antibodies are directed at BP180 and BP230 and are mainly of the IgG subclass, predominantly IgG1 and IgG4 isotypes [22]. There is a change with disease duration and remission in the relative amounts of inflammatory IgG1 and less inflammatory blocking IgG4 [23]. The pivotal role of complement has been demonstrated using the mouse model that had been used previously to deduce the autoimmune basis of BP [2]. Mice depleted of complement by pretreatment with cobra venom factor or a genetic C5-deficient mouse strain did not develop blisters following the injection of pathogenic rabbit BP180 antibodies, and $F(ab')_2$ fragments of the IgG antibody that cannot bind complement did not produce

disease when injected into animals [24]. Blister formation in C5-deficient mice could be restored if fragments of C5a were injected with the pathogenic anti-BP180 IgG. C5a fragments are thought to stimulate the recruitment of neutrophils to the site of inflammation [24]. The importance of neutrophil recruitment in the pathogenesis of this disease has been shown using the mouse model. Mice depleted of neutrophils by pretreatment with an antineutrophil serum become resistant to the pathogenic effects of BP180 antibodies [25], indicating that the inflammatory response in BP is in part mediated by neutrophils. The role of proteases in blister formation has been shown using mouse models either genetically deficient for neutrophil elastase or with elastase inhibitors, and by demonstrating that elastase can cleave BP180 *in vitro* and *in vivo* [26]. Eosinophil infiltration occurs [27] and releases a 92-kDa gelatinase (gelatinase B or MMP-9) at the blister site that can cleave BP180 [28]. Mice genetically deficient for gelatinase B did not produce blisters after infusion with antibodies to BP180, unless reconstituted with neutrophils from normal mice [29].

All these data taken together suggest a mechanism for blister formation. Autoantibodies bind to the BP antigens and activate complement. Complement components set off an inflammatory cascade attracting leukocytes, degranulating mast cells and releasing inflammatory mediators. The activated inflammatory cells release lysosomal enzymes and proteases, cleaving the target antigens and disrupting the hemidesmosomes, resulting in blister formation.

Pathology. The blister in BP is subepidermal with an intact and often viable epidermis forming the roof. The blisters may contain numerous eosinophils and neutrophils. Biopsies of blisters and from erythematous areas of skin show a dermal inflammatory infiltrate containing many eosinophils and neutrophils with lymphocytes and histiocytes; eosinophilic spongiosis may also be seen. There are patients with BP in whom the dermal infiltrate is so intense in the papillae that it cannot be distinguished from dermatitis herpetiformis. Old blisters may

demonstrate re-epithelialization along the base giving an artefactual intraepidermal blister. Biopsies taken from apparently normal and non-inflamed skin are non-diagnostic or normal.

The findings with immunofluorescence are summarized in Table 41.6 and in a review [1]. Positive direct or indirect immunofluorescence is essential to confirm the clinical and histological diagnosis.

Direct immunofluorescence studies should not be performed on a blister, as the immunoreactants are often lost from the roof of a blister. They are best performed on a perilesional biopsy (within 2 cm of a lesion). The biopsy for immunofluorescence can also be taken from clinically uninvolved skin, the front of the thigh or flexor forearm, if this is more convenient or there are no active lesions, and from mucosal surfaces [2,3]. A 3–4-mm punch biopsy is ideal, and need not be deep. The biopsy will show either IgG and C3, or C3 alone along the basement-membrane zone (Fig. 41.13); deposition of IgA and IgM may also occur. The patient's biopsy can be split with 1 molar sodium chloride (salt-split) to provide additional information as to the localization of the target antigens, as the immune deposits should be associated with the hemidesmosomes, and thus present on the epidermal side of the split (roof of the artificial blister) [1,4]. The raising of a suction blister in the patient can give similar information but is rather cumbersome [5].

Indirect immunofluorescence can be performed on blood, blister fluid or urine (although less often positive), the latter two being useful substitutes for blood with an uncooperative child or adult [6,7]. About three-quarters of BP patients have a circulating IgG autoantibody to the basement-membrane zone. False-positives are rare, and the finding of circulating antibodies is diagnostic. The circulating autoantibodies in BP react with the epidermal side of normal human skin that has been split by prolonged incubation with salt or suction (Fig. 41.14) [5,8,9]. The use of salt-split skin increases the sensitivity of autoantibody detection and differentiates patients with BP from those with epidermolysis bullosa, and is to be recommended as a routine technique [8]. There are rare dermal binding BP patients and these can only be identified with immunoelectron microscopy or immunoblotting [10].

Recently, the use of ELISA techniques to detect antibodies against specific epitopes has been used as a research tool, and in time this may have a routine diagnostic application.

There is a change with time from inflammatory IgG1 to less inflammatory blocking IgG4 associated with diminution in disease activity, even though an overall diminution in titre may not be seen [11].

Occasionally, patients with BP have pemphigus-like antibodies, and the diseases may coexist. This may relate to the homology between BP230 and desmoplakin [12,13].

Immunoelectron microscopy demonstrates that the autoantibodies are deposited in the lamina lucida *in vivo* [14], but in contrast bind to the target antigens in association with the dense plaque (antibodies to BP230) and hemidesmosome surface (antibodies to BP180) *in vitro* [15].

Immunoblotting demonstrates that the majority of patients have circulating autoantibodies that react with the BP230 and BP180 antigens. The individual patient may react with either or both [16,17]. There is some suggestion that patients who have autoantibodies to BP180 may have more severe or prolonged disease [18–20]. A clinical pattern indistinguishable from BP may be seen in association with other target antigens [21].

Human autoantibodies against the 230-kD bullous pemphigoid antigen (BPAG1) bind only to the intracellular domain of the hemidesmosome, whereas those against the 180-kD bullous pemphigoid antigen (BPAG2) bind along the plasma membrane of the hemidesmosome in normal human and swine skin. *J Clin Invest* 1993; **91**: 1608–15.

Clinical features. Bullous pemphigoid commonly starts with itching and a non-specific rash. The itch may continue for days to years before the rash appears. The non-specific rash often starts on the limbs and may be either urticaria-like or occasionally eczematous and rarely may simulate vesicular eczema. When urticarial, the prodrome lasts 1–3 weeks before blisters occur; when eczematous, the blisters may not develop for several months. Severe irritation with a faint dusky erythema in a figurate pattern may sometimes precede blister formation (Fig. 41.15). These changes may closely resemble erythema multiforme or dermatitis herpetiformis. Sudden generalization of the true eruption of BP follows the prodromal phase and most of the body may be affected within a week.

Fig. 41.15 Bullous pemphigoid. Figurate erythema with large tense bullae. (Courtesy of Dr R.J. Pye, Addenbrooke's Hospital, Cambridge, UK.)

Blisters may arise on erythematous and on normal skin and may be associated with oedema. The blisters are tense and dome-shaped, obtaining a diameter of many centimetres (Figs 41.15 & 41.16). They appear mainly on the flexural aspects of limbs and on the central abdomen. Their contents are usually clear serous exudate, although occasionally this is bloodstained. The blisters are tough and may remain intact for several days, the contents often becoming jelly-like with coagulated fibrin. In some blisters, the fluid is reabsorbed and the epithelium settles back in place like a skin graft. Those that do rupture leave erosions which heal rapidly, leaving mild post-inflammatory changes. Erythema may persist at the sites of previous blisters for many weeks or months. Milia may be profuse during the healing phase (Fig. 41.17). Mucosal lesions occur less frequently and are less severe than in mucous membrane pemphigoid and pemphigus vulgaris and are usually confined to the mouth. The oral lesions consist of small blisters which, like those of the skin, may remain intact and, if they rupture, heal rapidly.

Fig. 41.16 Bullous pemphigoid. Tense haemorrhagic bullae. (Courtesy of Dr R.J. Pye, Addenbrooke's Hospital, Cambridge, UK.)

Fig. 41.17 Bullous pemphigoid. Milia at sites of severe blistering. (Courtesy of Dr R.J. Pye, Addenbrooke's Hospital, Cambridge, UK.)

The acute phase is usually accompanied by leukocytosis and eosinophilia, but fever is uncommon and, in spite of extensive blistering (Fig. 41.15), the patients' general condition remains good. Fresh crops of small blisters may continue to occur even after apparent control has been achieved with treatment.

Pemphigoid nodularis. This entity presents great diagnostic difficulty. Patients present with intensely itchy nodules, suggesting a diagnosis of prurigo nodularis. Blisters are rarely reported by the patient or seen, but when present are diagnostic. The eruption may be generalized or localized to the shins [1]. It may occur in children [2]. The immunopathology and antigens are the same as in ordinary pemphigoid [3]. Treatment is often difficult [1].

Localized pemphigoid. An unusual variant is the localized form of the disease, which occurs in 5–30% of patients with BP. This form is usually limited to the lower extremities and responds well to treatment [1–3]. Localized disease may progress to the generalized form.

Localized vulvar pemphigoid. This rarely reported entity is characterized by recurrent blistering confined to the vulva of young girls, which does not result in scarring [1,2]. A localized desquamative vaginitis has also described [3].

Lichen planus pemphigoides. Bullous pemphigoid can occur in the setting of lichen planus in both adults and children, tense subepidermal blisters arise from the lesions of lichen planus and normal skin. The blistering usually responds rapidly to treatment and is short-lived [1–5]. The disease has immunofluorescence findings identical to BP although there are antibodies to a characteristic epitope of BP180 (see Chapter 42) [6].

Induced BP and associated diseases. There are no well-defined causal agents, although a number of agents have been associated with the development of BP. Several drugs have been implicated [1], including frusemide [2], spironolactone [3], sulfasalazine, penicillins [4–6] and penicillamine [7]. These patients tend to have a younger average age than those in the idiopathic group. A case–control study suggests that antipsychotic drugs and aldosterone antagonists are associated with the development of BP [8]. Whether or not the drugs are exerting a direct effect on the immune system is not yet known.

Local irritation and damage to the skin have all been implicated in the induction of BP [9]. UV radiation or PUVA have been described as precipitating or exacerbating BP [10–14]. Other physical agents including thermal burns, wounds, localized trauma, skin grafts and radiotherapy have also been reported to induce BP in normal skin [9,15]. There have been a number of case reports of BP associated with radiotherapy for breast cancer [16,17]. Topical 5-fluorouracil has induced BP, but the role of topical chemical irritants such as dithranol (anthralin) and tar is less clear. Tetanus immunization has been reported to induce BP [18]. The mechanisms may be alteration or exposure of epitopes of adhesion complex proteins, or a change in the host immunological response.

Bullous pemphigoid is associated with certain other diseases; however, as it occurs in an elderly population, these patients often have other disorders at the same time. To determine whether the associations truly exist, prospective age-controlled studies are necessary. There are many individual case reports of BP in association with autoimmune diseases, although a case–control study did not show an overall association [19]. However, other systemic diseases have been reported in association with BP. These include diabetes mellitus [20,21], rheumatoid arthritis [22–24], ulcerative colitis [25–27] and multiple sclerosis [28,29]. There may be an association with neurological diseases [30]. More than 40 reports of BP in patients with psoriasis have been published, the blisters may be localized to the psoriatic lesions or independent of them, and in some instances therapeutic anthralin or UV radiation appeared to be the trigger [11,31]. A case–control study suggested an association between psoriasis and BP [32]. Bullous pemphigoid can occur in the setting of lichen planus (see above and Chapter 42).

There is controversy about the association between BP and malignancy. Initially, most large series concluded that there is no or only a very small increase in incidence of malignancy in BP patients compared with age- and sex-matched controls, although the association may exist in individual patients [33]. However, a large series of more than 1000 BP patients in Japan showed a 5.8% incidence of malignancy (with gastric carcinoma being the most common), which was significantly higher than that of age-matched controls [34]. A similar incidence was reported in Chinese patients with BP [35,36] and in Italy [37]. The carcinoma may express the BP antigens and evoke an immune response.

Differential diagnosis. It may not be possible to diagnose accurately the early pruritus, urticaria-like, eczematous and erythematous prodromal eruptions. The possibility of BP should always be considered in the elderly patient with unexplained itch or irritable fixed erythematous lesions. The lower leg in elderly people seems particularly prone to develop blisters, and it must be remembered that eczema or oedema at this site may blister.

When blisters have appeared, it is usually possible to differentiate BP from pemphigus vulgaris on clinical grounds alone. The large, tense, tough blisters of BP can be distinguished from the smaller, flaccid, more easily broken blisters of pemphigus, and the severe mucosal lesions of pemphigus vulgaris are a further distinguishing feature. Clinically typical cases of BP may be found to be linear IgA disease or epidermolysis bullosa acquisita on investigation. More atypical cases of BP with small or absent blisters and/or annular lesions may resemble dermatitis herpetiformis, linear IgA disease, erythema multiforme and a final differentiation must then be on histological grounds. Direct and indirect immunofluorescence should confirm the diagnosis.

A more difficult task may be separating mucous membrane pemphigoid from BP. The generalized eruption of mucous membrane pemphigoid may be clinically and histologically indistinguishable from BP, and BP may evolve into mucous membrane pemphigoid [1]. However, involvement of the mucous membranes with scarring is characteristic of mucous membrane pemphigoid.

1 Banfield C, Papadavid E, Frith P, Allen J, Wojnarowska F. Bullous pemphigoid evolving into cicatricial pemphigoid? *Clin Exp Dermatol* 1997; **22**: 30–3.

Prognosis. Untreated BP runs a chronic self-limiting course over a number of months or years. Remission may occur within a few months or the eruption may continue for many years. The disease duration is usually 3–6 years, with most patients achieving complete remission off all treatment. Bullous pemphigoid can be fatal, particularly in the active blistering phase in elderly people, and about one-third of untreated patients died. The features that predict a poor prognosis are age, generalized disease and low albumin, and mortality is associated with high doses of steroids [1–5]. Localized disease is very responsive to treatment and more of these patients appear to go into remission.

Treatment. The aim of treatment is to suppress disease activity with the minimum dosage of drugs necessary. BP patients are elderly, commonly on many drugs and very susceptible to adverse drug reactions and side effects. During prolonged treatment, it is advisable to aim for the presence of a blister once every few weeks so as to be certain that the patient is not being overtreated. The treatment of BP has recently been the subject of a systematic review and guidelines have been produced [1,2].

Topical and systemic corticosteroids are the mainstay of treatment. For localized BP, very potent topical steroids are worth trying first. Topical corticosteroids should be considered in all patients with BP, they aid control and may reduce the dosage of systemic agents. The recom-

mended initial dosage of prednisolone is 20 mg/day or 0.3 mg/kg/day in localized or mild disease, 40 mg/day or 0.6 mg/kg/day in moderate disease and 50–70 mg or 0.75–1 mg/kg/day in severe disease. Measures to prevent osteoporosis should be implemented from the start of systemic steroid therapy, whenever practicable. For mild to moderate disease, tetracycline and nicotinamide should be considered. Corticosteroid dosage can often be reduced over the course of a few weeks to 15–20 mg/day and thereafter more slowly. The majority can be managed on less than 10 mg/day prednisolone, which can be slowly withdrawn. We use a reducing regimen of 1 mg/month reduction once the dosage is below 10 mg/day. Immunosuppressants cannot be recommended routinely, but should be considered if the steroid dosage cannot be reduced to an acceptable level. Azathioprine is the one best established; methotrexate may be considered in patients with additional psoriasis [1].

There may be occasional flares which will require temporary increases in therapy.

Corticosteroid therapy has lowered the morbidity from the disease considerably and most patients achieve remission off all therapy. The mortality of BP still remains at 15–20%, and is nearly always treatment-related. However, treatment is essential to control this distressing disease.

Mucous membrane pemphigoid

SYN. CICATRICIAL PEMPHIGOID; BENIGN MUCOSAL PEMPHIGOID; OCULAR PEMPHIGUS; SCARRING PEMPHIGOID

Definition. A chronic blistering disease of the mucosa, which may involve the skin, and usually results in permanent scarring of the affected area, particularly the conjunctiva. Recently, this entity has been defined on the basis of the clinical picture and renamed mucous membrane pemphigoid [1]. In the previous edition it was called cicatricial pemphigoid. The new entity includes patients formerly diagnosed as having oral pemphigoid and some linear IgA disease and epidermolysis bullosa acquisita patients, and excludes Brunsting–Perry pemphigoid. Brunsting–Perry pemphigoid will, however, still be discussed in this section, as some patients have mucosal involvement and identical cutaneous signs.

The clinical features, immunopathology and immunogenetics are summarized in Tables 41.5 and 41.6.

REFERENCE

Aetiology. Mucous membrane pemphigoid is a disease of late middle to old age [1,2], but can affect children and teenagers and is more common in females [3,4]. The annual incidence in western Europe is approximately 1 in 1 million [3,4] and is probably less in China and the East [5,6].

There is an association with HLA-DQ7 (DQB1*0301) in all types of mucous membrane pemphigoid [7–16].

Pathogenesis. Mucous membrane pemphigoid is assumed to have a pathogenesis similar to BP. Some but not all patients have circulating autoantibodies, usually of low titre, that recognize proteins in the adhesion complex. The

reasons for the localization of mucous membrane pemphigoid to mucosal areas and limited areas of skin, and the scarring pattern are still not understood (see below). The antigens are identical to those of BP in many patients, although the binding site of the autoantibodies seems to be associated more with the anchoring filament than the hemidesmosome.

The major autoantigens in mucous membrane pemphigoid are all components of the basement-membrane zone (Fig. 41.11), and are associated with the hemidesmosome, the anchoring filament, and the anchoring fibrils (see below). There is an animal model for the pathogenicity of autoantibodies against laminin 5 (an anchoring filament component) [1] and *in vitro* models for other antibodies in mucous membrane pemphigoid [2–4].

Immunoblotting and immunoprecipitation have shown multiple target antigens (summarized recently in [5]). Many patients' autoantibodies target the BP antigens BP230 and BP180 [6,7]. BP180 is considered to be the major antigen, and numerous different epitopes, including the shed ectodomain, have been characterized as targets for the autoantibodies (Fig. 41.11) [8–11]. Some patient's antibodies bind to the α6 or β4 subunits of the α6β4 integrin [4,12–14]; a minority with dermal binding antibodies with salt-split skin target laminin 5 [15] or collagen VII [5,16].

The autoantibodies in mucous membrane pemphigoid may be IgG and/or IgA, and the presence of a dual antibody response is a marker for more severe disease [17–20]. The reason for the scarring is unclear. The demonstration of the autoantibodies is more difficult than in BP, and other mechanisms may be involved. Many patients share target antigens and HLA-DQ7 with BP and thus the scarring cannot be attributed solely to the site of the immune reaction or to differing immunogenetics. The nature of the inflammatory response and the cytokine network activated is a current focus for investigation, and probably determines the outcome of the lesions.

Pathology. Histological examination of a blister is helpful only if it is intact and recent. Biopsy of an erosion is rarely helpful. Blisters in the mouth and on the skin show subepithelial or subepidermal blister formation, but often lack distinctive and diagnostic features. There are usually fewer eosinophils present in the cutaneous lymphohistiocytic infiltrate than in BP. At a later stage there is fibrosis, the distinctive feature of mucous membrane pemphigoid. The conjunctiva shows invasion of the epithelium by inflammatory cells and an appearance of granulation tissue in the submucosa. The corneal epithelium may later be transformed into an epidermis-like structure.

The findings with immunofluorescence are summarized in Table 41.6 and there is a detailed review [1].

The site for biopsy for direct immunofluorescence often presents a problem. The involvement of mucosal surfaces may mean that there is no perilesional area accessible to the dermatologist. However, it is worth taking a 3–4-mm punch biopsy or shave biopsy from uninvolved skin and from the inner lower lip [2]. The help of other specialities is needed to take biopsies from bulbar conjunctiva and other mucosal surfaces. The direct immunofluorescence

findings are of linear basement-membrane zone IgG or C3, and less commonly IgA and IgM [3,4]. Not all patients with the clinical disease have positive immunofluorescence; in one series, the conjunctiva was most frequently positive [2].

With indirect immunofluorescence, the serum in mucous membrane pemphigoid does not always contain detectable circulating autoantibodies, the use of salt-split skin increases the sensitivity of the technique, and often demonstrates the presence of IgA autoantibodies that are not detected on intact skin [5–7]. The majority of sera bind to the epidermal aspect of split skin (Fig. 41.14). However, there are some that bind dermally [5–7], and these usually have circulating antibodies to laminin 5 [8], or rarely collagen VII [7]. The use of intact or salt-split mucosa does not improve the overall sensitivity [9]. The IgG autoantibodies are most commonly detected and are usually of the IgG1 and IgG4 isotypes, with IgG4 being present in nearly all cases [10]. The IgA autoantibodies are present in a minority of cases and are all IgA1 [5].

The immunoelectron microscopy data suggest that the antigens of mucous membrane pemphigoid are within the lamina lucida or associated with the lamina densa [11–13]. Thus, the antigens or their epitopes do seem to differ in their location from those of BP.

There are multiple target antigens including BP180, BP230, α6β4 integrin, laminin 5 and collagen VII (summarized recently in [7]), explaining the variation in immunofluorescence patterns.

Clinical features. The striking features are the recurring blisters on either a mucous membrane or an area of skin often near one of the orifices (Fig. 41.18) [1], together with the tendency for scars to form at these sites. The initial site may be any mucous membrane including the conjunctiva, the oral mucosa and those of the nose, larynx, pharynx, oesophagus, penis (Fig. 41.19), vulva, vagina and anus.

Oral lesions occur in the majority of patients [1]. In the mouth, vesicles or small blisters, which remain intact for some time, may be seen and when erosions form they are slow to heal. Persistent extensive erosions may be present

Fig. 41.18 Mucous membrane pemphigoid. Erosions around the gingival margins. (Courtesy of Dr R.J. Pye, Addenbrooke's Hospital, Cambridge, UK.)

Fig. 41.19 Mucous membrane pemphigoid. Recurrent bullae and ulceration of the penis resulting in some scarring. (Courtesy of Dr R.J. Pye, Addenbrooke's Hospital, Cambridge, UK.)

in the buccal mucosa and especially the palate. Desquamative gingivitis with eroded bleeding gums and occasionally blisters is common (Fig. 41.18). Localized oral pemphigoid was the name previously given to patients in whom there were only oral lesions without scarring. Adhesions may develop between the buccal mucosa and the alveolar process and around the uvula and tonsillar fossae. Extension of the disease to the pharynx and oesophagus causes dysphagia and may give rise to strictures, which can result in weight loss often necessitating surgical intervention [2]. The disease can involve the larynx manifesting with hoarseness and, in rare cases, may give rise to strictures causing stridor and even asphyxiation requiring surgical intervention [3]. Deafness from involvement of the middle ear has been reported [4].

The genitals are involved in half of female patients, with blisters and erosions of the vulva [5]. Scarring leads to obliteration of the vulval architecture with labial fusion, introital shrinkage and end-stage scarring that may be indistinguishable from lichen sclerosus [6]. The penis may be involved with blisters and erosions and adhesions may form between the prepuce and the glans penis.

Conjunctival lesions may start in one eye but will later involve both. At first, there may be a simple conjunctivitis causing redness, soreness and discomfort, and this may last for years, with alternating periods of activity and remission. Occasionally, episodes of blistering may be associated with pain and discomfort, and blisters or erosions may rarely be visible on the tarsal conjunctiva. Scarring can also occur without any preceding symptoms. There is progressive scar tissue formation, with forniceal shrinkage, linear scarring, formation of symblepharon, adhesions between the palpebral conjunctiva and corneal involvement. It becomes difficult to move the eyes. The conjunctiva becomes shrunken and dry and the lower lids become inverted causing entropion (Fig. 41.20). In the final stages, the cornea becomes dry and opaque, the 'statue eye'. The conjunctivae are eventually affected in many patients, but other areas may be involved for several years before the eyes become affected.

Fig. 41.20 Mucous membrane pemphigoid. Severe scarring and blindness. (Courtesy of Dr R.J. Pye, Addenbrooke's Hospital, Cambridge, UK.)

Two types of skin lesion may occur, the most common of which is a generalized bullous eruption such that an initial diagnosis of BP is made [7]. The second is a localized erythematous plaque, which becomes the site of recurrent blisters with subsequent scarring and hyperpigmentation. These localized lesions are often near affected mucosal surfaces. The scalp may be involved and the scarring and atrophy produce permanent alopecia [8].

Localized oral pemphigoid. These patients were previously regarded as a variant of BP, as they had disease confined to the mouth, and without scarring.

Brunsting–Perry pemphigoid. In 1957, Brunsting and Perry [1] described a group of patients who developed disease localized to the scalp or face, with grouped subepidermal bullous skin lesions that leave scars and may result in permanent alopecia. In the initial description, the patients did not develop mucous membrane involvement. However, in many such patients mucosal involvement does ensue and they are best diagnosed with mucous membrane pemphigoid.

Associated diseases. There is an association with autoimmune disease, both organ- and non-organ-specific [1]. There is also an association with lichen sclerosus [2] with which it may share clinical similarities in the genital area as well an association with HLA-DQ7 (DQB1*0301) [3,4]. There is no overall association with malignancy [5], apart from patients with laminin 5 antibodies [6]. Most of the case reports of malignancy are associated with laminin 5 mucous membrane pemphigoid [7,8].

Prognosis. Mucous membrane pemphigoid is a chronic debilitating and mutilating disease. It can affect the general health causing blindness, weight loss, respiratory, sexual and urinary problems. Impairment of vision is the most important complication, with some patients becoming blind in both eyes. In rare cases, patients may die from laryngeal stenosis or complications of treatment. Unlike BP, it does not appear to be self-limiting, and prolonged remissions are rare [1,2] except in localized oral or skin disease [3]. The disease often extends over many years with periods of activity and extension followed by quiescent phases. Very rarely, carcinoma has arisen in chronic oral or oesophageal lesions [4].

Differential diagnosis. The oral lesions, which may appear first, are difficult to differentiate from pemphigus vulgaris or from erosive lichen planus. Desquamative gingivitis may be a manifestation of mucous membrane pemphigoid or lichen planus. The clinical signs elsewhere differentiate these conditions, but there are patients in whom initial differentiation may be impossible.

End-stage scarring of the conjunctiva may resemble scarring that can occur as a result of severe infective conjuctivitis, chronic allergy, reactions to topical drugs, erythema multiforme and toxic epidermal necrolysis, epidermolysis bullosa or burns. Similarly, the end-stage scarring of the genital region may mimic the more common lichen sclerosus and erosive lichen planus. The history of the mode of onset and the evidence of other active lesions should be helpful in diagnosis. The generalized skin eruption is indistinguishable from that of BP; however, the presence of mucosal lesions and scarring favour the diagnosis of mucous membrane pemphigoid. Fixed scaly patches near the face and scalp may resemble pemphigus erythematosus.

Histological examination of a recent blister but not an erosion is helpful. Direct immunofluorescence on perilesional or clinically uninvolved mucosa and skin and indirect immunofluorescence are diagnostic if positive.

Treatment. Treatment is difficult and a systematic review has demonstrated how little evidence there is for the treatments used [1,2]. The disease activity fluctuates without treatment, and most treatments modify disease activity rather than totally suppressing it [3]. Treatment approaches have recently been summarized by an international consensus [4].

Local treatments are crucial and may be sufficient to control the disease to an acceptable level [3,5].

Systemic treatments are required for severe mucosal and laryngeal lesions and the control of generalized bullous eruptions, but are not always successful. The best evidence is for the use of cyclophosphamide in severe ocular disease, and for dapsone or sulfonamides in moderate to severe disease [1,2,6–8]. Dapsone and sulfamethoxypyridazine or sulfapyridine may be of value in controlling oral and cutaneous blistering and ocular disease [9,10]. Azathioprine is used but there are no trials to support this. There are recent reports that systemic tetracyclines alone or combined with nicotinamide may be helpful for oral lesions [11]. Recently, the use of intravenous immunoglobulins has been advocated [4,12]. The usual approach is to start with the least toxic therapies, in mild to moderate disease. In rapidly advancing disease threatening sight or airway, more aggressive treatment is needed.

Oral lesions are often helped by local treatment with topical steroids, as mouthwashes, sprays or applications, or tetracycline mouthwashes. The sprays and mouthwashes may also help the pharynx and oesophagus. Tetracyclines and nicotinamide can be helpful [5]. Oesophageal strictures may necessitate dilatation, which gives excellent results. Tracheotomy, which may need to be permanent, can be life-saving if there is stridor.

The management of ocular disease needs to be performed by an ophthalmologist with experience in treating mucous membrane pemphigoid, and includes topical steroids and subconjunctival injections of corticosteroid suspension and mitomycin [13] that may be temporarily effective for conjunctival disease, but neither these treatments nor systemic dapsone, cyclophosphamide, intravenous immunoglobulins and/or corticosteroids will halt

the progress in every case. Surgery to the lashes, division of adhesions and grafting may be required. Some patients will become blind.

Genital lesions may respond to potent topical steroids or to the combination of topical steroid and tetracycline. Vulval adhesions may require surgical division, and a Fenton's procedure to enlarge the introitus may be required in sexually active patients. Circumcision may be required in men.

Persistent skin erosions on the scalp or face can be helped by potent topical steroids.

The role of mucosal grafts is controversial and in the eye may have an adverse effect [14].

Mucous membrane pemphigoid is frustrating for the patient and the physician, and the patients endure many years of discomfort and morbidity, and rarely mortality from the disease and its treatment.

Pemphigoid gestationis

SYN. HERPES GESTATIONIS

Definition. Pemphigoid gestationis is an intensely pruritic bullous eruption that may develop in association with pregnancy or rarely the trophoblastic tumours, hydatiform mole and choriocarcinoma. The clinical features, immunopathology and immunogenetics are summarized in Tables 41.5 and 41.6.

Aetiology. Pemphigoid gestationis is a rare condition that may affect from 1 in 10 000 to 1 in 60 000 pregnancies [1,2]. In western Europe the incidence is approximately 0.5 per million population [3,4]. It does occur in Afro-Caribbeans, but is very rare in the Far East [5].

The disease arises only in the presence of paternal derived tissue, the fetus, and rarely hydatiform mole or choriocarcinoma, and thus tissue expressing HLA antigens from the father [6–8]. The fathers are more often HLA-DR2 than the control population [9]. It is considered that an HLA mismatch between mother and fetus triggers an immune response that cross-reacts with the maternal skin. There is clinical evidence of placental insufficiency (see below), and immunohistochemical findings of immune activation in the placenta [10,11], and affected mothers have high titres of antibodies to HLA class 1 antigens [12].

The mothers frequently manifest the autoimmune haplotype, HLA-B8, -DR3 and -DR4 [6,13,14], and this association has been verified in a Mexican population [15]. They also have, as predicted for this HLA haplotype, a linkage disequilibrium with certain immune response genes and thus a high incidence of the C4 null allele, which influences clearing of immune complexes [16]. The immunogenetics of the mothers increases susceptibility to the development of pemphigoid gestationis.

Pemphigoid gestationis is associated with other autoimmune diseases (see below) implying an autoimmune basis [6,17,18].

The clinical course of pemphigoid gestationis may be modified by changes in oestrogen and progesterone levels; exacerbations may occur with oral contraceptives and the severity may vary during the menstrual cycle [6,18].

Pathogenesis. The autoantibodies are directed at the same hemidesmosome target antigens as in BP, namely BP180 and, less commonly, BP230 [1,2]. The extracellular region of BP180 adjacent to the transmembrane portion, the NC16A domain (Fig. 41.11), is the immunodominant epitope [3], and the antibody response seems to be restricted to this region [4–6]. This extracellular location makes it a likely target for pathogenic autoantibodies. The same epitopes are recognized by the autoantibodies and T cells [5]. There is a report of a target antigen of 200 kDa in an individual patient [7].

An animal model has demonstrated that autoantibodies to BP180 are pathogenic and require complement (see p. 41.24) [8,9].

The autoantibodies react with the basement membrane of amnion placenta from the second trimester onwards and are found in the fetal skin and cord blood [10–13]. The autoantibodies are IgG antibodies of the IgG1 and IgG3 subclasses [14,15]. These IgG1 antibodies avidly bind C3, and often this binding is detected rather than the IgG antibodies themselves. There is a single case report of IgA antibodies [16].

Pathology. The histopathology of the early urticated lesions of pemphigoid gestationis shows epidermal and papillary dermal oedema with occasional foci of eosinophilic spongiosis. The bullous lesions are subepidermal and contain numerous eosinophils. The split is through the lamina lucida.

The findings with immunofluorescence are summarized in Table 41.6. Direct immunofluorescence studies show that in all active cases of pemphigoid gestationis there is C3 deposition at the basement-membrane zone. In some cases, IgG is also found. C3 and IgG deposition are found in the placenta and fetal skin [1–4].

Indirect immunofluorescence studies demonstrate binding of C3 to the basement-membrane zone; this serum factor was known as the HG factor. Although conventional immunofluorescence techniques are able to demonstrate IgG in only approximately 25% of cases, it is now clear that the autoantibody is an IgG of the IgG1 subclass [5,6]. The autoantibodies bind to the epidermal side of salt-split skin [7].

Immunoelectron microscopic studies have confirmed that IgG is deposited along the basement-membrane zone chiefly within the lamina lucida and localized to proximal part of the anchoring filament [8–10].

Immunoblotting techniques have shown that the major antigen recognized by the circulating autoantibodies is BP180 [11,12].

Clinical features. Pemphigoid gestationis may begin at any time between 4 weeks' gestation and 5 weeks' postpartum, with the majority presenting in the second and third trimester [1,2]. Almost half of cases develop in the first pregnancy. There is a high risk of recurrence in subsequent pregnancies, the onset is likely to be earlier than in the previous one and the disease may be very different in severity. In many cases, the disease becomes relatively quiescent in late pregnancy, only to flare severely immediately postpartum [1]. Usually, the disease lasts several weeks to months, the average is 6 months, but sometimes it can continue for years afterwards [2]. The likelihood of prolonged disease is increased by older age, multiparity and mucosal involvement [3].

Pemphigoid gestationis is intensely itchy. The condition usually begins around the umbilicus, and then spreads to the abdomen, thighs, limbs, palms and soles (Fig. 41.21). Involvement of the oral cavity is relatively rare. Early in its course, the eruption consists of urticated papules, plaques, target lesions and annular wheals, associated with marked pruritus. Subsequently, vesicles and larger blisters appear (Figs 41.21 & 41.22).

Neonatal pemphigoid gestationis may occur in 3% of pregnancies [2], with positive direct immunofluorescence in the neonate [4,5], resulting from transfer of antibodies across the placenta. It usually resolves rapidly without treatment [2,4,5].

Associated diseases. Pemphigoid gestationis is associated with other autoimmune diseases, 14% in a recent study [1], particularly with Graves' disease (10%), hypothyroidism, vitiligo, alopecia areata and autoimmune thrombocytopenia [1–3].

Prognosis. Pemphigoid gestationis tends to improve postpartum, but it may be weeks, months or years before there is complete resolution. In rare cases, the disease may evolve into BP [1]. There are often flares with menstruation. There are usually dramatic flares with the oral contraceptive, which is contraindicated while the disease is still active.

There are reports of persistent disease postpartum and these cases are more likely to have previous disease and to be older [1,2].

Once pemphigoid gestationis has occurred, it is likely to recur in subsequent pregnancies, and may be more or less severe. Approximately 8% of subsequent pregnancies are spared [3]. Although a change in partner does not increase the risk of developing pemphigoid gestationis, it is unclear whether it alters the risk of recurrence [3]. Patients should be counselled as to the risk of recurrence, but not advised from having further pregnancies because they have had pemphigoid gestationis.

The modern view is that pemphigoid gestationis is associated with premature delivery and a risk of low birth weight [4–6]. Deliveries from mothers with pemphigoid gestationis should take place in departments of obstetricians that have facilities for special care of the newborn.

Differential diagnosis. The main problem is the differentiation of pemphigoid gestationis from the much more common urticarial eruption that begins in later pregnancy, termed polymorphic eruption of pregnancy (see Chapter 70). This usually begins in the stretch marks and almost never blisters. The histopathology often differentiates the two conditions, and immunofluorescence is negative in polymorphic eruption of pregnancy.

Treatment. In mild cases of pemphigoid gestationis, topical potent or very potent steroids can be successful, and this was so in approximtely 20% in a recent retrospective study [1]. They are often combined with a systemic antihistamine (suitable for use in pregnancy) [1]. Once the blisters develop systemic steroids are usually necessary. Moderate disease responds to prednisolone 20–30 mg/day, severe disease may need prednisolone 40–80 mg/day. Prednisolone can usually be reduced fairly rapidly to a much lower maintenance dosage. Because postpartum exacerbations are so frequent, it is worth increasing the corticosteroid dosage temporarily at the first sign of a flare. Plasmapheresis can be considered in the most severe cases [2]. The role of dapsone is unclear and the drug can cause haemolytic disease in the neonate [3]. There is only anecdotal support for the use of pyridoxine [4].

Postpartum treatment can be a problem if the mother wishes to breastfeed, as the drugs pass into the breast milk. Antihistamines can cause drowsiness in the baby, steroids at high doses (more than 40 mg/day prednisolone) can cause adrenal suppression, and dapsone can cause haemolysis. Paediatricians should therefore be consulted in this situation. In the non-breastfeeding woman there are reports of the successful use of tetracyclines, sometimes with nicotinamide [5–7]. Immunosuppressive treatment and immunomodulating treatments such as intravenous immunoglobulins have also been used [8–10].

Linear IgA disease

SYN. CHRONIC BULLOUS DISEASE OF CHILDHOOD; JUVENILE DERMATITIS HERPETIFORMIS; JUVENILE PEMPHIGOID; LINEAR DERMATITIS HERPETIFORMIS; LINEAR IgA BULLOUS DERMATOSIS

Definition. Linear IgA disease is a chronic acquired subepidermal disease of children and adults, with cutaneous and mucosal involvement, characterized by IgA basement-membrane antibodies. The disease responds to dapsone and has a tendency to remit.

Two main clinical syndromes are distinguished: chronic bullous disease of childhood, beginning in childhood, and adult linear IgA disease, beginning any time in adult life. They differ in their age of presentation and to some extent regarding their clinical signs, but there is much overlap, and the immunopathology and immunogenetics are common to both diseases. Clinical features, immunopathology and immunogenetics are summarized in Tables 41.5 and 41.6.

Aetiology. Linear IgA disease affects all ages, from babies of a few months to the elderly. The majority of children present while toddlers or preschool children. Teenagers and young adults also present with the disease and there is a second peak over 60 years [1]. Linear IgA disease is one of the less common subepidermal blistering diseases in western Europe with an incidence of less than 0.5 per million, chiefly adults [2,3]. It is more common in China where it is about one-third as common as BP [4], and is reported from South-East Asia [5–7]. Moreover, one-third of Chinese patients are children [4]. There seem to be more children with the disease in developing communities (e.g. China, Malaysia, Sri Lanka, India, Thailand, Tunisia, Mali) and black children in South Africa than in western Europe [8–15]. The sex incidence is about equal or there may be a slight excess of female patients.

There is a strong association between linear IgA disease and the extended autoimmune haplotype HLA-B8, -CW7 and -DR3 in UK and black South African patients and possession of this haplotype is associated with an early disease onset [11,16]. This extended haplotype is in linkage disequilibrium with a high producing allele of TNF, and this association exists in linear IgA patients and confers a worse prognosis [16].

Pathogenesis. The autoantibodies in linear IgA disease are IgA, which is unusual for an autoimmune disease, and usually IgA1 and monomeric [1–3]. However, IgG antibodies can also be detected by immunoblotting techniques, although their antigen repertoire is more limited [4–6].

The IgA antibodies are directed at a number of different target antigens within the adhesion complex (Table 41.5; Fig. 41.11). The major antigen in linear IgA disease is BP180/collagen XVII and its shed ectodomain, formerly known as LAD1, with molecular weights of 97 and 120 kDa (Fig. 41.11). There are also antibodies to BP230 and a unique antigen LAD285, which has a molecular weight of 285 kDa [5–10]. The autoantibodies recognize many different epitopes on BP180, including the NC16A domain (Fig. 41.11) [11–13]. T-cell responses to BP180 have been demonstrated [14]. Collagen VII, the anchoring fibril component, is a rare antigen and is almost never associated with a mechanobullous scarring phenotype, unlike classic epidermolysis bullosa acquisita (see below) [15–18]. There are other unidentified dermal antigens [6,19].

There is indirect evidence that the antibodies are pathogenic, in that they cause splitting of skin in culture and binding of neutrophils to the basement-membrane zone [20,21].

Pathology. The histological features are not specific for the condition. The subepidermal vesicles may contain numerous eosinophils suggestive of pemphigoid. In some blisters, neutrophils predominate and dermal capillary microabscesses are seen, suggesting dermatitis herpetiformis. Others show subepidermal blisters with non-specific features. An old blister will give misleading results. In a child, it is not always worthwhile performing a biopsy on a lesion, as direct immunofluorescence will give the diagnosis and is often easier and less traumatic to perform. The findings with immunofluorescence are summarized in Tables 41.6 and a detailed review has been published [1].

Direct immunofluorescence can be performed on clinically uninvolved skin, and the back is often convenient (and out of sight) in a child. The forearm is the least satisfactory site [2] and mucosal biopsies from the mouth, but not necessarily the conjunctiva, are also positive [3]. In all cases there is linear deposition of IgA along the basement-membrane zone. There may also be other immunoreactants, IgG, IgM or C3, on direct immunofluorescence [4,5]. Direct salt splitting of the biopsies or the raising of suction blisters in patients shows that the deposition of autoantibodies can be associated with the epidermal aspect of the artificial blister, with the dermal aspect or both [6,7].

The significance of the rare linear granular pattern of IgA deposition at the basement-membrane zone is still unclear [4]. Some patients with this pattern have true dermatitis herpetiformis but others may have autoantibodies to unusual target antigens.

Indirect immunofluorescence for IgA basement-membrane zone antibodies is more often positive in children (approximately 80%) than adults (approximately 30%) [5]. The titres are usually low, of the order of 1 : 5 or 1 : 10, but occasionally much higher. The use of normal human skin split through the lamina lucida with suction or, more commonly, 1 molar salt increases the sensitivity and gives additional information as to the site of the target antigen. The majority of sera demonstrate binding to the epidermis, implying an antigen associated with hemidesmosomes or the upper lamina lucida; a few have a combined pattern, and a larger minority bind to the dermal aspect of the artificial blister, suggesting a lower lamina lucida or dermal antigen [5,6,8].

Blister fluid is an alternative to serum for indirect immunofluorescence and may be easier to obtain in a child [9]. However, urine did not prove a practical alternative [10].

The presence of IgG autoantibodies on direct or indirect immunofluorescence causes problems with disease definition, and has been used to define a further entity, mixed immunobullous disease (see below) [11–13].

Immunoelectron microscopy studies have shown that the immunoreactants and target antigens are either associated with the hemidesmosomes, within the lamina lucida, in the subbasal lamina zone or in a mirror-image pattern on each side of the lamina densa [14–20].

Immunoblotting studies have demonstrated a variety of target antigens, in keeping with the multiple localizations found with split skin and immunoelectron microscopy studies. The antigens include both epidermal and dermal associated antigens, and the major one is BP180 (see above).

Clinical features (Figs 41.23 & 41.24). The clinical features of children and adults are described separately as they are distinctive.

Chronic bullous disease of childhood. The mean age of onset is under 5 years, it is usually acute and the initial attack more severe than subsequent recurrences. Symptoms vary from absent or mild pruritus to severe burning. The face and perineum are involved, particularly in younger children. The perioral area, the eyelids, ears and scalp may be affected. The involvement of the perineum and vulva (Fig. 41.23) has been mistaken for sexual abuse in some patients. The eruption may spread to the trunk, thighs, limbs, hands and feet. The lesions comprise urticated plaques and papules, and annular polycyclic lesions often with blistering around the edge, the 'string of pearls' sign. Large blisters may develop and become very extensive, they are occasionally haemorrhagic, and usually arise on previously normal skin. Papules and vesicles also occur.

Mucosal involvement is common. The mouth may be involved, with ulcers and erosions, and hoarseness may indicate pharyngeal involvement. There can be nasal stuffiness and bleeding. The eyes are often sore or gritty and there is conjunctivitis [1]. The children who progressed to conjunctival scarring and blindness are most appropriately diagnosed with mucous membrane pemphigoid [1–4].

Linear IgA disease of adults. This commences at any age from the postpubertal teenager to the ninth decade, most commonly after the age of 60 years. The onset may be insidious or, more usually, abrupt. Symptoms vary from mild pruritus to severe pruritus and burning. The trunk is almost always involved, and the limbs, face and scalp, hands and feet are commonly affected. The lesions comprise urticated plaques, papules and vesicles, and blisters. The blisters may arise from normal skin (Fig. 41.24) or from urticated plaques and can be haemorrhagic. The characteristic annular lesions with blistering around the edge are less common than in children (Fig. 41.24). Milia are almost unknown.

Mucosal involvement is common [1]. The mouth may be involved, with ulcers and erosions. Hoarseness indicates pharyngeal involvement. There is often nasal stuffiness, crusting and bleeding. The eyes are often sore or gritty. Involvement of the genitals and also the vagina can occur. Those few patients who progress to scarring, including blindness, are most appropriately diagnosed with mucous membrane pemphigoid [2,3].

Dermal associated linear IgA disease. There does not seem to be a mechanobullous scarring phenotype for linear IgA disease when associated with dermal antigens including collagen VII [1,2]. Classic IgA epidermolysis bullosa acquisita with antibodies to collagen VII is very rare and progresses to a mucous membrane pemphigoid-like phenotype [3,4].

Linear IgA mucous membrane pemphigoid. Patients with typical clinical signs of mucous membrane pemphigoid who have linear IgA on direct immunofluorescence should, following the International Consensus on Mucous Membrane Pemphigoid, be regarded as having mucous membrane pemphigoid [1]. Interestingly, this has been described in several children and some adults, and the case of linear IgA desquamative vaginitis is also best regarded as such [2–8].

Mixed immunobullous disease. A small number (14) of patients with a dual antibody response of IgA and IgG autoantibodies have been studied. This immunopathological finding was seen in both children [1,2] and adults [3]. In most cases, the patients had a clinical picture compatible with linear IgA disease and a good response to dapsone or sulfonamides. The exact position of this entity is still unclear, but for practical purposes the patients are best managed as for linear IgA disease.

3 Sheridan AT, Kirtschig G, Wojnarowska F. Mixed immunobullous disease: is this linear IgA disease? *Australas J Dermatol* 2000; **41**: 219–21.

Induced linear IgA disease and associated diseases. A number of precipitating factors are observed (namely infection and antibiotics (penicillins)) in approximately one-quarter of adults and more children [1,2], and the presence of building work in the home in approximately half of adult patients and three-quarters of the children [3]. The significance of these findings is unclear. Drug-induced linear IgA disease is commonly reported, vancomycin being the drug most frequently implicated [4–6] and diclofenac and other non-steroidal anti-inflammatory drugs less

commonly [7–12]. However, a large range of drugs has been reported [9,13,14]. Local skin trauma has initiated the disease in some cases [1,2,15].

Patients with linear IgA disease were originally thought to have dermatitis herpetiformis, but it is now clear that this is a totally distinct disease and there is no overall association with gluten-sensitive enteropathy [1,16,17]. There is an association with ulcerative colitis and other inflammatory bowel disease in a small number of patients [18]. There is no overall association with autoimmune disease, although autoantibodies are common [1].

There is an increased incidence of lymphoproliferative disorders in adults with linear IgA disease, which may occur after remission of the skin disease [2,19,20]. There are a number of case reports of various cancers in association with linear IgA disease, of which bladder and renal cancer are the most common, but there is no overall increase [2,21,22].

Prognosis. Spontaneous remission occurs in the majority of patients after an average of 3–6 years, the TNF genotype of the patient influencing disease duration [1–3]. Initially, there were no reports of chronic bullous disease of childhood extending beyond puberty, but cases have now been documented [2,4]. Some of these patients are women of childbearing age. In pregnancy, often there is improvement or remission of the disease from the second trimester, and the women may be able to discontinue all drugs. However, there is usually a relapse at approximately 3 months postpartum [5]. There does not appear to be any fetal damage [5].

Differential diagnosis. In the young infant, bullous impetigo may resemble the initial lesions, but its response to antibiotics differentiates it. Genetic epidermolysis bullosa is often present at birth and the family history further differentiates it. Bullous papular urticaria rarely affects the face or genital region and is usually of short duration. Childhood BP may give a similar clinical picture, but the deposition of IgG and C3 at the basement-membrane zone is diagnostic. The adult disease is frequently confused with atypical erythema multiforme, neurotic excoriations and nodular prurigo, dermatitis herpetiformis and, most commonly, BP. Histology is helpful and direct immunofluorescence is essential for diagnosis.

Treatment. A few patients have mild disease and can be controlled with topical steroids alone. The treatment of children can be difficult, because side effects limit the dosage of drugs used, but the drugs used are identical in

children and adults. The recent favourable reports of erythromycin suggest that this should be tried as first-line treatment in children [1]. Dapsone in regimens starting at less than 0.5 mg/kg, which often means giving it as 25 mg on alternate days or less in young children and 25–50 mg/day in an adult, may be slowly increased to a dosage of 1 mg/kg or a little more in a child and 100–150 mg in an adult to keep the patient comfortable and without significant side effects. Too rapid an increase in the dosage often results in haemolytic anaemia, which does not reach its maximum for a month. A fall in haemoglobin with a low mean corpuscular volume (MCV) indicates iron deficiency (resulting from intravascular haemolysis) rather than pure haemolytic anaemia. Patients at risk of glucose-6-phosphate dehydrogenase deficiency should be screened prior to treatment. Met-haemoglobinaemia is common, reaching a steady state after approximately 2 weeks, and may cause cyanosis, breathlessness and angina. Hepatitis, the dapsone syndrome (lymphadenopathy and hepatitis) and agranulocytosis are serious, usually early complications. Motor neuropathy may occur. Most complications occur in the first 3 months. Sulfonamides are alternatives. Sulfapyridine is often poorly tolerated and may cause an allergic reaction, hepatitis or agranulocytosis, and is used at a dosage of 250 mg/day to 3 g/day, which usually controls the eruption rapidly, but the dosage may need frequent adjustment. Sulfamethoxypyridazine (adult dose 250 mg/day to 1.5 g/day) is an alternative, which is often better tolerated. Dapsone and sulfonamides can be combined. Some patients do not respond to either of these, and corticosteroids may need to be added. A few patients are very difficult to control and may need azathioprine or ciclosporin. Success has been reported in small numbers of patients with other antimicrobials. These include tetracyclines and nicotinamide/niacinamide [2–4], penicillins [5–7] and recently erythromycin [1]. Colchicine has been used successfully in children and adults [8–13]. The cutaneous lesions are always much more responsive than the mucosal lesions, which can be treated with topical steroids (see p. 41.39).

In view of the ultimate spontaneous recovery in the majority of patients, attempts should be made to avoid overtreatment and the production of side effects with steroids.

Epidermolysis bullosa acquisita

SYN. ACQUIRED EPIDERMOLYSIS BULLOSA; DERMOLYTIC PEMPHIGOID

Definition. Epidermolysis bullosa acquisita (EBA) is a rare condition in which patients may have chronic acquired trauma-induced subepidermal blistering or a clinical picture indistinguishable from BP. There is a distinctive immunopathology, and the disease is defined in terms of the target antigen (collagen VII). However, there are patients with the same clinical pattern in whom antibodies to collagen VII cannot be identified [1], and antibodies to collagen VII are found in patients with mucous membrane pemphigoid (see above) [2,3]. It is interesting that this acquired mechanobullous disease was named for its clinical resemblance to genetic dystrophic epidermolysis bullosa (see Chapter 40) and that the molecular basis of both these diseases is collagen VII. The clinical features, immunopathology and immunogenetics are summarized in Tables 41.5 and 41.6.

Aetiology. EBA can occur at any age. It has been described in children and adults [1–5]. The original reports from the USA included many African American patients, and it may be more common in African races and orientals [6–9]. It is one of the rarest subepidermal bullous diseases in western Europe, with an incidence of about 0.25 per million, but may be more common in the Far East [7–11].

There is an association with HLA-DR2 in the USA [6] but not in Korean patients [12].

Pathogenesis. Collagen type VII, the major component of the anchoring fibrils, is the target antigen recognized by autoantibodies from patients with EBA [1]. Collagen type VII comprises a globular amino non-collagenous domain (NC1) and a collagenous triple helix (Col-1), and the gene is located to the short arm of chromosome 3 [2]. The autoantibodies in EBA are directed at epitopes chiefly within the fibronectin-like region at the globular amino non-collagenous NC1 domain [3–7], although antibodies to the collagenous triple helix and NC2 and can be demonstrated [8,9].

The autoantibodies are IgG, and are of all the IgG isotypes, although the IgG1 and IgG4 isotypes may predominate in the chronic mechanobullous forms [10–12]. Some of the antibodies bind complement [12,13].

There is evidence that the autoantibodies are pathogenic. Complement-binding autoantibodies from patients with EBA bind to skin and attract neutrophils to the basement-membrane zone [14,15] and also induce blistering in the presence of neutrophils in sections of human skin [16]. There has been an animal model in which the immunopathological features and some histological features of the disease were induced in neonatal mice using serum from a single patient [17].

Pathology. The blistering is subepidermal, but the precise histological findings depend on the stage of the disease. In inflammatory disease, there is a heavy predominately neutrophil infiltrate. In the mechanobullous non-inflammatory phase, the infiltrate is usually absent or sparse. The findings with immunofluorescence are summarized in Table 41.6 and a detailed review has been published [1].

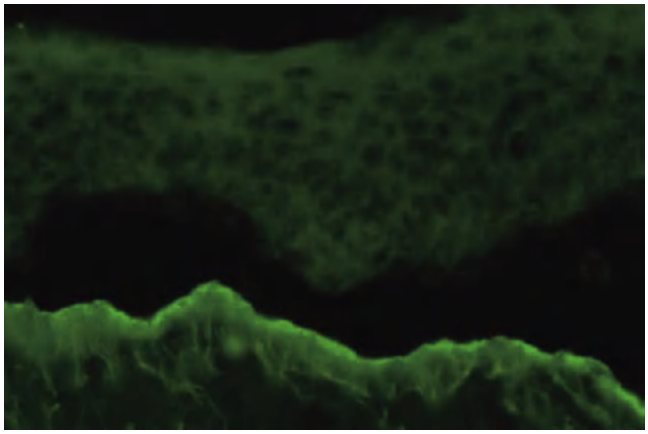

Fig. 41.25 Epidermolysis bullosa acquisita. Indirect immunofluorescence showing dermal binding of autoantibodies to salt-split skin. (Courtesy of Dr J. Allen, Oxford Radcliffe Hospital, Oxford, UK.)

On direct immunofluorescence, linear IgG at the basement-membrane zone is found in all patients, and linear IgA and IgM may also be seen. C3 has been reported in most cases. The basement-membrane staining may be broader than that seen in BP. Patients' skin split through the lamina lucida with suction (applied *in vivo*) or with 1 molar salt demonstrates the IgG antibodies to be bound to the dermal aspect of the blister [2].

Positive indirect immunofluorescence has been demonstrated in approximately half of patients tested with circulating autoantibodies binding to the basement-membrane zone. However, if skin is separated through the lamina lucida using 1 molar sodium chloride, or suction, and then used as substrate, the fluorescence is seen on the dermal aspect of the artificial blister (floor of the split skin) (Fig. 41.25) [3]. EBA serum is negative on toad skin [4,5]. An ELISA technique is more sensitive, but is not in routine use [6].

Electron microscopy has shown dermolysis and cleavage in the upper dermis with preservation of the basal lamina, but no reduction in the number of anchoring fibrils [7]. Amorphous material has been found beneath the basal lamina, sometimes in a band-like distribution [7–9].

Immunoelectron microscopy has shown that the IgG was deposited in the upper dermis beneath the basal lamina and within the sublamina densa zone [7]. Immunogold studies demonstrate that the autoantibodies bind to the non-collagenous ends (NC1 domain) of the anchoring fibrils and elsewhere [10,11].

Immunoblotting and ELISA techniques demonstrate that EBA autoantibodies recognize proteins of 290 and 145 kDa shown to be collagen VII, and that the immunodominant epitopes are within the NC1 domain, but that other regions are immunogenic (see above).

Clinical features. Early in the disease, clinical manifestations may be very variable and may mimic a number of bullous dermatoses. Blisters may be serous or haemorrhagic, tend to be localized to areas of trauma, especially on the dorsa of the hands, tops of the feet and elbows, and heal with scarring, milia and hyperpigmentation (Fig. 41.26). Nails may be dystrophic but are often normal. Some patients have disease indistinguishable from BP,

Fig. 41.26 Epidermolysis bullosa acquisita. Milia and scarring and dystrophic nails. (Courtesy of Dr S. Wakelin, St John's Dermatology Centre, London, UK.)

although some of these evolve into a more typical mechanobullous picture [1,2]. Mucosal involvement is variable but both erosions and intact blisters may be present in the mouth, larynx and oesophagus, and may cause dysphagia and laryngeal stenosis, and ocular involvement and blindness have been reported. Those patients in whom mucosal symptoms predominate are now regarded as having mucous membrane pemphigoid [3].

Induced EBA and associated diseases. A number of conditions have been associated with EBA: inflammatory bowel disease, ulcerative colitis and Crohn's disease [1–6]. Collagen VII is expressed in human colon, and autoantibodies to collagen VII react with the epithelial mesenchymal junction; moreover, antibodies to collagen VII are present in Crohn's disease and to a lesser extent in ulcerative colitis, suggesting that cross-reactivity and epitope spreading may explain this association [7]. There are reports of EBA in association with multiple myeloma, amyloidosis and lymphoma [8–13]. Individual cases have been associated with carcinoma [14–16]. The association with systemic lupus erythematosus is discussed below (see p. 41.54). Drug-induced EBA has been described [17].

Prognosis. The prognosis is very variable. Those patients with a BP-like picture may go into remission. However, patients with mechanobullous disease tend to have disease that is difficult to suppress and is very prolonged.

Differential diagnosis. Cases of EBA are often confused with dominant dystrophic epidermolysis bullosa, BP or porphyria cutanea tarda. Clinically, the mechanobullous epidermolysis bullosa acquisita patients most closely resemble mild dominant dystrophic epidermolysis bullosa, but the lack of family history, late onset and positive direct immunofluorescence distinguish them. The lesions on the hands may mimic porphyria cutanea tarda but this can be ruled out by porphyrin studies. Bullous pemphigoid presents the greatest diagnostic problems, because the direct immunofluorescence may be similar in these conditions. The conditions may be separated by using salt-split skin or toad skin as a substrate for indirect immunofluorescence and the additional finding on electron microscopy of cleavage beneath the basal lamina and the deposition of IgG in the dermis.

Treatment. The rarity of the condition has precluded controlled trials but the mechanobullous condition is characterized by resistance to the usual treatment modalities. A recent systematic review identified only 10 reports of studies on two or more patients (20 adults and 11 children) [1] and much of the information on treatment is anecdotal. Corticosteroids, azathioprine, ciclosporin, other immunosuppressants, vitamin E, gold, dapsone and sulfonamides have been reported to give inconsistent benefit, intravenous immunoglobulins and photopheresis have both had occasional success [2]. Steroids in combination with dapsone or sulfonamides are probably the best first-line treatment, certainly in children [1].

Bullous systemic lupus erythematosus

SYN. VESICULOBULLOUS SYSTEMIC LUPUS ERYTHEMATOSUS

Definition. An autoimmune blistering condition, often transient, that occurs in the setting of systemic lupus erythematosus [1,2]. There is some controversy as to whether the term bullous systemic lupus erythematosus (BSLE) should include all subepidermal autoimmune bullous diseases that arise in patients with systemic lupus erythematosus or should be reserved for those patients with dermal antigens [2,3].

The clinical features, immunopathology and immunogenetics are summarized in Tables 41.5 and 41.6 and a review has been published [2].

Aetiology. BSLE occurs only in patients with systemic lupus erythematosus. It affects young adults, chiefly women, often of African or Hispanic descent, and has been reported in children [1,2]. It is very rare in western Europe, with an incidence of 0.2 per million [3,4] and has been reported from China and Singapore [5,6]. In the USA, there is an association with HLA-DR2 [7].

Pathogenesis. The bullous disease is mediated by autoantibodies to the basement-membrane zone, as demonstrated by positive direct immunofluorescence at the basement-membrane zone. The autoantibodies initially were demonstrated to react with collagen VII and to bind to fibronectin-like domains of the NC1 terminal [1,2]. However, as more cases have been studied it has become obvious that other dermal and epidermal antigens can also be involved, and in some cases no circulating autoantibodies can be detected [3–7]. Basement-membrane autoantibodies have been detected in patients with systemic lupus erythematosus without blisters, although other groups have not confirmed this [3,4,8].

Both IgG and IgA autoantibodies are involved [4,5].

The target antigens and immunogenetic susceptibility are in many patients shared with EBA, and yet in general they differ in clinical presentation. The reasons for these marked differences in the clinical phenotype are intriguing but unexplained.

Pathology. Histologically, the bullae are subepidermal with a neutrophilic infiltrate, occasionally resulting in microabscesses resembling dermatitis herpetiformis.

The findings with immunofluorescence are summarized in Table 41.6. Direct immunofluorescence shows linear bands of IgG, IgA, IgM and C3 in the basement-membrane zone. With indirect immunofluorescence, circulating antibodies, when present, may bind to the basement-membrane zone and to either the dermal or the epidermal aspects of split skin, or may be absent [1,2].

Immunoelectron microscopy studies have demonstrated that circulating IgG autoantibodies bind below the lamina densa [3].

2 Gammon WR, Briggaman RA. Bullous SLE: a phenotypically distinctive but

immunologically heterogeneous bullous disorder. *J Invest Dermatol* 1993; **100**: 28S–34S.
3 Hall RP, Lawley TJ, Smith HR *et al*. Bullous eruption of systemic lupus erythematosus: dramatic response to dapsone therapy. *Ann Intern Med* 1982; **97**: 165–70.

Clinical features. The onset of the disease is usually in patients with established systemic lupus erythematosus. There is widespread blistering, which may include both vesicles and larger tense blisters, and there may also be erythematous macules. All cutaneous sites may be involved. Mucosal lesions are uncommon. In some patients, the eruption is photosensitive. Post-inflammatory hyperpigmentation may occur. The occurrence of the bullous eruption is not related to flares of the systemic disease, and shows clinical similarities to BP and dermatitis herpetiformis. The classical epidermolysis bullosa phenotype of a mechanobullous eruption with milia and scarring (see above) is rare [1,2]. In many patients, the disease is transient.

2 Eckman JA, Mutasim DF. Bullous systemic lupus erythematosus with milia and calcinosis. *Cutis* 2002; **70**: 31–4.

Associated disease. BSLE by definition only occurs in the setting of systemic lupus erythematosus. Vesiculobullous skin eruptions are uncommon but well recognized in patients with systemic lupus erythematosus, occurring in less than 10% of patients with systemic lupus erythematosus, while true BSLE was reported in 1 in 73 British and 1 in 186 Italian patients [1,2]. The classic widespread bullous skin eruption appears to be unrelated to the other systemic manifestations, exacerbations or the severity of the systemic lupus erythematosus [3–6]. There are many reports of other autoimmune diseases: pemphigus, BP, linear IgA disease, dermatitis herpetiformis and reactive bullous diseases, erythema multiforme and toxic epidermal necrolysis in association with systemic lupus erythematosus, but all the subepidermal ones are best regarded as BSLE [7].

7 Yell JA, Wojnarowska F. Bullous skin disease in lupus erythematosus. *Lupus* 1997; **6**: 112–21.

Prognosis. Most patients have a transient eruption. However, patients with the rare mechanobullous and scarring picture have a poorer prognosis.

Differential diagnosis. The presence of blistering in a patient with systemic lupus erythematosus can be caused by photosensitivity, acute lupus or a drug eruption. The histopathology and immunopathology will distinguish BSLE.

Treatment. Some of these patients appear to have responded to steroids used to control their systemic lupus erythematosus. Dapsone has been shown to be very effective in those patients with steroid-resistant blistering [1,2]; methotrexate has also been reported to be helpful [3].

Dermatitis herpetiformis

SYN. DUHRING–BROCQ DISEASE

Definition. Dermatitis herpetiformis (DH) is a rare, intensely pruritic, chronic, recurrent, papulovesicular disease. The eruption is symmetrical and pleomorphic, consisting of erythematous, urticarial, papular, vesicular or bullous lesions (Fig. 41.27). There is an underlying gluten-sensitive enteropathy that may be asymptomatic.

The characteristic clinical and immunopathological features are shown in Tables 41.5 and 41.6.

Aetiology. Dermatitis herpetiformis is a disease of all ages. In Italy and Hungary the disease commonly presents in childhood [1,2], in the UK in young and middle-aged adults, with a slight male preponderance, and in southern Sweden it may present in old age [3]. The incidence is over 3000 per million in Ireland, 200–390 per million in Sweden, 110 per million in Scotland and Finland, and probably less elsewhere in Europe [3]. DH is rare in the Far East.

There is a family history of DH or coeliac disease in 10.5% of patients [4]. The disease has been reported in monozygous twins [5].

All patients have an underlying gluten-sensitive enteropathy, although this may be asymptomatic. Others will

have been investigated for abdominal pain, and may be misdiagnosed. There is an association with exposure to infection with adenovirus, as has been observed in coeliac disease [6].

HLA studies in patients who on clinical and immunological criteria have DH, have shown identical findings to coeliac disease. There is a very strong association with DR3 and DQw2 [7–10].

Pathogenesis. The characteristic finding is deposition of IgA in a granular pattern in the papillary dermis (Fig. 41.28), although IgM, IgG and C3 may be found. The IgA deposits are gluten-dependent, and are slowly cleared from the skin once gluten is removed from the diet [1,2]. The mechanism by which gluten causes the IgA deposition in the skin is still unknown, although non-immunological binding of gliadin to reticulin has been shown [3]. The IgA deposits are often but not exclusively associated with the microfibrils [4,5]. The antigen within normal human skin to which IgA antibodies from DH sera bind is still unknown.

The IgA deposits have been shown to be chemoattractant to neutrophils [6]. C3 has been demonstrated in the papillary dermis of both lesional and perilesional skin. Properdin and factor B have been found and support the suggestion that complement is activated via the alternative pathway [7]. C5 and fibrin are often detected in similar sites [8]. The activated fraction, C5a, is highly chemotactic for neutrophils and may contribute to the inflammatory change at the papillary tip. Lymphocytes also play a part with the neutrophils in initiating an inflammatory cascade (reviewed recently in [9]).

Characterization of the IgA deposits has shown the IgA

to be almost exclusively IgA1 and to be both monomeric and polymeric, with J chains and secretory components present [10–12]. These data suggest that the IgA is derived from mucosa and serum.

In 1967, the link with gluten-sensitive enteropathy (coeliac disease) was established [13]. Further studies showed that the small bowel changes of villous atrophy were secondary to gluten sensitivity and responded to a gluten-free diet [14]. The gluten-sensitive enteropathy is present in all patients, although difficult to demonstrate in some [15]. Patients were found to have antireticulin antibodies and, in addition, antigluten or antigliadin antibodies [15–19]. IgA endomysial antibodies, directed at smooth muscle, are frequently found in DH and coeliac disease and fall with the introduction of a gluten-free diet [20,21].

The most exciting development of recent years has been the recognition that autoantibodies and T-cell reactions to tissue transglutaminases, and in particular transglutaminase 2, are relevant to the pathogenesis of coeliac disease [22]. These antibodies have been demonstrated in DH [23–25]. In addition, it is now clear that the previously recognized antireticulin and endomysial antibodies are associated with these antibodies [26], and require transglutaminase 2 to bind to tissues [27]. The tissue transglutaminases cleave gliadin to antigenic peptides and this may contribute to their role in pathogenesis [28]. There is a difference in autoantibody profile between DH and coeliac disease, in that there are antibodies to epidermal transglutaminases in DH but not coeliac disease [29]. The IgA precipitates in the dermis contain epidermal transglutaminases [29]. However, the precise chain of events leading to IgA deposition in the skin and blistering is still to be unravelled [9].

Pathology. Diagnostic histological changes are best seen in the vicinity of early blisters or in lesions that have not yet blistered. Neutrophils and eosinophils accumulate within the dermal papillae and form microabscesses. The surrounding collagen is degraded, resulting in detachment of the epidermis and a subepidermal vesicle. Multilocular vesicles may coalesce to form blisters; at that stage the cellular infiltrate is mixed and distinction from pemphigoid may be difficult.

The characteristic immunofluorescence findings are shown in Table 41.6 and Fig. 41.28. Direct immunofluorescence is always positive [1]. However, sometimes when there is a high degree of clinical suspicion, serial sections and multiple biopsies may be necessary to confirm the diagnosis. The biopsy (a 3–4-mm punch biopsy is suffi-

cient) should be taken from clinically normal skin. The forearm or buttock is usually suitable. There are granular deposits of IgA in the dermal papillae (Fig. 41.28). There may also be C3 and IgG.

The diagnostic significance of the rare linear granular pattern of IgA deposition at the basement-membrane zone is still unclear [2]. Some patients with this pattern have true DH and others may have autoantibodies to unusual target antigens.

Indirect immunofluorescence is negative for basement-membrane zone or dermal autoantibodies. However, if monkey oesophagus is used, IgA endomysial antibodies may be detected [3].

Immunoblotting studies are negative.

Electron microscopy shows that the blisters are subepidermal and can occur beneath the basal lamina. In the lesions, the basal lamina may be fragmented or lost. However, in adjacent skin, the basal lamina may be thickened and reduplicated. The basal cells show cytolysis, but these changes are probably secondary to the effects of the inflammatory cells [4].

Ultrastructurally on immunoelectron microscopy, the IgA deposits appear to be closely associated with the dermal microfibrillar bundles [5,6]. However, immunogold studies have shown that not all of the IgA is associated with any recognizable structure [6].

Gastrointestinal investigations. All the abnormalities found in coeliac disease may be found in DH [7]. A full blood count may reveal anaemia. The additional signs on the blood film depend on whether it is caused by iron deficiency or folate deficiency. There may also be Howell–Jolly bodies on the film, indicating splenic atrophy [8]. There may be antireticulin antibodies and antigliadin antibodies as well as antiendomysial antibodies. A jejunal biopsy will demonstrate signs of gluten-sensitive enteropathy in almost all cases; these signs may be a raised intraepithelial lymphocyte count or, in more severe cases, a flat biopsy.

Clinical features. DH presents mainly between the ages of 20 and 55 years, but does present both in childhood and old age. The onset may be acute or gradual, and pruritus is usually the first and predominant symptom. Early lesions on the skin are erythematous papules, urticarial wheals or groups of small vesicles often excoriated so rapidly that it may be impossible to find one intact. The vesicles are usually grouped together on plaques of erythema but, rarely, blisters 1–2 cm in diameter occur (Fig. 41.27). This happens more frequently in relapses when suppressive treatment has been discontinued. Papules without blistering are not uncommon and eczematous changes, which may be lichenified, are sometimes seen. Progressive pigmentation of the sites of the skin lesions occurs in some patients.

The distribution of the lesions is characteristic. The extensor aspects of the limbs, especially the knees, just below the point of the elbows, buttocks and the natal cleft, are affected in the majority of patients (Fig. 41.27). The axillary folds, shoulders, trunk, face and scalp are all frequently involved. Oral lesions are common but asymptomatic [1].

Provocation or exacerbation by iodides, either by mouth or by patch test, is not specific for DH and is now considered outmoded as a diagnostic test [2,3]. Skin cleansers containing iodine and iodine-containing preparations must be avoided, as they can exacerbate DH.

There may be a feeling of malaise with the acutely active disease. In addition, constitutional symptoms caused by the gluten-sensitive enteropathy can be present. The patient may experience bouts of abdominal pain, constipation and diarrhoea, and be undernourished. Patients are often tired and lack a feeling of well-being.

Associated diseases. There are often associated autoimmune diseases, particularly thyroid disease, pernicious anaemia and diabetes [1,2]. There is an association with thyroid disease in up to 30% of patients [3]. A variety of organ-specific and non-organ-specific autoantibodies have been detected in patients with DH, notably antithyroid antibodies [4].

Lymphoma is a well-recognized complication of DH as are other malignancies [5–11]. Moreover, the protective role of a gluten-free diet for the lymphomas has been established [11,12].

Differential diagnosis. The diagnosis should be suspected when any persistent pruritic symmetrical eruption resists topical treatment. In view of the pruritus and involvement of the axillary folds and buttocks, many patients are thought to have scabies, but the absence of burrows or of contact cases should help with the diagnosis. The most difficult diagnostic problem is the group of patients with chronic exudative eczema, papular urticaria and chronic prurigo, some of whom may be dapsone-responsive. The histology and the lack of IgA deposition should help to establish the correct diagnosis.

Treatment. The treatment of DH has been reviewed recently [1]. Dapsone is the most widely used treatment. The dosage needed for the average case is 100–200 mg/day but a few may require 400 mg/day. It is wise to start at 25–50 mg/day in an adult and slowly increase to a dosage that keeps the patient comfortable and without significant side effects. Too rapid an increase in the dosage often results in haemolytic anaemia, which does not reach its maximum for a month. A fall in haemoglobin with a low MCV indicates iron deficiency (resulting from intravascular haemolysis) rather than pure haemolytic anaemia. Patients at risk of glucose-6-phosphate dehydrogenase deficiency should be screened prior to treatment. Methaemoglobinaemia is common, reaching a steady state after about 2 weeks, and may cause cyanosis, breathlessness and angina. Hepatitis, the dapsone syndrome (lymphadenopathy and hepatitis) and agranulocytosis are serious, usually early complications. Motor neuropathy may occur. Most complications occur in the first 3 months. Sulfapyridine 1.5 g/day is an alternative in patients who cannot tolerate dapsone; however, a few may not be controlled even on 4 g/day [2,3]. Side effects include nausea, lethargy, haemolytic anaemia and bone marrow suppression. The long-acting sulfonamide, sulfamethoxypyridazine, is an alternative treatment; usually 0.5–1.5 g/day is sufficient to control DH, the incidence of side effects increasing with dosage above 1 g/day [4]. Although systemic corticosteroids are in the main ineffective and not indicated, topical steroids may be helpful in lessening symptoms. Heparin, with or without tetracyclines in combination with nicotinamide (niacinamide), has been advocated for patients who cannot tolerate dapsone or sulfonamides [5,6].

A gluten-free diet is the treatment of choice in the long term. It has been shown not only to improve the enteropathy, but also to allow discontinuation of drug therapy. The patients gain weight, lose their abdominal symptoms and often feel generally much better. In order to obtain strict adherence to the diet, the patient needs to be highly motivated, intelligent and leading a regular life. Sometimes it may be wise to postpone starting the diet until a more settled period. Wheat must be avoided, but oats are not damaging [7,8]. Unlike patients with coeliac disease, ingestion of small quantities of gluten does not always precipitate symptoms. The help of a dietitian and the Coeliac Society are essential. It is usually many months and sometimes years before patients are able to reduce their dapsone requirements. Often dapsone can be discontinued altogether after 2–3 years on a strict gluten-free diet, but some patients take much longer [9]. Reintroduction of gluten in selected patients produced a relapse in skin lesions [10,11]. After 5–10 years the gluten-free diet protects patients from lymphoma, and this is an additional reason to recommend it [12].

12 Lewis HM, Renaula TL, Garioch JJ *et al*. Protective effect of gluten-free diet against development of lymphoma in dermatitis herpetiformis. *Br J Dermatol* 1996; **135**: 363–7.

Prognosis. The disease runs a very long course with exacerbations and remissions [1]. Ten per cent of patients experience remissions. Acute infection and even emotional disturbances may precipitate an attack. A strict gluten-free diet will result in remission of the skin and the gut.

Interestingly, patients with DH on a normal diet or a gluten-free diet do not have a decreased life expectancy, despite the increase in lymphoma, and there may be a reduction in ischaemic heart disease [2–5].

Chapter 42

Lichen Planus and Lichenoid Disorders

S.M. Breathnach & M.M. Black

Definition of lichenoid eruptions

The term 'lichenoid' is used by clinicians to describe a flat-topped, shiny, papular eruption resembling lichen planus (LP), or by histopathologists to describe a type of tissue reaction consisting principally of basal cell liquefaction and a band-like inflammatory cell infiltrate in the papillary dermis [1]. The prototype of all lichenoid eruptions is LP itself but a number of other diseases may develop a lichenoid tissue reaction [2,3].

Pathogenesis

LP is thought to be an immunologically mediated disorder, not least because a lichenoid eruption may be seen as part of graft-versus-host disease (see below). Cloned murine autoreactive T cells produce a lichenoid reaction in recipient animals following injection [1]. T cells, both $CD4^+$ and $CD8^+$, accumulate in the dermis, while $CD8^+$ T cells infiltrate the epidermis, in LP lesions; it has been proposed that $CD8^+$ cytotoxic T cells recognize an antigen (currently unknown) associated with major histocompatibility complex (MHC) class I on lesional keratinocytes and lyse them [2–6]. T cells and keratinocytes express interferon-γ (IFN-γ) and interleukin-6 (IL-6) [2], and T cells also express lymphocyte function associated antigen-1 (LFA-1) [4] and secrete IFN-γ *in vitro* [7]. Mononuclear cells infiltrating the skin, the majority of which are $CD8^+$, as well as basal keratinocytes, express tumour necrosis factor-α (TNF-α) and TNF-R1 [7]. Activated T cells secreting IFN-γ induce keratinocyte expression of human leukocyte antigen (HLA)-DR [8], and the presence of epidermotropic T cells correlates with that of HLA-DR expressing keratinocytes and Langerhans' cells [9]. It has been proposed that keratinocyte cytokines up-regulate expression of cell surface adhesion molecules on, and migration by, T cells [10–12]. $CD1a^+$ Langerhans' cells and factor $XIIIa^+$ cells are increased in LP [4,13,14] and may be involved in antigen presentation to T cells. Vascular endothelial expression of the adhesion molecules intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1) is also elevated [4]. Infiltrating $CD8^+$ T cells, as well as keratinocytes, express a variety of different chemokines [15–17]. RANTES (regulated upon activation, normal T-cell expressed and secreted) secreted by T cells may trigger mast cell degranulation with consequent release of TNF-α, which in turn up-regulates lesional T-cell RANTES secretion; such mechanisms may contribute to chronicity of T-cell infiltration and clinical disease [18]. Mast cell degranulation [19], and T-cell secretion of matrix metalloprotein 9 [20], may contribute to basement membrane disruption, enabling migration of $CD8^+$ T cells into the epithelium.

There may be a genetic susceptibility to idiopathic LP. Familial cases are reported [21–26], and a familial incidence of 10.7% was quoted in one series [24]. LP has also been reported in monozygotic twins [27,28]. An association with HLA-3 and HLA-5 has been documented [29],

although others found no such association [30,31], as have associations with HLA-B7 [21], HLA-28 in Jews with LP and carbohydrate intolerance [32], HLA-DR1 [33] and HLA-DR10 [34]. Genetic heterogeneity in LP has led to a suggestion that idiopathic cutaneous, and purely mucosal, LP may have a different pathogenesis [35]. Anxiety and depression may be risk factors for the development of LP [36].

An epidemiological association of LP with hepatitis C virus (HCV) infection has been recorded, especially in patients from Italy, certain parts of France, Spain, Japan and Pakistan [37–43], and HCV RNA has been isolated from lesional skin in patients with LP and chronic HCV infection [44,45]. Thus, an HCV-related product has been postulated as a possible antigen in LP. However, no association between LP and HCV infection has been noted in patients from Northern Europe including the UK, the USA or Nepal [46–50]. It has been suggested that the observed geographical differences with regard to HCV infection and LP could be related to immunogenetic factors such as the HLA-DR6 allele, significantly expressed in Italian patients with oral LP and HCV infection [37,38].

Another putative antigen in oral LP is mercury in dental amalgam. Eighty-seven per cent to 97% of patients with oral LP associated with dental amalgam fillings benefit from amalgam removal, but only 28–39% have positive patch test reactions to amalgam or inorganic mercury [51–54]. Patients who improve following removal of amalgam, but in whom patch testing is negative, are presumed to have an irritant reaction to amalgam. A recent study reported that the presence of amalgam or of gold is not associated with an increased risk of oral LP, but corrosion of amalgams, and a 'galvanic effect' from dissimilar dental materials in continuous contact with the mucosa (bimetallism) are associated with an elevated risk of oral LP [55].

Incidence

LP has a worldwide distribution with no overt racial predisposition. LP represented about 1.2% of all new patients in London [1] and Turin [2], 0.9% in Copenhagen [3] and 0.38% in India [4]. Hypertrophic cases were reportedly common in Nigeria [5]. Both oral and cutaneous LP have rarely been reported in childhood [3,6–12]. Familial cases are recorded (see above).

Histology [1,2]

The earliest finding is an increase in epidermal Langerhans' cells [1], associated with a superficial perivascular infiltrate of lymphocytes and histiocytes, impinging on the dermal–epidermal junction (DEJ). Mild spongiosis is followed by vacuolar alteration and clefting along the DEJ, with accumulation of necrotic keratinocytes (colloid bodies) [3].

The characteristic histological changes are best seen in biopsies of fully developed LP papules [4] (Fig. 42.1). The centre of the papule shows irregular acanthosis of the epidermis, irregular thickening of the granular layer, and compact hyperkeratosis. The mid-epidermal cells appear larger, flatter and paler than usual [4]. In oral LP, epithelial proliferation is increased [5]. Parakeratosis is rarely found in idiopathic LP, in contrast to some drug-induced lichenoid tissue reactions. A focal increase in thickness of the granular layer and infiltrate corresponds to the presence of Wickham's striae [6]. Degenerating basal epidermal cells are transformed into *colloid bodies* (15–20 μm diameter) which appear singly or in clumps [7–9]. The rete ridges may appear flattened or effaced (*'saw-tooth' appearance*), and focal separation from the dermis may lead to

Fig. 42.3 Lichen planus. Photomicrograph of follicular lesion. Scanning view. H&E, × 20. (Courtesy of St John's Institute of Dermatology, London, UK.)

Max Joseph spaces (Fig. 42.2). In older or hypertrophic lesions, the number of colloid bodies is considerably reduced. In 'active' LP, a *band-like infiltrate* of lymphocytes and histiocytes, rarely admixed with plasma cells [10,11], obliterates the DEJ. Epidermal melanocytes are absent or considerably decreased in number [4], while *pigmentary incontinence* with dermal melanophages is characteristic. When the disease is becoming inactive, the infiltrate, with melanophages, becomes sparser and arranged around papillary blood vessels, which may show ectasia and surrounding fibroplasia.

In hypertrophic LP, the epidermis may show a pseudoepitheliomatous appearance with extreme irregular acanthosis. Follicles may be expanded and at times have a 'cyst-like' appearance. The infiltrate may not appear very 'band-like', but serial sections will usually show foci of basal cell liquefaction and colloid-body formation, often around the follicular epithelium. Long-standing cases usually demonstrate coexistent dermal fibrosis adjacent to the inflammatory changes.

In atrophic LP, the epidermis may be greatly thinned almost to the level of the granular layer; although relative compact hyperkeratosis remains. The rete ridges are usually completely effaced with relatively few colloid bodies. The papillary dermis shows fibrosis and loss of elastica.

In follicular lesions (Figs 42.3 & 42.4), an infiltrate extends around, and may permeate, the base of the hair follicle epithelium, with follicular keratin plugging [12,13].

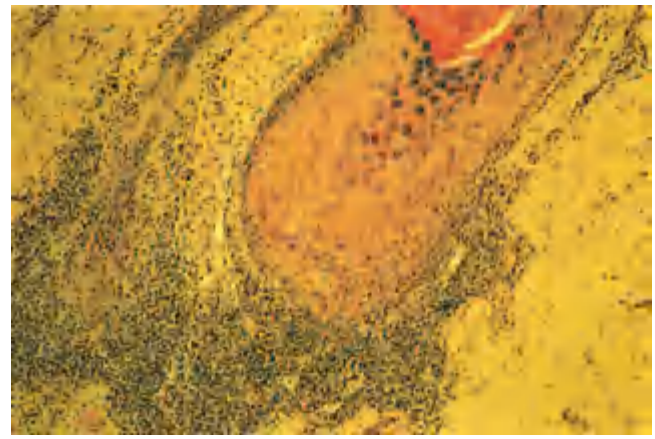

Fig. 42.4 Lichen planus. Photomicrograph of follicular lesion. Higher power, H&E, × 40. (Courtesy of St John's Institute of Dermatology, London, UK.)

In mucosal LP, the epithelium is usually thinned with parakeratosis, although both types of keratinization may be seen [14]; the epithelium may resemble epidermis from skin, plasma cells may be prominent in the 'band-like' infiltrate, and colloid bodies are fewer than in typical cutaneous papular LP. The erythematous subtype of oral LP is associated with increased cell proliferation compared

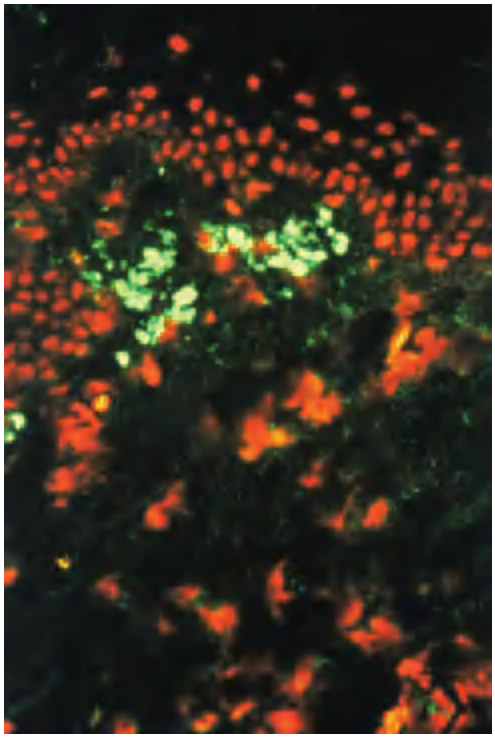

Fig. 42.5 Lichen planus. Photomicrograph of direct immunofluorescence. Bright fluorescence of cytoid bodies with anti-IgM × 100. (Courtesy of St John's Institute of Dermatology, London, UK.)

with the reticular form [15]. Moderate or severe epithelial dysplasia on oral biopsy should probably be regarded as an increased risk for subsequent cancer development [16].

Bullous LP is rare; blister formation takes place predominantly between the basal lamina and cytomembranes of basal keratinocytes (i.e. intrabasal) [7], such that there is a wide separation between the epidermis and infiltrate.

Direct immunofluorescence (IMF) shows globular deposits of IgM (Fig. 42.5), and occasionally IgG and IgA, representing apoptotic keratinocytes [17,18], around the DEJ and lower epidermis, with fibrin deposition at the region of the DEJ. Direct IMF studies may be useful in differentiating LP from lupus erythematosus or LP pemphigoides [19,20], and can be carried out on routine histological material [21].

A clinicopathological study of lichenoid dermatitis concluded that it was usually possible to provide a specific diagnosis [22]. Occasionally, lichenoid dermatitis can become generalized and clinically mimic an exfoliative dermatitis; such eruptions are usually triggered by drugs [23].

Benign lichenoid keratoses (BLKs) are usually solitary but may be multiple, and show characteristic lichenoid infiltrates of lymphocytes, occasional parakeratosis, and apoptotic bodies in the epidermis without nuclear atypia of keratinocytes [24]; rarely, the histology may show features of mycosis fungoides [25]. Malignant melanoma may be associated with a lichenoid tissue reaction [26], and melanoma *in situ* with lichenoid regression may mimic a BLK histologically [27].

Fig. 42.7 Lichen planus papules showing Koebner effect. (Courtesy of St John's Institute of Dermatology, London, UK.)

Clinical features

LP is characterized by shiny, violaceous, flat-topped polygonal papules which retain the skin lines, and which vary in size from pinpoint to a centimetre or more across; they may be closely aggregated or widely dispersed. The size of the papules is often fairly uniform in an individual patient, but minute and large papules coexist in some cases. White lines, known as Wickham's striae [1] (Fig. 42.6), may traverse the surface of the papules. Papules can remain discrete or appear in groups, in lines or in circles. Linear lesions often appear along scratch marks or in scars (Koebner phenomenon) (Fig. 42.7), while annular lesions may be formed either by groups of papules arranged in rings or by single, large papules clearing in the centre and leaving an active margin. Annular lesions are especially common on the penis (Fig. 42.8) and rarely may be the predominant type of lesion present, leading to atrophy later [2].

A variant in which groups of 'spiny' lesions resembling keratosis pilaris develop around hair follicles (lichen planopilaris) (Fig. 42.9) is not uncommon. Lichen planopilaris more often forms only a minor feature of the disease, but occasionally this type of lesion may predominate.

Although a few cases evolve rapidly and clear within a few weeks, the onset is usually insidious. In most cases, the papules eventually flatten after a few months, often to be replaced by an area of pigmentation that retains the shape of the papule and persists for months or years.

Fig. 42.10 Lichen planus. Classical eruption on volar aspect of wrist. (Courtesy of St John's Institute of Dermatology, London, UK.)

There may be a gradual change in colour from pink to blue to black. The residual pigmentation may be intense, especially in dark-skinned races, or almost imperceptible in fair-skinned individuals. New papules may form while others are clearing. Some papules persist much longer, enlarge and thicken, and develop a roughened surface with a prominent violaceous hue, so-called hypertrophic LP. Such lesions may resolve with atrophy or scarring. More warty lesions are seen occasionally. Areas of pigment loss are described in black South Africans [3]. Colocalization of LP and vitiligo has been reported [4].

LP can affect any part of the body surface, but is most often seen on the volar aspect of the wrists (Fig. 42.10), the lumbar region and around the ankles. The ankles and shins are the commonest sites for hypertrophic lesions. When the palms and soles are affected, the lesions tend to be firm and rough with a yellowish hue (Fig. 42.11) [5,6]. A rare erosive flexural variant of LP has been described [7]. Isolated lesions of LP have been reported to involve one or

Fig. 42.11 Lichen planus of palm showing hyperkeratosis and a yellow colour. (Courtesy of St John's Institute of Dermatology, London, UK.)

both eyelids [8,9] or the lips [10–12]. Milia have been recorded in LP [13], and LP was confined to a radiation therapy site in one patient [14].

Mucous membrane lesions are very common, occurring in 30–70% of cases, and may be present without evidence of skin lesions. They are, however, much less common in black people. The buccal mucosa and tongue are most often involved, but lesions may be found around the anus, on the genitalia, in the larynx and, very rarely, on the tympanic membrane of the ears or even in the oesophagus. White streaks, often forming a lacework, on the buccal mucosa are highly characteristic (Fig. 42.12). They may be seen on the inner surface of the cheeks, on the gum margins or on the lips. On the tongue, the lesions are usually in the form of fixed, white plaques, often slightly depressed below the surrounding normal mucous membrane, especially on the upper surface and edges (Fig. 42.13). Ulcerative lesions in the mouth are uncommon, but may be the site of epitheliomatous transformation (Fig. 42.14). There may be striking pigmentation of oral LP in darkly pigmented races [15]. Diabetes is a possible associated disease of oral LP [16,17], and candidiasis may coexist with LP in some patients.

Itching is a fairly consistent feature in LP and ranges from occasional mild irritation to more or less continuous, severe itching, which interferes with sleep and makes life almost intolerable; occasionally, itching is completely

absent. Hypertrophic lesions usually itch severely. Paradoxically, there is seldom evidence of scratching, as the patient rubs, rather than scratches, to gain relief. Itching at sites without visible skin lesions can occur. Burning and stinging are less common complaints. In the mouth, the patient may complain of discomfort, stinging or pain; ulcerated lesions are especially painful. Great discomfort may be caused by hot foods and drinks.

Variants

LP principally involving mucous membranes

Lesions confined to the mouth, or with minimal accompanying skin involvement, are not uncommon [1–5], and account for about 15% of all cases [1]. The prevalence of oral LP was 1.5% among the villagers of Kerala in southern India [6], possibly related to chewing tobacco, and ranges between 0.5% and 2.2% of the population in other epidemiological studies [2,7]. The lesions do not differ from those found in connection with skin lesions, but, being confined to the mouth, may lead to great difficulty in diagnosis. They are often referred first to a dental surgeon. Distinct clinical subtypes such as reticular, atrophic, hypertrophic and erosive forms are well recognized; more than one type may be present [2]. On the tongue and

buccal mucosa, they are most likely to be mistaken for leukoplakia and on the gum margin for gingivitis or chronic candidiasis, or the latter may coexist. Other conditions that must be excluded are 'smoker's patches', which characteristically involve the palate, and white-sponge naevi, in which the mucous membrane is thickened, irregularly folded and feels soft to the touch. These occur mainly on the floor of the mouth and histologically many of the prickle cells are vacuolated. It is important to bear in mind the possibility of a lichenoid drug reaction in patients with oral lichenoid changes (see below). Oral lichenoid reactions may be asymmetrical on the buccal mucosa and occur adjacent to dental amalgam fillings. If patch testing reveals mercury allergy, changing to another type of filling may prove beneficial [8–13].

Very occasionally, LP lesions extend to the larynx or oesophagus [14–18]. Oesophageal LP may result in dysphagia and the formation of benign strictures.

In young men, the lesions are sometimes restricted to the genitalia and/or the mouth [19,20]. Genital lesions, which are usually characteristic, may be present on the penile shaft (see Fig. 42.8), glans penis, prepuce or scrotum. Ulceration is very unlikely, and syphilis can usually be excluded without difficulty; the presence of buccal mucosal lesions will usually confirm the diagnosis. Circumcision may be helpful [19].

Lesions on the female genitalia are fairly common [21–27]; they may occur alone, be combined with lesions in the mouth only, or be part of widespread involvement. The clinical presentation of LP of the vulva spans a spectrum from subtle, fine, reticulate papules to severe erosive disease accompanied by dyspareunia, scarring and loss of the normal vulvar architecture. The condition should be distinguished from lichen sclerosus or leukoplakia, but this may be difficult when there is coexisting atrophy or vaginal stenosis. The association of erosive LP of the vulva and vagina with desquamative gingivitis has been termed the *vulvovaginal–gingival syndrome* [20,22] (Fig. 42.15). Coexisting vulval lichen sclerosus and lichenoid oral lesions have been described [28].

Hypertrophic LP

This usually develops during the course of a subacute attack, but occasionally only hypertrophic or warty lesions are found. They most often occur on the lower limbs, especially around the ankles; venous stasis has been put forwards as an explanation (Fig. 42.16). The development of hypertrophic lesions greatly lengthens the course of the disease, as they may persist for many years. When such lesions eventually clear, an area of pigmentation and scarring may remain and there is often some degree of atrophy. They must be distinguished from lichen simplex chronicus and lichen amyloidosus (papular). Multiple cutaneous horns overlying hypertrophic LP are recorded [1], as are keratoacanthoma [2,3] and malignant transformation [4] arising in hypertrophic LP, as well as metastatic squamous cell cancer [5].

Follicular LP

SYN. LICHEN PLANOPILARIS

Follicular lesions usually appear during the course of typical LP, but occasionally they predominate and diagnosis may then be difficult. Presentation with alopecia of the trunk is recorded [1]. Follicular lesions occurring in the scalp are accompanied by some scaling and are likely to lead to a scarring alopecia (Fig. 42.17). Very rarely, the scalp alone is involved. The clinical, histological and IMF overlap between the so-called Graham Little–Piccardi–Lassueur syndrome and LP with follicular involvement (lichen planopilaris) has recently shown them both to be variants of LP [2–5]. Follicular LP must be distinguished by biopsy from keratosis pilaris, Darier's disease, follicular mucinosis, lichen scrofulosorum and, in the scalp, from lupus erythematosus.

Linear LP

Linear lesions as a Koebner effect are frequently found in LP. Isolated linear lesions, usually made up of small papules in close apposition, sometimes becoming confluent, are rare [1,2]; they are more common in childhood [3]. Linear LP lesions are usually only a few centimetres in length, but long, narrow linear lesions extending the whole length of a limb may occur. Such cases may overlap with epidermal naevi, and the term lichenoid epidermal naevus has been introduced [3]. Multiple linear LP lesions following the lines of Blaschko have been reported [4,5], and multiple linear LP was documented in a human immunodeficiency virus (HIV) patient [6]. Segmental LP was colocalized with vitiligo in one case [7]. Zosteriform LP has been described [8–11] (Fig. 42.18). The histology of linear or zosteriform LP is characteristic, and enables distinction from other linear dermatoses such as lichen striatus, linear naevi and linear psoriasis.

Actinic LP

SYN. LICHEN PLANUS SUBTROPICUS

'Actinic' or (sub)tropical LP generally occurs in children or young adults with dark skin living in tropical countries; virtually all cases originate from the Middle East, East Africa or India [1–4]. Lesions occur on exposed skin (usually the face) as well-defined annular or discoid patches, which have a deeply hyperpigmented centre surrounded by a striking hypopigmented zone (Fig. 42.19). Erythematous actinic LP has been associated with oral erosive LP and chronic active hepatitis [5]. Sunlight exposure appears to be central to the pathogenesis of actinic LP [6], although evidence for photo-induction of lesions in actinic LP is still lacking [7]. Actinic LP may mimic melasma [8]. There is a histological spectrum comprising a form with features of classical idiopathic LP; an intermediate form (lichenoid melanodermatitis) with foci of spongiosis and parakeratosis; and a more overtly eczematous type [9]; all share striking pigmentary incontinence. Some of these 'hybrids' of actinic LP may not be mere variants of LP. Actinic LP has been treated with acitretin and topical corticosteroids [10].

LP pigmentosus [1–3]

This is a pigmentary disorder seen in India or in the Middle East, which may or may not be associated with typical LP papules. The macular hyperpigmentation involves chiefly the face, neck and upper limbs, although it can be more widespread, and varies from slate grey to brownish black; it is mostly diffuse, but reticular, blotchy and perifollicular forms are seen [3]. The duration at presentation ranged from 2 months to 21 years in one series [3]. Occasionally, there is a striking predominance of lesions at intertriginous sites, especially the axillae [4]. The mucous membranes, palms and soles are usually not involved, but involvement of mucous membranes has been observed [5]. LP pigmentosus has been anecdotally reported in association with acrokeratosis of Bazex [6].

Annular LP

Although small annular lesions are common in LP, cases showing a few large annular lesions only are unusual. They may be widely scattered, and usually have a very narrow rim of activity and a depressed, slightly atrophic, centre (Fig. 42.20). Much less often, the margin is wide, and the central area is quite small. Annular lesions are characteristically found on the penis (see Fig. 42.8), sometimes associated with lesions on the buccal mucosa. The differential diagnosis includes granuloma annulare.

Atrophic LP

Lesions tend to be few in number; the atrophy may be the result of faded annular lesions [1], or resolved hypertrophic lesions on the lower legs especially. The histology

is likely to be non-specific, but allows lichen sclerosus or guttate morphoea to be excluded.

REFERENCE

1 Mseddi M, Bouassida S, Marrakchi S *et al*. Annular atrophic lichen planus. *Dermatology* 2003; **207**: 208–9.

Guttate LP

Lesions are widely scattered and remain discrete, may be all small (1–2 mm across), or larger (up to 1 cm) (Fig. 42.21), and individual lesions seldom become chronic. Guttate psoriasis must be differentiated.

Acute and subacute LP with confluence of lesions

In these forms, small lesions are widely distributed; where they become confluent, eczema may be simulated. Colour changes may be marked, with individual lesions initially red but progressing rapidly to black as they fade. Successive crops may occur, such that the total time for clearance may be little different from other forms; a small minority clear in under 3 months. Differential diagnosis includes pityriasis rosea in the earliest phase, and eczema later; drug-induced lichenoid eruptions may present in this fashion.

LP of the palms and soles

Although lesions on the volar aspect of the wrists or at the ankles occur in more than 50% of cases of LP, lesions on the adjacent palms and soles are less common, lack the characteristic shape and colour of lesions elsewhere, and are firm to the touch and yellow in hue [1,2] (see Fig. 42.11). They may be broadly sheeted or show up as punctate keratoses [3]. Vesicle-like papules are recorded [4]. Itching may be absent. When such changes occur in isolation, diagnosis is very difficult; syphilis, psoriasis, callosities and warts must be exluded.

A rare, very chronic form of LP involves large, painful indolent ulcers on the sole of one or both feet [5], with gradual permanent loss of toenails; there may be secondary webbing of the toes [6]. The sole may resemble lichenified dermatitis or psoriasis rather than LP before the ulcers appear. The onset is insidious and there may be no other evidence of LP, although cicatricial alopecia has been associated in some cases.

Complications

Hair. Alopecia is uncommon in LP, but most often occurs in small areas on the scalp, producing patches of atrophic cicatricial alopecia [1–5] (see Fig. 42.17). It results from follicular destruction by the inflammatory infiltrate, with scarring. Areas of alopecia may continue to appear, or to extend, for months after the skin lesions have faded. The final result is one of pseudopelade [2,5]; this is probably best considered as a clinical entity due to a number of independent conditions, of which LP is only one. Lichen planopilaris is more common in women and about half will develop involvement of glabrous skin, mucous membranes or nails [1]; it may occur in children [3]. Tumid forms of LP follicularis have been described in which clusters of milium cysts and comedones develop [6]. LP pilaris has been reported in association with dermatitis herpetiformis [7].

Nails. Nail involvement occurs in up to 10% of cases, but is usually a minor feature of the disease [8,9]. The majority of cases present during the fifth or sixth decades; long-term permanent damage to the nails is rare [10]. Fingernails are more frequently affected than toenails [10], with initial involvement of two or three fingernails before subsequent spreading to the remaining digits. The most common changes are exaggeration of the longitudinal lines and linear depressions (Fig. 42.22), due to slight thinning of the nail plate. These changes usually occur in the context of severe generalized LP, although skin lesions may not be

Fig. 42.22 Lichen planus of thumbnail showing thinning of nail plate and longitudinal lines. (Courtesy of St John's Institute of Dermatology, London, UK.)

seen in the vicinity of the affected nail. Elevated ridges may be seen on the nail [9]. Adhesion between the epidermis of the dorsal nail fold and the nail bed may cause partial destruction of the nail (pterygium unguis) (Fig. 42.23). Rarely, the nail is completely shed; there is usually clinical evidence of LP at the base of the nail before shedding. Nails may partially regrow or be permanently lost (Fig. 42.24); the nails of the great toes are the ones most often affected.

LP has been shown to cause childhood idiopathic atrophy of the nails [11]. LP of the nails in childhood is rare [12], but may overlap with the condition of twenty nail dystrophy of childhood (idiopathic trachyonychia); the exact relationship is unclear [13–18]. The rare variant of LP that causes ulceration of the soles is often accompanied by permanent destruction of several toenails. LP of the nail bed may give rise to longitudinal melanonychia [19], hyperpigmentation, subungual hyperkeratosis or onycholysis [9], or changes mimicking the yellow nail syndrome [20,21].

Mucous membranes. Squamous cell cancer developing on mouth lesions is uncommon, but is a potential danger, especially with ulcerated lesions [21–30], although the incidence varies greatly in different series. Lesions may occur on the lip (Fig. 42.25), the buccal mucosa or the gum margin. Squamous cell cancer arising on LP cutaneous

lesions [31] and anogenital lesions [32,33] is definitely a rare phenomenon. Cicatricial conjunctivitis [34] and lacrimal canalicular obstruction are recorded [35].

Associated conditions

Idiopathic LP has been reported in association with diseases of altered or disturbed immunity, including ulcerative colitis [1–4], alopecia areata [2,4,5], vitiligo [4], dermatomyositis [6], morphoea and lichen sclerosus [7], systemic lupus erythematosus [8,9], pemphigus [8] and paraneoplastic pemphigus [10,11]. In addition, LP has been observed in association with thymoma [5,8,12,13], myasthenia gravis [3,4,13], hypogammaglobulinaemia [5,14] primary biliary cirrhosis [15–17], especially in those treated with penicillamine, and primary sclerosing cholangitis [18]. The literature with regard to LP and HCV infection is reviewed in the section on pathogenesis above. In Italy, possibly because of a higher prevalence of hepatitis B virus (HBV) and HCV infection, LP patients seem more prone to develop liver disease including chronic active hepatitis [19–23]. A high prevalence of anticardiolipin antibodies has been documented in patients with HCV-associated oral LP [24]. Elsewhere, the association between LP and chronic active hepatitis or primary biliary cirrhosis is unusual and probably coincidental [25–27]. Overall, the majority of patients with LP live to old age, despite an association with autoimmunity [28].

LP has also been associated with diabetes mellitus [29]. Anecdotally, LP has occurred in patients with Castleman's tumour (giant lymph-node hyperplasia) [30] or with generalized lichen amyloidosus [31]. LP has been described in certain tattoo reactions, particularly in those areas where there is coexisting mercury hypersensitivity to the injected dye [32,33].

Differential diagnosis

Typical cases of LP need be distinguished only from lichenoid eruptions induced by drugs or colour developer. Less typical cases of LP may be mistaken for plane warts, eczematous eruptions with lichenification from scratching, pityriasis rosea, lichen simplex chronicus [1] and other lichenoid eruptions such as papular lichen amyloidosus. Occasional cases of LP without itching must be distinguished from secondary syphilis.

The differential diagnosis of the special variants has already been mentioned; in case of doubt, a biopsy should establish the diagnosis. Although erythema dyschromicum perstans (ashy dermatosis) has a characteristic clinical appearance, it has been regarded as simply a macular variant of LP (LP pigmentosus) [2,3].

Prognosis [4–8]

Occasional cases clear in a few weeks, but skin lesions more usually subside within 9 months in about 50% of cases, and in 85% have cleared within 18 months, unless treated with systemic corticosteroids or potent topical steroids. Itching disappears first, then papules flatten, to be replaced by a corresponding area of post-inflammatory hyperpigmentation.

If hypertrophic patches develop, they are likely to persist for many more months, and occasionally for 20 years or more. The development of large, annular lesions is also a poor prognostic sign. Hair fall is usually permanent. Mucous membrane lesions clear more slowly than those on the skin and may remain visible for years after all evidence of the skin lesions has cleared [8]. Only 13% of patients with oral LP under follow-up in a large series went into remission [9], although mucous membrane lesions in Indian people were reported to be short-lived and without a tendency to malignancy [10]. About one case in five relapses, and frequent attacks occur in a small minority of cases.

Treatment

A large number of different forms of medication have been advocated, without adequate controlled trials [1]. Symptomatic treatment is usually sufficient, and largely consists of the use of the fluorinated topical steroid creams and ointments. These should be of the 'potent' variety (e.g. fluocinonide 0.05%, clobetasol proprionate 0.05%) to have any real chance of being effective. They are recommended for use for comparatively small areas, but in a diluted form (e.g. 1 : 4 in white soft paraffin) can cover much larger areas. Oral antihistamines such as promethazine hydrochloride, trimeprazine tartrate, brompheniramine maleate or hydroxyzine hydrochloride may be helpful in counteracting pruritus. If hypertrophic lesions form, they may be treated by using occlusive dressings of tar or flurandrenolone tape, or by the use of topical steroid preparations under polythene occlusion. Occasionally, intralesional injections of a suitable steroid preparation may be of great value. Skin grafting has been used for ulcerative lesions on the soles [2]. Topical calcipotriol is of limited use [3].

Systemic corticosteroids, in the form of adrenocorticotrophic hormone (ACTH) or tetracosactrin (Synacthen®), or prednisolone at 15–20 mg daily for about 6 weeks and thereafter gradually reduced, may be of great value in treating the 5% of severe cases with marked irritation, ulcerative mucous membrane lesions, or progressive nail destruction or alopecia [4]. Such doses are sufficient to retard growth in children [5]. Some relapse is liable to occur on discontinuation of systemic steroids, but the disease is self-limiting and corticosteroid therapy eases the patient through the worst part of its course.

Other agents used in treating severe cutaneous and erosive LP have included acitretin [6], itraconazole [7], metronidazole [8–10], low-molecular-weight heparin (enoxaparin) [11,12], narrow-band ultraviolet B phototherapy [13], oral or bath photochemotherapy with psoralen and UVA (PUVA) [14–16], Re-PUVA (retinoids with PUVA; this combination, however, has anecdotally induced dramatic hyperpigmentation) [17], cyclophosphamide [18], azathioprine [19–21], methotrexate [22], recombinant IFN-α-2b [23], basiliximab [24] and systemic ciclosporin (cyclosporin) [25–27]. Topical and systemic ciclosporin have been used to treat ulcerative LP of the feet [28,29]. Systemic ciclosporin [30,31] and thalidomide [32,33] have been helpful in management of lichen planopilaris of the scalp.

Mucous membranes. Treatment of oral lesions has been reviewed [34,35]. Topical lidocaine (lignocaine) gel or diphenhydramine may alleviate discomfort, and topical tetracycline may be useful [36]. Topical corticosteroids, such as triamcinolone in Orabase®, clobetasol propionate as an ointment or a paste [37–41], corticosteroid lozenges (Corlan®), betamethasone (Betnesol®) mouthwashes 0.5 mg three to four times daily [41], or fluticasone propionate spray [41], are often beneficial. Vaginal hydrocortisone suppositories have been advocated [42,43]. The use of silastic prosthetic devices to enhance the delivery of topical corticosteroids to mucosal surfaces (e.g. vagina and oral) has been documented [44]. Intralesional injections may be used but are painful [45]. Reactivation of human papillomavirus may occur at genital sites with topical steroids [46]. Extensive ulcerative lesions should be treated with systemic steroid preparations, but the starting dose will need to be higher than for treatment of skin lesions.

Initial reports of the efficacy of griseofulvin [47] have not stood the test of time [48,49]. Dapsone [50], hydroxychloroquine [51], retinoids, either topical in the form of retinaldehyde [52], isotretinoin gel (0.1%) [53], or tazarotene [54], or systemic as with etretinate [55], isotretinoin [56] or acitretin [57], and thalidomide [58], have all had their advocates. Topical ciclosporin for chronic mucosal LP has been of variable benefit and is expensive [59–63]. The heparinoid sulodexide given systemically was judged as effective as topical ciclosporin [64].

Oral ciclosporin can be effective [65]. There has been a spate of recent papers on the merits of topical tacrolimus in oral, genital and perianal mucous membrane LP [66–74]. Carbon dioxide and Nd : Yag laser therapy [35], as well as the 308-nm UVB excimer laser [75], have been utilized in the treatment of oral LP. Surgical excision of persistent ulcers has been recommended [76], and malignancy demands immediate surgery combined with radiotherapy.

'Mixed' LP/discoid lupus erythematosus disease patterns

Discoid lupus erythematosus (DLE) and LP are usually considered as distinct entities with characteristic clinical, histopathological and immunopathological features, with basement membrane deposition of IgG in DLE [1,2]. However, similarities between LP and DLE have been noted [3]. In addition, there have been several reports of patients showing overlapping features of both disorders [4–11]. Chronic atrophic DLE-like lesions on the head, neck and upper trunk may accompany reticular white lesions in the oral cavity, and combinations of lichenoid or verrucous lesions are seen. Eyelid involvement is recorded [12]. The association of extensive generalized LP with subacute cutaneous DLE has been documented [13]. Both ciclosporin [13] and acitretin [14] can be of benefit in treating LP/DLE overlap syndrome.

Bullous LP and LP pemphigoides

Lichen ruber pemphigoides was first described by Kaposi in 1892 [1]. Bullous LP and LP pemphigoides were in the past differentiated solely on clinical and histological criteria [2], but can now be differentiated using IMF procedures and immunoelectronmicroscopy [3,4]. In bullous LP, blisters arise only on or near the lesions of LP, as a result of severe liquefaction degeneration of the basal cell layer [5]. Histologically there is subepidermal bulla formation with typical changes of LP, and direct and indirect IMF is negative [3]. The eruption of is usually only of short duration [3].

In LP pemphigoides [6–9], the LP tends to be acute and generalized and is followed by the sudden appearance of large bullae on both involved and uninvolved skin (Fig. 42.26). Occasionally, even in LP pemphigoides, blisters may arise only on the lesions of LP [10]. LP pemphigoides has been precipitated by PUVA [11]. An LP pemphigoides-like eruption has been reported to overlap with paraneoplastic pemphigus [12,13]. In LP pemphigoides, the histology shows a subepidermal bulla with no evidence of associated LP [3]. Direct IMF shows linear basement-membrane-zone deposition of IgG and C3 in perilesional skin [3,9]. Immunoelectron-microscopic studies reveal deposition of IgG and C3 in the base of the bulla and not in the roof as found in bullous pemphigoid [14].

Immunoblotting data have revealed that circulating autoantibodies in LP pemphigoides react with an epitope within the C-terminal NC16A domain of bullous pemphigoid 180-kDa antigen, and also with a 200-kDa antigen

Fig. 42.26 Lichen planus pemphigoides. Large bulla arising on and around vicinity of lichen planus around ankle. (Courtesy of St John's Institute of Dermatology, London, UK.)

detected in bullous pemphigoid [15–20]. It seems that epidermal damage from liquefaction degeneration in LP exposes basement-membrane antigens, and consequent stimulation of autoantibody production.

The mean age of cases of LP pemphigoides is lower than that of classical bullous pemphigoid, and the course of the disease also tends to be less severe. Nevertheless, some cases require treatment with systemic steroids or azathioprine and fatalities occur [9]. A combination of corticosteroids and acitretin has been used [20,21].

Symptomatic lichenoid reactions

Lichenoid reactions occur in persons handling developer used in the processing of colour films. Many drugs may produce an eruption identical with or similar to LP.

LP-like contact dermatitis due to contact with colour developing agents and methacrylic acid esters

An LP-type eruption was reported in up to 25% of persons exposed to chemicals in colour developer [1–5]. Lesions began in areas of contact with the developer, but sometimes extended widely; the mucous membranes were usually spared. Resolution was slow, and lesions persisted for months, with residual pigmentation lasting for a year or more. The responsible chemicals were substituted paraphenylene diamines. Current automated equipment minimizes contact with these, and LP-like eruptions due to this source are now rare [5]. Two types of reaction were observed—acute (eczematous) and subacute (lichenoid)—but either evolved into the other. It is not clear why exposure to colour developers caused a spongiotic dermatitis in some patients and a lichenoid dermatitis in others [5]. Patch-test reactions were usually positive to the substituted paraphenylenediamine and were eczematous in nature, but might become lichenoid [4].

LP-like lesions have developed on sites exposed to methacrylic acid esters used in the car industry [6]. As dental devices contain methacrylic acid esters, it is possible that methacrylic acid esters may be one of the causative agents in oral LP [6]. Other inducers of contact lichenoid eruptions include dental restorative materials, musk ambrette, nickel, aminoglycoside antibiotics and gold.

Lichenoid eruptions due to drugs

The reader is also directed to Chapter 73, Table 73.8, as well as to information on individual drugs. The mechanisms by which drugs induce a lichenoid tissue reaction are unknown, but they may develop as a result of autoreactive cytotoxic T-cell clones directed against a drug/class II MHC antigen complex, such that keratinocytes and

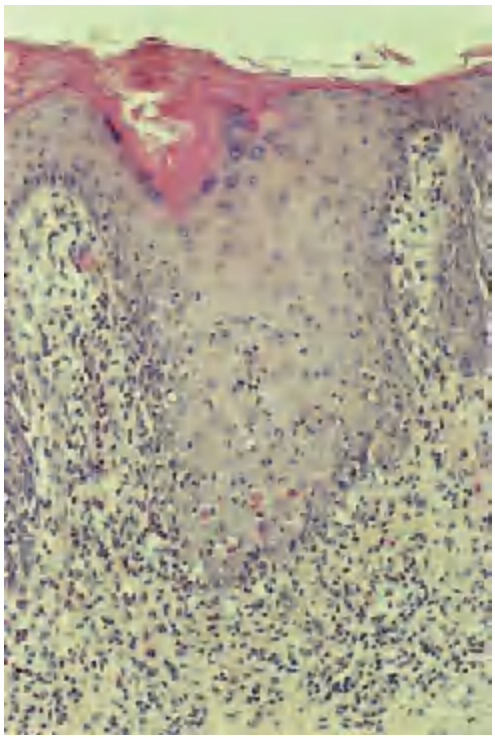

Fig. 42.27 Lichenoid drug eruption (gold). Photomicrograph showing the presence of higher level cytoid bodies with several eosinophils amongst the lichenoid infiltrate. H&E, × 20.

Langerhans' cells are viewed by the immune system as 'non-self'. Cloned murine autoreactive T cells produce a lichenoid reaction in recipient animals following injection [1]. The presence of epidermotropic T cells correlates with that of class II MHC (HLA-DR) expressing keratinocytes and Langerhans' cells in lichenoid eruptions [2]. Macrophage migration inhibition factor (MIF) assays are significantly increased in lichenoid drug eruptions [3].

Histologically, the pattern of an LP-like eruption can be indistinguishable from idiopathic LP, although the cellular infiltrate tends to be more pleomorphic and less dense; helpful histological features indicative of a drug reaction include the following: focal parakeratosis; focal interruption of the granular layer (Fig. 42.27); cytoid bodies situated higher in the granular and cornified layers; presence of a few eosinophils; exocytosis of lymphoid cells into the upper epidermis; and a deeper perivascular infiltrate [4]. Later, there may be scarring with destruction of the sweat glands. The histopathology of photodistributed, as opposed to non-photodistributed, lichenoid drug eruptions has been shown to be often indistinguishable from that of idiopathic LP [5]. Occasionally, the degree of lymphoid epidermotropism may simulate mycosis fungoides [6]. The IMF findings in lichenoid drug eruptions are identical to those in idiopathic LP [7].

Lichenoid drug eruptions tend to be extensive, and may develop weeks or months after initiation of therapy; they

Fig. 42.28 Diffuse psoriasiform lichenoid drug eruption due to β-blocker administration. (Courtesy of St John's Institute of Dermatology, London, UK.)

may progress to an exfoliative dermatitis [8,9]. Lesions may be rather more psoriasiform than in idiopathic LP (Fig. 42.28), and oral involvement is rare. Long-lasting deep hyperpigmentation, alopecia and skin atrophy with anhidrosis due to sweat gland atrophy may develop. Resolution of the skin eruption may be slow after cessation of therapy, on average from 1 to 4 months, but up to 24 months with gold [9].

The list of drugs causing LP-like eruptions is already long and continues to increase steadily. Gold is probably the most common drug producing an LP-like eruption [10]; oral involvement tends to be rarer in LP-like drug eruptions, but occasionally it can be severe and involve the oesophagus [11]. Mercury-induced lichenoid eruptions are recorded [12], and may be or particular relevance in oral LP (see above). During the Second World War, millions of troops took mepacrine to prevent malaria, and many cases of an LP-like eruption occurred [13]. Mepacrine (quinacrine) lichenoid eruptions may be followed by skin cancers, up to 34 years later. Photodistributed lichenoid lesions [9] may be seen with quinine and quinidine [6,14,15], demeclocycline [16] and other tetracyclines, thiazide diuretics [17] (Figs 42.29 & 42.30), furosemide (frusemide), diazoxide, amlodipine [18], chlorpromazine, carbamazepine, 5-fluorouracil, pyritinol and ethambutol [19]. Other drugs implicated include streptomycin, isoniazid [20], pyrazinamide [21], pyrimethamine [22], metropromazine, levopromazine, amiphenazole, methyldopa, β-blocking agents including propranolol [23], oxprenolol [24] and labetalol [25], sulphydryl drugs such as penicillamine [26], tiopronin [27], captopril [28–30] and enalapril [31], non-steroidal anti-inflammatory drugs (NSAIDs) [32] including acetylsalicylic acid [33], naproxen [34] and salsalate [35], levamisole [36], proton pump inhibitors [37], chlorpropamide and tolazamide [38], carbamazepine [39], simvastatin [40] and pravastatin [41], antihistamines

Fig. 42.30 Close-up of dorsum of finger shown in Fig. 42.29.

[42] including chlorpheniramine [43], roxatidine and ranitidine [44], isotretinoin [45], alendronate [46], PUVA therapy [47], sildenafil [48], sparfloxacin [49], imatinib [50], intravenous immunoglobulin [51], ursodeoxycholic acid given for neonatal hepatitis [52], and hepatitis B vaccination [53–59]. Lichenoid reactions have been documented at the sites of injection of granulocyte colony-stimulating factor [60]. Ulcerative lesions may occur with hydroxyurea [61,62], methyldopa, propranolol and lithium carbonate. Oral LP lesions are associated with drugs metabolized by major cytochrome P450-enzymes [63]. Oral involvement may be caused by NSAIDs, gold salts, penicillamine, sulphonylureas, angiotensin-converting enzyme (ACE) inhibitors, methyldopa, allopurinol, ketoconazole, antiretroviral agents including zidovudine [64], clopidrogel [65] and lithium carbonate [66]. Social use of betel nut is relatively common in India and South-East Asia; the product that is chewed, betel quid, is a mixture of substances, including the areca nut and betel leaf, and is associated with oral LP [67,68]. An LP pemphigoides-like eruption has been reported following administration of captopril, cinnarizine [69] and simvastatin [70]. Bullous lesions are recorded with labetalol and tiopronin; LP pigmentosus with gold; and exfoliative dermatitis with nifedipine. Lichenoid photoeruptions have been described in advanced HIV infection; black patients are disproportionately affected and all were taking potential photosensitizing drugs [71]. Hydroxyurea has induced a lichenoid chronic graft-versus-host disease-like acrodermatitis [72].

Treatment. Treatment is to withdraw the drug; with gold eruptions, dimercaprol (BAL) or ethylene diamine tetraacetic acid (EDTA) may be used. Subsequent treatment is symptomatic, but severe cases may require corticosteroid therapy as outlined for idiopathic LP.

Nékam's disease [1,2]

SYN. KERATOSIS LICHENOIDES CHRONICA; POROKERATOSIS STRIATA LICHENOIDES; LICHEN RUBER MONILIFORMIS; LICHEN VERRUCOSUS ET RETICULARIS

The variety of synonyms used implies that there is no complete consensus of agreement about this rare disorder. The great majority of cases are adults between the ages of 20 and 40 years [2], although children are occasionally affected [3]. Nékam's disease is characterized by violaceous, papular and nodular lesions typically arranged in a linear and reticulate pattern (Figs 42.31 & 42.32), most marked on the extremities and buttocks, and accompanied by a seborrhoeic dermatitis-like eruption on the face. Nékam's original case was also associated with palmoplantar keratoderma [4]. The individual lesions are erythematous verrucous papules covered by a hyperkeratotic plug that can only be removed with difficulty, revealing irregular indentations and prominent capillary loops [1,5]. In extensive Nékam's disease, the lesions tend to be

symmetrical bilaterally, mainly involving the antecubital fossae, extensor forearms, lumbosacral area and buttocks, posterior thighs, popliteal fossae, and less commonly the oral cavity and genitalia. Oral manifestations occur in 50% of patients, recurrent aphthous ulcers, larger chronic ulcers or erythrokeratotic papules being the commonest oral features [2]. The nails can become thickened, longitudinally ridged and prone to paronychia [6]. Cases have followed trauma [7] and erythroderma [8]. A limited variant of Nékam's disease presenting with erythematous hyperkeratotic papules and plaques on the face, clearing in the summer months, has been described in two young siblings [9].

Histologically, changes are often non-specific and consistent with a chronic dermatitis, but lichenoid features can be seen [1,5]. Some authors [1] believe that the condition is an unusual variant of LP, while others [10] consider that it is a distinct entity. A case of Nékam's disease associated with porokeratotic histology and amyloid deposition may also point against the view that Nékam's disease is a subset of LP [11]. A possible association of Nékam's disease with glomerulonephritis and lymphoproliferative disorders has been commented on [2]. The course of the dermatosis is chronic and progressive and very resistant to therapeutic approaches, but has shown a favourable response to photochemotherapy [12] and etretinate [13].

Lichen nitidus [1]

Lichen nitidus is a rarer condition than idiopathic LP and is clinically characterized by the presence of pinpoint to pinhead-sized papules, which are usually asymptomatic, flesh coloured, with a flat, shiny surface.

Aetiology. The view that lichen nitidus represents a variant of LP tends to be supported by the fact that early tiny LP papules may be clinically and histopathologically indistinguishable from lichen nitidus [2,3]. Immunophenotypic studies also reinforce the association between LP and lichen nitidus [4]. However, some authorities favour a separation into two dermatoses, because of histopathological differences, or differences in cytokine expression in lichen nitidus [5]. Surprisingly, direct IMF studies in lichen nitidus have given negative results [6,7]. However, ultrastructural studies have shown identical changes in lichen nitidus and LP [6].

Histology. The histology of a typical papule is characteristic. The papule is formed by an intense infiltrate situated

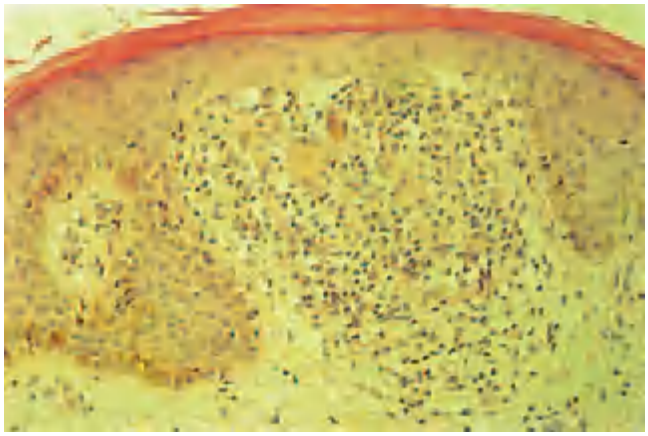

Fig. 42.33 Lichen nitidus. Typical histology showing the focally dense infiltrate containing a few giant cells. H&E, × 100. (Courtesy of St John's Institute of Dermatology, London, UK.)

Fig. 42.34 Lichen nitidus. Close-up of aggregated pinhead-sized papules. (Courtesy of St John's Institute of Dermatology, London, UK.)

immediately below the epidermis and is well circumscribed. The infiltrate consists of lymphocytes and histiocytes and there are often a few Langhans' giant cells (Fig. 42.33). Sometimes, plasma cells are numerous in the infiltrate [8]. The overlying epidermis is flattened and sometimes there is liquefaction degeneration of the basal cell layer. The rete ridges at the margin of the infiltrate are elongated and tend to encircle it. Although tuberculoid in appearance, there is never true tubercle formation or caseation. The histology of a palmar lesion may show a deep parakeratotic plug, which distinguishes it from the palmar lesions of LP [9]. Perifollicular granulomas can occur in spinous and follicular lichen nitidus, which may simulate lichen scrofulosorum [10]. Perforating lichen nitidus has also been described [11].

Incidence. In its characteristic monomorphic form, lichen nitidus is rare, but lesions of lichen nitidus occurring in association with LP are more common [3]. The age incidence tends to be lower than that of LP. Most cases occur in children or young adults. Familial lichen nitidus has rarely been observed [12].

Natural history. Typical lichen nitidus may clear in a few weeks or last a very long time, and may show little or no response to treatment. There have been no large series reporting the natural history of this disorder. With our present knowledge, its course is unpredictable.

Clinical features. Typical lichen nitidus papules are minute, pinpoint to pinhead sized, and have a flat or dome-shaped, shiny surface. They usually remain discrete, although they may be closely grouped (Fig. 42.34). They are found on any part of the body but the sites of predilection are the forearms, penis (Fig. 42.35), abdomen, chest and buttocks. The eruption is sometimes generalized [13,14]. When the palms or soles are involved, the changes can be those of a confluent hyperkeratosis resembling chronic fissured eczema, or there may be multiple, distinctive, minute papules [15,16]. On the palms, the minute papules can become purpuric [9] and may occasionally resemble pompholyx [17]. Such cases may lack lesions of lichen nitidus elsewhere, so a biopsy is essential to confirm the diagnosis [9,15].

Fig. 42.35 Lichen nitidus. Aggregates of pinhead-sized papules on shaft of penis. (Courtesy of St John's Institute of Dermatology, London, UK.)

Linear lichen nitidus has been described, but is exceptionally rare [18]. The development of lesions along

scratch marks is not uncommon. The lesions are flesh coloured or reddish brown. Although intense pruritus can occur [14], the lesions are generally quite symptomless.

Coexistence with LP is common, and Wilson and Bett [3] claim that lesions clinically identical to those of lichen nitidus can be found in 25–30% of all cases of LP. Nail pitting may coexist with lichen nitidus [19], or the affected nails may appear rough due to increased linear striations and longitudinal ridging [15,20].

Mucous membrane lesions occur occasionally and are much rarer than in LP. Krook [21] described a generalized case as having mucosal lesions mainly on the hard palate and maxillary alveolar margins, which consisted of fairly closely grouped, greyish yellow, round, sharply demarcated, discrete papules up to 1 mm in diameter; many were petechial. In other cases, lesions occur that are similar to those in LP.

Lichen nitidus must be distinguished from lichen scrofulosorum [10], where there are grouped follicular papules in small patches on the trunk, and from keratosis pilaris, where there are horny follicular papules mainly on the extensor surface of the limbs. In cases of doubt, a biopsy usually clarifies the diagnosis.

Lichen nitidus has been described in association with Crohn's disease [22], trisomy 21 and congenital megacolon [23].

Treatment. As the disease is often asymptomatic and eventually self-limiting, no treatment is required in most cases, but fluorinated topical steroid preparations may be recommended if treatment is demanded, for example for lesions on the penis, and can be dramatically successful [24]. Clearance of generalized lichen nitidus has been described with sun exposure [25], PUVA [26] and astemizole [13,27,28]. Acitretin can lead to a gradual improvement in palmoplantar lichen nitidus [29].

Graft-versus-host disease (see also Chapter 56)

Haematopoietic cell transplantation is the preferred therapy for a certain life-threatening diseases of the lymphohaematopoietic system [1], including acute leukaemias, aplastic anaemia and certain immunodeficiency disorders, as well as for some inborn errors of metabolism. Graft-versus-host disease (GVHD) occurs when lymphoid cells from an immunocompetent donor are introduced into a histo-incompatible recipient incapable of rejecting them, and is a major obstacle to successful transplantation. Moderate to severe acute GVHD affects 9% to 35% of patients undergoing standard allogeneic bone marrow transplantation, despite using HLA-matched sibling donors and immunosuppression after grafting [2]. The incidence of chronic GVHD is approximately 40% to 50%. Patients with stages 2, 3 and 4 acute GVHD had median survivals of only 5.4, 3.6 and 2.5 months, respectively, while the overall 10-year mortality rate of patients with chronic GVHD was 42% in one recent series [2]. A systemic autoimmune syndrome resembling GVHD, termed autologous GVHD, may follow autologous or syngeneic bone marrow transplantations and ciclosporin therapy [3–6]. Blood transfusions involving transfer of unirradiated immunocompetent cells into immunodeficient children or adults, including those with malignancy, are an important cause [7–12]. GVHD has followed liver trans-

plantation [13–15]. GVHD can also occur after materno–fetal cell transfer (engraftment) in immunodeficient children [16,17]. GVHD has been reported rarely to develop 'spontaneously' in response to a disseminated carcinoma [18,19].

The main targets of GVHD in humans are the skin, the gastrointestinal tract and the liver. GVHD is of importance to the dermatologist since skin manifestations, amongst them lichenoid eruptions, are prominent; in addition, cutaneous GVHD provides us with a unique biological model for the study of lymphocyte-mediated skin disorders [20–22].

Pathogenesis of GVHD

Genetic factors may influence the risk of development of acute and chronic GVHD [1,2]. There is an increased frequency of HLA-A1-B1 and -B2 in chronic GVHD with scleroderma-like complications [3]. $CD4^+$ T cells, of both Th1 and Th2 type, as well as $CD8^+$ Tc2 type, mediate and regulate GVHD [4,5]; T cells are also involved in the pathogenesis of syngeneic or autologous GVHD [6,7] and transfusion-related GVHD [8]. Viral infection may have an adjunctive role [9,10]. Host dendritic cells, rather than alloantigen expression by host epithelium, play a critical role in triggering T-cell-mediated GVHD before they disappear [11–15]. Langerhans' cells are reduced in number, and appear to be targets for destruction, in acute GVHD [16–19]. Keratinocytes express certain minor non-HLA histocompatibility antigens not expressed by haemopoietic cells, which may explain in part why the skin is a particular target organ for GVHD [20]. Host endothelial cells may also be targeted in chronic GVHD [21]. Cytokines are intimately involved in the pathogenesis of GVHD [22–24]. The use of mutant mice lacking critical proteins has helped map out the molecular pathways by which GVHD targets organ damage [25]. Donor T-cell-derived TNF-α is required for GVHD [26], and neutralization of TNF-α and IL-1 prevents acute GVHD in a murine model [11]. Polymorphisms for TNF-α and TNF receptor genes [27,28], and for IFN-γ and IL-6 genes [29], affect the outcome of bone marrow transplantation. IL-5 [30], IL-18 [31] and macrophage MIF [32] are up-regulated in acute GVHD. The chemokines MIP-1α, MIP-2, MCP-1 and MCP-3 may contribute to the preferential recruitment of inflammatory cells into the skin [33]. Absence of IFN-γ promotes the development of chronic GVHD and autoimmunity [34]; IL-10 and IFN-γ may be critical mediators for the development of autologous GVHD [35]. Fibrosis in sclerodermatous GVHD may be driven by infiltrating transforming growth factor (TGF) -β1-producing donor mononuclear cells as critical effector cells, with C–C chemokines playing an important role [36]. Apoptotic keratinocytes arise in the skin of bone marrow transplant patients due to both GVHD and the effects of conditioning regimes; keratinocyte damage in GVHD is mediated by both cytotoxic T-cell-dependent and -independent mechanisms [37].

Clinical manifestations [1–3]

GVHD that develops between 1 week and 3 months after transplantation is termed acute, while that appearing after 3 months is termed chronic. The severity of the reaction, clinically and histologically, varies from mild to severe and provides a basis for a grading of 1–4. Grades 2–4 carry a mortality exceeding 75%. Early diagnosis of GVHD can be difficult, as drug reactions, viral infections and cutaneous reactions to radiation therapy may have clinical and histological similarities [1]. Survival of patients receiving marrow/stem cells from one antigen mismatched related donor is inferior to that of controls with HLA-identical related donors [4]. Risk factors for acute cutaneous GVHD in one recent series were a diagnosis of chronic myeloid leukaemia, HLA disparity, receipt of more than one stem cell transplant, conditioning regimens that include total body irradiation, and GVHD prophylaxis regimens other than ciclosporin plus methotrexate [5]. GVHD has been reportedly triggered by use of contrast media [6], and followed use of roquinomex [7].

Acute GVHD

The earliest cutaneous features are accompanied by a fever and include a malar flush, erythema of the palms or soles, and a generalized erythematous morbilliform rash.

Occasionally erythematous to violaceous follicular papules [8], a pustular acral erythema [9], or an ichthyosiform rash [10] occur. The rash can be more severe with scarlatiniform features. Rarely, serious toxic epidermal necrolysis [11] or a severe exfoliative erythroderma may occur.

Watery diarrhoea may develop within days to weeks after the cutaneous lesions, its severity often paralleling that of the skin involvement; it may become bloody and protracted. Liver involvement is expressed clinically by jaundice and hepatomegaly with tenderness. Monitoring of total bilirubin, stool output, extent of rash and overall clinical stage of GVHD is important during the first 40 days after bone marrow transplant in formulating the prognosis of early acute GVHD in allogeneic bone marrow transplant patients receiving ciclosporin [12].

The differential diagnosis of acute GVHD includes drug reactions, e.g. to ciclosporin, use of recombinant human cytokines [13], the eruption of lymphocyte recovery (ELR) [14,15] and opportunistic infections. The ELR presents as an erythematous maculopapular rash usually between 14 and 21 days, and coincides with the earliest return of lymphocytes to the peripheral circulation after marrow ablation. The histological findings in ELR are non-specific, but the diagnosis can be suspected from the association of an increased peripheral lymphocyte count with the development of a transient erythematous maculopapular rash. Eruption of lymphocyte recovery occurs in more than 50% of cases undergoing intensive marrow-aplasia-inducing chemotherapy [14]. Dyskeratosis congenita in children may simulate GVHD [16]. The differences can usually only be established by histology and cultures.

Histology [17]. Characteristic histopathological features are present in all patients with acute GVHD. The epidermis shows focal vacuolar alteration of the basal layer with a few lymphoid cells at the dermal–epidermal interface. 'Satellite' lymphocytes often abut ovoid eosinophilic bodies called 'mummified' cells, so-called satellite cell necrosis [18]. However, the presence of dyskeratotic keratinocytes and satellite cell necrosis is not specific for GVHD [19]. Coagulative necrosis and acantholysis in the lower layers of the epidermis and pilosebaceous units may also be present. It has recently been shown that apoptosis contributes to the keratinocyte destruction in GVHD [20]. The numbers of dermal and epidermal mononuclear inflammatory cells correlate positively with the probability of developing more severe acute GVHD [21]. Immunoglobulin M deposits may occur at the DEJ [22].

Chronic GVHD

Chronic GVHD presents between 3 and 14 months post-haematopoietic stem cell transplant in approximately 20% of matched sibling transplants and 40% of matched unrelated donor recipients. Involvement of the skin, liver, eyes, mouth, upper respiratory tract, oesophagus, lower gastrointestinal tract and skeletal muscles is common. Patients may develop chronic GVHD *de novo* in about 15% of cases, or as a gradual progression from continuously active acute GVHD, or following resolution of acute GVHD.

Fig. 42.36 Lichenoid graft-versus-host disease showing marked nail involvement. (Courtesy of Dr C.T.C. Kennedy, Bristol Royal Infirmary, Bristol, UK.)

The initial eruption is usually lichenoid, and may involve the oral cavity [23,24] with mucoceles [25], skin, and nails [26] (Fig. 42.36), sometimes causing a scarring alopecia. Hyper- or hypopigmentation are often prominent features and total leukoderma has been described [27]. The cutaneous changes can be generalized or localized. The localized forms can be linear or whorled; in the latter, the lesions occur in the lines of Blashko [28,29]. It is not clear whether this linear distribution is due to viral infection or cellular mosaicism [30]. Dermatomal chronic GVHD at the site of previous herpes zoster has been described [31]. The development of chronic GVHD solely in an area of piebaldism suggests that piebaldism-affected skin is immunologically different from normal skin [32].

Chronic GVHD may resemble Sjögren's syndrome, lupus erythematosus, dermatomyositis or polymyositis [33,34]. A severe cicatrizing conjunctivitis mimicking cicatricial pemphigoid has been documented [35]. A GVHD-like condition can occur after fluorouracil administration for metastatic carcinoma [36], and has been described in a patient with Hodgkin's disease associated with serological features of paraneoplastic pemphigus and systemic lupus erythematosus [37]. Crusted scabies may cause a confusing clinical picture if it complicates chronic GVHD [38].

The late phase of chronic generalized GVHD may result in a disabling type of sclerodermatous skin reaction, which develops after about a year. There is severe poikiloderma with widespread cutaneous sclerosis, contractions, malabsorption, wasting, alopecia and areas of ulceration

Fig. 42.37 Chronic graft-versus-host disease. Seven years post-transplant, showing widespread sclerosis and focal areas of ulceration. (Courtesy of Dr C.T.C. Kennedy, Bristol Royal Infirmary, Bristol, UK.)

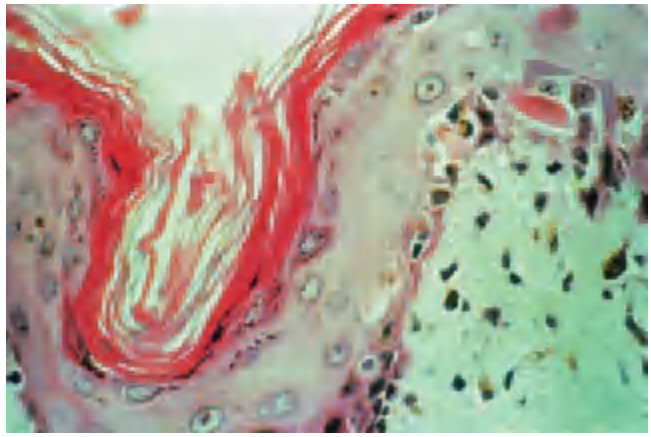

Fig. 42.38 Graft-versus-host disease. Histology showing cytoid bodies and liquefaction degeneration of the basal layer. Note the virtual absence of inflammatory infiltrate. H&E, × 100. (Courtesy of Dr P.H. McKee, UMDS, Guy's and St Thomas' Hospitals, London, UK.)

[39] (Fig. 42.37). Bullous changes [40], changes of lichen sclerosus et atrophicus [41] and dermal mucinosis [42] are recorded.

Chronic cutaneous GVHD is associated with a decreased number of melanocytic naevi [43]. Squamous cell carcinoma development in an indolent ulcer in chronic GVHD has been reported [44]. Other systemic complications include progressive hepatic fibrosis, autoimmune haemolytic anaemia, lung fibrosis and obstructive bronchiolitis [1]. The mortality of chronic GVHD is about 10%.

Histology [45]**.** In the earlier phase of chronic GVHD, the epidermis is acanthotic with hyperkeratosis. The changes at the dermal–epidermal interface closely resemble LP, although the infiltrate is not as dense and may contain eosinophilis (Fig. 42.38). Involvement of pilar units, vessels, nerves and sweat glands is not uncommon. In the final stages of the disease, the epidermis becomes atrophic and gross fibrosis involves the dermis, skin appendages, or even the subcutis.

Treatment of GVHD

The future success of bone marrow transplantation depends on the extent to which GVHD can be prevented or modified, as treatment of established GVHD is difficult. Prophylactic regimes [1–4] include use of ciclosporin or tacrolimus [5] with methotrexate, and lymphocyte depletion of donor infusions using alemtuzumab (CAMPATH-1H), a humanized monoclonal antibody directed against lymphocyte CD52 antigen [6]. A new approach in the prevention of acute GVHD involves use of genetically manipulated donor T cells expressing the herpes simplex virus thymidine kinase (HSV-tk) suicide gene [3,7,8]; acute GVHD may be effectively controlled by ganciclovir-induced elimination of the transduced cells. Extensive vitiligo has, however, followed ganciclovir treatment [9]. Systemic steroids remain the standard regime for the treatment of acute GVHD. When this approach fails, patients with GVHD require secondary therapy [1–3,10–13] such as mycophenolate mofetil [14,15], sirolimus (rapamycin) or humanized or chimeric monoclonal antibodies directed against cytokines or their receptors. The latter include infliximab (anti-TNF-α); anti-IFN-γ; antibodies directed against activated T cells, including basiliximab and daclizumab (IL-2 receptor antagonists), visilizumab and ABX-CBL; antibodies to adhesion molecules (such as LFA-1) or targeting distal effector mechanisms (such as Fas ligand); and tolerance-induction agents such as cytotoxic T-lymphocyte antigen (CTLA)-4 Ig and anti-CD40 ligand. Pentostatin may also be useful [16]. Intravenous immunoglobulin is of uncertain benefit in the prevention of GVHD [17,18]. IL-18 has the capacity to modulate acute GVHD when administered either to the donor or the recipient [19].

Initial treatment of chronic GVHD has tended to be ciclosporin and prednisolone [20]. For refractory cases, combined mycophenolate mofetil and tacrolimus, both systemically and topically [21], etretinate [22] and hydroxychloroquine [23] may be helpful. Thalidomide has been used successfully as an adjunct in the therapy of chronic, but not acute, GVHD [24–26], but use of this drug in GVHD has been followed by severe cutaneous ulceration [27]. Low-dosage UVB therapy, both broad-band [28,29] and narrow-band [30], can be successful as an adjunctive therapy in chronic oral and cutaneous GVHD, and UVA-1 phototherapy [31,32] has been advocated for sclerodermatous chronic GVHD. Photochemotherapy (PUVA and bath PUVA) may similarly clear skin lesions in chronic GVHD [33–36]. Extracorporeal photochemotherapy involves the reinfusion of a patient's own white cells following exposure to 8-methoxypsoralen and UVA *ex vivo*, and is a safe and effective adjunctive therapy for both acute and extensive chronic cutaneous GVHD resistant to conventional therapy [37–39]. Addition of an overnight incubation period may further improve results [40]. The effects on systemic involvement are more variable.

Chapter 43

Disorders of the Sebaceous Glands

N.B. Simpson & W.J. Cunliffe

Structure and distribution

The sebaceous gland [1] is holocrine; its secretion is formed by the complete disintegration of the glandular cells. The cells are replaced by cell division at the periphery of the lobes or acini of the glands, with the consequence that differentiating cells are displaced towards the centres of each acinus. The average transit time of the cells, from formation to discharge, has been given as 7–25 days in the human gland [2], a figure similar to that estimated for the rat [3,4]. However, the dynamics of the human gland are complicated. The gland consists of a series of lobes, each with a duct lined by a keratinizing squamous epithelium. The lobule ducts converge towards the main sebaceous duct, which normally opens into the pilary canal, whose epithelium is continuous with the surface epidermis. Within any one glandular unit, the acini vary in differentiation and maturity: some are completely undifferentiated, showing little or no lipid accumulation in any of their cells, and some are full of lipid-laden cells that extend to the outer periphery of the acinus [5]. New acini can apparently arise from the walls of the ducts, grow into sebaceous units and fuse with adjacent ones. Three proliferative regions were recognized by Plewig *et al*. [6,7] using ^{3}H-thymidine autoradiography. The duct displayed fast cellular migration with a renewal time of 2–4 days. An undifferentiated cell pool, with a renewal time of 4–7 days, could be distinguished from the differentiating lipid-producing cells in the glandular fundus, with a replacement time of more than 14 and probably 21–25 days [8]. The synthesis and discharge of the lipid contained in the sebaceous cells require more than a week [9].

Sebaceous glands occur over much of the body, although not normally on the palms or soles, and only sparsely on the dorsal surfaces of the hand and foot. Sebaceous glands are largest and most numerous on the face, scalp, upper trunk, in the external auditory meatus and on the anogenital surfaces. On the scalp, forehead, cheeks and chin, for example, there are between 400 and 900 glands/cm^2; elsewhere there are fewer than 100 glands/cm^2 [10–12].

In a number of sites, sebaceous glands open directly to the surface of the skin, and not by way of a hair follicle.

Examples of such glands are the Meibomian glands of the eyelids and the Tyson's glands of the prepuce [13]. Free sebaceous glands are also found on the mucocutaneous surfaces of the female genitalia, the areolae of the nipples, and ectopic sites such as the tongue and the cervix uteri [14]. Free sebaceous glands in the margin of the upper lip are often visible to the naked eye as pale-yellow bodies, which vary in size from minute specks to about 1.5 mm in diameter; they are known as Fordyce's spots [15].

Many mammals have specialized aggregations of sebaceous units that function as scent glands [16–19]. Some such glands also include tubular 'apocrine' units (Chapter 45). Of special interest as possible models for the study of compounds that affect sebaceous activity [20] are the costovertebral organs of the golden hamster [13,20–23], the supracaudal gland of the guinea pig [24,25], the abdominal gland of the gerbil [26] and the preputial glands of many species of rodents [27].

Development

The development of the sebaceous glands is closely related to the differentiation of hair follicles and epidermis [1,2]. In about the third week of fetal life, the epidermis consists of a single layer of undifferentiated cells, but by the fourth week an outer periderm and a basal stratum germinativum can be distinguished. Between the 10th and 12th weeks, a stratum intermedium becomes apparent, and at about the same time developing hair germs are quite distinct (Chapter 3). In the following weeks, the follicles extend downwards into the dermis and the rudiments of the sebaceous glands appear on the posterior surfaces of the hair pegs; by 13–15 weeks, the glands are clearly distinguishable.

The cells at first contain glycogen. This lingers at the periphery of the gland, but is quickly lost at the centre, where large lipid drops are visible at 17 weeks [3–5]. At the point of their origin from the follicle, centrally positioned cells degenerate to form a lumen, and surrounding cells keratinize to form the sebaceous duct [6]. The glands become multi-acinar by the formation of buds on the peripheral wall.

Sebaceous glands are functional from their formation; sebum is the first demonstrable glandular product of the human body. Their development and function before birth and in the neonatal period appear to be regulated by maternal androgens and by endogenous steroid synthesis by the fetus [7]. Hydroxysteroid dehydrogenases and 5α-reductase, which reduces testosterone to 5′α-dihydrotestosterone (5′α-DHT), are present after 16 weeks [8,9]. The glands reach a peak of activity in the third trimester, and their secretion forms part of the vernix caseosa. The vernix lipids resemble sebum in their content of fatty acids, squalene and wax esters, but also contain

sterols and sterol esters [10]. Sebaceous glands remain active in the neonatal period, but then involute and remain quiescent until puberty [11].

Ultrastructure, histochemistry and immunocytochemistry of the sebaceous gland and duct

Undifferentiated sebaceous cells at the periphery of the gland are rich in ribonucleoproteins and stain with basic dyes [1]. As the cells move towards the centre of each lobe they contain more lipid and become progressively acidophilic. All the cells have numerous mitochondria, usually appearing as short or wavy rods. The undifferentiated cells contain coarse, osmium-staining particles around the nucleus; as differentiation proceeds, these particles increase in number and size and develop lipid droplets in their centres, which gradually enlarge. This complex corresponds to the Golgi body: at completion of sebaceous synthesis it is no longer recognizable.

In studies with the electron microscope [2–4], the undifferentiated cells at the periphery of the gland can be seen to rest upon a basement membrane, and to be connected with each other by desmosomes. The membranes of the granular endoplasmic reticulum are coated with ribosomes, and there are in addition particles of ribonucleoprotein and glycogen scattered free in the cytoplasm. At this stage, the Golgi zones are usually inconspicuous; the nucleus is relatively very large. Differentiation of the cell becomes evident with the appearance of one or more small sebum vacuoles within it. During the active phase of lipid synthesis, the cytoplasm becomes packed with smooth-surfaced membranes of the endoplasmic reticulum. In some partially differentiated cells, a large Golgi zone becomes apparent; typically, it consists of parallel, smooth-surfaced, thick membranes, slightly dilated cisterns and small vesicles. The Golgi appears to be the centre where lipid aggregates to form sebum vacuoles. At an early stage of sebaceous transformation, one of the cisterns in the Golgi zone becomes more dilated than the others, and forms the centre of the developing sebum vacuole. At a later stage, the smooth membranes of Golgi apparatus and the endoplasmic reticulum become orientated around the edge of the developing vacuole, forming a sort of 'husk'. The fully differentiated cells contain very large sebum vacuoles, which compare in size with the nucleus; the cell may have a complement of more than 60 (Fig. 43.1). In the final stages of differentiation, the mitochondria become widely separated, indicating that their numbers have decreased, and the nucleus becomes irregularly shaped, with clumping of the nucleochromatin and dispersal of the nucleolar material. Lysosomes are prominent in peripheral and other cells in the early stages of differentiation, but are found at all stages [2]. They may be concerned with hydrolysing precursors of sebaceous lipids or the breakdown of mature cells.

The sebaceous cells of prepubertal and hypogonadal males are qualitatively similar to those of normal adults, even though the glands are smaller [1].

Immunocytochemical techniques, supported in some instances by investigating messenger RNA (mRNA) expression of the peptide, performed both on human skin biopsies and on immortalized sebocytes, have also helped in our understanding of the hormonal and cytokine control of the sebaceous gland and duct in health and disease [3].

Androgen receptors are present both in the gland and the duct [4]. Peroxisome proliferator-activated receptors (PPARs) are a subfamily of former so-called orphan receptors within the non-steroid receptor family of nuclear hormonal receptors. There are three subtypes (PPAR-α, γ and δ) all of which are expressed by sebocytes, with PPAR-γ 1 gene expression being much greater than in the epidermis; this subtype is also expressed in the ductal cells of normal skin and of comedones. In the sebaceous gland these receptors are located in basal and early differentiated sebaceous gland cells [5] and are likely to be important for sebocyte formation of the intracellular fused lipid droplets that constitute the holocrine secretion of differentiated cells. They may also inhibit skin inflammation by diverse mechanisms not necessarily related to lipid metabolism [6].

Sebocytes are target cells for several neurohormones. Immunocytochemical studies have shown that human sebocytes express melanocortin (MC)-1 receptors and are target cells for α-melanocyte-stimulating hormone (α-MSH) [7].

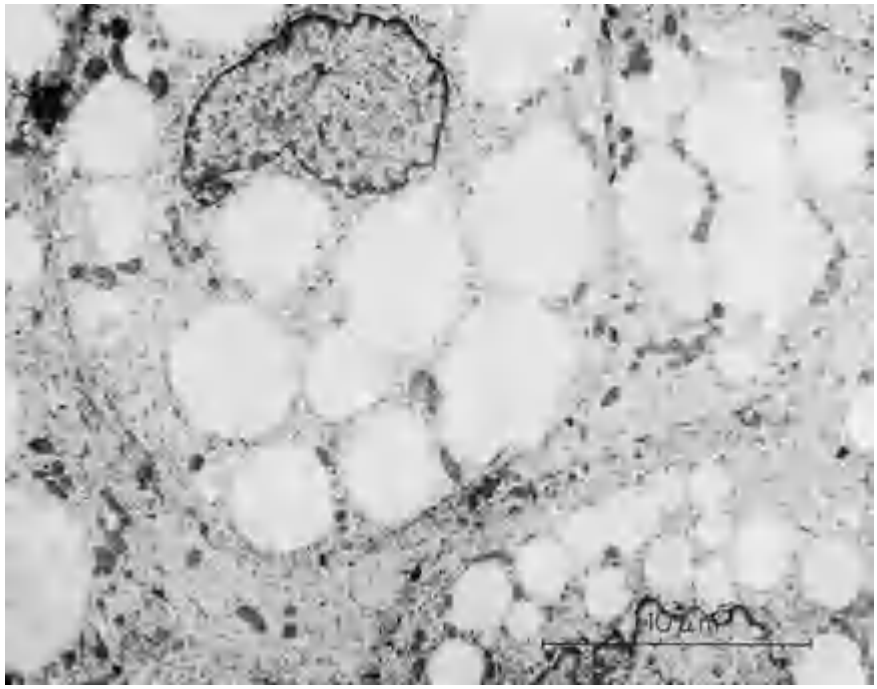

Fig. 43.1 Transverse section of the sebaceous gland of a 24-week fetus. The cytoplasm of the cells is honeycombed with spaces occupied by lipid droplets, which have been leached away during processing. (Courtesy of Professor A.S. Breathnach, St John's Institute of Dermatology, London, UK.)

The sebaceous gland constitutively expresses other cytokines without any influence of external factors. Interleukin-1 (IL-1) is present in the normal human sebaceous gland [8] and mRNA for IL-1-α, IL-1-β and tumour necrosis factor-α (TNF-α) are also present in the sebaceous glands. Cultured human sebocytes also express IL-1-α at the mRNA and protein levels. The presence of such cytokines may relate to the development of inflammation [9].

Composition and biosynthesis of sebum

Sebum is a complex mixture of lipids, which varies widely from species to species [1–3]. The analysis of human sebum is complicated by several factors. The principal difficulty is that the surface film contains not only sebum, but also lipid from the keratinizing epidermis and possibly from eccrine glands. In addition, the pure sebaceous secretion undergoes degradation as it passes through the ducts, or on the skin surface as a result of bacterial lipase activity [4]. Some material, for example, hydrocarbons, may also be acquired from environmental sources.

Surface lipid can be collected by simple non-invasive tests, such as wiping the skin with a sponge soaked in an organic solvent such as hexane or ether [5]. However, skin biopsies are necessary to investigate sebum synthesis and the analysis of pure sebum. Incubation of isolated human sebaceous glands showed that acetate and glucose appeared to be equally efficient as substrates for triglycerides but not for squalene [6].

An unusual feature of sebaceous lipogenesis is a partial or complete inhibition of cholesterol biosynthesis at some point in the pathway. Thus, in human and in some other animal glands, there is little or no conversion of squalene to cholesterol, and squalene remains a major product.

In vivo studies suggest that the synthesis of some sebaceous lipids is indirect, with newly synthesized fatty acids becoming first incorporated into phospholipids and later recycled into non-polar lipids. In human scalp, the label of intradermally injected ^{14}C acetate is immediately taken up

Table 43.1 Comparison between constituents of sebum and epidermal lipid.

Constituents	Sebum (%)	Epidermal lipid (%)
Glycerides (plus free fatty acids)	57.5	65
Wax esters	26.0	—
Squalene	12.0	—
Cholesterol esters	3.0	15
Cholesterol	1.5	20

by squalene, wax esters and triglycerides, but as the cells mature the proportion in wax esters increases [7].

Human skin surface lipid consists of glycerides, free fatty acids, wax esters, squalene, cholesterol esters and cholesterol. Lipid production varies according to site, for example 5–10 μg/cm^2 were recovered from the trunk and limbs of subjects who washed 3 h prior to extraction, compared with 150–300 μg/cm^2 from the forehead [8]. When amounts were in the range 5–10 μg/cm^2, the skin surface lipid contained virtually no wax esters or squalene. However, as the quantity of surface lipid increased, so did the proportion of wax esters and squalene, while at the same time the proportions of cholesterol esters decreased. The proportion of each of the constituents became nearly constant when the amount of lipid reached 50–100 μg/cm^2.

These results are consistent with the view that wax esters and squalene are produced by the sebaceous glands only, and not by the epidermis. When the surface lipid is as low as 4–10 μg/cm^2 no sebum is present, and this level of lipid represents that contributed by the epidermis. However, when the surface lipid is greater than 100 μg/cm^2, its composition approximates to that of sebum. The percentage proportions of constituents are shown in Table 43.1. It may be concluded from these figures that the sebaceous glands do not, to any great extent, convert squalene to sterols, whereas in the epidermis squalene synthesized in the lower layers is rapidly and totally converted to sterols, either to precursors of vitamin D or to cholesterol. Squalene is unique to sebum and is virtually unique to humans [2].

Between birth and sexual maturity, surface lipid undergoes two distinct changes [9,10]. Shortly after birth it resembles adult sebum, presumably because maternal hormones have activated the sebaceous glands. Thereafter and up to 8 years of age, the wax esters and squalene remain low, and epidermal lipids, i.e. cholesterol and its esters, are high. In this age range, sebum constitutes less than half the total surface lipid of the forehead, compared with 95% or more in the adult. Between 8 and 10 years of age, the wax esters and squalene rise to about two-thirds of the adult level, and between 10 and 15 years the composition comes to resemble that of the adult.

Free fatty acids constitute 10–30% of the human skin surface fat [11–13], but occur in only small amounts in the skin lipids of most other animals. This difference is presumably due to the rather unique bacterial flora of humans, in particular *Propionibacterium acnes*, and its lipase action on sebaceous triglycerides. Analysis of pure sebum from isolated human sebaceous glands showed the presence of triglycerides, but not free fatty acids, monoglycerides or diglycerides [14,15]. It thus seems that, prior to secretion, all the fatty acids are combined as triglycerides, which are subsequently subjected to lipolytic activity by enzymes present in the sebaceous ducts and on the skin surface. This conclusion is reinforced by the demonstration that the skin surface can hydrolyse triglycerides of exogenous origin; when ^{14}C-labelled tripalmitin was spread on the back, labelled free fatty acids were isolated from the surface fat 3 h later [7].

The fatty acid components [1–3,16] have both odd- and even-numbered carbon chains up to C25 in length, although more than half are C16 and C18 compounds. They are both saturated and unsaturated, and of particular interest is the presence in both classes of unusual branched chains. These are of two kinds, one having an even number of carbons with the methyl group attached to the penultimate (iso series), the other having an odd number of carbons with the methyl group attached to the antepenultimate (antiso series). Such branches are present in the chains of the wax esters, which are virtually limited to 18 carbons and produced only by the sebaceous glands and, in higher proportion, in the longer chains of the sterol esters, which probably arise from both sebaceous glands and epidermis.

It is possible to modulate sebum composition as a result of dietary, hormonal or drug manipulation. Although various effects have been ascribed to diet, there is no evidence from either humans or experimental animals that any components of sebum are directly derived from ingested fats. In humans, most of the unsaturated fatty acids in the surface film are Δ6 compounds, whereas dietary lipids are Δ9 compounds [3]. Prolonged starvation of human subjects [17,18] decreased the rate of sebum synthesis by about 40%, without any decrease in the actual amount of squalene, which thus rose as a proportion of the total surface lipid.

Administered hormones can also influence the composition of the skin surface fat. In rats, testosterone, at the same time as increasing the amount of sebaceous secretion (see below), increases the ratio of palmitate to stearate and the ratio of oleate to stearate; oestrogens and antiandrogens antagonize these effects [19–21]. In female patients prescribed co-cyprindiol (35 μg ethinyl estradiol and 2 mg cyproterone acetate [CPA]) there is a significant increase in sebaceous linoleate, which might explain in part the anticomedogenic effect of the therapy [22]. A

reduced sebaceous linoleate may induce comedogenesis. Oral isotretinoin not only significantly reduces sebum production, but produces a tremendous change in lipid composition. There is a great reduction in sebaceous-related lipids (i.e. squalene, wax esters and fatty acids) [23].

For comprehensive discussions of lipid biosynthesis in the sebaceous glands, the reader is referred to detailed references [3,24].

Functions of sebum

Several functions have been ascribed to sebum, but they are by no means undisputed. In humans, it has been stated that the lipid film both controls moisture loss [1] from the epidermis and protects the skin from fungal and bacterial infection. The colonization of the skin by *P. acnes* may have an immunomodulatory role. Aggregations of holocrine glands play an important part in scent production in many mammals, and components of sebum may possibly contribute to body odour [2].

It was believed that the sebaceous lipids were essential factors for the barrier function of the skin. This is clearly not so. A healthy prepubertal child who produces no sebum has no impaired barrier function. Certain surface free fatty acids markedly reduce the growth of pathogenic organisms, such as *Staphylococcus aureus*, *in vitro* [3], and suppression of sebaceous gland activity by isotretinoin maybe followed by impetigo towards the end of a 4-month course [3]. Circumstantial evidence supports the view that sebum, or at least the product of its hydrolysis, is fungistatic. Fungi causing tinea pedis preferentially colonize areas that are not supplied with sebaceous glands: ringworm of the scalp becomes rare after puberty, when sebum production increases.

Propionibacterium acnes is unique to humans and this fact may equate with the rather unique composition of human sebum.

Shuster [4] made the interesting suggestion that the capacity to develop delayed immune hypersensitivity may be augmented and maintained by the *P. acnes*, which colonizes sebaceous glands in adults. A sequel of this may be an enhanced immunoregulatory effect, producing some protection against cancers such as leukaemia and melanoma, which occur with less frequency in acne patients [5].

The sebaceous gland has also been shown to secrete vitamin E into the upper layers of facial skin. This mechanism may in part serve to protect skin surface lipid and the upper stratum corneum from harmful oxidation [6].

Measurement of sebaceous activity and sebum production

Various methods have been used for collecting lipids from human skin, and for measuring their production [1]. They include swabbing by pads soaked in solvent [2], washing lipid solvents over areas of skin circumscribed by rings, caps or apertures of bottles [3–6] and absorption on paper [7,8]. Another method is removal by pressing a ground-glass plate on the skin followed by photometric assessment [9–14]—for both stages an instrument known as a Lipometer®/sebometer has been devised [15]. The rate of sebum production has been calculated from the squalene content of skin biopsies [16]. Analysis of the ratio of wax esters/(cholesterol plus cholesterol esters) may provide an indirect measure of lipid synthesis per sebaceous cell [17–19].

A simple, practical, but time consuming, method for measuring human sebaceous secretion is to place a pad of specially absorbent cigarette papers for 3 h on a delimited area of the forehead, and then to extract the sebum with diethyl ether. In view of circadian changes in secretion [20], the measurement should be carried out between standard times. It does not give the absolute sebum production rate, which is indefinitely sustainable [21], but it is valuable for comparative purposes, and provides more reproducible results than many other methods. The method that follows was originally devised by Strauss and Pochi [7,8,14].

1 Two areas on either side of the forehead (2.0 × 3.5 cm) are delineated by pre-cut Micropore® tape.

2 A pad of four or five cigarette papers is placed carefully, to avoid creasing, over the forehead and held in place by a gauze pad and a stocking-weave bandage encircling the head (Fig. 43.2).

3 In order to remove the accumulated surface lipids, two or three pads are so applied for 10–15 min and then discarded. After 30–40 min, close examination of the final paper in contact with the forehead will reveal a follicular pattern of sebum emerging from the follicles.

4 A pad of papers of known weight (previously prepared by washing in ether and being allowed to dry) is then applied. At the end of a 3-h collection period, the lipid-containing papers are then reweighed [22].

Control papers must be used to control for variation in environmental factors (such as humidity), which may influence the weight of the papers. Precision in weighing techniques is essential. The weight of sebum multiplied by the time of collection and divided by the area of collection provides a figure, which is referred to as the sebum excretion rate (SER).

The sustainable rate of sebum production on the forehead can be measured by first depleting the follicular reservoir by an application of an aqueous gel of bentonite clay, into which a rectangle of non-woven polyester cloth is pressed. The cloth is removed after 14 h, and the sebum is then collected for 3 h on two discs of clay, each 2 cm in diameter. The lipid is extracted and quantified by thin-layer chromatography [23–25] or by weighing [26]. The method also makes possible an estimation of the extent of the follicular reservoir [26]. According to Saint-Leger and Cohen [27], the forehead can be defatted with 70% ethanol and the rate of sebum excretion is then linear.

Fig. 43.2 Patient with a firm but comfortable headband which is holding in place the special absorbent papers for measurement of sebum production.

The introduction of a sebum-absorbent tape (Sebutape®) has made it possible to observe the lipid output of individual follicles [28,29]. Computerized image analysis has been used for quantification [30–32].

Several authors have described methods for the isolation, from skin biopsies, of whole human glands [33,34] or sebaceous cells [35], and their cultivation *in vitro* for study of their activity. These techniques reflect reasonably well the *in vitro* situation. In particular, the sebocyte culture system has provided much information on the hormonal and cytokine control of the sebaceous gland [36]. Sebum production in the rat has been measured by total immersion of animals in lipid solvents [37], by changes in hair fat lipid [38,39], or by absorption of lipid on paper from areas denuded of hair [40]. To study responses to hormones, the size of the sebaceous glands has also been estimated from histological sections using planimetry [41]. Mitotic activity, estimated after injecting the rats with colchicine, which arrests mitoses in the metaphase, has also been used as a measure of glandular activity [41]. Other experimental models, such as the preputial glands of rodents

[42], which can be dissected out and weighed, or the visible costovertebral glands of the hamster [43,44], to which hormones can be topically applied, have been reviewed by Ebling [1].

When interpreting the results of animal experiments it is important to realize that the reactions of supposed homologues of the sebaceous glands may vary not only from species to species but also within species. Thus, the responses to hormones of the preputial and sebaceous glands of the rat may not be identical. Moreover, because of the miscellaneous parameters involved, it is also important to understand the relationships between the different facets of sebaceous activity. The rate of secretion of sebum depends on two factors: the synthetic capacity of each sebaceous cell and the rate of production of the cells. The size of the glands depends partly on both these things, but also of critical importance is the time taken for each cell to mature and pass through the gland, i.e. the turnover time or cell life. If, for example, the rate of production of cells were doubled, with a consequent increase in sebum production, no alteration in gland size need occur if at the same time cell life were halved. As a general principle, it seems to be true that, the greater the mitotic rate, the lower the turnover time [45]; but in practice the changes do not keep pace with each other, and glands under stimulation do increase in size as well as in rate of secretion.

Endocrine control of sebaceous gland activity [1]

The link between sebaceous gland activity and puberty has been recognized for many years [1]. Much pioneering work was performed on the rat, which has a simple unilobular sebaceous gland, and on the Syrian hamster, whose flank organ is a good model for the human sebaceous gland. The development of techniques to grow human sebocytes and ductal cells in culture [2–4] has confirmed and built on previous observations of human physiological and pathological states. This section will concentrate on the human sebaceous gland, with reference to animal work where the evidence in humans is lacking or uncertain.

Androgens

Androgens are responsible for the development and maintenance of sebum secretion in both sexes. They are without doubt the most important hormones controlling sebaceous gland activity. The level of sebum excretion at birth is similar to that in adults [5]. There is a significant correlation between maternal and neonatal sebum excretion rate (SER) perinatally. This observation suggests an important role for the maternal hormonal environment on the infant's sebaceous glands [6]. The sebaceous glands regress to become minute during the prepubertal period, but undergo vast enlargement at puberty, when the sebum output of males increases more than fivefold [7]. Sebum production remains essentially unchanged in both sexes until around the age of 60 years, when it declines [8]; paradoxically, in old age the sebaceous glands become larger because cell turnover is decreased [9].

The most effective androgens are the 17β-hydroxy group (testosterone, 5α-dihydrotestosterone (5α-DHT) and 5α-androstene-3β-17β-diol). Sebaceous glands possess many enzymes for the interconversion of androgens, notably the relatively weak adrenal androgens dehydroepiandrosterone and androstenedione, to testosterone and DHT. The latter conversion requires the enzyme 5α-reductase, which is thought to be of pivotal importance in the development of sebaceous glands and acne [8]. There are two isoforms of this enzyme, and it is the type-2 isoenzyme that is important for most androgen action in sexual organs [10–12]. However, sebocytes [11] and epithelia [13] in the pilosebaceous unit possess the type 1 isoenzyme, and individuals who are genetically deficient in type 2 5α-reductase develop normal sebaceous glands and suffer from acne [14,15]. Androgens exert their effect in target cells via the androgen receptor, which has similar binding affinities for testosterone and DHT. The androgen receptor has been found by immunohistochemical localization in human sebaceous glands in basal and differentiating sebocytes, and in the keratinocytes of the pilosebaceous duct and hair follicle, but not in keratinocytes elsewhere [16–19]. There is evidence from cell culture experiments that androgens stimulate the growth of sebocytes and other components of the pilosebaceous unit by action on specific stromal components, and interact with retinoic acid to regulate directly sebocyte differentiation [16]. Administration of testosterone dramatically increases the size of the sebaceous glands and the sebum output of prepubertal boys (Fig. 43.3). In adult males the glands are almost but not completely maximally stimulated by endogenous androgen [20–23]. Adrenal androgens increase sebum production [23,24] but appear to require conversion to testosterone within the sebaceous gland.

Eunuchs secrete about half as much sebum as normal males, but substantially more than prepubertal boys [25].

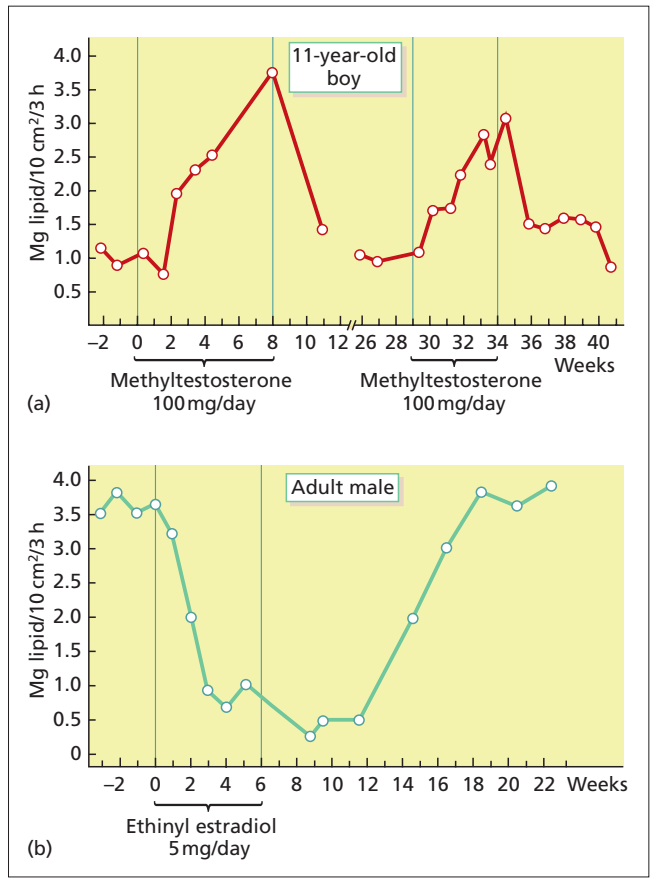

Fig. 43.3 (a) Sebum output of an 11-year-old boy given two courses of methyltestosterone orally (100 mg/day). Sebaceous secretion promptly rose with androgenic stimulation and quickly declined to the original level when the drug was stopped. (b) Suppression of sebum production in an adult male given 5 mg of ethinyl estradiol orally daily for 6 weeks. In this subject the decrease was readily detectable in 2 weeks and was nearly maximal after 3 weeks. Sebum production returned to pre-oestrogen levels approximately 11–12 weeks after discontinuation of oestrogen. (From Strauss *et al*. [23].)

Sebum production by eunuchs is quantitatively correlated with the urinary excretion of 17-hydroxycorticoids and 17-oxosteroids [26]; thus, the activity of the sebaceous glands of eunuchs appears to be dependent on adrenal androgens.

The secretion of sebum by adult women is only a little less than that of normal men. Up to the age of 50 years it is greater than in castrated men, but after that age it falls [7]. This pattern, and the fact that women do not normally produce more adrenal androgens than men, suggest that sebaceous glands are affected by extra-adrenal sources of androgen. Evidence also implicates secretion or conversion of androgens and oestrogens in the ovary and conversion in the skin [27]. However, there is only a small reduction in skin-surface lipid following bilateral oöphorectomy [25].

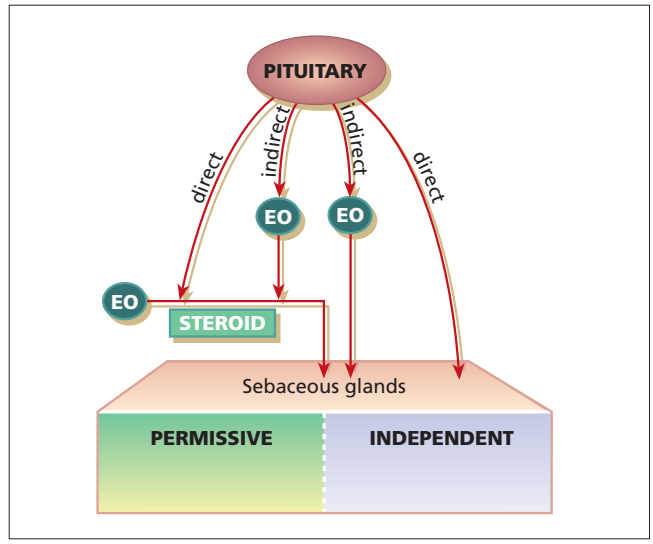

Fig. 43.4 Possible ways in which pituitary hormones may affect the sebaceous glands. The effect may be direct or indirect, and in addition may be either independent or permissive, in the sense that the pituitary hormone facilitates the response of another hormone, for example a steroid. EO, endocrine organ.

Progesterone

The effect of progesterone on sebaceous glands has been a matter of dispute. The fluctuation of sebum production in women during the menstrual cycle has been blamed on progesterone [28], but this has not been proved experimentally. Progesterone administration can produce acne [29], and when given to elderly women it increases sebum production [30], but no such effect could be demonstrated in young women [31,32]. Progesterone is a competitive inhibitor of 5α-reductase and might be expected to reduce sebaceous gland activity; in humans its sebosuppressive effect is minimal [33–35]. Experiments in the rat showed varied responses, depending upon when progesterone was administered in relation to birth, puberty, castration and oöphorectomy [35–39].

Adrenocortical hormones

Adrenal androgens have been discussed above. Sebum production fell after adrenalectomy for Cushing's syndrome [24]. Adrenocorticotrophic hormone (ACTH) causes hypertrophy of sebaceous glands in prepubertal human males and postpubertal human females [40], and increases the size of sebaceous glands [37,41] and sebum production [42] in hypophysectomized and gonadectomized rats.

There is little information on the effect of glucocorticoids on sebaceous gland activity. Hydrocortisone given to a prepubertal boy caused enlargement of sebaceous glands [40]. Sebum production is decreased in adrenal insufficiency, but replacement of glucocorticoids has no effect [24, 43].

Pituitary hormones

The pituitary has a major effect on sebaceous gland activity (Fig. 43.4). The mechanisms are different in the human and rat particularly in respect of pro-opiomelanocortin peptides, which seem to dominate in the rat but probably have little effect in humans. The pituitary acts indirectly through its various target glands, and as a result of a direct action by some of its hormones on sebaceous glands. Gonadotrophins stimulate sebum secretion in the human male [44], but probably do not have any direct independent action on the sebaceous gland.

ACTH has an effect through adrenal androgens (see above). Patients with hypopituitarism and those with isolated growth hormone deficiency have low levels of sebum [45], while patients with acromegaly show increased sebum secretion [46,47]. Growth hormone levels can be raised in prepubertal boys by supplemental testosterone administration, through increased growth hormone-releasing hormone secretion [48].

The effect of growth hormone may be mediated by insulin-like growth factors such as somatomedin C [49], which has been suggested as a mediator of the induction of 5α-reductase [50].

Alpha-melanocyte-stimulating hormone (α-MSH) is an important stimulator of sebaceous gland growth and development in the rat [51,52] and has synergistic action alongside testosterone [38,52,53]. Alpha-melanocyte-stimulating hormone is a member of the pro-opiomelanocortin peptide family, which includes ACTH. However, there is no evidence for a sebotrophic role for α-MSH in the human, despite slight elevations of plasma concentrations in Cushing's disease [54]. At the local level the sebocytes expressed MC-1 receptor; the precise relevance of this is not clear [55].

There remains some circumstantial evidence for a pituitary sebotropic hormone in humans. The drug levodopa decreases the seborrhoea of Parkinsonism, but has no effect in normal subjects [56]. The increase in sebaceous gland activity in pregnancy [57], lactation [58] and after taking phenothiazine drugs could be due to a pituitary-derived sebotrophic factor [1].

Oestrogens

Oestrogens undoubtedly depress sebaceous activity, especially in pharmacological doses. They decrease the size of sebaceous glands when injected into rats [59–61] or when given orally to adult human males [42], and have also been shown to reduce sebum production in both animals [62–64] and humans [23,65–68]. On the grounds that it was not possible to demonstrate a local, as distinct from a systemic, effect by topical application of oestrogen ointment to the human forehead [23], it has been suggested that oestrogens may act by reducing endogenous androgen production [44]. This view that they suppress gonadotrophin secretion by the pituitary receives support from the finding that sebum-suppressing doses of oestrogen reduced the levels of testosterone in the plasma and urine of normal men [68], although not from the evidence that they suppressed sebum secretion in eunuchs [26].

Evidence from animal experiments favours the hypothesis that oestrogens act peripherally and directly upon the sebaceous glands [60,69–73]. However, in humans oestrogens are very likely to influence hormonal levels by some systemic action through the pituitary–gonadal axis.

Hormonal actions on sebocytes in culture

Data from sebocytes in culture have supported the *in vivo* evidence presented in the previous sections. Several groups [2,74–78] have made significant contributions. Zouboulis's group [76–78] has established an immortalized human sebaceous gland cell culture system that has been passaged over 50 times; cells have been cloned and show no signs of senescence after 4.5 years *in vitro*, whereas normal human sebocytes can only be grown for 3–6 passages. These immortalized sebocytes have large cytoplasm profiles with abundant organelles, including vacuoles and myelin figures, which indicate lipid synthesis. The cells express molecules typically associated with human sebocytes such as keratins 7, 13 and 19. Functional studies have revealed that the synthesis of the sebaceous lipids is virtually identical to that of the human sebaceous gland cells. They have also showed an increased cell proliferation after the addition of 5α-DHT and a significant inhibition in the proliferation of these immortalized cells after the addition of retinoids, in particular 13-*cis*-retinoic acid (13-*cis*-RA).

These culture systems have demonstrated that the skin is a factory of androgen metabolism [76–78]. Studies on immortalized sebocytes have demonstrated that the four major enzymes involved in the intracellular activation and deactivation of androgens are: (i) 3β-hydroxysteroid dehydrogenase Δ^{4-5} isomerase (Δ^5-3β-HSD), (ii) 17β-hydroxysteroid dehydrogenase (17β-HSD), (iii) 5α-reductase and (iv) 3α-hydroxysteroid dehydrogenase (3α-HSD). Three-beta-hydroxysteroid dehydrogenase Δ^{4-5} isomerase (isotype 1), which converts dihydroepiandrosterone to androstenedione, is almost exclusively located in the sebaceous glands. Sebaceous glands express isoforms 2 and 3 of 17β-HSD and thus are able to reversibly convert androstenedione to testosterone. Five-alpha-reductase isotype 1, which irreversibly metabolizes testosterone to 5α-DHT, is also predominantly expressed in the sebaceous glands [13]. Zouboulis's group also demonstrated that corticotrophin-releasing hormone (CRH) is a sebaceous gland autocrine hormone and is a byphasic regulator of lipogenesis in human sebocytes [79]. This evidence was obtained from sebocyte cell culture experiments and suggests that human sebocytes possess a complete CRH/CRH-receptor system. These proteins are expressed at the mRNA and protein level. Could it be, in part, that the influence of stress on acne is explained by this local hormonal pathway?

In contrast, keratinocytes have different expression and metabolic rates of some of these enzymes. For example, sebocytes are able to synthesize testosterone from adrenal precursors and to inactivate them in order to maintain androgen homeostasis, whereas keratinocytes are responsible for androgen degradation. These unique expressions of different androgen activity in different cutaneous cells suggests that there may be differentially programmed duties of skin cell populations for androgen metabolism [76–80].

In addition to androgens, other physiological and pharmacological candidates have been reported to control the development of sebocytes and to stimulate the proliferation of human sebocytes. Growth factors such as epidermal growth factor (EGF), transforming growth factor-α (TGF-α) and basic and fibroblast growth factor are paracrine and autocrine mediators of the proliferation and differentiation of a wide variety of cells [81,82]. Studies on hamster sebocytes have shown that these growth factors have mitogenic activity and act as antilipogenic factors [82].

Retinoid control of sebaceous gland activity

Interest in retinoid metabolism within sebocytes and the sebaceous gland has been stimulated by the extreme clinical effectiveness of 13-*cis*-RA (isotretinoin) in severe acne. Other retinoid drugs including retinoic acid and all-*trans*-RA (tretinoin) have been shown to have a clinical effect in acne. Retinoids exert their effect through cell proliferation, lipid synthesis and keratin expression.

Sebocyte proliferation and lipid synthesis are suppressed when cells are cultured in the absence of vitamin A [1]. Pharmacological quantities of 13-*cis*-RA or all-*trans*-RA also suppressed sebocyte proliferation and lipid synthesis in a dose-dependant manner [2]. 13-*cis*-Retinoic acid down-regulated the expression of keratins 5, 6, 14 and 16 and up-regulated keratin 7, whereas all-*trans*-RA down-regulated keratin 5, 6 and 16 expression and up-regulated the expression of keratin 19 [2]. Recent studies have suggested that all-*trans*-RA may be the active metabolite of isotretinoin within cells following enzymic conversion from 13-*cis*-RA [3]. Evidence comes from the preferential binding of all-*trans*-RA to retinoic acid receptors (RARs) [3]. Figure 43.5 illustrates probable interconversion of retinoids within cells.

Inhibitors of sebaceous activity

Acne is associated with an increased sebum secretion and proliferative activity of sebaceous glands. Much effort has therefore gone into developing treatments for acne, which reduce sebaceous gland activity.

Possible mechanisms include reducing the circulating levels of serum androgens through an effect on the pituitary, adrenal or gonads, or by affecting the transport of androgens. Alternatively, the pharmacological/physiological suppression of androgens could be achieved through a direct effect on sebocyte metabolism. Such mechanisms include blocking enzyme activity (5α-reductase type 1, Δ^5-3β-HSD, cytochrome p450), or by blockage of androgen or retinoid receptors.

The effect of topically applied hormones shows a considerable species difference between animals and humans. Some topical therapies significantly reduce sebum excretion in animals but have no effect in the human. The most likely explanation is anatomical, because the animals under investigation have sebaceous glands that are situated very close to the epidermis; the human sebaceous gland is relatively deep in the dermis and connects to the epidermis by a long pilo-sebaceous duct, which would make it more difficult for these compounds to reach the gland itself. Clinical benefit does not occur until sebum suppression achieves a minimum of 30%.

Co-cyprindiol (Dianette® and Estelle 35®), which contains 35 μg ethinyl estradiol and 2 mg cyproterone acetate (CPA), reduces sebum excretion by 28% [1–3]. When combined with additional CPA (100 mg/day) from the fifth to the 14th days of cycle, the sebum suppression rises to 68%.

CPA appeared to be ineffective when applied topically in 50% dimethylsulfoxide (DMSO) or in cetomacrogol [4–5], but to have some effect in ethanol [6]. Various other agents have been proposed for topical effectiveness [7–12] including 17α-propyltestosterone, 17α-mesterolone and flutamide, all of which have been shown to be of no clinical benefit in patients with acne. Inocoterone, another non-steroidal receptor blocker, reduces sebaceous gland activity when applied topically to rat and hamster sebaceous glands [13,14], and appears to lack systemic effects. In humans, topical inocoterone produced only a small reduction in sebum excretion in adult males, and a minor improvement in clinical acne [15]. Seventeen substituted α-chloro and 17β-sulphinyl steroids have been suggested as inhibitors of sebaceous activity [16], but have been disappointing in humans. Spironolactone, given systemically, has been shown to inhibit the hamster flank organ [17], and, given topically, to block androgen activity in sebaceous glands of the hamster pinna [18]. However, there was no effect on sebum excretion when applied topically to humans [19]. In contrast, spironolactone given orally significantly reduces sebum excretion in humans in a dose-dependent manner: there is a reduction of around 30% with 100 mg/day, and a reduction of 60–70% with 200 mg/day [20]. Oral administration of the H_2-receptor antagonists ranitidine and cimetidine reduces sebum excretion in humans [21], but not to a clinically significant level, and these drugs lack effect topically [22].

Substances that inhibit the conversion of testosterone to DHT, without blocking attachment to the intracellular receptor, also reduce sebum production [23]. A reduction in the rate of sebum excretion by topically applied progesterone [24,25] may involve such a mechanism. Topical progesterone only has a relatively small and temporary sebosuppressive effect in humans; this is likely to be of no clinical significance to the patient with acne.

Certain derivatives of vitamin A, in particular isotretinoin (13-*cis*-RA) have marked effects on the sebaceous glands when given systemically. They have been shown to reduce the size of the hamster flank organ [26] and human sebaceous glands [27], in which they profoundly inhibit sebum excretion [28–30]. Isotretinoin reduces 5α-reductase activity in human liver and skin [31–33], and reduces the binding capacity of the androgen receptor in back skin [33]. Isotretinoin reduces the synthesis of DNA and the incorporation of a lipid precursor ^{14}C-acetate in human sebaceous glands *in vitro* [34,35]. The metabolism of retinoids in the human sebaceous gland has been described above (see also section on oral isotretinoin below). Topical retinoids, in contrast to certain oral retinoids, have no effect in reducing sebum production or excretion.

It has been assumed that topical antibiotics do not influence sebum production or sebum excretion. However, it has been shown that topical erythromycin plus zinc acetate (Zineryt®) reduces SER by about 20% (using Sebutape® technology) in contrast to topical erythromycin alone [36]. The mechanism for this is unclear, but may relate to the drug affecting sebum outflow from the duct.

Acne vulgaris

Definition. Acne is a chronic inflammatory disease of the pilosebaceous units. It is characterized by seborrhoea, the formation of comedones, erythematous papules and pustules, less frequently by nodules, deep pustules, or pseudocysts and, in some cases, is accompanied by scarring.

Four major factors are involved in the pathogenesis: (i) increased sebum production, (ii) hypercornification of the pilosebaceous duct, (iii) an abnormality of the microbial flora especially colonization of the duct with *P. acnes*, and (iv) the production of inflammation.

Natural history. The condition usually starts in adolescence and frequently resolves by the mid-twenties [1]. Prevalence data shows some variation from study to study, which may relate to the population studied and the time when the study was performed. In one study prevalence of significant acne was 56% in boys and 45% in girls aged between 14 and 16 years, being moderate to severe in 11% [2]. A peak in prevalence and severity occurs between 14 and 17 years in females, when 40% are affected, and 16 and 19 years in males, when 35% are affected [1]. A study from the USA [3] indicated that the prevalence by the mid-teens was virtually 100%. On the other hand only about 20% of sufferers needed the help of a physician. In those patients with very mild disease the problem is referred to as physiological acne. Acne develops earlier in females than in males [1,4], which may reflect the earlier onset of puberty. Significant prepubertal acne is only rarely found to be a cutaneous marker of an endocrine abnormality, such as adrenogenital late-onset syndrome. Mild, comedonal acne can be the first sign of pubertal maturation; significant comedones usually precede inflammatory lesions by 2–3 years [5,6]. Some subjects show small non-inflamed lesions by the age of 8–9 years [1]. Site of involvement is linked to the age of onset of the disease with inflammatory lesions in the midline of the face presenting early in sexual maturation [5].

After the age of somewhere between 20 and 25 years the acne resolves slowly [7]. However, in 7–17% of individuals clinical acne persists beyond the age of 25 years [8] with physiological acne in females having a prevalence of 24% [9]. A study from Denmark suggested that there has been a decrease in the prevalence of acne in females, and

this may relate to the widespread use of oral contraceptives [10]. On the other hand, some clinicians consider that they are now seeing an increase in the number of patients with mature acne. In a recent study [8], 25% of acne patients referred to an acne clinic had a mean age of 24 years. Most had acne persisting from adolescence, but 8% had late-onset (age over 25 years) acne. This may be a reflection of a more demanding and articulate group of mature acne patients [11]. At the age of 40 years, significant lesions are still present in 1% of males and 5% of females [7]. On the other hand, questionnaire-based studies in France [12] and in the USA [13] have shown that as many as 80% of patients treated for acne have some level of disease activity that persists into the 30–40 year age range.

Factors that underlie the resolution of acne are not understood, nor is the relative persistence in females. Recent studies on the natural history of acne are limited, because improved treatment has modified the prevalence, severity and age of presentation to dermatological clinics [14].

Genetic factors. Several studies have shown that genetic factors influence susceptibility to acne [15,16]. A survey in Germany [17] showed that acne had been present in one or both parents of 45% of schoolboys with acne but in only 8% of parents of boys without acne. A genetic influence is confirmed by the very high concordance between monozygotic twins, in whom the SER is virtually identical. Comedone numbers are also similar in identical twins but not in dizygotic twins, which suggests a genetic role in comedone formation [16]. Furthermore, in three pairs of identical twins, severe nodular acne developed at approximately the same time in each pair. On the other hand, in less than half of affected dizygotic twins did both twins have acne [17]. Patients with persistent acne have a strong family history of persistent acne, in contrast to patients with adolescent acne [8].

The decreased incidence of atopic dermatitis in acne sufferers [18] may be genetically determined, but it could be otherwise explained. Patients with eczema have a low sebum excretion. The association of very severe acne with the XYY syndrome [19,20] has been recorded.

Racial studies provide an insight into genetic and environmental factors. Acne in black Americans is less evident than in white Americans, who, in turn, have more severe acne than Japanese [21]. The incidence of acne is said to be low in Inuits, who eat a diet rich in fish, but increases markedly when they change to a 'Western' (Canadian) diet with more saturated fats. Similar changes have been noted in Japanese people who emigrate to Hawaii and consume an American-style diet [21].

Since the last edition of this textbook, there has been a dramatic increase in knowledge about the human genome. The authors know of several clinical/laboratory groups who are exploring the links between acne and its inheritance. It is essential that these workers relate their laboratory data to a more focused description of the disease rather than just the term acne. For example, patients with acne persisting into their thirties have a strong family history of this event [8]. Acne severity, distribution, site of the lesions, scarring and response to treatment could also be genetically determined.

The size of the problem [1]. A person is more likely to develop acne than any other disease [2]. The major burden of acne is experienced during the teenage years, but acne may continue as a clinical problem into the twenties and older. Data are more reliable for school-aged children than for those in the later teens or older because of the ease of data capture.

Studies of European schoolchildren in Switzerland in 1931 [3], Newcastle upon Tyne, England, in 1971 [4] and Glasgow, Scotland, in 1989 [2] have shown a consistent level of maximum prevalence, approaching 100% for 16–17-year-old boys and 85–100% in 16-year-old girls. However, the same period has seen a major reduction in severity. In the 1931 study, 57% of boys and 19% of girls had severe acne [3]. These figures had fallen to 30% and 20% in 1971 [4] and changed to 35% and 13% respectively in a further study in Newcastle upon Tyne in 1981 [5]. By 1989, the Glasgow study showed no schoolchildren with severe acne, only 1.8% of boys with moderate acne and no girls with worse than mild acne [2]. Only the Newcastle upon Tyne and Glasgow studies were randomized cross-sectional views. Similar prevalence levels were found in New Zealand [6] and Southern Australia [7], but both countries showed significantly larger numbers of school students with the more severe grades of acne than were found in the UK. Unfortunately, most studies have been affected by selection bias due to place of work, educational institution or hospital/surgery attendance. Questionnaire-based surveys in the USA and the UK [8,9] have shown a lower prevalence, as might have been expected from the Glasgow study, which found clinical acne in 18% of boys, many of whom denied the presence of spots.

The clinical problem of acne in older patients in their twenties and thirties appears to be increasing [8–12], but better epidemiological data are required.

The size of the problem is also influenced by patients' beliefs and perception [13,14]. Twelve per cent of teenage boys denied the presence of clinical acne [2] and, in another study, 49% of patients believed their acne to be curable within 6 months [13].

Aetiology of acne

The four major factors involved in the aetiology of acne are:

1 seborrhoea
2 comedo formation (comedogenesis)
3 colonization of the duct with *P. acnes*
4 inflammation.

Seborrhoea

Patients with increased sebum production complain of seborrhoea (greasy skin). Active sebaceous glands are a prerequisite for the development of acne. Acne patients, male and female, excrete, on average, more sebum than normal subjects [1], and the level of secretion correlates reasonably well with the severity of the acne (Fig. 43.6) [2,3]. Sebaceous activity is predominantly dependent on androgenic sex hormones of gonadal or adrenal origin [4–6]. Abnormally high levels of sebum secretion could thus result from high overall androgen production, increased availability of free androgen, due to a relative reduction of sex hormone binding globulin (SHBG) or an amplified target response mediated either through 5α-reduction of testosterone or an increased capacity of the intracellular receptor to bind androgens.

There is general agreement that plasma testosterone levels are not abnormally high in males with acne [6–8]. In females with acne, the situation is more complicated. Some investigators have found testosterone levels to be normal [9–11], while others have found raised levels [12–15], albeit often lower than in males with no acne whatsoever. Most studies have shown that mean SHBG

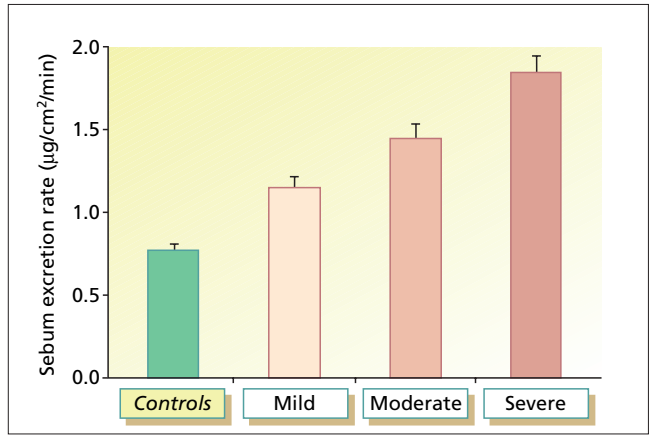

Fig. 43.6 Correlation between acne severity and sebum excretion.

levels are significantly below normal, with free testosterone consequently above normal. However, for every endocrine assay, there has been a considerable overlap between the values found in acne patients and normal ranges. Lawrence *et al.* [12] found that only 41% of their acne patients had free testosterone levels above normal. Lucky *et al.* [13] measured a number of androgens and their precursors, as well as SHBG, and found that 52% of non-hirsute women with acne had at least one abnormal hormone level. Cibula *et al* [16] found that 81% (73 of 90 patients) had an elevation of at least one androgen hormone of the four that they measured. In their study, 21% had hirsutism and 50% had polycystic ovarian syndrome, but there was no correlation between the severity of acne and abnormalities of the sex hormones. Darley *et al.* [17] examined 38 women with acne and found high serum testosterone in 26%, low SHBG in 45% and high prolactin in 45%, but 24% had no hormonal abnormality at all. Peripheral androgen metabolism may be important, for example increased androsterone metabolism has also been reported in females with normal circulating androgen levels [15]. Insulin may affect SHBG, thereby influencing androgen clearance [18]. However, post-meal transient hyperinsulinaemia does not seem to play a role in hyperandrogenaemic acne patients [19].

Thus, on reviewing published papers, it would seem that androgenic hormonal balance is disturbed to some degree in 50–75% of female acne patients. However, this does not establish a causal link and at least a quarter of all cases remain unexplained. Furthermore, in many of the reports the patients were older than the modal value for all female acne patients, and not infrequently had other features of endocrine disease, such as significantly irregular menstruation and hirsutism. There are no correlations between the severity of acne, hirsutism and menstrual irregularity [20]. Moreover, if the development of acne were simply related to systemic hormone levels, it should have a similar frequency on the face, back and chest, but this is not so. In general, acne patients are not endocrine misfits.

The fact that acne does not occur simultaneously on all susceptible sites is consonant with the finding that sebum excretion varies from follicle to follicle (Figs 43.7 & 43.8) [21]. In acne patients, there is marked heterogeneity in individual follicular sebum excretion. This allows us to hypothesize that certain follicles may be prone to acne [22]. An enhanced peripheral response to androgens must thus be considered as a probable factor in many subjects. The possible role of increased 5α-reduction of testosterone to its more active metabolite 5α-DHT is supported, both by the demonstration that sebaceous glands in acne-prone regions show abnormally high 5α-reductase activity *in vitro* [23], and by the finding of abnormally high amounts of 5α-androstanediols in the urine of female acne patients [9]. Data on androgen receptors in acne suggest that

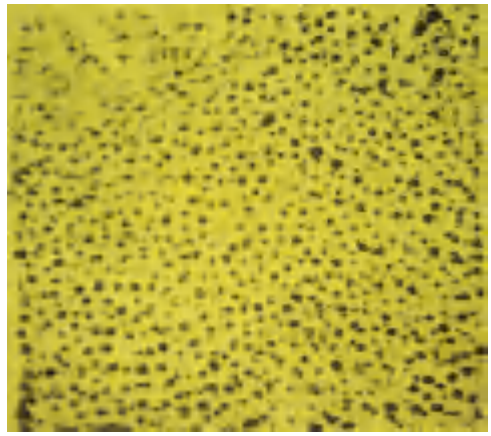

Fig. 43.7 Homogeneous sebaceous outflow in a normal subject.

Fig. 43.8 Heterogeneous sebaceous outflow in an acne subject.

androgen action on the sebaceous gland may be independent of serum hormone levels [24]. There are two forms of 5α-reductase [25]. It is likely that 5α-reductase type I is the most relevant in acne for two reasons. First, finasteride, an inhibitor of type II 5α-reductase, does not reduce sebum production [26]. Second, patients with a deficiency of type II 5α-reductase have normal sebum levels [26]. Regional differences in the activity of type I 5α-reductase in isolated sebaceous glands from various body sites also support the end-organ hyper-responsiveness theory for acne [27–30].

In the authors' clinical practice and that of other acne centres [31], it is usually not necessary to investigate for an endocrinopathy. An endocrine evaluation may be indicated for adult females, with a sudden onset of severe acne; with acne that has proven resistant to conventional therapy especially in the presence of hirsutism; with very irregular menstrual periods or signs of hyperandrogenism. Androgen evaluation may also be warranted in women who experience relapse shortly after starting isotretinoin therapy. A medical history and physical examination should be performed before embarking upon relevant blood tests. Polycystic ovarian syndrome is the

Fig. 43.9 Ultrasound of the pelvis showing polycystic ovaries.

most frequently associated hormonal disease [32], and this can be detected by ultrasonography (Fig. 43.9). In most acne clinics, the majority of female patients with acne have no other clinical features of the syndrome, which consists of hirsutism, infertility or irregular menstruation [11]. There is no correlation between the presence of ovarian cysts and the severity of the acne [33]. Late-onset adrenal hyperplasia due to a partial deficiency of 21-hydroxylase should be considered in patients with persistent problems with their acne [34]. This enzyme deficiency results in a need to maintain cortisol levels, and so produces a shunting in the steroid biochemical pathways that results in an increase in androgen production. The disorder may uncommonly be a cause of severe acne in boys [35]. It is very rare to find virilizing tumours that present as acne alone. Thus, it is not often necessary to measure sex steroid levels, as this information usually contributes little to the patient's management. When thought necessary, appropriate initial tests should include measurement of total testosterone (ideally free testosterone, but only a few laboratories can measure this hormone), SHBG, androstenedione, dehydroepiandrosterone (DHEA), prolactin and follicle-stimulating hormones (FSHs) and luteinizing hormones (LHs) [36]. Since there are diurnal and menstrual variations in sex hormone levels it is important to relate the results to the time at which the blood was taken in relationship to the menstrual cycle and, for consistency, the test is best performed at 09.00. For reliability and repeatability, the tests should be performed in the luteal phase of the menstrual cycle (within 2 weeks prior to the onset of menstruation). If late-onset congenital adrenal hyperplasia is suspected, then a 09.00 cortisol and 17α-hydroxyprogesterone measurement should be performed. Clinicians should remember that hormonal therapy might also interfere with the results.

Either the adrenal gland or the ovary may produce excess androgens. Serum dehydroepiandrosterone sulphate (DHEAS) levels can be used to screen for an adrenal source of excess androgen production. Clinicians should check local normal values, but patients with a serum DHEAS greater than 21.7 μmol/L may have an adrenal tumour. Some adrenal tumours may also produce testosterone. Values of DHEAS in the range of 10.8–21.7 μmol/L may be seen with congenital adrenal hyperplasia, which is often associated with a slightly raised cortisol and a 17α-hydroxyprogesterone level of greater than 12.8 μmol/L.

An ovarian source of excess androgen can be suspected in cases where the serum total testosterone is elevated. Serum total testosterone in the range of 520–700 nmol/L or an increased LH : FSH ratio (greater than 2–3) is often seen in patients with polycystic ovarian disease. Greater elevations in serum testosterone may indicate an ovarian tumour.

The possibility that other hormones may affect the sebaceous glands, either directly or by enhancing their response to androgens, should not be neglected. In acromegaly, the rate of sebum excretion is high and correlates with skin thickness and growth hormone levels [37]. The SER is low in individuals with isolated growth hormone deficiency, and therefore is not associated with acne [38]. In clinical practice, these endocrinopathies are rarely encountered as presenting features in the dermatological clinic.

Sebaceous lipid composition

Irrespective of the rate of sebum excretion, could acne be related to a change in skin lipid composition? Sebum consists of a mixture of squalene, wax and sterol esters, cholesterol, polar lipids and triglycerides [39]. As the sebum moves up the duct, bacteria, especially *P. acnes*, hydrolyse the triglycerides to free fatty acids. The role of individual lipid components in causing acne is uncertain. Lipids may be involved in ductal hypercornification, or may be essential to the growth (stimulation and inhibition) of bacteria. Sampling of skin-surface lipids has shown that patients with acne tend to have higher levels of squalene and wax esters, lower levels of fatty acids [40–42], and a more frequent occurrence of particular free fatty acids [43,44]. Linoleic acid is significantly reduced in epidermal and comedonal lipids, and this may relate to ductal hypercornification.

Comedone formation (comedogenesis)

An important feature in the aetiology of acne is the presence of ductal hypercornification, which can be seen histologically as microcomedones, and clinically as blackheads, whiteheads and other forms of comedones such

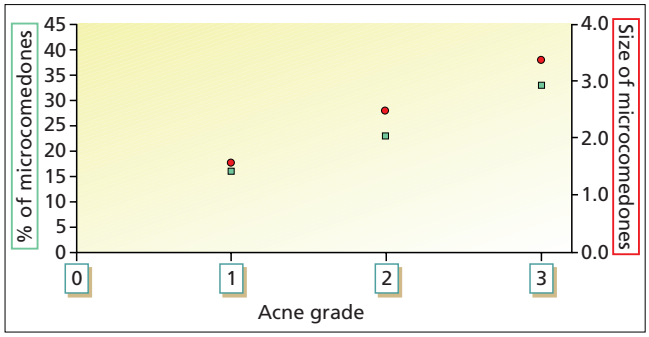

Fig. 43.10 Correlation between the number and size of microcomedones and acne severity.

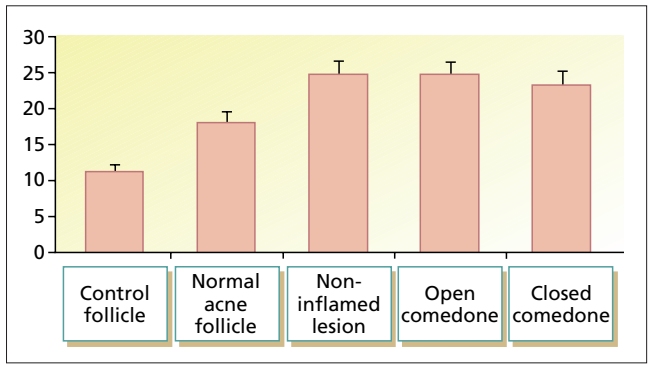

Fig. 43.12 Uptake of Ki-67, a marker of keratinocyte proliferation, in control skin, microcomedones and clinical comedones.

Fig. 43.11 Scanning electron microscopy of a microcomedo that has been sampled from an acne-prone skin using the skin-surface biopsy technique.

Fig. 43.13 *In situ* hybridization for keratin 6 (a marker of hyperproliferation) demonstrates little activity in a normal follicle (left) and considerable activity in a comedo (right). (Courtesy of Dr D.B. Holland, Leeds General Infirmary, Leeds, UK.)

as macrocomedones. There is a significant correlation between the severity of acne and the number and size of follicular casts (microcomedones), the presence of which is a measure of comedogenesis [45] (Fig. 43.10). Follicular casts (microcomedones) can be sampled by applying cyanoacrylate gel to the skin surface, followed by pressing a glass microscopic slide on top for 1 min [46,47]. The sample can be analysed by low-power microscopy or by digital image analysis [46,47] (Fig. 43.11).

Comedones are due to abnormalities in the proliferation and differentiation of ductal keratinocytes. They represent the retention of hyperproliferating ductal keratinocytes/corneocytes in the duct. The hyperproliferation has been confirmed by showing an increase in ^{3}H-thymidine labelling of comedones [48] and increase in the Ki-67 labelling (a marker of cell turnover) of ductal keratinocytes (Fig. 43.12) [49]. Ki-67 labels nuclear antigen expressed by cells in the late G1, S, M and G2 phases of the cell cycle [50]. This technique has also shown an increase in the proliferation of ductal keratinocytes of 'non-affected' follicles, which were biopsied as clinically 'normal' follicles from an area affected by acne [49]. This fits with the histological observation of microcomedones being found in 30% of tissue sections of clinically 'normal' skin taken from skin adjacent to acne lesions. Further evidence of ductal hyperproliferation is the presence of keratins 6 and 16 (keratin markers of hyperproliferation) in microcomedones and comedones (Fig. 43.13) [51]. The primary abnormality that gives rise to hypercornification is not related to changes in keratin expression [51,52]. There is as yet no evidence to suggest that comedogenesis

may be related to failure of ductal keratinocytes to separate. Studies of involucrin expression and desmosomes, which are features of terminal differentiation, have shown no difference between follicles from acne and control biopsies [53].

Several factors have been implicated in the induction of keratinocyte hyperproliferation, and include sebaceous lipid composition, androgens, local cytokine production and bacteria.

Of the abnormal sebaceous lipids in acne patients, the linoleate levels may be relevant. Examination of polar lipids recovered from comedones shows that the acyl ceramides contain only 6% linoleate among the esterified fatty acids, compared with 45% in normal human epidermis [54,55]. Similarly, linoleic acid is reduced in sebum from acne subjects, but returns to normal with resolution of acne following treatment with isotretinoin [56] and antiandrogens [57]. In animal experiments, a low linoleate produces hypercornification, which may parallel the increased scale found in comedones. In these animals, a low linoleate produced a decreased epidermal barrier function, which might have rendered the comedonal wall more permeable to inflammatory substances. Membrane-coated granules [58–60] are probably more related to barrier permeability than cell separation, and are decreased in comedones, but the significance of this is as yet unclear.

Other lipids have been incriminated; in particular, free fatty acids and squalene have been blamed for inducing comedones [61,62] in the rabbit-ear model [63]. The development of a human model for comedogenesis has, however, suggested that the rabbit model is inappropriately over reactive [64]. Laboratory animals do not develop whiteheads or inflamed acne lesions, even though the rabbit ear readily produces comedones [65]. The rhino mouse is an alternative useful model for comedogenesis [66]. From experiments in the rhino mouse, it has been suggested that comedone formation may be associated with an abnormality in apoptosis (programmed cell death) [67]. Evidence is accumulating to propose that androgens may play an important role in comedogenesis. There is a correlation between comedone numbers in early acne and DHEAS levels [68]. Cells of the pilosebaceous duct have androgen receptors [69], and 5α-reductase type I is also present in these cells both in health and in disease [70–72]. Antiandrogen drugs, such as CPA in the drug co-cyprindiol (Dianette® and Estelle 35®), reduce comedones. Co-cyprindiol also increases the sebaceous linoleate concentration [57], and thus antiandrogen therapy could modulate comedogenesis both directly and indirectly by influencing sebaceous lipid.

Cytokine production by ductal keratinocytes is also likely to be important. Kealey and colleagues have developed an excellent *in vitro* model for growing the duct [73–75]. IL-1-α is present in many comedones at levels that are likely to be biologically and pathologically relevant [76]; IL-1-α induces comedogenesis (Fig. 43.14). Furthermore, EGF markedly disrupts the duct comedo *in vitro* [75]. Kealey and colleagues have extended their studies, and provided further supporting data to show that the isolated, maintained infundibulum is also a good culture model for studying the effects of inflammatory cytokines on the pilosebaceous duct, and that IL-1-α acts on the fundibular keratinocytes to induce cornification [76]. They have also shown that EGF and TGF-α inhibit sebum secretion [77].

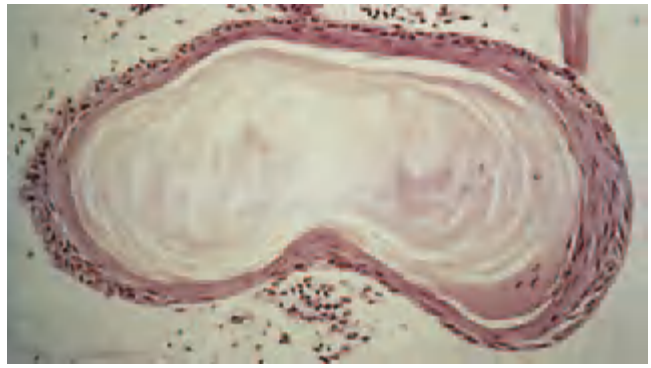

Fig. 43.14 An *in vitro* comedo, induced by interleukin-1-α (IL-1-α). (Courtesy of Dr T. Kealy, Cambridge University, UK.)

Bacteria are probably not involved in the initiation of comedones. Electron microscopy of early non-inflamed lesions taken from prepubertal and early pubertal individuals has demonstrated few or no bacteria [78]. Quantification of bacteria from comedones suggests that follicular colonization may be unrelated to comedogenesis [79]. Biopsy and culture of early non-inflamed lesions has shown that 30% of these are without bacteria [80], suggesting that ductal bacteria are not needed for the initiation of cornification in the development of comedones.

Comedones are temporary structures. Using markers of cell cycling (Ki-67) and keratinocyte proliferation, it has been shown that, like the hair follicle, normal pilosebaceous follicles and comedones undergo cyclical growth [81]. Extracted blackheads refill over 2–6 weeks. Functionally, some comedones are blocked [82], but others can become blocked temporarily following skin hydration [83], and this obstruction is associated with a decrease in outflow of sebum. Such observations could help to explain tropical acne and premenstrual flare of acne [84].

Certain external chemicals may contribute to comedogenesis. These substances include the ingredients of some cosmetics such as isopropyl myristate, propylene glycol, and D and C red dyes [85]. It has been suggested that the excretion of products from the sebaceous gland occurs through an organized acellular tubular conduit—the sebolemmal sheath produced by the sebaceous duct cells; rupture of this sheath may contribute to comedogenesis [86]. However, this concept has yet to be confirmed by others.

Relationship between *P. acnes* and acne

Acne is not infectious. The three major organisms isolated from the surface of the skin and the pilosebaceous ducts of patients with acne are *P. acnes*, *Staphylococcus epidermidis* and *Malassezia furfur* [87]. There are three major subgroups of the propionibacteria—*P. acnes*, *P. granulosum* and *P. avidum*. Almost certainly *P. acnes* and, to a lesser extent, *P. granulosum* are the most important. Nevertheless, as they live in association with *S. epidermidis* and *M. furfur*, the latter organisms probably have some control over the growth of *P. acnes* [88].

Adolescence and its attendant seborrhoea are associated with a significant increase in *P. acnes* numbers [89], but there is little or no relationship between the number of bacteria on the skin surface and the severity of acne [90–92]. There is a much closer relationship between follicular organisms recovered from 4 mm punch biopsies and the severity of the disease [93]. In a study in which the cutaneous microflora of patients with persistent and late-onset acne were compared with individuals with adolescent acne and normal control volunteers without acne [93], the microflora consisted in the main of *Propionibacterium*, staphylococci and *Malassezia*, and at all sites there were significantly more *Propionibacterium* spp. than the other two microorganisms. Female facial skin and male back skin showed significantly higher numbers of microorganisms in the upper parts of the follicles from patients compared with control volunteers. In all, 26 papules and 48 normal follicles were biopsied and analysed [93]. There was a bimodal distribution of microbial colonization, with about 90% of normal follicles and about 10% of acne follicles having no detectable viable microorganisms. There were fewer microorganisms in normal follicles than in inflamed lesions. Although the presence of microorganisms, especially *P. acnes*, cannot be deemed to be singularly responsible for the onset of the inflammatory lesion, the significant difference between the number of inflamed lesions, which were colonized, when compared with normal follicles, lends support to the theory that these microorganisms may be involved in the inflammatory process at some point.

It is possible that the number of microorganisms increases at each stage as the follicle progresses from normal to comedone and on to an inflamed lesion. There is a 10-fold increase in the number of organisms found in inflamed lesions [93]. The biological significance of this is uncertain. It seems plausible that microorganisms might contribute to the inflammatory process but, conversely, an inflamed lesion may simply provide an enriched environment for the proliferation of cutaneous microorganisms. The microenvironment within the pilosebaceous unit produced by the bacteria is probably more important than their absolute numbers for the development of acne lesions. *In vitro*, it has been shown that oxygen tension, pH and nutrient supply markedly affect the growth of *P. acnes*, and the bacterial production of active substances such as lipases, proteases, hyaluronate lyase, phosphatase and smooth muscle contracting substances [94–96]. *In vivo*, the pH of blackheads markedly varies between 3.6 and 6.7 [97], and this is likely to affect the bacteria. Oxygen tension is also likely to be important. *Propionibacterium acnes* grows well at low oxygen tensions. In the presence of light at high oxygen concentrations, *P. acnes* grows well, but growth is inhibited because of photodamaging reactions involving excess oxygen and endogenous microbial porphyrins [98]. These factors could determine whether or not a follicle develops into a non-inflamed comedo and, subsequently, into an inflamed lesion.

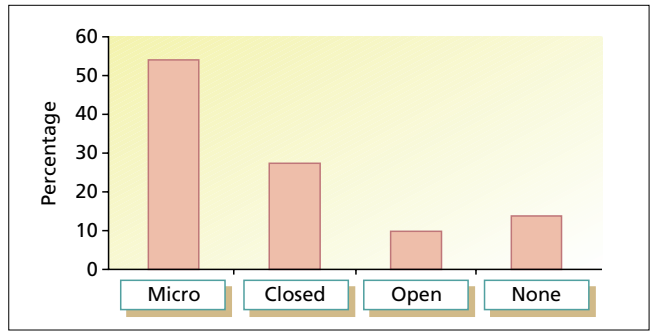

Fig. 43.15 Most, but not all, early inflamed lesions are associated with a microcomedo or clinical comedo.

The once-fashionable 'lipase' theory for acne [99] no longer has much support, because injection of fatty acids into the skin produces only mild inflammatory reactions [100]. Lipids are not found in the dermis in the early inflammatory infiltrate of acne, and a specific lipase inhibitor produced no improvement in acne [101].

Propionibacterium acnes is non-motile but easily colonizes the duct. Just how this event occurs is unknown. To colonize, *P. acnes* organisms must clump; free fatty acids aid clumping, and so bacterial lipases may be necessary for clumping and ductal colonization [102].

Mediation of inflammation

The precise factors that induce inflammation in acne lesions are unknown, but the subject has been well reviewed by Webster [103]. A microcomedo or comedo is present in 88% of early inflamed papules (Fig. 43.15). Duct rupture is seen in only 33% of papules at 36 h after the onset of clinically detectable inflammation, but by 72 h duct rupture has occurred in 67% [104]. Thus, in early inflammation pro-inflammatory mediators move through the duct wall into the dermis (Fig. 43.16). In papules, helper T cells are the first inflammatory cells to be seen [104,105].

The dermal inflammation of acne is not caused by the presence of bacteria in the dermis, as these are rarely

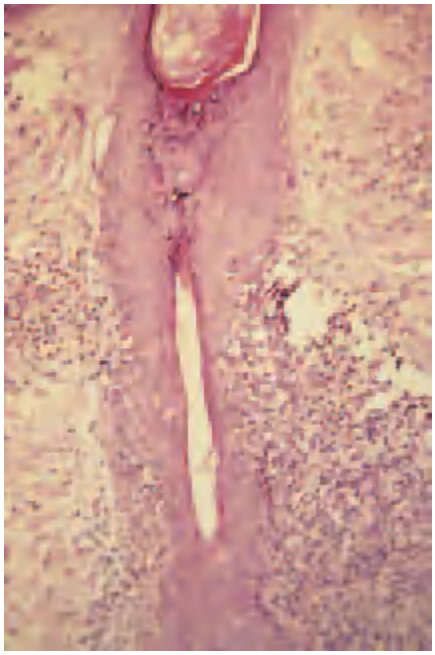

Fig. 43.16 An early inflamed papule (6 h). Note spongiosis and a lymphocytic infiltrate but no obvious rupture of the duct.

Fig. 43.17 A late-stage papular nodular lesion (7 days). Note total disruption of the duct and a macrophage, giant cell reaction.

demonstrable by routine and immunofluorescence methods [105]. It probably results from biologically active mediators that diffuse from the follicle, where they have been produced by *P. acnes*.

As the lesions progress, timed biopsies using a bank of inflammatory markers have shown that, prior to obvious duct rupture, the inflammation represents a classical type IV immunological reaction to as yet not fully identified antigens [106]. Later, in moderate and severe inflammation there is disruption of the duct and a macrophage giant cell foreign-body reaction (Fig. 43.17). Direct immunofluorescence studies have shown that there is activation of the classical and alternative complement pathways in early non-inflamed and in inflamed lesions [107,108].

The microorganisms, especially *P. acnes*, are an obvious source of antigenic stimuli. *In vitro*, *P. acnes* produces many enzymes, including three proteases, lipase, phosphatases and hyaluronate lyase, all of which might, in theory, be implicated in the development of inflammation [94,95]. *In vitro*, *P. acnes* has little effect in modulating peripheral blood mononuclear cell derived IL release or keratinocyte-derived cytokine release [109]. *Propionibacterium acnes*, in particular its cell wall fraction, is a potent chemoattractant for polymorphonuclear and mononuclear cells [110–113]. Recent research has shown two mechanisms of lymphocyte activation by *P acnes* cells; the activation is both antigen and mitogen driven [114]. These results are consistent with the histological evidence of inflammation in acne lesions. There is also increasing evidence to support the involvement of toll-like receptors in acne inflammation. Toll receptors recognize 'abnormal' organisms. In a way, *P. acnes* can be looked upon as 'abnormal', as it is not often present in follicles from subjects without acne. The toll receptors in turn regulate the production of cytokines which may contribute to acne inflammation. *Propionibacterium acnes* also produces a prostaglandin-like substance [115] which might be involved, as non-steroidal anti-inflammatory drugs have an anti-acne effect [116].

Cytokines are known to play a role in inflammatory acne. Ductal corneocytes constitutively produce interleukins (including IL-1-α and IL-β) and TNF [77].

The sebaceous gland also expresses several pro-inflammatory cytokines at steady state, without any influence of external factors such as bacteria. IL-1 is present in normal sebaceous glands and mRNA for IL-1-α, IL-β and TNF are also present in the sebaceous glands, and these cytokines may be involved in inflammation [117].

Leukotriene B4 (LTB4) is a pro-inflammatory mediator synthesized from arachidonic acid. Synthesis of LTB4 is catalysed by 5-lipoxygenase and is increased by inflammatory mediators including complement fragments, TNF-α and interleukins. Leukotriene precursors are synthesized in the sebaceous gland [118]. LTB4 induces recruitment and activation of neutrophils and monocytes. It also stimulates the production of a number of pro-inflammatory cytokines and mediators that augment and prolong tissue inflammation. These events are

independent of bacteria. Limited data from pharmacological inhibition studies support a role for LTB4 in the pathogenesis of neutrophil-mediated tissue damage. A preliminary, small-scale clinical study of an oral anti-inflammatory agent that specifically blocks the formation of LTB4 [119] showed a 70% reduction in inflammatory lesions at 3 months in patients with acne. These data support the suggestion that bacterial involvement may not always be necessary for expression of inflammation.

Some investigators have focused on the systemic immunological response as a possible factor in acne inflammation. Circulating immune complexes have not been demonstrated in sera from acne patients [120]. Skin testing with a heat-killed suspension of *P. acnes* demonstrated that subjects with severe acne produced a greater inflammatory response at 48 h than other subjects, suggesting that the host response may be important [121]. Observed changes in neutrophil chemotaxis may be a secondary event [122]. *Propionibacterium acnes* polypeptides are detected in the serum of acne patients but not in normal individuals [123]. This host response is of uncertain significance. Some lipids are likely to get into the dermis when the duct ruptures and may act as irritants. Other lipids such as linoleic acid can down-regulate neutrophil oxygen metabolism and phagocytosis [124]. Acne-prone sebaceous glands contain less linoleic acid than those of non-acne controls and this could contribute to the inflammation [56]. One group [125] reported elevated IgE levels that related to clinical severity, but another group found no changes in total IgE or its subclasses [126]. It is uncommon to see females with very severe acne, and it has been proposed that females muster a better defence mechanism than males against *P. acnes* [127]. In summary, acne patients are not usually immunological misfits, but some immunological reactions may verge on the abnormal in a very small number of patients. For example, some patients with acne fulminans show a markedly exaggerated delayed hypersensitivity to *P. acnes* [128].

It had been suggested that persistent mature acne could be explained by an abnormal humoral response to *P. acnes*. However, neither a deficient nor heightened humoral response to *P. acnes* accounts for persistent adult acne [93].

Hormones can also influence inflammatory processes, and in several other biological/clinical situations androgens are known to be pro-inflammatory; there is no evidence for this in acne.

Probable sequence of pathological events in acne

Microcomedones are the earliest observable abnormality. There is much debate as to whether the seborrhoea in certain acne-prone follicles, or comedogenesis, is the initial trigger. Microcomedones can be found in 30% of biopsies taken from apparently normal looking skin from an acne-prone site, and 85% of early papules are associated with a comedone. Colonization of the duct with *P. acnes* and the production of inflammation are late stages in the development of acne, even though it is often the inflammation and its severity which brings the patient to the clinic.

The role of drugs, in particular retinoids, in reducing comedones is discussed in detail in the therapy section. Most publications on oral and topical antimicrobial therapy of acne clearly show a significant reduction in comedonal lesions. This reduction is very similar to that seen with topical retinoids. The Leeds group have published a paper demonstrating that a significant number of biopsies from normal looking skin of acne patients without any evidence of microcomedones or ductal hyperproliferation have a significant inflammatory cell infiltrate around the follicle (in particular $CD3^+$, and $CD4^+$ cells and macrophages). Such cells are significantly suppressed by antimicrobial therapy, and so such therapies will reduce comedones [129].

Mechanisms inducing acne scarring

Scarring is a consequence of abnormal resolution or wound healing following the damage that occurs in the sebaceous follicle during acne inflammation. A cell-mediated immune response has been found to be involved in these inflammatory events, but such a response not only contributes to the clearance of antigen but also to tissue damage. Previously, no attention has been paid to the influence that this response may have on the resolution of acne lesions. The inflammatory response has been implicated as an important component in the development of scars [130]. Holland *et al.* [131] investigated the differences in cell-mediated immune responses in developing and resolving inflamed lesions between those acne patients who were prone to scarring and those with the same degree of inflamed acne who were not prone to develop scarring. The numbers and activation states of lymphocytes, macrophages and endothelial cells were examined in biopsies of timed inflamed lesions of known duration at less than 6 h, 24 h, 48 h, 72 h and 6/7 days using standard immunohistochemical methods.

Clear differences in the cellular infiltrate present in lesions from the two groups of patients were identified. In acne patients who were not prone to scarring, the time course was typical of a type IV delayed hypersensitivity response. In developing lesions there was significant angiogenesis and vascular adhesion molecule expression, with a large influx of activated $CD4^+$ T cells, macrophages ($CD68^+$) and Langerhans' cells ($CD1a^+$). Cell recruitment peaked at 48 h, after which there was a decrease in leukocytes, cellular activation and a return to normal levels of blood vessels and vascular adhesion molecules in resolving lesions. Of the $CD4^+$ T cells, 50% were skin homing

memory effector cells ($CD45RO^+$, CLA^+) and naïve cells ($CD45RA^+$) cells, whilst the remainder were unclassified ($CD45RO^-$, $CD45RA^-$, CLA^-), which suggests that effective resolution occurred by both non-specific/innate and adaptive immune mechanisms.

In lesions from acne patients who were prone to scar, a predominantly adaptive immune response was present, which was persistent and up-regulated in resolving lesions. The number of $CD4^+$ T cells were approximately half of those found in lesions of non-scarrers, but a high percentage of these cells were skin homing memory/effector cells, suggesting that these patients were sensitized to the causative antigen(s). In developing lesions, although the numbers of macrophages, blood vessels and vascular adhesion molecules were high and similar to those present in lesions of non-scarrers, the numbers of Langerhans' cells and the level of cellular activation was low and comparable to levels found in normal skin, indicative of an ineffective response. However, in resolving lesions there was an up-regulation of the response with greater cellular activation, and a further influx of macrophages and skin homing memory/effector cells. Certainly, the strong macrophage presence represents a dominant force in this response. Thus, it may be interpreted that, in patients prone to scarring, there is a chronic delayed-type hypersensitivity reaction provoked by a persistent antigen which these patients are initially unable to eliminate.

The different inflammatory cell profiles elicited by the two patient groups could explain the different qualities of repair observed. Lymphocytes and macrophages secrete an extensive array of cytokines and growth factors that are known to modulate dermal fibroblast recruitment, proliferation and phenotype, and will affect fibroblast functions such as wound remodelling and contraction, both contributory factors in scarring. This model suggests that the type and magnitude of the inflammatory response in 'resolving' lesions from patients with such a dominant macrophage presence, would lead to abnormal healing and pathological scarring. It is possible that the management of either numbers or activation states of inflammatory cells during the development and resolution stages of acne may help to control scarring.

Resolution of acne

This can be considered in two ways, resolution of individual lesions and resolution of the disease as a whole. The evolution of acne has received considerable attention; its resolution has been largely ignored. Limited studies suggest that the resolution is not related to reduction of sebum production or changes in surface bacteria [88]. The relationships between ductal hypercornification, inflammatory mediators, changes in the host response and resolution are obscure. Pierard [21] has shown that individual sebaceous glands function at different rates in acne patients. Resolution may be associated with specific changes in these acne-prone hypersecreting glands. Resolution of individual lesions could relate to cytokine activity within the pilosebaceous duct. For example, EGF and TGF-α are *in vitro* not only associated with disruption of the follicle but also with inhibition of sebaceous secretion [78]. Could this switch off an acne-prone follicle—albeit temporarily—and convert it into a non-acne-prone follicle?

Biological significance of acne, sebum and *P. acnes*

Activity of the sebaceous glands is unlikely to be essential for healthy skin, because prepubertal skin appears perfect unless severely challenged by soap and water! Yet the ubiquity of both hypersecretion of sebum and the presence of *P. acnes* suggests that their apparent undesirability may be outweighed by some selective advantages: the possible biological role of sebum is discussed above and it has been suggested that *P. acnes*, which enhances immune responses, may provide protection against malignant haematological disease [132], although not against solid tumours [133]. Independent of bacterial colonization, there is now evidence that the sebaceous gland is an immunocompetent organ [134].

Clinical features

Acne is a polymorphic disease, which occurs predominantly on the face (99% of sufferers) and, to a lesser extent, occurs on the back (60%) and chest (15%) [1]. In young men, it affects mainly the face, and in older males the back is also significantly affected. Seborrhoea is a frequent feature [2,3]. We have recently (unpublished observations) investigated the importance of the symptoms of acne to the patient. To our surprise seborrhoea was as important to the patient as the inflammatory papules.

Non-inflamed lesions (comedones) develop earlier than inflamed lesions in younger patients [4]. Comedones may be blackheads (open comedones), in which the black colour may be due to the presence of melanin (not dirt or oxidized sebum), whiteheads (closed comedones) (Fig. 43.18) and the so-called intermediate non-inflamed lesions, which show features of both blackheads and whiteheads (Fig. 43.19) [5]. There are also several subtypes of comedone that can easily be missed by the physician, but which may markedly influence response to therapy [6]. These non-inflamed lesions may be part of the primary acne process or secondary to some external influence. Comedonal lesions called 'sandpaper comedones' consist of multiple very small whiteheads and are found most often on the forehead (Fig. 43.20). There may even be as many as 500 such lesions, which feel rough to the touch—a fact that is often appreciated by the patient. Macrocomedones are large whiteheads or blackheads (usually whiteheads) greater than 1 mm in diameter. Both macrocomedones and sandpaper comedones respond poorly to conventional topical treatments (see below). 'Submarine comedones' are large comedonal structures

Fig. 43.18 Multiple whiteheads (closed comedones); only seen clearly on stretching the skin.

Fig. 43.19 Multiple whiteheads and blackheads, which are made more apparent by stretching the skin.

Fig. 43.20 A patient with sandpaper acne. Note the very small and multiple whiteheads.

greater than 0.5 cm in diameter and occur fairly deep in the skin; they are frequently the source of recurrent inflammatory nodular lesions (Fig. 43.21). Secondary comedones may be produced after exposure to dioxins (chloracne), pomades (pomade acne), topical steroids and other drugs (drug-induced acne).

Inflammatory lesions may be superficial or deep, and many arise from non-inflamed lesions [7]. The superficial lesions are usually papules and pustules (5 mm or less in diameter) (Fig. 43.22), and the deep lesions are deep pustules and nodules (Fig. 43.23). The term nodulo-cystic acne is incorrect. Acne 'cysts' are not true cysts because they are not lined by an epithelium. It is more appropriate to describe such lesions as nodules [8].

Nodules more frequently occur in males and, if exudative or haemorrhagic, are particularly disfiguring and messy (Fig. 43.24). Nodules may extend over areas of a few to many centimetres, and may be remarkably deep with very little surface involvement. Sinus track acne is due to sinus formation between nodules and/or deep

Fig. 43.21 This patient had submarine comedones requiring stretching the skin in order for them to be detected.

Fig. 43.22 Multiple superficial papules.

Fig. 43.23 Deep inflammatory nodules.

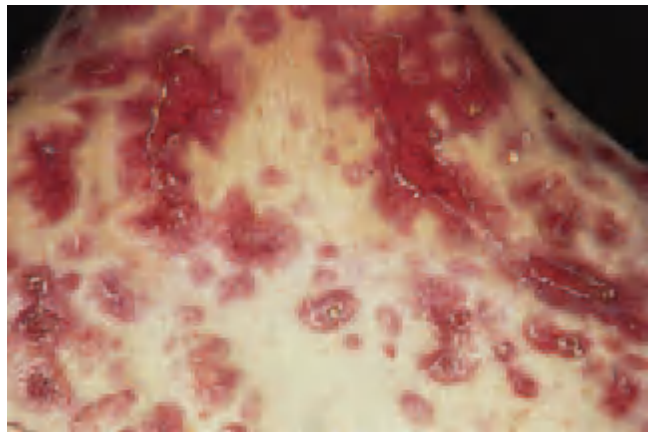

Fig. 43.24 Exudating haemorrhagic lesions.

pustules and leads to devastating cosmetic effects and scarring [9,10]. These lesions can be very tender and are very chronic and resistant to treatment. Although such lesions, like other acne lesions, have a relatively slow onset over a few days, sometimes patients acutely develop large nodules within a 24-h period, or an acute exacerbation of their sinus track disease. There is usually no obvious reason for this flare up, but eruptive and severe inflammatory acne has been reported to be precipitated by glandular fever [11]. Itching is a rare symptom of acne, but may be seen earlier on in therapy, and is possibly due to the release of histamine-like compounds from *P. acnes* [12]. Pyogenic granulomas develop very infrequently [13,14], and occur predominantly in patients with very severe disease of the trunk. They can also be precipitated during the early phase of treatment with oral isotretinoin. Nodules, including haemorrhagic nodules, are also a feature of acne conglobata, which is characterized by extensive acne and is found particularly on the trunk. There are many grouped polyporous comedones, which are frequently inflamed and develop scarring. Acne conglobata is characteristically a chronic disorder, and may last up to 40–50 years of age.

Inflammatory macules are often not recognized as a physical sign of acne; these represent regressing lesions that may persist for many weeks and contribute markedly

Fig. 43.25 Post-acne keloid scar.

to the general inflammatory appearance [5]. Although the classification of lesions may be helpful in choosing the appropriate management, it must not be forgotten that inflammatory lesions frequently may change from one type to another.

Scarring usually follows deep inflammatory lesions,but may often happen after superficial lesions in scar-prone patients [15]. Close inspection of acne skin under a bright light can reveal some scarring in up to 90% of patients who attend a dermatologist [16], but significant (socially noticeable) scarring occurs in about 22% of sufferers. Scars may show increased collagen (hypertrophic scars and keloids) or be associated with loss of collagen (i.e. ice-pick scars, depressed fibrotic scars, atrophic macules and perifollicular elastolysis). Keloids (Fig. 43.25) are the least common, and are most prevalent on the trunk. Technically, hypertrophic scars do not extend beyond the extent of the original inflammation, but keloids do. Some scars are difficult to classify in their earlier phases of development and should be classified as intermediate scars; with time they may then become more obviously hypertrophic or keloid scars, or perhaps in some instances become atrophic and hardly noticeable. Atrophic macular scars are frequently multiple, and normally retain a purple colour for many months before becoming white and less conspicuous (Fig. 43.26). Ice-pick scars are self-explanatory; they are small jagged atrophic scars 1–2 mm in size—including depth. They often exceed 50 in number, and are most evident on the cheeks. A common type of scarring on the back and chest consists of relatively inconspicuous small, follicular, macular and almost, but not quite, atrophic lesions—so-called perifollicular elastolysis [16]. This sign may be seen occasionally in subjects who have no clinical evidence of acne. The natural genesis of scars is not known and is a subject that should be investigated.

Calcification is a rare complication of scarring [17,18]. Persistent post-inflammatory hyperpigmentation is a

Fig. 43.26 Vascular atrophic macular scars.

Fig. 43.27 Post-inflammatory hyperpigmentation.

common feature of pigmented skin and may be more disabling than the original disease (Fig. 43.27).

Associated features. Certain diseases that occlude the follicular pores, for example hidradenitis suppurativa [19] and dissecting folliculitis (perifolliculitis capitis abscedens et suffodiens) [20] of the scalp may accompany acne, and are classified as the follicular occlusion triad when accompanied by acne conglobata. All conditions have in common a deep, recurrent, chronic folliculitis that results in abscess formation, sinus track formation and scarring. These diseases are discussed later in this chapter.

Physiological and environmental factors that influence acne

There are many myths about factors that might help or aggravate acne.

Diet

A wealth of folklore has blamed acne on certain foods, in particular chocolate and pork fat, but scientific proof is lacking. Chocolate, for example, appears to have no significant influence [1–3]; severe dietary restriction resulting in marked weight loss reduces seborrhoea, but cannot be considered as routine treatment [4]. Acne occurs less frequently in Zambia, Nigeria and Japan [5], where diets differ markedly from those in Western Europe, but the lower incidence could be due to other environmental or genetic factors. A detailed epidemiological study of Kitavan islanders of Papua New Guinea and Aché hunter-gatherers of Paraguay failed to find a single male or female with significant acne [6]. The authors proposed that the absence of acne was due to dietary factors, but these are closed communities in which genetic factors must be important. These authors suggest that the diet in the Western civilization has a high glycaemic index, which in turn can trigger insulin and insulin-like growth factor that influence androgens and retinoids. This could thereby induce seborrhoea, comedones and acne. The possible effect of nutrition on the age of puberty may be relevant, as acne is more likely after the start of sexual development, and this occurs when the body weight attains about 48 kg [7]. The trend of increased weight among children and earlier puberty may be reflected in early clinical acne [8]. A personal study of 100 acne patients found no link between acne severity, caloric intake, carbohydrates, lipids, proteins, minerals, amino acids or vitamins.

Premenstrual flare

About 70% of women complain of a flare 2–7 days premenstrually [7,8]. It is unlikely that any possible variation in sebum excretion during the menstrual cycle [9] could be substantial enough to explain the flare. Possibly it is related to a premenstrual change in the hydration of the pilosebaceous epithelium [10]. Progesterone and oestrogen also have both pro- and anti-inflammatory effects [11]. Up-regulation of aspects of the inflammatory response would make some teleological sense at this vulnerable time.

Sweating

Up to 15% of acne patients notice that sweating causes a deterioration in their acne, especially if they live or work in a hot humid environment; for example, for a cook, ductal hydration may be the responsible factor [12].

Ultraviolet radiation

Patients and doctors alike accept that natural sunlight often improves acne, but there is no scientific evidence for this belief. The cosmetic effect of tanning may be the entire explanation. Artificial UV radiation appears to be less satisfactory than natural radiation, and psoralen and UVA (PUVA) have been reported to very uncommonly induce acne lesions [13]. Furthermore, UV radiation may enhance the comedogenicity of sebum [14,15]. Recently several new light therapies for acne have been investigated and these are discussed later.

Occupation

Hydration of the ductal stratum corneum may induce acne in such occupations as catering and steam cleaning. Patients dealing with oil may develop an acneiform oil folliculitis, particularly on their trunks and limbs, but

usually need their overalls to be very heavily contaminated. The induction of chloracne by accidental release of halogenated hydrocarbons or other chemicals is discussed elsewhere in this chapter.

Smoking and acne

One study has shown a linear relationship between acne prevalence and the number of cigarettes smoked daily [16].

Psychosocial effects of acne

Data from the older literature suggests that it is unlikely that stress alone induces the formation *de novo* of acne lesions [17,18]. A recent paper, however, in which acne grade was assessed before and during exams would suggest that stress can induce acne [19]. In addition, acne itself induces stress, and the 'picking' of the spots will aggravate the appearance [19]. This is particularly obvious in young females who present with acne excoriée [20]. Questionnaire studies have shown that many acne patients experience shame (70%), embarrassment and anxiety (63%), lack of confidence (67%), impaired social contact (57%) and a significant problem with unemployment [21,22]. Severe acne may be related to increased anger and anxiety [23].

Appearance is an important factor in social and emotional functioning. When people first meet each other, it will often be their appearance and mostly their face, which draws attention. From psychosocial research it is known that physically attractive strangers attributed more positive qualities such as friendliness, intelligence and higher social skill levels to each other than were attributed by physically unattractive strangers. This effect is strongly reinforced through television commercials and advertisements, in which flawless facial skin is the only model that guarantees social success.

There has been a renewal of interest in the psychological effects of acne and other skin diseases over the past 10 years. Several groups have developed simple questionnaires to better understand the impact of acne in inducing anxiety, depression and impaired quality of life. These questionnaires can be very helpful in the clinic; they take only a few minutes for the patient to complete and can help the physician to quantify the psychological and social effects of the disease [24–26], and allow an appreciation of the overall response to therapy [27,28]. In most research, a combination of generic and dermatology-specific questionnaires have been used [29–39] to assess the effect of facial disease on the psychosocial behaviour of the patient and the modulating effects of treatments. General health measures that have been used to assess a variety of diseases include the Short-Form 36 (SF-36) and the General Health Questionnaire (GHQ). These tools allow comparison between skin diseases and a spectrum of other diseases. Questionnaires that relate specifically to acne include the Cardiff Acne Disability Index (CADI) and the Assessment of the Psychosocial Effects of Acne (APSEA) from Leeds and the Acne Quality of Life Scale (Acne-QoL) [28,33,34,36,37,39]. Comparisons with other chronic illnesses have shown that acne patients have levels of social, psychological and emotional disability that are similar to those reported by patients with 'more serious' diseases such as asthma, epilepsy, diabetes or arthritis. Acne also affects patients' functional abilities. Patients are also prone to embarrassment and social withdrawal, depression, anxiety and anger. In addition, younger acne patients are subject to bullying, teasing and stigmatization from their peers. There are still widely held beliefs in some communities that acne is a penalty for 'impure' thoughts or deeds.

We consider the use of quality of life and psychosocial questionnaires essential to adequately understanding just how the disease is affecting the patient, and to better understand the progress of the disease. For example, Newton *et al.* [40] demonstrated in 111 patients that treatment with oral isotretinoin or combined oral and topical antibiotics subsequently improved quality of life. Similarly, Kellett and Gawkrodger demonstrated significant psychological and emotional effects of acne which improved with oral isotretinoin [41].

Differential diagnosis

Acne is rarely misdiagnosed. The commonest mistaken diagnosis is rosacea, which occurs in older patients and lacks comedones, nodules, cysts or scarring. Occasionally, patients may have both rosacea and acne (Fig. 43.28). The presence of facial flushing that is induced by heat, hot food or alcohol is a useful pointer towards a diagnosis of rosacea. Rosacea patients may also have ocular involvement, but rarely have truncal lesions. In females, confusion with perioral eczema is possible, but in these patients the lesions itch, the skin is dry and there are no comedones. Whiteheads (closed comedones) may be confused with milia. Milia are predominantly infraorbital in distribution and are whiter. They are very common and can occur in association with, although unrelated to, acne. Acneiform drug eruptions are discussed in this chapter and in Chapter 73. Folliculitis due to Gram-negative organisms can complicate acne therapy [1], and the rare folliculitis due to *Candida* may also present as multiple pustular eruptions, as may *S. epidermidis* folliculitis. Demodex folliculitis can present as non-responsive acne. It is difficult to diagnose since many people have this mite in their normal pilosebaceous follicles. The best diagnostic help is the therapeutic response to metronidazole or topical permethrin. Localized pustular eruptions may be due to animal ringworm, and some infections with zoopilic fungi may result in kerion formation. Rarely, dermatitis herpetiformis may present as a vesicular pustular facial eruption, but it is very itchy. Linear IgA disease can also present very uncommonly as a papular facial rash without comedones. Biopsy, including immunofluorescence studies, is essential to confirm this particular diagnosis. *Pityrosporum* folliculitis presents on the upper trunk as moderately ill-defined superficial plaques, among which

Fig. 43.28 A patient who, having had acne vulgaris since the age of 14 years which never resolved, developed at the age of 35 years obvious rosacea.

Fig. 43.29 Typical distribution of *Pityrosporum* folliculitis.

are scattered many papules or pustules (Fig. 43.29). It is likely, but unproven, to be a host reaction to *M. furfur*, which is a normal skin commensal [2,3]. *Pityrosporum* folliculitis does not usually respond well to isotretinoin [4], and response to topical imidazoles is often poor. Plane warts, particularly on the face, can also cause confusion, as can pseudofolliculitis barbae. Rare diseases that may produce difficulties include acne agminata (granulomatous rosacea) and tuberous sclerosis. Acne agminata presents as a facial rash in the acne age group. The lesions are light brown in colour (somewhat darker in black skin) and on diascopy may reveal an apple jelly colour [5]. Tuberous sclerosis lesions are relatively monomorphic papules, often with a brownish appearance. A micropapular, sarcoidal facial eruption has been reported to be due to the selective perifollicular absorption of oils present in certain bubble gums [6]. The severe papulo-pustular eruption associated with zinc deficiency can be mistaken for marked acne, and several cases have been reported after prolonged intravenous feeding without zinc supplementation [7]. Acne necrotica (varioliformis) is associated with itching and smallpox-like scars, usually on the trunk. Biopsy shows a necrotizing lymphocytic folliculitis [8]. It can be mistaken for severe acne excoriée, but the response to isotretinoin can be excellent [9]. Behçet's disease may produce an acneiform eruption. A dental sinus can be confused with a persistent facial acne nodule (Fig. 43.30). Epidermoid cysts may become inflamed and be mistaken

Fig. 43.30 A persistent 'acne nodule' due to a dental sinus.

for acne nodules. Of course, acne may coexist alongside one of these alternative diagnoses.

Acne scarring can mimic scarring due to hydroa vacciniforme, ulerytherma ophryogenes, acne keloidalis [10,11], varioliform atrophy and porphyria cutanea tarda.

Treatment

General principles of acne treatment

The management of acne starts with education. Treatment procedures involve detailed patient discussion, acne assessment and appropriate prescribing based on the history, acne severity, lesion type, psychological effects of the disease and cause of the disease [1–3]. The cause of the acne should be discussed, as should the goals and outcome (including patient expectations) of therapy. Patient leaflets are essential. The patient should be told that in

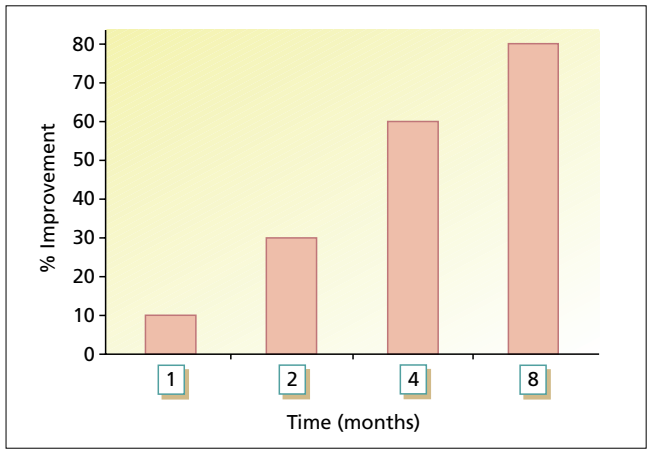

Fig. 43.31 The anticipated rate of improvement with therapy other than oral isotretinoin in the absence of significant clinically resistant *Propionibacterium acnes*.

mild cases the acne will persist for 4–6 years, but in severe cases the natural history could be in excess of 12 years. The patient, however, should be informed that, if the acne does not respond well to a reasonable trial of oral antibiotics and appropriate topical therapy, oral isotretinoin would probably be prescribed. Such therapy is an almost guaranteed success [4]. However, because of cost, teratogenicity and other side effects of isotretinoin, many patients will appropriately receive a variety of alternative oral and topical treatments. For 35 years these have been the standard therapy. Appropriate patient expectations for these treatments would be little improvement after 1 month of therapy, 20% improvement at 2 months, 60% at 6 months and 80% at 8 months (Fig. 43.31).

Acne grading

Grading is very useful in the assessment of acne in the clinic. A grading scale similar to that shown in Figs 43.32–43.35 is recommended. A good light and palpation, as well as inspection, are required [5]. The acne can be graded on a 0–10 scale on the face, back and chest. Little practice is required to become reasonably efficient, and it does not matter if the grading scale used is somewhat different from the published techniques, so long as the observer is consistent. Lesion counts are essential for clinical trials but not for use in the day-to-day clinic [6].

Choice of therapy

This is largely determined by the severity and extent of the disease but should be tempered by patient choice and cost. Patients with mild acne usually receive topical therapy alone; patients with moderate acne receive oral and topical therapies; patients with severe acne should immediately receive oral isotretinoin unless contraindicated.

Fig. 43.32 Mild acne.

Fig. 43.33 Mild to moderate acne.

The severity assessment should include not just the extent of the inflammatory and comedonal lesions, but also the presence of scarring, the psychological effects of the disease, and the degree of success or failure with previous

Fig. 43.34 Moderate acne.

Fig. 43.35 Severe acne.

treatment. A family history of persistent acne may also influence the choice of therapy.

The choice of treatment should also be based on a logical understanding as to how the treatments influence the aetiology of acne.

Table 43.2 Choice of topical treatment.

Predominantly anticomedonal
Adapalene
All-*trans*-retinoic acid (tretinoin)
Azaleic acid
Isotretinoin
Predominantly antimicrobial
Azaleic acid
Benzamycin® (benzoyl peroxide/erythromycin)
Benzoyl peroxide
Clindamycin
Duac® (benzoyl peroxide/clindamycin)
Erythromycin
Tetracycline
Zineryt® (erythromycin/zinc)
Predominantly anti-inflammatory
Adapalene
Nicotinamide
Topical antibiotics

Topical treatment (Table 43.2)

The most widely used topical drugs are benzoyl peroxide, retinoids, antibiotics and azaleic acid, either as monotherapy or in combinations [7–9]. Patients with predominantly inflamed lesions should receive topical benzoyl peroxide, antibiotics or azaleic acid. However, because of the central role of the microcomedone, a topical retinoid should probably be added for most patients [1,8,9].

Benzoyl peroxide is supplied in concentrations of 2.5%, 5% and 10%, either alone or in combination with imidazole, hydroxyquinolone, glycolic acid or zinc lactate [10–14]. Despite the wide range of concentrations of benzoyl peroxide in gels, creams or washes there are few dose–response studies. The value of some combined therapy is uncertain, although a miconazole (2%)/benzoyl peroxide (5%) combination may be marginally better than benzoyl peroxide alone [14]. Fixed combinations of benzoyl peroxide with topical antibiotics are clinically superior to the antibiotic alone [15].

Topical antibiotics include tetracycline, erythromycin and clindamycin [16–21]. They are used in concentrations of 1–4%, usually in a cream or lotion base. Topical tetracycline is probably the least effective topical antibiotic and may fluoresce under UV light. Combinations of antibiotics with zinc or benzoyl peroxide are superior to single therapies [20–23]. Clinical experience with azaleic acid has not delivered the improvement suggested by the original clinical trials [9,24,25].

Patients with predominantly non-inflamed lesions should have topical retinoids as the first choice. Most topical retinoids are very similar in their clinical benefit. The major difference lies in the increased tolerability with the more recently (within the last 10 years) developed formulations. Retinoic acid (vitamin A acid) is available in 0.01–0.05% concentrations as either a gel or a cream

[26–30]. Recently, new formulations have been developed: the so-called microsponge or polymer formulations [27–29]. The newer formulations are less irritant than the original formulation. Isotretinoin is a second-generation retinoid; a 0.05% topical formulation [31–32] similar in efficacy to benzoyl peroxide [31] and topical tretinoin [32]. A third-generation retinoid, adapalene, has a greater benefit/risk ratio than tretinoin [33–37]. In the USA and a few other countries, there is a fourth-generation retinoid on prescription for acne called tazarotene [38,39]. Adapalene has a significant anti-inflammatory action in the first few days of therapy [40]. Patients with mixed lesions should be prescribed anticomedonal therapy at night and anti-inflammatory therapy in the morning. Even patients with predominantly inflammatory acne should be prescribed a topical retinoid as part of their regime, given the fact that a microcomedone or comedone is a central and early feature of most inflammatory lesions [9]. Topical therapy should be prescribed alone for mild acne, in conjunction with appropriate oral acne therapy for moderate acne, and as maintenance therapy after oral therapy has stopped.

In many acne patients topical therapy may be necessary for many years. It is also important to stress to the patient that topical therapy must, if appropriate, be applied to the trunk, as well as to the face. It is necessary to apply the topical therapy not just to the spots but also to the whole of the site prone to acne. The reason for this relates to the observation that the apparently normal skin adjacent to acne lesions is likely to have many early microscopic lesions, in particular microcomedones. The concept of spot prevention must be stressed to the patient.

Mechanisms of action

Benzoyl peroxide is primarily antimicrobial [11,41] and rapidly reduces both surface and ductal *P. acnes* [41]. It also reduces the number of non-inflamed lesions, and is anti-inflammatory [11], but it is unlikely that it significantly affects sebum production [42,43]. Vitamin A acid and other retinoids act by removing non-inflamed lesions, making the microenvironment less favourable for the development of inflammation [9,44]. Tretinoin binds to cytosolic retinoid acid-binding protein (RAR) with high affinity, but adapalene does not bind at all [45]. Tretinoin has high affinity for all nuclear receptors, but adapalene has selective affinity for RAR-β and RAR-α [45]. Some of the actions are receptor modulated. Adapalene also has anti-inflammatory actions, notably against leukotriene [46]. It, like tretinoin, reduces, *in vitro*, the functions of toll receptors (type 2) that are involved in the production of pro-inflammatory cytokines. Topical antibiotics have some effect on the non-inflamed lesions by reducing perifollicular lymphocytes which are involved in comedogenesis [1,9,]. They also significantly reduce numbers and function of *P. acnes* [47–49]. Some topical antibiotics also have a direct anti-inflammatory action; for example, erythromycin in a benzoyl peroxide/erythromycin combination (but not benzoyl peroxide alone) had an antioxidant effect on leukocytes [50]. Azaleic acid (1 : 2 heptanedicarboxylic acid) is not sebosuppressive; it has been reported to reduce the numbers and function of *P. acnes* [51,52], but recent studies have thrown doubt on this observation. Azaleic acid reduces comedones by normalizing the disturbed terminal differentiation of keratinocytes in the follicle infundibulum [53].

A detailed analysis of 144 clinical trials of topical antimicrobial therapy rejected over 50% because of poor trial design [54]. Adequate conclusions could not be drawn from the remaining data because of the different protocols, but benzoyl peroxide emerged as a successful treatment and was probably similar in effectiveness to topical erythromycin and clindamycin, with topical tetracycline less effective. The clinical benefit of topical erythromycin can be improved by combining it with either zinc or benzoyl peroxide [20–23,55–57]. Comparative studies between topical and oral antibiotics were often biased, due to the use of less oral antibiotic than is currently recommended. The general clinical impression is that topical therapy appears less effective than oral treatment, providing the correct oral dose is prescribed. However, a large randomized controlled trial in a primary care (general practitioner) setting showed that topical Benzamycin® and its components given separately (erythromycin and 5% benzoyl peroxide) were more effective than oral tetracycline and minocycline [58].

There has been an alarming increase in worldwide resistance of *P. acnes* to antibiotics [59–62]. There is evidence to show some correlation between *P. acnes* resistance and clinical failure, and this is in part explained by variation in comedonal levels of antibiotic after topical application [63]. It is important to note that, should a strain of *P. acnes* be reported microbiologically resistant, it does not necessarily mean that the acne will be clinically resistant to such therapy. If the concentration of the same antibiotic at the relevant skin site is equal to or greater than the minimal inhibitory concentration (MIC) of that same *P. acnes* strain, the patient will be clinically responsive. Many antibiotics with anti-acne properties have additional non-antimicrobial anti-inflammatory mechanisms of action [64], which may partly offset problems with antibiotic resistance.

Up to 61% of patients referred to special acne clinics in Leeds, UK, had resistant *P. acnes* [60,65]. Resistance is most frequently seen to erythromycin and clindamycin, less so to tetracycline and doxycycline (Fig. 43.36). Multiple resistances are seen in 18% of patients. Resistance to minocycline is rare (1%). In 2002, as a consequence of a change in antibiotic prescribing policies, the levels of resistance had fallen to 56% from 61% [66]. There were

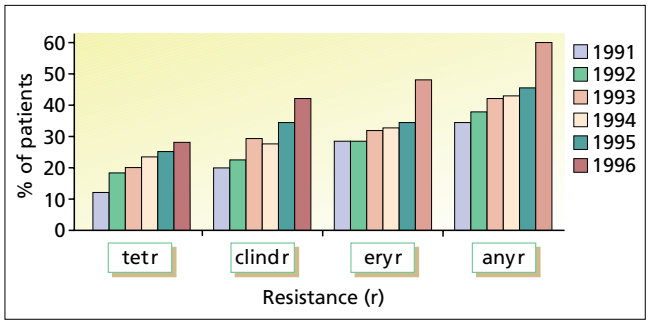

Fig. 43.36 Increase in the prevalence of resistant *Propionibacterium acnes* in Leeds, UK. Note the resistance of *P. acnes* to several antibiotics. r, resistance; tet, tetracycline; clind, clindamycin; ery, erythromycin.

also significantly greater numbers of resistant *P. acnes* on the skin of close contacts of acne patients who use antibiotics compared with controls [67]. Given the fact that the resistance is due to a mutant gene [68], it is likely that *P. acnes* resistance is going to last for many years. Benzoyl peroxide alone significantly reduces *P. acnes* resistance [69]. The combination of topical benzoyl peroxide with oral antibiotics and a topical combination of erythromycin and benzoyl peroxide are associated with the least resistance both *in vitro* and *in vivo* [69]. Physicians should also avoid prescribing dissimilar oral and topical antibiotics. Other topical treatments such as azaleic acid and topical retinoids are not antibiotics, and are therefore not associated with resistance.

Topical nicotinamide 4% also does not induce *P. acnes* resistance. Nicotinamide has anti-inflammatory actions [70]. Double-blind studies have shown it to be better than the vehicle alone against inflamed lesions, although the improvement with the placebo was considerable (32–76%) [71]. A comparison of 4% nicotinamide gel demonstrated it to be similar in efficiency to 1% clindamycin gel [72].

The efficacy of other topical treatments has not been established by controlled studies. Sulphur is a long-standing anti-acne therapy, which may be both comedogenic and comedolytic [73–75]. Sulphur is unpopular because of its smell, and is rarely used. Salicylic acid in several formulations is probably useful [76], but the many formulations of resorcin appear to be totally ineffective [77]. A few topical preparations contain weak corticosteroids but proof of their efficacy is lacking. However, potent steroids such as clobetasol propionate (Dermovate®) applied twice a day for 5 days can dramatically reduce the inflammation of a severely inflamed nodule [78]. There have been clinical data published on the potential value of traditional 'herbal' medicines from the eastern hemisphere. So far the clinical benefits of certain plant alkaloids have not been established [79]. It is very important that all new treatments are validated for safety and efficacy against standard medicines before their release to patients.

In conclusion, topical therapies, alone or in combination, should be used for patients with mild inflammatory acne. Retinoids should be the first choice for treatment of comedonal acne. In mild inflammatory acne a topical retinoid should be used in the evening and an anti-inflammatory agent in the morning [9]. Topical therapies, especially retinoids, should also be used in conjunction with oral antibiotics in patients with moderate and severe acne [1,9,80], and as maintenance treatment after cessation of oral therapy [1,9].

Oral therapy

Oral treatments for acne include antibiotics, hormones, isotretinoin and, occasionally, steroids [1]. Other drugs such as dapsone [2], clofazimine, and vitamin A acid (10–20 mg/day) [3] are very occasionally used; there is very little evidence for their effectiveness. Oral zinc is discussed later on in this section.

Oral antibiotics are the most widely prescribed oral therapy worldwide. Tetracyclines (tetracycline, oxytetracycline, doxycycline, lymecycline, minocycline and azithromycin) are the antibiotics of choice [4–11], but erythromycin is preferable in the female who is, or might, become pregnant or is breastfeeding [12]. Trimethoprim (400–600 mg/day), which is similar in efficacy to tetracycline [13], can be reserved as a third-line antibiotic [14]. Oral clindamycin, most helpful because of its lipid solubility, should not be used routinely because of the possible risk of pseudomembranous colitis [15].

Not all patients respond in the same way; it is clear that young males with marked seborrhoea and truncal acne respond less well than females with purely facial acne [10]. Patients who require antibiotics should be given 1 g/day of tetracycline or erythromycin in appropriately divided doses [16]. The major disadvantage of tetracycline (and less so of erythromycin) is the need to take the tablet with water (not milk) half an hour before food: otherwise there is reduced absorption [17]. Thus, daily doxycycline (100 mg/day) or lymecycline (408 mg/day) or the more expensive minocycline (100 mg/day), which are better absorbed, may enhance patient compliance. Recent data, however, have also shown that the absorption of minocycline is reduced by food [18]. In the Western world, minocycline is very extensively used but it should not be the first-line treatment. A large randomized controlled trial in primary care practice in the UK demonstrated that oral minocycline and oral tetracycline were of similar efficacy, and so given the cost and the increased side effect potential of oral minocycline, minocycline should not be the first choice of oral antibiotic therapy in acne [19]. Indeed, the same study showed that topical therapies such as benzoyl peroxide and combined topical benzoyl peroxide and erythromycin were of similar efficacy. However, this study did not include a topical retinoid nor combined oral and topical therapy.

Oral therapy should be given in combination with topical therapy for a minimum of 6 months [16]. There should be 20% improvement by 2 months, 60% by 4 months and 80% by 6 months. With 1 g/day, relapse is less likely than with smaller doses [16,20]. However, if there is no improvement after 2–3 months, then alternative therapy is necessary. In patients with non-responding disease, minocycline (100 mg) is more effective than tetracycline [21]. Limited dose–response studies have shown that doubling the dose of minocycline to 200 mg/day is more effective than continuing on an average dose of 100 mg where acne has not responded [21]. Daily doses of doxycycline (100 mg), minocycline (100 mg) and lymecycline (408 mg) are equally effective, provided *P. acnes* is not resistant to doxycycline and lymecycline [22–25]. Sixty per cent of patients who attended an acne clinic in Leeds, UK, were found to harbour resistant *P. acnes*. Within this subgroup, 20% had *P. acnes* resistant to tetracycline and doxycycline [26]. When acne recurs it is safe to prescribe repeated courses of the same antibiotics if the previous course was successful.

Oral treatment will be required in the following groups of patients: those with moderate and moderate/severe acne; patients who are significantly depressed, even if the acne is physically mild; patients with body dysmorphic disorder; and patients with scarring or who are prone to scarring. Patients who are likely to develop post-inflammatory pigmentation should also receive oral therapy sooner rather than later, since such pigmentation is usually very persistent and very difficult to treat. Patients with acne fulminans and patients with Gram-negative folliculitis may also benefit from oral antibiotics. However, in the latter two groups, oral isotretinoin is the preferred treatment. If isotretinoin is not available, trimethoprim is the preferred antibiotic for Gram-negative folliculitis.

There is very little scientific information to guide physicians about the precise duration needed for optimum oral antibiotic therapy, whether or not combined with topical therapy. Likewise, there are very few data on the rate of relapse on stopping oral therapy even if adequate topical therapy is continued, as it should be. Available data definitely supports the use of combined oral antibiotics with topical therapies—especially a topical retinoid [27]. There are several potential mechanisms of action for oral antibiotics; obviously they have antibacterial activity, but they also have direct effects in reducing inflammation [27–34]. Tetracycline and erythromycin are bacteriostatic, especially in larger doses. In smaller doses (500 mg/day or less), oral antibiotics do not reduce the number of organisms, but they do affect their function. The antibiotics can also inhibit various enzyme activities and modulate chemotaxis, lymphocyte function and pro-inflammatory cytokines, in particular IL-1-α expression [33,34].

Side effects of topical treatments and oral antibiotics

Topical agents. Many topical preparations produce a mild primary irritant dermatitis (Fig. 43.37) [1,2] and the patient must be warned, so that treatment is not stopped prematurely. Indeed, with some preparations such as benzoyl peroxide and retinoids, the total absence of skin irritation should lead the physician to suspect that the topical therapy is not being used correctly. If a primary irritant reaction occurs, the product should not be used for a few days and the dermatitis should be treated with moisturizers and/or a low potency steroid cream temporarily. Thereafter, the acne preparation can be restarted at a somewhat reduced frequency of application. Some topical therapies have a comparatively lower irritant profile than others. For example, azaleic acid is relatively non-irritant [3]; adapalene is less irritating than tretinoin [4–6];

Fig. 43.37 A typical primary irritant dermatitis from topical anti-acne therapy.

Fig. 43.38 Photo-onycholysis due to doxycycline.

Fig. 43.39 A phototoxic reaction in a patient on doxycycline.

Fig. 43.40 Minocycline pigmentation in acne scars.

the newer formulations of tretinoin (microsponge or polymer based) are less irritating than the early formulations [7–9]. Certain antibiotic/benzoyl peroxide combinations are less irritating than benzoyl peroxide alone [10], which is possibly due to the anti-inflammatory action of the antibiotic. True allergic contact dermatitis is extremely rare with any of the topical anti-acne preparations. From animal studies and much clinical experience there is no evidence to support the claims that benzoyl peroxide and vitamin A acid induce skin carcinomas, and continued use of these two drugs is recommended [11,12]. Benzoyl peroxide bleaches clothes and hair and the patient must be informed of these inconvenient side effects. Significant systemic absorption of topical retinoids does not occur [13,14]. Nevertheless, it is prudent to stop topical retinoid therapy should a female patient become pregnant. The patient should also be told that she should avoid becoming pregnant whilst on topical retinoids.

Oral antibiotics. Oral tetracycline and erythromycin are both relatively safe [15,16]. Gastrointestinal effects, especially colic and diarrhoea, may occur in 5% of patients, but are easily controlled with a combination of diphenoxylate hydrochloride and atropine sulphate (Lomotil®). Vaginal candidiasis occurs in 6% but is rarely a problem; it is important to treat the patient and her partner with appropriate anticandidal therapy. Significant candidiasis can be helped by the prophylactic use of intravaginal clotrimazole cream mid-cycle.

Uncommon complications of oral tetracycline therapy include onycholysis (Fig. 43.38) [17], oesophagitis with ulceration [18], fixed drug eruptions [19] and photosensitivity (Fig. 43.39), including porphyria-like cutaneous changes [20], especially with the longer-acting tetracyclines. Doxycycline causes a phototoxic rash in up to 3% of patients, especially at doses greater than 100 mg/day, when exposed to significant sunshine [21]. Widespread drug eruptions are rare except with trimethoprim, where the incidence is 2.5% [22]. Tetracyclines, especially minocycline, may produce benign intracranial hypertension [23–25], which presents with headache, loss of concentration and sometimes papilloedema, and quickly disappears on stopping therapy. This side effect is dose dependent and the patient should be warned of this potential problem. Minocycline produces a blue-black pigmentation in a dose-dependent way, and in the skin this presents in three forms: pigmentation in inflamed acne lesions, in scars (acne and non-acne) (Figs 43.40 & 43.41) and, more rarely, generalized dark-grey discoloration [25–33]. The pigmentation is due to a melanin–drug complex and lasts for an average of 8–15 months post therapy. It lasts longer in older patients [31]. If therapy is required, local lesions can be treated reasonably successfully with the Q-switched ruby laser [31]. The brown-grey pigmentation due to minocycline may also occur in the nails, oral mucous membranes [33] and sclera [34] (Fig. 43.42). At these sites, the pigmentation tends to last for longer than it does in the skin. When present in the mucous membranes, only a small percentage of affected patients are aware of its presence [35], particularly if the tongue is affected. Even more uncommon but quite dramatic is black breast milk due to minocycline therapy [36,37].

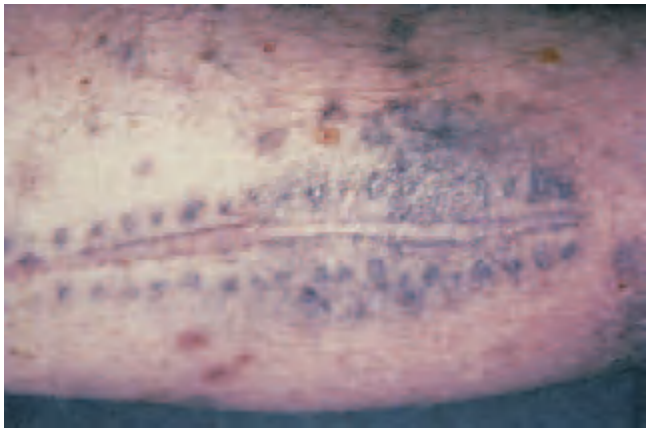

Fig. 43.41 Minocycline pigmentation in non-acne scars.

Fig. 43.42 Minocycline pigmentation in the sclera.

Minocycline has been used in a large number of acne patients worldwide. Reports of serious systemic minocycline-induced side effects have prompted much debate [38–42]. The serious side effects are of three types, all of which are relatively uncommon. Hypersensitivity syndrome reactions (including pulmonary eosinophilia) and serum sickness-like reactions occur within 3 months of treatment, and are characterized by fever, malaise and arthralgia, possibly with major organ involvement. The late-reaction pattern occurs much later, usually at about 6–48 months. These patients, predominantly female, present with a symmetrical polyarthritis or polyarthralgia in the small joints. Some of these patients have concomitant liver disease, which may occur in the absence of joint symptoms. A lupus facial rash may also be present, and occasionally lupus rashes occur at the body sites. A liver biopsy if appropriate shows chronic active hepatitis, and serology for lupus is usually positive. Very rarely the liver damage is devastating resulting in death or needing liver transplantation [43]. Thus, minocycline should be avoided in patients with a personal or family history of systemic lupus erythematosus. We recommend that every 3 to 6 months the patient's liver function, antinuclear antibody (ANA) and perinuclear antineutrophil cytoplasmic antibody (pANCA) be checked, even if there are no symptoms, and obviously earlier if necessary. Any patient with any of these iatrogenic side effects should be advised to avoid all classes of tetracycline antibiotics. Pseudomembranous colitis is an exceedingly rare consequence of oral antibiotic therapy, and was a particular problem with long-term oral clindamycin treatment, but oral clindamycin is virtually no longer used in acne therapy.

The clinical significance of a possible interaction between oral antibiotics and the contraceptive pill is unclear. There is a small risk of failure of contraception [44–46]. All sexually active females should be made aware of this problem. Tooth discoloration from tetracycline does not occur in patients treated after the age of 9 years, when the permanent teeth are established. Should therapy be required in pregnancy, oral erythromycin is safe; topical acne therapy has very rarely been implicated as a cause of fetal deformity. In pregnancy, the safest therapies are therefore topical benzoyl peroxide and/or topical erythromycin [47]. The increasing problem of *P. acnes* resistance is discussed above.

Hormonal treatments

Various oral hormonal regimens have been recommended for reducing sebaceous gland activity. Hormonal treatments are indicated usually when standard antibiotic regimens have failed, when concomitant menstrual control or contraception and acne therapy are required, and when oral isotretinoin is inappropriate or not available. Topical therapy should be prescribed with hormonal regimens.

Table 43.3 Suppressive effects of oral drugs on sebum excretion rate (SER) at 3 months' treatment.

Dianette®*	28%
Dianette®* + 50 mg CPA	42%
Dianette®* + 100 mg CPA	67%
Spironolactone 100 mg	35%
Spironolactone 200 mg	70%
Isotretinoin 0.5–1.0 mg/kg/day	92%

CPA, cyproterone acetate.
* Dianette® is 35 μg ethinyl estradiol +2 mg CPA.

Hormonal regimens include: prednisolone plus oestrogen; oestrogens plus antiandrogens; and spironolactone [1–8]. Low-dose glucocorticosteroids (i.e. 2.5 mg prednisolone on waking and 5 mg on retiring) to suppress adrenal androgens, with or without a contraceptive pill, will reduce sebum production by up to 50% with a concomitant improvement in acne [1]. Cyclical oestrogen (30 μg) with medroxyprogesterone acetate (5 mg for 7 days) is also of benefit [2].

Antiandrogens are a logical approach to the treatment of acne, as they suppress sebum production to an extent that depends on the drug and dose prescribed (Table 43.3) [4–8]. The antiandrogen CPA is prescribable in most European countries, but not in the USA. Clinically effective topical antiandrogens are not available, although it appears possible to reduce sebum production slightly by topical applications [9,10]. Co-cyprindiol (Dianette® and Estelle 35®) is an oral contraceptive that ameliorates acne. It is as effective as 1 g/day of oral tetracycline over a 6-month period, although it is slower in action [11]. It is also of potential benefit in women with acne resistant to other therapies [6]. In males, 25 mg CPA has been used with success, but it reduces libido and produces gynaecomastia and possible azoospermia. In women, the side effects of CPA with oestrogen are different from those of conventional contraceptive pills that contain lower amounts of oestrogen. Recently it has been suggested that, because of the risk of deep venous thrombosis associated with the higher oestrogen content [12], once the acne is brought under control then the co-cyprindiol formulations should be replaced by a birth pill containing a lower dose of oestrogen. Yasmin® (drospirinone 3 mg, ethinyl estradiol 30 mg) is one possibility, and a comparative study [13] has shown that Yasmin® is similar to co-cyprindiol in its efficacy against acne. Another possibility is to prescribe one of the triphasic pills such as Trinordiol® (ethinyl estradiol/levonorgestrel in varying concentrations), which suppresses sebum excretion by 20%. In the past few years, clinical trials have shown the benefit of other oral contra-

ceptives in acne. These include Belara® (30 µg ethinyl estradiol and 2 mg chlormadinone acetate), which has been registered in some European countries for a few years [14]. In the USA, a placebo-controlled clinical trial showed the benefit of a low oestrogen dose oral contraceptive (20 µg of ethinyl estradiol and 100 µg of levonorgestel) [15]. Co-cyprindiol is more likely than the lower dose pills to cause weight gain [5].

For how long CPA (2 mg) combined with 35 µg ethinyl estradiol (co-cyprindiol) can be given is uncertain. We know that many physicians have patients on these preparations for many years. Given the recent evidence [12], it is prudent to change to a lower oestrogen-containing pill when the acne has been brought under control. Because co-cyprindiol reduces sebum production only by about 30%, it is likely that it acts by an additional mechanism, such as a direct effect on comedogenesis, which is also androgen-mediated [16]. The clinical efficacy of this combination can be enhanced by giving an extra 50 mg or 100 mg CPA from the fifth to 14th day of the cycle [17]. At this dosage, the reduction in sebum production is 50–67%. Spironolactone is an effective treatment (it is not a contraceptive), but is more likely to be prescribed for females over 30 years of age. Its effects are dose dependent, and it is usually prescribed at a dose of 100–200 mg daily for 6 months [18–20]. The main side effects are menstrual irregularity, occasional fluid retention and, rarely, melasma. A question mark remains over its long-term use because of a theoretical increase in breast cancer, which has been shown in animal but not human studies [21]. All hormonal regimens should be combined with appropriate topical therapies. Effective hormonal regimens seem to have a dual mechanism of action, suppressing gonadotrophin release and having an additional peripheral effect on the sebaceous gland [22].

For the patient with intractable moderate or severe acne, or if appropriate antiandrogens are unavailable, isotretinoin is the treatment of choice. Isotretinoin is more effective than co-cyprindiol for acne patients [4].

The patient with slow response or failure of response to treatment

There are several reasons as to why some patients show a slow response or no response to therapy. These include poor education of the doctor or patient, poor compliance, *P. acnes* resistance and Gram-negative folliculitis. Other explanations include incorrect diagnosis, the fact that certain acne subtypes respond poorly and side effects of therapy.

Poor compliance

Chronic disorders are associated with poor compliance and acne is no exception [1]. In a study that assessed acne patients after 18 weeks of treatment, compliance was less than 40% both for oral and topical treatment. Young age, smoking and excess alcohol were risk factors for poor compliance. Ways of improving compliance include better education of patients and doctors, and the constant reminding of patients that acne is a chronic disease which responds slowly to treatment, and that it is necessary to apply topical treatment not just to the acne spots but to the whole of the acne-prone skin. More time spent with patients and the development of nurse-led clinics could also help to improve compliance.

Propionibacterium acnes resistance

Resistance of *P. acnes* to commonly used antibiotics is a further reason for failure of adequate response. *Propionibacterium acnes* resistance has been recognized in most Western countries [2–6] (see Fig. 43.36). *Propionibacterium acnes* resistance has risen dramatically, and in 2003 the prevalence rates in a pan-European study [4] were lowest in Hungary (50.8%) and highest in Spain (93.6%). The incidence in the non-hospital community in the UK is 20%. Resistance is seen to tetracycline and doxycycline in 20% of subjects (see Fig. 43.36) and these antibiotics share a similar resistance profile [4]. Resistance to erythromycin is the most common, and these organisms share a cross-resistance to clindamycin [2–4]. Resistance to trimethoprim occurs in 12%, and multiple resistances are found in 24% of patients with resistant *P. acnes* [3]. Resistance to minocycline is relatively uncommon [3,4]. It should be emphasized that microbiological resistance does not necessarily equate with clinical resistance. Clinical resistance will occur if the MIC of the *P. acnes in vitro* exceeds the concentration of the antibiotic in the pilosebaceous duct. The concentration of ductal antibiotics varies considerably [6]. There are several factors that contribute to a less than optimal concentration of the drug in and around the pilosebaceous duct. Poor compliance will reduce drug availability, and a high sebum excretion is likely to wash out what might otherwise be an effective drug concentration [7]. A low tissue drug concentration will encourage the acquisition of antibiotic resistance by *P. acnes*. The incidence of *P. acnes* resistance in non-antibiotic-treated close contacts (i.e. mother, father, girl/boyfriend) is 50% [8], and thus may account for the apparent difficulty in treating some of our younger acne patients who have older siblings who have had antibiotics to treat their acne.

There are no data relating to failure of clinical response in patients who have been treated with an antibiotic to which their resident *P. acnes* have high levels of resistance; the authors suspect that the figure is probably of the order of 20%. The reasons are complex and include the fact that antibiotics also have some direct anti-inflammatory actions. There is clinical evidence that, in some patients, a change to an antibiotic to which the *P. acnes* are sensitive will bring about clinical benefit.

Molecular studies have demonstrated that the resistance of *P. acnes* to erythromycin and clindamycin is due to a mutation [9]. The same is likely to be the situation with tetracycline [10]. This means that resistance is likely to persist even after the selective pressure of that specific antibiotic has been removed. Thus, clinicians must develop strategies to prevent *P. acnes* resistance, and to use therapies that may reduce the resistant organisms where present. The authors' recommended strategies include the following:

1 Prevent overuse of a particular oral or topical antibiotic. A 6-month course of oral therapy should be adequate in most patients. When further oral antibiotics are required and the initial clinical response was good, re-use the same drug.

2 Avoid prescribing different oral and topical antibiotics at the same time.

3 Resistance may be avoided by using topical retinoids and azaleic acid, which do not promote *P. acnes* resistance *in vitro*.

4 Topical benzoyl peroxide and certain benzoyl peroxide/antibiotic combinations may be helpful because they appear to reduce the induction of antibiotic resistance by *P. acnes in vitro* and *in vivo* [11–12].

Propionibacterium acnes is, contrary to belief, quite an easy organism to grow in the laboratory, but many hospital microbiology departments do not provide information on resistance patterns in *P. acnes*. Therefore, clinicians must be alert to possible clinical resistance to a particular oral and/or topical antibiotic, which should be suspected in four circumstances:

1 If the patient's acne fails to respond when compliance is thought to be good.

2 If the patient's acne relapses after an improvement while still on therapy.

3 If the patient has had multiple courses of oral and topical antibiotics.

4 If the patient has a history of poor compliance with therapy.

Fortunately, *P. acnes* resistance to minocycline is uncommon (1%), but the authors' laboratories have shown that MIC levels to minocycline are gradually increasing and this should be seen as a warning for the future. When *P. acnes* resistance is suspected, alternative therapy may be necessary depending upon the circumstances. Options include alternative oral and topical antibiotics (including high-dose antibiotics), topical retinoids, antiandrogens and oral isotretinoin.

High-dose antibiotics (such as minocycline 200 mg/day or trimethoprim 600 mg/day) have been shown to be successful in overcoming apparent resistance [13]. These doses will increase the drug concentration in the duct, where it will act as a better antimicrobial agent, and in the dermis, where it will enhance the drug's anti-inflammatory action. In the USA, minocycline is frequently prescribed at 200 mg/day, even to the so-called normal acne patient, but our practice is to routinely use half that dose. In a female patient whose acne fails to respond, and in whom contraception or menstrual control is also required, combined co-cyprindiol plus additional CPA (50/100 mg) taken from the fifth to the 14th day of the cycle will often be beneficial [14].

Gram-negative folliculitis due to *Klebsiella*, *Escherichia*, *Proteus*, *Serratia* or *Pseudomonas* organisms may be the cause of apparent failure to respond [15]. Clinically, this may present with an acute flare of many pustules, the development of nodules, or simply as the deterioration of ordinary acne. Bacteria from the skin and nose of these patients must be sampled with a moistened swab. In this

Fig. 43.43 Multiple macrocomedones: a frequent cause of persistent inflammatory acne.

situation, hospital microbiology departments should be able to identify the offending organism. The current antibiotic should be stopped and oral isotretinoin prescribed (0.5–1.0 mg/kg/day). An alternative is oral trimethoprim (200–300 mg twice a day), but relapse is more common after antibiotic therapy and after oral isotretinoin.

Certain subtypes of acne are more frequently associated with clinical failure. As discussed above, some patients have specific types of comedones. Patients with sandpaper comedones respond poorly to the more standard antibiotic/topical retinoid therapy and frequently require oral isotretinoin (0.5 mg/kg/day for 4–6 months). Patients with macrocomedones (Fig. 43.43) require physical treatment with gentle cautery under a local anaesthetic (EMLA®) [16,17]. Ill-advised prescription of isotretinoin to patients with multiple macrocomedones may precipitate a bad flare of acne, which may produce significant scarring. This disease flare probably relates to the release of large quantities of inflammatory mediators due to death of *P. acnes* organisms within the duct system. Similar treatment with gentle cautery is also required for patients with submarine comedones, but in contrast to those patients with macrocomedones who respond very well to this physical treatment, only about 50% of patients with submarine comedones show a satisfactory response.

Patients with severe inflammatory acne such as acne fulminans, acne conglobata and sinus tract disease also respond badly to standard therapy.

Most other non-responding patients will respond successfully to isotretinoin [18].

Oral isotretinoin

Oral isotretinoin (13-*cis*-RA; Roaccutane®; Accutane® in the USA) revolutionized the treatment of acne when it was introduced in the UK in 1983. Two decades later, it remains the most clinically effective anti-acne therapy, producing long-term remission in many patients.

Mechanism of action

Isotretinoin is the only treatment that has an effect on all the major aetiological factors involved in acne [1–6]. It significantly reduces elevated sebum production, comedogenesis, and surface and ductal colonization with *P. acnes*; it is also anti-inflammatory.

Oral isotretinoin dramatically reduces sebum excretion by the order of 90% within 6 weeks of the patient receiving 0.5–1.0 mg/kg/day. Isotretinoin has an effect on sebocytes, but may act as a pro-drug with metabolites that have greater intracellular activity. Isotretinoin has at least five biologically important metabolites: 13-*cis*-4-*oxo*-retinoic acid (4-*oxo*-isotretinoin), all-*trans*-RA (tretinoin), all-*trans*-4-*oxo*-retinoic acid (4-*oxo*-tretinoin), 9-*cis*-retinoic acid and 9-*cis*-4-*oxo*-retinoic acid (see Fig. 43.5).

Studies of SER in sufferers of severe acne have shown that, within 4 weeks, 4-*oxo*-isotretinoin (30–60 mg/day orally) produces a mean reduction of 70% of that achieved by 30–60 mg/day of oral isotretinoin (N. Shear, personal communications).

In vitro studies of human sebocyte proliferation in cell culture, keratin 7 induction in pig sebocytes, HL-60 cell differentiation, the limb bud assay and the production of hypervitaminosis A in rats, have shown that isotretinoin and its three main metabolites; tretinoin, 4-*oxo*-isotretinoin and 4-*oxo*-tretinoin have comparable activities. In the human sebocyte proliferation assay, which is the most relevant model for the anti-acne effect, all three isotretinoin metabolites inhibit sebocyte proliferation at slightly lower concentrations than isotretinoin. All three metabolites have similar activity in the limb bud assay, which defines teratogenic potential, and in the hypervitaminosis A assay, which predicts the overall side effect potential. It is reasonable therefore to conclude that all three metabolites may contribute to the overall efficacy and safety, and side effects, of isotretinoin. These four compounds activate retinoid receptors RAR-α, RAR-β and RAR-γ in SZ 95 sebocytes, but only tretinoin and 4-*oxo*-tretinoin bind to RAR-γ, which is the receptor that is thought to be important in retinoid treatment of acne. Incubation of SZ 95 human sebocytes with isotretinoin led to significantly higher intracellular concentrations of tretinoin than isotretinoin [7]. The incubation with tretinoin generated very high intracellular concentrations of tretinoin and negligible concentrations of isotretinoin. These data suggest that tretinoin may be the active intracellular form of isotretinoin and prompted Tsukada *et al.* [7] to conclude that isotretinoin should be considered as a pro-drug. Differences in the plasma concentrations of these metabolites could therefore explain the differences in the intensity of the therapeutic response and the severity and/or occurrence of side effects in individual patients.

Just how oral isotretinoin influences a significant reduction in comedogenesis (by up to 80% or more) is uncertain [3]. Oral isotretinoin has no direct antimicrobial action, but by dramatically reducing SER and the size of the pilosebaceous duct it markedly alters the microenvironment within the duct. The result is a $\log_3$ reduction in *P. acnes*—a suppression much greater than that seen with oral and topical antibiotics [4,5]. Oral isotretinoin also modifies monocyte chemotaxis, which in part explains the anti-inflammatory effects of the drug [6]. The significant reduction in the *P. acnes* population also contributes to the reduction in acne inflammation.

Clinical benefit of oral isotretinoin

Almost all patients who receive oral isotretinoin will be free from acne by the end of 4–6 months of treatment. Recent clinical experience suggests that the long-term cure rate may be lower than was initially thought by dermatologists when isotretinoin became prescribable in the mid 1980s [1,8–10]. One explanation is that isotretinoin is being used to treat patients with less severe acne, who then have high expectations of a totally acne-free life, whereas the initial cohorts of patients had severe disease and were less concerned by the reappearance of a few spots. Furthermore, some of the early reported 'cures' may have been due to the fact that patients had eventually grown out of their acne.

Fordyce's disease		√	

* Especially if associated with scarring and/or psychological problems.
† Also needs pre-isotretinoin therapy with oral steroids.

The clinical effectiveness of isotretinoin in acne and acne variants is summarized in Table 43.4. When isotretinoin was first introduced, its prescription was restricted predominantly to patients suffering from severe nodular acne (Figs 43.44–43.46) [1–3]. With increasing clinical experience, use of the drug has been expanded worldwide to include less severely affected patients who have responded unsatisfactorily to what have been called conventional treatments, including long-term antibiotics and/or appropriate topical antimicrobial or retinoid-like therapies [8–13]. Failure of conventional treatment may occur for many reasons, including resistance of *P. acnes* to antibiotics [14].

The risk of teratogenicity has led some physicians to restrict the prescription of isotretinoin in female patients to those with severe acne only. However, there are convincing published data [9–12] to show that isotretinoin should be prescribed for patients with moderate acne who are failing to respond to conventional therapy, for whatever reason. Acne may produce scars in 30% of patients with moderate disease, and significant psychological morbidity in 12–13%. Thus, any failure of conventional

Fig. 43.44 A patient with severe acne before treatment with oral isotretinoin.

Fig. 43.45 The same patient at 3 months of treatment with isotretinoin.

treatment should be followed by a course of isotretinoin unless specifically contraindicated. In the UK, the National Institute for Clinical Excellence (NICE), a government-supported group, has provided guidelines for primary care physicians concerning referral to a consultant dermatologist. Providing the guidelines are adhered to, then in most instances the role of the dermatologist will be to prescribe oral isotretinoin, but some dermatologists may consider high-dose antibiotics plus appropriate topical therapy such as topical retinoids.

Fig. 43.46 The same patient 3 years after treatment with isotretinoin.

The definition of poor response should be made against objective or semi-objective criteria. The authors recommend the use of a clinical acne scoring system [15], and both quality of life and psychological profile indexes [16]. Physical and psychological severity of acne and local financial pressures will all play a role in the decision whether to prescribe isotretinoin. Conventional anti-acne treatment that fails to produce any improvement over 3 months should be changed. Some physicians take the failure of three successive treatment courses as an absolute indication for oral isotretinoin. There is abundant evidence to show that isotretinoin significantly reduces the psychological problems associated with acne [17,18].

A small number of patients with mild acne have disproportionate psychological effects when compared with the majority of acne sufferers. These patients may have a condition called body dysmorphic disorder and should be considered for the prescription of isotretinoin [19].

Age should not be a barrier to the use of isotretinoin. A very small number of neonates or juveniles with acne that had not responded to all appropriate topical or oral therapy have been treated successfully with isotretinoin, the usual dose being 0.5 mg/kg/day [20]. Some pre-adolescent youngsters, even under 10 years of age, develop

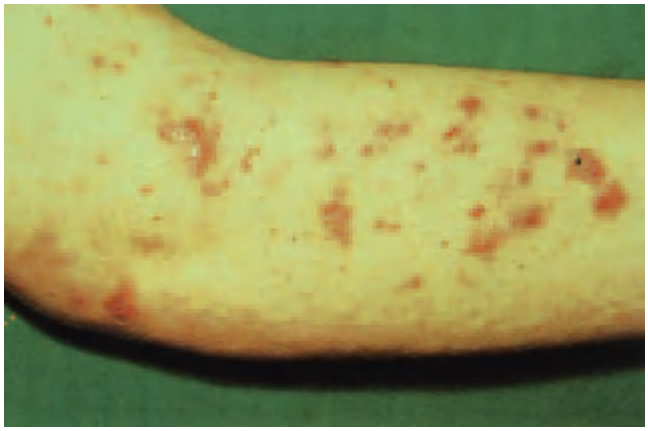

Fig. 43.47 The unusual extent of acne in a patient with Apert's syndrome.

Fig. 43.48 The typical appearance of the fingers of a patient with Apert's syndrome.

troublesome acne with scarring. Oral isotretinoin should be prescribed for paediatric acne patients if there are sufficient clinical indications [21]. Apert's syndrome is a rare disorder associated with a hyperresponse of the epiphyses (Figs 43.47 & 43.48) and sebaceous glands to androgens, which results in premature epiphyseal fusion, particularly of the long bones and skull, and in acne respectively. These patients, presumably because of the hypersensitivity of the sebaceous glands to androgens, respond poorly to conventional therapy, and are therefore often treated successfully by oral isotretinoin [22].

Most dermatologists are treating increasing numbers of patients with acne that has persisted beyond the age of 25 years. The reasons for this change in the age/referral pattern are unclear, but may reflect increased expectations for cure based on the widely known clinical effectiveness of isotretinoin. Although the acne severity in these patients is not usually as great as it was when they were 15–25 years old, the persistence of the disease results in an increased risk of scarring and disproportionate psychological distress [23]. Isotretinoin is an important treatment in this age group. Data from a clinic in Leeds, UK, show that an adult with acne persisting at the age of 30 years is likely to have acne for at least a further 10 years. Small, intermittent-dose isotretinoin therapy (see below) may be appropriate for this subgroup of patients, but relapse often occurs quickly following a successful acne-free interval while on therapy.

Isotretinoin for patients with significant systemic disease. Patients with significant systemic disease can be treated with oral isotretinoin [24,25]. The authors feel that these patients fall into three subgroups, and recommend three appropriate protocols (Table 43.5) to minimize any negative effect in the associated disorder. In all instances it is necessary that a careful check be made by the dermatologist and/or the relevant physician at monthly intervals to ensure that there are no significant clinical or laboratory changes in the systemic disease.

1 Patients in Group 1 are those patients for whom there is evidence to show that the full dose of isotretinoin can be safely given.

2 Patients in Group 2 are those patients for whom there is limited information but, on balance, the drug probably does not cause any change in the associated disorder. These patients usually can start on a dose regimen of 0.25–0.5 mg/kg/day. If all is well, the dose can be increased at 2-monthly intervals to 0.5 mg/kg/day, and beyond if required, and therapy usually maintained for 24 weeks.

1 Protocol A: standard regimen	**2** Protocol B: initially half the standard regimen	**3** Protocol C: once-a-week regimen with gradual dose increase
Crohn's disease	Chronic renal failure	Behçet's syndrome
Diabetes mellitus	Renal dialysis	Cerebellar spongiform encephalopathy
Epilepsy	Hypertriglyceridaemia	Idiopathic thrombocytopenic purpura
Spina bifida	Immunosuppression	Leukaemia
Ulcerative colitis	Manic depressive psychosis	Mitochondrial degeneration
	Myalgic encephalopathy	Paroxysmal nocturnal haemoglobinuria
	Motor neurone disease	Polymyalgia rheumatica
	Multiple sclerosis	

Table 43.5 Isotretinoin dose schedules that may be most appropriate for patients with significant systemic disease.

3 Group 3 includes patients who have rare diseases, or where not much information exists.

In these uncommon circumstances, it is recommended that therapy begins at 20 mg isotretinoin/week. The dose is increased by 20 mg each week so that at the end of 7 weeks patients are taking 20 mg/day. The cycle can then be repeated to achieve a higher dose, so that by the end of a further 7 weeks they are taking 20 mg twice a day. In this group of diseases, it is particularly important that the dermatologist links with the appropriate physician so that a very careful clinical and, where appropriate, laboratory measurement is made of the associated disease. The authors recommend publication of these cases to help other similarly affected patients.

Isotretinoin in the treatment of acne variants. These diseases are very rare, and represent a small but essential indication for oral isotretinoin. This group includes patients with acne fulminans, rosacea fulminans, Gram-negative folliculitis, dissecting cellulitis of the scalp, hidradenitis suppurativa and acne conglobata.

Patients with acne fulminans and rosacea fulminans respond to oral isotretinoin [26,27]. The best response in these conditions is obtained by starting with a course of prednisolone 0.5–1.0 mg/kg for 4–6 weeks [26,27]. The steroids can usually be reduced gradually over the following 2 weeks, and isotretinoin can be introduced at a dosage of 0.5 mg/kg body weight/day and this can be increased gradually to 1 mg/kg/day according to the response.

Patients with acne conglobata and Gram-negative folliculitis usually do not require oral steroids, and can be started immediately on oral isotretinoin at a dose of 0.2 mg–1.0 mg/kg/day [28]. Hidradenitis suppurativa is a distressing disease that is difficult to treat. The response to isotretinoin is variable [29,30]. However, it may be worth trying a course of oral isotretinoin in patients who have not responded to hormonal regimens or long-term high-dose antibiotics such as minocycline. Dissecting cellulitis of the scalp also responds variably to oral isotretinoin, but a 4-month course ought to be tried [31].

Steatocystoma multiplex does not respond well to isotretinoin, which does not reduce the size of the non-inflamed cysts. However, while the inflammatory component of this disease may improve, it may also respond equally well to long-term oral antibiotics [32]. Other uncommon diseases related to acne that may respond to isotretinoin are oil acne [33], especially where there is an inflammatory component, and extensive Fordyce's disease [34]. See Table 43.4 for a summary of the acne-related indications for oral isotretinoin.

Recommended doses and duration of therapy. Most physicians prescribe a dose within the range 0.5–1.0 mg/kg body weight/day. There are variations in the way treatment is started [35–38]. Treatment regimes usually begin at 0.5 mg/kg/day and may be increased to 1.0 mg/kg/day, but in some centres treatment is started at 1.0 mg/kg/day. Published data suggests that optimal benefit is achieved by the higher dose. Absorption of isotretinoin is markedly affected by the presence of fat, which accompanies the drug in the intestine. Pharmacokinetic studies show that absorption can be doubled by taking isotretinoin with, or after, a meal compared with the fasting state [37]. The authors would advise patients to take their capsules along with the largest meal of the day. The majority of physicians, whether they start on a higher or lower dose, will adjust the dose according to the response and the presence or absence of side effects.

The duration of therapy varies from centre to centre. The range is usually 16–30 weeks, with a mean between 16 and 20 weeks. Studies to derive a cumulative dose for maximum benefit and reduced relapse rate [36] have confirmed that there is a definite effect of both dose and duration of therapy but that there is no *a priori* pharmacokinetic reason to support the concept of accumulation of drug or a cumulative dose effect. Post-therapy relapse is minimized by treatment courses that amount to a total of at least 120 mg/kg, but there is no added benefit when 150 mg/kg is exceeded [36]. Typically, this total dose can be achieved by 4–6 months at 0.5–1.0 mg/kg/day. The duration of therapy should be adjusted to give at least 90% clearing of acne based upon acne scoring techniques followed by 4 weeks of consolidation.

Demographic factors, such as age, sex and duration of acne, may also govern the rate of response and relapse. For example, males with more truncal acne and more severe acne, or who have had acne for less than 7 years, fail to respond as well as, and relapse more quickly than, female patients with predominantly facial acne and those with less severe acne.

Eighty-five per cent of patients who receive a dose of 0.5–1.0 mg/kg/day are virtually clear of their acne by 16 weeks. Thirteen per cent require 5 or 6 months to clear, and 3% require a longer course. Fewer than 1% of patients may need up to 12 months of continuous therapy, and it is the authors' experience that these patients are usually sons and daughters of physicians and lawyers! Low-dose courses of isotretinoin are successful in mature adults with persistent and late-onset acne. Typical treatment consists of 0.5 mg/kg/day taken 1 week out of 4 for a period of 6 months. Ninety-one per cent will be clear of acne using this regimen [39] but relapse is disappointingly frequent. Furthermore some patients wish to stay on the drug for many years at this lower dosage because of its benefit and relative lack of side effects. Some of these patients are almost addicted to this regime, which clearly would be totally inappropriate for a female of reproductive potential.

Table 43.6 Side effects of isotretinoin and their management.

Side effect	Management if disease is: Mild	Moderate	Severe
Cheilitis Facial dermatitis Discoid dermatitis Xeroderma	Lubricant	Intermediate steroid ointment	Potent steroid ointment combined with antiseptic and oral antibiotic
Nasal dryness and soreness	Lubricant	Nasal mupirocin	Nasal mupirocin + oral antibiotic
Blepharoconjunctivitis	Lubricant	Mild steroid/antibiotic combination	Antibiotic eye ointment + oral antibiotics
Arthralgia and myalgia	Nil	Paracetamol Aspirin Non-steroidals	Paracetamol Aspirin Non-steroidals
Headache	Nil	Paracetamol, dose reduction	Consider BIH Stop therapy
Pyogenic granuloma	Nil	Potent steroid ointment ± cautery and curettage	Potent steroid ointment ± cautery and curettage

Note: if in doubt reduce the dose of or stop isotretinoin.
BIH, benign intracranial hypertension.

What are the reasons for a slow response to isotretinoin? Analysis of slow responders to isotretinoin shows that the cause is due to the presence of macrocomedones (see Fig. 43.43) in 70% [40], nodular acne in 15% and unknown in about 5%. It may be necessary to stretch the skin to detect macrocomedones. These must be sought prior to starting isotretinoin, and treated by light cautery. This is best conducted after the application to the skin of a local anaesthetic cream, such as EMLA®, for 60 min beneath an occlusive dressing. Thereafter, the areas are touched gently with light cautery [41]. This procedure should initially be performed on a test area of 10 cm^2, so as to ensure that the patient does not develop any disproportionate scarring or, in the case of black skin, hypo- or hyperpigmentation. An acne flare early in treatment often needs dose reduction and possibly the addition of oral steroids. This observation may also contribute to a slow response [42].

When macrocomedones are not the cause of the poor response, the dosage of isotretinoin should be carefully considered. Patients may be given an increased dose providing that the side effects are tolerated, but if the acne is very inflammatory, then a significant reduction in the dose of isotretinoin and addition of oral steroids may be required (e.g. 0.5–1.0 mg/kg/day for 2–3 weeks) Some female patients with hormonal dysfunction, due, for example, to polycystic ovarian syndrome, may need additional treatment with a hormonal preparation such as co-cyprindiol.

Persistent deep pustules in about 1% of patients may be due to *S. aureus*, and bacterial swabs should always be sent from these patients, whose lesions respond to antistaphylococcal therapy.

Table 43.7 Some uncommon side effects of isotretinoin.

Achilles tendonitis
Acne fulminans
Depression
Diarrhoea
High-tone deafness
Mood changes
Night blindness
Sticky palms
Urticaria
Vasculitis

Some patients have multiple reasons for the slow response, and compliance with the prescribed regime must always be considered. The presence of mucocutaneous side effects (see below) is usually a good indicator of absorption.

Further courses of therapy are usually successful when required. There is no contraindication, apart from pregnancy and other significant side effects, to re-prescription, and there is no tachyphylaxis. Some patients have needed two or three courses, and fewer than 3%, in the authors' experience, have required up to five courses, usually, with no signs of cumulative toxicity.

Side effects

Isotretinoin has many side effects (Tables 43.6 & 43.7). In particular it is very teratogenic [43]. Fifty per cent of pregnancies spontaneously abort, and of the remainder about half of the infants are born with cardiovascular or skeletal deformities. The authors recommend that a negative (if

possible blood) pregnancy test be obtained on the first or second day of the period with treatment being started the day after the negative result is available. Adequate counselling about the risks of pregnancy and teratogenicity is essential, even in a 10-year-old girl. It is best that someone who is experienced in family planning issues should give the counselling. Female patients must acknowledge risk by signing a document to indicate that they have been informed of the teratogenic hazard. In the USA, the guidelines are even more stringent, requiring two negative blood pregnancy tests before starting therapy, and monthly negative blood pregnancy tests before the pharmacist is allowed to dispense the next month's supply. In the UK, very similar guidelines have recently been introduced; consult the British Association of Dermatologists (London) if practising in the UK.

Mood changes including depression are common among adolescents and may occur in patients who are being treated with isotretinoin. Two studies that looked at spontaneous reports of side effects for the Food and Drug Administration (FDA) in the USA [44,45] found little or no increase in psychiatric disease including depression and suicide over the background prevalence in the adolescent population. A further study of general practice databases in Canada and the UK showed similar findings [46]. The authors recommend that clinicians should be aware that patients might develop mood changes and clinical depression during their 4–6-month treatment with isotretinoin, and in the first few months post therapy, and should enquire about symptoms at each clinic visit. A suggested short questionnaire with good stringency is:

Over the past 2 weeks have you consistently …

1 Been feeling unusually sad or fed up?

2 Lost interest in things that used to interest you?

3 Felt any more short tempered or irritable than you used to?

Discussion about the teratogenicity and recognized side effects should be recorded in the notes at each visit, even witnessed by the patient, and patients given appropriate documentation. If significant depression is identified, then a psychiatric referral may be indicated. Increased aggression has been identified in some male patients and the FDA in the USA has advised clinicians to warn potential patients about this side effect. If there is any doubt, the drug must be stopped.

Most other side effects of oral isotretinoin are predictable and rarely interfere with the patient's management [2,8–13]. They are rendered tolerable by modification of the dose and/or additional symptomatic therapy. Table 43.6 shows the common and uncommon side effects and strategies for their optimum management.

An acne flare early in the course of isotretinoin occurs in 6% of subjects, and in half of these is clinically important [42]. The physician must inform the patient that should there be an acne flare (or any other concern whatsoever), then they must immediately call the dermatology department, as sometimes these flares can be devastating both physically and psychologically. Risk factors for this flare include the presence of macrocomedones in two-thirds and nodules in almost one-third of patients [42]. Should a patient flare badly, oral prednisolone should be given in a dose of 0.5–1.0 mg/kg/day over a period of 2–3 weeks, and the dose slowly decreased over the next 6 weeks. When the acne flares, the isotretinoin should either be stopped or reduced to a dosage of 0.25 mg/kg/day depending on the extent of flare. If stopped, the drug can be slowly reintroduced at a dose of 0.25 mg/kg/day, and then increased or decreased as necessary.

The mucocutaneous side effects can usually be minimized by the very regular use of moisturizers and lip salves, but occasionally retinoid dermatitis, a severe retinoid cheilitis or conjunctivitis occur (Figs 43.49 & 43.50), often complicated by secondary infection with *S. aureus*. These patients may need treatment with an intermediate-strength steroid ointment combined with an antiseptic. If there is impetiginization, oral antistaphylococcal therapy such as

Fig. 43.49 Patient with troublesome cheilitis due to oral isotretinoin.

Fig. 43.50 Patient with troublesome conjunctivitis due to oral isotretinoin.

Fig. 43.51 Patient with troublesome nasal crusting (and *Staphylococcus aureus* infection) due to oral isotretinoin.

flucloxacillin and/or topical mupirocin 2% ointment may be required [47]. A nasal preparation of mupirocin can be used to eradicate nasal carriage of staphylococci (Fig. 43.51).

Significant systemic effects are uncommon, and mainly consist of headaches, which may uncommonly be an early feature of benign intracranial hypertension, and arthralgia. Tetracyclines, including doxycycline and minocycline, must not be prescribed with isotretinoin, as both drugs may produce benign intracranial hypertension [48]. Systemic side effects are usually well controlled by dose reduction and concomitant the use of non-steroidal anti-inflammatory drugs or aspirin. There is a long list of very uncommon systemic side effects (see Table 43.7 and Chapter 73); a detailed review of these is beyond the scope of this chapter.

There is much debate as to whether liver function tests and lipids should be monitored while on therapy. Elevations in these tests occur in almost all patients and rapidly return to pretreatment levels after therapy has been stopped [1,2,49]. It is, however, essential to carry out these tests before starting therapy. Published evidence suggests that the laboratory tests need not be repeated except in groups at risk, such as diabetics and patients with known familial hypertriglyceridaemia [12,49]. The reader is referred to an excellent detailed overview on the many side effects of oral isotretinoin [50].

Cost-effectiveness. Oral isotretinoin is clearly more effective than oral antibiotics in acne of all grades of severity. However, its relative expense and side effects have deterred some physicians from prescribing it. Cost-effectiveness comparisons in the UK [51,52], France [53], New Zealand [54] and Australia [55] have shown that a 4–6-month course of isotretinoin is significantly cheaper than a 3-year therapeutic regimen of rotational courses of antibiotics and topical treatment. In fact, only patients treated with isotretinoin achieved complete clearance of acne when assessed 3–5 years post-treatment [43]. Funding bodies should look more logically at the way isotretinoin is prescribed, so that it can be prescribed appropriately in acne to prevent the many physical and psychological problems of the disease.

Other oral treatments

Before the advent of the retinoids and antiandrogens, several other oral treatments were used, and may occasionally be tried in difficult cases of acne if the newer drugs are contraindicated, unobtainable or ineffective. Oral zinc is of some value [1–6]. Two double-blind studies showed a significant benefit, particularly with zinc gluconate (200 mg/day). Comparison with minocycline 100 mg/day showed that the antibiotic improved acne by 63% at the end of 3 months—in contrast to an improvement of 32% with 30 mg/day of elemental zinc—but there was no placebo in the study. Certain non-steroidal anti-inflammatory drugs, such as ibuprofen and benoxaprofen, have been shown to reduce inflamed lesions [7]. More recently, a new 5-lipoxygenase inhibitor has, in a small pilot study, been shown to reduce inflamed lesions and seborrhoea, but with little effect on comedones [8]. Clofazimine (200 mg three times a week) has been shown to improve acne fulminans [9], but should not be given as a first option. Dapsone (100–300 mg/day for 6 months) has also been tried with varied success [10,11]; it is much less effective than isotretinoin [11].

Oral vitamin A has been advocated [12,13]. Doses of less than 40 mg/day are not effective. In our experience, oral vitamin A proved considerably less effective than 1 g/day of either tetracycline or erythromycin. The side effects of oral vitamin A are similar to oral isotretinoin, and the period of therapy should not exceed 6 months.

Oral prednisolone (0.5–1.0 mg/kg body weight/day) should be prescribed in patients with severe inflammatory acne vulgaris and in acne fulminans and pyoderma faciale [14]. The steroids should be prescribed at this dosage for 2–4 weeks, and then gradually reduced over a further 2–4-week period. In patients with acne fulminans and pyoderma faciale, it is preferable to prescribe the steroids for 2–4 weeks before prescribing isotretinoin. Oral steroids in similar doses are also indicated in patients whose acne flares badly while taking oral isotretinoin [14]. If such patients have many macrocomedones, they should be urgently treated with light cautery under a local anaesthetic cream such as EMLA® [15].

Physical modalities for treating active acne

Some of the physical modalities used as an adjunct to treatment require considerable skill. The many abrasive materials, usually based on polyethylene and aluminium oxide, are of little or no value. Facial saunas, heat and massage probably worsen the condition by precipitating the development of inflamed lesions. Removal of comedones can, however, be aided by hot compresses. Comedone removal can be surprisingly uncomfortable, and a variety of specially shaped tools, particularly for blackhead removal, are available. Some patients have very visible closed comedones, which often become inflamed. For these lesions, the eccentrically placed pore may be widened with a small blade under a good light, which allows enucleation of the cornified plug with the comedo remover. The limitations of comedonal extraction include incomplete extraction, refilling and the risk of tissue damage. Light cautery after the application of a local anaesthetic (EMLA®) [1] has been shown to help patients with multiple macrocomedones; these are usually whiteheads but occasionally blackheads (up to 1.5 mm diameter), and chloracne can be improved [1,2]. The EMLA® is applied for 60–75 min beneath an occlusive dressing. The cautery is used at a very low setting so as to produce little or no pain. The tip of the cautery should be just sufficiently warm to char paper towelling. The aim is to produce very low-grade thermal damage so as to stimulate the body's own defence mechanisms to eradicate the comedo. The actual cautery procedure takes 5–10 min; the treatment of each lesion takes 1–2 s and is associated with very little scarring or post-inflammatory pigmentation. This therapy is more effective than topical tretinoin for macrocomedones [3].

Until recently there has been little objective assessment of treatment by UV radiation. Broad-spectrum sunlamp therapy is probably not as good as natural sunlight: both provide only short-term benefits in acne. A combination of blue light (peak at 415 nm) and mixed blue and red light (peaks at 415 and 660 nm) was investigated in 107 patients with mild to moderate acne [4]. The light sources were portable and the treatment performed daily for 15 min over a 12-week period. At 12 weeks of active treatment there was a mean improvement of 76% with blue-red light therapy; this was significantly superior to the improvement seen from blue light, benzoyl peroxide and the control white light. The final mean improvement in comedones from exposure to the blue-red light was 58%—again better than that achieved by the other active treatments, although the differences did not reach significant levels [4]. The lamp is commercially available as the DermaLux® lamp.

Topical amino laevulinic acid (ALA) plus broad-band light (550–700 nm) has been shown to produce statistically significant clearance of inflammatory acne for at least 20 weeks after multiple treatments, and 10 weeks after a single treatment [5]. The therapy produced acute damage to the sebaceous glands, resulting in significant sebum suppression for up to 20 weeks post-therapy; this was associated with a significant decrease in *P. acnes* for many weeks. Similar long-term benefits in facial acne were achieved using a combination of ALA and polychromatic visible light (600–700 nm) [6].

Laser therapy with the NLite laser, which emits light at 585 nm, has recently been reported in a small randomized controlled trial to produce a 50% improvement in acne grade and lesion counts by 12 weeks after a single treatment [7]. In general, these regimes also significantly suppress a range of comedonal and pro-inflammatory cytokines [5,8]. Furthermore, there is a differential cytotoxic effect, in that cutaneous bacteria, including *P. acnes*, are more susceptible to short-term damage from, for example, photodynamic therapy, than keratinocytes [9]. These observations could explain some of the action of 'light' therapy regimes.

Superficial freezing with liquid nitrogen will hasten the resolution of chronic fluctuant nodular lesions and is comparatively painless [11]. Two freeze–thaw cycles of 15–30 s each are recommended, depending on the size of the nodule. It is uncertain how this treatment works, but it probably invokes an inflammatory reaction, so breaking down the indolent tissue surrounding the lesion. Cryotherapy is probably preferred to intralesional steroid injections in the treatment of older (7 or more days) nodular lesions, whereas intralesional steroid is preferred in lesions less than 7 days old [11]. Triamcinolone, 2.5 mg/mL, may be administered from a syringe with a 30-gauge needle [11,12]. Placement too superficially or too deeply may cause atrophy; 0.025–0.1 mL should be injected into the middle of the lesion, causing slight distension. Aspiration before the steroid injection is desirable but not always possible because of the nature of the fluctuant nodular lesions, which are not true cysts. Aspiration is best performed from the lower part of the nodule to facilitate drainage, with the steroid being injected into the upper part and then gently massaged into the lesion.

Deep X-ray treatment must not be prescribed because of its carcinogenic risk. Superficial X-ray therapy (no more than 8.1 Grays given in fractionated doses to any one area of skin in a lifetime) has been advocated, but is of questionable benefit.

Chemical peels [13,14]. Some dermatologists in certain countries use light chemical peels to help remove comedones as well as possibly helping superficial scarring and hyperpigmentation. Peeling agents include α-hydroxy acids (glycolic acid), salicylic acid and trichloroacetic acid. Chemical peels are supposed to promote desquamation and may help dislodge comedonal plugs. There is limited scientific evidence to support the use of chemical peels.

Treatment of scars

Response to treatment is variable and sometimes not that successful. Some scars will become less conspicuous over a period of many months. Recent interest in the pathogenesis of wound healing and scars may pave the way for new oral and topical therapies. The expansion of dermatological surgery and new lasers hold some promise. Surgical/laser therapies for scars are probably best performed when the acne is under good control. Treatment of facial scars associated with loss of tissue may include excision, planing and filling techniques. Such techniques are rarely used for scars on the trunk.

Treatment of atrophic scars

Excision of scars. Small, well-defined scars can sometimes be satisfactorily excised [1].

Dermabrasion and laser resurfacing [2–7]. These may be of value for depressed scars of even depth, but multiple ice-pick scars of irregular depth respond badly. Dermabrasion involves the use of a high-speed wire brush or diamond fraise to plane the skin under local or general anaesthesia. It is best avoided in summer because of the risk of post-inflammatory hyperpigmentation. Hypopigmentation can also occur in some patients. Postoperative care is very important, and should include the use of a topical sunscreen and prophylaxis with oral aciclovir to prevent herpes simplex infection. Improvement ranges from 30% to 75%; the patient's estimate of improvement often surpasses that of the surgeon. In the past 5 years laser resurfacing has taken over from dermabrasion. An increasing array of lasers is used for this practice and the reader is referred to specialized texts. Although scientific data on their precise benefit are limited, the future outlook may be promising [6,7].

Collagen injection. Injections of purified bovine dermal collagen to augment tissue defects are of limited benefit, but have been shown to help soft scars that are easily stretched [8–10]. Deep ice-pick and fibrotic scars show little improvement. Hypersensitivity, which is rare, must be excluded by waiting 42 days after an intradermal test before the collagen is injected. Technical expertise is necessary for a successful outcome. It is best to overfill the scar above the normal skin contours; even so, repeated treatments every 18 months may be needed. Recollagenation of acne scars refers to a technique in which an implant of freeze-dried irradiated human cadaver fascia lata is placed in an intradermal pocket at the site of each scar through a needle hole to elevate the depressed epidermis [11]. A further alternative is the injection of autologous fat into atrophic scars.

Gelatin matrix implant. One or two injections of this preparation have been shown to help scars and the improvement was maintained over 2 years [12].

Chemical peeling. Chemical peeling has been used in the treatment of atrophic acne scars. Expertise is required for such a procedure. Several chemical agents are used, including α-hydroxy acids, glycolic acids and resorcinol. The reader is referred to detailed texts on how, when and why to use chemical peels [13–15].

Multiple treatments. If several approaches are required, it is probably best to excise the larger scars and then re-plane the skin surface by dermabrasion or carbon dioxide lasers. Refilling with collagen or autologous fat may then be necessary. In older patients with much loss of tissue, facelifts may help.

Treatment of hypertrophic and keloids scars

Keloids (see Fig. 43.25) and hypertrophic scars also vary in their response to therapy, but several options are worth

trying. These include steroids, either potent topical steroid creams or triamcinolone depot injections, excision, cryotherapy or topical application of silicon gels. There are several papers that testify to both the benefit and pitfalls of such therapy [16,17]. Potent steroids such as clobetasol propionate need to be applied carefully to the scar, usually twice daily, avoiding adjacent skin to prevent atrophy of the perilesional skin. Each treatment should be used initially for 2 months. Intralesional triamcinolone (2.5 mg/mL—0.05–0.1 mL) injections into the scars can be tried at monthly intervals for a few months and the decision about subsequent therapy based on the response. Excision is frequently followed by recurrence, which may be larger than the original lesion. Double-blind studies are needed to confirm the optimum therapy for hypertrophic and keloid scars. It is important to remember that some scars improve with time and without treatment. Vascular keloids may benefit from therapy with the pulsed tunable dye laser [18]. Silicone gel sheeting applied for 12/24 h per day for at least 2 months to young hypertrophic and keloid scars has been reported to be of benefit [19]. Such sheets are available without prescription in many countries but adequate trials are lacking.

Many patients have multiple scars, and since multiple treatments are available then different treatments could be used for different scars—perhaps with some not being treated to act as an internal control. This approach might determine the natural resolution of the patient's scars.

Cosmetic camouflage. Although certain cosmetics may induce acne, it is not unreasonable, and is often psychologically necessary, for the female acne patient to use some form of cosmetic camouflage. She should be advised that she can wear light, non-greasy make-up. When scarring is a physical and psychological problem, cosmetic camouflage may be essential. In certain countries, professional advice is available, and in the UK these cosmetics are available on prescription. Make-up is often needed for the post-inflammatory increase in pigmentation, which may occur in the skin of dark-skinned people and may persist for years. Indeed, where this risk occurs, even mild acne should be treated aggressively with long-term antibiotics. Topical all-*trans*-RA and azaleic acid may be of possible therapeutic benefit in reducing post-inflammatory pigmentation, but therapy has to be continued for many months.

Uncommon associations with acne

Under this heading we have included a miscellaneous group of either distinct diseases or unusual physical features which may coexist with acne. In some, the association is unquestionable, but in others the association is debatable. In many of these clinical situations much more research is required to provide clarity. For no reason other than simplicity we have listed these associations alphabetically.

Acne excoriée

This variant (Fig. 43.52) occurs predominantly in females. Two subgroups exist: one with some primary inflammatory acne lesions, and another with almost none. Both groups usually consist of females who 'fiddle' with the skin to exacerbate even the smallest lesions. There is often some personality or psychological problem [1,2]. The disease merges into dermatitis artefacta. A contact dermatitis needs to be excluded [3]. Treatment with oral antibiotics such as oxytetracycline 0.5 g twice daily, or for better compliance lymecycline, one tablet daily, for several months and advice not to pick the spots is of considerable benefit to females with mild acne. By markedly reducing the number of lesions, the regimen leaves the patient fewer to 'play' with. Topical treatment tends to irritate the skin and aggravate the problem. In the group with virtually no acne spots, trifluoperazine hydrochloride (5–30 mg/day) or pimozide (2 mg twice a day) and appropriate psychotherapeutic support may help.

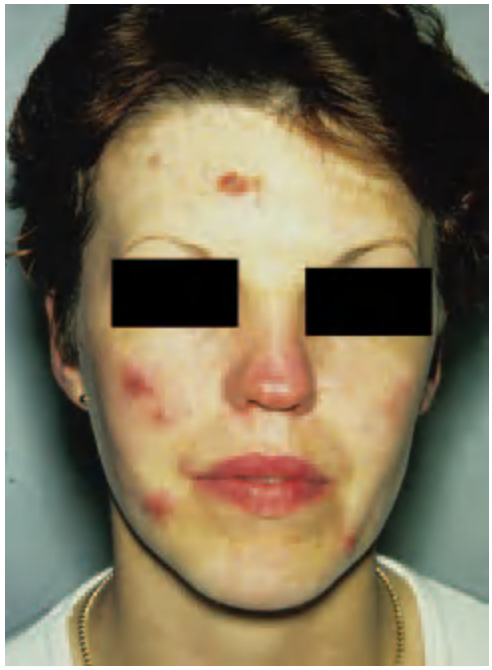

Fig. 43.52 A patient with acne excoriée.

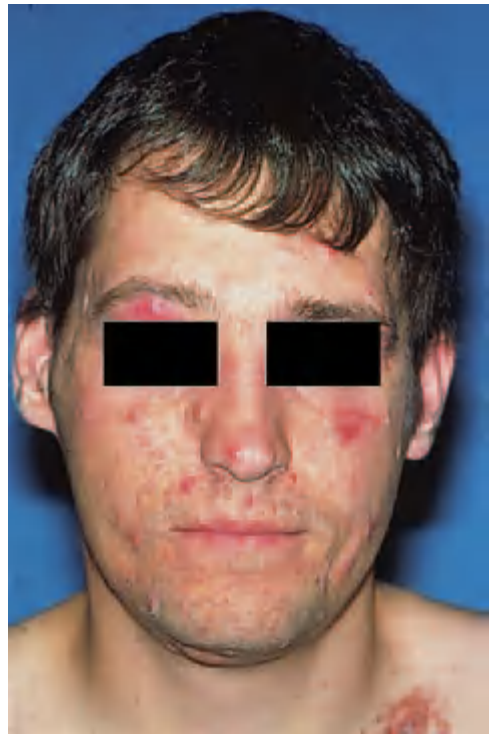
Apert's syndrome

There is an association between acne and Apert's syndrome [4,5] (see Figs 43.47 & 43.48). These subjects develop early epiphyseal closure, which, like acne, is an androgen-mediated event. The characteristic facial abnormalities are: hypertelorism, a flattened occiput, proptosis due to shallow orbits, prognathism, a parrot-beaked nose and fused shortened digits. Two genetic mutations on receptor 2 fibroblastic growth factor have been defined as a cause of this syndrome [6].

Consequently, the patient has a characteristic appearance as well as extensive acne, which often occurs at unusual sites such as on the arms (see Figs 43.47 & 43.48). The acne responds relatively less well to oral antibiotics, and patients frequently need a course of isotretinoin [7,8].

Body dysmorphic disorder and acne

A small number of patients with body dysmorphic disorder have acne as their prime symptom [9]. The acne is usually very mild, and the patient's complaint is out of all proportion to the physical signs. These patients require much support; they are often depressed or obsessional and have a significant risk of suicide [2]. Unfortunately, they usually tolerate psychiatric treatment badly, and the dermatologist must treat the acne enthusiastically with one of the more effective therapies such as minocycline 100–200 mg/day for 6 months. Isotretinoin given for 4 months is the preferred therapy. The authors consider that 'relapse', either real or perceived, is common and requests for further isotretinoin are also common [10]. This subject is dealt with in greater detail in Chapter 61.



(a)

(b)

Fig. 43.53 (a) A patient with acne conglobata, which can coexist with Darier's disease (b).

Darier's disease

This disease is discussed in detail in Chapter 40, but it is possibly associated with acne; some patients with Darier's disease have significant nodular acne that can be very difficult to treat with antibiotics, oral isotretinoin or acitretin. The variable penetrance of Darier's disease means that sometimes the clinical features are relatively inconspicuous, such that Darier's disease may be initially missed in patients with severe nodular acne (Fig. 43.53).

Table 43.8 Drugs reported to cause acne or acne-like eruptions.

Hormones and steroids	*Antituberculous drugs*
Gonadotrophins	Isoniazid
Androgens	Rifampicin
Anabolic steroids	
Oral and topical steroids	*Miscellaneous*
	Chloral hydrate
Halogens	Cyanocobalamin
Bromides	Disulfiram
Iodides	Lithium
Halothane	Psoralens (with UVA)
	Quinine
Anti-epileptic drugs	Sulphur
Diphenylhydantoin (phenytoin)	Thiouracil
Phenobarbitone	Thiourea
Troxidone	

Two patients with prominent nodular and comedonal lesions on the face and scalp showed histological features of Darier's disease on examination of a comedone [11].

Drug-induced acne/acneiform eruptions

The many drugs that have been incriminated as possible aggravators of acne are listed in Table 43.8 [12–34]. Much of the evidence consists of isolated case reports, and many of the reported reactions are idiosyncratic. Only those substances that definitely induce acne or acneiform eruptions will be discussed.

Corticosteroids, orally, topically, intranasally, intrathecally and ACTH by injection, may provoke an acneiform reaction (Fig. 43.54) [17–21]. The precise mechanism is uncertain. Corticosteroids induce cornification in the upper part of the pilosebaceous duct, but do not affect the number of surface bacteria [17,19]. Steroid acne is usually, but not invariably, more monomorphic than true acne vulgaris; however, both inflammatory and non-inflammatory lesions may be present on the face, back and chest.

Androgens including anabolic steroids and gonadotrophins may precipitate acne, especially in athletes who take performance-enhancing drugs (Fig. 43.55) [22–25]. In the former group, both testosterone and stanazolol have been shown to increase sebum excretion and the surface population of *P. acnes* [25]. Contraceptive pills that reduce SHBG levels may also result in deterioration of pre-existing acne.

Antiepileptic drugs, especially phenytoin, have been incriminated in case reports in the past, but a study of severe epileptics taking several different anticonvulsants showed that they were at no more risk of acne than the normal population, but some patients with severe epilepsy showed features of hypogonadism [26].

Isoniazid, especially in patients who slowly inactivate the drug, provokes an acneiform rash [27]. A small number of patients receiving PUVA treatment have been reported

Fig. 43.54 A patient with acne due to oral steroids.

Fig. 43.55 A patient with acne due to anabolic steroids.

to develop a perioral dermatitis and/or an acneiform eruption on the face [29,30].

An acneiform eruption has also been described in patients taking amineptine [15,16,31]. Most reported cases

Fig. 43.56 A patient with acne due to lithium. (Courtesy of Dr V.M. Yates, Royal Bolton Hospital, Bolton, UK.)

have involved adult females. Comedonal lesions are the most prevalent and inflammatory lesions are usually absent or few in number. The pathomechanism is unknown; the drug contains no halogenated substances. The drug should be withdrawn but the response is variable and oral isotretinoin (0.5–1.0 mg/kg/day) plus physical treatment of the comedones appears to be the most appropriate treatment.

A follicular acneiform eruption has been reported in cancer patients treated with the anti-EGF receptor antibody ZD 1839 [32]. The consistency of lesion morphology and timing following monotherapy with this antibody suggest a direct biological effect of the antibody. Histological examination of the lesions, which occur within a few weeks of receiving the antibody, has demonstrated a superficial dermal inflammatory cell infiltrate surrounding a dilated follicular infundibulum.

Iodides and bromides used to be a common cause of follicular pustules that were marked by the rapidity of onset after starting these preparations [33,34]. In contrast to acne vulgaris, all people and all ages were affected. Lithium is currently still an occasional cause of iatrogenic acne (Fig. 43.56).

In all cases, the risks and benefits must be assessed, and the causative drug should be stopped if possible. Appropriate topical or systemic acne therapy, according to the severity of the condition, is often successful.

Endocrine acne

The role of the endocrine system in the aetiology of acne is discussed elsewhere in this chapter. Most female patients do not have evidence of virilism and require no further investigation. The term endocrine acne should be reserved for cases of acne associated with significant clinically manifest endocrine disease such as Cushing's disease, late-onset congenital adrenogenital syndrome and polycystic ovarian syndrome. The latter is the commonest cause of 'endocrine' acne. Also reported is the so-called SAHA syndrome (*s*eborrhoea, *a*cne, *h*irsutism and *a*lopecia), which can be associated with polycystic ovarian syndrome, cystic mastitis, obesity and infertility [35]. The association of these clinical features should also alert the physician to exclude an androgen-producing tumour.

Externally induced acne

Cosmetic acne

This variant is reported more commonly in the USA [36] than in Europe and elsewhere, perhaps because of the greater use of potentially comedogenic cosmetics in the USA. The lesions characteristically occur in the perioral area of mature females, especially those who had acne as adolescents and have used cosmetics for a long time. The rabbit-ear model, which is oversensitive for humans, has shown that some cosmetics, especially those containing lanolin, petrolatum, certain vegetable oils, butylstearate, lauryl alcohol and oleic acid, are comedogenic. Many cosmetics, especially in the USA, are now screened by the rabbit-ear test and appropriate cosmetics are labelled as being non-comedogenic [36–37]. Patients should be warned that switching to a non-comedogenic cosmetic does not bring rapid clinical results in cosmetic acne. Treatment with topical retinoids or benzoyl peroxide is usually successful.

Pomade acne

Pomades are greasy preparations used to defrizz curly Negroid hair. The rash is similar to cosmetic acne and consists predominantly of many non-inflamed lesions around the forehead and other areas where greasy pomades may extend onto the hairless skin (Fig. 43.57) [38]. It may also coexist with true acne vulgaris. The rabbit-ear model has shown that certain pomades are comedogenic. Restriction of the use of pomades is essential, and the treatment of choice is with topical retinoids.

Detergent acne

This uncommon form of acne develops in patients who wash many times each day, in the mistaken hope of

Fig. 43.57 A patient with pomade acne.

improving their existing acne. Trauma and the alkalinity of soap are likely to be involved in the mechanism. Pustular and papular lesions are most noticeable [39]. Several bacteriostatic soaps contain weak acnegenic compounds, such as hexachlorophene.

Folliculitis on the scalp (dissecting cellulitis of the scalp/folliculitis decalvans) and acne

Scalp folliculitis

About 1% of acne patients complain of, or are found on examination to have, small papules or pustules in the scalp. In patients with moderate and severe acne, it is not unusual to see inflammatory papules, pustules and nodules in and around the hairline in the occipital area. Despite the frequent occurrence of this association, there have been few clinical and research studies.

Follicular pustules in treated acne patients are also seen in subjects with Gram-negative folliculitis. Patients receiving treatment with oral isotretinoin may develop a pustular scalp folliculitis, which is either due to *S. aureus* infection or may arise for unknown reasons; in the latter instance they can be quite persistent for several weeks after stopping therapy. If due to a *S. aureus* infection, response to therapies such as oral flucloxacillin is very successful. Significant, very persistent scalp folliculitis associated with an acneiform eruption has been recorded in patients with cyclical neutropenia [40].

Folliculitis decalvans

Folliculitis decalvans is a chronically progressive disorder of the hairy scalp that leads to scarring, alopecia and atrophy [41–43]. The aetiology is unknown. In some patients, it is associated with very severe acne (often acne conglobata) and hidradenitis suppurativa, forming part of the so-called poral occlusion triad. In others, the disease occurs by itself and may possibly have an infectious aetiology; sometimes *S. aureus* may be identified in the lesions. When this occurs, appropriate oral antibiotics are necessary; the greater tissue penetration of oral clindamycin or rifampicin may help, possibly combined with topical mupirocin [44]. In other instances, therapies including oral antibiotics or oral isotretinoin can be tried, but the response is often very poor. Differential diagnosis of folliculitis decalvans in the younger patients includes pustular psoriasis, erosive pustular dermatosis of the scalp, folliculitis keloidalis nuchae, tufted folliculitis and trauma.

Dissecting folliculitis of the scalp

SYN. PERIFOLLICULITIS CAPITIS ABSCEDENS ET SUFFODIENS

This condition is more frequently seen in Afro-Caribbean males [45–47]. It is a chronically progressive inflammatory disease of the scalp similar to nodular acne of the face and trunk. The common pathogenesis of this disorder, the associated severe acne and the occasional concomitant hidradenitis suppurativa is occlusion of the follicular pores and a subsequent granulomatous response to the ruptured duct contents. The lesions characteristically last many years and are cosmetically very unpleasant, painful and foul smelling. It has been reported to occur with marginal keratitis [45]. Response to therapy is poor. Options include acne-type oral antibiotics, often in higher than average doses (such as minocycline 100 mg twice daily, trimethoprim 300 mg twice daily), and oral and topical isotretinoin; success has been reported with oral zinc sulphate, 135 mg three times a day [46,47]. Many different treatments have been tried, including potent topical, intralesional and systemic steroids and widespread surgical excision with skin grafting.

Granulomatous/lymphoedematous acne

This is sometimes reported as solid facial oedema in association with acne (Fig. 43.58). Solid symmetrical or asymmetrical facial oedema is likely to be due to pre-existing hypoplastic lymphatics. The disorder is frequently progressive, and the associated acne must be treated aggressively to minimize the swelling, which can become permanent. High-dose antibiotics or oral isotretinoin are usually mandatory [48], and often need to be combined with a short or intermittent course of oral steroids; how-

Fig. 43.58 A patient with granulomatous acne.

ever, the problem may be precipitated by oral isotretinoin. Clofazimine may help [48].

Extensive localized acne may also be due to an extensive granulomatous reaction to the mediators of acne inflammation. The precise mechanism producing localized granulomatous acne is not known. The clinical picture is usually that of deep, very well-demarcated lesion(s), especially on the cheeks. Response to therapy is slow and sometimes unsatisfactory—antibiotics and isotretinoin are of limited benefit; oral steroids are also often required.

These patients often have recurrent relapses and therefore long-term follow-up is recommended.

Hidradenitis suppurativa

This entity is described in more detail in Chapter 27. However, given its occasional association with severe nodular acne, often of the conglobate type, a brief note is necessary. There is often a family history and the onset is usually in late adolescence; the disease may persist up to the age of 40 or 50 years [49–54]. There are very occasional reports of early- or late-onset disease. It is a persistent disease that affects the axillae, breasts, and the genital and perianal areas, and may sometimes spread extensively on to the buttocks and lower back. There is clinical evidence of comedones (often polyporous), papules, pustules, deep nodules, large abscesses, sinus track formation and scarring. There is much discharge from the inflammatory lesions, which makes the simple activities of sitting, walking, working and sexual relationships at times almost impossible. Pain is a common feature; the foul smell is often dreadful both for the patient and close associates. Thus, the disease produces a high degree of morbidity, higher than for previously studied skin diseases, which correlates with disease intensity as expressed by new lesions per month [51].

It is primarily a disorder of the follicles at these sites, especially of the apocrine units, which become occluded. It is not a primary disease of the apocrine gland. Aetiological factors such as hyperandrogenism, obesity, smoking and local irritation (e.g. from excessive sitting) are not consistently associated with the disease, but in some patients may be relevant aggravating factors.

Treatment is usually very disappointing. Therapeutic options include long-term antibiotics as used in acne but in high doses, such as minocycline at 100 mg twice daily, trimethoprim 300 mg twice daily; co-cyprindiol plus additional CPA (100 mg/day taken from the fifth to the 14th day of the cycle); topical retinoids; topical antiseptic washes; oral isotretinoin; oral zinc; and potent topical, intralesional and intermittent pulsed oral steroids (the dose of steroid prescribed depending upon the severity of the inflammation). Combinations of such therapy may also be tried. At the moment, there are no good clinical data to indicate which therapy should be prescribed first and in what order. More recently, finasteride 5 mg/day has been reported to be successful [53] as has infliximab [54].

Infantile and juvenile acne

Infantile and juvenile acne, which mainly affects males, presents as facial acne in children between 3 and 24 months, and may last up to 5 years of age (Fig. 43.59) [55–65]. The lesions are more localized than in adults and particularly affect the cheeks. The individual lesions may include not just comedones, papules and pustules, but also both nodules and scarring. In the neonatal period, the differential diagnosis is neonatal cephalic pustulosis [66]. This disorder usually presents in the first 3 weeks of life, and is characterized by papular/pustular lesions especially on the cheeks. It may be associated with *Malassezia sympodialis*. Treatment is often not required for this self-limiting disorder, but a topical anti-fungal cream helps.

A study of 29 patients with infantile/juvenile acne over a period of 25 years [55] showed that the median age of onset was 9 months; the disease was mild in 24%, moderate in 62% and severe in 14%. In 59% the acne was predominantly inflammatory. Five patients (17%) were left with scarring (Fig. 43.60). It is important to note that this single study was from a specialist acne centre, and therefore the data may not reflect completely the overall clinical pattern of patients with infantile acne. It is thought that infantile/juvenile acne initially results from

Fig. 43.59 A patient with infantile acne.

Fig. 43.60 A patient who has scarring as a consequence of infantile acne.

transplacental stimulation of the adrenal gland, as most sufferers have elevated plasma adrenal androgens [57]. Sebaceous glands are unique, in skin, in having enzymes capable of converting the adrenal androgen dehydroepiandrosterone to androstenedione and testosterone. It is uncertain why the acne should sometimes last for several years. Infantile acne is very rarely associated with other clinical features of androgen excess such as hirsutism or premature closure of epiphyses; very occasionally, there may be transient or more persistent high plasma levels of testosterone, LHs and FSHs. An associated virilizing tumour or underlying congenital adrenal hyperplasia is extremely rare. If the child is otherwise well and there are no other abnormal features, no endocrine investigations are required. However, such investigations may be appropriate in a patient who develops acne between 5 and 8 years of age. Occasionally, a drug such as phenytoin has been incriminated, but the evidence is weak [60].

The principles of treatment are the same as for patients with adult acne, except that the tetracycline group of drugs is not prescribed because of the risk of discoloration of permanent dentition. For mild disease, topical therapies such as topical retinoids, benzoyl peroxide, topical erythromycin or clindamycin are recommended. Perhaps the preferred choice is a combination of a topical retinoid and a topical antimicrobial agent. For moderate disease, a topical retinoid and/or benzoyl peroxide combined with oral erythromycin (as ethyl succinate, 125 mg three times a day) for 6 months is essential until lesions have totally disappeared. Alternatives include oral trimethoprim (100 mg twice daily) [55]. Infantile acne may take several months to resolve—the more severe the disease the longer the disease lasts [55]. Isotretinoin is rarely needed, and only for severe non-responding cases [61]. Patients with infantile acne may develop significant acne as teenagers [62–65].

Mechanical acne

SYN. ACNE MECHANICA

This term covers a mixed group of disorders in which the acne occurs at the site of physical trauma, as indicated by the pattern of the lesions [67–69]. Examples are so-called fiddler's neck, which occurs on the neck of violin players, and is also characterized by the presence of lichenification and pigmentation. Headbands (as worn by sports-people and hippies) and tight bra straps are other causes. Continuous friction from turtleneck sweaters may localize acne to the neck [68]. The mechanism of mechanical acne is unclear. Most patients have a tendency to develop acne, and its localization may be caused by an irritant dermatitis of the upper part of the pilosebaceous duct or excessive hydration at that site. Adolescent patients lying in bed for a long time, for example following a fractured femur in the orthopaedic ward, may develop a flare of acne—so-called 'immobility acne'. This is probably due to a change in the environment of the skin, which may enhance bacterial colonization of the duct [69]. Treatment of these conditions is the same as for other forms of acne but, in addition, advice on removal of the causative stimulus is essential.

Occupational acne

Oil and tar acne

This acneiform eruption occurs in areas of skin that are in contact with oils and crude tars [70–73]. It is now much less uncommon because of improved working practices. However, outbreaks do still occur. In a controlled study of 55 workers in a tar distillation plant, 18% in the study group and 4% of the control group had periorbital comedones [71].

Not surprisingly, men are more often affected than women. The skin may show conspicuous comedones and only occasionally do frank inflammatory lesions arise; these are usually superficial. Lesions can occur within 6 weeks of exposure on almost any site, but the thighs and lower arms are especially prone. It has been suspected, but not proven, that individuals with acne vulgaris are more likely to develop oil acne. The commonest oils involved are the impure paraffin mixtures used in the engineering industry. Petroleum products can affect oilfield and refinery workers; workers exposed to heavy coal-tar distillates, especially pitch and creosote, may also develop acne. Dichlorodiphenyltrichloroethane (DDT), asbestos and heavy water distillate has caused acne in some patients.

The treatment is removal from the source of the disease and the use of topical retinoids. If significant inflammatory lesions are present, then topical and oral antimicrobials may help. Very infrequently, oral isotretinoin has been successfully prescribed [73].

Chloracne

This variant is part of a syndrome that follows exposure to certain toxic, chlorinated hydrocarbons. Chloracne lesions consist of multiple comedones; inflammatory lesions are infrequent [74–89]. Comedones are often localized on both sides of the face (Fig. 43.61), especially the temporal regions, but in more severe cases may occur on other parts of the body. Other skin lesions may also occur, including porphyria-like changes, pigmentation, hypertrichosis and palmar and plantar hyperhidrosis. Ophthalmic chloracne may occur, due to the Meibomian gland involvement. Systemic abnormalities are less frequent, and include fatigue, anorexia, neuropathy, impotence, disturbed liver function and hyperlipidaemia. Often the chloracne and the systemic disturbances may last for many years following exposure [78,81,83,88]. Persistent chloracne, goitre, headache, broken teeth, anaemia and arthritis were more prevalent in patients compared to controls in a 14-year follow-up study following exposure to polychlorinated bihenyls and polychlorinated dibenzofurans [88].

Chloracne has been reported following exposure to chlornaphthalenes, polychlorbiphenyls, polychlorinated dibenzofurans, chlorophenol contaminants, trifluoromethyls, pyrazole derivatives and chlorobenzenes. Contamination often follows an explosion resulting in the uncontrolled liberation of the chemical [74,80,84]. The chloracnegens have been identified in the blood [80,87,89]. They have not been identified in the pilo-sebaceous apparatus, but in one instance exposure to dioxin was reported to produce a hyperproliferative reaction of the cutaneous epithelium with squamous metaplasia of the pilosebaceous duct, with subsequent atrophy of the sebaceous gland [85].

Fig. 43.61 A patient with multiple blackheads typical of chloracne.

The skin lesions are relatively persistent and resistant to treatment. Topical therapy with retinoids such as adapalene and tretinoin are worthy of a therapeutic trial; long-term oral antibiotic therapy may be needed for the inflammatory lesions. Oral isotretinoin does not help. This is not surprising, since the sebaceous gland has already undergone atrophy [86]. Gentle cautery under local anaesthetic cream (EMLA® applied for 60–75 min under polythene occlusion) produces excellent results [90]. Litigation is frequent when the contamination follows an industrial accident.

Osteoma cutis

Calcification, i.e. osteoma cutis, is an uncommon complication of acne and usually needs no treatment [91–93]. The calcification presumably occurs in areas of inflammation and presents as small, 2–4 mm persistent papules, which

are slightly firm to touch and usually skin or ivory coloured. They are occasionally associated with hyperpigmentation. The lesions are often suspected to be persistent closed comedones. A biopsy will reveal calcified trabecular bone formation surrounded by a perivascular proliferation, sometimes with increased fibrous tissue formation. The only successful treatment is carbon dioxide laser therapy. This is associated with quite a considerable local inflammatory response and so it is best to treat a small test area first before proceeding to treat all lesions.

Pilosebaceous naevoid disorders

Some of these disorders are only tenuously linked with the pilosebaceous system; they are described in more detail in Chapter 15.

Acne and non-acne naevi

Patients have been described with symmetrical areas of normal skin set in the midst of severe acne on the back [94], or with acne localized to one side of the back [95]. A reduced rate of sebum excretion with a reduction in surface bacteria has been demonstrated in the normal (non-acne) areas.

Comedo naevus

SYN. NAEVUS COMEDONICUS; NAEVUS FOLLICULARIS; NAEVUS UNILATERALIS COMEDONICUS

This uncommon naevus is usually a developmental defect of the hair follicles [96–102]. The associated sebaceous glands may be normal, hypoplastic or hyperplastic. In one case, however, the sweat duct was the origin of the lesions [98]. Lesions usually occur on the scalp, face and trunk, and occasionally at unusual sites such as the penis. The individual lesions are large comedones, often grouped or linear in arrangement (Fig. 43.62). Occasionally, inflammatory acne lesions may be found. Although usually present at birth, they can appear much later in life [102]. The symptoms are mainly cosmetic, but at times can be psychologically and physically devastating. An association with epidermolytic hyperkeratosis has been reported [101]. Treatment is usually only of limited success. Topical retinoids are a logical treatment. Twelve per cent aqueous ammonium lactate solution has been reported to be of benefit. Gentle cautery can help the less severe cases [102].

Familial comedones

This uncommon genetic disorder shows autosomal inheritance. The earliest lesions are monoporous, but later the face may be extensively involved with polyporous comedones and cysts, and scarring may follow. New lesions may continue into middle age.

Fig. 43.62 A patient with a comedo naevus (predominantly consisting of blackheads) on the lower abdomen.

Pyogenic granulomas in acne

Pyogenic granulomas are a rare complication of healing severe nodular lesions [108], and this occurs more frequently following isotretinoin therapy [109]. The lesions can either be left alone or, if single, treated with cautery; if multiple, they will usually respond to clobetasol priopionate (Dermovate®) cream topically twice daily applied carefully to the lesions over a 2–3-week period.

Sebaceous naevus

SYN. NAEVUS SEBACEUS OF JADASSOHN

This is an organoid naevus, consisting of a mixture of relatively normal-looking epidermis, dermis, sweat and sebaceous glands. It usually presents on the scalp as an area of alopecia associated with a pinkish yellow, fleshy swelling [103–107]. At puberty, the sebaceous glands enlarge and the epidermis becomes verrucous. Co-occurrence with aplasia cutis has been reported [104]. Trichoepithelioma and eccrine syringoadenoma has been reported to develop in naevus sebaceus [106]. Unusual haematopoietic proliferation at birth that spontaneously resolved at 4 months has been documented [107]. Lesions occurring in the midline are often associated with mental subnormality and

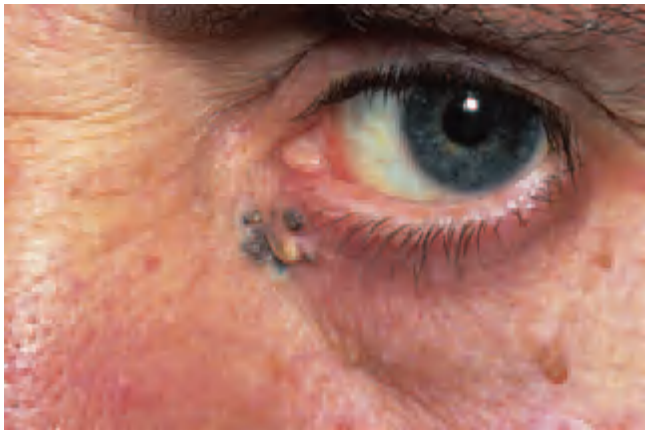


Fig. 43.63 A patient with senile comedones.

epilepsy. Excision is usually recommended because of malignant change into a squamous or basal cell carcinoma in later life [105].

Seborrhoea

Excessive grease production is an uncommon reason for referral, but many patients with severe acne complain bitterly of seborrhoea. In a recent unpublished personal survey, we demonstrated that many patients found seborrhoea to be as important a problem to the patient as inflammatory lesions. It can persist after acne has regressed [110]. Patients with acromegaly or parkinsonism, especially the post-encephalitic type, often have seborrhoea. Antibiotic and desquamating agents used in the treatment of acne do not influence the seborrhoea, but oral isotretinoin, CPA combined with oestrogen (cocyprindiol) and spironolactone all significantly reduce the seborrhoea. Physicians have to decide whether the patient's distress justifies the use of these systemic drugs.

(Acne with) solar comedones

SYN. SENILE COMEDONES; FAVRE–RACOUCHOT SYNDROME

These are seen in elderly people, especially in the periorbital areas (Fig. 43.63). Most patients have had high exposure to UV radiation, and the solar damage to the supporting dermis allows the pilosebaceous duct to become more easily distended with impacted corneocytes. The clinical presentation is that of multiple, open, and sometimes closed, comedones superimposed on a sun-damaged skin, usually symmetrically affecting the periorbital areas and the cheeks; occasionally the lesions are unilateral [111]. Similar lesions may be seen in pseudoxanthoma elasticum and after radiotherapy. In patients with isolated lesions, the edge of the adjacent skin may be mistaken for the pearly edge of a basal cell carcinoma. The lesions are easily removed with a comedo expressor, but they slowly recur. A topical retinoid to suppress the formation of future comedones may help. Gentle electrocautery can eliminate the smaller comedones [90].

'Tropical' acne (hydration acne)

Troops in the Second World War suffered badly when posted to the Far East, but US Marines in Vietnam were relatively spared, possibly because acne-prone individuals were not selected for service [112]. Certain occupations may aggravate pre-existing acne; for example, workers in a hot, humid environment, such as cooks and pressers, are at risk. It is thought that hydration of the pilosebaceous duct pores may accentuate blockage of the duct and so precipitate inflamed lesions [113]. A similar explanation may apply to 'Mallorca acne', in which small, follicular papules appear, especially on the upper trunk, during or after a holiday in a hot, humid environment. Potentially comedogenic sunscreens may be an additional factor in these patients [114]. These patients often need prolonged treatment as the event often precipitates or exacerbates troublesome pre-existing acne. Treatment options are the same as for acne vulgaris.

'Virally' induced acne

Acne can occur at unusual sites and at unusual ages with little involvement of the commonly affected sites. An acneiform rash has been reported at the site of previous herpes zoster infection. Histology revealed follicular occlusion and the disease was quite persistent [115].

A very small number of patients with severe acne and significant glandular fever responded poorly to oral antibiotics and oral isotretinoin. It was proposed that the viral illness in some way played an important role in the poor response [116].

Severe acne variants

Six severe acne variants will be discussed in this section. For ease of reference, they are discussed alphabetically.

Acne conglobata

This is a most uncommon but severe form of acne, found particularly in males; the lesions usually occur on most of the trunk and upper limbs. In contrast to ordinary acne, facial lesions are less common. The condition usually appears in early teens, but unlike other forms of acne, becomes increasingly active in the second to third decades of life. It is characterized by multiple inflammatory papules and tender nodules which frequently fuse to form multiple draining sinuses (Figs 43.64 & 43.65) [1]. Grouped, multiple, fused blackheads and extensive scarring are also features. In some patients, the scarring is very mutilating [2]; in addition, malignant change may occur in

Fig. 43.64 A patient with extensive acne conglobata.

Fig. 43.65 Sinus formation in a patient with acne conglobata.

chronic scars [3]. Familial cases have been reported. Uncommonly it is associated with hidradenitis and folliculitis decalvans, which is a rare and chronic progressive hair disorder that produces scarring alopecia and atrophy [4]. Significant scarring is an inevitable consequence. Acne conglobata may persist to 40–50 years of age. Therapy is difficult; options include long-term high-dose antibiotics, colchine, dapsone and topical therapy. Oral isotretinoin (1 mg/kg/day) for 4–6 months is the treatment of choice. Isotretinoin may need to be combined with oral antibiotics such as erythromycin or trimethoprim. Concomitant short intermittent courses of oral steroids may be required to control acute exacerbation. Surgery may be required [2,5].

Acne fulminans

This was originally described as an acute form of febrile ulcerative acne conglobata. It is an uncommon, immunologically induced, systemic disease in which the offending antigen is *P. acnes*. The patients are predominantly young males who quite suddenly develop extensive inflammatory lesions, especially on the trunk (Fig. 43.66) [6–29]. Associated features are fever, polyarthropathy, marked leukocytosis (even a leukaemoid reaction), weight loss, anorexia and general malaise. Painful splenomegaly [19], erythema nodosum [20] and bone pain due to aseptic osteolysis have also been reported [17,21]. Bone involvement is common [22]; in a series of 24 patients, 48% had

Fig. 43.66 A patient with severe truncal acne who had acne fulminans.

lytic bone lesions on X-ray and 67% showed increased radiolabel uptake; 25% showed destructive lesions resembling osteomyelitis [21,22]. The prognosis for bone lesions is good, and chronic sequelae, if any, are mild leading to sclerosis and hyperostosis [23]. Blood cultures from the pustular lesions are universally sterile. Skin tests with *P. acnes* demonstrate a very extensive, immediate and delayed reaction, the immunohistology of which reveals a type III or type IV hypersensitivity reaction [23].

Testosterone treatment, either legal or illegal, or oral isotretinoin may induce acne fulminans [24,25]. An acne fulminans-like picture has been reported in association with Epstein–Barr virus infection. Thus, patients with a sudden exacerbation of previously relatively mild acne should be checked for infectious mononucleosis [26].

Oral prednisolone therapy is required urgently (0.5–1.0 mg/kg/day), decreasing to zero over 6 weeks. The acute myalgia, arthralgia and fever can also be helped by oral salicylates or non-steroidal anti-inflammatory drugs and graduated physical exercise. The underlying skin condition requires high-dose antibiotics or oral isotretinoin (0.5 mg/kg/day), which should be started after 4–6 weeks of steroids and is the treatment of choice [23,27–29]. Topically, crusts need to be removed by soaking the skin with emollient oil, followed by the use of a potent steroid/antiseptic cream for 2–3 weeks.

Gram-negative folliculitis

This is a complication of long-term treatment of acne with antibiotics (usually taken orally, uncommonly by the topical route) [30–34]. It presents either as a sudden eruption of multiple, small follicular pustules (Fig. 43.67) or with nodular lesions. In the authors' clinic, 35% presented as a worsening of acne that had been under good control. Microbiological sampling from the nose and lesions reveals one or more Gram-negative organisms, including

Fig. 43.67 A patient with the typical multiple pustules of Gram-negative folliculitis.

Klebsiella, *Escherichia coli*, *Proteus* or *Pseudomonas*. Therapy usually involves stopping the current antibiotics and replacing them with either ampicillin (250 mg four times a day) or trimethoprim (600 mg/day). However, the response may be slow and relapse is common. Isotretinoin is the treatment of choice; relapse following oral isotretinoin is less frequent than in patients receiving oral antibiotics.

Of our acne patients who present with many pustules (i.e. pustular folliculitis), about 1% have significantly high counts of *S. epidermidis*, and very occasionally this may cause signifant folliculitis [35]. Therapy usually requires stopping all antibiotics and using topical benzoyl peroxide, which is particularly helpful.

Pyoderma faciale

SYN. ROSACEA FULMINANS

This was initially believed to be a variant of acne but it is suggested that it is more related to rosacea (Chapter 44) [36–40]. However, there is still much debate, and further clinical and basic research is required on this devastating facial dermatosis. It is uncommon, and occurs in patients who usually have mild skin disease that suddenly erupts producing many pustules and nodules, especially on the face. It mainly affects post-adolescent women (aged 20–40 years), often following a period of stress (Figs 43.68 & 43.69). Comedones are rare, and facial flushing frequently precedes the acute illness. In contrast to acne fulminans, there are usually no systemic symptoms. The reason for the sudden flare is unknown. Rosacea fulminans has been reported in association with Crohn's disease—the significance of which is unclear [38]. The daily ingestion of high-dose vitamin B supplements has been reported to be associated with the sudden onset of rosacea fulminans [39].

Treatment consists of minocycline (100–200 mg/day) plus intralesional steroids or liquid nitrogen to the nodules, but the best treatment is perhaps oral isotretinoin (0.5 mg/kg) for 4–6 months (see Fig. 43.69) [36–39]. To minimize an acute exacerbation, oral prednisolone (0.5–1.0 mg/kg body weight/day decreasing to zero over 4 weeks) should be prescribed initially for 2–3 weeks

Fig. 43.68 A patient with rosacea fulminans.

Fig. 43.69 The same patient as in Fig. 43.68 after 4 months treatment with oral isotretinoin.

Fig. 43.70 A patient with very significant vasculitic acne.

Fig. 43.71 Pyoderma gangrenosum-type scarring in a patient who had suffered from vasculitic acne.

before starting oral isotretinoin, which can then be taken at the same time. Alternatives include oral metronidazole and dapsone [40]. The prognosis is difficult to assess, but scarring is infrequent. Recurrence occurs more frequently than was believed some 5 years ago.

SAPHO syndrome

This acronym represents a syndrome of *s*ynovitis, *a*cne, *p*ustulosis, *h*yperostosis and *o*steitis [41,42]. In adults, and occasionally in children, chronic recurrent multifocal osteomyelitis can be associated with certain skin disorders. Severe acne is one of the less frequently associated disorders. The syndrome may be under recognized by dermatologists, since the skin manifestations in some patients can be quite mild. The disease may represent an immune reaction to a particularly skin or bacterial antigen.

Vasculitic/pyoderma gangrenosum acne

A few patients, who previously had very mild acne, have developed the sudden onset of severe vasculitic, pyoderma gangrenosum-like lesions (Fig. 43.70). Very significant scarring is the inevitable consequence (Fig. 43.71). The mechanism of this devastating acne is probably an immunological reaction to *P. acnes*. Such patients appear to be unresponsive to oral isotretinoin alone, but settle to some extent with oral steroids and azathioprine (200 mg/day) over a 3–4-month period [43].

Ectopic sebaceous glands

These are commonly seen in the mouth—the so-called Fordyce spots—as multiple, symmetrical, barely elevated, discrete, yellow papules on the buccal mucosa [1]. They are present in 25% of the population over the age of 35 years, and are usually asymptomatic. When extensive they can, on the lip, be quite disfiguring and do respond to oral isotretinoin [2]. There are no adequate data that indicate whether or not they relapse post-therapy.

Similar lesions are common on the penile shaft, especially on the ventral surface, and at this site inflamed acne lesions may be seen, but usually the patient needs no more than reassurance. Other sites are occasionally affected such as the areolar area of the breast [3].

Sebaceous gland hyperplasia, adenoma and carcinoma

Sebaceous gland hyperplasia

The sebaceous glands sometimes become prominent in middle-aged or elderly people. In white people they produce numerous yellowish pink papules, each 1–3 mm in diameter. They are seen especially on the forehead and temples, and are of no clinical significance. They also are present occasionally on the light-exposed skin of renal transplant patients who are receiving ciclosporin (cyclosporin) [1]. Treatment is rarely requested, but cosmetic camouflage may be used. If requested and appropriate, some physical treatments such as gentle cautery, cryotherapy, trichloroacetic acid, and carbon dioxide and pulsed dye laser may be used [2]. Sometimes, but very uncommonly, the lesions are diffuse, producing a yellowish hue to the skin. In such patients, oral isotretinoin has been reported to be of considerable benefit [3]. Co-cyprindiol (Dianette® and Estelle 35®), with or without additional oral CPA, will also produce regression of sebaceous hyperplasia whilst on therapy. A therapeutic trial of oral isotretinoin may help to differentiate between sebaceous hyperplasia and multiple early basal cell carcinomas in transplant recipients, and may avoid multiple biopsies if there are many lesions.

Sebaceous gland tumours

These are very uncommon. The adenomas in particular may be associated with a systemic tumour.

Sebaceous adenoma

This is a benign tumour composed of incompletely differentiated sebaceous cells. It occurs in both sexes and is seen mainly in elderly patients on the face or scalp [1]. The pink or waxy yellow tumours are round, raised, sessile or pedunculated; they are usually 10 mm or less in size, but may form plaques and ulcerate. Excision is the best treatment, but they are radiosensitive. Very infrequently, sebaceous gland adenomas can be associated with multiple visceral carcinomas. The internal tumours are usually

of relatively early onset (45 years) and include adenocarcinoma of the colon, breast, ovary and prostate [2,3]. This association is referred to as the Muir–Torré syndrome, which is linked to the same chromosomal region as the familial cancer syndrome [4]. Such patients are characterized by the concurrent or sequential development of sebaceous gland tumours (adenoma, epithelioma or carcinoma) and at least one internal malignancy. With the Muir–Torré syndrome microsatellite instability can often be demonstrated in tumour DNA as a result of an inherited mutation in one of several known mismatch repair genes; however, the role of microsatellite instability in sporadic sebaceous carcinoma has until recently not been demonstrated. Of the nine tumours recently reported, five tumours were from four renal transplant recipients and four were from otherwise healthy individuals [5].

Fig. 43.72 A patient with extensive steatocystoma multiplex. There are both inflammatory lesions and non-inflammatory cysts.

Sebaceous carcinoma

This is a very uncommon malignant tumour usually involving men over the age of 40 years. It presents as a solitary, firm tumour, yellow–orange in colour, especially on the face and scalp. Sebaceous carcinomas have a well-recognized association with the Muir–Torré syndrome. The tumour grows slowly, but those arising in the eyelid (from the Meibomian glands) have a greater predilection for metastasizing [6,7]. Treatment is by excision or radiotherapy [7].

‘Sebaceous’ (epidermoid) cysts and steatocystoma multiplex

The classical ‘sebaceous’ cyst (wen) is an epidermal structure; strictly, it should be referred to as an epidermoid cyst, and it is discussed in Chapter 36. However, true sebaceous cysts occur as so-called steatocystoma multiplex, a naevoid condition that histologically shows a mixture of a keratinizing epithelium and sebaceous lobules attached to the epidermis by a thin epidermal strand [1–3]. Steatocystoma multiplex is uncommon, and in some patients is associated with type 2 pachyonychia congenita (PC-2 or Jackson–Lawler syndrome), in which natal teeth are also a feature [4–6]. Histologically, the cysts in PC-2 may be true steatocysts, eruptive vellus hair cysts or keratinous cysts, even in the same family or individual [7–9]. To date, mutations in the Ia domain of keratin 17 (K17) have been found in all cases [9,10]. In some families with clinically and histologically typical steatocystoma multiplex, mutations in the K17 gene are also found [10]. In these families, close inspection shows that some but not all members have nail changes, which are usually but not always milder than those of PC. Familial steatocystoma multiplex has also been associated with natal teeth in the absence of nail dystrophy [11], and it seems likely that these cases are also due to keratin gene mutations. However, in a case of steatocystoma multiplex/eruptive vellus hair cyst (EVHC) and in another of EVHC, mutations in K17 were not found along the Ia domain [10], and hence it is likely that steatocystoma multiplex is genetically heterogeneous.

The lesions are multiple, smooth, elastic, yellow dermal swellings varying from a few millimetres to 20 mm in size (Fig. 43.72). They appear or enlarge at puberty, and mainly occur on the trunk or limbs. They last indefinitely, and whether they resolve with old age is uncertain. Inflamed lesions due to rupture of the cysts are common and, when extensive, can produce the so-called steatocystoma multiplex suppurativa, which mimics acne conglobata. Treatment is very difficult [1]; excision of the larger cysts is possible, but total removal of all cysts is impractical because of their number. Tetracycline (1 g/day) or minocycline (100–200 mg/day) for 3–6 months is required if the lesions suppurate. Topical therapy is of limited benefit. Oral isotretinoin is of some help in reducing inflammation, but does not affect the primary disease process.

Chapter 44

Rosacea, Perioral Dermatitis and Similar Dermatoses, Flushing and Flushing Syndromes

J. Berth-Jones

This chapter brings together a range of dermatoses presenting with facial eruptions and/or flushing. It includes rosacea, the rosacea-like eruptions and carcinoid syndrome.

Rosacea

Definition. Rosacea is a disease lacking an entirely satisfactory definition. It is a chronic disorder affecting the facial convexities, characterized by frequent flushing, persistent erythema and telangiectasia, interspersed by episodes of inflammation during which swelling, papules and pustules are evident [1]. However, not all cases fit this description since not all features are always present. A recent attempt to define diagnostic criteria [2] concluded that the presence of one or more of the following signs with a central face distribution is indicative of rosacea: flushing, non-transient erythema, papules and pustules, telangiectasia. Clearly, if all individuals with one or more of these features are to be included, rosacea is both a common and highly heterogeneous entity.

Many authorities have expressed the view that vascular changes, particularly flushing, are the initial and constant feature, followed by progression to inflammatory changes (papulation and pustulation) and that the development of chronic lymphoedema, thickening of affected skin and rhinophyma are late complications. However many cases do not seem to demonstrate such a clear pattern of evolution.

Nomenclature. The term 'acne rosacea' is used synonymously with rosacea but is better avoided. It reflects the occurrence in both diseases of facial papules and pustules. However, the epidemiology, aetiology and pathology of rosacea are quite distinct from acne vulgaris. The latter is primarily a disorder of pilosebaceous units but it is not clear to what extent the same is true of rosacea.

Epidemiology. Rosacea is a very common disease. It is much more common in fair-skinned than darker-skinned individuals, although it does occur in black people [3]. Meaningful figures on prevalence are scarce, but in Swedish 'white-collar' workers the figure is probably about one in 10 [4], representing about 1–3% of dermatological consultations. Women are more commonly affected than men, although the development of rhinophyma is not common in women, who generally experience less severe disease than men. It is predominantly a disease of young to middle-aged adults, but it can occur occasionally in children [5].

Pathogenesis. The cause, or causes, of rosacea remain uncertain. In contrast to acne vulgaris, rosacea is not associated with seborrhoea [6]. Marks [1] has proposed that damage to dermal connective tissue, often caused by solar irradiation, may be the initiating event. This may result in dysfunction of the unsupported facial blood vessels with consequent endothelial damage, leakage, oedema and inflammation. Others have argued for the central role of abnormal vascular reactivity [7]. The association of rosacea with migraine seems to support this hypothesis [8].

As there is no associated sweating, it has been argued that flushing in rosacea is mediated by released vasoactive

substances rather than a neural reflex mechanism [9], but this cannot yet be taken as established and both mechanisms may play a role. Proposed mediators included serotonin, bradykinin, prostaglandins [10], substance P, opioid peptides and gastrin. Blood levels of substance P were raised in some patients but not consistently [11]. Opioid peptides have been proposed as mediators of flushing in rosacea on the basis of the suppressive action of the opioid antagonist naloxone [12].

It is often stated that rosacea is associated with gastrointestinal symptomatology, although there is little evidence to support this [13–15]. No consistent evidence of gastritis was obtained in a controlled endoscopic study [16]. An association between jejunal mucosal atrophy and rosacea has also been proposed [17] but has not been confirmed [18].

In recent years, the possible role of *Helicobacter pylori* infection of the gastric mucosa has been the subject of particular controversy. A high prevalence of this infection has been reported in patients with rosacea [19,20], reaching up to 100% in one uncontrolled series [20]. In controlled studies prevalence rates have sometimes been similar to controls [21–24] and sometimes higher than controls [15,25–27]. It has been suggested that the prevalence of seropositivity in patients with rosacea might be artificially reduced as a result of antibiotic treatment [15], increasing the difficulty in drawing conclusions from these data.

The role of *H. pylori* in rosacea might be clarified if it could be established that eradication of the organism cured the disease, but the available data are inconclusive in this regard. There are anecdotal reports of impressive responses. A patient who had suffered from rosacea for 9 years cleared and remained free of the disease 2 years later [28]. A case of granulomatous rosacea of 4 years duration resolved after eradication of *H. pylori* and remained clear 3 years later [29]. Significant improvement was seen in an uncontrolled trial of *Helicobacter* eradication, which studied 22 patients with rosacea and evidence of *H. pylori* infection [24]. In a placebo-controlled trial of *Helicobacter* eradication in 44 *H. pylori*-infected patients with rosacea, the disease abated in almost all the patients in both treatment groups, although none were cured [30]. There was no significant difference between placebo and active treatment at the 60-day end point, although improvement was somewhat greater in the active limb. In an open-label study comparing the response of rosacea to a *Helicobacter* eradication regimen in groups of patients with and without evidence of *Helicobacter* infection, both groups were improved when assessed at 3 and 6 weeks with a somewhat larger response being seen in those with *H. pylori* infection [26]. Szlachcic *et al*. [27] treated 53 *H. pylori*-infected patients with rosacea with an eradication regimen, and reported clearing of rosacea within 2–4 weeks in 51 cases. The clinical improvement was accompanied by resolution of gastritis and reduction in serum levels of gastrin, interleukin-8 (IL-8) and tumour necrosis factor-α (TNF-α), possible mediators of the vascular changes in rosacea.

A range of different eradication regimens were used in these studies but all contained antibiotics known to be effective in rosacea. Antibiotics used in treatment of rosacea are all potentially effective in treatment of *H. pylori*. Whilst these do have anti-inflammatory properties and may therefore work by other mechanisms, it remains an interesting and plausible hypothesis that suppression of *H. pylori* might partially explain their efficacy.

A potential role has often been proposed for the follicle mites *Demodex folliculorum* and *D. brevis* in the pathogenesis of rosacea. Infestation with these mites is extremely common in the general population, reaching up to 100% of subjects in some studies [31]. These organisms have traditionally been considered harmless commensals, but there is increasing evidence that they are potentially pathogenic, especially when present in very high numbers. Eruptions strongly resembling rosacea and associated with the presence of large numbers of *D. folliculorum* have been reported under the title of rosacea-like demodicosis [32,33]. These cases have improved following treatment to eradicate the mite.

Several investigators have reported increased numbers of *D. folliculorum* in the facial skin of patients with rosacea relative to controls [31,34–38]. *Demodex* mites have also been demonstrated in the dermis associated with an inflammatory response and undergoing phagocytosis by multinucleate giant cells. This phenomenon has been observed both in localized and in more widespread facial eruptions resembling rosacea [39,40]. Furthermore, *D. brevis* is often present in the eyelid in hair follicles, eyelash follicles and meibomian glands [41,42], and is often reported in association with periocular pathology including blepharitis and meibomianitis [43–45]. These observations would suggest that the presence of *Demodex* mites might also play a role in some of the ophthalmic complications of rosacea. Against a central role for *Demodex* is the relatively infrequent observation of the mites (in 19% or less of the biopsies) in some of the larger histological studies of rosacea [46–48]. However in a histological study specifically examining the prevalence of mites these were observed in 51% of patients with rosacea, and perifollicular inflammation was observed around infested hair follicles [49].

Further insight into the role of *Demodex* in the pathogenesis of rosacea might be gained by investigating the effects of eradication of this organism, but there has been limited formal study of this. In a small left/right comparative study permethrin cream and topical metronidazole both yielded similar results [50]. In a parallel group study permethrin was superior to placebo and equivalent to metronidazole in reducing papules and erythema [51]. Some improvement has been reported in an uncontrolled study

using crotamiton [37]. Benzyl benzoate reduces mite numbers but seems to be irritant in patients with rosacea [52]. A florid rosacea-like facial eruption associated with *Demodex* and accompanied by dermal inflammatory response and phagocytosis of the mites responded to metronidazole [40]. This is not easy to explain as metronidazole is not considered to be mitocidal [53]. However the mites may be associated with bacteria, both in their gut and on their skin [37], providing a potential microbial target for antibiotics.

Recently, rosacea has been reported as a manifestation in the skin of human immune deficiency virus (HIV) infection [54], and the same is true of rosacea-like demodicosis [33,55].

Clinical features. Rosacea is a polymorphic disease with several variants, each of which may require a different approach to treatment. The areas characteristically affected are the central convex areas of the face (nose, forehead, cheeks and chin) (Fig. 44.1). Occasionally, the scalp, upper chest, back and even the limbs may be involved [56]. In cases of rosacea showing the classical pattern of progression the onset is most often marked by vascular changes, notably episodic flushing usually unaccompanied by sweating. Erythema, which is accompanied by a burning sensation, gradually becomes more persistent, is easily triggered by minor irritants, and is associated with increasingly prominent telangiectasia. More advanced cases show follicular and non-follicular papules and pustules without comedones followed by persisting tissue thickening due to oedema, fibrosis and glandular hyperplasia, leading ultimately to a *peau d'orange* appearance and rhinophyma (Figs 44.2–44.4).

Fig. 44.3 *Peau d'orange* appearance of advanced rosacea. (Courtesy of Professor M. Greaves, Singapore General Hospital, Singapore.)

Factors which trigger flushing include emotion and stress [57], hot drinks [58], alcohol [12] and other vasodilating drugs, and spicy food. Despite traditional beliefs to the contrary it is the heat, not the caffeine content of hot drinks, which causes flushing [58]. Aggravating factors include the use of topical steroids on those occasions when they are used (usually in error) to treat rosacea. Sun exposure may worsen or improve rosacea [59].

The classical progression of rosacea is summarized in Table 44.1. Many cases do not follow this pattern. Some show predominantly the vascular features (erythematotelangiectatic rosacea), others develop mainly inflammatory lesions (papulopustular rosacea), others develop mainly chronic thickening and induration and still others

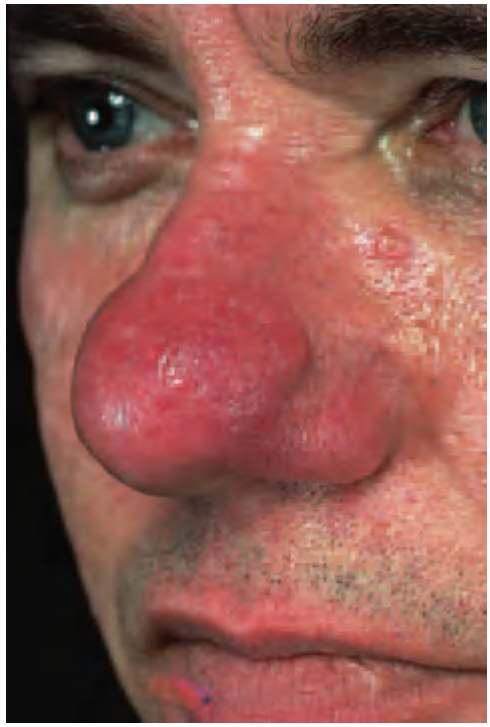

Fig. 44.4 Rosaceal rhinophyma. (Courtesy of Professor M. Greaves, Singapore General Hospital, Singapore.)

Table 44.1 Rosacea: clinical progression.

Early	Episodic flushing Mild telangiectasia Transient oedema
Progressive	Papules Pustules Sustained oedema Extensive telangiectasia
Late	Induration Rhinophyma

develop only rhinophyma. Each of these patterns may occur in isolation or in any combination.

Complications. Rosacea, usually of long duration, is associated with several important complications.

Chronic lymphoedema. This is a relatively rare complication of rosacea which can affect any part of the face and the ears (Fig. 44.5). In time this may develop into a coarsening of the features known as leonine facies. A characteristic pattern of lymphoedema of the upper half of the face developing as a complication of chronic rosacea has been termed chronic upper facial erythematous oedema or Morbihan's disease [60]. The orbital skin is often affected resulting in severe eyelid swelling and sometimes ectropion [61,62]. Histological examination reveals features of

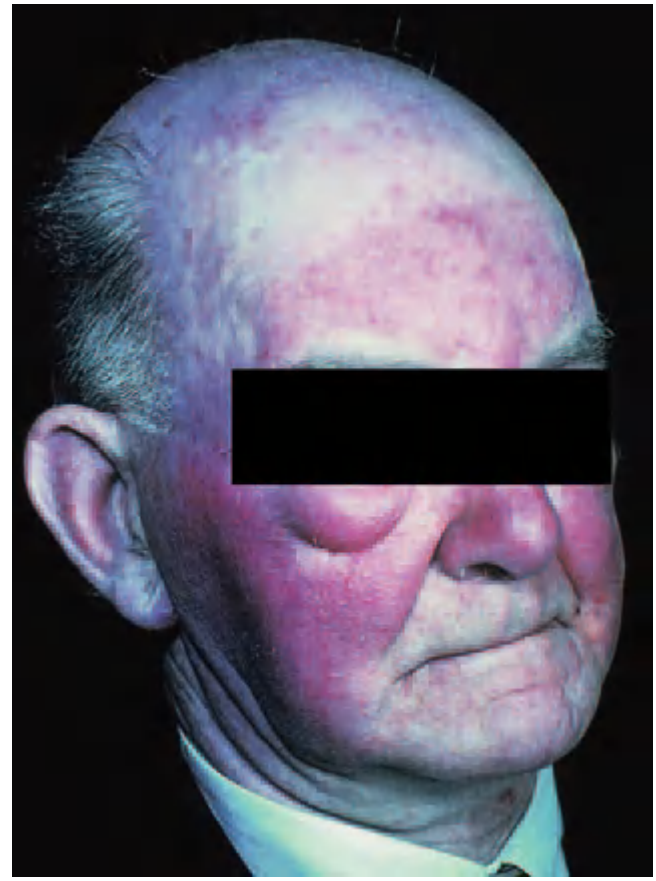

Fig. 44.5 Chronic lymphoedema in a patient with a long history of rosacea. (Courtesy of Professor M. Greaves, Singapore General Hospital, Singapore.)

lymphoedema and inflammatory cell infiltration of variable intensity.

Eye involvement. Ophthalmological complications are common, occurring in over 50% of patients with rosacea [63], although the pathogenesis is still not well understood. These include a sensation of grittiness or irritability of the eyes, often accompanied by visible reddening of the conjunctiva. Blepharitis, episcleritis, chalazion and hordeolum are also common. Rosacea keratitis is a more serious and quite common complication, occurring in 5% of patients including children [64]. The conjunctivitis, keratitis and other complications seem likely to be at least partly secondary to reduced tear secretion and Meibomian gland dysfunction which result in an unstable tear film [65,66].

Histopathology [46,47,49,67]. The histological features are predominantly dermal and tend to reflect the clinical features. Thus, telangiectasia is indicated by the presence of dilated superficial capillaries. Lymphatic channels may also be dilated but tend to be located rather deeper in the mid-dermis. Solar elastosis is commonly present and often

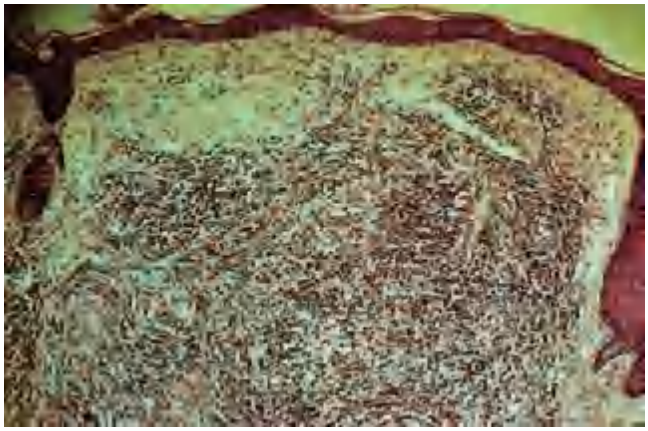

Fig. 44.6 Histological appearance of granulomatous rosacea (H&E × 40). (Courtesy of Professor M. Greaves, Singapore General Hospital, Singapore.)

prominent. The intensity and pattern of inflammation is variable, ranging from a mild perivascular lymphohistiocytic infiltrate in erythematotelangiectatic cases to more intense infiltration, which may be perifollicular, interfollicular and perivascular in papular rosacea. Some lesions show a granulomatous appearance (Fig. 44.6) and foreign-body type giant cells may be observed. Pustules are evidenced by polymorph accumulation in the upper parts of hair follicles. Areas of necrosis are occasionally conspicuous, sometimes marking the remnants of inflamed hair follicles. *Demodex folliculorum* has been observed in up to 51% of cases in one series [49] and may densely populate the pilosebaceous follicles. However, the mites have not consistently been associated with inflammation.

Differential diagnosis. Important differential diagnoses include acne vulgaris, lupus erythematosus, perioral dermatitis, seborrhoeic dermatitis and nasal sarcoidosis. Although acne vulgaris and rosacea are quite distinct diseases, there are occasional patients in whom the distinction is difficult. Since both conditions are common, it is to be expected that, by chance, both will occasionally occur in the same patient. Acne vulgaris affects a younger age group and often has an extensive distribution over the face, neck and trunk whereas extra-facial rosacea is rare. Typical acne vulgaris lacks the redness, telangiectasia and flushing of rosacea, whilst rosacea lacks the comedones and seborrhoea characteristic of acne vulgaris [68].

Scarring, scaling and follicular plugging are not features of rosacea and therefore readily distinguish it from facial discoid lupus erythematosus. However, patients are often referred to the dermatology clinic with a 'butterfly' erythema and a tentative diagnosis of systemic lupus erythematosus (SLE). The latter is not pustular and is usually associated with systemic symptoms. In some cases, lupus serology and a skin biopsy for histological and immunofluorescent examination may be necessary.

The pattern of the rash in seborrhoeic dermatitis differs markedly from that of rosacea. The former, but not the latter, characteristically involves the scalp, retroauricular area, eyelids and nasolabial folds. That scaling is not normally a feature of rosacea but is the rule in seborrhoeic dermatitis may also be helpful. However, rosacea and seborrhoeic dermatitis often seem to occur concurrently.

Nasal sarcoidosis (lupus pernio) superficially resembles rhinophymatous rosacea and both are granulomatous. However, sarcoidosis often affects the nasal septum (causing nasal obstruction); additionally, the surface of the thickened nose in lupus pernio, although telangiectatic, is smooth and lacks the rugose *peau d'orange* surface which characterizes rhinophyma. Patients with lupus pernio almost invariably have evidence of multisystem disease.

Demodex folliculitis can clearly mimic rosacea but is generally considered to be a separate entity.

The possibility of carcinoid syndrome should be considered when the symptoms are predominantly vascular and unusually severe (see p. 44.16).

Prognosis. The duration of the disease and the eventual outcome are highly variable and difficult to predict. In a follow-up study on 70 patients after 6 months treatment with tetracycline, two thirds had relapsed after a mean follow-up period of 2.6 years [69]. In a questionnaire survey of 92 patients 10 or more years after a diagnosis of rosacea, 48 of whom replied, 25 still had active disease whilst 23 had cleared [70]. In those patients in whom the rosacea had resolved, the duration of the disease had ranged from 1 to 25 years. There is no evidence that treatment affects the likelihood of resolution. When it persists, rosacea usually follows a fluctuating course. In males, and less often in females, the persistence of rosacea may result in chronic thickening and induration of the face (leonine facies) and rhinophyma. Eye involvement is usually mild and reversible, though occasionally ocular keratitis can lead to severe scarring and even corneal perforation [71]. Most symptoms of rosacea can usually be successfully controlled (see below) but the flushing is often impossible to suppress.

Treatment. Papulopustular rosacea responds well to treatment in the majority of cases, but improvement may be gradual and so perseverance is sometimes required. Relapse is often prompt when treatment is discontinued [69]. It is important to avoid irritants such as strong soaps and alcohol-based cosmetic cleansers. Although many patients say that their rosacea improves in the sun, solar exposure should probably not be encouraged in view of the marked photodamage often seen in these patients and the possible role of this elastotic change in the pathogenesis.

Papulopustular rosacea. Both topical and systemic modalities can be highly effective and patients often have a

particular preference for one route or the other. Effective oral agents include tetracyclines (e.g. tetracycline or oxytetracycline 250 mg twice daily) and erythromycin 250 mg twice daily. Higher doses are often prescribed in the belief that they are more effective, although there is little evidence that this is true. More recently developed tetracyclines such as minocycline, lymecycline and doxycycline are often used and offer the advantages of once daily administration and lower potential for interaction with dietary calcium, enabling them to be taken with food. Ampicillin appears superior to placebo but less effective than tetracycline [72]. Oral metronidazole can also be effective [73], although this can cause peripheral neuropathy if used for more than 3 months. Development of Gram-negative folliculitis has been reported as a rare complication of broad-spectrum antibiotic treatment of rosacea [74].

Oral isotretinoin (10–60 mg/day) is an alternative in resistant rosacea [75] and can even improve rhinophyma [76]. This is most often used in relatively low dosage in rosacea, partly due to concern about the potential to worsen ocular disease. Treatment may need to continue for several months and particular caution is required with this teratogenic drug in fertile female patients.

Topical treatment with metronidazole 1% cream is effective [77]. A 0.75% gel formulation is also available and is preferred by some patients. Tetracycline and erythromycin are also available in topical formulations, although these are lotions developed for treatment of acne vulgaris and they can prove irritant on skin affected by rosacea. Clindamycin gel, also developed for the treatment of acne, may be better tolerated. Additional topical therapies reported as effective include azelaic acid 20% cream and 15% gel, 0.025% retinoic acid and 10% sulphur cream.

Combinations of topical and systemic treatment are often used. There is little point in discontinuing treatment before 3 months and in many cases it is necessary to continue for several years.

Treatments directed at eradication of *H. pylori* or *Demodex* are discussed above. The final place of these modalities will be determined when the pathogenic role of these organisms has been established or excluded. On current evidence, the author would suggest that these treatments may prove helpful in individual cases where there is reason to believe that these organisms may be playing a role.

Flushing. It is important to explain to patients with papulopustular rosacea that none of the above measures will significantly suppress the troublesome flushing, or the burning discomfort which often accompanies this. Flushing and burning are the most difficult features of rosacea to treat. Non-cardioselective β-blockers such as propranolol 40 mg twice daily or nadolol 40 mg daily [78] are often used but generally provide rather limited benefit. Clonidine 50 μg twice daily and the related but less sedative drug rilmenidine 1 mg daily may also provide some modest improvement, perhaps due to a non-specific vasoconstrictor effect [79]. On occasions, removal of telangiectasia with vascular lasers or intense pulsed light can be surprisingly beneficial in reducing flushing and burning.

Cosmetic camouflage may also be helpful for patients with persistent facial redness. The British Red Cross provide cosmetic camouflage clinics free of charge throughout the UK in association with hospital dermatology departments (British Red Cross Beauty Care and Camouflage Service, 9 Grosvenor Crescent, London SW1 7EJ, UK).

Telangiectasia. The advent of vascular lasers and intense pulsed light sources has provided a range of highly effective treatments for ablation of telangiectasia [80–82].

Lymphoedema of rosacea. Treatment is far from satisfactory. Reduction of the inflammatory component of rosacea by broad-spectrum antibiotics may slow down progression. Jansen and Plewig [60] have suggested the use of low-dose isotretinoin 0.1–0.2 mg/kg/day over a period of 2–4 months, which may be combined with ketotifen 1–2 mg daily and a potent H_1 antihistamine. Marked reduction in facial swelling was reported in one case treated with a reducing course of prednisolone, starting at 30 mg daily, and metronidazole 400 mg/day over a 4-month period, followed by metronidazole 200 mg/day [83]. For established leonine facies, regular facial massage may help. In cases of severe eyelid oedema, surgical debulking of the tissue has proved helpful [84].

Rhinophyma. This is discussed below (p. 44.8).

Ocular rosacea. Ocular rosacea is most frequently treated with systemic tetracyclines. A comparison of doxycycline 100 mg/day and tetracycline 1 g/day showed improvement in both treatment groups. The tetracycline was significantly more effective at 6 weeks, but the difference between groups was insignificant at 3 months [85]. In another trial, a topical ophthalmic formulation of fusidic acid appeared more effective than systemic oxytetracycline [86]. The use of retinoids should be avoided in patients with eye involvement. Patients also find regular application of a liquid paraffin eye ointment symptomatically helpful.

Rhinophyma and other phymas

The phymas are localized swellings of facial soft tissues due to variable combinations of fibrosis, sebaceous hyperplasia and lymphoedema [1]. They develop almost entirely in males. The commonest is rhinophyma, a swelling of the nose which may become grossly distorted in contour (Fig. 44.7). Other areas which may be affected include the forehead (metophyma) (Fig. 44.8), chin (gnathophyma), eyelids (blepharophyma) and ears (otophyma) [2]. In many cases rhinophyma develops in patients with a long history of other features of rosacea, and it is often regarded as a complication or 'end stage' of the disease. However, rhinophyma is sometimes also seen in patients who do not have any history of other manifestations of rosacea. Occasionally rhinophyma is complicated by the development of a malignancy and this can be difficult to recognize [3].

It is likely, but not proved, that active treatment of rosacea may inhibit the development of rhinophyma. Unfortunately neither systemic nor topical treatments for rosacea have any useful impact on established rhinophyma. One exception is systemic isotretinoin, which can significantly reduce the bulk of rhinophyma although it does not restore normal skin contours [4]. Treatment of rhinophyma and other phymas therefore usually involves surgical removal of excess tissue or other means of physical ablation. Remodelling can often be successfully achieved simply by paring off the excess tissue with a scalpel. Electrosurgery is an inexpensive alternative method. Excision and vaporization with argon, carbon dioxide or Nd : Yag lasers is effective. Other treatments have included cryotherapy and ionizing radiation [5]. The latter approach is probably most useful in cases with coexisting malignancy.

Corticosteroid-induced rosacea

The use of potent topical corticosteroids on the face often results in a papulopustular eruption accompanied by erythema which may closely resemble rosacea (Fig. 44.9) [1,2]. Patients of all age groups and either gender are susceptible, although this seems to happen rather more often in females. It is usually necessary to apply potent corticosteroids for 8 weeks or more before steroid rosacea develops. If application of the steroid continues, fixed erythema and telangiectasia develop, further increasing the similarity to idiopathic rosacea. Patients experience exquisite sensitivity of the involved skin to the slightest irritant: itching, burning and intense redness being the major complaints. Whenever the corticosteroid is discontinued, the eruption flares, leading to a state of dependence. Patients affected by steroid rosacea often fail to recognize the causal link between the corticosteroid treatment and the rash. On the contrary, the application of the corticosteroid usually produces prompt, if transient, improvement in the symptoms, creating the illusion of significant benefit.

On occasions, even 1% hydrocortisone may provoke steroid rosacea in children [3]. The use of steroid nasal spray may also be responsible [4]. A granulomatous eruption described as resembling rosacea developed 9 months into therapy with topical tacrolimus 0.1% ointment [5]. This resolved on treatment with doxycycline and did not recur when the tacrolimus was reintroduced.

Treatment. The first and most important step is withdrawal of the causative topical corticosteroid. Patients must be advised to anticipate a flare of the rosacea at this stage. In order to reduce the severity of this flare it is often necessary initially to introduce a less potent steroid. The author has found that a topical or systemic antibiotic, used in the same way as in idiopathic rosacea, can also be very useful in the early stages of steroid withdrawal. Topical application of tacrolimus 0.075% ointment proved helpful in three cases [6]. Steroid rosacea may take several weeks or even months to subside but eventually complete resolution can be anticipated.

Perioral dermatitis

Definition. Perioral dermatitis is a persistent erythematous eruption consisting of tiny papules and papulopustules with a distribution primarily around the mouth [1]. A similar eruption involving the eyelids and periorbital skin has been termed periocular dermatitis [2,3].

Epidemiology. First described in the late 1950s and 1960s, it became a commonplace diagnosis in the 1970s [1]. Over the past decade there has been an apparent fall in new cases—possibly attributable to a decline in the use of potent topical steroids on the face. It almost entirely affects young adult females, the age range tending to be somewhat younger than that of rosacea and occurrence in childhood more frequent. It has a worldwide distribution.

Aetiology. Although infectious agents and infestations including *Candida* spp. [4], *Demodex* [5] and fusiform bacteria [6] have been incriminated, none has been confirmed to play a significant role. A variety of primary irritant

Fig. 44.10 Perioral dermatitis. (Courtesy of Professor T. Luger, Münster, Germany.)

and allergic contact factors have been proposed but not substantiated, including toothpaste and intimate contact with a partner's beard stubble [2]. Despite the prevalence among young female adults, there is no evidence to incriminate the oral contraceptive pill. Cosmetic products, especially foundation, may play a role, possibly resulting from an occlusive effect [7]. Topical corticosteroid therapy is known to be an important aetiological factor. Prescribed initially for trivial facial eruptions, regular application of potent topical corticosteroids leads to papulation and pustulation in the 'muzzle' area of the face [8,9]. Even brief exposure may occasionally cause the disease [8]. The more potent the corticosteroid the more likely it is to cause perioral dermatitis, although even hydrocortisone may very occasionally be sufficient [10]. The use of inhaled corticosteroids for treating asthma, particularly from nebulisers, may also cause perioral dermatitis [11]. Systemic corticosteroids may be an additional triggering factor [12]. Periocular dermatitis may be caused by corticosteroid eye ointment [3].

Clinical features. Characteristically, the eruption begins abruptly in the nasolabial areas, spreading rapidly to the perioral zone but sparing the lip margins (Fig. 44.10). The course of the condition may be continuous, intermittent or remittent. Occasionally it may spread to the forehead, eyelids and glabella; rarely, there may be periocular lesions alone. Pruritus, burning and soreness are prominent symptoms. The lesions consist of monomorphic small papules and pustules occurring against a background of redness and variable scaling. The papules may occur in recurrent crops and are usually less substantial than those of rosacea. Strong soaps, sunlight and even contact with water may cause discomfort.

Histopathology. There is not a large amount of data published on the histology of perioral dermatitis, probably because of concern over the risk of scarring from facial biopsies. One study of 26 cases [13] showed a perivascular and perifollicular mononuclear cell infiltrate with mild eczematous changes. In another study of 36 patients similar features were observed but, in addition to epidermal spongiosis, oedema of the papillary dermis was prominent. There was often perifollicular inflammation and some follicular pustules were observed. Granulomatous infiltration was observed in only two cases and *Demodex* mites were also rarely present [14].

Differential diagnosis. The clinical picture of perioral dermatitis is distinctive. The important differential diagnoses include rosacea, seborrhoeic dermatitis, contact allergic dermatitis, late-onset acne vulgaris, acne agminata and facial Afro-Caribbean childhood eruption (FACE, see below). Unlike rosacea, there is usually no telangiectasia or flushing in perioral dermatitis. Seborrhoeic dermatitis, like perioral dermatitis, affects the nasolabial area, but is not usually circumoral and the scalp, ears and eyebrows are commonly involved. Contact dermatitis does not usually spare the immediate perioral area, but may present a problem which can only be resolved by patch testing. Acne vulgaris usually shows evidence of comedones, large papules and cysts in a wider distribution and responds more slowly to treatment than perioral dermatitis. Acne agminata may be difficult to distinguish if confined to the perioral area but can be differentiated histologically, if necessary, as the lesions are more consistently granulomatous. Similarly, FACE may be difficult to distinguish when the lesions are predominantly perioral, although they do not spare the perilabial skin as in perioral dermatitis and pustules do not occur. FACE occurs in Afro-Caribbean children and, unlike perioral dermatitis, seems to occur often in males.

Prognosis. Most patients experience permanent remission after a fairly short course of broad-spectrum antibiotics [15]. Relapses occur in a small minority [16]. However, if untreated and especially if the provoking topical corticosteroids are continued, perioral dermatitis can persist for years [17].

Treatment. The most important measure is usually to discontinue the application of topical corticosteroids. Other applications, including cosmetics, should also be stopped. The patient must be warned that an initial flare may develop after withdrawal of a topical corticosteroid. A 4-week course of oral tetracycline is usually all that is required. Topical tetracycline is also effective [18], as is topical metronidazole cream 1% [19] and topical erythromycin [20].

Acne agminata

SYN. LUPUS MILIARIS DISSEMINATUS FACIEI; ACNITIS; FACIAL IDIOPATHIC GRANULOMAS WITH REGRESSIVE EVOLUTION (FIGURE)

Acne agminata is seen mainly in young adults and adolescents of either gender, although a case has been reported in a 71-year-old Japanese woman [1]. It presents as multiple, monomorphic, symmetrical, reddish-brown papules on the chin, forehead, cheeks and eyelids (Fig. 44.11). The lesions may cluster around the mouth or on the eyelids or eyebrows so that the term 'agminata' is appropriate, although paradoxically, in many cases, the lesions are widely disseminated around the face and the term 'disseminatus' seems more applicable. Diascopy of larger lesions often reveals an apple-jelly nodule-like appearance indicating their granulomatous histology, which also shows central caseation. The lesions are not consistently related to hair follicles [2]. This eruption tends to be self-limiting, resolving completely over a few months or up to 2 years. In some cases there is scarring. There are reports of similar eruptions having an extra-facial distribution but this seems to be very rare [3].

The clinical picture in classical cases of acne agminata is quite distinctive and does not closely resemble rosacea or acne vulgaris since the other features of these diseases are not present. The synonym 'lupus miliaris disseminatus' results from a historical classification of this condition as a presentation of tuberculosis. It now seems most unlikely to be tuberculous in aetiology and more likely that this condition is a distinct entity. The recently proposed acronym 'FIGURE' (facial idiopathic granulomas with regressive evolution) is perhaps more appropriate as it avoids linking the condition to acne or tuberculosis [4].

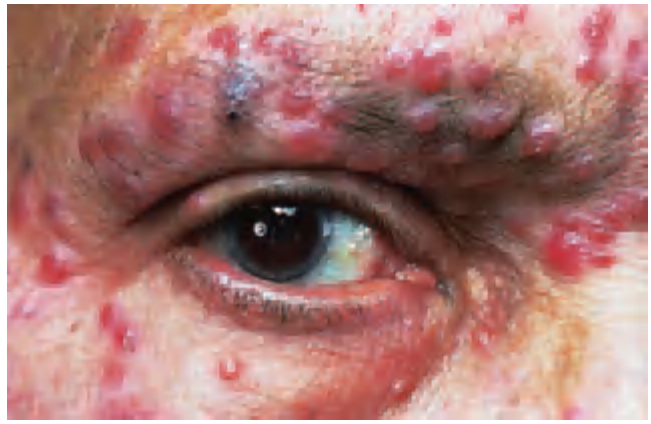

Fig. 44.11 Acne agminata. (Courtesy of Professor M. Greaves, Singapore General Hospital, Singapore.)

The aetiology remains unknown. It has been considered by some to be a variant of rosacea and may represent a self-limiting variant of the granulomatous form of this disease. Whilst the distribution of lesions is similar the natural history and the tendency to affect male and females approximately equally argue against this being a form of rosacea. It can be difficult to distinguish from micropapular sarcoidosis.

The response of acne agminata to tetracyclines has been variable, as has the response to isotretinoin. Dapsone may be effective [5], and a good response to low-dose prednisolone has been reported [6]. In one case the use of clofazimine 100 mg three times weekly was followed by complete resolution within 8 weeks [7].

Granulomatous perioral dermatitis in children

SYN. FACIAL AFRO-CARIBBEAN CHILDHOOD ERUPTION (FACE); GIANOTTI-TYPE PERIORAL DERMATITIS; GRANULOMATOUS PERIORIFICIAL DERMATITIS; SARCOID-LIKE GRANULOMATOUS DERMATITIS

This eruption, which is seen in prepubertal children, may represent a juvenile form of perioral dermatitis or of acne agminata. It is considered relatively common in Afro-Caribbean children giving rise to the acronym FACE (Fig. 44.12) [1] (see also Chapter 69).

This is a papular eruption that is generally confined to the face, with lesions clustering around the mouth, eyes and ears [1–4]. In contrast to perioral dermatitis it does not spare the narrow zone bordering the lips and pustules are not seen. The histology has been variously described as showing non-specific inflammation with hyperkeratosis or, more often, as granulomatous, with the inflammatory changes often, but not invariably, being perifollicular. Blepharitis has occasionally been present. A series of cases with typical facial lesions accompanied by more disseminated lesions involving the trunk, limbs and labia majora has recently been described [5].

Complete resolution usually occurs after a few months, either spontaneously or in response to treatment. In some cases small, pitted scars have been reported. Treatment with systemic erythromycin or topical metronidazole seems to have hastened resolution in several cases.

Pyoderma faciale

SYN. ROSACEA FULMINANS

Although pyoderma faciale is also known as rosacea fulminans it is not yet clear whether this condition is a variant of rosacea or acne vulgaris or a separate entity.

Pyoderma faciale affects mainly adult females. This is a sudden severe eruption of pustules and cystic swellings, which may be interconnected by sinuses (Fig. 44.13). Marked erythema and oedema are usually present. Comedones are usually absent or inconspicuous, as are other features of acne vulgaris or rosacea [1,2]. There is often no preceding history of acne. Some cases have developed during pregnancy, suggesting that hormonal factors may play a role. As the name implies, the eruption is usually confined to the face, involving the cheeks, chin, nose and forehead. Localized forms may be confined to the cheeks, jaw line or chin. Culture of the purulent discharge may be sterile or may yield a growth of commensal organisms including *Staphylococcus epidermidis* and *Propionibacterium acnes*. This investigation can be helpful in excluding Gram-negative infection. Significant scarring develops in many cases.

Fig. 44.13 Pyoderma faciale. (Courtesy of Dr G. Dawn, Carlisle, UK.)

In view of the distressing nature of this disease and the risk of severe scarring it is usually treated initially with systemic corticosteroids. In one series 10 of the 20 cases were hospitalized to commence treatment with prednisolone at 1 mg/kg/day, before adding isotretinoin 0.2–0.5 mg/kg/day. The corticosteroid was tapered off over 2–3 weeks and the isotretinoin continued for 3–4 months [2]. Others have used moderately potent topical corticosteroids combined with systemic isotretinoin [3], application of Vleminckx packs (containing sulphur, calcium polysulphide and calcium thiosulphate), UVB, benzoyl peroxide, systemic antibiotics [1], or dapsone [4].

Flushing and flushing syndromes

SYN. BLUSHING; HOT FLUSHES; HOT FLASHES

Flushing is intermittent redness, often accompanied by a sensation of warmth or burning due to cutaneous vasodilatation. This is usually most evident on the face and neck but less conspicuous changes may occur over the entire body. Flushing may arise from the action of a circulatory vasodilator substance, for example histamine, or it may be caused by changes in the neurological control of the cutaneous vasculature in the affected areas. In the face, neck and upper trunk, where flushing is most apparent, vascular tone is predominantly influenced by autonomic vasodilator nerve fibres rather than by relaxation of vasoconstrictor tone [1]. These fibres are found in somatic nerves supplying the affected skin, including the trigeminal nerve [2]. Since autonomic nerve fibres also supply sweat glands, neurally activated flushing is frequently associated with sweating ('wet flushing') whereas flushing due to circulating vasodilator mediators usually does not involve sweating ('dry flushing'). The presence or absence of sweating has therefore been proposed as a clinical guide to the mechanisms of flushing [3]. This is not entirely reliable in practice and it should be noted, in particular, that severe sweating occurs in some cases of carcinoid syndrome. Causes of flushing are summarized in Table 44.2.

Table 44.2 Causes of flushing.

Cause	Proposed mediator(s)
Physiological	Autonomic
Menopausal	Autonomic
Drug induced	Various
Alcohol	Acetaldehyde
Chlorpropamide and alcohol	Acetaldehyde
Food	Autonomic
Scombroid fish poisoning	Histamine
Carcinoid syndrome	Serotonin
	Prostaglandins
	Bradykinin
	Histamine
Mastocytosis	Histamine
Thyrotoxicosis	Thyroxine
Medullary carcinoma of the thyroid	Prostaglandins
	Calcitonin
Pancreatic tumours	Vasoactive intestinal peptide
Insulinoma	?
POEMS syndrome	?

Physiological flushing

Flushing develops as part of the normal thermoregulatory response in a hot environment or following exercise. A similar mechanism is responsible for facial flushing due to hot drinks, which cause a rise in temperature of blood in the oral cavity, which in turn leads, by a countercurrent heat-exchange process involving the internal jugular vein and internal carotid artery, to a rise in temperature of blood perfusing the hypothalamus [4].

Emotionally triggered flushing due to embarrassment or anger may be a problem in some patients in whom the threshold for this response may be low or the reaction itself unusually intense or extensive. It is often associated with telangiectasia and with sweating and can be a significant social handicap. Such patients are occasionally referred for investigation to exclude an underlying carcinoid tumour.

Explanation, accompanied if necessary by the β-blocker propranolol, may alleviate the symptom, which is essentially due to exaggeration of a normal response. Transthoracic endoscopic sympathectomy can be effective, but seems justifiable only in the most severe cases and perhaps those with concurrent severe palmar hyperhidrosis [5,6]. This procedure can result in compensatory hyperhidrosis at other sites, Horner's syndrome and other complications.

Menopausal flushing

About 80% of menopausal women develop troublesome flushing often associated with sweating. Attacks, which are often preceded by a feeling of heat, may be provoked by emotion, exertion and hot food or drink. The mechanism remains imperfectly understood, but it is likely that the endocrine changes associated with the menopause result in a disturbance of thermoregulation and that the flushing and sweating represent a hypothalamic response

Table 44.3 Drugs which cause flushing.

5-HT_3 receptor antagonists: odansetron, ramosetron, tropisetron
ACE inhibitors: captopril, enalapril, lisinopril, perindopril, ramipril

Phentolamine
Pilocarpine
Prostacyclin
Prostaglandin E
Sildenafil and vardenafil
Venlafaxine

ACE, angiotensin-converting enzyme.
* With ethanol.

to reduce body temperature [7]. A similar syndrome may also occur in men with prostatic cancer receiving treatment by gonadotrophin-releasing hormone analogues such as buserelin [8].

Menopausal flushing usually improves with oral or transdermal oestrogen replacement therapy. Combined oral contraceptives are effective and even the use of progestogens alone may be beneficial. Non-hormonal approaches to management include the use of clonidine 0.05 mg twice daily or selective serotonin reuptake inhibitors (SSRIs) [9].

Flushing caused by drugs

Numerous drugs cause flushing as an unwanted side effect, most frequently those listed in Table 44.3. There seems to be considerable variation between individuals in susceptibility to this side effect. It is not surprising that vasodilating drugs such as calcium antagonists and sildenafil may do this. Flushing occurs in an estimated 12% of patients taking sildenafil and may be accompanied by headache [10].

Fumaric acid esters, used in treatment of psoriasis, produce flushing in about one third of patients [11]. Some state that this regularly occurs 20–60 min after each dose, but in others the timing is not consistent. Flushing episodes may be quite severe but are usually very evanescent, lasting for only a couple of minutes. They may be accompanied by headache. Some patients do not notice this flushing at all, whilst occasionally it is so severe that the drug cannot be tolerated. The flushing may sometimes be reduced by addition of pentoxifylline (oxypentifylline), perhaps due to antagonism of TNF-α by the latter drug [12].

Flushing is observed as part of generalized vasodilation in reactions to gold therapy for rheumatoid disease which have been termed 'nitritoid reactions' [13]. These occur most commonly with gold sodium aurothiomalate but have also been reported with other formulations. The reaction may develop after several years of regular treatment and may be more severe if angiotensin-converting enzyme (ACE) inhibitors are used simultaneously. This phenomenon may be accompanied by hypotension and has occasionally been complicated by stroke or myocardial infarction. It is usually quite benign.

A reduction in the normal flushing response induced by systemic or topical nicotinic acid has been proposed as the basis of a diagnostic test for schizophrenia [14].

Flushing associated with alcohol intake

Most information on alcohol-evoked flushing in otherwise healthy individuals has been acquired by study of Japanese, Chinese and Korean volunteers, since a majority of these oriental genotypes show extensive flushing in response to low doses of alcohol [15]. The high prevalence of this reaction in occidentals is associated with higher plasma levels of acetaldehyde, the initial metabolite of ethanol. Acetaldehyde may act partly by causing histamine release from mast cells [16]. Harada *et al*. [17] demonstrated deficiency of an isoenzyme of liver aldehyde dehydrogenase (low K_m aldehyde dehydrogenase ALDH-1) in 50% of Japanese and showed that these, but not other, Japanese individuals developed flushing after alcohol intake. This population can be detected using an ethanol patch test, which shows erythema due to accumulation of acetaldehyde in the ethanol-treated skin [18]. In a Caucasian population patch testing with acetaldehyde proved more reliable [19]. Symptoms can be alleviated by aspirin [20] and also by antihistamines, H_1 and H_2 antagonists being most effective used in combination [21].

The chlorpropamide–alcohol flush is a special type of alcohol-induced flushing, occurring in patients receiving this oral antidiabetic sulphonylurea drug. Even small amounts of alcohol provoke intense flushing within a few minutes of ingestion [22]. There is no associated sweating, and no systemic symptoms. The abnormality is dominantly inherited, and is associated with familial non-insulin-dependent diabetes and with a low frequency of diabetic complications. The flush is mediated by elevated acetaldehyde plasma levels, but release of prostaglandins is also involved since aspirin and other non-steroidal anti-inflammatory agents block the flush [23].

Flushing associated with food

It is a matter of common experience that eating spicy foods causes facial flushing, usually associated with sweating. This type of flushing, termed gustatory, is due

Fig. 44.14 Unilateral gustatory flushing. (Courtesy of Professor M. Greaves, Singapore General Hospital, Singapore.)

to a nerve reflex involving autonomic neurones carried by the branches of the trigeminal nerve. Sour foods may also cause a similar response that, curiously, may be unilateral, as demonstrated by a child in whom the right (but not the left) side of the face manifested a 'slapped cheek' appearance (without sweating) a few seconds after sucking an acid drop (Fig. 44.14).

Monosodium glutamate has a reputation for causing flushing associated with sweating and faintness ('Chinese restaurant syndrome'). Although first described by Kwok [24], his account did not include flushing; this was added to the symptom complex by later authors [25]. A more recent study involving oral challenge of volunteers with and without a history of previous monosodium glutamate reactions by both monosodium-l-glutamate and its cyclized derivate monosodium-l-pyroglutamate failed to provoke flushing over a range of doses, although burning and tightness of the skin was noted in some volunteers [26]. Similar negative results have subsequently been reported [27]. Flushing due to monosodium glutamate, if it exists at all, must be an extremely rare occurrence.

Scombroid fish poisoning

The scombroid families of edible fish include tuna and mackerel, but non-scombroid fish including dolphin and herring have occasionally been reported to cause this syndrome [28]. Scombroid fish poisoning, which is the commonest form of ichthyotoxicosis worldwide, is due to the ingestion of fish which has 'gone off', usually due to having been left on the fishmonger's counter in a warm atmosphere for several hours. Ingestion of the affected fish causes flushing, heat, sweating, vomiting and diarrhoea. That the symptoms are due to histamine intoxication is indicated by recent studies of the histamine content of affected fish and measurement of urinary histamine excretion in affected individuals [29]. Bacterial biosynthesis (by histidine decarboxylation) is thought to be the source of histamine in the spoiled fish.

Patients poisoned in this way should be treated with a combination of H_1 and H_2 antihistamines. Epinephrine (adrenaline) and corticosteroids may be required in severe cases.

Other causes of flushing

Persistent flushing is sometimes observed in thyrotoxicosis as part of a picture of generalized vasodilatation. Mastocytosis is discussed elsewhere (Chapter 47). Medullary carcinoma of the thyroid [30] and certain pancreatic tumours [31] have been found to cause attacks of flushing. There are also single case reports of the association of flushing with an insulinoma [32] and the POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M-protein, skin changes) [33]. These may therefore cause confusion with the carcinoid syndrome, which may also present with flushing (see below).

Carcinoid syndrome

The carcinoid syndrome results from secretion of a variable and diverse range of endocrinologically active substances by a malignant carcinoid tumour and its metastases. It may present with cutaneous features alone so it is of particular importance that dermatologists remain alert to this disease.

The term 'Karzinoid' was first used in 1907 to denote an intestinal tumour which behaved less aggressively than the more common adenocarcinoma [1]. A variety of other terms have been used to describe these tumours, which are probably derived from a primitive endocrine stem cell. Some of these reflect staining characteristics (argentaffinoma, enterochromaffinoma), others reflect their functional capacity to secrete a range of hormonally active substances (neuroendocrine tumours, amine precursor uptake and decarboxylation tumours (APUDomas)).

The tumours are variable in their degree of malignancy and in the pattern of hormones they secrete. Clinical manifestations are also highly dependent on the anatomical situation in which they arise, as their secretory products are substantially metabolized during passage through the liver and lungs when these organs lie downstream of the circulation from the tumour.

Carcinoid tumours are found most commonly in the embryological mid-gut (appendix, small bowel), especially in the appendix where they may cause appendicitis. Estimates of the prevalence of appendiceal carcinoids range between 0.03% and 0.69% [2]. Most are asymptomatic and only a minority metastasize. Small bowel carcinoids are also common, whereas foregut (stomach, pancreas, biliary tract) and hind-gut (colon and rectum) tumours are relatively rare. Occasionally, carcinoid tumours arise outside the intestinal tract (lung, ovary, testis).

The low levels of endocrine activity associated with most carcinoid tumours are asymptomatic, probably as a result of rapid hepatic metabolism of endocrine products in portal blood. The symptoms of the carcinoid syndrome normally develop as a consequence of metastasis to the liver, although pulmonary carcinoids release hormonal products directly into the systemic circulation and can therefore cause symptoms without metastases. The considerable range of products with potential for endocrine activity known to be produced by carcinoid tumours includes 5-hydroxytryptamine (5-HT, serotonin), 5-hydroxytryptophan, histamine, dopamine, kallikrein, prostaglandins, tachykinins (neuropeptide K, substance P), gastrin, motilin, somatostatin, calcitonin and pancreatic polypeptide [2,3].

Clinical features. The cardinal features of carcinoid syndrome are flushing, diarrhoea, asthma and right-sided cardiac dysfunction. The relative prominence of these varies considerably between patients. Flushing and diarrhoea are the most common symptoms.

Flushing is observed in 80% of cases and may develop long before other symptoms. This is usually episodic and may be spontaneous or precipitated by exercise, alcohol, stress or meals. Certain foods, especially those containing tyramine or catecholamines (red wine, chocolate, blue cheese) are especially likely to induce flushing.

The character of the flush can vary considerably and seems to depend particularly upon the site of origin of the tumour. Mid-gut tumours usually produce diffuse, transient flushes of pink to red colour, lasting 2–10 min, and affecting the face, neck, arms and upper chest. The flush is often mingled with areas of pallor, especially as it resolves (Fig. 44.15) [4]. Foregut carcinoids tend to produce slightly more prolonged and violaceous flushes, sometimes associated with a permanent cyanotic hue, facial telangiectasia, watery eyes and injected conjunctivae [2]. Gastric carcinoids are often associated with increased histamine secretion and bright red, patchy 'geographic' flushing (Fig. 44.16) [5]. Bronchial carcinoids may result in particularly severe episodes of fiery violaceous-red flushing lasting up to 2 weeks and associated with profuse lacrima-

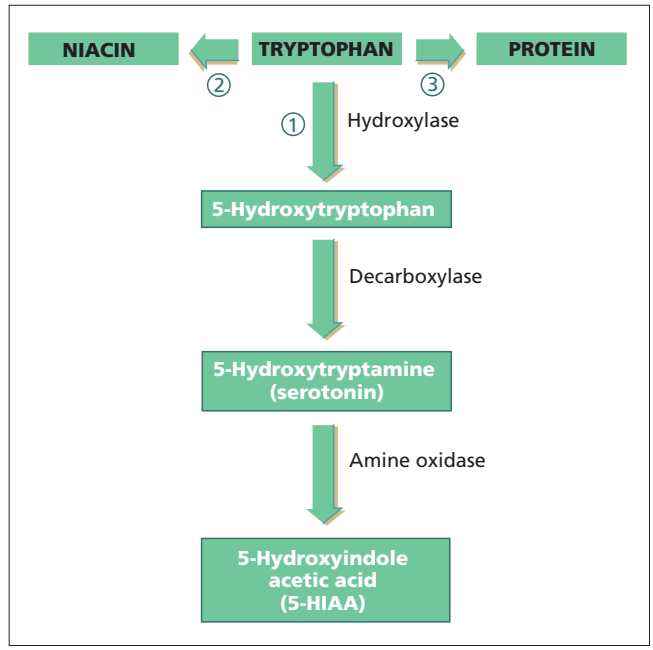

Fig. 44.17 Pathways for transformation of tryptophan to 5-hydroxytryptamine (5-HT, serotonin) (pathway 1); niacin (pathway 2); and protein (pathway 3).

tion, salivation and sweating, nasal congestion, swelling of the salivary glands, facial oedema, tachycardia, increased cardiac output and hypotension [6]. In contrast, rectal carcinoid tumours very rarely result in the carcinoid syndrome, tending to present with local symptoms such as bleeding, pain, constipation or pruritus ani.

The pathophysiology of the flushing is not fully understood. It is likely that histamine plays a major role in the distinctive bright red, geographical flushing associated with foregut (especially stomach) carcinoids [5]. The cause of the more classical flushing of mid-gut carcinoids is less clear. Serotonin, the major product of these tumours, seems unlikely to be the primary mediator. Serotonin infusions do not consistently induce flushing, and flushing is not consistently associated with a rise in serotonin [7]. Serotonin antagonists inhibit the diarrhoea associated with the carcinoid syndrome but not the flushing. It seems more likely that carcinoid tumours may release kallikrein, which may produce flushing by acting on kininogen to release bradykinin [8]. Other proposed mediators of flushing include prostaglandins [9] and substance P [7].

A photosensitive eruption resembling pellagra may occur as part of the carcinoid syndrome and is believed to result from diversion of tryptophan metabolism away from synthesis of niacin (Fig. 44.17). Additional cutaneous manifestations reported in association with carcinoid tumours have included scleroderma [10], pyoderma gangrenosum [11] and pruritus [9]. Fixed facial erythema, telangiectasia and lymphoedema may give rise to an incorrect diagnosis of rosacea [12].

Gastrointestinal symptoms are common. An estimated 76% of patients develop watery (secretory) diarrhoea [2]. This seems likely to be mediated substantially by serotonin. Abdominal pain is often reported and arises from a range of causes including altered motility, bowel obstruction, intussusception or appendicitis. Cardiac involvement results from the development of right-sided endocardial fibrosis which may lead to pulmonary stenosis, tricuspid incompetence and congestive cardiac failure. The pathogenesis of the fibrotic changes is unknown. The asthma associated with carcinoid syndrome is a less constant feature than the flushing and the diarrhoea, occurring in about 25% of cases [2]. The episodes of wheezing often coincide with flushing and/or diarrhoea.

Diagnosis. The clinical diagnosis is not difficult in patients with advanced disease who present with flushing, diarrhoea, wheezing, weight loss and a large liver. Early recognition of the carcinoid syndrome is not so easy and some cases have been misdiagnosed for years as suffering from benign causes of flushing. These symptoms may even be dismissed as psychogenic in origin.

The diagnosis is usually confirmed by determining the urinary excretion of 5-hydroxyindole acetic acid (5-HIAA), the major metabolite of serotonin. The normal excretion is rate is up to 10 mg (150 µmol) in 24 h. In carcinoid syndrome the level often exceeds 40 mg daily and may be much higher, especially after flushing episodes. However levels can vary considerably from day to day. If attacks are infrequent, it may be helpful to wait until a flushing episode occurs before performing the urine collection. Foods containing serotonin, such as avocados, aubergines, bananas, pineapples, plums, tomatoes and walnuts, should be avoided for 3 days before the urine collection is made, in order to avoid false positive results. The elevation of 5-HIAA due to these is usually only marginal. Various drugs including bromocriptine, caffeine, levodopa, paracetamol, phenothiazines and salicylates may also cause marginal changes in 5-HIAA excretion or interfere with the assay, so the laboratory should be advised about the patient's drug intake.

Further confirmation of the diagnosis may be obtained by induction of the flushing, which can usually be provoked by alcohol ingestion (4 mL of 45% ethanol) or the infusion of norepinephrine (noradrenaline) 6 µg. This response to norepinephrine can be blocked by phentolamine (5–15 mg i.v) [13].

If hepatic involvement is evident by abdominal palpation there is little point in elaborate attempts to locate the primary tumour, unless it is suspected to be causing obstruction. Many imaging techniques have been employed to investigate the extent of liver and lymph node metastases, including angiography, ultrasound, endoscopic ultrasound, computed tomography (CT) scanning and positron emission tomography [2]. Octreotide receptor imaging using radiolabelled octreotide can be used to localize both primary and secondary tumours [14].

In some cases further investigation may be indicated to exclude additional neuroendocrine tumours. Carcinoid tumours, especially those of foregut origin, may occur in association with multiple tumours of the pancreas, parathyroid and pituitary as a feature of type I multiple endocrine neoplasia [15]. This condition is inherited as an autosomal dominant trait.

Table 44.4 Food items which may cause flushing in carcinoid syndrome.

Alcohol
Aubergine
Avocado
Bananas
Chocolate
Hickory nuts
Kiwi fruit
Pecan nuts
Pineapples
Plums
Red wine
Spicy foods
Tomatoes
Walnuts

Prognosis. About one-fifth of patients with the carcinoid syndrome undergo a protracted course. In the remainder, deterioration can be rapid. The mean survival in one series was 8 years, the longest survivor living for 20 years [16].

Treatment. Alcohol and foods which may exacerbate symptoms (listed in Table 44.4) should be avoided, as should exercise and stress. Nicotinamide supplements are often provided to reduce the risk of pellagra.

A range of pharmacological agents have been employed with variable degrees of success in providing control of symptoms. Serotonin antagonists such as cyproheptadine, ketanserin and methysergide, and the inhibitor of serotonin synthesis parachlorophenylalanine, can help control the diarrhoea but these are less effective against flushing [17]. Codeine phosphate and loperamide can also be useful for reducing diarrhoea. Clonidine has been reported to suppress flushing at low doses (0.05 mg twice daily) [18] and higher (antihypertensive) doses (0.4 mg/day) [19]. Antihistamines, both H_1 and H_2 types [20], are effective in blocking the flush of foregut carcinoids, especially gastric carcinoids, due to the dominant role of histamine in carcinoids at this location. Corticosteroids can be highly effective in controlling prolonged flushing associated with bronchial carcinoids [6]. Alpha-adrenoceptor blockers such as phentolamine and phenoxybenzamine have been helpful in improving flushing, diarrhoea and wheezing in some cases [21].

Octreotide, a somatostatin analogue given by subcutaneous injection at total daily dosage of 50–600 μg, lowers plasma levels of serotonin and tachykinins and relieves both flushing and diarrhoea [22]. The requirement for subcutaneous injections two or three times daily has been a disadvantage, but a long-acting depot injection is now available and can be used at the dose of 20 mg i.m. every 28 days. In some cases treatment for 6–12 months has resulted in partial or complete tumour regression [23]. Another somatostatin analogue, lanreotide, is also now available in depot formulation.

Surgical excision of carcinoid tumours is performed when possible. In metastatic disease, reduction of tumour mass can be useful in reducing symptoms and a similar effect can often be achieved by hepatic artery ligation or embolization [24]. Some patients have had multiple embolizations over a number of years. This treatment is based upon the dependence of metastatic malignant tissue, but not healthy liver parenchyma, on an intact hepatic arterial blood supply. Chemotherapy with agents such as streptozotocin, dacarbazine, adriamycin and 5-fluorouracil has also been employed [2]. All these 'tumour ablative' interventions run the risk of provoking an acute carcinoid crisis (profound flushing, bronchospasm and shock), due to massive release of mediators. This can be prevented or treated with intravenous octreotide [25]. Interferon-α has also proved helpful in reduction of symptoms and 5-HIAA levels in some cases, but side effects include flu-like symptoms and bone marrow suppression [26].

Chapter 45

Disorders of Sweat Glands

I.H. Coulson

Comparative anatomy and physiology

Sweat glands are described as merocrine; unlike the holocrine sebaceous glands, their cells are not destroyed in the process of secretion. Merocrine glands have been further subdivided into two major types, usually known as apocrine and eccrine. The nomenclature is attributed to Schiefferdecker [1,2], who believed that secretion by apocrine glands involved decapitation of the apical cytoplasm, in contrast with eccrine glands, in which no breakdown of any cellular material occurs. Such a distinction between modes of secretion has been denied [3–5]. However, in the rabbit chin gland [6] and the lemur antebrachial organ [7], large portions of secretory epithelium do appear to be sloughed during secretion. In the axillary organ of humans, although some authors have claimed that decapitation of apical cells can sometimes occur [8], most believe this to be abnormal. The favoured view is that secretion occurs by small portions of apical cytoplasm becoming pinched off [9].

Even though the mechanisms of secretion may be debatable, there are a number of characteristic differences between the two types of gland (Fig. 45.1). The alternative designations of 'epitrichial' (where the sweat duct opens into the hair follicle) for 'apocrine', and 'atrichial' (where the duct does not enter the hair follicle) for 'eccrine', are not entirely satisfactory, because glands which on developmental and histochemical grounds must be classed as apocrine do not invariably open into the hair ducts. On balance, therefore, there is no strong case for abandoning the well-established terms.

The terminology has become further complicated by the use of 'apoeccrine' to describe a distinct type of tubule present in the human axilla. The axilla contains not only typical eccrine and apocrine elements, but numbers of large, irregularly shaped glands which cannot be assigned to either category, although they have some characteristics of each [10]. Such glands consistently occur in adults, but not in children, and become apparent between the ages of 8 and 14 years. Whether their precursors are apocrine or eccrine is unclear, but their ducts do not open into hair canals.

Apocrine glands occur in all known orders of mammals except whales, elephants, sea cows and scaly ant-eaters, although in some species only as part of specialized aggregates [11]. When dispersed, their density varies widely, ranging from 20 to 30/cm^2 in the pig to over 2000/cm^2 in Zebu cattle [5].

Eccrine glands occur in the footpads of many mammals; the exceptions again include whales, sea cows, elephants and scaly ant-eaters, with the addition of bats. Such glands probably serve to moisten the surface of the skin to improve their grip.

In hairy skin, however, eccrine glands are found only in tree shrews, Old World monkeys, apes and humans. The evolution of eccrine glands in primates is discussed in Chapter 2. They appear to replace, but not to evolve from, apocrine glands. Only in humans do eccrine glands

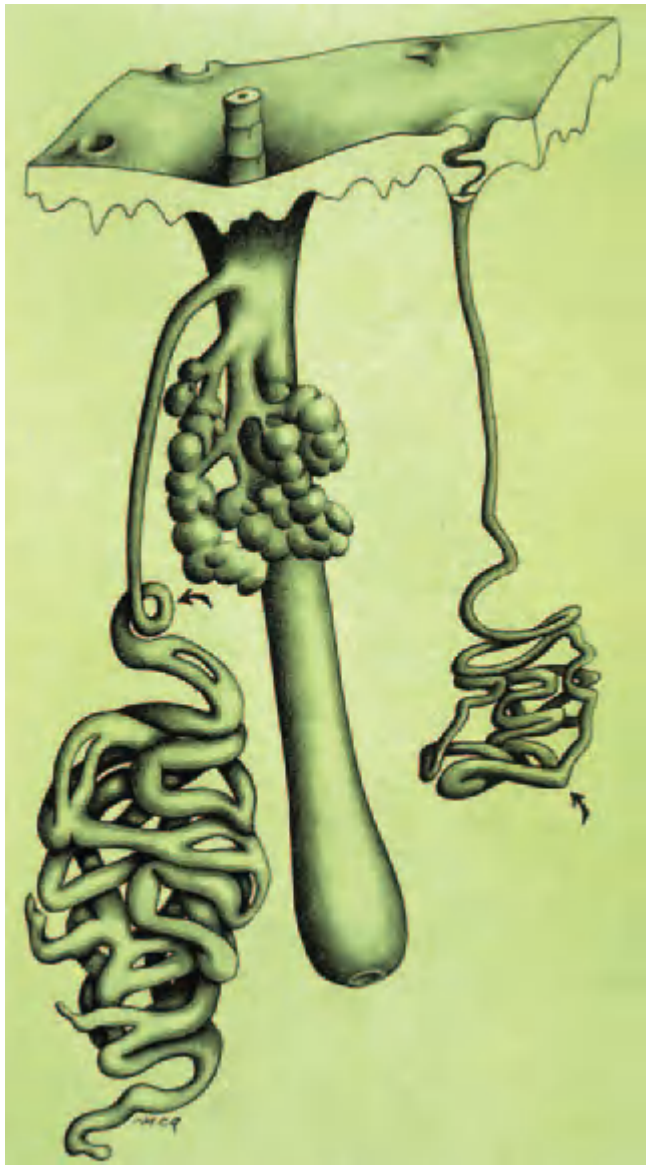

Fig. 45.1 An apocrine, sebaceous and eccrine gland and their relationships to the hair follicle. (Courtesy of Dr W. Montagna.)

completely replace apocrine glands over the major areas of hairy skin. In the human embryo, such glands develop later than those on the friction surfaces, and thus should probably be placed in a different category and distinguished from mammalian footpad glands in general.

Specialized glands, i.e. aggregations of secreting units, are not only widespread amongst mammalian orders but, in different species, can be found in almost every area of the body, from the head to the rump and the extremities [11]. Some—for example, the chin and anal glands of the rabbit—contain only tubular units [12,13]; others—for example, the supracaudal gland of the guinea pig, the flank organ of the golden hamster, the abdominal gland of the gerbil and the preputial glands of rodents—are purely sebaceous. Both types of unit may be associated, as in the muzzle glands of certain bats [14], the side glands of shrews, in which batteries of tubular glands underlie the sebaceous elements [15], and the inguinal glands of the rabbit, which consist of a discrete pair of each type [16].

Similar glandular aggregations occur in primates [17]. In humans, rudiments of apocrine glands attached to each follicle appear during development, but survive to become functional only in the axillae, the genital area and the areolae.

In animals, two main functions, thermoregulation and odour production, are performed by apocrine glands. The first is carried out by glands dispersed over the general body surface or, in some species, limited to areas such as the scrotum. Odour production is a property of specialized aggregates, although possibly not exclusive to them.

The extent to which the glands respond to environmental heat loads, and the exact nature of the control mechanisms, have been studied mainly in domestic animals. They vary widely. In horses, oxen and camels, the glands secrete in response to a rise in ambient temperature, but in pigs, dogs and deer they do not [18]. Apart from the primates, Equidae and some Bovidae, sweat glands appear to play a minor role in the control of body temperature in warm conditions [5,19], although they may cool local areas, such as the scrotum in sheep [20]. By sympathetic denervation of the skin, it has been shown that sweating is under adrenergic nervous control, even in species which lack a demonstrable nerve supply. In addition, in most species studied, the glands also respond to administration of epinephrine (adrenaline), although in contrast with human eccrine glands they are much less sensitive to acetylcholine. Although various interpretations have been made of the experimental results, it is now accepted that apocrine sweating is, in general, controlled by adrenergic nerves, and that in some species—for example, the horse—epinephrine from the adrenal medulla supplements the sweating caused by exercise, although not that caused by heat exposure [18,19].

Odour production is known to occur in 15 out of 29 mammalian orders, but has received detailed study in only a few species. Chemical signals serve a number of social purposes, of which the marking of territory, the maintenance of social hierarchy, alarm signals and individual, group or species recognition are only a few [13,21–23]. They are also concerned with sexual attraction, either of the female by the male, as has been well established, for example, in the boar [24], or of the male by the female, as in the hamster [25] and the rhesus monkey [26,27].

Notwithstanding social pressures to devalue its impact, odour is undoubtedly important in human communication [28], as Havelock Ellis recognized in his comprehensive and entertaining, if almost entirely anecdotal, review in 1905 [29]. The odorous steroids 5-alpha-androsterone and 5-alpha-androsterol, known to act as pheromones in

pigs, have been found in axillary sweat, as well as in human urine, plasma and fatty tissue [30–34]. The role of odour in human social behaviour is discussed in Chapter 4.

The limited evidence available suggests that at least some of the tubular glands of apocrine type are, like the sebaceous glands, controlled by hormones. In the rabbit, all three sets of apocrine glands are stimulated by androgens and inhibited by oestrogens [35].

It seems likely that the human apocrine glands of the axillary and pubic regions are similarly under some androgenic control [36]. The glands do not become active until puberty, at the same time as the development of the sexual hair with which they are associated.

Anatomy and physiology of human eccrine glands [1–4]

Human eccrine sweat glands have two distinct functions: they allow body cooling by evaporation, and have thus contributed in a major way to adaptation to a hot environment by humans (major illness or death may ensue with sweat gland failure, even in temperate climates); they also moisten the skin on the palms and soles at times of activity, and thus improve their grip. Apocrine glands are responsible for body odour.

Eccrine sweat glands are distributed over the whole skin surface, including the glans penis and foreskin, but not on the lips, external ear canal, clitoris or labia minora. The number varies greatly with site, from 620/cm^2 on the soles and about 120/cm^2 on the thighs to 60/cm^2 on the back [5]. The total number on the body surface is between 2 and 5 million, and is the same in black people as in white people. It has been calculated that the weight of the eccrine glands totals 100 g. The glands vary in size from person to person by a factor of five, and this probably accounts for individual as well as regional differences in sweat rate (maximal individual gland secretion rates ranging from 2 to 20 nL/min/gland).

Embryologically, sweat glands are derived from a specialized down-growth of the epidermis at about the third month of intrauterine life on the palms and soles and at about 5 months elsewhere, and they resemble adult glands by 8 months. Sweat glands are morphologically normal at birth, but may not function fully until about 2 years of age. No new eccrine glands develop after birth. Unlike the apocrine glands, they have no developmental relationship with the pilosebaceous follicle, although some glands may eventually come to open into the follicular

Fig. 45.2 Section of a secretory coil of an eccrine sweat gland stained with osmium. The coil contains three types of cell: (i) serous or clear cells (S) containing finger-like processes and bordering a canaliculus (c); (ii) mucous or dark cells (M); and (iii) myoepithelial cells (me). D, dermis; L, lumen of coil. (Courtesy of the late Professor A.S. Breathnach, St John's Dermatology Centre, London, UK.)

neck. The gland consists of a secretory coil in the lower dermis and subcutaneous tissue, and a duct leading through the dermis to the intraepidermal sweat duct unit. Apoeccrine glands have features of both eccrine and apocrine glands, but seem to be nearer to eccrine in function. They open onto the surface, and produce a copious watery fluid. They may account for 10–45% of adult axillary glands [6].

The secretory coil contains three types of cell: large clear cells, which are the main secretory cells, small dark cells, which resemble mucus-secreting cells of other organs but whose function is not known, and myoepithelial cells [7] (Figs 45.2 & 45.3). The large and small cells of the secretory coil, unlike those of the duct, are attached to the basement membrane, although individual sections may at times suggest a double layer. Outside the basement membrane are the longitudinally arranged myoepithelial cells, whose function is probably to support the gland, but they may also help propel the sweat towards the surface. They respond to cholinergic stimuli. The function of the coil is to produce from plasma a watery isotonic secretion which can subsequently be modified by the duct. Ultrastructurally, the large clear cells are characterized by the presence of many mitochondria and by both intricate basal infoldings and intercellular canaliculi. Paranitrophenyl phosphatase activity, which reflects catalytic activity of Na-K-ATPase, is evident in the basal infoldings but not the intercellular canaliculi, suggesting that the basal areas are the sites of active ion transport requisite for sweat secretion. The classical theory suggests that acetylcholine passively increases entry of sodium into the cell, and this is then pumped out by the sodium pump into the intercellular canaliculi rather than directly through the luminal margin. However, there are other theories [4]. Fluid secretion is believed to be mediated osmotically, but the mechanism by which water moves has long been obscure. However, recently a membrane protein with water-transporting properties has been described in a range of tissues, including the human eccrine sweat gland [8]. The sodium pump in the gland can achieve a pressure up to 500 mmHg [9]. During active secretion, and in certain pathological conditions, well-marked histological changes occur in the gland [10]. Many different monoclonal antibodies can be shown to react with different portions of the sweat glands [11].

The duct consists of two or more layers of relatively uniform cuboidal cells. About one-third of the coil has this histology, as well as the uncoiled part passing up to the epidermis. The basal cells are rich in mitochondria and their entire membranes are rich in Na-K-ATPase activity, suggesting that sodium pumping occurs along the entire duct membrane and performs an active part in modifying the secretion produced by the coil.

It has been suggested that sweat glands do not cool the skin only by evaporation of heat from the surface, but also act as heat pipes. According to this theory, evaporation of the fluid at the base of the duct allows water vapour to pass up the duct and condense nearer the surface, and thence return to the deeper parts by capillary action. Such systems are a very effective way of transferring heat quickly [12].

The intraepidermal sweat unit is lined by a layer of specialized cells which may sometimes be distinguished only with difficulty from the surrounding epidermis. On the palms and soles, it has a well-developed coil structure that is not so apparent in other sites.

The techniques for studying the function of the eccrine sweat glands [12–14] include the following:

1 Collection of sweat in bags or pads at rest, after heat, or after injection or iontophoresis of pilocarpine or other cholinergic agonists.

2 Direct measurement of water loss.

3 Microcannulation of the duct or coil [15].

4 Measurement of electrical potentials and electrical resistance of the skin, which depends on both the sweat

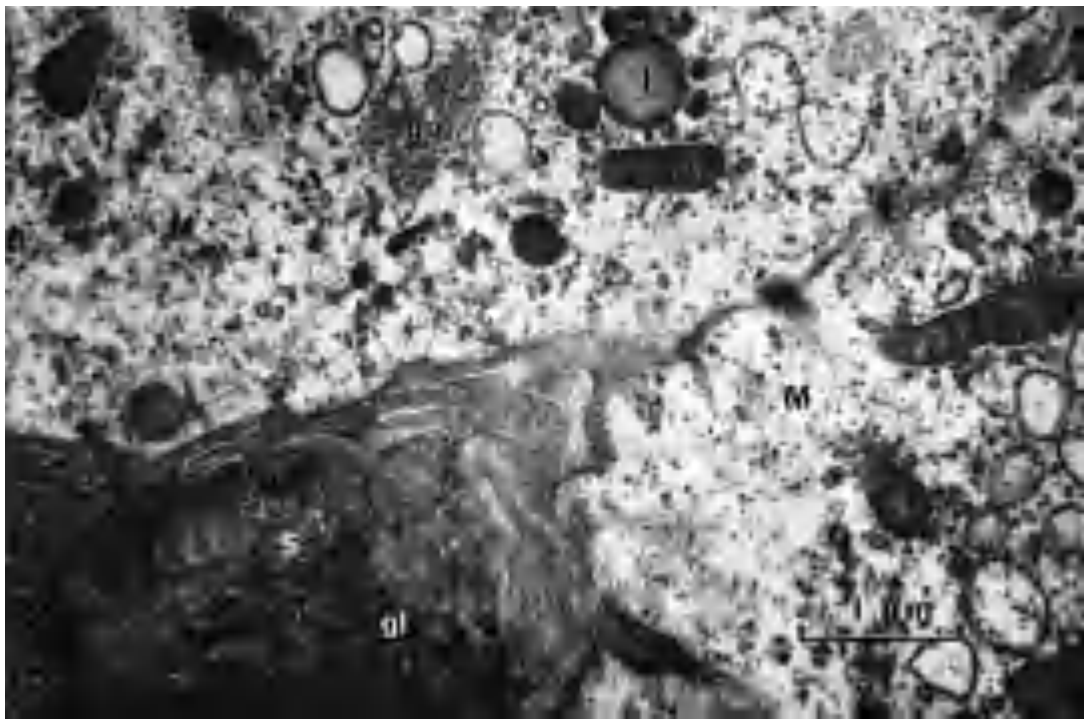

Fig. 45.3 Portions of two mucous (dark) cells (M), showing a Golgi complex (go) and lipid globules (l) and a serous (clear) cell (S) with glycogen granules (gl). (Courtesy of the late Professor A.S. Breathnach, St John's Dermatology Centre, London, UK.)

present on the epidermis and the column present within the duct [16,17].

5 Visualization of the individual sweat droplets. This may be achieved by direct microscopy, by *in vivo* staining, by forming plastic impressions [18] or by indicators which become coloured on contact with water, such as the starch/iodine technique [19], bromophenol blue [13], quinizarin [20] and the food dye edicol ponceau. The plastic or silicone impression techniques are probably the most reliable, and can produce a permanent record. A simple modification of the starch/iodine test is to dry the skin, paint it with 2% iodine in alcohol, allow it to dry, and then press the skin against a good-quality paper. The starch in the paper reacts with iodine in the presence of water, so that each sweat droplet shows up as a minute dark spot. Alternatively, the starch may be suspended in castor oil (50 g in 100 mL) and painted onto the iodine-treated skin (Fig. 45.4). Special dry starch/iodine powders can be dusted directly onto the skin [21].

6 Isolated glands. Recently, it has become possible to isolate single eccrine glands (and also hair follicles, sebaceous glands and apocrine sweat glands) by the relatively simple technique of shearing tissues with scissors [22,23]. This allows the physiology, biochemistry and tissue-culture behaviour to be studied *in vitro*.

Control of eccrine sweating [1–4]

Eccrine glands alter their activity in response to thermal, osmotic, mental and gustatory factors. When the core temperature of the body rises above a certain level, termed

the temperature set point, eccrine sweating is initiated. Thermosensitive receptors are present both in the preoptic area and the anterior hypothalamus, and, in experimental animals, warming of these areas of the brain activates functions to facilitate cooling, including sweating, panting and vasodilatation. Conversely, cooling the same areas initiates shivering. Different receptors respond to heat and cold. Microelectrode recording has demonstrated that the firing rate of the warm sensitive receptors is increased not only by the local receptor temperature, but also by a rise in skin temperature, indicating the effect of local skin and spinal thermoreceptors. The effect of core temperature rise is about nine times more efficient than skin temperature in stimulating sweating. The efferent pathways from the hypothalamus involve nerve fibres relaying in the medulla, lateral horn of the spinal cord and sympathetic ganglia [2].

Thermoregulatory sweating occurs especially on the upper trunk and the face [24], but also occurs over the whole body surface, including the palms and soles. The hypothalamic thermal set point is also influenced by alterations in blood osmotic pressure. Hyperosmolarity results in an elevation of the thermal set point and reduced sweating (as sweat is hypotonic, this is a response to conserve further water loss).

The centres and pathways controlling mental sweating are not fully known, but responsible centres within the frontal region of the brain have been identified. Mental stimuli produce sweating, especially on the palms and soles, perhaps to improve the grip at times of activity. Mental activity also produces some general increase in sweating over the body surface. The activity may be emotional or intellectual—for example, mental arithmetic.

Innervation of the eccrine sweat gland

The efferent sudomotor pathway consists of the cerebral cortex to the hypothalamus, hypothalamus to medulla, medulla (mostly crossed) to the lateral horn of the spinal cord, then to the sympathetic ganglia, and finally from the ganglia to the sweat gland as postganglionic non-myelinated fibres.

The functioning of the eccrine sweat gland is dependent on intact non-myelinated C fibres of sympathetic nerves. Glands deprived of their postganglionic nerve supply soon cease to respond to any stimuli, although they remain histologically normal. The main sympathetic nerve supply of sweat glands is unusual in being cholinergic. Recent work in rats has shown that there is a complex interrelationship between the developing sweat glands and peripheral nerves. The glands influence the nerves to produce the appropriate neurotransmitter [25]. Adrenergic agents and nerve stimulation also increase sweat-gland activity [26–28], and a single isolated eccrine gland can respond to both cholinergic and adrenergic stimuli. The ratio of maximal secretory rates for human sweat glands *in vitro* and *in vivo* is 5 : 1 : 1 for cholinergic, alpha-adrenergic and beta-adrenergic stimulation, respectively. The adrenergic nerve supply seems to play little part in the normal control of eccrine sweating in humans. Vasoactive intestinal peptide (VIP), calcitonin gene-related peptide, atrial natriuretic peptide and galinin immunoreactivity can be found in human axillary periglandular neurones, but whether physiologically relevant concentrations are present remains to be established [29].

Other factors may modify the quantity and quality of sweat in the presence of an intact sympathetic nerve supply—for example, local temperature [30], hormones, circulatory changes, and axon and spinal reflexes. Sweat coils contain androgen receptors [31], and androgens may be at least partly responsible for the increase in sweating around puberty, and for the greater activity in males. Androgens do not play a significant role in the day-to-day regulation of eccrine sweat gland activity.

By these mechanisms, the quantity and quality of the sweat may be varied greatly. Under basal conditions, there may be few or no impulses passing to the sweat gland. Some insensible perspiration always occurs, partly due to transepidermal water loss and partly to sweat gland activity. Only the latter can be suppressed by atropine. Under maximal stimulation, the body can produce up to 12 L in 24 h, or for short periods 3 L in 1 h; this rate exceeds the ability of humans to drink [32].

The composition of sweat [4,33] varies greatly from person to person, time to time and site to site. It has a basic similarity to the plasma from which it is derived. The sweat duct is largely responsible for the modification in sweat constituent concentration which occurs, and this will therefore vary according to how rapidly the sweat is passing through the duct. The most important constituents are sodium, chloride, potassium, urea and lactate. Sweat is hypotonic and this is largely due to reabsorption of sodium in the duct. At increased sweat rates, the sodium concentration rises, presumably because there is reduced time for ductal reabsorption. The normal sodium concentration is between 10 and 20 mmol/L at low sweat rates, and up to 100 mmol/L at high rates. Aldosterone can increase ductal sodium reabsorption and in Addison's disease high sweat sodium can be demonstrated (70–80 mmol/L). Antidiuretic hormone may reduce sweat rates in humans, but it also induces local vasoconstriction.

An increase in sweat electrolytes occurs in cystic fibrosis, and is sufficiently constant to be a most useful diagnostic test [34]. The basic defect seems to be an abnormal diminished permeability of many cells to chloride ions [35–37]. The gene responsible has been identified [38]. Sweat may be collected after intradermal injection or iontophoresis of pilocarpine or methacholine (Mecholyl), or

after heating. In normal children, it is not unusual to have a sweat sodium level above 60 mmol/L, but the majority of children with cystic fibrosis have levels greater than this, often above 90 mmol/L. Sometimes a normal level is present, but the normal fall in sweat sodium concentration after deoxycorticosterone acetate (DOCA) or aldosterone is not seen. In adults, the normal levels are higher, and the test is of much less value. Initial suggestions that partial forms and carriers of cystic fibrosis could be diagnosed in this way have not been substantiated. An increase in sweat potassium has been reported in infants with apparent life-threatening events ('near-miss sudden infant death syndrome') [39].

Lactate is found in a concentration of 4–40 mmol/L, which greatly exceeds the concentration found in plasma. It is formed in the gland from glucose from the blood. It is interesting to speculate whether urea and lactate can act to moisturize the stratum corneum.

Glucose is present in small quantities only (usually 0–3 mg/100 mL, although levels up to 11 mg/100 mL may be found). High sweat glucose may be found in uncontrolled diabetes and this may create a favourable environment for skin infections. The pH is 4–6.8.

The concentration of these substances varies greatly in health and disease. Such changes seldom give rise to any symptoms referable to the skin, but may help in the understanding of disease.

A variety of other substances may be found in sweat, including pharmacologically active substances and inhibitors, antigens, antibodies and drugs [4]. Some of these seem to be excreted, and have no special function; others may have a definite function—for example, a urokinase-type plasminogen activator may play a part in digestion of glycoprotein plugs in sweat pores [40]. Active excretion or secretion of drugs such as griseofulvin and ketoconazole may contribute to their efficacy.

Atopic dermatitis patients often have IgE antibodies against an antigen found in their own sweat. The importance of this in the pathogenesis of the disease is uncertain [41].

Hyperhidrosis [1,2]

Hyperhidrosis is the excessive production of sweat, and can be a major inconvenience to sufferers. In theory, when there is over- or underproduction of sweat it should be possible to determine whether the change is in the sweat glands, due to pharmacologically active agents acting on the gland, to abnormal stimulation of the sympathetic pathway between the hypothalamus and the nerve ending, or to overactivity of one of the three different 'centres' responsible for thermoregulatory, mental and gustatory sweating. Any difficult case should be approached from first principles in this way. In practice, most cases of hyperhidrosis fall into the clinical groups outlined below.

Generalized hyperhidrosis

There is marked physiological variation in thermoregulatory sweating from person to person in the absence of disease. An increase in the temperature of blood bathing the hypothalamus increases heat loss by sweating and vasodilatation. Some instability of the sweat regulating centre is caused by many febrile conditions, so that sweating may occur at times when there is no fever. This instability may persist for days, or even months, after the fever has subsided, and in some cases is such a prominent feature that the term 'sweating sickness' has been used [3]. Generalized sweating may occur in disorders of unknown aetiology, which alter the setting of the thermoregulatory centre, and may be associated with episodic hypothermia [1]. Generalized sweating can occur with a wide range of medical and neurological disorders, but seldom in the absence of other neurological symptoms or signs (Table 45.1). Thermoregulatory sweating occurs during or after many infective processes, and may be the presenting manifestation of malaria, tuberculosis, brucellosis, lymphoma, subacute bacterial endocarditis, etc. Night sweats are often part of the clinical picture. A similar mechanism may account for the hyperhidrosis associated with alcohol intoxication or gout, and after vomiting. The mechanism of generalized hyperhidrosis which may be associated with diabetic autonomic neuropathy, hyperthyroidism, hyperpituitarism, hypoglycaemia, obesity, the menopause and malignant disease is unknown. Increased sweating has been documented in some patients with Parkinson's disease, but others have noted the combination of patchy anhidrosis and compensatory hyperhidrosis, suggesting autonomic dysfunction. Paroxysmal sweating, tachycardia and headaches strongly suggests phaeochromocytoma. Hypertension is noted during attacks. Two sisters have been reported who had generalized sweating in a thermal pattern, but induced by cold [4]. Hyperhidrosis is seen in association with peripheral neuropathies, as in familial dysautonomia, or the Riley–Day syndrome, a recessively inherited disorder of Ashkenazi Jews comprising an absent axon reflex flare after histamine injection, pupillary meiosis, diminished tendon reflexes, diminished pain sensation and absent fungiform papillae of the tongue. Excess sweating is thought to be due to sweat centre excitability. Congenital autonomic dysfunction with universal pain loss is similar, but individuals are not Ashkenazi, have complete absence of pain sensation with accidental self-mutilation, corneal opacities and episodic fever. Cold-induced profuse sweating has been reported with a peripheral motor and autonomic neuropathy. Generalized hyperhidrosis may be associated with brain lesions (diencephalic lesions, malformations of the corpus callosum, microgyria) and may be accompanied by episodic hypothermia. Some drugs—for example, fluoxetine—are able to cause generalized hyperhidrosis. In many cases of generalized hyperhidrosis of the thermal type, but with no obvious underlying disease, the aetiology remains unknown, even after extensive investigation.

Table 45.1 Causes of generalized hyperhidrosis.

Febrile infective illnesses
Tuberculosis, malaria, brucellosis, endocarditis, etc.
Metabolic diseases
Diabetes, hyperthyroidism, hyperpituitarism, hypoglycaemia
Menopause
Underlying solid malignancy and lymphoma
Parkinson's disease
Congestive heart failure
Cold-induced generalized hyperhidrosis
Neurological disorders
Peripheral neuropathies
Familial dysautonomia (Riley–Day)
Congenital autonomic dysfunction with universal pain loss
Cold-induced profuse sweating
Brain disease
Episodic hypothermia with hyperhidrosis
Generalized hyperhidrosis without hypothermia
Drugs
Fluoxetine

Palmoplantar, axillary and craniofacial ('emotional') hyperhidrosis

Emotional or mental activity increases sweating, especially on the palms, soles, axillae and to a lesser extent, groin and face. It should be emphasized that mental activity devoid of any clear emotional content may provoke sweating. There may be some generalized increase in sweating. Thermal stimuli and physical effort increase this effect in many cases. Most cases of hyperhidrosis presenting to the dermatologist are of this type, affecting

Fig. 45.5 Disabling palmar hyperhidrosis.

especially the palms, soles and axillae, and may affect up to 1% of the population in the UK. The head, neck and scalp may be affected in craniofacial hyperhidrosis in the absence of other areas being affected. Although mental or emotional factors are the usual trigger for this type of sweating, and in some patients deep-seated emotional disturbances may be found, in many there seems to be some facilitation of the nervous pathways causing physiological mental sweating.

The sweating of the palms and soles may be either continuous or phasic [5]. When continuous it is worse in the summer, and not so clearly precipitated by mental factors. When phasic, it is usually precipitated by minor emotional or mental activity, and is not markedly different in summer and winter. The hands may be cold, and show a tendency to acrocyanosis. Hyperhidrosis may be associated with Raynaud's phenomenon and reflex sympathetic dystrophy [6], or may follow cold injury.

Hyperhidrosis may be a significant disability, in that sweat drips from the hands onto the floor (Fig. 45.5), rusting of metal objects may be an industrial problem, or clothing may be saturated. This disorder occurs in either sex, and commonly begins in childhood or around puberty. Frequently there is a family history, and it is one component of various syndromes in which palmoplantar keratoderma occurs (Chapter 34). It also occurs with the nail–patella syndrome (Chapter 62). Hyperhidrosis may persist for some years, but there is a tendency to spontaneous improvement after the age of 25 years. Apart from the embarrassing nature of the disorder, complications include pompholyx (Chapter 17) and contact dermatitis. Control of plantar hyperhidrosis may reduce the exacerbations of contact dermatitis to footwear constituents.

Sweating affects the hands, feet and axillae in any combination, but only a minority of patients with axillary hyperhidrosis also have involvement of the palms and soles. Troublesome hyperhidrosis of the feet occurs especially in young adult men. When this is associated with vasomotor changes, so that the sodden skin is also cold and cyanotic, the name 'symmetrical lividity' is sometimes applied (Fig. 45.6). The condition of pitted keratolysis (Chapter 27) of the feet, due to infection with *Micrococcus sedentarius*, is associated with hyperhidrosis.

Axillary sweating may be continuous, or more commonly phasic, and may or may not be aggravated by heat or mental activity. It is uncommon before puberty. Axillary sweating on undressing is very common. Axillary hyperhidrosis is due to overactivity of eccrine glands, unlike axillary odour which is mainly apocrine in origin. Craniofacial hyperhidrosis is often phasic, occurs in middle age and may be exacerbated by heat, exercise and eating, but unlike true gustatory hyperhidrosis, not

exclusively so. Sweating sufficient to soak the hair is an additional embarrassment (Fig. 45.7).

Localized and asymmetrical hyperhidrosis

The causes of localized hyperhidrosis are outlined in Table 45.2.

Excessive sweating may be due to neurological lesions involving any part of the sympathetic pathway from the brain to the nerve ending. It may be the presenting symptom, but it is quite exceptional for this to occur as an isolated phenomenon in the absence of other neurological symptoms or signs. Such lesions may be within the central nervous system [1,7–9] (cortex, basal ganglia or spinal cord), the sympathetic pathway and ganglia, or in the peripheral nerves. It must be remembered that the distribution of the sympathetic nerves does not exactly correspond with sensory dermatomes. One sympathetic grey ramus may supply 10 or more sensory segments, and one white ramus extends over at least five. Asymmetrical sweating may also occur reflexly from visceral disturbances [10], adjacent to an area of anhidrosis or due to axon reflex stimulation, around a leg ulcer, for example [7], or around glomus tumours, blue rubber bleb naevi or sudoriparous angioma [11]. Compensatory hyperhidrosis occurs in normal sweat glands when those elsewhere are not functioning because of neurological or skin disease, or after sympathectomy (see also Ross's syndrome). Functional sweat gland naevi have been reported [12], but must be distinguished from sweat gland hypertrophy associated with local hyperhidrosis of some other aetiology. There are some bizarre cases of hyperhidrosis which cannot be explained in these ways. Areas of skin which may be localized [13] (Fig. 45.8), termed idiopathic circumscribed hyperhidrosis, or as extensive as one-half of the body [14], may sweat continuously, or, more commonly, with mental activity. They may represent functional naevi, where the eccrine glands show increased sensitivity to cholinergic neurotransmitters. Sometimes, some psychological disturbance accounts for the distribution [15], but more often such cases remain a mystery. In the absence of other neurological symptoms or signs, they are seldom a manifestation of a progressive neurological lesion.

Gustatory hyperhidrosis (Table 45.3)

Sweating on the lips, forehead and nose after eating certain foods occurs physiologically in many people. Hot spicy foods are the most likely cause. The central connections of this reflex are not fully known. Gustatory hyperhidrosis also occurs in pathological conditions involving the autonomic nervous system. Localized areas of intense hyperhidrosis may occur on the face [1], and even on the knee [2]. These disorders are very rare, usually start in childhood and are not progressive (Fig. 45.9). Their nature is little understood.

Also uncommon is gustatory hyperhidrosis due to a lesion within the central nervous system [3].

Much the commonest cause is damage to the sympathetic nerves around the head and neck. After damage to sympathetic nerves, regeneration occurs not only from the proximal ends of the damaged sympathetic nerves, but also from damaged or undamaged parasympathetic nerves [4,5]. In this way, abnormal connections are made. Thus, the reflex arcs which normally allow chewing or taste stimulation to cause parotid or gastric secretion may cause sweating in a localized zone corresponding to the area of the skin in which the sympathetic innervation has been damaged. The commonest site is within the distribution of the auriculotemporal nerve, following injury, abscess or operation in the parotid region (auriculotemporal or von Frey's syndrome) [6–8]. Submental gustatory sweating [9,10] follows injuries involving the chorda tympani, and sweating in the distribution of the greater auricular nerve commonly follows radical neck surgery [11]. On the upper arm, fibres from the vagus may cause gustatory sweating after cervical sympathectomy [12].

Gustatory sweating may occur in diabetes as part of a widespread autonomic neuropathy [13,14]. It has also followed herpes zoster [15].

Gustatory sweating is by no means uncommon, and occurs in 50–80% of patients subjected to operations on the parotid gland [16,17]. Usually the symptoms appear 4–7 months after operation, and either persist indefinitely or wane after 3–5 years. The stimuli required to initiate the reflex vary, as does the severity. Sometimes chewing, without taste sensation, is the most important stimulus. In many cases, it is merely a curiosity, but in others it can be a significant disability. As well as sweating there is usually

Table 45.3 Classification of gustatory hyperhidrosis.

Idiopathic

vasodilatation, which rarely occurs by itself in the absence of visible sweating.

Treatment of severe cases may require surgical interruption of the parasympathetic pathway—for example, section of the glossopharyngeal nerve within the skull, or tympanic neurectomy [4]. Excision of the auriculotemporal nerve is usually followed by recurrence. Topical therapy with aluminium chloride [18], topical glycopyrronium bromide [19] or botulinum toxin may be helpful.

Olfactory hyperhidrosis, in which the trigger stimulus is olfactory in origin, has also been recorded [20].

Treatment of hyperhidrosis

In many patients all that is necessary is simple reassurance and explanation of the nature of the disorder, and that it is likely to improve spontaneously, perhaps in several years. Topical and systemic treatments are by no means satisfactory and, at best, only temporarily suppressive.

Topical treatment

Topical anticholinergics. Atropine-like drugs may be absorbed sufficiently to produce a beneficial local effect without associated systemic side effects, but none of those at present available can be relied upon to do so [1]. Poldine methosulphate, 1–4% in alcohol, suppresses experimentally induced sweating, but unfortunately is less valuable on the palms, soles and axillae [2]. Topical 0.5% glycopyrronium bromide cream has been successfully used in gustatory hyperhidrosis in diabetics.

Eccrine duct blocking agents. These drugs act by impeding the delivery of sweat to the skin surface. Formalin 1% soaks have long been used for treatment of hyperhidrosis of the feet, but are unsuitable for the hands and axillae. Glutaraldehyde 10% in a buffered solution, pH 7.5, swabbed onto the feet three times weekly, has helped some patients [3], but may cause allergic sensitization and stains the skin, so that it is suitable only for the feet. For axillary hyperhidrosis (as opposed to bromhidrosis) the most commonly used topical applications are aluminium (or other metal) salts. Aluminium chloride, the first to be introduced, is in many ways the best, but may be irritant to the skin and damage clothes. Many other salts—for example, the chlorhydrate—are in use in cosmetic preparations [4]. Improved results can be achieved by applying 20% aluminium chloride in absolute ethanol at night, when the axilla is dry, with or without polythene occlusion, at first nightly and later every 1–4 weeks [5,6]. Commercial preparations are available. Mild irritation of the skin from such therapy may be helped by a weak topical steroid. The same treatment can also be tried on the hands and feet, or other localized areas of hyperhidrosis, but usually with rather less success. The mode of action of aluminium salts is uncertain, but they can be shown to affect both the duct and secretory coil [7].

Iontophoresis. One of the more satisfactory methods of controlling hyperhidrosis of the hands and feet is by iontophoresis, either using tap water or anticholinergic drugs such as glycopyrronium bromide [8–11]. The mode of action of tap water iontophoresis is not known. It is more effective than using saline, and duct occlusion does not occur. Direct current is usually used, with each palm or sole being treated for 30 min with 20 mA initially three times a week, but once euhidrosis is established, maintenance treatments once a month only may be required. Alternating current is less effective, but may usefully be combined with direct current (alternating current offset) to produce a safer, more comfortable treatment [12]. Once control has been achieved, a single treatment may prove effective for some weeks. Minor systemic side effects due to absorption of anticholinergic agents, such as dry mouth and eye symptoms, are not uncommon, and can be avoided if tap water alone is used. The author's practice is to initiate thrice-weekly treatment on a hospital outpatient basis, and if this is successful, a small battery-operated home unit can be purchased for maintenance

therapy [13]. Less frequent treatment will then be required. When the sweating is controlled, the associated lividity, coolness and oedema improve. Similar treatment has also been used for the axilla, but is less often needed because topical applications are more effective in this site.

Botulinum toxin A injection. This compound produces prolonged blockade of neuronal acetylcholine release at the neuromuscular junction and in cholinergic autonomic neurones and has been used to treat dystonic conditions for many years. In recent years, intradermal injection of various sites has been used to produce marked reduction of sweating in hyperhidrotic areas produced by a variety of conditions [14–17]. Different preparations of botulinum A toxin have different activities, and dose schedules differ for each product. 0.1 mL of appropriately diluted botulinum toxin administered by high intradermal injections can be given to 1 cm^2 areas of skin appropriately anaesthetized—topical eutectic lignocaine/prilocaine is sufficient for axillary skin, but palms and soles require regional nerve blockade. Each axilla usually requires 12 injections, hands 20 and each foot 24–36 injections. It will produce reduction in sweating within 48 h and the benefit will last for up to 8 months in axillary and 6 months in palmar hyperhidrosis [18]. Reinjection seems to be effective, and to date resistance has not been seen in hyperhidrosis, although it eventually occurs in 5% of patients treated intramuscularly for dystonia. Botulinum toxin has been used for idiopathic circumscribed and gustatory hyperhidrosis, including Frey's syndrome, the hyperhidrotic areas in Ross's syndrome, and frontal and craniofacial hyperhidrosis. Slight transient reduction of thenar and hypothenar muscle power is a minor problem after palmar injections [18].

Systemic drug treatment

Atropine-like drugs have been used to block the effect of acetylcholine on the sweat glands, but their side effects are often more troublesome than the hyperhidrosis itself. These include dryness of the mouth, constipation and disturbances of vision, due to paralysis of accommodation, but more serious side effects, for example glaucoma, hyperthermia and convulsions, can occur. Atropine itself is seldom employed. Propantheline may be prescribed in doses of 15 mg three times daily, increasing, if tolerated, to as much as 150 mg daily [19], but overall the results are disappointing. Ganglion-blocking drugs can inhibit sweating, but side effects from hypotension are usually too troublesome. Calcium-channel blockers, such as diltiazem [20] have helped some cases. In cases with a pronounced emotional factor, sedative or tranquilizing drugs are often useful, but psychiatric treatment may be necessary. Both clonazepam [21] and amitriptyline have helped isolated cases of unusual localized hyperhidrosis.

Surgical treatment

Sympathectomy, when complete, causes anhidrosis, whether performed cervically, transaxillary or endoscopically [22–25]. Sweating may return after a period of some years, due either to regeneration of sympathetic fibres or to fibres which do not pass through the sympathetic ganglia [26]. The open approach has been largely replaced by an endoscopic procedure, which may be successful in treating palmar, axillary and craniofacial hyperhidrosis. A pneumothorax is induced, and an operating endoscope inserted into the thorax via a small axillary incision, allowing visualization of the sympathetic trunk. Interruption of the sympathetic fibres between the second and fourth thoracic ganglia can be achieved by surgical transection, radiofrequency ablation, phenol destruction, cautery or clipping [27] (the latter technique has the potential advantage of partial reversibility). Most surgeons treat both sides at a single session. With both the open and endoscopic approaches, satisfactory reduction of palmar hyperhidrosis is achieved in over 95% of cases; it is a little less successful for axillary hyperhidrosis. In a series of 650 patients treated endoscopically, the initial failure rate was 2%, and there was recurrence in 2%; overall, 98% were satisfied with the result [28]. Large case series using endoscopic techniques in children show it to be an acceptable option, with a low recurrence rate [29]. Complications of sympathectomy include haemothorax, pneumothorax, chylothorax, nipple sensitivity and Horner's syndrome. There are rare instances of transient or permanent bradycardia complicating the technique. Other disadvantages are that the palms or soles may become excessively dry, and irritant eczema after sympathectomy has been reported [30]. Postoperative compensatory hyperhidrosis is a problem, particularly in warmer climates, as it may occur in up to 80% of those treated, affecting the trunk, legs and face, where it may be gustatory. It is usually mild and preferable to severe palmar hyperhidrosis, but rarely is disabling. In five patients who had undergone a clipping procedure who developed compensatory hyperhidrosis, removal of the clips resulted in return of the palmar sweating and abolition of the compensatory hyperhidrosis [27]. It has been suggested that ablation at the level of the third thoracic ganglion does not produce this side effect. Abolition of severe facial blushing may be a desirable consequence, and resolution of palmar eczema has been reported after endoscopic sympathectomy. In general, only those patients in whom a severe disability is arising from the hands or axillae warrant surgery, and in these selected cases the results can be very gratifying. Endoscopic sympathectomy has been used successfully in the treatment of severe craniofacial hyperhidrosis [31]. Pedal sympathetic denervation requires removal of the second lumbar sympathetic ganglion; bilateral operations will usually result in ejaculatory impotence, so it is best avoided.

Axillary hyperhidrosis may be greatly helped by local excision of the axillary vault [32,33]. Variations of this technique include subcutaneous curettage of the axillary skin [34] and tumescent liposuction of the axillae [35].

Anhidrosis

Anhidrosis is the absence of sweat from the surface of the skin in the presence of an appropriate stimulus. This may be caused by an abnormality of the sweat gland itself, or at any level in the nervous pathway. There are many causes [1], and a number of the more important of these are listed in Table 45.4.

A full account of the assessment of sympathetic nerve activity is beyond the scope of this book [2–10].

Extensive anhidrosis may impair heat regulation to such a degree that hyperpyrexia occurs on exposure to heat. It characteristically occurs in anhidrotic ectodermal dysplasia and in otherwise normal premature or full-term infants under the age of 1 month [11]. It may be associated with compensatory hyperhidrosis of the remaining functionally active glands. It has been reported as an isolated finding [12,13]. Cessation of sweating is the cause of heat hyperpyrexia. The anhidrosis associated with ichthyosis may be more apparent than real. Localized areas of anhidrosis are of little clinical importance, except that they may help in the diagnosis of neurological lesions or leprosy. Sweat gland function can be a useful way to assess damage to the sympathetic nervous system—for example, in patients with postural hypotension [2,10,14]. Sweat retention is the cause of miliaria (see below), and plays an important part in producing crises of irritation in patients with atopic dermatitis, eczema and other dermatoses. It also occurs in psoriasis, where sweat duct blockage, and perhaps also impaired ductal absorption, occurs [15].

Ross's syndrome [16]

This rare syndrome consists of widespread hypohidrosis combined with patchy, sometimes very striking, compensatory hyperhidrosis (Fig. 45.10), together with tonic pupils (appearing asymmetrical and irregular in their outline, constricting and dilating slowly to light and dark,

respectively) and loss of deep tendon reflexes (Holmes–Adie syndrome). Patients with the Holmes–Adie syndrome often show asymptomatic changes in sweating [17]. The anhidrosis may be quite localized—for example, mainly on one palm, mimicking a *Trichophyton rubrum* infection [18]. When the anhidrosis is extensive, remaining areas of functioning eccrine glands may show compensatory hyperhidrosis. Cardiac sympathetic denervation which may be asymptomatic has been shown to develop [19]. The compensatory hyperhidrosis may be striking and severe enough to require therapy, for example with iontophoresis [20] or botulinum toxin injection [21], although eventually it may be lost as complete anhidrosis develops. The changes are due to selective degeneration of the sympathetic pathways [21].

Miliaria

Aetiology and pathology [1–3]. The three forms of miliaria—miliaria crystallina (sudamina), miliaria rubra (prickly heat) and miliaria profunda—occur as a result of either obliteration or disruption of the eccrine sweat duct. They differ in clinical form due to the different levels at which obliteration occurs, although some authorities have suggested that disruption of the duct rather than obliteration is responsible [4]. In miliaria crystallina, the obstruction is very superficial within the stratum corneum and the vesicle is subcorneal. In miliaria rubra, the later changes include keratinization of the intraepidermal part of the sweat duct, with leakage and then formation of a vesicle around the duct. In miliaria profunda, there is rupture of the duct at the level of or below the dermal–epidermal junction.

Miliaria crystallina can easily be produced experimentally by minimal non-specific epidermal injury and profuse sweating [5]. It is often seen in febrile illnesses associated with profuse sweating. It occurs commonly in

(c)

Fig. 45.10 Ross's syndrome. (a) There is generalized anhidrosis, with large islands of severe compensatory hyperhidrosis (delineated with edicol ponceau powder, which turns red in the presence of water). (b) The hyperhidrosis is sufficient to soak the underclothes, with consequent embarrassment. (c) An abnormal pupil, showing an irregular outline and meiosis. It responds sluggishly to light.

infants due to a delay in patency developing in the sweat ducts. In a large Japanese study, it was identified in 4.5% of babies, with a peak frequency at 1 week [6].

The incidence of miliaria rubra is highest in hot, humid conditions, but it may occur in desert regions, affecting up to 30% of people exposed to these climatic conditions [7]. It may begin within a few days of arrival in a tropical climate, but is maximal after 2–5 months. There is a striking variation in individual susceptibility. Infants are especially prone. Lesions may be produced experimentally in susceptible subjects by epidermal injury. They can be reproduced regularly by occlusion of the skin under polythene for 3–4 days, following which anhidrosis lasts for about 3 weeks. Prolonged exposure of the skin to sweat achieves the same effect. The first event may be an increase in the skin flora, perhaps with *Staphylococcus epidermidis* being responsible for producing an extracellular polysaccharide substance or slime which blocks the lumen of the sweat duct [1,8]. The parakeratotic plugs which are a notable feature of the later stages of the disease are not the primary cause of the obstruction, but arise in the repair process, and may further aggravate the obstruction. Leakage of sweat into the epidermis is responsible for the final production of the lesions, and for their further aggravation.

Miliaria profunda is due to more severe damage to the sweat duct, and usually follows repeated attacks of miliaria rubra. It may be reproduced by experimental injury [7].

Clinical features of the three types of miliaria are as follows.

Fig. 45.11 Miliaria rubra on a baby's cheek. (Courtesy of Dr Richard Logan, Bridgend General Hospital, Bridgend, Mid Glamorgan, UK.)

Miliaria crystallina. Clear, thin-walled vesicles, 1–2 mm in diameter, without an inflammatory areola are usually symptomless and develop in crops, mainly on the trunk. In persistent febrile illnesses, recurrent crops may occur. The vesicles soon rupture, and are followed by superficial branny desquamation.

Miliaria rubra. The typical lesions develop on the body, especially in areas of friction with clothing, and in flexures. They may also commonly be seen after occlusive therapy with polythene. The lesions are uniformly minute erythematous papules, which may be present in very large numbers. Miliaria rubra is common on the trunk in hospitalized patients, who have to be nursed on their backs on bedding that has waterproof occlusive membranes below the sheets (Fig. 45.11). Characteristically, the lesions produce intense discomfort in the form of an unbearable pricking sensation. Relief is often instantaneous when the stimulus to sweating is abolished by a cool shower. Outbreaks on the legs in miners working in tropical climates have been reported [9]. In infants, lesions commonly appear on the occluded skin of the neck, groins and axillae, but also occur elsewhere.

Miliaria profunda. This nearly always follows repeated attacks of miliaria rubra, and is uncommon except in the tropics. The lesions are easily missed. The affected skin is covered with pale, firm papules 1–3 mm across, especially on the body, but sometimes also on the limbs. There is no itching or discomfort from the lesions.

Patients often refer to polymorphic light eruption as 'prickly heat', but the relationship of the rash to light, particularly on newly exposed sites, is usually straightforward.

Natural history. The course depends mainly on environmental factors. If continued sweating occurs, recurrent episodes lasting a few days are usual, but discomfort may be continuous. However, after a few months some degree of acclimatization occurs, and the disorder becomes less prevalent.

The most important complications of miliaria are secondary infection and disturbance of heat regulation. Secondary bacterial infection is common and sometimes serious. This may present as impetigo. In other cases, the pustules are more clearly related to sweat ducts, although in *pustular miliaria* factors other than bacterial infection are concerned [10]. Periporitis staphylogenes [11] is the name given to multiple staphylococcal abscesses superimposed on miliaria rubra in young infants. In most cases of miliaria rubra, the changes are reversible if further sweating is avoided, but permanent damage to the sweat duct may occur, especially after miliaria profunda.

Treatment. The only really effective prevention or treatment for miliaria is avoidance of further sweating. Even if this is achieved only for a few hours a day, as in an air-conditioned office or bedroom, considerable relief is experienced. For the very susceptible person, a move away from tropical climates may be essential. Avoidance of excessive clothing, friction with clothing, excessive use of soap and contact of the skin with irritants will reduce the incidence. The large number of treatments advocated for prickly heat is the best indication of their relative ineffectiveness if sweating is not reduced. In the absence of gross secondary sepsis, the effect of topical or systemic antibiotics or other antibacterial preparations on established miliaria is disappointing, but they may have some role in prophylaxis [1]. Oral ascorbic acid 500 mg b.d. was found to diminish the severity of miliaria, as was the degree of subsequent anhidrosis in experimentally induced disease [12]. Calamine lotion is probably as effective as anything for the relief of discomfort, but because of its drying effect, a bland emollient, for example oily cream, may subsequently be required to prevent further epidermal damage. Isotretinoin was reported to help a recalcitrant case of miliaria profunda [13].

The role of sweating in some other dermatoses

The role of sweating in pompholyx or dyshidrosis is discussed in Chapter 17, in Grover's disease or transient acantholytic dermatosis in Chapter 34 and in cholinergic urticaria in Chapter 47.

Disorders associated with abnormal eccrine histology

Neutrophilic eccrine hidradenitis

Necrosis of the eccrine epithelium and secretory coil with a dense surrounding neutrophilic infiltrate is seen in a variety of clinical entities (Table 45.5).

Chemotherapy-induced neutrophilic eccrine hidradenitis. The most commonly reported variant occurs during cancer chemotherapy [1–3], and has been reported in adults and children. The clinical presentation is of painful erythematous papules and plaques arising on the limbs, neck, face and ears 8–10 days after the start of chemotherapy, often associated with fever and a neutropenia. Cases featuring only erythematous swelling of the periorbital areas [4] and the ears [5] have been described. The eruption lasts for about 10 days, resolving without therapy, and only rarely recurs at subsequent chemotherapy exposures [6]. No one chemotherapeutic agent has been identified as the culprit; indeed, most cases have arisen after administration of a cocktail of chemotherapeutic agents given for myeloproliferative disorders, lymphomas and solid tumours. It has been reported after granulocyte colony-stimulating factor [7]. The histological changes have been experimentally induced in healthy volunteers given intradermal bleomycin, suggesting that a direct toxic effect of the drug on the eccrine gland is responsible [8]. In a case of recurrent chemotherapy-triggered disease, dapsone prophylaxis was effective [9].

Table 45.5 The classification of neutrophilic eccrine hidradenitis.

Chemotherapy-induced eccrine hidradenitis
Infectious neutrophilic hidradenitis
Palmoplantar hidradenitis
Neutrophilic eccrine hidradenitis with HIV infection and Behçet's disease

HIV, human immunodeficiency virus.

Neutrophilic eccrine hidradenitis (NEH) and other diseases. NEH has recently been associated with Behçet's disease [10], and has been reported in association with human immunodeficiency virus (HIV) infection [11].

Infectious neutrophilic eccrine hidradenitis [1]. The sweat glands are resistant to infection, and there are few reports of bacterial hidradenitis. *Serratia* and staphylococcal hidradenitis have been reported in immunocompromised hosts. Enterococci have been cultured from an otherwise healthy woman with hidradenitis on the trunk.

Idiopathic recurrent palmoplantar hidradenitis

This disorder, first described in 1994, is probably more common than the literature suggests [12]. Tender, erythematous plaques develop on the soles and occasionally the palms of children; it has been reported between the ages of 18 months and 15 years [13]. It may mimic a vasculitis. Attacks, lasting up to 3 weeks, are more frequent in autumn and spring. Resolution occurs spontaneously, and in almost half of the cases, the condition is recurrent. Vigorous exercise has been implicated in initiation of some attacks; exposure to cold, damp footwear was believed to be important in another small series [14]. Histology shows eccrine epithelial necrosis, dense infiltration of the periglandular dermis with neutrophils and sometimes abscess formation. Rest, cool compresses, topical and oral steroids have been used as symptomatic treatment.

Syringosquamous metaplasia

Syringosquamous metaplasia is a histopathological term describing the transformation of normal cuboidal duct epithelium into cells with an eosinophilic cytoplasm and a larger more irregular nucleus, so that in some areas it seems that ducts appear in islands of squamous epithelium mimicking squamous carcinoma, or as dilated structures reminiscent of syringomas. The eccrine gland coils are not affected [15]. The histological changes may be seen around areas of cutaneous ulceration of diverse causes, such as burns and arterial ulcers, but also adjacent to pyoderma gangrenosum and extravasated chemotherapy sites [16]. It may represent a non-specific reaction pattern.

Drugs and eccrine glands

A number of drugs are concentrated and secreted by eccrine glands, and in part this may account for their therapeutic effect. Drugs known to be secreted include sulfaguanidine, sulfadiazine, amphetamines, iodides, phenytoin, phenobarbital, carbamazepine, griseofulvin, ketoconazole, fluconazole, ciprofloxacin, diamorphine, cocaine and nicotine. Thiotepa excretion may result in hyperpigmentation of the skin where it is occluded under bandages.

Coma-induced eccrine necrosis

Necrosis of the eccrine glands is the most consistently reported feature of drug-induced coma, whether it be caused by barbiturates, benzodiazepines, narcotics or antidepressants. Similar changes are seen in blisters resulting from coma induced by hypoglycaemia or neurological events, suggesting that the changes are due to pressure rather than the drug *per se*. Areas not usually subject to pressure are the areas that usually show these changes. Early features are necrosis of the secretory coil; later, the duct may be similarly affected. Subsequently, epidermal spongiosis, and subepidermal and intraepidermal blisters form with minimal dermal inflammatory infiltrate.

Radiation-induced eccrine damage

High-dose radiation (> 50 Gy) resulting in radiation dermatitis will abolish eccrine function. Lower doses of radiation will reduce eccrine function within 2 weeks of exposure, reaching a nadir at 8 weeks and recovering to a final dose-dependent deficit by 30 weeks. Radiation-induced keratoses have been described that block the eccrine duct, resulting in milia-like lesions. Histologically, dilated eccrine orifices filled with keratin were identified. Resolution occurred a few months after completion of the radiotherapy.

Disorders with sweat gland cellular inclusions

Accumulation of substances within the secretory cells occurs in a number of metabolic conditions, and their identification in skin biopsies can be used diagnostically. In the Hurler and Sanfilippo types of mucopolysaccharidosis, membrane-bound vacuoles may be seen in the secretory cells [1]. Intracytoplasmic lipid occurs in Sandhoff and Niemann–Pick lipid storage disease [2]. Secretory cell inclusions are seen in Fabry's disease, fucosidosis [3] and Kanzaki disease [4], and in amaurotic idiocy, maltase deficiency and adrenoleukodystrophy [5]. Periodic acid–Schiff (PAS)-positive granules in the outer duct cells characterize Lafora's myoclonic epilepsy [6].

Granulosis rubra nasi [1–3]

The pathogenesis of this rare disease is obscure. Most cases are genetically determined, but the mode of inheritance is uncertain.

The disease usually starts in childhood, from the age of 6 months to 10 years. Excessive sweating may precede other changes by several years. Diffuse erythema first appears on the tip of the nose, gradually extends, and may involve the cheeks, the upper lip and the chin. The erythema is covered by small beads of sweat, which may also be evident over a wider area. Small red macules and papules, and sometimes vesicles, later form at the sweat duct orifices. The condition usually subsides spontaneously at puberty, but may persist indefinitely. In such

cases, telangiectasia becomes a conspicuous feature, and small cysts may be present. Many of those affected have poor peripheral circulation and hyperhidrosis of the palms and soles. Response to treatment is usually disappointing. A single case has been associated with phaeochromocytoma [4].

Apocrine sweat glands

Anatomy and physiology [1–4]

Apocrine sweat glands derive their name from the way their secretion appears, on light microscopy, to be derived by pinching off parts of the cytoplasm. They are epidermal appendages, and develop as part of the pilosebaceous follicle in the fourth to fifth month of intrauterine life. In the embryo, they are present over the entire skin surface, but most glands subsequently disappear, so that in the adult the characteristic distribution in the axillae, perianal region and areolae of the breasts is found. So-called ectopic glands may be found elsewhere. The mammary glands and glands in the external auditory meatus are modified apocrine glands. Apocrine glands are poorly developed in childhood, and begin to enlarge with the approach of puberty. The activity of the glands is androgen-dependent, and the glands show marked testosterone 5α-reductase activity [5]. The glands are larger than eccrine glands, and in the dissected specimen are visible to the naked eye. They are situated in the subcutaneous tissue. Each consists of a tubule and a duct. The latter is often quite short, and opens into the neck of the hair follicle above the sebaceous gland. Despite their embryological origin from the hair follicle, some apocrine glands eventually come to open on the surface of the skin. The secretory coil is a simple convoluted tube. It is lined by a single layer of columnar or cuboidal cells resting on a basement membrane. The free edge of the cells may show the appearance of apocrine secretion. Electron microscopy shows that this may be partly an artefact, but eccrine, apocrine and even holocrine secretion may all be found in places [3,6,7] (Fig. 45.12). The apocrine duct closely resembles the eccrine duct, and consists of a double layer of cuboidal cells. Outside the basement membrane of the gland and duct is a longitudinal layer of myoepithelial cells. Their function is to support the duct and to propel the secretion to the surface, and waves of peristalsis have been seen in them [8]. Where the duct opens into the neck of the hair follicle, there is the equivalent of the acrosyringium of the eccrine duct, although it is less obvious [9].

Fig. 45.12 Section of a secretory coil of an apocrine gland from the human axilla; lying next to the basement membrane are myoepithelial cells (me), followed by cuboidal secretory cells, with prominent nuclei (N) and apical caps (A), projecting into the lumen (L). D, dermis. (Courtesy of the late Professor A.S. Breathnach, St John's Dermatology Centre, London, UK.)

Apocrine glands secrete very small quantities of an oily fluid, which may be coloured. This secretion is odourless on reaching the surface, and bacterial decomposition is responsible for the characteristic odour; *trans*-3-methyl-2-hexanoic acid, which is water-soluble, is one of the substances which contributes to the odour [10]. The glands have no thermoregulatory function in humans, although they may play some part in human olfactory communication. The epithelium of the secretory coil produces its secretion continuously, with some variation depending on hormonal factors—for example, menstruation and pregnancy. The ducts have an adrenergic sympathetic nerve supply and are also stimulated by circulating epinephrine. Nervous control of secretion is unimportant, and it is even disputed whether the glands have any motor innervation [4,11]. Expulsion of apocrine sweat may occur continuously or be provoked by emotional stimuli. It seems possible that histologically normal apocrine glands may fail to produce any secretion, and that only the axillary glands in humans are important in producing body odour [12].

Abnormal sweat odour (bromhidrosis and osmidrosis) [1–3]

Odour of the skin in humans is, to a large extent, determined by apocrine gland secretion, although there are other sources. Sebaceous secretion has some odour, and decomposition products of keratinization, especially in the presence of hyperhidrosis, produce offensive smells. Eccrine secretion is usually odourless, but various substances may be excreted in it—for example, garlic, drugs, arsenic. Characteristic odours may be associated with various uncommon amino-acidurias (see below). Old textbooks of medicine report that sweat has a characteristic odour in gout, diabetes, scurvy, typhoid and other diseases [4]. Cases of generalized bromhidrosis associated with nasal foreign bodies have been recorded in children [5,6], and the symptom may be a clue to premature puberty. Other patients complaining of body odour may be suffering from paranoia or phobias (monosymptomatic delusions of malodour) or from organic lesions of the central nervous system.

Apocrine secretion is odourless as it reaches the surface, apart from excreted substances such as garlic. Bacterial decomposition liberates fatty acids, etc., with characteristic smells. This process occurs only after some hours, and frequent removal of apocrine sweat prevents its decomposition. A strong axillary odour tends to be associated with a richer bacterial flora, and especially with more corynebacteria [7,8]. Increased axillary pH may facilitate the overgrowth of these bacteria, and some deodorants may help by acidifying the axillary skin.

There is marked individual and racial variation in body odour, and what is socially acceptable varies greatly with race and social upbringing. Recent studies have demonstrated histological differences between normal and bromhidrotic apocrine glands; in the bromhidrotics, the apocrine glands were larger and more numerous [9]. Elevated activity of type I 5α-reductase activity has been shown in those with bromhidrosis [10].

Treatment of axillary bromhidrosis includes omission of foodstuffs like garlic from the diet, frequent washing of the axillary regions and local antibacterial substances [2]. There is little evidence that measures used to control axillary eccrine hyperhidrosis—for example, aluminium salts and anticholinergic drugs—have much effect on the apocrine glands, although excessive eccrine excretion may favour the spread of apocrine secretion. Surgical excision of axillary subcutaneous tissue by a variety of surgical techniques (axillary shave and subsection of subcutaneous glands, laser ablation, ultrasound ablation and liposuction), which removes both eccrine and apocrine glands, has been performed with good effect in those dissatisfied with conservative measures [11,12].

Fish odour syndrome (trimethylaminuria)

This disorder results from excessive amounts of the offensively smelling tertiary amine trimethylamine appearing in the both eccrine and apocrine sweat, breath and urine and imparts an unpleasant rotting fish smell to sufferers [1]. Affected individuals are unable to oxidize this substance, which is produced by the intestinal bacterial degradation of choline and carnitine in food to the odourless trimethylamine N-oxide. This can occur as a primary problem, as a result of a mutation in the flavin-containing monooxygenase 3 (*FMO3*) gene [2]. The ability to N-oxidize trimethylamine is distributed polymorphically,

and sufferers are homozygous for an allele which determines this impaired reaction. One per cent of the population are heterozygous carriers of the allele. Secondary trimethylaminuria can occur when there is an increased burden of trimethylamine, and is seen when there is an increased production of trimethylamine (TMA) from its precursors by gut bacteria, in conditions such as blind loop syndrome, uraemia and liver disease.

The unpleasant odour, which is often worse after eating seafood, during periods of stress and during menstruation, can be the source of much distress, rejection and resentment. Sufferers are sometimes unaware of their smell, which may be intermittent and may not be detected by physicians when consulted. Trimethylaminuria was found in 7% of a series of individuals who perceived themselves to be malodorous [3]. The condition can be diagnosed by direct estimation of TMA in the urine; both affected individuals and heterozygous carriers have abnormal elevated excretion of TMA after an oral TMA challenge. A diet low in carnitine and choline may help. Short courses of metronidazole or neomycin may temporarily reduce the bacteria that degrade the carnitine and choline in the gut.

Chromhidrosis [1,2]

Apocrine sweat may be tinged with a yellow, green or blue hue in up to 10% of the population, but only rarely does it occur to the striking degree that merits the term chromhidrosis (Fig. 45.13). Most commonly blue-black, yellow or green, it results from the secretion of lipofuscins in apocrine sweat, and may be associated with the secretion of coloured breast milk. The more oxidized lipofuscins appear deeper in colour; the lighter-coloured pigments may fluoresce. The diagnosis can be confirmed by finding lipofuscin pigment granules that may fluoresce on fluorescence microscopy in the apocrine secretory cells. The secretion of coloured sweat starts at puberty and persists until there is a gradual regression of apocrine function in old age. Coloured sweat may be discharged from the glands in response to exercise and emotional stimuli, and after manipulation of the skin. The axillae are the most frequently affected sites, although facial [3] and areolar chromhidrosis [4] are recorded. Topical capsaicin has satisfactorily reduced facial and nipple chromhidrosis.

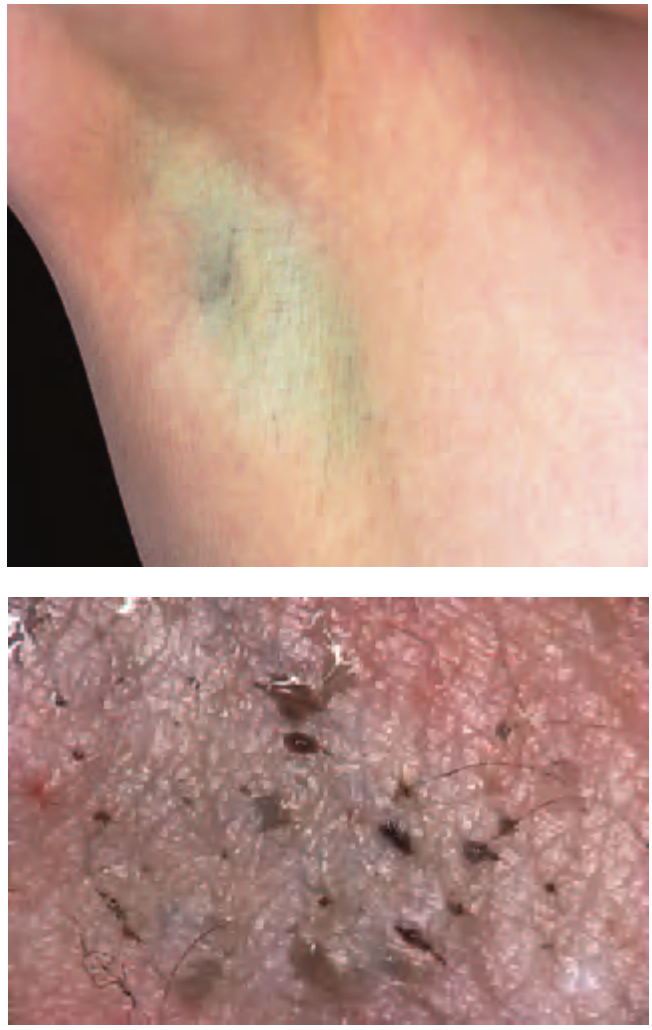

Fig. 45.13 Axillary chromhidrosis. (Courtesy of Dr D. Shuttleworth, Essex County Hospital, Colchester, UK.)

Pseudochromhidrosis refers to the coloration of otherwise colourless sweat when it reaches the surface of the skin due to dyes, paints or chromogenic or porphyrin-producing bacteria on the skin. Blue pseudochromhidrosis has been reported in workers occupationally exposed to copper salts. An outbreak of red pseudochromhidrosis occurred in a group of flight attendants who had new red-dyed labels put into their uniforms [5]. Erythromycin eradicated a presumed bacterial facial pseudochromhidrosis of the face in a young girl [6]. Eccrine chromhidrosis is usually due to exogenous dyes and is usually weak in hue. A case of red pseudochromhidrosis resulting in red staining of underwear was attributed to eating excessive quantities of a snack containing a red food dye [7]. Dark perspiration has been reported to occur in alkaptonuria (ochronosis).

Fox–Fordyce disease

Aetiology and pathology [1]. Fox–Fordyce disease is a disorder of the apocrine glands comparable to prickly heat of the eccrine glands. The aetiology is unknown. Obliteration of the apocrine duct at the infundibulum is felt to be the cause. The earliest visible change histologically is a small vesicle in the apocrine duct [2]; early changes may be seen most easily in transverse histological sections. This progresses to an inflammatory lesion, followed by rupture and plugging of the duct. Apocrine sweat retention therefore follows. Hormonal influences are important, but there is little evidence of a primary hormonal abnormality.

Clinical features. The disease occurs mainly in women soon after puberty, but can be postmenopausal [3]. It can occur in males or in children, and has been reported in females with Turner's syndrome and in identical twins [4]. Itching, which may be intense, occurs in the axillae, and to a lesser extent in the anogenital region and around the breasts. Objectively there may be little to see at first, but later skin-coloured, or slightly pigmented, dome-shaped, follicular papules develop (Fig. 45.14). Hair loss in the axillae usually ensues. The itching is often provoked by those emotional stimuli which normally cause apocrine secretion. The disease runs a very prolonged course, and may persist until the menopause. Some remission may occur in pregnancy.

Treatment. Response to treatment is unsatisfactory. Topical and intralesional steroids provide some benefit, but their use is limited by atrophy. Topical clindamycin is reported to have been of help [3]. Treatment with four to six weekly doses of ultraviolet radiation (UVR), sufficient to cause exfoliation, helps some patients [5]. Topical retinoic acid may also be helpful [6], as may oral contraceptive agents [7,8], and oral retinoids [9]. Other cases are sufficiently severe to require electrocautery [10] or surgical excision of the affected skin, or subcutaneous removal of the apocrine glands [11].

Chapter 46

Disorders of Connective Tissue

N.P. Burrows & C.R. Lovell

Introduction

The connective tissue of the normal skin is discussed in Chapter 3.

Diseases which predominantly affect the cutaneous connective tissue (collagen, elastin and ground substance) can be divided into three main groups.

1 Genetic abnormalities that affect connective tissue formation or metabolism. Examples include Ehlers–Danlos syndrome (EDS) (which affects collagen), pseudoxanthoma elasticum (PXE) (elastic tissue) and the mucopolysaccharidoses (ground substance).

2 Acquired metabolic or degenerative disorders, such as scurvy and solar elastosis, which are liable to affect people with no genetic defect if the environmental cause is present.

3 Inflammatory 'collagen vascular' or 'connective tissue' diseases, which damage connective tissue as a result of complex immunological reactions involving autogenous antigens. This group includes systemic lupus erythematosus, rheumatic fever, systemic sclerosis and dermatomyositis. Both genetic and acquired factors (including the possibility of infective agents) may play some part in producing these conditions, which are fully discussed in Chapter 56.

The attempt to classify the pathological changes according to whether ground substance, collagen, elastin or cellular components are mainly or wholly involved is not always easy, and may have been inaccurate in the past.

In this chapter, some of the genetic and acquired diseases which affect mainly collagen or elastin are discussed. Disorders of the ground substance are discussed elsewhere (see myxoedema, cutaneous mucinosis, myxoid cyst and mucopolysaccharidoses).

There are, in addition, many other disorders, including developmental defects, reactive or scarring conditions and benign or malignant neoplasms, which may involve the connective tissue.

Cutaneous atrophy

Atrophy of the skin is a term which is applied to the clinical changes produced by a decrease in the dermal connective tissue. It is characterized by thinning and loss of elasticity. The skin usually appears smooth and finely wrinkled, and it feels soft and dry. Veins or other subcutaneous structures may be unduly conspicuous. There is often associated loss of hair follicles, and telangiectasia may also be present, due to the loss of connective tissue support of the capillaries. There may or may not be an associated atrophy of the epidermis.

Atrophy of the skin occurs in varying degree in a large number of skin conditions, and the underlying histological changes are also variable, because the several components of the connective tissue may be involved to a different degree. Atrophy that includes subcutaneous tissue or even deeper structures is referred to as *panatrophy*.

The main causes of cutaneous atrophy are as follows.

1 Generalized cutaneous thinning:
  (a) ageing;
  (b) rheumatoid disease;
  (c) glucocorticoids (exogenous or endogenous).
2 Poikiloderma.
3 Atrophic scars (striae).
4 Anetoderma:
  (a) primary;
  (b) secondary to another inflammatory disease.
5 Chronic atrophic acrodermatitis (borreliosis).
6 Follicular atrophoderma.
7 Vermiculate atrophoderma.
8 Atrophoderma of Pasini and Pierini (probably morphoea).
9 Atrophic naevi.
10 Panatrophy:
  (a) local panatrophy;
  (b) facial hemiatrophy.

Generalized cutaneous atrophy

The skin becomes increasingly thin and atrophic in elderly people, and both the epidermis and the dermis are affected [1] (see Chapter 70 for further details). As a result, the aged skin becomes fragile, translucent, lax and wrinkled, with a tendency to easy bruising.

Dermal thickness is considerably decreased in the elderly [1]. Wound healing is delayed in the elderly because of a decrease in the numbers and synthetic capability of fibroblasts [2]. With increasing age, both keratinocytes and fibroblasts show a decreased response to various growth factors [3].

Ageing and wrinkles

Wrinkles may be defined as creases or furrows in the skin surface. They are generally distinguished from the lax pendulous folds of skin which occur in conditions such as PXE and cutis laxa, but the distinction is somewhat arbitrary, because loss of dermal elastic tissue is common to all these conditions. Deepening of the furrows occurs with advancing age [4]. Histologically, there is epidermal thinning, decrease in chondroitin sulphate and deposition of abnormal elastic tissue in the papillary dermis [5].

Wrinkles can be classified into three morphological types [6].

1 *Crinkles*. This is a very fine wrinkling which occurs in aged skin, even in areas protected from sunlight. These fine wrinkles disappear when the skin is slightly stretched. They are caused by deterioration of elastin, especially the vertical subepidermal fine elastic fibres which keep the epidermis in tight apposition to the dermis [7,8]. Ultrastructural studies have shown that even in normal people the elastic fibres begin to deteriorate from the age of 30 years onwards, regardless of the amount of sun exposure, although sunlight undoubtedly increases the damage [9]. Crinkles are seen in a marked form in mid-dermal elastolysis (see below).

2 *Glyphic wrinkles*. These creases are an accentuation of the normal skin markings. They occur on skin which has been prematurely aged by elastotic degeneration caused by sunlight, for example on the sides and back of the neck (see actinic elastosis).

3 *Linear furrows*. These are long, straight or slightly curved grooves that are usually seen on the faces of elderly people. They include the horizontal frown lines along the forehead, the 'crows' feet' radiating from the lateral canthus of the eye and the creases from the nose to the corners of the mouth.

The facial skin has a remarkably complex and dense intradermal elastic tissue mesh. This sheath of elastin is unique to the face, not being found in such complexity elsewhere. In youth, the linear furrows caused by facial muscle contraction disappear due to elastic recoil, but in older people they become permanent. There is some controversy regarding the histology of these linear furrows. Several groups have claimed that the linear wrinkles cannot be distinguished by light or electron microscopy from the surrounding skin, and Kligman *et al*. [6] claim the furrow is merely a configurational change like the crease in an old glove. Tsuji *et al*. [8], however, claim that the upper dermis in the furrow shows less elastotic change than the surrounding skin. Other authors [9,10], on the other hand, claim that the trabeculae of the retinacula cutis (which anchors the dermis to the underlying fascia)

are broader and much shorter underneath the wrinkles than in the surrounding skin. The hypertrophy of these subcutaneous septa is probably related to repetitive mechanical stimuli generated by the facial muscles over the years.

Wrinkles are a characteristic feature of photodamaged skin (Chapter 24). Cigarette smoking is also a potent, independent cause of wrinkling. The so-called 'cigarette face' is characterized by pale, grey, wrinkled skin with rather gaunt features, so that heavy smokers can often be recognized from their facial appearance alone. Heavy smokers are five times more likely to be wrinkled than non-smokers of the same age, and cigarette smoking probably has at least as much effect on facial wrinkles as sun exposure [11,12]. The pathogenesis of these deleterious effects on facial skin is unknown, but causative factors might include ischaemia due to the vasoconstriction induced by nicotine or sympathetic nerve stimulation, decreased tissue oxygenation, increased tissue carboxyhaemoglobin, increased platelet aggregation, decreased prostacyclin formation and reduced collagen deposition [12]. Both UVA and tobacco smoke may cause wrinkling through additive induction of matrix metalloproteinase-1 (MMP-1) expression [13].

Treatment of wrinkles. See Chapter 77.

Idiopathic mid-dermal elastolysis

Several cases have been described in which idiopathic loss of the elastic fibres in the mid-dermis has led to widespread wrinkling of the crinkle type in an otherwise healthy young or middle-aged woman (Fig. 46.1) [14,15]. The exact relationship between this condition and other elastolytic disorders such as acquired cutis laxa (p. 46.19) and anetoderma (p. 46.11), is uncertain. Maghraoui *et al.* [16] have distinguished post-inflammatory elastolysis, with or without features of cutis laxa, from non-inflammatory elastolysis. Inflammatory triggers may include UV radiation, insect bites and borreliosis. Localized elastolysis adjacent to varicose veins has also been reported [17].

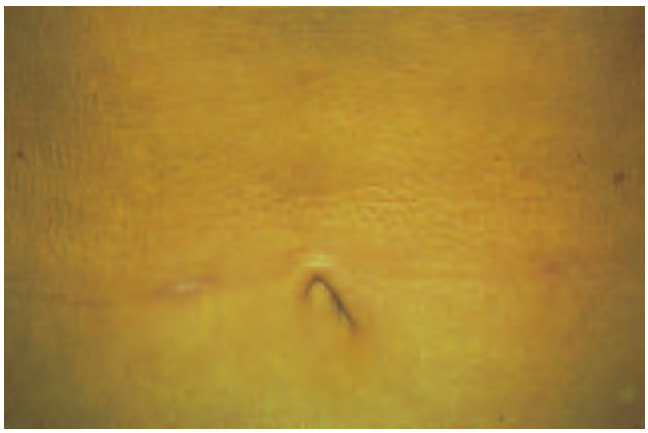

Fig. 46.1 Idiopathic mid-dermal elastolysis. (Courtesy of Dr L. Ostlere, St George's Hospital, London, UK.)

Ultrastructural studies of mid-dermal elastolysis demonstrate elastic fibres engulfed by macrophages [18]. Immunological studies of affected skin show a non-specific profile of immune activation [19]. Localized areas may clinically resemble PXE, although they are histologically distinct [20,21].

The histology of idiopathic mid-dermal elastolysis is similar to that of post-inflammatory elastolysis and cutis laxa (PECL), which occurs in young African girls (see below). Those lesions are preceded by inflammatory lesions, but the lesions of idiopathic mid-dermal elastolysis may also occasionally be preceded by erythema, urticaria or a burning sensation, and the two conditions are similar, if not identical.

No definite treatment exists but topical retinoic acid (0.01% gel) produced some cosmetic improvement in one patient [19].

Post-inflammatory elastolysis and cutis laxa

PECL is a distinctive severe variant of anetoderma (p. 46.11), which occurs predominantly in black girls living in a tropical climate [1–3]. It has a prolonged course, with relapsing inflammatory phases lasting for months or years. In the acute phase, there are firm, infiltrated plaques or rings, with a collarette of scale, and these progress to leave a diffuse, fine, wrinkled skin with the appearance of premature ageing. In some cases, most of the body surface may be involved. There is no internal involvement, and no preceding infection, such as syphilis or tuberculosis. Histological examination shows destruction of the elastic fibres in the upper and mid-dermis.

It is thought that PECL is a reaction to arthropod bites because some patients have eosinophilia, other family members may suffer from papular urticaria, the lesions show a predilection for exposed parts and no new lesions develop when the patient is in hospital. There is a resemblance to erythema chronicum migrans (Chapter 27).

Atrophic skin with rheumatoid disease

In rheumatoid patients over the age of 60 years, especially women, the skin on the dorsa of the hands may become thin, loose, smooth, inelastic and transparent, so that the details of veins and tendons are clearly seen. The change is generalized but is seldom conspicuous except on the hands and forearms. Histologically, the dermis is thinned but shows no distinctive changes.

There is a significant association between transparent skin, rheumatoid arthritis and osteoporosis, and it is assumed to form part of a general connective tissue defect [1]. Steroid therapy is not a factor but it will potentiate the problem [2]. Skin collagen is structurally abnormal [3]. A reported association with PXE may be coincidental [4].

Glucocorticosteroid-induced atrophy

Both systemic and topical glucocorticoid therapy can produce cutaneous atrophy by a dose-related pharmacological effect. The effect is more severe with the more potent steroids (as assessed by the vasoconstrictor assay test) but both fluorinated and non-fluorinated topical steroids can cause atrophy. The effect is most marked when potent steroids are applied topically under an occlusive dressing. The skin becomes thin, fragile and transparent, and striae may develop (see below) (Fig. 46.2).

Severe dermal atrophy can follow injection of intralesional steroids, such as triamcinolone acetonide (particularly if the higher concentration of 40 mg/mL is used, instead of the more usual 10 mg/mL, which is less likely to cause atrophy) (Fig. 46.3).

The earliest histological change is marked thinning of the epidermis, with flattening of the rete ridges and decreased corneocyte size [1]. This is followed a few weeks later by thinning of the dermis, which can be measured by skinfold calipers, ultrasonography or a radiographic technique [2–4].

The epidermal thinning probably results from a reduction of mitotic activity in the germinal layer [5], but the mechanism by which dermal thinning is produced is uncertain.

Fig. 46.2 Striae of the legs due to long-term application of a potent topical steroid in a young woman with psoriasis.

Fig. 46.3 Localized atrophy due to injection of a steroid (triamcinolone, 40 mg/mL) into the skin between the second and third metatarsals.

Loss of dermal ground substance leads to a reorganization of the dermal architecture. The spaces between the collagen and elastic fibres become smaller, so that the dermis becomes more compact but thinner [6]. Steroids are known to inhibit the formation of glycosaminoglycans [7,8]. The fibroblasts become shrunken, although their numbers do not decrease, but the number of mast cells is markedly reduced.

Topical steroids also inhibit the activity of enzymes involved in collagen biosynthesis [9,10], and they have been shown to depress synthesis of types I and III collagen *in vivo* [11–13]. Type III collagen synthesis is preferentially reduced in fibroblast cultures [14]. They can also depress collagenase production and collagen breakdown [15], and the rate of collagen turnover is probably decreased. Even a weak steroid, such as hydrocortisone, can suppress the stimulatory effect of cyclic nucleotides on collagenase production. Studies of the effect of topical steroids on collagen and elastic fibres *in vivo* have given conflicting results [6,16,17]. Collagen microfibrils may form globular microfibrillar bodies, although the changes are not specific for steroid atrophy [18]. These ultrastructural changes can develop in the early stages before there is clinical or histological evidence of atrophy. Digestion of collagen fibrils in the endocytic vesicles of fibroblasts may be involved in the production of steroid-induced atrophy [15].

Capillaroscopic studies have shown that steroid-induced vasoconstriction involves the superficial capillary network, and prolonged superficial ischaemia could also play a role in producing atrophy [10].

Treatment. It has been suggested that local and oral vitamin C therapy might help restore the normal skin thickness [19].

Concurrent application of retinoic acid may partially prevent the epidermal atrophy due to steroids [20].

Achenbach's syndrome [1–4]

SYN. PAROXYSMAL HAEMATOMA OF THE FINGER

This syndrome presents with the sudden spontaneous onset of one or more painful haematomas in the fingers,

Fig. 46.4 Achenbach's syndrome. (Courtesy of Dr J. Verbov, Royal Liverpool University Hospitals, Liverpool, UK.)

usually in a middle-aged female (Fig. 46.4). It may recur at intervals for several years. The cause is unknown—there is no evidence of vasculitis or amyloid on skin biopsy, and the condition, although troublesome, has a good prognosis. It may be mistaken for easy bruising due to steroid atrophy.

Striae

SYN. STRIAE ATROPHICANS; STRIAE DISTENSAE; 'STRETCH MARKS'

Definition. Striae are visible linear scars which form in areas of dermal damage produced by stretching of the skin. They are characterized histologically by thinning of the overlying epidermis, with fine dermal collagen bundles arranged in straight lines parallel to the surface.

Aetiology. The factors which govern the development of striae are poorly understood. Many authors have suggested that striae develop as a result of stress rupture of the connective tissue framework [1], but others disagree. It has been suggested that they develop more easily in skin which has a critical proportion of rigid cross-linked collagen, as occurs in early adult life [2]. They are common during adolescence [3], and they seem to be associated with rapid increase in size of a particular region. They are very common over the abdomen and breasts in pregnancy, and they may develop on the shoulders in young male weight lifters when their muscle mass rapidly increases [4]. They are a feature of Cushing's disease, and they may be induced by local or systemic steroid therapy [2,5]. The effects of glucocorticoids on the dermal connective tissue are outlined above. Together with other steroid effects, striae have been reported in human immunodeficiency virus (HIV)-positive patients receiving the protease inhibitor, indinavir [6].

Fig. 46.5 Striae due to obesity in a young man.

The importance of genetic factors in determining susceptibility of connective tissue is emphasized by their presence as one of the (minor) diagnostic criteria for Marfan's syndrome (MFS) [7], but they are commonly absent in pregnancy in EDS.

Pathology. In the early stages, inflammatory changes may be conspicuous; the dermis is oedematous and perivascular lymphocytic cuffing is present. In the later stages, the epidermis is thin and flattened [8]. The dermal collagen is layered in thin eosinophilic bundles, orientated in straight lines parallel to the surface in the direction of the presumed stress. Scanning electron microscopy shows amorphous sheet-like structures [9,10]. With Luna's stain, the elastic fibres are numerous, close together, fine and straight, in the same direction as the collagen bundles [9]. On scanning electron microscopy in collagen-free preparations there is an abundance of thin, curled and branched elastic fibres. The histology is that of a scar.

Clinical features. Striae are very common, and occur in most adult women, as they readily develop at puberty or during pregnancy. Adolescent striae may first develop soon after the appearance of pubic hair. The commonest sites are the outer aspect of the thighs and the lumbosacral region in boys (Fig. 46.5), and the thighs, buttocks and breasts in girls, but there is considerable variation, and other sites, including the outer aspect of the upper

arm, are sometimes affected. Early lesions may be raised and irritable, but they soon become flat, smooth and livid red or bluish in colour. Their surface may be finely wrinkled. They are commonly irregularly linear, several centimetres long and 1–10 mm wide. After some years, they fade and become inconspicuous.

The striae in Cushing's syndrome or those induced by steroid therapy may be larger and more widely distributed, and involve other regions, including sometimes the face. In pregnancy, the striae appear first and are most conspicuous on the abdominal wall, and later on the breasts, but may involve most or all of the pubertal sites [11].

The striae induced by topical steroid therapy occur particularly in the flexures, but may appear in other sites if occlusive plastic films increase absorption [12,13]. They may disappear or become less conspicuous when treatment is stopped.

Usually, striae are only a cosmetic problem, but occasionally, if extensive, they may ulcerate or tear easily should the patient be involved in an accident.

Diagnosis. The diagnosis of striae is usually simple. The possibility of Cushing's syndrome must be considered, although this is rarely the cause. In linear focal elastosis the lesions are yellow and palpable (p. 46.26).

Treatment. In the case of common adolescent striae, the patient may be reassured that in time they will become less conspicuous. Numerous unproven remedies are available from cosmetic companies.

Some cases appear to respond to treatment with topical tretinoin [14]. The erythema of 'younger' striae is claimed to respond to the 585 nm pulsed dye laser [15].

Congenital reticulate scarring

Three children have been described who presented at birth with vesicles, deep erosions and erythematous patches. The vesicles were generalized, but spared the palms, soles and face, superficially resembling 'scalded skin syndrome'. Healing at around 3 months was followed by fragile reticulate scars; the affected areas were anhidrotic [1]. Two further children with this condition had epilepsy and delayed intellectual and motor milestones [2]. Histological examination showed that the reticular dermis was partially replaced by collagenous scar tissue, and eccrine glands were absent. The differential diagnosis includes Goltz syndrome, Rothmund–Thomson syndrome, acrodermatitis chronica atrophicans and aplasia cutis [1,2].

Localized cutaneous atrophy

Focal facial dermal dysplasia

Scar-like depressions on the face are a feature of this syndrome, which may be a variant of the Setleis syndrome (Chapter 12) [1,2].

Atrophic scars and pseudoscars

Atrophy may result from the destruction of connective tissue by trauma or by inflammatory changes. The distribution and character of the atrophic lesions may be so distinctive as to betray their origin, and is sometimes of considerable importance in diagnosis. Viral infections, such as varicella, can leave widespread, small, circular, atrophic scars [1]. The scars left by tertiary syphilis, certain tuberculides and some deep mycoses, especially sporotrichosis, are usually completely atrophic. Lupus erythematosus may also leave atrophy without clinical evidence of sclerosis. Lupus vulgaris and the chronic follicular

Fig. 46.6 Stellate pseudoscars on the forearm of an elderly woman. There was no history of trauma.

pyodermas, and some cases of lupus erythematosus, leave a combination of atrophy and sclerosis, in which the latter predominates. Lesions that have been treated by intralesional steroid injections may also leave atrophic scars.

Exposure to ionizing radiation gives rise to a very striking combination of atrophy, pigmentation and telangiectasia (Chapter 76).

The wide atrophic scars which follow injuries in EDS (p. 46.31) emphasize the importance of constitutional factors in determining the pattern of dermal response to a known external injury.

Stellate and discoid pseudoscars [1,2]

Stellate pseudoscars are white, irregular or 'star-shaped' atrophic scars (Fig. 46.6). They are common on light-exposed skin, particularly on the extensor aspects of the forearms, often in association with senile purpura. These are seen in 20% of patients aged 70–90 years, and a much less common presenile form occasionally occurs before the age of 50 years. These pseudoscars are secondary to mild trauma, and are probably always preceded by haemorrhage into the dermis.

Fig. 46.7 Brown pseudoscars of the legs due to diabetic dermopathy. There was no history of trauma.

Stellate scars following trivial trauma can also occur in other conditions which cause fragile skin, for example porphyria cutanea tarda and prolonged use of potent topical steroids.

Brown pseudoscars may also develop over the shins of diabetic patients with no history of trauma (Fig. 46.7).

Spontaneous atrophic scarring of the cheeks

SYN. VARIOLIFORM ATROPHY; ATROPHIA MACULOSA VARIOLIFORMIS CUTIS

This is a very rare condition in which spontaneous scars develop on the cheeks (Fig. 46.8) in young adults [1,2] or children [3]. The shallow atrophic lesions have sharp margins and may be linear, rectangular or varioliform. They may be preceded by slight erythema and scaling. Histology shows mild loss of collagen or elastic fibres; there may be thickening of the stratum corneum [4]. Familial cases are recorded [1,5]. The differential diagnosis includes vermiculate atrophoderma (p. 46.9), chickenpox scars and artefact.

Atrophoderma

Follicular atrophoderma

In this distinctive syndrome dimple-like depressions at the follicular orifices are present from birth or early life, usually on the backs of hands (Fig. 46.9) and feet and sometimes in the elbow region.

Histology shows widened follicular ostia with thickening of the connective tissue sheath of the follicle.

It appears to be due to a variety of genetic defects and it may be associated with the following conditions [1]:

1 calcifying chondrodysplasia (Conradi's syndrome) (Chapter 12);
2 Bazex syndrome (Chapter 12) [2];
3 hyperkeratosis palmoplantaris, follicular keratosis or palmoplantar hyperhidrosis.

It may also occur as an isolated defect of limited extent.

Vermiculate atrophoderma

This rare condition has been described under a variety of other names, including atrophoderma reticulatum, folliculitis ulerythematosa reticulata and honeycomb atrophy. It is a characteristic reticulate or 'honeycomb' type of atrophy, which seems to develop as a late reaction to inflammation around horny follicular plugs on the cheeks (Fig. 46.10). The condition is now regarded as part of the keratosis pilaris syndrome, and is further discussed in Chapter 34.

Familial focal facial dermal dysplasia

Atrophic macules occur on the temples in this rare autosomal dominant disease (Chapter 12).

Hallermann–Streiff syndrome

There may be focal atrophy of the scalp skin in this condition (Chapter 15) [1].

Fig. 46.10 Vermiculate atrophoderma on the cheek of a child. (Courtesy of Dr P. Frosch, Heidelberg, Germany.)

1 Grattan CEH, Liddle BJ, Willshaw HE. Atrophic alopecia in the Hallermann–Streiff syndrome. *Clin Exp Dermatol* 1989; **14**: 250–2.

Atrophoderma of Pasini and Pierini

Definition. This condition appears to be an atrophic variant of morphoea (Chapter 56) in which one or more patches of skin become bluish and sharply depressed, with no surrounding erythema [1–3].

Aetiology. The cause is unknown. No genetic factor has been reliably incriminated, although familial cases have been reported [4], and morphoea and atrophoderma of Pasini have occurred in siblings with phenylketonuria [5].

Pathology [3]. The histological changes are slight. There may be increased pigmentation of the basal layer. During the earlier stages, the collagen in the lower dermis may be oedematous, and elastic tissue clumped and scanty. There may be a dermal perivascular infiltrate consisting of macrophages and T lymphocytes. Immunofluorescence studies may show IgM and C3 staining in the dermal blood vessels [6]. Later, the oedema subsides and there is some reduction in the total thickness of the dermis. Collagen bundles appear homogeneous and clumped in the reticular dermis. Eventually there may also be some epidermal atrophy.

Fig. 46.11 Atrophoderma of Pasini and Pierini. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

Clinical features [3,7,8]. The lesions, which may be single or multiple, range in size from 2 cm to many centimetres in diameter, and are round or oval in shape, but may become confluent to form irregular patches (Fig. 46.11). They are smooth, slate-coloured or violet brown, and are slightly depressed below the level of the entirely normal surrounding skin. The back is almost always involved, the chest and abdomen frequently, and the proximal parts of the limbs occasionally. The patches extend very slowly, increase in number for 10 years or more, and then usually persist unchanged. The eventual development of sclerodermatous changes within the patches has been observed, as has the presence in the same patient of lesions typical of atrophoderma and of morphoea.

Diagnosis. Clinical differentiation from morphoea, possibly an academic exercise, is based on the ivory-white, indurated plaque with an oedematous lilac ring so characteristic of the latter. Histologically, sclerosis may be prominent in morphoea and is usually absent in atrophoderma.

Serological tests for *Borrelia burgdorferi* are negative [3].

Treatment. None is of proven efficacy, but psoralen and UVA (PUVA) has helped some patients.

Linear atrophoderma

Pigmented atrophic bands follow Blaschko's lines [1] on the trunk, arms and legs. Histologically, collagen bundles are normal or thickened; the apparent atrophy may be due to loss of fat. The condition may reflect mosaicism for an autosomal lethal gene [2].

Anetoderma

SYN. MACULAR ATROPHY

Definition and nomenclature. The term anetoderma (*anetos* = slack) refers to a circumscribed area of slack skin associated with a loss of dermal substance on palpation and a loss of elastic tissue on histological examination.

'Primary' anetoderma implies that there is no associated underlying cutaneous disease, whereas 'secondary' anetoderma can be attributed to some associated condition.

In the past, cases of primary anetoderma were divided into the *Jadassohn–Pellizari* type, in which the lesions are preceded by erythema or urticaria, and the *Schweninger–Buzzi* type, in which there are no preceding inflammatory lesions. This is now of historical interest only, because in the same patient some lesions may be preceded by inflammation and others may not, and the prognosis and histology are identical in the two types [1–3].

Primary anetoderma

Aetiology. The cause is unknown. Familial cases are reported [4,5] and there is an association with inherited bony or ocular abnormalities. The Blegvad–Haxthausen syndrome comprises anetoderma, blue sclerae and osteogenesis imperfecta (OI) (p. 46.41).

The histology of anetoderma suggests that the basic abnormality is focal elastolysis [1,6,7]. This may be secondary to the release of elastase from the inflammatory cells, which are probably always present in the early stages. Metalloproteinases are increased in lesional skin [8].

Complement activation may be involved, as C3 is deposited on the remaining elastic fibres [9]. It has been suggested that decay-accelerating factor (DAF) and vitronectin (an inhibitor of the membrane-attack complex) may protect elastic fibres against this type of damage [10]. Abnormalities in the protective system could play a role in primary anetoderma. Fibrinolytic activity may also be reduced in anetoderma [11].

Secondary anetoderma

This arises in association with another identifiable disease, but the atrophic areas do not always develop at the sites of the known inflammatory lesions. They are soft, round or oval areas which occur mainly on the trunk.

Syphilis. The lesions occur in association with secondary, latent, congenital or tertiary syphilis, but even where cutaneous syphilitic lesions are present the atrophy develops independently on the trunk, and not at the sites of the lesions.

Anetoderma has also been reported in five patients with false-positive syphilis serology, three of whom also fulfilled the criteria for the antiphospholipid syndrome [12].

Lupus erythematosus. Anetoderma has occurred in association with systemic or chronic discoid lupus erythematosus, not always in relation to the lesions. Biopsy shows a focal loss of elastic tissue, and a perivascular infiltrate with prominent plasma cells [1,2]. Generalized elastolysis (cutis laxa) has also occurred [13]. Anetoderma is also associated with lupus profundus [14,15] and discoid lupus with hereditary complement (C2) deficiency [16].

Some cases of primary anetoderma have direct immunofluorescent findings similar to those of either chronic cutaneous or systemic lupus erythematosus, even though there may be no other features of lupus erythematosus [17,18].

No antibodies have been demonstrated against elastic fibres [18].

Other diseases [2]. Some of the other reported associations may be coincidental, but it is probable that many inflammatory diseases may occasionally be complicated by anetoderma. It has been reported in association with leprosy [19], urticaria pigmentosa [20], pityriasis versicolor [21], granuloma annulare [22], lymphoma [23] and other conditions. Localized anetoderma-like changes on histology have been reported in association with pilomatricoma [24], dermatofibroma [25] and hamartomatous congenital naevi [26]. Penicillamine-induced anetoderma has also been reported [27].

Localized anetoderma may occur in premature infants, possibly due to the application of transcutaneous oxygen monitoring devices [28,29].

Post-inflammatory elastolysis and cutis laxa, described in African children, may follow arthropod bites (p. 46.4).

Pathology [2,6]. During the early stages, the dermis is oedematous, and a lymphocytic infiltrate (predominantly helper T cells) surrounds the blood vessels and appendages

Fig. 46.12 Primary anetoderma. (Courtesy of Dr J. Ellis, Princess Margaret Hospital, Swindon, UK.)

[1,7]. Plasma cells and histiocytes, with some granuloma formation, may also be seen. Later, the oedema and perivascular infiltrate subside and elastic fibres become scanty. The persistence of fine, irregular or twisted elastic fibres is common. The dermal collagen may also be diminished, but the fragmentation and disappearance of elastic tissue is the essential change, beginning superficially in the subpapillary zone and extending downwards. Electron microscopy shows phagocytosis of elastic fibres by macrophages [30,31].

Clinical features [2]. This rare disorder occurs mainly in women aged 20–40 years, but is occasionally reported in younger and older patients of both sexes. It is perhaps more frequent in central Europe than elsewhere, which suggests a possible relationship to chronic atrophic acrodermatitis (due to *Borrelia* sp.) in some cases. In the most usual form, crops of round or oval, pink macules 0.5–1.0 cm in diameter develop on the trunk, thighs and upper arms, less commonly on the neck and face and rarely elsewhere. The scalp, palms and soles are usually spared. Each macule extends for a week or two to reach a size of 2–3 cm. Sometimes, there are larger plaques of erythema, and nodules have also been reported as a primary lesion [32]. Slowly, each lesion fades and flattens from the centre outwards to leave a macule of wrinkled, atrophic skin, which yields on pressure, admitting the finger through the surrounding ring of normal skin (Fig. 46.12). The colour varies from skin colour to grey, white or blue. The number of lesions varies widely, from less than five to 100 or more. The lesions remain unchanged throughout life, and new lesions often continue to develop for many years. If the lesions coalesce they form large atrophic areas, which are indistinguishable from acquired cutis laxa [2].

In some cases, the lesions are initially urticarial weals which, after a succession of exacerbations and remissions, perhaps continuing for many weeks, are succeeded by atrophy. They may become confluent, to cover large areas, especially at the roots of the limbs and on the neck.

Diagnosis. The white cicatricial lesions of 'white spot disease' (Chapter 56) around the base of the neck and shoulders should not be confused with anetoderma.

Histological examination establishes the diagnosis. Focal dermal hypoplasia and atrophic scars (e.g. following varicella) must also be considered.

Acquired cutis laxa is probably a variant of anetoderma.

The diagnosis of 'primary' anetoderma can be established only by excluding the presence of any of the diseases known to be associated with 'secondary' atrophy, e.g. perifollicular elastolysis (p. 46.20).

Treatment. Penicillin and the antifibrinolytic drug ε-aminocaproic acid have been advocated [33], but Venencie *et al.* [2] studied 16 patients and found no treatment was beneficial once the atrophy had developed. Colchicine may prevent some atrophic changes [34].

Acrodermatitis chronica atrophicans

SYN. CHRONIC ATROPHIC ACRODERMATITIS; LATE-PHASE LYME BORRELIOSIS

Definition. This is a late skin manifestation of Lyme borreliosis (Chapter 27). It is characterized by the insidious onset of painless, dull-red nodules or plaques on the extremities, which slowly extend centrifugally for several months or years, leaving central areas of atrophy.

Aetiology. The condition is due to infection with a spirochaete, *Borrelia burgdorferi sensu lato*, which is transmitted by ticks [1]. The disease occurs mainly in northern or central Europe, Italy and the Iberian Peninsula. Occasional cases occur in other parts of Europe and Africa, but it is very rare in the UK, America, Australia and Asia [2]. These geographical variations are related to different strains of the organism [3–5]. *Borrelia afzelii* is the predominant species associated with acrodermatitis chronica atrophicans. This species is transmitted by ticks in Western Europe, but is rare in the USA, where *Borrelia burgdorferi sensu stricto* predominates.

Pathology [6]. During the early stages, there is non-specific dermal oedema with perivascular inflammatory infiltration. Subsequently, the epidermis becomes atrophic and the epidermal appendages are destroyed. Beneath a subepidermal zone of degenerate connective tissue lies a dense, band-like infiltrate, predominantly consisting of lymphocytes, histiocytes and plasma cells. Ultimately, the infiltrate is reduced to narrow bands between collagen fibres. In some patients, scleroderma-like changes may develop [7,8]. *Borrelia afzelii* has been cultured from the atrophic skin [7] but culture is usually negative. *Borrelia afzelii* can be identified by polymerase chain reaction (PCR). The organism may be resistant to attack by the complement system and may lurk in immunologically protected areas such as fibroblasts and endothelial cells. Expression of cytokines, such as interferon-γ (IFN-γ), is impaired [9].

Clinical features [10]. Most cases occur in country dwellers between the ages of 30 and 60 years.

The onset is usually insidious, and constitutional symptoms are exceptional. Painless, dull-red or bluish red nodules or plaques, more or less infiltrated, develop on the feet or legs, and less often on the forearms and hands. The lesions themselves are typically painless, but there may be associated acral pain or paraesthesiae. Erythema chronicum migrans (Chapter 27) may have been present at the same site some years earlier. Extension to the trunk and the greater part of the body, including the face, is sometimes seen. Single or multiple lesions may be present. They slowly extend centrifugally, the active inflammatory stage persisting for months, years or even decades. Marginal extension may continue once the central areas have already entered the atrophic phase, in which the skin is smooth, hairless and tissue-paper-like, dull red, pigmented or poikilodermatous (Fig. 46.13).

Subcutaneous nodules may develop around the knees or elbows, and fibrous bands along the ulnar margin of the forearms. Gaiter-like sclerosis of the lower third of the legs, often accompanied by ulceration, is a further complication. Morphoea of the trunk and lichen sclerosus et atrophicus (both genital and extragenital) have also been reported as associated lesions [2,11], and it is interesting that *Borrelia* antibodies have been found in five of 10 patients with morphoea [12], although others have not confirmed this [13].

In some cases, involvement of the joint capsule or bone results in limitation of movement of the joints of the hands and feet, or of the shoulders.

Very rarely, squamous carcinoma has developed in the atrophic skin, and lymphoma has also been reported in the non-affected skin [14,15].

Other late syndromes of Lyme borreliosis (lymphocytoma, neurological, etc.) have been fully reviewed by Steere [1].

Diagnosis. The appearance of erythema chronicum migrans may be similar, but the evolution of the annular lesions establishes the differentiation. In the atrophic

Fig. 46.13 Atrophic skin of the knee in acrodermatitis chronica atrophicans. (Courtesy of Dr T. Robinson, University College Hospital, London, UK.)

stage, diagnosis is usually readily made, and can be confirmed histologically.

Immunoblotting, using *B. afzelii* flagellar antigen (41 kDa) is confirmatory [5]. Serology is used to confirm the diagnosis of Lyme disease, but false-negative and false-positive results are common. In chronic atrophic acrodermatitis, however, the antibody titre is very high. Serology may be positive on enzyme-linked immunosorbent assay (ELISA) but negative on immunoblotting, particularly in patients with neurological disease [16]. A high titre of antibodies may reflect occult central nervous system involvement, when the antibodies can also be demonstrated in colony-stimulating factor [17].

When it occurs on the lower legs, the condition can mimic venous insufficiency [18], with thick, cyanotic, itchy skin.

Treatment. Oral antibiotics should be given for 1 month, for example doxycycline or amoxicillin in standard doses [1]. The improvement occurs gradually, several weeks after the course of treatment, but there may be no response if treatment is delayed until atrophy has developed. If the antibody titre is high, or there are clinical features of systemic disease (e.g. neuroborreliosis), intravenous penicillin G, ceftriaxone or cefotaxime should be given for 3 weeks [17].

Local panatrophy

Definition and aetiology. Local panatrophy is a rare disorder involving partial or total loss of subcutaneous fat and atrophy of overlying skin, sometimes associated with atrophy or impaired growth of muscle or bone. A primary neurogenic disturbance has been postulated but not proved. The syndrome may represent the end result of more than one pathological process, but many cases may be due to a variant of morphoea.

The atrophic areas exhibit a reduced sympathetic response and aberrant production of non-esterified fatty acids after stimulation with norepinephrine (noradrenaline), and it has been suggested that there may be a primary abnormality of the sympathetic nervous system [1].

Two groups of cases can be differentiated.

1 *Panatrophy of Gower*: no scleroderma or other sclerotic process accompanies or follows the loss of subcutaneous tissue. Most cases have occurred in women, usually in the second to fourth decades.

2 *Sclerotic panatrophy*: either typical morphoea or similar

sclerotic change in dermal collagen precedes the atrophy [2].

Clinical features of the two groups are as follows.

Panatrophy of Gower [3]. Sharply defined areas of atrophy, irregular in size, shape and distribution, develop over a period of a few weeks, without preceding inflammatory stages. In each affected area, the subcutaneous tissue disappears and the overlying skin appears atrophic but is otherwise normal. There may be a single area of atrophy or two or more. In size they range from 2 to 20 cm across, and in shape they are very variable but are sometimes triangular or quadrangular. Most lesions have occurred on the back, buttocks, thighs or upper arms, but some have involved forearms or lower legs. The atrophy reaches its maximum extent within a few months and then remains unchanged indefinitely.

Sclerotic panatrophy. Atrophy of the subcutis, and sometimes of underlying muscle and bone, may follow clinically and histologically typical morphoea, especially when the process begins in childhood and involves a limb (Chapter 56).

Sclerotic panatrophy may also occur in the absence of morphoea. The sclerosis involves subcutaneous tissue and muscle, and dense, sclerotic, scar-like, linear bands develop along a limb, or encircle the trunk in a metameric distribution, or encircle a limb. These lesions have also usually occurred in childhood. They cease to progress after a few months and, although new areas may be involved, most lesions have been solitary.

It is possible that Gower's panatrophy and linear morphoea are at the ends of a continuous disease spectrum. The histology of linear morphoea reveals thickened bundles of collagen, which appear to be intact on B-scan ultrasound imaging [4].

In the differential diagnosis of panatrophy, the various forms of *panniculitis* must be excluded. The preceding inflammatory changes are the single most distinctive feature, but they are not always easy to distinguish.

Facial hemiatrophy

SYN. PARRY–ROMBERG SYNDROME

Definition and aetiology. Facial hemiatrophy is an atrophic dysplasia of the superficial facial tissues, but the underlying muscles, cartilage and bone may also be affected. The cause is unknown, but it may be a disorder of the sympathetic nervous system in some cases. Other cases have followed lupus panniculitis [5].

There is no evidence that it is usually genetically determined, but it appears to be hereditary in a few pedigrees. Some cases have been associated with syringomyelia, epilepsy or cerebrovascular disease, but in 90% of cases no such association is demonstrable. The sexes are equally affected.

Clinical features [6–8]. This rare disease usually starts within the first two decades. The first manifestation is usually increased or decreased pigmentation in irregular patches on cheeks, forehead or lower jaw. Occasionally, there may be premonitory muscle spasms or neuralgia. Progressive atrophy gradually develops in the affected sites, involving skin, subcutis, muscle and bone, and may extend in area—and sometimes in depth—for months or years with temporary remissions. The skin becomes dry, thin and atrophic, but may be scar-like and adherent in some areas. When the atrophy is fully developed, the contrast between the sunken, haggard, pigmented affected half of the face and the unaffected half is dramatic. The hair may be lost in the frontoparietal region on the affected side but is often normal; occasionally, localized canities is an early change. A variety of neurological signs have been reported, of which Horner's syndrome is the most frequent. Heterochromia of the iris has developed at the same time as the facial atrophy in about 5% of cases, and other ocular changes may also be present [9]. There can be ipsilateral cerebral atrophy [10].

The atrophy may remain limited both in extent and depth. It may be confined to the distribution of one division of the trigeminal nerve or involve the whole of the side of the face, sharply demarcated at the midline. Rarely, it may be bilateral, and very rarely may involve half the body, usually on the same side as the face but exceptionally the opposite side—crossed hemiatrophy. The atrophy may, in such cases, begin on the trunk or a limb and only later involve the face.

The degree of bone atrophy as established radiologically is usually much less than the clinical appearance suggests, and is severe only in some cases of early onset. In such cases, the cerebral cortex may also be affected, and contralateral epilepsy may result.

Scleroderma of the 'sabre-cut' paramedian form may be associated with some degree of facial hemiatrophy, especially if it begins early in life. However, it is a more superficial process than progressive facial hemiatrophy. The skin in scleroderma is bound down and adherent, and loss of hair and pigmentary changes are conspicuous. In progressive facial hemiatrophy, the skin may remain mobile and grossly normal. The two processes have been confused frequently in the literature, and may coexist [11].

Diagnosis. When the cutaneous involvement is early and conspicuous, the diagnosis presents few difficulties. Hypoplasia following radiotherapy given in infancy, perhaps in treatment of a naevus in the region of the temporomandibular joint, could cause confusion. If the skin changes are slight, or of later onset, physiological asymmetry, unilateral mandibular agenesis, hemihypertrophy

and atrophy secondary to facial paralysis must be excluded. Hemihypertrophy is always congenital. When the limbs are involved, infantile hemiplegia and lipodystrophy must also be considered.

Treatment. Plastic surgery using large buried pediculated flaps of dermis and fat, or silicone implants, offers some cosmetic benefit [5,11–13].

Scleroatrophic syndrome of Huriez

This autosomal dominant congenital syndrome is discussed in more detail in Chapter 34. It comprises a triad of diffuse scleroatrophy of the hands, mild palmoplantar keratoderma and hypoplastic nail changes [1–4]. Scleroatrophy is accentuated on the palms and fingers, which are tapered as in sclerodactyly; however, Huriez syndrome is congenital, and Raynaud's phenomenon is absent. The acral hyperkeratosis is associated with dry skin, resulting in painful fissures in winter months. Nail changes include prominent lunulae, elongated cuticles, longitudinal and transverse ridging, increased longitudinal curvature [5] and V-shaped notches [6]. Squamous carcinoma may develop in the scleroatrophic skin, sometimes as early as the third or fourth decades of life [1,6]; fatal metastases may occur [7].

Histology shows marked orthokeratosis, acanthosis with a prominent granular cell layer, and mild fibrosis of the upper and mid-dermis. Elastic fibres are reduced. Epidermal Langerhans' cells are reduced in number, perhaps contributing to the risk of malignant change [6].

Patients should be followed throughout life, with early excision of suspected malignancies. Acitretin reduces the painful hyperkeratosis [7] and could reduce the incidence of skin cancer.

Localized abdominal wall atrophy

Congenital cutis laxa (p. 46.18) may rarely be confined to an area such as the abdomen. There may be other associated defects, for example dysplasia of the abdominal muscles, deformity of the thorax or mediastinal hernia. This condition must be distinguished from *centrifugal abdominal lipodystrophy* (Chapter 55) and the *prune belly syndrome*, in which wrinkled abdominal skin due to underlying abdominal muscle deficiency is associated with malformation of the urogenital tract [1,2].

Poikiloderma

Poikiloderma is a descriptive term, often somewhat loosely applied. Atrophy, macular or reticulate pigmentation and telangiectasia are the essential features. Depigmentation, miliary lichenoid papules, fine scaling and small petechial haemorrhages are less constantly present.

Congenital poikiloderma

Poikiloderma may occur as an apparently primary abnormality in certain genetically determined syndromes, including the Rothmund–Thomson syndrome, dyskeratosis congenita (Chapter 12) and the Mendes da Costa syndrome (Chapter 34).

Several other syndromes have been described in which poikiloderma is a prominent feature [1].

Hereditary sclerosing poikiloderma of Weary [2]

This rare autosomal dominant syndrome was described in a large black family. Generalized poikiloderma, which developed in early childhood, was accompanied by sclerosis of the palms and soles, and linear hyperkeratotic and sclerotic bands developed in the flexures of the arms and legs.

Weary–Kindler syndrome

Hereditary acrokeratotic poikiloderma of Weary [1–3]. This autosomal dominant condition produces vesicopustules of the hands and feet, which start at the age of 1–3 months and resolve in childhood. There is also a widespread eczema, and the gradual appearance of poikiloderma, which persists into adult life. Keratotic papules develop in childhood on the hands, feet, knees and elbows, and these also persist indefinitely. Mucosal involvement is frequent. Histological examination shows an intraepidermal cleft [4].

Kindler syndrome [4,5]. This may be a variant of hereditary acrokeratotic poikiloderma [6], although acral blistering is present at birth. Poikiloderma is progressive, resulting in thin, wrinkled skin without surface markings. Cutaneous atrophy is most pronounced on the hands and feet. Photosensitivity is common and, like other cutaneous features, tends to improve with time. However, recurrent acral blisters have been described in a 46-year-old Japanese male [7]. Colloid bodies that show IgM deposition on direct immunofluorescence have been described [8]. Ultrastructural studies show separation of the sub-basal lamina. Activated fibroblasts are present in the subepidermal region, suggesting a transient mechanobullous dermatosis, and enabling distinction from epidermolysis bullosa [9]. Detailed immunohistochemical and ultrastructural analyses indicate that Kindler syndrome is not a variant of dystrophic epidermolysis bullosa [10]. Some cases have been reported which do not fit clearly into either Weary's or Kindler's syndromes [11].

Diffuse and macular atrophic dermatosis [12]

This rare condition is characterized by the presence from birth of generalized poikilodermatous changes that give the appearance of prematurely sun-damaged skin. The facies, hair and skeleton are normal. Biopsy shows thinning of the epidermis, with large hyaline bodies in the superficial dermal collagen, and these stain positively with periodic acid–Schiff (PAS) and elastin stains. Electron microscopy shows that these globular structures consist of microfibrillar material, and the adjacent fibroblasts may be degenerative.

Fig. 46.14 Poikiloderma in a prelymphomatous eruption. The patient eventually developed cutaneous T-cell lymphoma.

Degos–Touraine syndrome [13]

In this condition, incontinentia pigmenti is accompanied by poikiloderma of light-exposed areas, often with gastrointestinal symptoms. Both gastrointestinal and skin manifestations are said to disappear following treatment with diiodohydroxyquine. Small bullae on the extremities have been described, but the initial bullae appear on the face. Hyperpigmentation follows a chronic erythrodermatous phase.

Acquired poikiloderma

Poikiloderma may occur as a pattern of cutaneous response to injury by cold, heat or ionizing radiation [14]. So-called poikiloderma of Civatte (Chapter 39) is a similar reaction mediated by photosensitizing chemicals in cosmetics. Some inflammatory dermatoses, such as lichen planus, may also give rise to poikilodermatous changes.

Poikiloderma is also a feature of some inflammatory 'connective tissue' diseases, and is particularly characteristic of dermatomyositis. It is also seen in lupus erythematosus and rarely in systemic sclerosis. Poikiloderma occurs as a manifestation of some lymphomas, especially mycosis fungoides (Fig. 46.14).

Disorders of elastic fibres

The capacity of the skin to adapt to local or general changes in body size and contour, and to allow for movement of head and limbs and a wide range of facial expression, depends upon its tension, elasticity and tensile strength. These properties may be congenitally defective or modified by ageing or disease [1–5].

Tension. The tension of the skin—its resistance to deforming forces—is provided by abundant elastic fibres, and is reduced when they are defective or degenerate. Tension decreases with age.

Elasticity. The elasticity of the skin is the measure of its ability to resume its original shape after deforming forces have ceased to act. There is wide individual variation, but a tendency to decrease with age. Several diseases such as cutis laxa decrease cutaneous elasticity.

Tensile strength. The tensile strength of the skin is the degree to which it can be elongated before it tears. It is greatest in infancy and decreases with age, but is also abnormally low in diseases associated with collagen defects such as EDS and Cushing's syndrome [5].

Lax skin

Increased laxity of the skin due to ageing (accelerated by dermal photodegradation) is of course extremely common, but cutaneous laxity can occasionally be due to marked weight loss (especially after gross obesity) or can follow recovery from severe oedema. Less commonly, the skin may become lax due to localized or generalized defects in elastic tissue resulting from other causes, and these may be grouped as follows.

1 Generalized elastolysis (cutis laxa):
(a) congenital;
(b) associated with other inherited disorders (PXE, SCARF syndrome (*s*keletal abnormalities, *c*utis laxa, *c*raniostenosis, *a*mbiguous genitalia, *r*etardation and *f*acial abnormalities), de Barsy syndrome, geroderma osteodysplastica);
(c) acquired (numerous associated disorders, for example inflammatory skin disease, multiple myeloma, systemic lupus erythematosus, hypersensitivity reactions, complement deficiency, penicillamine therapy.)

2 Localized elastolysis:
(a) anetoderma—(i) primary; (ii) secondary to syphilis, tuberculosis, sarcoidosis, bacille Calmette–Guérin (BCG) vaccination, etc.; (iii) PECL (possibly due to insect bites);
(b) blepharochalasis;
(c) chronic atrophic acrodermatitis (due to *Borrelia*);
(d) granulomatous slack skin (due to lymphoma).

Generalized cutis laxa [1]

SYN. GENERALIZED ELASTOLYSIS; GENERALIZED ELASTORRHEXIS; GENERALIZED DERMATOCHALASIS

Definition. Cutis laxa is characterized clinically by lax, pendulous skin and histologically by loss of elastic tissue in the dermis. It is a heterogeneous condition, with several causes and associations, and it may be inherited or acquired.

Aetiology. Cutis laxa may be *inherited*, either as an autosomal dominant or autosomal recessive trait [2]. Occipital horn syndrome was originally described as X-linked recessive cutis laxa and subsequently EDS type IX, but is now classified with Menkes' syndrome as a condition in which secondary changes in connective tissue are caused by abnormal copper metabolism [3–5] (p. 46.40).

Cutis laxa may also be *acquired* following inflammatory skin disease [6], and it has occurred in babies born to women taking penicillamine [7]. An immunological pathogenesis has been suggested in some acquired cases because of the rare associations with drug hypersensitivity, complement deficiency, systemic lupus erythematosus and multiple myelomatosis [8–10]. Amyloidosis seems to provoke cutis laxa in some cases [11], and it is known that amyloid can coat elastic fibres [12,13].

Several studies suggest a biochemical defect in elastin in cutis laxa. In one patient, there was a greatly increased activity of a neutral protease which degraded tropoelastin [14]. In other cases, the production of elastin by skin fibroblasts was reduced, as measured by elastin messenger RNA (mRNA) and desmosine levels [15–17]. Mutations have been identified in the elastin gene in several patients with autosomal dominant cutis laxa [18,19] and recently in fibulin-5 (a microfibrillary protein) in the more severe, autosomal recessive form [20].

Pathology. The skin is of normal thickness, but the elastic fibres are sparse, short, fragmented and clumped, particularly in the upper dermis, and they show granular degeneration [15]. The elastic fibres are deficient in elastin but their microfibrils appear normal [4,17]. Similar changes in elastic fibres may occur in the lungs and aorta.

Various ultrastructural changes have been described, including separation of the elastin microfibrils from the amorphous matrix, the presence of a 'wood-grain' pattern and aggregation, fragmentation and clumping of the elastic fibres [6,17,21].

Clinical features. In this rare condition, the skin becomes inelastic and hangs in redundant folds. The face and neck are often affected, which produces a 'bloodhound' appearance of premature ageing. The internal elastic tissues may also be affected, and emphysema and cardiovascular abnormalities occur in some types.

Hereditary forms [22,23]

Various clinical types have been described [24,25]. In the *autosomal dominant* form, the skin changes may develop at any age but tend to present later than in the recessive form. Those presenting in adult life usually have no internal defects, and the life expectancy is normal [25]. When the condition presents in infancy there is intrauterine growth retardation, delayed fontanelle closure and ligamentous laxity [26]. The skin changes may be preceded by episodes of oedema, usually within the first 2 months of life, and the child may look aged by the end of the second year. Affected males may be impotent, with infantile genitalia and scanty body hair. Pulmonary emphysema due to a loss of elastic tissue in the lungs is common [2].

In the commoner, but more severe, *autosomal recessive* form there is a characteristic facies with downward slanting palpebral fissures, a broad flat nose, sagging cheeks and large ears. There are prominent skin folds around the knees, abdomen and thighs [25]. Herniae, diverticula, severe pulmonary emphysema and cor pulmonale are important complications. Dental caries, aortic aneurysm and osteoporosis may also occur. These children have a short lifespan.

The *de Barsey syndrome* is a rare type in which cutis laxa is accompanied by retarded psychomotor development and corneal clouding due to degeneration of the tunica elastica of the cornea [27–29]. Growth is retarded and there may be pseudoathetoid movements.

Congenital cutis laxa has also been associated with SCARF syndrome [30], osteoporosis [31] and geroderma osteodysplastica, which is characterized by skeletal abnormalities including joint hypermobility, wormian bones and osteoporosis [32].

Acquired forms [33]

Cutis laxa may rarely develop at any age following episodes of urticaria or angio-oedema, extensive inflammatory skin disease (such as systemic lupus erythematosus or erythema multiforme) or febrile illness. It may also follow hypersensitivity reactions such as penicillin allergy [18].

Cutis laxa has also been reported in association with complement deficiency, sarcoidosis, syphilis, multiple myeloma [8–10] and the Klippel–Trenaunay syndrome [4]. Focal elastolysis can also occur in association with lupus erythematosus [34] and severe rheumatoid arthritis [35].

There may be widespread, massive folds of lax skin, or the changes may be mild and confined to a limited area, in which case it cannot be distinguished from anetoderma. Purpura may follow slight trauma and fibrotic nodules may form over bony prominences. Organs other than the skin may also be involved. Emphysema, gastric fibromas and tracheobronchomegaly have been reported [36].

In acquired cutis laxa, dermal elastic tissue is markedly reduced, although collagen is normal. Fibroblasts express increased elastolytic activity (cathepsin G). Levels of serum α_1-antitrypsin and elastase inhibition are decreased [37].

Post-inflammatory elastolysis and cutis laxa also appears to develop as a distinctive syndrome in African children, with clinical features intermediate between anetoderma and cutis laxa [38] (p. 46.4). This condition might represent an unusual reaction to an arthropod bite, as the lesions are preceded by urticaria or multiple red papules, which slowly enlarge to form rings 2–10 cm in diameter.

Diagnosis. The diagnosis, which is suggested by finding loose skin that recoils only slowly after stretching, may be confirmed by histology.

In EDS, the skin is hyperextensible but not lax, and it recoils quickly. In PXE, the skin may be lax, but it is yellowish and the face is usually spared. It is distinguished histologically by the presence of calcification. There may be circumscribed folds of lax skin in neurofibromatosis, and loose folded skin may also occur in leprechaunism, Patterson syndrome, trisomy 18 and wrinkly skin syndrome, but these conditions are distinguished by their associated features.

In Costello's syndrome there is skin laxity with joint hyperextensibility, but the elastin fibres are normal under

both light and electron microscopy [39]. The other features of this rare syndrome include poor postnatal growth, developmental delay and a distinctive facies with macroglossia, bilateral ptosis, epicanthic folds and posterior rotation of the pinnae, with prominent helices and thickened lobes.

In severe actinic damage, there may be marked skin laxity due to damage to elastic fibres.

Treatment. Plastic surgery ('face-lift') may reduce the cosmetic disability. Investigations for emphysema are indicated, with referral to a pulmonary physician if necessary.

Perifollicular elastolysis

Anetoderma-like changes in a perifollicular distribution have been described in three women aged 30–40 years [1]. The lesions were small, grey–white, finely wrinkled, round or oval areas, each with a central hair follicle. Some exhibited a balloon-like bulge above the surface. They occurred on the upper trunk, neck, earlobes and arms. Histology showed a non-inflammatory perifollicular loss of elastin fibres, and it was suggested that the lesions might have been caused by an elastase-producing strain of *Staphylococcus epidermidis* [2]. Similar changes are more commonly seen in acne scars (Chapter 43) [3].

Granulomatous slack skin

This rare disease is characterized by the slow development of pendulous folds of lax erythematous skin, which on histological examination contains a dense granulomatous

Fig. 46.15 Blepharochalasis. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

dermal infiltrate, with destruction of dermal elastic tissue. It is now considered to be a type of lymphoma (Chapter 54).

Blepharochalasis [1–3]

Definition. Laxity of the eyelid skin due to a defect in the elastic tissue.

Aetiology. The cause is unknown. Most cases are sporadic, but some pedigrees show autosomal dominant inheritance. Some cases may be a localized form of post-inflammatory elastolysis, and in one patient, blepharochalasis followed angio-oedema [4].

Pathology [3]. In the early stages there may be a mild dermal lymphocytic infiltrate, and in the later stages the elastic tissue in the lids becomes decreased and fragmented. A recent case report described IgA deposition in the residual elastic fibres, implying that an immune mechanism may be involved [5].

Clinical features. Blepharochalasis is an uncommon condition that usually develops insidiously around the time of puberty. Repeated transient attacks of painless swelling of the eyelids lasting for 2 or 3 days are followed by laxity, atrophy, wrinkling and pigmentation, predominantly of the upper eyelids (Fig. 46.15). There may be multiple telangiectases. These changes produce an appearance of tiredness, debauchery or premature ageing.

Reduplication of the mucous membrane of the upper eyelid is associated with blepharochalasis in about 10% of cases, and this may make the eyelids appear thick.

Blepharochalasis is occasionally a manifestation of generalized cutis laxa, and it may form part of Ascher's syndrome (see below). Laxity of the eyelid skin also occurs in EDS but other features of this syndrome will also be present.

Diagnosis. The many other causes of eyelid swelling must be excluded (Chapter 64). Ptosis is easily distinguished because the skin appears normal.

Treatment. Plastic surgery can be performed, but the condition may recur [2].

5 Grasseger A, Romani N, Fritsch P *et al*. Immunoglobulin A (IgA) deposits in lesional skin of a patient with blepharochalasis. *Br J Dermatol* 1996; **135**: 791–5.

Ascher's syndrome

Ascher's syndrome is the association of blepharochalasis with progressive enlargement of the upper lip due to hypertrophy and inflammation of the labial salivary glands [1–4]. The lip feels soft and lobulated and there may be excessive salivation. In some cases, the accessory lachrymal glands are also affected, with increased thickness of the eyelids. Enlargement of the thyroid has also been reported.

Pseudoxanthoma elasticum

SYN. SYSTEMATIZED ELASTORRHEXIS; GRÖNBLAD–STRANDBERG SYNDROME

Definition. PXE is an inherited disorder characterized by generalized fragmentation and progressive calcification of elastic tissue in the dermis, blood vessels and Bruch's membrane of the eye. This leads to laxity of the skin, arterial insufficiency and retinal haemorrhage.

Aetiology. Until recently the basic defect was unknown. Because the pathology affects elastic fibres the genes responsible for elastin and microfibrillary proteins were initially studied, but linkage analysis excluded these early candidate genes [1,2]. Positional cloning identified candidate genes on chromosome 16p13.1 and mutations have subsequently been identified in the *MRP6/ABCC6* gene [3–5]. This is a member of the ATP-binding cassette (ABC) family and acts as a transmembrane transporter. Mutations in the gene affect transport of anionic peptides [6]. *ABCC6*

is expressed primarily, if not exclusively, in the liver and kidneys and absence of normal *ABCC6* may allow certain metabolic compounds to accumulate resulting in progressive calcification of elastic fibres. This suggests that PXE may in fact be a primary metabolic disorder with secondary involvement of elastic fibres [7]. It is not clear whether any genotype/phenotype correlation exists.

The inheritance of PXE has been controversial over the past few years, and historically at least five genetic groups have been described [8–10]. With molecular testing it is now apparent that most cases are autosomal recessive and no confirmed autosomal dominant form has yet been shown [7]. Clinical features of PXE can be seen in unambiguously identified heterozygous carriers, and this explains some earlier reports of different clinical types and modes of inheritance.

Pathology [11–17]. In the fully developed skin lesions, the elastic fibres in the mid-dermis are clumped, degenerate, fragmented and swollen, and the abnormal fibres stain positively for calcium. The collagen fibres are also abnormal, being split into small fibres.

Similar changes occur in the connective tissue of the media and intima of the blood vessels, Bruch's membrane of the eye, and in the endocardium and pericardium. The heart may occasionally be enlarged, with extensive calcification [18], and pulmonary calcification has been reported [19]. Calcification may occur in other viscera [20].

The vascular involvement may be generalized but may involve predominantly the larger arteries, the mesenteric and visceral arteries, or those of the extremities [21]. Calcification of the internal elastic lamina of the arteries leads to vascular occlusion. Hypertension, angina, myocardial infarction, cerebrovascular accidents and recurrent mucosal haemorrhages may result. The changes in Bruch's membrane give rise to angioid streaks, and rupture of the retinal vessels to haemorrhages and choroiditis.

The complete syndrome consists of the distinctive skin lesions, retinal changes (angioid streaks) and vascular disturbances. The characteristic skin changes and angioid streaks have also been reported as isolated findings, but this is unusual, and in patients with angioid streaks but no obvious skin abnormalities, a biopsy of normal-looking skin will often show histological changes in the elastic tissue [16]. The relative severity of the cutaneous, ocular and vascular changes determines the wide variations in the clinical picture.

Skin changes. The skin lesions are characteristic. They consist of small (1–3 mm), yellowish papules in a linear or reticular pattern, in confluent plaques, although the changes are sometimes very subtle. The skin is soft, lax and slightly wrinkled, and may hang in folds, especially in elderly people. There may be a slightly pebbly surface, which has been variously described as a 'cobblestone', 'Moroccan leather' or 'chicken skin' appearance (Fig. 46.16). The sites of predilection are the sides of the neck, below the clavicles, the axillae (Fig. 46.17), abdomen, groins, perineum and thighs. Reticulate pigmentation on the abdomen may occur [22]. Numerous acneiform lesions have been reported [23]. Although usually limited, the eruption may occasionally involve most of the body. It may develop in early childhood, and usually does so before the age of 30 years, but it may also first appear in

Fig. 46.16 Pseudoxanthoma elasticum, showing the typical 'chicken skin' appearance involving the neck.

Fig. 46.17 Pseudoxanthoma elasticum of the axilla, showing the characteristic yellow discoloration of the skin and the loose folds. The changes in this condition are often much more subtle than in this patient.

Fig. 46.18 Angioid streaks of the retina in pseudoxanthoma elasticum. (Courtesy of Professor D. Easty, Bristol Eye Hospital, Bristol, UK.)

old age. It usually persists unchanged indefinitely. Similar changes may occur in the soft palate, inside the lips and in the mucous membranes of stomach, rectum and vagina. In the mouth, the lesions may mimic sebaceous glands (Fordyce spots). Rarely, chronic granulomatous nodules have developed in the skin lesions [24].

Occasionally, there may be spontaneous perforating lesions, with transepidermal elimination of the fragmented elastic fibres. These present as hyperkeratotic papules, which leave a bleeding surface when dislodged.

Cardiovascular changes. The arteries throughout the body are affected. There may be intermittent claudication with diminished peripheral pulses, and there is accelerated atheroma, often with hypertension [25]. The circulatory disturbances are detectable by plethysmography or oscillometry, and angiography may show angiomatous malformations, aneurysmal dilatation, and narrowing or occlusion of peripheral or visceral arteries [26]. Signs of arterial degeneration may be seen by the age of 30 years, and death may result from cerebral haemorrhage, coronary occlusion or massive haemorrhage into the gut [27]. Cardiomyopathy has been reported [28,29].

Arterial involvement may not be clinically manifest until adult life, but intermittent claudication and angina have occurred in early childhood. Some patients, however, survive to old age.

Mitral valve prolapse occurs in about 5–8% of the normal population. In one series of 14 patients with PXE, 11 had mitral valve prolapse [30], but these individuals probably had an overlap with Marfanoid features [31].

Ocular changes. Angioid streaks [32,33] of the retina are seen as slate-grey, poorly defined streaks radiating from an incomplete greyish ring, surrounding the nerve head (Fig. 46.18). They are bilaterally symmetrical, and usually first appear between the ages of 20 and 40 years. There may be no impairment of vision, but progressive visual failure may occur, and haemorrhages and choroiditis occasionally result in total blindness.

Other associated ocular findings include small, raised, pearly white *drusen*, or punched-out atrophic areas in focal areas of dehiscence of Bruch's membrane [34]. There may also be speckled yellowish mottling at the posterior pole, and this change, which has been called 'leopard spotting', may antedate the angioid streaks [35]. About 50% of patients also have a random scattering of small, round pigment dots throughout the macula and optic nerve [36]. These may resemble a string of pearls in some cases, and they are best seen on fluorescein angiography.

Abnormal visibility of the choroidal vessels has been present in some apparently unaffected members of some families with PXE [37].

Obstetric risk. There is an increased risk of miscarriage in the first trimester, possibly related to failure of placental development [38], and abdominal striae develop during pregnancy in virtually all patients [39]. Opinions differ regarding the risk to the mother. Berde *et al.* [40] reviewed the literature and concluded that there was a serious risk of cardiovascular complications during pregnancy, but Viljoen *et al.* [39] reported 54 pregnancies in which there were no serious maternal complications. Subsequent reports also agree that whilst skin manifestations may worsen, the risks of pregnancy have been overstated [41].

Associated abnormalities. In most cases of PXE the serum calcium and phosphate levels are normal, but in a few patients the phosphate levels are increased, with mild hypercalcaemia and abnormalities of vitamin D metabolism [20,42]. The biochemical changes resemble those of tumoral calcinosis [43], although the clinical changes are those of PXE. This seems to be a distinctive rare type of PXE which may be associated with renal failure in other members of the family. Some of these patients also have systemic sclerosis [44].

Other patients have been reported with multiple calcified cutaneous nodules, with angioid streaks and hyperphosphataemia, but without pseudoxanthoma [45].

Skin changes of PXE and/or angioid streaks are occasionally seen in patients with osteitis deformans (Paget's disease). Pseudoxanthoma elasticum has also been reported in association with *osteoectasia*, which is characterized by dwarfism, bizarre radiographic changes and elevated serum alkaline phosphatase levels [46].

The development of both clinical and histopathological PXE-like changes, involving skin, eyes and vasculature, in sickle cell disease and β-thalassaemia has been well documented [47]. The abnormalities are most probably acquired and related to the consequences of the primary disease. The clinical features are of later onset and milder than in inherited PXE.

Table 46.1 Diagnostic criteria for pseudoxanthoma elasticum (PXE). (From Lebwohl *et al*. [17].)

Major criteria
1 Flexural yellow cobblestone lesions
2 Characteristic histological features of lesional skin, using elastic tissue and calcium stains (e.g. van Gieson and von Kossa)
3 Angioid streaks in the retina
Minor criteria
4 Characteristic histological changes in non-lesional skin
5 Family history of PXE in first-degree relatives

The typical features of PXE have been reported in a patient with true MFS but it is likely that this is a chance association [48].

Diagnosis. The clinical and histological changes of PXE are often distinctive, and the diagnosis is usually readily made when skin lesions are present. The disseminated form of dermatofibrosis lenticularis (Buschke–Ollendorff) can be clinically similar and juvenile elastoma, which is a feature of this condition, shows thickened elastic fibres on histology. If laxity of the involved skin is extreme, other forms of dermatochalasis must be excluded.

In cases without skin lesions, the diagnosis may be difficult and attempts have been made to establish diagnostic criteria [1,17]. These are summarized in Table 46.1. It should be suspected in obliterative arterial disease of early onset and in unexplained gastrointestinal haemorrhage. The presence of angioid streaks or mucosal lesions should be sought. A skin biopsy from the side of the neck may be helpful, even if there are no clinically evident changes, although the characteristic histological changes are not necessarily diagnostic [17]. Soft-tissue or vascular calcification may be detectable radiologically [49] and angiography may be helpful [26]. Ultrasound can detect early renal parenchymal calcification although its prognostic significance remains uncertain [50].

Definitive diagnosis is made by molecular analysis of the *ABCC6* gene. This also provides a means for prenatal and presymptomatic testing in families at risk for recurrence [7]. Emerging evidence also suggests that heterozygosity for an *ABCC6* mutation (*R1141X*) confers a fourfold risk of developing coronary artery disease [51].

Treatment. It is important that the condition is accurately diagnosed so that appropriate genetic advice may be given. The most important aspect of treatment is to ensure that complications from vascular involvement are prevented or dealt with speedily by the appropriate specialist. Ophthalmologists will recommend that the patient learns to use an Amsler grid in the early detection of visual loss. Patients should avoid any activity that might cause sudden increase in blood pressure or contact injury to the eyes. Laser photocoagulation may be helpful in preventing further retinal haemorrhage. Cardiovascular risks should be minimized with control of blood pressure and serum lipids, and avoidance of smoking. The cosmetic appearance of the skin lesions may be improved by plastic surgery. Restriction of dietary calcium has been tried with apparent benefit in some cases [43], but this treatment remains controversial.

Perforating PXE

Transepithelial elimination (TEE) of altered elastic fibres can occasionally occur in generalized hereditary forms of PXE (see above), but it can also occur as a localized acquired defect in patients who do not have the other features of PXE [1]. These localized lesions usually occur in the periumbilical area in obese, multiparous black women, and it is possible that this represents a response to repeated cutaneous stretching [2,3]. A similar lesion on the breast was reported in a patient undergoing haemodialysis [4].

Clinically, there is a well-demarcated, hyperpigmented plaque which slowly enlarges. The surface may be atrophic, grooved, fissured or verrucous, and compression of the edge of the lesion may produce a liquid discharge.

It seems likely that most cases previously described as perforating serpiginous elastosis in association with PXE were really examples of perforating PXE [5]. The histology of the two conditions is similar, but in perforating PXE there is TEE of altered basophilic, calcified, elastic fibres, which are short, fragmented, curled and predominantly in the mid-dermis, whereas in perforating serpiginous elastosis the fibres are abnormally large, non-calcified, eosinophilic and straight.

Pseudo-PXE

Skin changes which are virtually identical to those of PXE can rarely be produced by penicillamine, although the systemic features do not occur [1]. The skin changes can be explained by the known effect of penicillamine in inhibiting collagen and elastin cross-linking, with the production of vastly increased amounts of abnormal elastin in the dermis [2]. Transepidermal extrusion of elastin has been reported in this condition [3].

Saltpetre-induced disease mimicking PXE

A condition which resembles the skin changes of PXE clinically, histologically and ultrastructurally has been described in a group of elderly farmers, who years earlier had spread a fertilizer containing a mixture of various nitrates (Norwegian saltpetre) [4,5]. The patients developed cutaneous ulcers, which quickly healed to leave yellowish-white papules and plaques. None of the patients had a positive family history or other signs of PXE.

Williams–Beuren syndrome

The Williams–Beuren syndrome is a developmental disorder characterized by premature laxity of the skin, congenital heart disease (notably supravalvular aortic stenosis), metabolic abnormalities and dysmorphic facial features, which include baggy connective tissue around the eyes, full cheeks, prominent lips and dental malocclusion [1]. Delayed motor and perceptual development are sometimes masked by above-average language skills allied to a 'cocktail party' personality [2].

In situ hybridization techniques have revealed both inherited and new deletions at the elastin locus on chromosome 7 [3]. Multiorgan involvement occurs as a consequence of contiguous gene deletions and at least 14 genes may be involved [4]. An 'epidemic' of the Williams' syndrome was reported in the UK following the administration of excessive doses of vitamin D to prevent rickets in pregnant women [5]. Vitamin D is known to down-regulate elastin gene expression [6].

Linear focal elastosis

SYN. ELASTOTIC STRIAE

This condition is characterized by asymptomatic, yellow, linear bands arranged horizontally on the lower back [1–3]. Superficially, the lesions resemble striae distensae, but they are palpable rather than depressed and yellow rather than purplish or white. Although the two conditions are generally unrelated, linear focal elastosis has been reported adjacent to striae distensae in one case [4]. The condition was originally described in elderly males [1], although it has been reported in a young black male whose father was similarly affected [5]. It may be commoner than is suggested by the paucity of reports. Ultrastructural studies reveal active elastogenesis. The middle and lower dermal collagen is separated by bluish grey, fine, fibrillar material, which is composed of thin, wavy elastic fibres and fragmented elastic fibre bundles. The elastic fibres are near to, or even in contact with, fibroblasts [6], and elastogenesis may occur in response to local trauma, perhaps following the development of striae distensae [7].

Actinic elastosis

SYN. SOLAR ELASTOSIS

Definition. This is a degenerative change in the dermis caused by prolonged exposure to electromagnetic (usually solar) radiation. It is characterized clinically by yellowish discoloration and histologically by degeneration of elastic fibres.

Aetiology. Solar elastosis usually results from prolonged exposure to sunlight, but it can also result from infrared (IR) radiation [1,2]. It is related to the cumulative dose of radiation, as it is more common in older people, outdoor workers and in sunny climates. There is, however, considerable variation in susceptibility between individuals. Fair-skinned people are the worst affected, although the condition can occur in black people [3,4]. Severe elastosis may occur in photosensitized skin, for example in porphyria cutanea tarda. UVB wavelengths are the most likely to cause solar elastosis, although UVA and PUVA therapy can also accentuate it [5,6].

Ageing normal skin becomes atrophic, with fewer elastic fibres [3]. In contrast, sun-damaged ('photo-aged') skin exhibits hypertrophy of elastin tissue, secondary to a prolonged inflammatory process [7]. Skin on the back of the neck exposed to chronic UV radiation shows partially degranulated mast cells in close apposition to fibroblasts. Metalloproteases produced by mast cells and macrophages degrade skin collagen [8].

Pathology [9,10]. At an early stage, there is a perivenular lymphohistiocytic infiltrate, with degranulating mast cells [7,11]. The vessel walls become thickened due to deposition of a basement-membrane-like material [4]. The

elastic fibres of the upper and middle dermis then become curled and fibrillar to form thick, irregular masses [12]. At a later stage, the elastotic degeneration becomes more diffuse, forming long swollen bands of irregular texture, with finely granular elastin and dense microfibrillar masses. Actinic elastosis originates in elastic fibres rather than collagen, as shown by the findings that the abnormal fibres stain with antielastin antibody HB8, disappear with elastase but resist collagenase, and have a high desmosine content.

In the early stages of actinic elastosis, there is also an increase in collagen and in glycosaminoglycans, although ultimately the collagen decreases. Eventually, the fibrous network degenerates into an amorphous elastotic mass, and the dermal blood vessels become sparse and tortuous [3,4]. The increased dermal glycosaminoglycans are deposited on the elastotic material in the superficial dermis [13].

Clinical features. The condition is more common in later life. In temperate climates, it is rare before the fourth decade, but it starts earlier and is more severe in sunnier climates. The light-exposed areas are affected, particularly the forehead and the back of the neck. Mild degrees of elastosis may not be apparent until the skin is pinched up, when it may assume a wrinkled appearance. Elastosis is usually more advanced in the tissue than the clinical appearance would suggest.

The affected skin is diffusely thickened and yellowish (Fig. 46.19), and on the neck it may be divided by well-defined furrows into an irregular rhomboidal pattern (cutis rhomboidalis nuchae). There may also be more sharply marginated, thickened plaques on the face or neck. These are usually, but not always, symmetrical.

When the skin around the orbits is affected, it is often studded with numerous comedones, and this has been called the *Favre–Racouchot syndrome* (Fig. 46.20). Favre–Racouchot syndrome is usually confined to facial skin and is bilaterally symmetrical, but unilateral and circumscribed forms have been reported [14]. The term actinic-comedonal plaque has been suggested for similar lesions which can rarely occur on other parts of the body, such as the forearm [15,16].

Skin which is affected by actinic elastosis is likely to develop other signs of sun damage, including irregular pigmentation, wrinkling, scaling, solar keratoses and malignancy. This range of changes due to chronic sun damage has been called *dermatoheliosis* [17].

Actinic elastosis may also be complicated by actinic granuloma (see below).

Photodamage is markedly exacerbated in smokers [18].

Diagnosis. Plane xanthoma, PXE and colloid milium may sometimes cause confusion, but the combination of the clinical and histological features is distinctive.

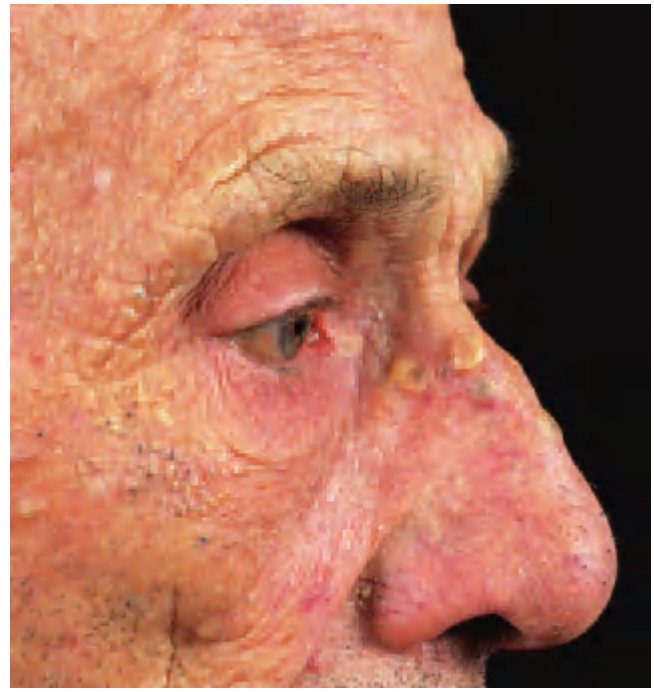

Fig. 46.20 Favre–Racouchot syndrome, showing comedones and actinic elastosis. (Courtesy of Professor R. Marks, St Vincent's Hospital, Melbourne, Victoria, Australia.)

Treatment. Sunscreens protect against the development of photodamage both in humans and animals [19]. In hairless mice exposed to UVB radiation, synthesis of subepidermal collagen has been demonstrated in animals protected with a sunscreen [20]. Topical application of α-hydroxy acids ('fruit acids'), i.e. lactic, glycolic and citric acids, led to a modest improvement in photodamaged skin [21]. More impressive results have been obtained with topically applied tretinoin cream [22,23]. A double-blind study [24] demonstrated a decrease in papillary dermal collagen type I in photodamaged skin, and subsequent treatment with 0.1% tretinoin cream for 10–12 months resulted in an 80% increase in dermal collagen. Several studies have shown clinical and histological improvement after prolonged use [19]. Tretinoin may also repair skin changes due to intrinsic ageing [24,25]. Similar results have been obtained in double-blind trials of topical isotretinoin [26] and tazarotene cream [27]. There has been interest in the use of so-called non-ablative lasers, including the 1320 nm Nd : YAG and 1540-nm erbium glass lasers, which are claimed to wound the upper dermis without epidermal damage [28].

Digital papular calcific elastosis

Digital papular calcific elastosis (DPCE) is an acquired papular eruption in which keratoderma is associated with changes in dermal connective tissue. Predominantly it affects the radial aspect of the index finger, first web space and ulnar aspect of the thumb [1]. Histologically there is hyperkeratosis, with sawtoothing of the rete ridges. The dermal collagen fibres are thickened and arranged haphazardly; there are basophilic elastotic masses, often containing calcium, in the upper reticular dermis. Cases are sporadic, unlike the clinically similar disorders acrokeratoelastoidosis and focal acral hyperkeratosis (Chapter 34) [2]. The distribution suggests photodamage; the condition has been reported entirely from geographical areas with high solar irradiation. Digital papular calcific elastosis has been regarded as a variant of actinic elastosis [3]. However, in DPCE, the elastotic process relatively spares the papillary dermis and the basophilic areas containing calcium differ from the changes in actinic elastosis. Squamous carcinoma has been reported, arising from the lesion [4].

Actinic granuloma

SYN. O'BRIEN'S GRANULOMA

Definition. This is an annular inflammatory reaction with a giant cell dermal infiltrate, which develops in an area

of actinic elastosis. Some authors feel that this is not a specific entity, and the changes could be a feature of granuloma annulare or some other granulomatous disease that happens to occur on light-exposed skin [1]. Others point out that a similar granulomatous reaction to elastotic material can occur in pinguecula of the eye [2]. A recent histopathological study supports histological distinction of the two conditions [3]. There is minimal or no lysozyme activity in the histiocytes in the inflammatory area of actinic granuloma, in contrast with those of granuloma annulare, which exhibit abundant lysozyme activity [4].

The condition is more common in sunny countries, and fair-skinned or freckled subjects are particularly susceptible. A similar condition has been described in dark-skinned people under the name of granuloma multiforme (Chapter 57).

Pathology [3–6]. A biopsy taken radially across the thickened edge of the lesion shows three distinct zones in the dermis. In the external 'normal' skin, there is actinic elastosis. In the thickened annulus, there is a histiocytic and giant cell inflammatory reaction in relation to elastotic fibres, and in the centre, within the annulus, little or no elastic tissue remains. The cellular infiltrate slowly expands outwards, leaving behind a central area from which elastic fibres have been removed by 'elastoclasis'.

The epidermis may be normal or it may show signs of actinic damage.

Clinical features. Lesions develop in the exposed 'weather-beaten' skin of patients after the third decade, particularly in fair-skinned or freckled subjects. They start insidiously as small, pink papules, which progress slowly to form an annulus of firm superficial dermal thickening. This is smooth, slightly raised and measures 0.2–0.5 cm in width. The ring may expand up to 6 cm in diameter. The centre may become slightly atrophic, and variable depigmentation may occur. The lesions are usually asymptomatic, but a sunburn reaction may provoke severe erythema and irritation.

Diagnosis. The condition must be distinguished from granuloma multiforme, granuloma annulare, serpiginous perforating elastosis, Miescher's disciform granuloma, sarcoidosis and necrobiosis lipoidica [7]. The lesions of actinic granuloma are confined to light-exposed skin, and the infiltrate lacks the tidy palisaded arrangement that is normally seen with granuloma annulare. Rarely, granuloma annulare can occur in an actinic distribution [8,9].

Treatment. Infiltration of the annular edge of the lesions with triamcinolone may be effective. Sunscreens should be used to prevent further damage.

Isotretinoin (0.5 mg/kg/day) arrested the development of lesions in an elderly male [10].

Elastofibroma [1–5]

Elastofibroma occurs predominantly in elderly women, and in most cases is situated beneath the lower angle of the scapula. The painless or slightly tender swelling, from 2 to 10 cm in diameter, is often discovered fortuitously. It may enlarge slowly, displacing neighbouring structures, and it can be clinically confused with a sarcoma. This is a benign lesion, however, despite the fact that it is poorly circumscribed. The growth is composed of mature fibrous tissue, containing fibres which stain as elastic fibres. The lesions may be solitary or multiple.

Histologically, the lesion contains abundant large elastic fibres, some broken into irregular masses, and large amounts of relatively acellular collagen. The elastic fibres are composed of true elastin surrounded by a large amount of hydrophilic material forming an orderly array of tubules [4]. It is generally regarded either as a type of reactive hyperplasia, or as a hamartoma. It is cured by simple excision.

Elastoderma

Elastoderma is a very rare condition which is due to excessive elastogenesis. A young woman developed a localized defect of the skin of one arm, which became pendulous and lax, but lost its elastic recoil. Histological

and biochemical investigation showed this was due to accumulation of excessive elastin, with derangement of elastin fibrillogenesis [1].

In a further case, clinically uninvolved skin showed thin elastic fibres on haematoxylin and eosin staining [2].

Marfan's syndrome

Definition. This is an autosomal dominant inherited disorder of connective tissue with variable clinical manifestations, both between and within families, and a prevalence of one in 5000–10 000 [1]. Up to 30% of cases are new mutations [2]. The full syndrome is characterized by aortic dilatation, ectopia lentis and skeletal abnormalities [3].

Aetiology. Mutations in the fibrillin-1 (*FBN1*) gene, located on chromosome 15q21.1, cause MFS [4]. Fibrillin is one component of the elastin-associated microfibrils, which are especially important in the ciliary zonule of the eye (the suspensory ligament of the lens). Patients with Marfan's syndrome (MFS) show a striking lack of fibrillin in their skin and on culture of their dermal fibroblasts [5,6]. Mutations in *FBN1* probably exert their effect by dominant-negative mechanisms, but recent studies also suggest altered susceptibility to proteases and disturbances of elastic fibre homeostasis [7].

Pathology. The cardiovascular lesions are the most important. Fragmentation and sparsity of elastic fibres, with accumulation of mucinous material, occur in the media of the aorta [8–10]. These changes lead to aortic incompetence, dissecting aneurysm, or rupture of the aorta [11]. Mitral incompetence is common [12]. Dermal elastic fibres are narrower than normal and more resistant to neutrophil elastase [13].

Clinical features [3,9,14,15]. Despite recent advances in mutation detection, the diagnosis of MFS is primarily clinical and relies on the Ghent nosology [3]. The full syndrome comprises skeletal, ocular and cardiovascular defects. The patient is often, but not invariably, exceptionally tall, but the skeletal proportions are abnormal. The extremities are long, the excess being greatest distally, giving rise to arachnodactyly, and the length of the hallux is often particularly conspicuous. The skull is dolichocephalic, the paranasal sinuses are large and the palate high and arched [16]. Lax capsules result in unstable or hyperextensible joints, kyphoscoliosis, pectus excavatum and flat foot. Muscles may be underdeveloped and hypotonic, and subcutaneous fat is sparse.

The common ocular abnormalities [17] include ectopia lentis (usually upward), a trembling iris, myopia and retinal detachment; less frequent are blue sclerotics and heterochromia of the iris.

Aneurysmal dilatation of the ascending aorta is the most important abnormality of the cardiovascular system, and aortic and mitral incompetence are common. Aortic dilatation may begin in childhood. Mitral valve prolapse occurs in 80% of cases [18].

Skin changes may be under-reported. Serpiginous perforating elastosis may occur [15]. In a recent study [19], striae atrophicae were observed in 7% of children and 35% of adults. Other features include papyraceous scars and skin hyperextensibility [20]. Several patients have been described with concomitant EDS and MFS [21].

Other abnormalities are frequent—nerve deafness occurs in 6%; pulmonary malformations are often reported at autopsy; renal abnormalities are manifest as proteinuria and raised blood urea [14].

The prognosis is related to the severity of the cardiac defects, the localization and progression of which are dependent on haemodynamic stresses [9,22]. Survival beyond the fifth decade is unusual, and some cases die in childhood. The average age at which dissection of the aorta develops is 30 years. Early death from cardiovascular disease may occur, even in apparently mild cases, and the correlation between cardiac and skeletal problems is poor [23–25].

Diagnosis [3,26]. The full syndrome is unmistakable, but diagnostic certainty is impossible in the partial forms. Clinical features are divided into major and minor according to their specificity. To make a diagnosis major criteria must be present in two organs and involvement in a third is required [3].

Simple screening tests that may be helpful include the thumb sign (positive if the thumb when completely opposed in the clenched hand projects beyond the ulnar border), the wrist sign (positive if the thumb and little finger overlap when wrapped around the opposite wrist) and the ratio of the lower segment (pubic ramus to floor) to the upper segment (height minus lower segment), but this ratio varies with age and sex.

Some tall people have high, arched palates and some degree of arachnodactyly. This is probably of no consequence in many cases, although a marfanoid habitus in women may be associated with mitral valve prolapse [18,27].

Joint hypermobility may also be associated with mitral valve prolapse [28]. Other causes of joint hypermobility, such as homocystinuria, may be confused with the partial forms of the syndrome. Homocystinuria should be considered in marfanoid patients with myopia or downward ectopia lentis. Urine screening is unreliable; blood levels of methionine and homocysteine should be measured. Prompt diagnosis and treatment reduce the risk of coronary artery or cerebrovascular thrombosis [29].

The marfanoid habitus has been reported in association with distal pigmentation, neuroma of the eyelids and tongue, medullary carcinoma of the thyroid and phaeochromocytoma [30] (see also multiple endocrine neoplasm syndrome (Chapter 59)).

Congenital contractural arachnodactyly is another fibrillinopathy, which is caused by mutations of the fibrillin-2 gene [31]. It is primarily an orthopaedic condition unrelated to MFS [32,33]. It produces multiple joint contractures, arachnodactyly, kyphoscoliosis, distorted pinnae and dolichostenomelia (long, thin limbs), but there are no cardiovascular complications.

Management [26]. Patients should be seen by an ophthalmologist and an orthopaedic surgeon, and they should be reviewed regularly by a cardiologist. Beta-blockers may be used to retard the development of aortic dilatation, and surgical replacement before the diameter exceeds 5.5–6.0 cm is recommended [10,34].

Oestrogen therapy has been used to prevent excessive stature in female patients [35].

Pregnancy is inadvisable, because of the 50% risk of inheritance in the fetus, and because of the risk of acceleration of aortic degeneration and vascular rupture. A pregnant patient with no cardiac signs needs monthly checks from the third month. Those with aortic or mitral valvular disease or dilatation of the aortic root are at high risk during pregnancy [36,37].

The majority of *FBN1* mutations are unique to one affected individual or family, but despite this and the presence of sporadic cases, prenatal and preimplantation diagnosis is feasible [2].

Disorders of collagen

Ehlers–Danlos syndrome

SYN. CUTIS HYPERELASTICA

Definition. EDS is a heterogeneous group of inherited disorders of connective tissue. Estimates of its prevalence vary between 1 : 560 000 and 1 : 5000 [1]. For many

patients the symptoms are so mild that they may not be recognized. The hallmarks of EDS are fragility of the skin and blood vessels, hyperextensibility of the skin, and joint hypermobility [2]. The original classification divided EDS into 11 clinical types; however, in 1986, the International Nosology of Heritable Disorders of Connective Tissue redefined EDS into subtypes I–VIII and X [3]. It is now clear that certain phenotypic subtypes (EDS types I and II) overlap and some patients do not fit neatly into one category. Progress in molecular biology has been rapid in recent years, enabling further subdivision of some types [4].

Aetiology. Specific molecular and biochemical abnormalities have been identified in several types (see Table 46.2) [5,6]. Attempts should be made to delineate the clinical, biochemical and, if possible, molecular abnormalities in a patient with EDS in view of the widely differing prognosis between different types. Defects predominantly involve collagen, although a fibronectin defect has been reported in type X [7], and more recently mutations in tenascin-X have been found to cause a newly recognized autosomal recessive form of EDS.

Pathology [8,9]. Skin histology is variable and often within normal limits. Typically, there is a loose, disordered dermal collagen network. Elastic fibres are usually increased and orientated irregularly. The 'pseudotumours' seen in type I EDS consist of fat and mucoid material in fibrous capsules; they may be calcified. Bone mineralization is decreased, and the collagen fibres are irregular. Adventitial defects of small arteries and inadequate support from the surrounding connective tissue account for the vascular vulnerability in vascular EDS (type IV) [10,11]. Although bruising can be explained on the basis of skin and blood vessel fragility, a few patients also exhibit both ultrastructural and functional platelet defects [12,13]. Clotting factor deficiencies have been only rarely reported. Electron microscopy of dermal collagen consistently shows irregularities of fibril shape and size, although reliable subclassification of the more common subtypes is not possible [14]. By contrast, arthrochalasia type EDS is characterized by angular fibrils in cross-section, and dermatosparaxis by grossly distorted, hieroglyphic fibrils. Biomechanical studies confirm increased skin elasticity and hyperextensibility, particularly in classical EDS (type I) [15,16].

Clinical features. These are summarized in Table 46.2. The india-rubber men and circus contortionists who are affected by EDS turn the syndrome to their advantage. More details are given in the accounts of each type.

Classical type (EDS I/II)

This subgroup, which is inherited as an autosomal dominant, includes both EDS type I (gravis) and II (mitis).

Pathology. Histology may be within normal limits; alternatively there may be thin, weakly polarized, dermal collagen bundles. Elastic fibres may be irregular and relatively increased [8,9]. At ultrastructural level, collagen bundles are of variable size with abnormally large, composite 'cauliflower' fibrils, reflecting abnormal fibrilogenesis [14,17,18]. Linkage to *COL5A1* was originally identified in a British family with EDS II, and analysis of further families subsequently showed that EDS I and II are allelic [19,20]. Up to half of all classical EDS patients have mutations in *COL5A1* or *COL5A2*, which encode the α_1 and α_2 chains of type V collagen, respectively. Although quantitatively minor (approximately 2–5% of dermal collagen), collagen V plays an important role in the regulation of type I collagen diameter [21]. Missense and exon skipping mutations with dominant-negative effects or mutations giving rise to haploinsufficiency may occur [22,23]. Genetic heterogeneity is apparent with reports of classical EDS caused by a mutation in the collagen I gene [24]. Furthermore, knock-out experiments with mice suggest other extracellular matrix components such as decorin, fibromodulin, thrombospondin-2, lumican and biglycan may be important [25,26].

Clinical features. The skin is soft, velvety and hyperextensible (Fig. 46.21) but retains its normal recoil. The skin on the palms and soles may be redundant, like a loose glove. The skin is not usually otherwise lax until later in life, when redundant folds occur on the eyelids (blepharochalasis), face and limbs. Secondary cutis laxa has been described on the lower back of a patient with mild classical EDS [27]. Striae do not develop during pregnancy. Trivial lacerations form gaping wounds that heal very slowly to leave broad, atrophic 'cigarette paper' scars (Figs 46.22 & 46.23). Sutures may tear out repeatedly. Blue-grey, spongy tumours (molluscoid pseudotumours), due to accumulation of connective tissue, may form on the skin, especially in scars or over pressure points. Smaller, firm, subcutaneous nodules (spheroids), which show calcification on X-ray develop on the shins and forearms in up to a third of patients.

Easy bruising may be the presenting symptom, and pigmentation due to haemosiderin deposition is often found on areas of repeated trauma.

The facies may be distinctive, with widely spaced eyes, a wide nasal bridge, and epicanthic folds. The sclerae are sometimes blue.

There is marked joint hypermobility, which can impair walking, especially during pregnancy. Subluxation of the large joints may occur, and genu recurvatum and kyphoscoliosis are frequent [28]. Muscle tone is often poor, and hernias develop. Pedal piezogenic papules are seen more frequently. Diaphragmatic eventration and gastric torsion have been reported [29]. Symptomatic bladder diverticula may develop [30]. Varicose veins may develop in

Table 46.2 Clinical and molecular subtypes of Ehlers–Danlos syndrome.

EDS type	Synomym	Villefranche classification*	Mode of inheritance	Clinical features	Ultrastructural findings	Molecular defect
I II	Gravis Mitis	Classical	AD	Soft, velvety, hyperextensible skin; easy bruising; atrophic scars; hypermobile joints; pseudotumours	'Cauliflower' fibrils	*COL5A1* & *COL5A2* (& *COL1A1*) mutations
III	Hypermobile	Hypermobility	AD	Hypermobile joints; minimal skin abnormality	As above	?
IV	Acrogeric or ecchymotic	Vascular	AD	Thin skin; easy bruising; small joint hypermobility; vascular and bowel ruptures	Small variable fibrils	*COL3A1* mutations
V	X-linked	Other form	XLR	Resembles mild classical type; bruising more pronounced	–	?
VI	Ocular-scoliotic	Kyphoscoliosis	AR	Soft, hyperextensible skin; hypermobile joints; scoliosis; ocular fragility; keratoconus	Small collagen bundles; fibrils normal or similar to classical type	Lysyl hydroxylase mutations
VIIA, B	Arthrochalasis multiplex congenita	Arthrochalasis	AD	Floppy infant; congenital hip dislocation; hypermobile joints; soft skin; normal scarring; short stature	Angular fibrils	A & B: *COL1A1* & *COL1A2* mutations, respectively, result in loss of exon 6 (Procollagen *N*-proteinase/*ADAMTS2* cleavage site)
VIIC	Dermatosparaxis	Dermatosparaxis	AR	Markedly hypermobile joints; very soft and extremely fragile skin; easy bruising	Hieroglyphic fibrils	Procollagen *N*-proteinase (*ADAMTS2*) mutations
VIII	Periodontal	Other form	AD	Severe periodontitis; pigmented pretibial plaques and scarring	Small fibrils in some patients	Occasionally collagen III deficient
X	Fibronectin	Other form	AR	Similar to mild classical type	Large, irregular fibrils	Fibronectin deficiency abnormality
–	Progeroid	Other form	AR	Atrophic scars; lax skin and joints; aged appearance; short stature; osteopenia; mental retardation	–	*XGPT1* mutations
–	Tenascin-X	–	AR	Similar to mild classical type but no scarring	Normal fibrils but reduced density	Tenascin-X mutations

* The Villefranche classification simplifies EDS into six major types. The other types have been provisionally grouped under 'other forms' until more is known about their molecular basis.
AD, autosomal dominant; AR, autosomal recessive; EDS, Ehlers–Danlos syndrome; XLR, X-linked recessive.

Fig. 46.21 Cutaneous hyperextensibililty in classical Ehlers–Danlos syndrome.

Fig. 46.22 Atrophic scarring of the elbow in classical Ehlers–Danlos syndrome.

Fig. 46.23 Scarring of the forehead in classical Ehlers–Danlos syndrome.

early life. Prematurity due to ruptured fetal membranes is common.

As physical and mental development are normal, life expectancy is not reduced, hence large family pedigrees are not unusual. A mild variant of classical EDS has been described in 9% of a general dermatology population less than 50 years old, and merges with benign hypermobility syndrome and the normal spectrum [31]. A simple clinical scoring system, based on an assessment of joint hypermobility, skin extensibility and bruising might be useful in predicting which members of the general population are likely to produce poor scars following cutaneous surgery [32].

Hypermobility type (EDS III)

Hypermobile EDS and benign joint hypermobility syndrome (BJHS) are autosomal dominant and considered by some authors to be the same disorder. Revised criteria have been proposed for their diagnosis [33]. The Beighton score is a useful, quick method for assessing global joint hypermobility, and an adult score of four or more out of nine either currently or historically is considered hypermobile [34]. The genetic defect is not known but ultimately molecular analysis will determine whether these two groups are genetically heterogeneous. There is one report of a family with hypermobile EDS phenotype due to collagen III deficiency, as occurs in vascular EDS [35]. The ultrastructural changes resemble those in classical EDS. The skin is only minimally affected by scarring and hyperextensibility, whereas joint mobility is markedly increased, and dislocation and joint pains are common [36,37]. A study of a small number of hypermobile patients showed they were resistant to the effects of intradermal or topical local anaesthetic compared with BJHS patients or controls, suggesting that the disorders are distinct [38]. However, the criteria used to diagnose the hypermobile group were not clearly documented. In the authors' experience, patients with classical EDS may also be resistant to local anaesthetic.

Vascular type (EDS IV)

This very severe form is inherited as an autosomal dominant. Cases previously reported as autosomal recessive inheritance were probably due to sporadic mutations [39–41]. It is rare, the prevalence being between one in 10^5 and one in 10^6 [39].

Pathology. The condition is characterized by an abnormality of the synthesis, secretion or structure of type III collagen due to an abnormality of the collagen III gene (*COL3A1*) [6,42]. Segregation studies using polymorphic restriction sites in the gene may be of use in prenatal diagnosis [43]. The syndrome is biochemically heterogeneous

[5]. Several changes have been reported, the most common of which are point mutations (substituting other amino acids for glycine residues in the triple helical domain). Exon-skipping mutations are nearly as common; small genomic deletions within one exon and multiexon deletions have also been described [5,6,44]. It has been suggested that the region of the type III collagen molecule where mutation occurs may be linked with the clinical severity [6], although this has not been found in other studies [44].

These abnormalities all result in abnormal structure, synthesis or secretion of type III procollagen. Often, the skin is reduced to 25% of normal thickness, with small collagen fibre bundles. Fibril diameter is markedly variable in some patients [45]. In many patients, the fibroblasts contain prominent rough endoplasmic reticulum containing abnormal type III procollagen [45,46]. Cell strains from other individuals show markedly reduced extracellular accumulation of procollagen and collagen but without intracellular accumulation, perhaps due to rapid degradation of mutant chains [47]. Bizarre elastic fibres are often abundant.

The condition affects tissues rich in type III collagen, notably arterial media, bowel and uterus. Interestingly, type III collagen production by fibroblasts is decreased in some patients with ruptured cerebral aneurysm, even though they have no other stigmata of EDS [48]. The collagen deficiency in these patients does not appear to arise from *COL3A1* mutations, but may relate to abnormal post-translational modification or altered collagen metabolism [49].

Clinical features. The major clinical features are spontaneous rupture of large arteries, colon and gravid uterus. Dissecting aortic aneurysm is a common cause of sudden death [50]. Spontaneous carotid–cavernous fistula can also occur, resulting in unilateral exophthalmos [51]; it may respond to surgical repair or embolization [52]. Repair of rupture of the colon (usually sigmoid) is complicated by tissue friability and peritoneal contamination [53]. In one series complications of pregnancy led to death in the peripartum period in 12 of 81 women who had a total of 183 pregnancies [44]. Seven died following vessel rupture and five following uterine rupture.

Other features include prematurity (due to rupture of friable placental membranes), low birth weight, short stature, easy bruising (which may lead to the mistaken accusation of child abuse) [54] and pneumothorax [55,56]. Elastosis perforans serpiginosa is seen more commonly in this EDS subtype.

Two phenotypic groups are recognizable. In the *acrogeric* type, individuals appear prematurely aged with thin, translucent, fragile skin (Fig. 46.24), a hollow-eyed appearance, thin, peaked nose and thin lips. Easy bruising predominates in the *ecchymotic* type, often falsely suggesting a primary disorder of coagulation [13]. Unlike other forms of EDS, the skin is not hyperextensible, and joint hypermobility is chiefly restricted to the small joints of the hands and feet. Surface veins are usually readily visible. There is a tendency to form keloid scars.

Fig. 46.24 Cutaneous atrophy in vascular (acrogeric) Ehlers–Danlos syndrome.

The largest case series to date of 220 index cases of vascular EDS patients and 199 affected relatives showed the median survival as 48 years, with 25% of index cases having their first significant complication by 20 years [44]. Most deaths follow arterial dissection or rupture, mainly of the thoracic and abdominal vessels. Milder variants may occur, presenting with cardiac features in later life [57].

X-linked type (EDS V)

Two families have been described as type V EDS. Clinically, it resembles mild classical EDS, but bruising is more marked. However, it is distinguished by X-linked inheritance [58]. The biochemical defect is unknown, and skin collagen cross-links are normal [59]. Lysyl oxidase activity has been reported to be reduced in one family [60], but these patients appear to form a clinically distinct subgroup. In other families, the lysyl oxidase levels have been normal [59]. Until a precise genetic or biochemical abnormality is found, the status of this type must remain in question [5].

Kyphoscoliosis type (EDS VI; ocular-scoliotic)

This autosomal recessive condition was the first true disorder of collagen structure to be described [61–63]. The biochemical abnormality in most, but not all, patients, is a deficiency of lysyl hydroxylase [62]. Different mutations in the lysyl hydroxylase gene (*PLOD*) have been identified in unrelated families. One is homozygous for a stop codon at residue 319 (R319X) [64]. In another, duplication of 180 base pairs in the coding sequence of the complementary DNA resulted in decreased enzyme function [65], and a further family revealed a compound heterozygote

combining a 3-bp deletion and an amino acid substitution (G678A) [66].

Deficiency of the enzyme leads to reduced hydroxylation of lysyl residues in types I and III collagen in skin; hydroxylysine-containing cross-links are not formed [67]. Lysine-derived cross-links appear not to be as stable as those derived from hydroxylysine; the former do not mature as rapidly to stable intermolecular cross-links [68]. Types II, IV and V collagens are hydroxylated normally, which suggests that there may be different isoenzymes or different affinities of a single enzyme for specific collagen types [5]. Detection of abnormal pyridinoline cross-links in urine can be used as a diagnostic aid [69].

Clinical features include soft, velvety, hyperextensible skin and increased joint mobility. Scoliosis is common. Eye manifestations include microcornea, glaucoma, keratoconus and ocular fragility. Some patients have a marfanoid habitus. Bleeding may occur from major wounds, and there may be delayed motor development [70].

The kyphoscoliotic type of EDS appears to be rare, with less than two dozen cases reported in the literature [5]. Because it is inherited recessively, after the birth of an affected child there is a 25% risk of recurrence in each successive pregnancy. Measurement of lysyl hydroxylase activity in amniotic fluid enabled the prediction of a phenotypically normal heterozygous infant in a family at risk [71].

Some patients respond to treatment with ascorbic acid, which regulates collagen biosynthesis [72].

Arthrochalasia type (EDS VIIA and B; arthrochalasis multiplex congenita)

This rare autosomal dominant condition, like OI, results from mutations causing defects in type I collagen. Phenotypic overlap therefore occurs.

All or part of exon 6 of the *COL1A1* or *COL1A2* gene is deleted in types A and B, respectively, resulting in a defect in the cleavage sites of the substrate pro-α_1(I) or pro-α_2(I) chains [73–77]. Mutations appear to affect cross-link formation, decreasing tensile strength of tissues rich in type I collagen. Partially processed molecules accumulate in the dermis and other tissues, where they interfere with tissue function without much effect on fibrillar organization [73,77].

Arthrochalasis is characterized clinically by extreme joint hypermobility and multiple dislocations affecting both large and small joints [27]. Bilateral hip dislocation presents a major surgical problem. Some individuals have a short stature. There may be a chubby facial appearance due to lax facial tissues, and a depressed nasal bridge [77].

Dermatosparaxis type (EDS VIIC)

This very rare autosomal recessive form is characterized by extreme skin fragility (Fig. 46.25), bruising, droopy skin, joint laxity, umbilical hernia and blue sclerae [78–81]. The condition is akin to dermatosparaxis, a disorder causing fragile skin in animals [82,83]. It is caused by homozygous mutations in the gene encoding procollagen I *N*-terminal peptidase (*ADAMTS2*); the enzyme that excises the *N*-propeptide of type I and II procollagens [84]. Collagen fibrils from affected children and animals are small, with a bizarre hieroglyphic-like appearance in cross-section; they are ribbon-like in longitudinal section [5].

Fig. 46.25 Extreme cutaneous fragility and laxity in dermatosparaxis.

Fig. 46.26 Premature periodontal recession in periodontitis type Ehlers–Danlos syndrome (VIII).

Periodontitis type (EDS VIII)

This type has features similar to classical EDS but there is often only moderate small-joint hypermobility. The distinguishing clinical features are premature periodontal recession (Fig. 46.26), resulting in loss of teeth by the third decade, and heavily pigmented, pretibial plaques (Fig. 46.27) [85,86]. It is inherited as an autosomal dominant. Little is known about the biochemical defect,

Fig. 46.27 Pigmented pretibial plaques in periodontitis type Ehlers–Danlos syndrome (VIII).

although there is a reduced proportion of type III collagen in skin [87]. Some patients have small collagen fibrils [86].

EDS IX (occipital horn syndrome)

This is an X-linked recessive disorder allelic to Menkes' syndrome and is no longer considered a variant of EDS [3]. It was formely known as X-linked cutis laxa or 'occipital horn syndrome' and has been reclassified as a disorder of copper transport (p. 46.40).

Fibronectin-deficient type (EDS X)

Only one family has been identified to date with this autosomal recessive disorder. Skin and joint changes are mild, but bruising occurs readily due to defective platelet aggregation [7]. This defect is reversed *in vitro* by adding purified fibronectin to the assay. Some patients have composite fibrils in the dermal collagen, possibly due to a defect in fibronectin interactions [88].

Progeroid EDS

A rare association of EDS with progeroid facies, short stature, osteopenia and mental retardation is recognized [89]. Patients lack the full phenotype of progeria (p. 46.59) and do not fit in to the more well-defined progeroid syndromes. Galactosyltransferase I activity is reduced in patients' fibroblasts due to mutations in the *XGPT1* gene [90]. This enzyme is involved in the synthesis of glycosaminoglycans, suggesting that they may be involved in the process of senescence. The phenotype of decorin/biglycan double knock-out mice is similar to human progeroid EDS and occurs as the result of impaired binding of glycosaminoglycans to decorin and biglycan [25].

Tenascin-X-deficient type EDS

Tenascin-X deficiency causes a recently identified, clinically distinct, autosomal recessive form of EDS [91]. Patients have hyperextensible skin, bruising and joint laxity, but no scarring. The gene for tenascin-X overlaps the steroid 21-hydroxylase gene, and it was originally identified as a candidate gene for EDS in a patient with a contiguous-gene deletion giving rise to both 21-hydroxylase deficiency and EDS [92]. Tenascin-X is the first EDS gene that does not encode a fibrillar collagen or collagen-modifying enzyme. It is a large extracellular matrix protein that appears to be an essential regulator of collagen deposition by dermal fibroblasts [93].

Associated syndromes

Various unclassified forms of EDS overlap with other disorders, such as OI, PXE, MFS [94], renal tubular acidosis and medullary sponge kidney [95], and osteolysis of the terminal phalanges.

Diagnosis

The diagnosis is mainly clinical; a scoring system may be helpful in doubtful cases [96]. Confirmation of the subtype can require a combination of electron microscopy of dermal collagens, protein chemistry analysis from cultured fibroblasts and mutation detection. Immunofluorescent staining of fibroblasts for retained type III collagen may be a faster and cheaper method for the diagnosis of the important type IV EDS [97]. Similarly, the finding of reduced type III procollagen aminopropeptide in the serum of some, but not all, patients with EDS IV may help diagnosis [98]. Chorionic villus sampling may enable prenatal diagnosis of abnormalities of type I (and II) collagen [99]. Measurement of the ratio of urinary lysyl and hydroxylysyl pyridinolines is a non-invasive reliable diagnostic test for kyphoscoliosis type EDS [69].

EDS should be distinguished from cutis laxa, in which the skin hangs in flaccid redundant folds. In EDS, redundant skin folds may develop in late adult life, but they are usually limited to the elbows and the skin around the eyes. Hyperelastic skin is a feature of Turner's syndrome (Chapter 12), but the dwarfism, cubitus valgus and webbed neck are distinctive. Hyperelastic skin with abnormal elastic fibres in the papillary dermis has been reported in the rare cartilage–hair hypoplasia syndrome [100].

Treatment

All patients should receive genetic counselling. Treatment is highly unsatisfactory, although some features of EDS VI may respond to oral ascorbic acid [71]. Patients with type IV EDS should be advised to avoid pregnancy and trauma, including physical contact sports, and to avoid activities, such as trumpet playing, which raise intracranial pressure by the Valsalva effect. Bleeding should be managed conservatively if at all possible. The fragility of blood vessels makes arteriography and surgical procedures dangerous and difficult. Surgeons must be made aware of the patient's diagnosis prior to surgery. Sutures should be buttressed, and tension avoided. Although re-excision of ugly scars can give a good cosmetic result it is not generally recommended [101].

Occipital horn syndrome

SYN. X-LINKED CUTIS LAXA; EHLERS–DANLOS SYNDROME TYPE IX

In this rare X-linked recessive disorder, affected males have a defect in distribution of intracellular copper to copper-dependent enzymes, as in Menkes' syndrome [1]. Lysyl oxidase is a major copper-dependent enzyme, and its activity is markedly decreased in some patients [2], resulting in defective collagen cross-links. Serum copper and caeruloplasmin levels are low [1]. The disorder, like Menkes' syndrome, is caused by mutations in the gene (*ATP7A*) encoding for Cu^{2+}-transporting adenosine triphosphatase (ATPase) α-polypeptide [3,4].

Clinical manifestations include the development of bladder diverticula during childhood, inguinal herniae, mild laxity of skin and skeletal defects such as short humeri and clavicles. Bony occipital horns appear during adolescence [2]. Other features include mild chronic diarrhoea and orthostatic hypotension.

Prolidase deficiency

Definition. Prolidase (peptidase D) is involved in the latter stages of degradation of endogenous and dietary proteins and is particularly important in collagen catabolism. Deficiency of prolidase is a rare inborn error of collagen metabolism, associated with chronic skin ulceration and mental retardation.

Aetiology. The deficiency is inherited as an autosomal recessive [1,2]. Mutations in the prolidase gene (*PEPD*) result in loss of prolidase activity [3]. Some siblings of patients have the enzyme deficiency without clinical manifestations [4].

Pathology. Light and electron microscopy of cultured fibroblasts from affected patients suggest necrosis-like cell death with abnormal morphology and increased cytosolic vacuolization, and abnormal plasma membranes and mitochondria [3]. Large amounts of imidodipeptides are excreted in the urine [5,6], and the proline/hydroxyproline ratio in collagen is increased.

Fig. 46.28 Pitted skin in prolidase deficiency. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

Abnormal laboratory findings include mild anaemia, thrombocytopenia and hypergammaglobulinaemia.

Clinical features [7]. Most patients are mentally defective, with an abnormal facies, but there is no characteristic or consistent pattern. Skin changes occur in about 85% of cases. The skin may feel spongy, with pitting and scarring, especially on the legs (Fig. 46.28). The skin is fragile and leg ulcers are common. Occasionally, there may be photosensitivity, telangiectasia, purpura, premature greying and lymphoedema.

Splenomegaly, recurrent infections and obesity or a protuberant abdomen occur in about 30% of cases.

Diagnosis. This is confirmed by the finding of massive imidodipeptiduria with prolidase deficiency in the red cells, white cells or cultured fibroblasts. Mutations can be detected in the gene encoding for prolidase [3].

Treatment. Topical proline has been successfully applied to the leg ulcers [8]. Oral proline administration produces no clinical improvement. Enzyme replacement by transfusion of prolidase-containing red cells is a possibility, perhaps using manganese activation of the enzyme before transfusion [9]. Pulsed corticosteroids may help [10]. Apheresis exchange has improved skin ulceration in two patients [11].

Osteogenesis imperfecta

Definition. This term is applied to a heterogeneous group of heritable disorders characterized by osteoporosis with fractures, due predominantly to type I collagen abnormalities. Patients may also have blue sclerae (Fig. 46.29), deafness, skeletal deformity, abnormal dentine formation (dentinogenesis imperfecta), mild joint hypermobility, hernias, mitral valve prolapse, arterial fragility and thin, fragile skin [1,2].

Aetiology. Approximately 80–90% of patients with OI, who fit into types I–IV, have mutations in one of the type I collagen genes (*COL1A1*, *COL1A2*) [3]. The aetiology of the remainder is unclear. A variety of mutations are seen but very few families share the same mutation. Furthermore, considerable intrafamilial variation of phenotype occurs in type IA [4].

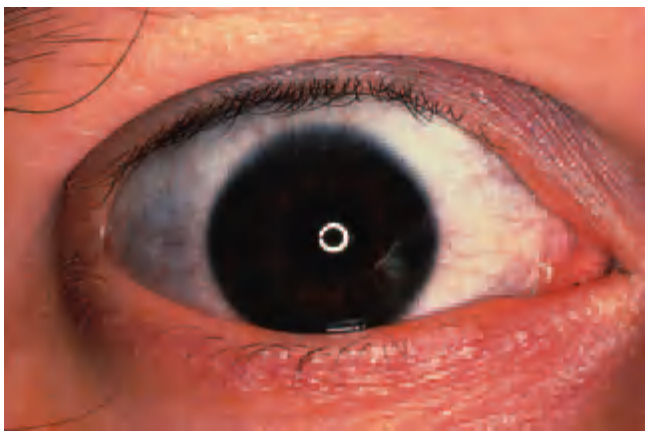

Fig. 46.29 Blue sclera in osteogenesis imperfecta.

Pathology [5]. The bones are markedly collagen deficient, and often have a distorted architecture. The dermis is thin, with a relative increase of argyrophil and elastic fibres, and a deficiency of adult collagen [6].

Clinical features [1,2,5]. The following broad groups exist, although some patients are difficult to classify.

Type IA: Classic form. This is the commonest form. It is inherited as an autosomal dominant, although sporadic cases also occur [7]. Fractures are common in childhood. The sclerae are blue or grey, and easy bruising and early onset deafness are common, but skeletal deformity is absent or mild. Joint laxity is common. The incidence of mitral valve prolapse is increased, and the aortic valves are thin and occasionally incompetent [8–10]. A few patients (type IB) have dentinogenesis imperfecta, but this is more common in the type IV group. Most patients have increased skin collagen, with an increased ratio of type I/type III [6]. Other patients have an abnormal α_2 chain, which is unduly susceptible to proteolysis by pepsin [11].

Type II: Lethal perinatal form. This is the rarest form. There are multiple fractures *in utero* and infants rarely survive for more than a few days after birth [12]. Avulsion of the limbs may occur during delivery due to a generalized connective tissue fragility. Radiography shows beaded ribs, crumpled femora and little skull calcification.

This form has been subdivided on the basis of rib and limb bone abnormalities [6,13]. Inheritance is usually autosomal dominant. Multiple recurrence of gonadal mosaicism can mimic autosomal recessive inheritance [14].

Type III: Progressively deforming form. In this condition, there are fractures *in utero* or at birth, and the long bones are thin and occasionally cystic. As the child grows older, progressive scoliosis and bowing of long bones cause crippling deformities. The sclerae are blue in childhood but become normal in the adult. The inheritance is uncertain, but the disease may be genetically heterogeneous.

Some patients with this form seem unable to synthesize α_2 chains [7,15].

Type IV: Mild form with normal sclerae. This condition is similar to type I in clinical features and inheritance, but the sclerae are not blue, dentinogenesis imperfecta is frequent and deafness is rare.

Diagnosis. Patients with short extremities and a large skull may be confused with achondroplasia, but bone fragility and thin skin do not occur in achondroplasia.

Prenatal diagnosis of the more severe forms is possible, using ultrasonography from week 16 [16]. The skin of patients with OI is stiffer and less elastic than normal skin, and these differences in mechanical properties may prove useful in diagnosis and prognosis [17]

Treatment. This is essentially an orthopaedic problem, although many children die of respiratory infections [18]. Medium-term studies show clinical improvement with the use of biphosphonates [2]. Somatic cell therapy, using allogenic bone marrow and mesenchymal stromal cell transplantation have been used [19,20].

Pachydermoperiostosis (see also Chapter 12)

SYN. PRIMARY (IDIOPATHIC) HYPERTROPHIC PULMONARY OSTEOARTHROPATHY; TOURAINE–SOLENTE–GOLÉ SYNDROME

In this rare condition [1,2], inheritance is autosomal dominant, with variable penetration. Digital clubbing is associated with cylindrical thickening of legs and forearms, hypohidrosis, seborrhoea, sebaceous gland hyperplasia and folliculitis. X-rays reveal symmetrical, irregular periosteal ossification, predominantly affecting the distal ends of long bones. Histology shows cutaneous sclerosis and hyalinosis, with perivascular infiltration by lymphoid cells in the dermis [2]. Additional clinical features include carpal and tarsal tunnel syndrome, chronic leg ulceration and calcification of the Achilles tendon [3]. Cultured dermal fibroblasts synthesize increased amounts of collagen and α_1(I) procollagen mRNA, and exhibit up-regulation of transcriptional activity of the α_1(I) procollagen gene promoter [4]. Proteoglycan synthesis is also affected [5].

When conventional treatments fail, intravenous pamidronate may help rheumatological manifestations [6].

Relapsing polychondritis

SYN. ATROPHIC POLYCHONDRITIS; SYSTEMIC CHONDROMALACIA

Definition. In this non-infective condition, focal inflammatory destruction of cartilage is accompanied by fibroblastic regeneration. It is characterized by (i) recurrent chondritis of the pinnae; (ii) chondritis of nasal cartilage; (iii) inflamed cartilage in the larynx, trachea or respiratory tract; (iv) ocular inflammation; (v) cochlear or vestibular lesions; and (vi) non-erosive arthritis. Three or more of these features are required for the diagnosis [1].

Aetiology. Relapsing polychondritis has been recorded as rare, but recent reports suggest that it is not so uncommon but is easily overlooked. The cause is unknown, but the association with rheumatoid arthritis, lupus erythematosus, vasculitis, Behçet's disease and Hashimoto's disease suggests that autoimmune mechanisms may be concerned (see also MAGIC syndrome, p. 46.45). Other reported associations include ulcerative colitis, Crohn's disease, psoriasis, glomerulonephritis, Sjögren syndrome,

thymoma, ankylosing spondylitis, myeloproliferative disorders and following intravenous injections [2–7]. Cutaneous manifestations have been reported in a patient treated for prostatic adenocarcinoma with goserelin, a luteinizing hormone releasing analogue [8].

Relapsing polychondritis probably overlaps with Wegener's syndrome. Auricular chondritis has been described in some patients with the latter [9], and cANCA, an antibody once regarded as specific for Wegener's syndrome, has been reported in patients with relapsing polychondritis [10].

Antibodies to type II collagen have been detected in the serum in acute polychondritis, and granular deposits of IgG, IgA, IgM and C3 at fibrochondrial junctions have indicated a possible role of immune-complex deposits [11–15]. Antibody production is T-cell dependent and major histocompatibility complex (MHC) restricted; the arthritis in experimental animal models can be suppressed by synthetic type II collagen peptides [16]. The intravenous injection of papain into rabbits produces loss of cartilage rigidity, manifested by floppy ears [17], and it has been suggested that local protease activity may play some part in causing relapsing polychondritis [18]. Cartilage oligomeric matrix protein (COMP) is decreased and cartilage matrix protein (matrilin-1) increased. Both revert to normal levels during successful therapy [19].

Pathology [20]. Areas of damaged cartilage, which have lost the normal basophilic staining, are separated by areas of predominantly lymphocytic infiltration. Later, the fragments of cartilage are surrounded and replaced by abundant granulation tissue and even nascent cartilage. Occasionally there is evidence of vasculitis [21].

Clinical features [1,22–24]. The condition affects both sexes equally and usually begins between the ages of 30 and 50 years. Chondritis ultimately involves three or more sites in most patients but may be limited to one or two for long periods. The following tissues may be involved in decreasing order of frequency: auricular, joint, nasal, ocular, respiratory tract, heart valves and skin [25,26]. During the acute stage, the affected area is swollen, red and tender, and may be mistaken for cellulitis (Fig. 46.30). Sparing of the ear lobe is a useful differentiating sign. Serous otitis media can occur, and there may be loss of hearing even in the absence of chondritis [27]. Involvement of the nasal cartilage leads to obstruction and later to a saddle-nose deformity (Fig. 46.31). Cutaneous and systemic vasculitis, cerebral aneurysms, superficial thrombophlebitis and toxic erythema have been described [1,21,24,28,29].

The joint changes, usually affecting the smaller peripheral joints, may simulate rheumatoid arthritis [30]. Involvement of the larynx, trachea or bronchi produces respiratory embarrassment and recurrent infection. Permanent tracheostomy may be required [20,27]. An

Fig. 46.32 Relapsing polychondritis, showing ocular involvement. (Courtesy of Dr N. Cox, Cumberland Royal Infirmary, Carlisle, UK.)

association with granulomatous lung disease has also been described. Ocular abnormalities are found in some cases—episcleritis, conjunctivitis and iritis (Fig. 46.32), or more rarely keratoconjunctivitis sicca or chorioretinitis. Proptosis occurs in 3% of cases [31,32]. Involvement of the heart valves may cause serious complications, including sudden valve rupture, even in a patient otherwise in remission [1,33,34].

The course of the disease is extremely variable [7]. Relapses are the rule, but they vary in frequency and severity. Some cases continue to relapse for over 20 years, but others become inactive within a short period. Pregnancy does not appear to affect the course of the disease, although complications are more frequent [35]. Deformity of the ears and nose is common, but in general the disease is a source of discomfort and disfigurement rather than a threat to life. Plasma viscosity or erythrocyte sedimentation rate is usually raised and anaemia is frequent. The rheumatoid factor and antinuclear factor are often positive. Leukocytosis is inconstant, but eosinophilia is found in 40% of cases. Lupus erythematosus cells may be present. The characteristic biochemical finding is the increased urinary excretion of acid mucopolysaccharides during each relapse.

Radiological abnormalities are not pathognomonic, but evidence of extensive destruction of joint cartilage without changes in adjacent bone is suggestive. In some cases, the changes are indistinguishable from rheumatoid arthritis.

Diagnosis. Polychondritis may present to the dermatologist as 'chronic otitis externa with cellulitis of the pinna'. The diagnosis is established by biopsy, or by other associated changes, and by the examination of urine for acid mucopolysaccharides. Wegener's granulomatosis and lethal midline granuloma can produce a similar histology, but in these two conditions the involvement is more purely destructive.

Treatment. The progression of the acute relapse can be controlled with corticosteroids. An initial daily dose of 30 mg prednisone can be gradually reduced and finally discontinued as remission develops. Remissions may also be induced with indometacin or dapsone [13]. Colchicine is also helpful in some patients [36]. Immunosuppressive agents such as methotrexate and ciclosporin [15] may have a role. Pulsed intravenous cyclophosphamide has been used for renal disease [37]. Remission has followed autologous stem cell transplantation [38].

MAGIC syndrome

At least 13 patients have been described with features of both relapsing polychondritis and Behçet's syndrome [1]. The term MAGIC syndrome (*m*outh *a*nd *g*enital ulcers with *i*nflamed *c*artilage) has been used for this overlap syndrome. The underlying immunological defects are still unclear, but circulating immune complexes and autoantibodies to elastic tissue have been suggested as possible factors [1,2].

Aortic valve disease has been associated with the syndrome [3], and features of the MAGIC syndrome have been described in an HIV-positive individual [4].

Fibromatoses

Fibrous overgrowth of dermal and subcutaneous connective tissue occurs most readily in certain sites and at certain ages, and some of the resulting syndromes are clinically and histologically distinctive and well defined. There are some cases, however, that defy precise classification, and others in which histological criteria may be a poor guide to prognosis. Invasiveness and a high local recurrence rate may or may not be associated with a tendency to metastasize. The borderline between simple overgrowth and a benign tumour may be equally difficult to define.

Fibromatosis is a benign fibrous tissue proliferation, which is intermediate between benign fibroma and metastasizing fibrosarcoma. The lesions of fibromatosis tend to infiltrate and recur when removed, but they do not metastasize. The term should not be applied to reactive fibrous proliferation, or to keloid, which is usually secondary to injury. The lesions in fibromatosis may be single or multiple, and the likelihood of recurrence after surgical removal varies with the location of the lesion and the age of the patient. The fibromatoses occur in two major groups.

1 Superficial fibromatoses (fascial fibromatoses):
(a) palmar (Dupuytren's);
(b) plantar;
(c) penile (Peyronie's);
(d) knuckle pads.

2 Deep fibromatoses (non-metastasizing fibrosarcoma). These are rapidly growing tumours that usually involve the musculature or aponeuroses. Their tendon-like consistency accounts for their alternative name of desmoid tumours.

These conditions are discussed in more detail elsewhere (Chapter 53).

Palmar fibromatosis

SYN. DUPUYTREN'S CONTRACTURE

Definition. This is a fibromatous hyperplasia of the palmar aponeurosis, which is characterized by nodular thickening of the fascia with associated flexion contractures of one or more digits (Fig. 46.33).

Fig. 46.33 Palmar fibromatosis (Dupuytren's contracture). (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

Aetiology. The condition seems to be due to a reactive proliferation of fibroblasts with no inflammatory component, and the basic cause is obscure. Free radical production secondary to ischaemia may be involved, and the concentration of hypoxanthine substrate capable of releasing free radicals is greatly increased in the affected tissue [1]. Localized ischaemia has been thought to play a part, and in animal studies allopurinol (a competitive inhibitor of xanthine oxidase) has been shown to limit the damage associated with acute ischaemia [2]. High concentrations of free radicals are toxic, but in low concentration they stimulate fibroblast proliferation [1]. The contractures, which are a late complication, appear to follow the conversion of the fibroblasts to contractile myofibroblasts [3].

Palmar fibromatosis is often familial, and may be inherited as an autosomal dominant trait [4].

Some families are described in which there is a predominantly female expression [5]. The prevalence in the general adult population is around 2–6% [6], but it may approach 20% or more in elderly males [7–9], in diabetic patients and in patients with acquired immune deficiency syndrome (AIDS). It is relatively rare in black and oriental races.

Associated disorders. The condition occurs more commonly in patients with alcoholic cirrhosis, epilepsy [10] and diabetes mellitus [9,11], but the prevalence is decreased in rheumatoid arthritis [12].

Palmar fibromatosis is also associated in about 5% of patients with other fibrosing conditions, such as knuckle pads, Peyronie's disease, keloid scarring or plantar fibromatosis [13], and this has been termed the *polyfibromatosis syndrome*. Other conditions which have been less convincingly claimed to be associated with Dupuytren's contracture include periarthritis of the shoulder, chronic lung disease, gout, trauma and ulnar nerve damage [14]. Phenytoin appears to stimulate fibrosis in the polyfibromatosis syndrome [15] and it may also cause gingival hypertrophy by stimulating fibroblasts and increasing collagen production [10,16].

There is one case report of a girl aged 14 years who developed Dupuytren's contracture while receiving growth hormone therapy for hypopituitarism [17].

Pathology [18]. Fibroblasts in Dupuytren's contractures are identical to those in normal palmar fascia. However, there are more of them in Dupuytren's contractures and they tend to be clustered around narrowed microvessels [19]. In the early stages, there are nodules in the subcutaneous tissue, or within the fascia, composed of proliferating fibroblasts with irregular hyperchromatic nuclei, but with no excess of collagen. Later stages are characterized by the presence of myofibroblasts which have a fibrillary ultrastructure in the cytoplasm and seem to have some other properties of smooth muscle. The nuclei are deeply indented, and these constrictions may be related to the contractile properties of the cell. The cell also has surface membrane differentiations which provide attachment to neighbouring cells and stroma. Myofibroblasts have also been identified in the normal aorta and in granulation tissue, hypertrophic scars, keloids, liver fibrosis,dermatofibroma, etc. [3], in which their contractile properties may be important. The advanced stages of Dupuytren's contracture are characterized by dense, fibrous connective tissue with a few elongated cells. An increased concentration of type III collagen is present in the nodules [20].

Clinical features. The age of onset is generally between 30 and 50 years, and the disease is less common and progresses more slowly in women [14]. The earliest sign is the development of a palmar nodule, usually in the ulnar half of the hand. There are usually no symptoms, but there may be a dull ache or tingling. Insidious progression of the fibrosis over several years causes flexion contractures of the affected fingers. There is often puckering of the overlying skin. Eventually, the function of the hand becomes impaired due to fixed flexion of one or more digits. If left untreated, there may be some improvement after many years.

Diagnosis. There are few diagnostic difficulties. There may be a histological resemblance to fibrosarcoma, but this is more pleomorphic, with larger nuclei and more mitoses. Juvenile aponeurotic fibroma may produce palmar or plantar nodules, but Dupuytren's contracture does not occur in young children.

Treatment. The advice of an orthopaedic or plastic surgeon should be sought. Complete removal of the palmar aponeurosis is generally recommended [21].

A recent study recommends subtotal fasciectomy and direct closure [22]. Some preliminary results suggest that allopurinol may be helpful, by decreasing free-radical production [23], and it has been suggested that vitamin C might prevent progression of the disease by acting as a free-radical scavenger [7]. Many other non-surgical approaches have been tried, including continuous slow skeletal traction, radiotherapy, dimethyl sulfoxide, vitamin E, steroid injections and interferon, although none has been proven to be clinically useful [24]. However, placebo-contolled trials of collagenase injections look very promising [25].

Another suggestion, which has yet to be tested clinically, is the use of immunosuppressive therapy as an adjunct to surgery, on the grounds that the presence of CD3 lymphocytes and the expression of MHC class II proteins in the affected tissue imply that Dupuytren's disease is a T-cell-mediated autoimmune disorder [26].

Camptodactyly

Camptodactyly is a non-traumatic flexion deformity affecting the proximal interphalangeal joint of one or more fingers [1]. Congenital camptodactyly may be familial, associated with non-inflammatory arthropathy [2]. Additionally, other serous membranes undergo fibrosis. Clinical features include *c*onstricting pericarditis *a*nd *p*leuritis (*CAP syndrome*) [3,4]. Familial camptodactyly of later onset has been described in association with an inflammatory arthritis with erosive changes [5]. *Blau's syndrome* encompasses familial camptodactyly, granulomatous arthritis, uveitis and an erythematous eruption [6]. In one family, taurinuria was associated [7]. Sporadic cases of camptodactyly have been linked with accelerated growth and osseous maturation, unusual facial appearance (including large ears, small mouth, broad forehead and hypertelorism), a hoarse, low-pitched cry and hypertonia (*Weaver's syndrome*) [8]. Other associated features include pectus excavatum and scoliosis. The underlying biochemical abnormality is unknown, although there may be a primary deficit in synthesis or deposition of type VI collagen in synovium. Treatment, if required, is surgical [1,9].

Streblodactyly

Streblodactyly [1] is inherited as a sex-limited autosomal dominant character. The affected females show from birth a flexion deformity at the metacarpophalangeal joints of the thumbs and the proximal interphalangeal joints of the little fingers. Some fingers show swan-neck deformities and hyperextensible metacarpophalangeal joints. In one family there was an abnormal α-amino acid in the urine.

Plantar fibromatosis [1,2]

SYN. LEDDERHOSE'S DISEASE

This is a much rarer condition than palmar fibromatosis. The lesions, which occur most often on the medial half of the mid-foot, present as one or more nodules, which may

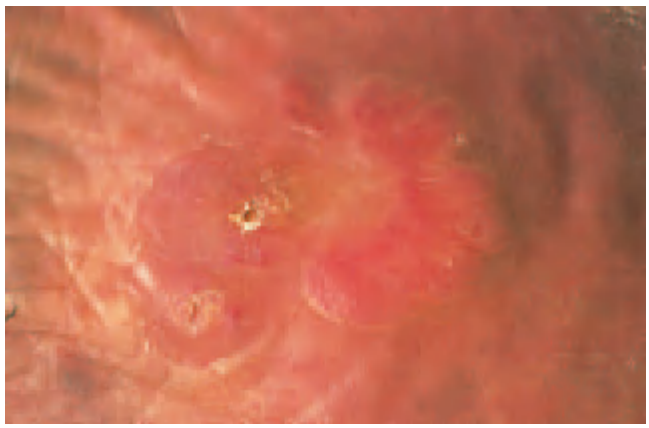

Fig. 46.34 Plantar fibromatosis. (Courtesy of Dr J. Ellis, Princess Margaret Hospital, Swindon, UK.)

become painful and may ulcerate (Fig. 46.34). They rarely produce contractures, but they tend to be locally invasive and to recur. Total excision of the lesion and the entire plantar fascia seems to give the best results, with the lowest incidence of recurrence. The differential diagnosis includes keloid and fibrosarcoma, and in younger patients aggressive infantile fibromatosis and aponeurotic fibroma must also be considered [3]. Similar nodules have been described symmetrically affecting the anteromedial heel pads in children. They are asymptomatic and may resolve spontaneously [4,5]. Surgery is contraindicated.

Penile fibromatosis

SYN. PEYRONIE'S DISEASE; PLASTIC INDURATION OF THE PENIS; FIBROUS SCLEROSIS OF THE PENIS

Definition. Penile fibromatosis is characterized by one or more irregular dense fibrous plaques in the penile shaft.

Aetiology. Penile fibromatosis may occur as an isolated abnormality, or as one component of polyfibromatosis in association with palmoplantar fibromatosis, keloids and knuckle pads. Atheroma predisposes to the condition, and it is now thought that the association with the use of β-adrenoreceptor blocking drugs is probably attributable to concomitant atheroma [1,2]. There may be a genetic factor, but reliable studies of the mode of inheritance are lacking. The condition is rare below the age of 20 years, and the highest incidence is between 40 and 60 years. It is much less common than palmar or plantar fibromatosis.

Pathology [3]. The thickened plaque shows cellular fibroblastic proliferation surrounded by dense masses of collagen. Calcification and ossification may occur. The process appears to begin as a vasculitis in the areolar connective tissue beneath the tunica albuginea, whence it extends to adjacent structures.

Clinical features. The disease presents with painful erections and curvature of the erect penis due to a thickened subcutaneous plaque, rubbery or hard, usually on the dorsal aspect of the penis in its distal third. The erectile deformity may make vaginal penetration impossible, and pain or anxiety about performance may cause secondary impotence. Fibrosis of the underlying cavernous erectile tissue may lead to a constriction or 'waisting' of the penile shaft, leading to flaccidity of the distal portion.

The course is unpredictable [4]. The pain generally subsides within a few months, but the fibrous plaque may resolve, remain unchanged or progress [5].

The severity of the disease and the response to treatment can now be evaluated by high-resolution ultrasonography [6], computed tomography [7] or magnetic resonance imaging of the erect penis [8]. If necessary, an erection can be induced by the intracavernosal injection of papaverine [9].

Treatment. Many treatments have been tried, but there is little evidence that vitamin E, potassium aminobenzoate, orgotein, radiotherapy, ultrasonic therapy or intralesional steroids affect the long-term outcome, although they may relieve the pain [4]. Clostridial collagenase injections have given promising results [10]. Surgery is probably the treatment of choice, using Nisbet's operation, in which ellipses of normal tunica albuginea are excised from the side of the shaft, opposite the point of maximum curvature. A semi-rigid penile prosthesis may also be inserted.

Knuckle pads [1–4]

SYN. HOLODERMA

Definition. Knuckle pads are circumscribed thickenings overlying the finger joints. The term is a misnomer as most lesions occur over the proximal interphalangeal rather than the metacarpophalangeal joints (knuckles).

Aetiology. The condition is usually sporadic but several pedigrees have shown an autosomal dominant inheritance. The age of onset and the distribution of the lesions tend to be more or less constant in each family, but show interfamily variation. The condition is not rare but the true prevalence is uncertain, as most patients ignore the lesions. Knuckle pads are thought to be idiopathic in children, although they occur at sites prone to picking, chewing or 'knuckle cracking' [4].

Pathology [1]. The epidermis is grossly hyperkeratotic and acanthotic. The dermal connective tissue is hyperplastic and individual collagen fibres may be obviously thickened. Histologically, the changes resemble those of palmar fibromatosis.

Clinical features [2,3]. Flat or convex, smooth, circumscribed keratoses develop slowly and almost imperceptibly over the course of months or years. In some patients they become very much raised and obviously indurated, but in others the dermal component is not clinically apparent. They are most commonly seen over the dorsa of the proximal interphalangeal joints, but occasionally develop over the knuckles or the distal interphalangeal joints. Any single site or combination of sites may be involved. Sites other than the hands are not often affected, but similar lesions on the knees were also present in one family [2].

The age of onset is variable but it is more common after the fourth decade. In some individuals, the lesions may not be conspicuous until they have been present for some years.

An association between Dupuytren's contracture and other fibromatous lesions has been recorded in some families. In one large family, knuckle pads were associated with sensorineural deafness and with leukonychia [5]. Two affected individuals also had palmoplantar keratoderma.

Another family has been described with knuckle pads in association with oesophageal cancer, hyperkeratosis and oral leukoplakia [6].

In differential diagnosis, occupational callosities, Heberden's nodes of osteoarthritis, pachydermodactyly, granuloma annulare, erythema elevatum diutinum and rheumatoid nodules must be excluded.

Treatment. There is no satisfactory treatment. Excision may be followed by keloidal scarring.

Pachydermodactyly [1–7]

This is a benign fibromatosis of the fingers that usually affects young adult males (Fig. 46.35). It produces a symmetrical diffuse swelling of the skin around the dorsal aspect and sides of the proximal phalanges of the index, ring and middle fingers. Pachydermodactyly has been recently reported in women [4,5] and two young girls, one of whom had tuberous sclerosis and the other EDS [6]. It may be associated with bilateral carpal tunnel syndrome [2] and varioliform atrophy [8]. A distal variant has been described in an elderly woman, who also presented with nodules over the extensor aspects of the elbows [9]. Affected families have been reported [10].

It has been suggested that repeated rubbing of the fingers or mechanical injury to the joints may contribute to the condition [3,6], but pachydermodactyly must be distinguished from occupational callosities, obsessive 'chewing pads' and true knuckle pads [11,12].

Fig. 46.35 Pachydermodactyly. (Courtesy of Dr A. Chamberlain, Churchill Hospital, Oxford, UK.)

Histology of the dermis shows marked thickening, with extension of collagenous fibres into the subcutaneous tissue. Types III and V collagen are increased, and electron microscopy shows increased numbers of fine-diameter collagen fibres.

Juvenile fibromatoses

The term juvenile fibromatosis has been applied to a group of disorders occurring in infants and children, and characterized by proliferative activity of the fibroblasts [1–6]. There is a tendency to local recurrence but, unlike fibrosarcomas, they do not metastasize. The group includes a number of well-defined clinical entities that affect the skin:

1 infantile myofibromatosis;
2 fibrous hamartoma of infancy;
3 juvenile hyaline fibromatosis;
4 infantile digital fibromatosis;
5 calcifying aponeurotic fibroma;
6 giant cell fibroblastoma.

These conditions are described in Chapter 53.

Juvenile hyaline fibromatosis

SYN. SYSTEMIC HYALINOSIS; PURETIC SYNDROME

Definition. This is a disorder of glycosaminoglycan synthesis, which is characterized clinically by skin papules or tumours, gingival enlargement, osteolytic lesions and joint contractures, and histologically by deposition of amorphous hyaline material.

Aetiology. The cause is unknown, but increased chondroitin synthesis has been demonstrated in skin fibroblasts cultured from the tumour tissue [1]. The disease is very rare and occurs sporadically, but it has occurred in siblings.

Pathology [1–4]. The skin lesions contain 'chondroid' cells embedded in amorphous eosinophilic ground substance in the dermis. In the early lesions, this consists of glycosaminoglycans, but in the later lesions the matrix is mainly composed of chondroitin sulphate [5]. The dermal collagen is decreased and the collagen fibrils are fewer and thinner than in normal skin. The hyaline material may also be present in the muscles and bones. Absence of pro-α_2 chains and type III collagen has been demonstrated in affected skin [6].

Clinical features [4,7–10]. Skin lesions are present at birth or develop in early childhood. There may be small, pearly papules or nodules, particularly on the face or neck. Large subcutaneous tumours may also occur, particularly on the scalp. These may be hard or soft, fixed or mobile, and they may ulcerate. Gingival hypertrophy is commonly present, and flexion contractures of the fingers, elbows, hips and knees may develop. Osteolytic lesions can occur in the skull, long bones or phalanges. The musculature is poorly developed. The condition persists into adult life and the joint contractures are disabling. Infantile systemic hyalinosis is probably an extreme variant, leading to death in infancy.

Treatment. This is unsatisfactory. The tumours do not respond to radiotherapy, and they may recur after excision [11]. Joint contractures may respond to intralesional steroid injections in the early stages and they may also respond to systemic steroids and physiotherapy.

Other benign fibrous cutaneous nodules

Nodular fasciitis

See Chapter 53. In this condition, there is fibroblastic proliferation of one or more nodules, usually on the limbs or trunk.

Collagenoma

Multiple fibrous dermal nodules with coarse, collagen fibres may develop as sporadic cases (*eruptive collagenoma*) or as a genetic disorder with a dominant inheritance (*familial cutaneous collagenoma*) (Chapter 15).

Collagen naevi

See Chapter 15.

Albopapuloid form of epidermolysis bullosa

SYN. PASINI'S SYNDROME

This rare form of epidermolysis bullosa is characterized by the development of ivory-white papules on the trunk, which histologically show connective tissue hyperplasia. Epidermolysis bullosa is discussed in Chapter 40.

Buschke–Ollendorf syndrome

Extensive nodular fibrosis may occur in the Buschke–Ollendorf syndrome (Chapter 15), in association with juvenile elastoma and osteopoikilosis.

Fibrous digital nodules

In addition to giant cell synovioma and infantile digital fibromatosis, fibrous nodules in the digits may be due to acquired digital fibrokeratoma, fibrous papule of the finger, dermatofibroma (Chapter 53) or the Koenen tumour (Chapter 12).

Infantile stiff-skin syndromes

Several rare syndromes have been described in which hard, stiff skin and joint contractures develop in early life. The relationship between these conditions is uncertain at present.

Systemic hyalinosis

In infantile systemic hyalinosis the skin becomes diffusely thickened and hard in the first few weeks of life, with limited joint mobility. Other characteristic features include small nodular thickenings of the perianal region, ears or lips, and gingival hypertrophy. There may also be hyperpigmentation, joint contractures, osteopenia, diarrhoea, frequent severe infections and growth failure. The prognosis is poor, and survival beyond the age of 2 years is unlikely [1].

The tissues show widespread deposits of hyaline material with the general staining properties of collagen.

Clinically, this syndrome appears distinct from juvenile hyaline fibromatosis (see p. 46.50), but it is possible that it represents a more severe form of the same condition, as some cases have been described with features of both conditions [2,3].

Winchester's syndrome

Diffusely stiff skin may also occur in Winchester's syndrome [4–6]. This is a rare autosomal recessive disease of infancy characterized by joint contractures, gingival hypertrophy, dwarfism, destructive small-joint arthritis and corneal opacities. In this condition, however, the prognosis is relatively good, and many patients survive into adult life.

Previously, similar cases have been described as *hereditary contractures with sclerodermatoid changes of skin* and *stiff-skin syndrome* [7], with increased mucopolysaccharides in the skin.

The skin changes resemble those of scleroedema of Buschke but are distinguished by their early onset. The condition must also be distinguished from sclerema neonatorum, but this is a disorder of subcutaneous fat rather than the skin.

Congenital fascial dystrophy

SYN. STIFF-SKIN SYNDROME

This hereditary connective tissue disorder is characterized by mild hirsutism, limitation of joint mobility affecting gait and localized areas of stony-hard skin, which are otherwise normal in appearance [8]. It appears in early infancy, and is only slowly progressive. The condition affects the deeper skin and fascia, which is much thicker than normal, and tends to be most pronounced on the buttocks and legs, with a sharp demarcation of subcutaneous sclerosis at the inguinal canal. Unlike morphoea, no inflammatory changes are seen on histology. Electron microscopy of the skin shows large collagen fibres, and bundles of aggregated microfibrils [8]. Thickening of the thoracic fascia may cause hypoventilation due to thoracic underdevelopment, but there are no other systemic features of this disease.

The condition appears to be analogous to the tight-skin mouse [9].

Infantile restrictive dermopathy

This is a very rare autosomal recessive disorder, which is probably due to a primary defect in collagen metabolism

[10,11]. It presents at birth with a taut, shiny skin, which restricts movement of the joints. The birth is premature due to ruptured fetal membranes, and the facies is characteristic, with a small, fixed, round, open mouth, micrognathia, small nose, low-set ears and widely spaced cranial sutures. The joints are all fixed in flexion, and gross restriction of the respiratory movements causes death within hours, or at most weeks. The epidermis shows hyperkeratosis and parakeratosis, and the keratohyaline granules are abnormal. The dermal–epidermal junction is flat, with a thin dermis, and a thick layer of subcutaneous fat. The eccrine and pilosebaceous glands are underdeveloped. The collagen bundles appear stretched, and orientated in parallel lines, as they are in a tendon.

The basic defect has not been identified. Immunohistochemistry shows increased expression of 48- and 56-kDa keratins. Their significance is unclear [12].

Prenatal diagnosis would be desirable, but biopsy specimens from a 20-week-old fetus were normal on light and electron microscopy [13].

Other causes of diffuse fibrosis

Environmental and drug-induced scleroderma
(see also Chapter 56)

A variety of environmental triggers may stimulate a localized or diffuse scleroderma-like reaction in a genetically susceptible host. Important causes are listed in Table 46.3. In most cases, the fibrotic process continues after withdrawal of the external stimulus. Sometimes, the ensuing clinical pattern resembles idiopathic forms of scleroderma (see Chapter 56).

Table 46.3 Cutaneous fibrosis due to chemical exposure.

Vinyl chloride
Silica dust
Organic solvents:
Aromatic hydrocarbons (e.g. toluene, benzene)
Aliphatic hydrocarbons:
Chlorinated (e.g. trichlorethylene, perchlorethylene)
Non-chlorinated (e.g. naphtha-*n*-hexane)
Epoxy resins
Toxic oil syndrome
Urea formaldehyde foam insulation
Breast augmentation (paraffin, silicone)
Drugs:
Reactions to local injection:
Phytomenadione, pentazocine, heparin
Reactions to systemic therapy:
Bleomycin
L-tryptophan (eosinophilia–myalgia syndrome)
Carbidopa and L-5-hydroxytryptophan
Penicillamine
Valproate sodium
Cocaine
Appetite suppressants (diethylpropion hydrochloride, amphetamine)
Diltiazem

Fig. 46.36 Vinyl chloride-induced osteolysis affecting fingertips.

Exposure to *vinyl chloride monomer* occurs in workers involved in polyvinyl chloride (PVC) production. One-third of male operatives in a British factory developed a clinical syndrome that included Raynaud's phenomenon, dyspnoea, cutaneous sclerosis, pulp atrophy and radiological evidence of acro-osteolysis (Fig. 46.36) [1]. Genetic marker studies have demonstrated an increased incidence of human leukocyte antigen (HLA) -DR5 in affected individuals; severe disease is linked with B8 and DR3 [2]. A similar syndrome has been reported in gold miners

exposed to silica dust [3], and in workers exposed to organic solvents, such as trichlorethylene [4] and perchlorethylene [5], which are structurally similar to vinyl chloride. Exposure to epoxy resin results in an acute syndrome of cutaneous sclerosis, muscle weakness, arthralgia, impotence, lung and oesophageal involvement [6]. The causative agent appears to be a cyclohexylamine.

Toxic oil syndrome is a multisystem illness, reported in Spain in 1981. Acute fever, severe but transient pulmonary oedema, myalgia, and a pruritic exanthem and eosinophilia were followed after several months by widespread cutaneous sclerosis in 30% of cases [7,8]. The syndrome was probably due to ingestion of imported rapeseed oil mixed with an aniline denaturant, designed to make the oil unfit for human consumption. Toxic oil syndrome bears a striking resemblance to the *eosinophilia–myalgia syndrome* [9–11], linked with consumption of L-tryptophan; this is used as a 'food supplement' to treat insomnia and depression. The offending batches of L-tryptophan contained impurities similar to the contaminants in toxic oil [12,13].

In environmental fibrotic disorders, as in idiopathic scleroderma, subpopulations of fibroblasts appear to be activated to synthesize excess collagen; this property is perpetuated by fibroblasts *in vitro*, indicating that the elevated collagen gene expression is independent of extracellular stimuli [11]. Cytokines appear to stimulate the proliferation of these abnormal clones of fibroblasts; thus, transforming growth factor-β (TGF-β) and platelet-derived growth factor (PDGF) are elevated in the eosinophilia–myalgia syndrome [14].

Numerous drugs have been reported to induce cutaneous sclerosis. Lesions resembling morphoea may follow injections of pentazocine [15], heparin [16] and vitamin K_1 (phytomenadione) [17–19]; in the case of vitamin K_1, the trigger may be a solvent rather than vitamin K_1 itself [20]. Morphoea-like plaques have also been reported in patients taking penicillamine [21] and valproate [22].

Diffuse scleroderma-like changes have been reported following bleomycin therapy [23]. A combination of L-5-hydroxytryptophan and carbidopa induced lesions resembling eosinophilia–myalgia syndrome [24]. Phenytoin and diltiazem both induce gingival hypertrophy [25,26]. A patient on phenytoin developed florid hypertrophic retro-auricular folds [27]. Thickened skin on the feet has been reported in a patient taking diltiazem [28].

Alcohol can provoke porphyria cutanea tarda, which can produce a sclerodermatous appearance (Fig. 46.37).

Fig. 46.37 Scleroderma and scarring of the face due to porphyria cutanea tarda. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

Nephrogenic fibrosing dermopathy

SYN. SCLEROMYXOEDEMA-LIKE ILLNESS OF RENAL DISEASE

Acute onset of skin thickening has been reported in patients with renal disease undergoing haemodialysis or renal transplant [1]. Irregular indurated plaques, with amoeba-like projections and islands of sparing, occur chiefly on the lower trunk and legs. Dermal mucin is detected with Alcian-blue staining and increased collagen is laid down in haphazard bundles; there are increased numbers of $CD68^+$ histiocytes, dermal dendrocytes and fibroblasts. Although initially described as 'scleromyxoedema-like', the lesions have a different distribution and morphology, and there is no associated paraproteinaemia or systemic involvement [2]. The cause is unknown. Although typically associated with haemodialysis, the condition preceded dialysis in one patient [3]. It may remit spontaneously, particularly with the correction of renal abnormalities. No treatment is of proven benefit, but thalidomide has been used empirically [4].

GEMSS syndrome

This is an autosomal dominant condition, comprising *g*laucoma, lens *e*ctopia, *m*icrospherophakia (small, spherical lens), joint *s*tiffness and *s*hort stature [1]. Affected individuals have a stocky, 'pseudoathletic' build. Associated cutaneous sclerosis notably affects the upper back and limbs but spares the face. Skin histology is reminiscent of systemic sclerosis. Increased synthesis of collagen is reflected by markedly enhanced gene expression of TGF-β_1 [2].

POEMS syndrome (see also Chapters 39 & 59)

SYN. CROW–FUKASE–TAKATSUKI SYNDROME

This acronym is derived from *p*olyneuropathy, *o*rganomegaly (of liver, spleen or lymph nodes), *e*ndocrinopathy (often diabetes mellitus), *M* protein (a monoclonal gammopathy) and *s*kin lesions. The skin features include hyperpigmentation, hyperhidrosis, hypertrichosis and diffuse thickening resembling scleroderma [1–3]. Rarer features include angiomas, white fingernails and alopecia [3].

The syndrome appears to be a rare variant of myelomatosis [4], although skeletal X-rays show single or multiple osteosclerotic lesions with areas of bony proliferation rather than the lytic lesions which are more typical of myeloma [5].

Overproduction of vascular endothelial growth factor (VEGF) may explain the microangiopathy, neovascularization and accelerated vasopermeability that occur in this syndrome [6].

Keloids and hypertrophic scars

Both conditions represent an excessive connective tissue response to injury, which may be trivial. A keloid (cheloid, meaning 'crab claw') is a benign, well-demarcated area of fibrous tissue overgrowth that extends beyond the original defect. A hypertrophic scar is similar, but remains confined to the initial defect and tends to resolve with time [1].

Aetiology. The cause is unknown, although both local and constitutional factors are involved. A scar at any site has the potential to become hypertrophic or keloidal, although the earlobes, chin, neck, shoulders, upper trunk and lower legs are especially vulnerable. Burns or scalds and infected lesions predispose to hypertrophy. Another risk factor is the presence of foreign material, either exogenous (e.g. suture material) or endogenous (e.g. embedded hair). Some African tribes introduce foreign bodies into tribal marks to induce scar hypertrophy. Scarring acne, particularly on the trunk, may become keloid-like. Isotretinoin has been reported to delay wound healing and induce keloids in patients who received argon laser or dermabrasion for acne or rosacea [2,3].

Some races, notably Afro-Caribbeans, are more prone to develop keloids than others. A positive family history is obtained in 5–10% of Europeans with keloids, particularly severe lesions [4]. Family studies suggest an autosomal dominant inheritance with incomplete penetrance [5]. There is a genetic association with other 'fibromatoses' such as Dupuytren's contracture [6]. Keloids form readily in acromegalics, and after thyroidectomy in young patients. They have been reported in a boy with Dubowitz's syndrome [7]. Keloids are also recorded in association with EDS, pachydermoperiostosis and Rubinstein–Taybi syndrome [8]. Keloids are rare in infancy and old age, occurring chiefly between puberty and the age of 30 years. Women have a greater predisposition, and keloids may occur or enlarge during pregnancy [9].

Linear keloids have been reported to occur in athletes taking anabolic steroids [10].

Pathology [11–13]. Although the histology may be difficult to distinguish from normal wound healing in the early stages, hypertrophic scars and keloids typically exhibit increased cellularity. In keloids of recent onset, endothelial proliferation is surrounded by increased numbers of fibroblasts, which form large, irregular nodules or whorls of collagen with a peripheral capsule-like band [11]. Mast cells are increased in hypertrophic scars [12]. Mucinous material is deposited focally in keloids but not in hypertrophic scars. The epidermis is normal, or thinned by the underlying lesion.

On electron microscopy, the nodules contain stellate fibroblasts. It is uncertain whether these are [14] or are not [15] myofibroblasts. Scanning electron microscopy of keloids shows more haphazard organization of collagen bundles than in normal skin or mature scars. The collagen filaments are about half the diameter of those of normal skin.

Biochemical studies confirm that collagen and proteoglycan synthesis is increased in keloids and hypertrophic scars. Collagen degradation appears to be normal [16]. Synthesis of both types I and III collagen is increased [17], and hypertrophic scar collagen possesses the reducible keto cross-link, dehydrohydroxylysinonorleucine, normally associated with embryonic skin and granulation tissue [18]. Several growth factors have been studied using keloid fibroblasts *in vitro*. Keloid fibroblasts, unlike those from hypertrophic scar tissue, are hyperresponsive to both TGF-β, which is abundant in healing wounds [19], and PDGF [20].

Fig. 46.38 Spontaneous keloids of the neck.

Keloid fibroblasts in culture secrete increased amounts of collagen and glycosaminoglycans for several passages in tissue culture [21]. It is unclear whether these cells represent a normal subgroup or have undergone transformation. Altered expression of proteoglycans in keloids may affect the three-dimensional organization of collagen fibres [22].

Immunohistochemical studies have shown that neuropeptide-containing nerves are present in hypertrophic scars but not in non-hypertrophic scars, and these may contribute to the symptoms of discomfort and itching in such scars [23].

Clinical features. Both hypertrophic scars and keloids become raised and thickened within 3–4 weeks of the provocative stimulus. The lesion becomes a firm, pink or red plaque, which may grow for months or years. Lesions often assume a 'dumb-bell' configuration, but sometimes become bizarre and irregular (Fig. 46.38). Usually, a hypertrophic scar shows signs of regression after a few months. The surface of a keloid becomes smoother and rounder, extending beyond the area of the original lesion. It is often irritable and hypersensitive, and sometimes exquisitely tender. Keloids tend to regress after several years; lesions on the beard area sometimes undergo central suppurative necrosis. Malignant degeneration has been reported [24], although a fibrosarcoma can mimic keloid clinically.

The diagnosis is usually simple if there is a history of trauma or an inflammatory skin lesion. Spontaneous keloids usually develop on the presternal region or upper

chest. Lesions which can cause diagnostic difficulty include sclerotic basal cell carcinoma, scar sarcoid or malignancy developing in a scar, and dermatofibrosarcoma. In endemic areas, blastomycosis and lobomycosis cause keloidal reactions.

Prophylaxis and treatment. Non-essential surgery should be avoided in the sites of predilection. If surgery is necessary, simple excision, aiming to minimize skin tension and secondary infection, is preferable to electrocoagulation or caustic chemicals. In an individual at risk, preoperative radiotherapy to the excision site may be useful.

Keloids usually recur following simple excision, although adjuvant therapy, such as radiation, local compression with a custom-made pressure garment [25], or intralesional steroids may reduce the risk of recurrence. Some lesions respond to pressure alone, or with occlusion with a hydrocolloid dressing. Small keloids can respond to silicone gel (e.g. Silastic) held in place with adhesive tape [26]. This treatment is also effective for hypertrophic scars [27,28].

Promising results have been obtained using a cream made of 20% silicone oil, applied under occlusion; this may be beneficial for sites where it is impracticable to apply gel-sheeting [29].

Radiotherapy, including superficial X-rays, electron-beam therapy or implantation with iridium-192 wires, may prevent recurrence following surgery [30], but electron-beam therapy offers no advantage over orthovoltage [31]. Intralesional triamcinolone (10 mg/mL) is useful, especially in early lesions. Several injections may be necessary at intervals of 3–6 weeks. Prior freezing with liquid nitrogen before the injection causes oedema, which allows the triamcinolone to be injected more readily. Acne keloids respond moderately well to either intralesional triamcinolone or cryotherapy, but the response to the latter is better in early vascular lesions [32].

Topical retinoic acid, applied daily, may be helpful [33,34], although systemic retinoids may enhance keloid formation [3]. Intralesional lathyrogens, such as β-aminoproprionitrile, have been used, but systemic penicillamine is ineffective [35]. Intralesional cytotoxic drugs may cause ulceration, but intralesional 5-fluorouracil and 585-nm flashlamp-pumped pulsed dye laser produced comparable improvement in one study [36]. Inhibitory cytokines, such as IFN-α and IFN-γ [37–39] and TGF-β analogues show promise. Interferons appear to reduce fibroblast collagen synthesis and increase collagenase activity by reducing the steady state levels of mRNA [39]. Different modes of laser treatment, e.g. the pulsed dye, Nd : YAG and carbon dioxide lasers, have a high recurrence rate.

Premature ageing syndromes [1,2]

Increasing age appears to cause many anatomical and functional changes in human skin, but some of these may be the result of cumulative damage due to sun exposure, etc. To date, no disease has been found to cause a true acceleration of the rate of ageing in all tissues. More than 150 diseases manifest one or more features of apparent premature ageing, but there are discrepancies between this process and true ageing. All the premature ageing syndromes are probably inherited, although the defect may not be obvious in the first few years of life. Cutaneous changes which may be a sign of a premature ageing syndrome include atrophy, loss of cutaneous fat, wrinkling, canities, hair loss, nail dystrophy, defective pigmentation, poikiloderma, sclerosis and ulceration.

The conditions associated with cutaneous signs of premature ageing are shown below.

1 Classical inherited premature ageing syndromes:
  (a) pangeria (Werner's syndrome);
  (b) progeria (Hutchinson–Gilford syndrome);
  (c) acrogeria (Gottron's syndrome).
2 Other congenital progeroid syndromes:
  (a) trisomy 21 (Down's syndrome);
  (b) neonatal pseudohydrocephalic progeroid syndrome (Wiedemann–Rauchenstrauch);
  (c) osteodysplastic geroderma;
  (d) wrinkly skin syndrome;
  (e) familial mandibulo-acral dysplasia;
  (f) progeroid EDS.
3 Excessive exposure to irradiation (usually UV).
4 Photosensitivity, especially congenital, for example poikiloderma congenitale, xeroderma pigmentosum, Cockayne's syndrome.
5 Diseases causing elastolysis, for example cutis laxa.
6 Thickened immobile skin, for example diabetic cheiroarthropathy.
7 Fragile skin, for example prolidase deficiency.
8 Loss of subcutaneous fat, for example generalized lipodystrophy.

Pangeria

SYN. WERNER'S SYNDROME; ADULT PREMATURE AGEING SYNDROME

Definition. An inherited disorder in which the ageing process is accelerated, starting after puberty. It is characterized by short stature, senile appearance, cataracts, joint contractures, early menopause, premature arteriosclerosis, various skin changes (including scleroderma-like features, premature canities, baldness and ulceration) and an increased risk of malignancy. Werner's syndrome is considered one of the genomic instability syndromes [1].

Aetiology. The syndrome is due to an autosomal recessive gene, with a calculated gene frequency of 1–5 per 1000 population [2].

Numerous abnormalities have been described in this syndrome, including chromosomal aberrations (most noticeably translocations, inversions and deletions), altered connective tissue metabolism, and abnormalities in the immune and endocrine systems [3–14].

Causal mutations have been identified in the RecQ type DNA helicase gene (*RECQL2*, *WRN* gene) [15]. It appears that the syndrome is the result of complete loss of the *WRN* gene product [16], but its exact role in preventing premature ageing has yet to be elucidated.

Pathology. Many tissues show premature ageing, but the changes are not uniform. Microsplanchnia and generalized atheroma are usually present. The epidermis is atrophic and some appendages are sparse. The dermis is thickened, with replacement of subcutaneous fat with hyalinized collagen, increased glycosaminoglycans, abnormal elastic fibres, disorganized nerves and vessel changes, which resemble those seen in diabetes mellitus. These abnormalities are more marked in the acral skin than on the trunk [3].

Clinical features [1]. The earliest manifestation of the syndrome is greying at the temples, which usually develops between the ages of 14 and 18 years but may rarely be present as early as 8 years. The greying rapidly becomes uniform and is sometimes associated with progressive alopecia. The first significant changes are usually noticed between 18 and 30 years but may begin earlier. The lower legs, feet, forearms and hands are most severely involved,

Table 46.4 Clinical features of the classical premature ageing syndromes.

	Pangeria (Werner's syndrome)	Progeria	Acrogeria
Stature	Small stature. Cessation of growth at 12 years	Small stature	Normal
Facies	Beaked nose; skin of ears atrophic and tightly bound down	Mid-facial cyanosis; bird-like facies; glyphic nasal tip; prominent frontal tuberosities and scalp veins; chin recessed	Micrognathia; atrophy of skin on tip of nose
Skin	Dry atrophic skin; mottled hyperpigmentation; telangiectasia	Dry, thin and wrinkled with mottled pigmentation; may present with scleroderma-like changes on limbs	Atrophic with telangiectasia and mottled hyperpigmentation on extremities
Scalp hair	Premature greying at 20 years; loss of hair at 20–25 years	Hair lost in first 2 years of life	Normal
Eyes	Bilateral juvenile cataracts (20–30 years); keratopathy; glaucoma	Prominent eyes; otherwise normal	Normal
Nails	Normal	Thin and brittle	Dystrophic or thickened
Limbs	Lower limb ulcers; hyperkeratosis over bony prominences; generalized loss of subcutaneous fat	Prominent joints; coxa valga; generalized subcutaneous fat loss; poorly developed muscular system; no acrosclerosis or Raynaud's phenomenon	Atrophy of skin most marked on extremities; no leg ulcers

the face and neck less so; atrophy of the skin and loss of subcutaneous fat results in a tense, shining and adherent appearance of the skin. Thin, spindly legs contrast with the normal or obese trunk, and there is a bird-like facies. The joints become fixed, and there may be sclerodactyly and acral gangrene. Mottled or diffuse pigmentation and telangiectasia are often conspicuous on the limbs, face and neck. Keratoses over pressure points on the feet and ankles separate to leave indolent ulcers. The voice may be high pitched and hoarse from thinning of the cords and fixation of the epiglottis. Intelligence is usually normal.

Most patients are of small stature and hypogonadal, with sparse or absent pubic and axillary hair, but some achieve normal stature and successful pregnancies. Other endocrine deficiencies are sometimes present; frank diabetes mellitus in at least 30% and abnormal glucose tolerance in many others. The diabetes is characterized by relatively low blood glucose levels and peripheral resistance to insulin [17,18].

Cataracts develop between the ages of 20 and 35 years in most cases and are usually posterior and subcapsular. Other ocular defects may occur [19].

The incidence of malignancy is high, especially fibrosarcomas, which occur in 10% of patients [20]. Carcinoma has developed in a chronic leg ulcer [21], but skin cancer is relatively rare. Generally, atheroma develops early. Abnormalities of metabolism are sometimes present but are not of uniform type. Death usually occurs in the fourth to sixth decade, due to myocardial infarction or malignancy [22].

The radiological changes [23] are often striking. There may be calcification of arteries, ligaments, tendons and subcutaneous tissues, with osteoporosis of the extremities, especially the legs.

Diagnosis. The prematurely aged appearance, the physical immaturity, the scleroderma-like changes and the cataracts, in combination, are unmistakable. In the Rothmund–Thomson syndrome, erythema, which is of early onset, is followed by poikilodermatous changes, and, although the facies may be superficially similar, there is no sclerosis. In systemic sclerosis, the hands are involved more than the feet and there is no premature ageing; in some advanced cases, confusion is possible but can be resolved by biopsy.

Huriez syndrome may require exclusion (Chapter 34). The differentiation from some of the other ageing syndromes is indicated in Table 46.4.

Mutational analysis of the *WRN* gene is now possible, although diagnosis by immunoblot analysis using a monoclonal antibody directed against the *WRN* gene product is also feasible [24].

Treatment. Only symptomatic measures are available. The management of the recurrent painful ulceration of the feet and legs is difficult, and amputation may be needed. Cataract surgery should be undertaken with special caution, for it is often complicated by severe degenerative changes of the cornea [19].

Progeria

SYN. HUTCHINSON–GILFORD SYNDROME

Definition. This is a rare disorder characterized by retarded physical development and abnormal facies, skeletal abnormalities and the onset in early childhood of scleroderma. Although progressive senile degeneration occurs, many of the more common features of ageing, such as cataracts, presbyacusis and presbyopia, are not seen.

Aetiology. It has been recently reported to occur following *de novo* mutations of lamin A (LMNA) that encodes for a major constituent of the inner membrane lamina [1]. Affected families have a high risk of spontaneous abortion.

Various abnormalities of mesodermal tissue have been identified [2]. In tissue culture, progeria fibroblasts have a decreased survival time [3]. The fibroblasts show a threefold increase in the production of hyaluronic acid, and the urinary excretion of hyaluronic acid is increased [4–6]. Animal studies suggest that increased hyaluronic acid in the tissues might produce a reduction in vascularity [4,7]. Tropoelastin production is increased [8], and it has also been suggested that type IV collagen may accumulate due to an interaction between activated T lymphocytes and fibroblasts [9,10]. A preliminary study of cultured fibroblasts from two affected patients suggests mitotic instability [11]. A polymorphism in the galactosyltransferase gene (*B4GALT1*) has been identified in affected cell lines [12].

Fewer than 100 cases have been reported to date, and 97% of patients have been white [7].

Pathology [13]. The major changes are in the skin, bone and cardiovascular tissues.

The skin shows atrophy of epidermis and dermis. There may be progressive hyalinization of dermal collagen and loss of subcutaneous fat. Scanning electron microscopy of hairs from one patient showed unusual longitudinal depressions with minor cuticular defects [10].

The cardiovascular system shows extensive atheroma, and there may be extensive myocardial fibrosis, with extensive lipofuscin ('age pigment') deposition characteristic of elderly adults [14,15].

The bones show a variety of changes including osteolysis, osteoporosis, necrosis, dislocations and poorly healing fractures [16,17].

Clinical features [18]. Affected children usually appear normal at birth, and growth may be only slightly retarded in the first year, but during the second year there is profound growth failure, with reduced subcutaneous fat on the face and limbs [7]. The facial appearance is reminiscent of a fledgling bird, with a disproportionately large cranium with patent fontanelles and frontal bossing, prominent eyes and scalp veins, very sparse, downy scalp hair, sparse or absent eyebrows and eyelashes, centrofacial cyanosis, micrognathia, thin lips and a 'beaked' nose. By the second year, the skin has become thin, taut and shiny in some areas but lax and finely wrinkled in others. Eccrine sweating is decreased. The veins are prominent and there may be easy bruising. After several years, progressive mottled hyperpigmentation develops, most marked on exposed sites, but there is no photosensitivity. Thickened sclerotic areas may be present on the lower trunk or thighs, and in one case multiple keloids developed on the hands and arms [10]. The nails are usually small, thin and dystrophic, and koilonychia and onychogryphosis may occur. Generalized alopecia often begins in the first year of life and the few remaining hairs are pale, fine and 'fuzzy'. The nipples may be hypoplastic.

The dentition is abnormal and delayed, and there may be skeletal abnormalities such as dystrophic clavicles and coxa valga, with joint contractures and a 'horse-riding' stance. Progressive bone resorption may lead to frequent fractures [17]. Sexual maturation is absent but intelligence is normal.

Death usually occurs in the second decade as a result of severe generalized atheroma.

Diagnosis. The large, bald head with conspicuous veins, the bird-like facies and the well-proportioned little body are distinctive. Bird-headed dwarfism (Chapter 12) is distinguished by the absence of skin atrophy.

Cockayne's syndrome may cause confusion, but progeria is distinguished by the loss of hair, the lack of photosensitivity and ocular changes, and the absence of disproportionately large extremities.

In metageria, sexual maturation and skeletal growth are normal [19].

Acrogeria [1–4]

SYN. GOTTRON'S SYNDROME

Definition. This disorder begins at birth or soon afterwards, and is characterized by cutaneous atrophy and loss of subcutaneous fat, particularly over the distal extremities, but with no tendency to atheroma, diabetes mellitus or decreased life expectancy. The term 'acrogeria' refers to premature ageing of the extremities.

Aetiology. Most cases occur without a family history, but presumed autosomal recessive as well as autosomal dominant inheritance has been reported [1,2]. Most patients have been female.

COL3A1 mutations cause variable phenotype, including Gottron-type acrogeria and vascular EDS [5,6].

Pathology. The subcutaneous fat is absent in the most severely affected regions. The dermis is atrophic, with sparse, thin collagen bundles, but there is abundant elastin, which appears clumped due to the deficiency of collagen.

Clinical features. The changes develop at or soon after birth. The skin becomes dry, thin, transparent and wrinkled, especially over the hands and feet, although the trunk and face may be affected to a lesser extent. The veins are prominent, and there may be easy bruising, poikiloderma and telangiectasia. The nails may be atrophic or thickened. The face appears 'pinched', with a hollow-cheeked 'owl-eyed' appearance, a beaked nose and thin lips. Micrognathism may be present. The lack of subcutaneous fat accentuates the appearance of premature senility. Some patients have low birth weight and persistent short stature, but the general health and life expectancy are normal. The hands and feet may be very small.

Diagnosis. The normal hair and eyes help to distinguish the condition from progeria and pangeria.

Cases are occasionally described which do not fit easily into any of the previously recognized categories and have been termed metageria and acrometageria [7,8]. It is not entirely clear whether these are separate entities.

Laboratory studies [1–3]

Fibroblasts from normal human skin have a limited lifespan in culture, which is inversely proportional to the age of the donor, and it seems that the *in vitro* ageing of fibroblasts may serve as a model for the *in vivo* ageing

of the whole body. All the premature ageing syndromes studied to date have shown a marked reduction in fibroblast growth potential *in vitro*. These include Werner's syndrome, progeria, poikiloderma congenitale, trisomy 21 and diabetes mellitus. In addition, fibroblasts from progeria patients have shown a decrease in mitotic activity, rate of outgrowth from explants, DNA synthesis and cloning efficiency. Studies on fibroblasts from patients with progeria and Werner's syndrome have also shown enzyme changes consistent with an accelerated ageing process.

In the normal ageing process, there is a threefold increase in the affinity of surface insulin receptors for native insulin between the first and seventh decades. This accounts for the clinical finding of relative insulin resistance in the elderly. Patients with progeria also show increased insulin binding and relative insulin resistance.

Other cellular abnormalities in Werner's syndrome and progeria include a decrease in surface-membrane HLA antigens and a marked increase in the activity of a procoagulant, which may predispose to atheroma.

Post-irradiation DNA repair appears to be normal in progeria and pangeria, although the cultured fibroblasts may have reduced karyotype stability. A reduction in DNA stability might increase the rate of genomic deterioration, and this might accelerate cellular ageing.

The fact that the premature ageing syndromes have multiple features which are difficult to attribute to a single enzyme or protein defect suggests that they may result from a defect in the genetic coding for structural proteins or DNA repair enzymes [4].

Other associated conditions

Premature ageing with short stature and pigmented naevi

SYN. MULVIHILL–SMITH SYNDROME

This rare syndrome [1] is characterized by low birth weight, short stature and moderate mental retardation, associated with multiple pigmented naevi and a distinctive bird-like facies. There is a small chin, with broad forehead, and the lack of facial subcutaneous fat gives an appearance of premature ageing. Other features include hypospadias, a high-pitched voice, irregular dentition, fine hair, hepatomegaly and low IgG. The clinical features tend to become more noticeable with increasing age.

Neonatal pseudohydrocephalic progeroid syndrome of Wiedemann–Rautenstrauch [1–3]

This rare autosomal recessive condition is characterized by mental and physical retardation and frontal and lateral bossing of the skull, with small facial bones, a small, beak-shaped nose, low-set ears and small mouth with dysodontia. The scalp hair is long and sparse, the extremities are thin, and the hands are large with long fingers and atrophic nails. The subcutaneous fat is decreased, the skin is thin and wrinkled, and the veins are prominent.

Gerodermia osteodysplastica [1]

Stunting of growth from early childhood is associated with senile changes in the skin, with normal scalp hair, generalized osteoporosis, multiple fractures, joint laxity and skeletal malformations, including wormian bones. The face appears sad, with drooping eyelids and jowls, malar hypoplasia and mandibular prognathism. Relatives presenting partial forms of the syndrome showed cutaneous ageing and osteodysplasia without dwarfism. Skin biopsy may show fragmented elastic fibres. Two consanguineous Arabian families showed features overlapping both gerodermia osteodysplastica and wrinkly skin syndrome, suggesting that they may represent variable manifestations of the same disorder [2].

Wrinkly skin syndrome [1]

This rare familial condition is characterized by the appearance at birth of dry, wrinkled skin of the hands, feet and ventral surfaces of the trunk. The veins are unduly

prominent. There may also be mental retardation, ocular defects and poor muscle tone. The cause is unknown, and the dermal collagen and elastin appear normal on light microscopy. There appears to be phenotypic overlap with gerodermia osteodysplastica [2].

Poikiloderma congenitale

SYN. ROTHMUND–THOMSON SYNDROME

This condition is fully described in Chapter 12. It may be considered as a premature ageing syndrome because of the atrophic hyperpigmented skin, the early onset of cataracts, and the premature greying and loss of hair. The striking poikiloderma is distinctive.

Cockayne's syndrome (Chapter 12)

The atrophic skin with mottled pigmentation and loss of subcutaneous fat on the face produce an appearance of premature senility, and the disease has often been confused with progeria.

Trisomy 21 (Chapter 12)

SYN. DOWN'S SYNDROME

This disorder shows more features of true ageing than the classical premature ageing syndromes [1]. These features include progressive dementia with the neurofibrillary tangle seen in senile dementia, amyloid and lipofuscin deposition in many organs, diabetes mellitus, cataracts, cardiovascular disease, increased incidence of autoimmune disease and malignancy, and a decreased life expectancy [2].

The cutaneous features include dry, lax skin, and premature greying and loss of hair [2].

Familial mandibulo-acral dysplasia

SYN. CRANIOMANDIBULAR DERMATODYSOSTOSIS

The main features of this rare syndrome are mandibular hypoplasia, delayed cranial suture closure, dysplastic clavicles, abbreviated club-shaped terminal phalanges

Fig. 46.39 Familial mandibulo-acral dysplasia, showing the short, club-shaped terminal phalanges, the so-called 'tree-frog' appearance. (Courtesy of Dr A.M. Zina, Turin University, Turin, Italy.)

associated with acro-osteolysis and atrophy of the skin over the hands and feet [1] (Fig. 46.39). Other characteristics may include short stature, multiple wormian bones, prominent eyes and a sharp nose [2,3]. In one family, the condition was also associated with the loss of the lower teeth and alopecia [4]. Partial lipodystophy may be present and associated with hyperinsulinaemia [5]. The condition is autosomal recessive and mutations have been identified in the gene encoding lamin A/C (*LMNA*) [6].

The cutaneous changes resemble those of a premature ageing syndrome, and some cases have been mistakenly diagnosed in the past as acrogeria or Werner's syndrome.

Diabetic thick skin [1,2]

SYN. CHEIROARTHROPATHY

Diabetes may be classified as a premature ageing syndrome because of the predisposition to cataracts and atheroma and the reduced life expectancy [1,3].

Some patients with diabetes mellitus have thick, tight, waxy skin and limited joint mobility. This combination has been called *cheiroarthropathy* [4]. Affected patients are

unable to bring their palms completely together, and their fingers will not bend backwards. The 'prayer sign', in which the patient tries to oppose the two palms, provides an easy screening test [5]. Skin and tendon sheath thickness has also been measured by ultrasound [6,7].

Cheiroarthropathy is present in 30–40% of insulin-dependent diabetics, and in non-insulin-dependent diabetics the figures have varied widely, from 4% to 70%. The changes may even precede the diagnosis of diabetes [8]. The changes are important because affected patients have an increased risk of retinal and renal disease due to microvascular damage [9]. Patients with diabetic cheiroarthropathy also have an increased incidence of frozen shoulder and Dupuytren's contracture [10]. There is often associated thickening of the plantar fascia [11].

The biochemical change is not fully understood, but it seems likely that non-enzymatic glycosylation in diabetic subjects might alter collagen metabolism [1,3]. The lysines in collagen are slowly glycosylated with increasing age, and during this process the glucose attaches to the lysine and undergoes an Amadori rearrangement, thus making the process irreversible [12]. Enzymatic digestion of tendon collagen from young patients who died from diabetes showed that their collagen behaved as if it was from patients who were 50–65 years older than their actual age [13].

Studies of viscoelastic ratio and skin extensibility in patients with type 1 diabetes have shown subclinical stiffness and loss of skin elasticity [14].

The histology of the skin changes resembles systemic sclerosis, but there is a subtle difference, with a predominance of large collagen fibres, thickening of the capillary basement membrane and increased mucin [15].

In some diabetic patients with thick skin, the extensor surfaces of the fingers develop a characteristic, minutely pebbled appearance over or near the knuckles (Huntley's papules). On histology, this shows a papillated epidermal hyperplasia with hyperkeratosis [16].

Because biochemical studies suggest that collagen is 'aged' by increased binding with glucose, it is desirable to maintain tight control of blood glucose levels in diabetic patients [17].

Leprechaunism

SYN. DONOHUE'S SYNDROME

Definition. Leprechaunism is a rare and poorly defined syndrome characterized by severe intrauterine and postnatal growth retardation, decreased subcutaneous tissue and muscle mass, and a characteristic facies [1]. Tissue resistance to insulin appears to be an important feature, as hyperinsulinaemia and pancreatic β-cell hyperplasia are frequently present [2,3].

Aetiology. The condition is inherited as an autosomal recessive trait. The basis for the insulin resistance is homozygous or compound heterozygous mutations in the extracellular domain of the insulin receptor, which leads to markedly impaired insulin binding [4]. Mutations that retain significant insulin binding activity cause the less severe phenotype of Rabson–Mendenhall syndrome.

The fibroblasts have a prolonged doubling time *in vitro*. They respond poorly to the metabolic actions of insulin, and to the actions of several other growth factors, such as epidermal growth factor.

Pathology [5]. In the skin, the elastic and collagen fibres are few and fragmented. On the extremities, the horny layer is markedly thickened. The muscles show a proliferation of abnormal connective tissue. In some cases, the ovaries are large and cystic, and there is β-cell hyperplasia of the pancreatic islets.

Clinical features [5–8]. The child is abnormal at birth, with low birth weight. The nose is broad, the ears low set and large, the eyes widely spaced. There is hypertrichosis of the forehead and cheeks. The skin appears too large for the body and is loosely folded at the flexures and may be corrugated with gyrate folds on the hands and feet, which may be disproportionately large. Muscle wasting, often

progressive, is usually present. The breasts and the penis or clitoris may be slightly hypertrophic. The bone age is retarded and there may be metaphyseal and epiphyseal dystrophy.

Growth is generally retarded, the nutritional status remains poor and susceptibility to infection is high. Death by the age of 1 year is usual.

Diagnosis. The cutaneous changes could be confused with cutis laxa, but in leprechaunism the skin, although folded, is thickened and not lax. The diagnosis is confirmed by the associated features and the finding of raised plasma insulin levels.

Lipoatrophy

The absence of subcutaneous fat may give the appearance of premature ageing if the face is affected. Lipoatrophy is fully discussed in Chapter 55.

Perforating dermatoses

Many dermatoses occasionally exhibit the phenomenon of *TEE*, in which material from the dermis is extruded through the epidermis to the exterior with little or no disruption of the surrounding structures [1]. The extruded material may include inflammatory cells, red cells, microorganisms and extracellular substances, such as mucin or altered connective tissue components [2,3]. In most of these conditions, the TEE is secondary to some underlying disease, such as granuloma annulare or PXE, but there are four conditions that are regarded as *primary perforating disorders*, i.e. Kyrle's disease (Chapter 34), perforating folliculitis (Chapter 27), reactive perforating collagenosis and perforating serpiginous elastosis. It is possible that these primary perforating disorders might be due to defects in the epidermal keratinocytes, hair follicle, collagen and elastic fibres, respectively, with TEE being the final common pathway [2,3].

In acquired reactive perforating dermatosis (see below), the bulk of the coarse granular basophilic material which is extruded by TEE appears to derive from the nuclei of polymorphonuclear leukocytes [4]. It has been suggested that lysosomal enzymes derived from leukocytes might be responsible for the altered staining of collagen fibres, the degradation of elastic fibres and the impairment of keratinocyte adhesion, which allows TEE of dermal components [4].

Acquired reactive perforating dermatosis

Until recently, the four conditions mentioned above were thought to be unrelated, but there have now been numerous reports of these perforating dermatoses occurring in diabetes mellitus or in patients with chronic renal failure, many of whom were undergoing haemodialysis [2,5–9]. An incidence of 11% has been reported, with a particular association with long-standing diabetes [9]. The keratotic lesions in this condition develop on the trunk and limbs, and are usually pruritic, dome-shaped papules with central crusts (Fig. 46.40). They are not related to trauma.

The distinction between the four dermatoses has not always been clear-cut, and the presence or absence of the Koebner reaction, and the presence or absence of collagen fibres in the epidermis, are not reliable distinguishing features [2,3]. Both collagen and elastic fibres can be extruded in the same patient [7], and it seems likely that at least in the case of haemodialysis patients these conditions may overlap. The name *acquired reactive perforating dermatosis* has been suggested for this skin problem. These four conditions, however, appear to be separate entities when they occur outside the setting of renal failure or diabetes mellitus.

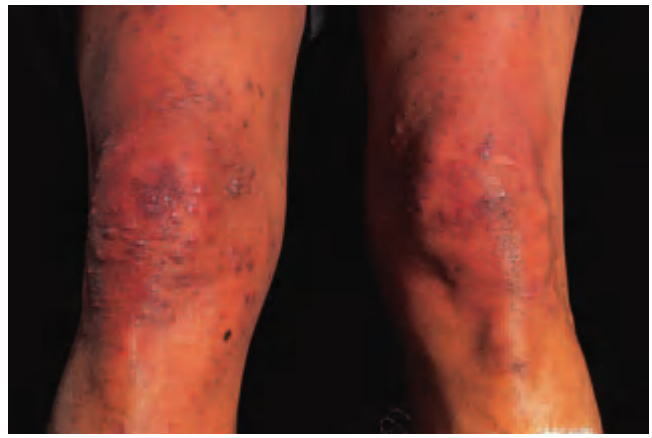

Fig. 46.40 Perforating dermatosis in a diabetic patient with renal failure. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

Topical or intralesional steroids or topical retinoids may be helpful, but some patients improve spontaneously [9]. Other reported treatments include rifampicin and allopurinol [10].

Perforating disease due to exogenous agents

Occasionally, a chemical which has been applied to the skin topically or by intradermal injection can be eliminated by the transepidermal route to produce a perforating disorder. Eight cases have been reported following occupational exposure to a caustic drilling fluid used in the petrochemical industry [1]. Each patient noted skin irritation following exposure to the fluid, and 1 or 2 days later developed tender papules with central umbilication, which ulcerated and crusted. Histological examination of the lesions revealed TEE of altered collagen and debris which stained for calcium.

It is possible that the lesions were due to follicular penetration by the calcium present in the drilling mud. The drilling fluids contain many additives, but calcium carbonate or calcium chloride are often present in high concentrations in the mud. Similar cases have been reported following the use of calcium-containing electroencephalography paste [2].

TEE of altered collagen has also been reported following the use of intradermal steroid injections [3,4].

Reactive perforating collagenosis [1–4]

Definition. A rare inherited form of TEE in which collagen is extruded through the epidermis. It is usually precipitated by environmental cold or trauma. The commoner, acquired, form is often referred to as acquired perforating dermatosis (qv) which is typically associated with haemodialysis, although lesions have been recorded with internal neoplasia [4].

Aetiology. The cause is unknown, but the condition is often familial [5,6]. The basic defect seems to be a type of focal damage to collagen, which is then extruded as a result of necrolysis of the overlying epidermis [7].

Pathology [2,7,8]. The lesion originates in the papillary dermis, where collagen is surrounded and engulfed by focal epidermal proliferation. The collagen appears normal on electron microscopy, but gives an abnormal staining pattern with trichrome and phosphotungstic acid haematoxylin. The central crater which develops contains inflammatory cells and keratinous debris. Elastic tissue is typically absent, and the abnormal collagen is eliminated by transepithelial migration.

Clinical features [7]. The inherited form usually starts in early childhood as small papules on the extensor surface of the hands, the elbows and the knees following superficial trauma. Each skin-coloured papule increases to a size of about 6 mm over 3–5 weeks and then becomes umbilicated, with a keratinous plug. The lesions regress spontaneously in 6–8 weeks to leave a hypopigmented area or slight scar, but new lesions may appear. Lesions can be produced experimentally, and Koebner's phenomenon may be present, with linear lesions [9]. The papules can also be provoked by inflamed acne lesions, but deep incisions do not produce the lesions. The condition persists into adult life. In some cases, the disease is associated with intolerance to cold and improves in warm weather.

Diagnosis. The condition may be mistaken clinically for molluscum contagiosum, papular urticaria, perforating serpiginous elastoma, perforating folliculitis, perforating granuloma annulare and Kyrle's disease, but the histology is characteristic [6]. Verrucous perforating collagenoma must also be distinguished (see below).

The nosological relationship between reactive perforating collagenosis and the acquired reactive perforating dermatosis of renal failure remains uncertain (see above) [4].

Treatment. Topical retinoic acid may reduce the number of lesions. Other treatments which may help include oral isotretinoin, methotrexate, emollient creams, topical steroids under occlusion [3,4] and PUVA [10].

Verrucous perforating collagenoma [1,2]

SYN. COLLAGENOME PERFORANT VERRUCIFORME

In this rare condition, severe (as opposed to superficial) trauma to the skin produces verrucous papules which show TEE of collagen. The eruption occurs as a single episode and is not familial.

Elastosis perforans serpiginosa

SYN. PERFORATING ELASTOMA; ELASTOMA INTRAPAPILLARE PERFORANS

Definition. In this reactive perforating dermatosis, the material extruded through the epidermis is derived from elastic fibres in the upper dermis.

Aetiology. The cause is unknown, but a genetically determined defect of elastic tissue may be involved [1]. The altered elastin resembles that seen in experimental animals subjected to lathyrogens or copper deficiency.

It is probable that the primary abnormality is in the dermal elastin, which provokes a cellular response that ultimately leads to extrusion of the abnormal elastic tissue. It may be significant that the lesions are commonly seen in areas subjected to wear and tear. The lesions may follow an abrasion.

Some 40% of reported cases have been associated with connective tissue disorders, such as PXE, EDS, MFS, OI and acrogeria [2,3]. It has also been reported in otherwise healthy individuals and in mental deficiency, especially Down's syndrome [4–6].

It sometimes occurs in patients taking penicillamine, which is known to cause the production of abnormal elastin [7–10].

The relationship to perforating PXE and pseudo-PXE due to penicillamine is discussed on p. 46.25.

Pathology [4,11–13]. The earliest detectable change is the focal development of elastotic staining tissue and basophilic debris in the dermis. This is followed by a reaction of the overlying epidermis, which grows down to engulf the elastotic material. The epidermis surrounding the fully developed lesion is acanthotic and hyperkeratotic. The papule consists of a circumscribed area of epidermal hyperplasia traversed by a channel communicating directly with the dermis and containing a mass of tissue, which projects above the surface. This plug consists of horny material in its upper third and of amorphous debris derived from elastin in its lower two-thirds [11]. In the dermis beneath and around the lesion, there is a foreign-body giant cell reaction. The elastotic material is finally extruded, to leave irregular scarring and warty thickening. Electron microscopy shows an increase in elastic fibres, with fine filaments on the surface similar to those seen in normal embryos, and the hydroxylation of the dermis is similar to that of newborn skin [12].

Clinical features [14,15]. The age of onset ranges from 6 to 20 years. Small, horny or umbilicated papules are characteristically arranged in lines, circles or segments of circles in a serpiginous pattern. The individual papules may remain small or may enlarge slightly to assume a crateriform appearance with an elevated edge and a central plug, or further to leave an area of atrophic skin surrounded by smaller papules, each with a horny plug. The rings may reach a diameter of 15–20 cm but are usually smaller (Fig. 46.41). The back and sides of the neck are

Fig. 46.41 Elastosis perforans serpiginosa in a patient with vascular Ehlers–Danlos syndrome.

most commonly affected, but the lesions may also occur on the cheeks or on the arms or thighs, and are sometimes bilaterally symmetrical. They may persist for several years, but eventually involute spontaneously to leave reticulate atrophic scars. Biopsy scars readily become keloidal.

Diagnosis. The annular or linear arrangements of the papules and their distribution suggest the diagnosis, which is confirmed by the characteristic histology. Conditions which may cause confusion include porokeratosis of Mibelli, reactive perforating collagenosis and perforating granuloma annulare.

A similar histological appearance can occur in the acquired reactive perforating dermatosis of renal failure (see above) [16].

Treatment. Careful removal of the nodules with a curette under local anaesthesia may give a reasonable cosmetic result. Freezing has been recommended [14,17]. Excision should be avoided, and dermabrasion may make the condition worse [4]. In a child with Down's syndrome and associated vitamin A deficiency, clinical improvement was observed with oral retinoid therapy, even though the treatment produced side effects [6]. Isotretinoin has been used successfully in a patient with penicillamine-induced disease [18]. There are reports of improvement following tazarotene [19], pulsed dye [20] and ultrapulsed carbon dioxide laser therapies [21].

Miscellaneous disorders

Colloid milium

SYN. COLLOID PSEUDOMILIUM; COLLOID DEGENERATION OF THE SKIN; ELASTOSIS COLLOIDALIS CONGLOMERATA

Definition. Colloid milium is a degenerative change characterized clinically by the development of yellowish, translucent papules or plaques on light-exposed skin, and histologically by the presence of colloid in the dermal papillae.

Aetiology. The cause is uncertain, and the condition may not represent a single entity. The rare juvenile form [1,2], beginning before puberty and often familial, can be distinguished from a non-familial form occurring in later life. Although light appears to play little part in provoking the lesions in the juvenile form, it is certainly implicated in older patients, among whom the incidence is highest in fair-skinned, outdoor workers in sunny climates [1,3,4]. Cases among refinery workers in the tropics suggest that trauma and the photodynamic effects of phenols in oxide fuel (gas oil) may be contributory factors [5]. Cases have also been reported after the long-term application of strong hydroquinone bleaching creams. These patients also had ochronosis [5].

Pathology [6–11]. The earliest histological change is the appearance of colloid globules at the tips of the dermal papillae. Homogeneous fissured masses of colloid occupy the upper dermis, each surrounded by bands of collagen. The colloid is usually eosinophilic but may be basophilic. Within it, small blood vessels and the nuclei of fibroblasts are well preserved. In the larger, plaque-like lesions, the colloid change occurs diffusely throughout the dermis.

In the juvenile form, the colloid masses may also occur in the epidermis, and elastosis is not present, whereas in the adult form the colloid is separated from the epidermis by a band of elastin, and elastosis is present. In

Fig. 46.42 Colloid milium of the infraorbital region. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

the juvenile form, 'immature' Civatte bodies occur in the epidermis.

The source of the colloid material is uncertain. It could be a protein synthesized by fibroblasts or it could be derived from degraded elastic fibres [1,3,8].

The histological changes may be difficult to distinguish from those of amyloidosis, especially lichen amyloid. Electron microscopy may be needed for definitive diagnosis [6,8,11]. In adult colloid milium, the colloid is amorphous, with wavy, branching filaments. In the juvenile form, it is composed of closely packed filaments, which are often in parallel rows, forming whorled fascicles [1,11].

Clinical features. Small dermal papules 1–2 mm in diameter, yellowish brown and sometimes translucent, develop slowly and more or less symmetrically in irregular groups in areas exposed to sunlight (Fig. 46.42). They feel soft and may release their gelatinous contents when punctured. The most frequently involved sites are the face, especially around the orbits, the dorsa of the hands, the back and sides of the neck and the ears. There is some variation in the clinical features according to the age of onset. In young children, the lesions are often confined to the face, with diffuse infiltration surmounted by innumerable small papules, which may appear vesicular. In older patients, the papules are often fewer and larger, and their potential distribution is much wider, although often only one or two sites are involved in each individual. The changes induced by prolonged light exposure are associated to varying degrees. Although colloid milium may become more severe and more extensive over the years, most cases reach their maximum development within 3 years and then remain unchanged.

A nodular form has been described in which lesions may be 5–50 mm in size and may be single or multiple [10].

Diagnosis. The histological and clinical findings together are unmistakable, although the former alone may be difficult to differentiate from amyloidosis. Trichoepithelioma, tuberous sclerosis and hidrocystoma are distinguished by biopsy.

Treatment. Improvement has been reported following dermabrasion [12]. Destruction of the lesions with the diathermy or with cryotherapy has also been advocated, but the cosmetic result is seldom satisfactory.

White fibrous papulosis of the neck

Asymptomatic, small, white, fibrous papules around the neck have been described in several Japanese [1,2], Iranian and European patients [3,4]. The number of papules ranges from 10 to 100; middle-aged to elderly men are predominantly affected. The papules are round to oval, clearly marginated and non-follicular (Fig. 46.43). Histology is unremarkable, showing bundles of thickened collagen fibres in the mid-papillary dermis. Although lesions clinically resemble disorders of elastic tissue, such as anetoderma and dermatofibrosis lenticularis disseminata, elastic fibres are morphologically normal on histology. Acquired connective tissue naevi could exhibit similar features, although the late age of onset makes this diagnosis unlikely. The condition appears to have no prognostic significance, and may be under-reported.

Recently, it has been suggested that there may be a relationship between fibrous papulosis of the neck and acquired elastolysis of the papillary dermis [5].

Papular elastorrhexis

This is a rare variant of connective tissue naevus. Adolescents or young adults present with non-follicular white or yellowish papules; dermal elastic fibres are decreased and fragmented on histology. Most case reports are sporadic, with no family history and no extracutaneous manifestations [1–3]. Similar lesions are seen in some patients with Buschke–Ollendorff syndrome (Chapter 15), in which osteopoikilosis is also a feature. To add to the confusion, abortive forms of Buschke–Ollendorff syndrome have been described, lacking osteopoikilosis [4]. A family has been described with this variant [5]. It is possible that papular elastorrhexis is not a separate entity. Intralesional triamcinolone may be beneficial [6].

Progressive osseous heteroplasia [1,2]

This rare condition typically affects female infants and is characterized by ossification of skin and soft tissues. Ossification begins in the dermis, progressing to deeper tissues and to adjacent areas of skin. It is not associated with trauma or infection [3]. Skin lesions begin as groups of small, firm papules resembling rice grains; later, larger ossified nodules may develop. A skin biopsy should include subcutaneous fat. Cancellous and even mature intramembranous bone is found in the dermis and subcutis. The differential diagnosis includes plate-like osteoma cutis (in which the lesion is solitary) (Chapter 53), Albright hereditary osteodystrophy (which is associated with dysmorphic features, including brachydactyly and short stature, and less severe ossification) and fibrodysplasia ossificans progressiva, in which ossification initially affects muscle or fascia and the great toes are malformed. The disorder is caused by a paternally inherited inactivating *GNASI* mutation, the gene for guanine nucleotide-binding protein (G protein) alpha stimulating activity polypeptide 1. This is similar to the mutation identified in Albright hereditary osteodystrophy [4].

The condition is progressive, and the morbidity depends on the site and the severity of the ossification. There is no effective treatment to prevent the ossification, but lesions which disrupt function or impair movement can sometimes be removed surgically.

Fascial hernias of the legs [1,2]

Small fascial hernias of the lower legs are not uncommon in athletes and heavy manual workers, and may present a problem in differential diagnosis. Herniation of muscle takes place through the hiatus in the deep fascia where it is perforated by communicating veins.

The hernias develop suddenly as nodules on the anterolateral aspect of the lower leg and are usually about 15 cm above the lateral malleolus. The nodules are soft,

compressible and 1.5–2.0 cm in diameter. If bilateral, they are strictly symmetrical. No treatment is required.

Constricting bands of the extremities

SYN. AINHUM AND PSEUDO-AINHUM

Definition. This is a constricting band around a digit or limb. The band may be shallow, involving only the skin, or it may be deeper, involving fascia or bone, and in some cases amputation may result. The term *ainhum* (an African word meaning 'to saw' [1]) is applied to a specific type in which a painful constriction of the fifth toe occurs in adults, with eventual spontaneous amputation. *Pseudo-ainhum* is the term applied to other constricting bands which are congenital or secondary to another disease.

Ainhum

SYN. DACTYLOLYSIS SPONTANEA

Aetiology. The condition appears to be due to an abnormal blood supply to the foot in some patients, as arteriography has shown that in these patients the posterior tibial artery is attenuated at the ankle, and the plantar arch and its branches are absent [2]. Mechanical factors, including trauma from walking barefoot, may then precipitate the development of a groove in the ischaemic toe. Chronic fissuring in hyperkeratotic skin also seems to be an important factor. A family history is common, and the disease is more common in certain races. Ainhum is most common in black Africans, but many cases have been reported in black Americans, and it can also occur in other races.

Various tropical infections, including leprosy, tuberculosis and yaws have been suggested as possible contributory factors, but these conditions are probably coexistent rather than causative [2,3].

Pathology [4]. Fissuring and hyperkeratosis on the medial aspect of the digit is followed by fibrosis, distal degeneration and osteoporosis, ultimately leading to spontaneous amputation. There may be secondary infection and osteomyelitis.

Clinical features. The condition is most common between the ages of 30 and 50 years, but the earliest stages may be seen in childhood. The presenting symptom is usually a painful fissure. The toe is held dorsiflexed at the metatarsophalangeal joint, and gradually becomes clawed. Rest pain, coolness and cyanosis of the digit distal to the groove suggest that ischaemia is present. Once the constricting band has encircled the toe, the condition tends to progress rapidly. The toe becomes globular, hangs by a thread of fibrous tissue and is eventually shed (Fig. 46.44).

Fig. 46.44 Ainhum, just before shedding of the fifth digit. (Courtesy of Dr D. Burley, Princess Margaret Hospital, Swindon, UK.)

Diagnosis. The condition must be distinguished from pseudo-ainhum.

Treatment. Control of secondary infection and protection from trauma may prevent extension of the scarring process. If symptoms are severe, or the dangling digit is a disability, amputation is indicated.

Pseudo-ainhum

Congenital. Congenital pseudo-ainhum may involve a digit, a limb or even the trunk, and it ranges in severity from a superficial groove to amputation *in utero* [5–8]. The cause is unknown, but familial cases have been reported. Some cases of pseudo-ainhum may be due to amniotic bands [9] or adhesions *in utero*, which may arise as a result of tearing of the amnion some time after the 45th day of pregnancy [10]. Cases have occurred in EDS and after amniocentesis [10,11].

Histology of the affected digit or limb reveals broad, finger-like projections of collagen, and coarse elastic bundles that penetrate deep into the subcutaneous fat [8].

Congenital pseudo-ainhum must be distinguished from: *aplasia* of the limbs with rudimentary digits; *acromelia* (in which part of the limb does not develop); and *hypoplasia* (in which the parts, although formed, are poorly developed).

Acquired. Pseudo-ainhum may be acquired as a result of infection (particularly leprosy), trauma, cold injury, neuro-

Fig. 46.45 Vohwinkel's disease with pseudo-ainhum of the fifth digit of the left hand. (Courtesy of Dr F.A. Ive, Dryburn Hospital, Durham, UK.)

pathy (especially congenital sensory neuropathy), systemic sclerosis, etc. [12], and it may occur in association with other hereditary diseases such as palmoplantar keratoderma (particularly Vohwinkel's disease) (Fig. 46.45), pachyonychia congenita, erythropoietic protoporphyria [13,14], and Olmsted's syndrome (Chapter 34). Factitial pseudo-ainhum has also been reported due to the self-application of a rubber tourniquet.

Multiple skin creases resembling constrictions may be seen in the Michelin baby syndrome (Chapter 15) and in 'multiple benign annular creases of the extremity' (Chapter 34).

Treatment. Staged Z-plasty sometimes gives an excellent result [15].

Heberden's and Bouchard's nodes

Heberden's nodes [1] are posterolateral bony outgrowths affecting one or more *distal* interphalangeal joints. Similar changes, affecting the *proximal* interphalangeal joints, are termed Bouchard's nodes. Both Heberden's and Bouchard's nodes are associated with osteoarthritis, although they may be inherited independently as an autosomal dominant trait [2]. Characteristically, they are asymptomatic and of insidious onset, although tender nodes may develop acutely with a red, swollen joint. The association of multiple symmetrical nodes with distal interphalangeal joint arthritis has been termed 'primary generalized osteoarthritis'. Because this is associated with the tissue types HLA-A1 and B8 and shows a marked female preponderance, it has been postulated to be an autoimmune disorder; increased amounts of immune complexes can be detected in cartilage and synovium [3].

Urticaria and Mastocytosis

C.E.H. Grattan & A. Kobza Black

Urticaria

Introduction

Urticaria is common and embraces many different clinical entities. Dermatologists, allergists, general physicians and general practitioners see a quite different selection of cases, and this may cause confusion. The literature is large, and there are several monographs that can be consulted for a detailed bibliography [1–5].

Definitions

The urticarias are characterized by short-lived swellings of the skin due to plasma leakage. Urticaria is often used to describe an eruption of weals, as distinct from angio-oedema—although this does lead to confusion with classification of the physical urticarias, and the term 'urticaria' is therefore better used as a collective term for weals and angio-oedema. Weals and angio-oedema often occur together and for practical purposes are similar processes. However, angio-oedema that is caused by C1 esterase inhibitor deficiency shows some differences clinically and in response to treatment.

Weals (syn. 'nettle rash', hives) is the descriptive term for transient, well-demarcated, superficial erythematous or pale swellings of the dermis, which are usually associated with itching.

Angio-oedema (syn. angioneurotic oedema, Quincke's oedema) swellings affect the deeper dermal, subcutaneous and submucosal tissues. They are usually painful rather than itchy, poorly defined, and pale or normal in colour.

Anaphylaxis, in the strict sense, is an acute life-threatening condition induced by an immunoglobulin E

(IgE)-mediated allergic reaction. It consists of a combination of symptoms and signs, including diffuse erythema, pruritus, urticaria and angio-oedema, hypotension and difficulty in breathing. A similar clinical picture from non-allergic causes is called an anaphylactoid reaction. However, 'anaphylaxis' is frequently used to describe the clinical picture whatever the cause (see Chapter 10).

Historical background

Urticaria has been recognized since the days of Hippocrates. The term dates back to the 18th century, when the stinging and burning was likened to the sting of a nettle (*Urtica dioica*). The changing opinions on the pathogenesis and management of urticaria provide a fascinating reflection of the changing fashions in medical thought [1,2].

Classification

Urticaria is a heterogenous group of disorders that may be broadly classified by duration of disease and clinical features.

Urticaria is traditionally classified into acute and chronic, with a time division arbitrarily chosen between 6 weeks and 3 months. When urticaria is present daily or almost daily for less than 6 weeks, it can be termed acute in retrospect. If urticaria occurs on most days for longer than this, it can be categorized as chronic. This applies to all patterns of urticaria, but is most relevant to the ordinary presentation of urticaria, because physical urticarias and urticarial vasculitis nearly always have a chronic course, whereas contact urticaria usually presents with intermittent acute episodes. This classification by disease duration is of limited value, but an exogenous cause is more likely to be found in acute urticaria than in chronic urticaria. 'Episodic' is the best term used to classify the many cases of recurrent acute attacks.

A classification based on clinical features and trigger factors is convenient, but has inherent inconsistencies (Table 47.1). Several types of urticaria may coexist in the same person—for example, ordinary urticaria and various forms of physical urticarias, including delayed pressure urticaria. The term 'ordinary urticaria' can be used when predominantly physical, vasculitic and contact urticarias have been excluded. There is now strong evidence that up to 50% of patients previously diagnosed with chronic 'idiopathic' urticaria have an autoimmune basis for their disorder. It is therefore best to use the broader term chronic 'ordinary' instead of chronic 'idiopathic' urticaria for this group, so as to make no assumptions about aetiology. The criteria for 'idiopathic' will vary between clinicians depending on whether or not non-specific aggravating factors (such as aspirin and food additives) are regarded as causes [1]. Acute ordinary urticaria may be due to allergy, especially in atopics, but this does not account for chronic disease. It is convenient to separate angio-oedema without weals from angio-oedema with weals in the same patient, because some of these will be due to C1 esterase inhibitor deficiency and some to angiotensin-converting enzyme inhibitors (ACEIs) or non-steroidal anti-inflammatory drugs, but many will remain 'idiopathic' after full evaluation.

Table 47.1 Clinical classification of urticaria.

1 Ordinary urticaria
Acute
Chronic (often called 'idiopathic')
2 Physical and cholinergic urticarias
3 Urticarial vasculitis
4 Contact urticaria
5 Angio-oedema without weals
6 Other syndromes resembling urticaria or angio-oedema, or with urticaria as a component

Associations

An association exists between chronic ordinary urticaria and autoimmune thyroid disease [1], and there is a higher frequency of autoimmune diseases in patients with autoimmune urticaria [2]. The older literature suggests that chronic 'idiopathic' urticaria may be associated with chronic infections, especially dental, and *Candida* infections of the bowel, but in the authors' experience this occurs rarely, if at all. A possible association between chronic 'idiopathic' urticaria and *Helicobacter pylori* infection remains to be proven with double-blind studies of eradication therapy. It has been proposed that *H. pylori* infection may play an indirect role in autoimmune chronic urticaria by molecular mimicry in genetically predisposed individuals [3]. Although there have been anecdotal reports of urticaria occurring with systemic malignancies, no association was found in a large epidemiological study [4].

4 Lindelöf B, Sigurgeirsson B, Wahlgren CF, Eklund G. Chronic urticaria and cancer: an epidemiological study of 1155 patients. *Br J Dermatol* 1990; **123**: 453–6.

Prevalence

Urticaria is a common problem, with a point prevalence of 0.1% in one survey [1]. Estimates of the cumulative lifetime prevalence of chronic urticaria have varied from 0.05% to 23.6% in the general population, but a range of 1–5% seems more realistic [2]. In one British dermatology centre, of 2310 cases of urticaria seen over 32 years, ordinary urticaria made up 72% (excluding IgE-mediated allergic cases), physical and cholinergic urticarias 20%, allergic 3.4% (excluding stings and injected drugs), urticarial vasculitis 2.1% and hereditary angio-oedema 0.5% [3].

3 Champion RH. Urticaria then and now. *Br J Dermatol* 1988; **119**: 427–36.

Genetics

Hereditary C1 esterase deficiency angio-oedema, Muckle–Wells syndrome, familial cold urticaria and a few other rare physical urticarias are inherited as autosomal-dominant traits. Recent work has shown a highly significant linkage of human leukocyte antigen (HLA)-DR4 and its associated allele DQ8 in chronic ordinary urticaria patients with evidence of histamine-releasing autoantibodies [1].
